Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method, and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editor assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

"To teach is to Learn Twice"

To those who invested in us that we might, in turn, pass on
their knowledge and wisdom to future generations of colleagues and students.

Preface
Musculoskeletal Rehabilitation Series

Musculoskeletal conditions have an enormous impact on society. Today, musculoskeletal conditions have become the most common cause of disability and severe long-term pain in the industrialized world. The knowledge and skill required by the community of health care providers involved in managing the impairments and functional limitations resulting from acute or chronic musculoskeletal injury/illness have grown exponentially as the frequency of visits to practitioners' offices for musculoskeletal system complaints has risen.

The art and science of musculoskeletal rehabilitation began as a consequence of the injuries suffered on the battlefields of Europe during World War I. Since that time, numerous textbooks have been published regarding musculoskeletal rehabilitation. These texts have encompassed the areas of basic science, evaluation, and treatment. However, these books have most often been developed and written in professional "isolation" (i.e., from a single discipline's perspective). As a consequence, topics have either been covered in great depth but with a very narrow focus or with great breadth with very little depth. Our goal in the development and production of this musculoskeletal rehabilitation series was to develop a series of four textbooks that complement and build on one another, providing the reader with the needed depth and breadth of information for this critical area of health care.

Volume I of the series is the 6th edition of David Magee's *Orthopedic Physical Assessment*. This now classic text provides the clinician with the most comprehensive musculoskeletal assessment text available on this topic. First published in 1987, it has withstood the test of time and is the most widely used text in this area. In 1996, three of the editors developed and published *Athletic Injuries and Rehabilitation*. Based upon feedback from both students and clinicians, we decided to expand and broaden the scope of *Athletic Injuries and Rehabilitation* into three new volumes. *Volume II, Scientific Foundations and Principles of Practice in Musculoskeletal Rehabilitation,* provides clinicians with currently available science regarding musculoskeletal issues and principles of practice that should guide clinicians regarding therapeutic intervention. In this *Volume III, Pathology and Intervention in Musculoskeletal Rehabilitation,* now in its second edition, we have attempted to provide readers with a comprehensive text containing information on the most common musculoskeletal pathologies seen and the best evidence behind contemporary interventions directed towards the treatment of impairments and limitations associated with acute, chronic, and congenital musculoskeletal conditions, which occur across the lifespan. *Volume IV, Athletic and Sport Issues in Musculoskeletal Rehabilitation*, covers those topics edited by the original editors plus a new editor, Robert Manske, updated and expanded the sports related topics from the original text and provided information to clinicians interested in treating high-level athletes.

International contributors have provided their unique perspectives on current diagnostic methodologies, clinical techniques, and rehabilitative concerns. We hope that our continued use of interdisciplinary author teams has in some small way broken down the professional "territorial turf" barriers that have existed in past decades of health care. Health care professionals involved in the contemporary care of musculoskeletal conditions must continue to share and learn from one another to advance the provision of the most time- and cost-efficient care possible in twenty-first century society.

Each volume in our series is liberally illustrated. Key concepts in each chapter are highlighted in text boxes, which serve to reinforce those concepts for the reader, and numerous tables summarize chapter information for easy reference. Because of the comprehensive nature of this multi-volume series, each text, although complete in itself, has been edited to build and integrate with related chapter materials from the other volumes in the series. It is the editors' hope that this series will find its way into use by faculty as a basis for formal coursework as well as a friendly companion and frequently consulted reference by students and those on the front lines of clinical care.

As with our previous collaborations, we look forward to the feedback that only you, our colleagues, can provide, so that we may continue the development and improvement of the *Musculoskeletal Rehabilitation Series.*

David J. Magee
James E. Zachazewski
William S. Quillen
Robert C. Manske

Preface
Pathology and Intervention, 2nd edition

Pathology and Intervention is the third book in the *Musculoskeletal Rehabilitation Series* dedicated to providing students and practicing clinicians with a comprehensive integrated musculoskeletal resource to consult regarding the most common area of practice for most clinicians involved in musculoskeletal rehabilitation. In this text, we have assembled an exceptional multidisciplinary group of clinicians to present the best evidence behind contemporary interventions directed toward the treatment of the impairments and functional limitations associated with acute, chronic, and congenital musculoskeletal conditions occurring across the lifespan. In this second edition, we have added chapters on skin and wound healing, rotator cuff pathology, and musculoskeletal bone and soft tissue tumors.

In an effort to maximize the volume of information presented on specific pathologies and methods of interventions, and to minimize the duplication of information, we have asked the authors, and edited the text, to refer readers to *Volume I, Orthopedic Physical Assessment,* and to *Volume II, Scientific Foundations and Principles of Practice,* for basic science information regarding inflammation, healing, tissue deformation, and the development of muscular strength and endurance. This has allowed the authors to provide the reader with as much information as possible on the specific pathologies most often seen in the clinic and the best methods of treatment intervention.

We have again asked the authors to concentrate on answering the key questions of who?, what?, when?, where?, why?, and how?. **Who** usually suffers from the types of injuries and conditions described? **What** are the best methods of intervention for these conditions? **When** should intervention be initiated? **Where** does the practicing clinician find the information on which the authors base their recommended methods of intervention? **Why** should the reader utilize the author's recommendations? **How** should the clinician progress the patient toward full recovery? We believe that the authors have effectively answered these questions, giving the reader a textbook that will prove valuable for years to come.

Finally, we would like to thank those authors who contributed to the first edition of this book but decided, for various reasons, not to be involved in the second edition. We would especially like to thank the previous authors and new authors who contributed to the second edition. Your expertise and taking the time to update and add new information to chapters and to add new chapters have been a great contribution to the book. Thank you!

David J. Magee

CHAPTER 1

Patient Education, Motivation, Compliance, and Adherence to Physical Activity, Exercise, and Rehabilitation

KEIBA L. SHAW

INTRODUCTION

The importance of physical activity and engagement in structured and planned activities through exercise has been considered to be one of the main determinants that influence the aging process as well as health-related quality of life. This concept of health-related quality of life exploded in 1996 with the Surgeon General's Report on Physical Activity and Health that brought forth the importance of engaging in an active lifestyle to prevent the onset of chronic disease and illness,[1] followed by the National Blueprint in 2001 that stressed the importance of physical activity in adults aged 50 years and older[2] and the U.S. Department of Health and Human Services (HHS) 2008 Physical Activity Guidelines for Americans document that provided "science-based guidance to help Americans aged 6 and older improve their health through appropriate physical activity" (p. vi).[3] The Centers for Disease Control and Prevention (CDC) issued a State Indicator Report on Physical Activity in 2014, presenting state-level information on physical activity behaviors and environmental and policy supports for physical activity. In this report, physical activity among adults and high school students was found to be higher in some states than others (e.g., Colorado >25% versus Mississippi <15%) and that overall most states have environmental and policy strategies that encouraged physical activity.[4] This is good news, but more work needs to be done. It can be safely said that being sedentary is one of the most important health problems of our time and increasing activity levels is often devalued by a large portion of the population as well as health care providers who perhaps believe that there is a "magic pill" that will reduce health care risks. Physicians and other clinicians are more likely to measure cholesterol, blood pressure, and body mass index (BMI) than measure parameters that assess fitness levels, such as a maximal exercise test or at the very least a questionnaire examining physical activity or exercise history.[5]

THE PROFESSIONAL'S ROLE IN MOTIVATION ADHERENCE

What is Meant by Motivation, Adherence, and Compliance?

Motivation is literally the desire to do things. It is the critical element in setting and attaining goals—and research shows that one can influence one's own levels of motivation and self-control. The word motivation is derived from the Latin term *movere*, meaning "to move."[6] In essence the term *motivation* attempts to capture the "how" and "what" that moves a person to make certain choices, engage in action, expend effort, and therefore persist in action. Although this definition captures the essence of motivation, there is considerable debate on what this term actually means to individuals and at times to a population as a whole. Motivation has a range of influences on human behavior, and because of this there is no one motivational theory in existence that gives a comprehensive and integrative account of this concept. Nonetheless, a discussion of some of the more prominent and pertinent motivational theories is warranted to

help explain or rather hypothesize why individuals think and behave as they do. Motivation to perform an action typically comes about through a gradual awakening of complex mental processes that takes initiative, planning, goal setting, intention formation, task generation, action implementation, action control, and outcome evaluation.

Obtaining a desired reward or experiencing pleasant sensations or escaping undesired, unpleasant consequences is often the impetus for engaging or not engaging in a behavior. Behavioral needs will often inspire individuals to act so as to avoid unwanted consequences or pursue desired responses. Socially, individuals will strive to be valued members of a group, thereby being able to imitate the positive (or negative) behaviors of others within the group. As biological beings, individuals strive to increase or decrease stimulation or arousal while seeking to maximize pleasurable sensations that affect our five senses (i.e., sight, touch, taste, smell, and hearing). In addition, individuals strive to minimize those unpleasant sensations, such as thirst, hunger, and anything that makes one uncomfortable, seeking to maintain homeostasis and balance as a system in the long term. At the cognitive level, individuals are inspired to maintain an attention to things that one deems interesting or threatening, while seeking to develop meaning and understanding to those things with which one is unfamiliar. Again, one strives to increase equilibrium while eliminating anything that one may see as a danger to his or her survival. In the affective domain, motivation plays a large role in order to decrease emotional dissonance. There is a drive to feel good and a need to increase one's sense of well-being and self-esteem. Security in one's surroundings and within oneself is sought after, and the individual strives to maintain adequate levels of optimism and enthusiasm to obtain it. Optimism is a cognitive construct (e.g., expectancies regarding future outcomes) that relates to motivation. People who are optimistic exert effort, whereas pessimistic people disengage from effort.[7] Evidence suggests that individuals who are pessimistic do not fare as well as those who are more optimistic with exercise participation. In a study assessing the relationship between optimism and indices of healthy aging, it was concluded that dispositional optimism was associated with healthy aging.[7] The relationship between optimism and healthy aging was assessed across three dimensions of health behavior: smoking, alcohol consumption, and physical activity. It was found that higher optimism was positively related to healthy behavior choices.[8]

Motivational Theories

In both the psychology and sport psychology literature, motivation has been classified as either being intrinsic (internal) or extrinsic (external). In addition, individuals will act to satisfy or meet basic needs (Figure 1-1).[9,10] In fact, people will satisfy a need or want by engaging or not engaging in certain behaviors. These needs can be classified as behavioral or external and social, biological, cognitive, affective, conative, or spiritual.[11]

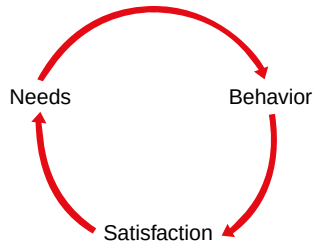

Figure 1-1 The basis of motivational theories.

Behavioral needs will often inspire individuals to act to avoid unwanted consequences or pursue desired responses. We strive to be valued members of a group and therefore will imitate the positive and/or negative behaviors of others within the group. As biological beings, we strive to maximize sensations that engage our five senses and are pleasurable while striving to minimize sensations that we find to be unpleasant (e.g., thirst, hunger). In this way, we seek to maintain homeostasis and balance in the long term. Cognitively, individuals maintain attention to things that are of interest or that they feel are a threat while seeking to construct meaning and to understand those things with which one is unfamiliar. This again serves to achieve equilibrium while eliminating things that may be seen as threat or danger to one's survival.

Research has shown that individuals who are pessimistic do not fare as well with exercise participation as those who are more optimistic.

Decreasing emotional dissonance is accomplished in part by how much one is motivated to feel good and to increase one's self-esteem. Individuals strive to increase feelings of security in their surroundings as well as within themselves. Seeking to maintain adequate levels of optimism and enthusiasm helps to secure this feeling. Research has shown that individuals who are pessimistic do not fare as well as those who are more optimistic with exercise participation.[12]

The framework surrounding the most popular theories on motivation revolves around three major areas: social cognition, humanistic, and multidimensional.

Taking control, developing and maintaining self-efficacy, and meeting individually developed goals are additional aspects of motivation. Individuals have personal dreams and needs related to fulfilling those dreams.

Social Cognitive Theory

Social cognitive theory, as developed and postulated by Albert Bandura, proposed reciprocal determinism as a leading factor in motivation.[13] Individuals act as

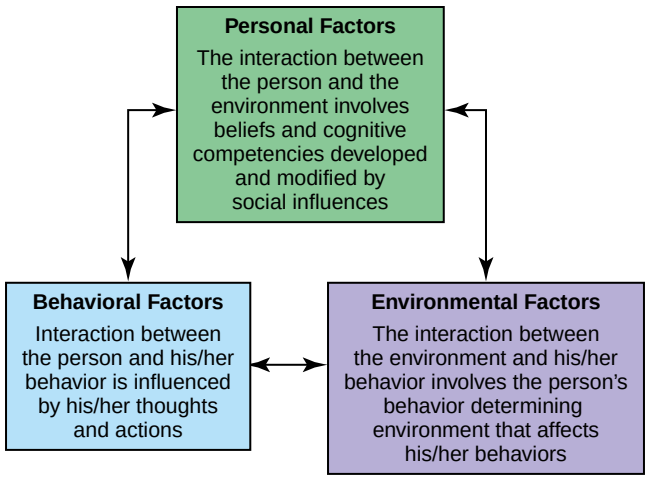

Figure 1-2 Social cognitive theory. (Redrawn from Kosling A, Heppner C, Elliott S: Motivation-project, wikispaces.com. Available at: http://motivation-project.wikispaces.com/Socio-cognitive+Theories+of+Motivation. Accessed December 5, 2014.)

contributors to their own motivation, behavior, and development. In addition, the environment interacts with the individual's behavior and characteristics in order to produce engagement or disengagement in an activity. Simply stated, human development is a back-and-forth interaction between the individual (his or her interpretation and retention of specific information), his or her behaviors, and the environment (Figure 1-2).

In addition, Bandura suggested that self-efficacy, which is the belief that a particular action is possible and can be accomplished, along with the ability to self-regulate, was the primary mediator in producing a change in behavior. He advocated that self-efficacy was a good predictor of intention. Self-efficacy and the mediating effect of cognition are seen as a circular process by which an increase in self-efficacy in turn produces success, thereby contributing to an increase in self-efficacy and the thought that one can indeed be triumphant in his or her actions. In turn, failures undermine self-efficacy, especially if failure occurs before one has developed a strong sense of self-efficacy. For example, a person who has successfully rehabilitated from an injury in the past will have the same belief that, if injured, he or she will be able to successfully recover from that injury and return to his or her accustomed activities. The more experience that one has in successfully overcoming the obstacles (i.e., multiple successes within the same area, in the example, injury recovery), the more one will believe that he or she has the "tools" with which to cope with other challenges to come. Bandura theorized that the best way to create a strong sense of efficacy was through mastery, whereby successes served as a base for development of the individual's personal efficacy. It is in this way that further mastery will promote repeat performances and improve adherence to physical activity, exercise, and rehabilitation.[14]

Self-determination Theory: An Empirical Framework for Understanding Health Behavior Change

Self-determination theory (SDT)[11] is a broad psychological theory of motivation particularly suited to understanding health behavior.[15] One of its basic tenets is that human motivation varies in the extent to which it is *autonomous* (i.e., when an individual engages in a behavior with a full sense of volition and choice) or *controlled* (i.e., when an individual engages in a behavior while experiencing internal or external pressure) along a continuum. *Identified regulation* (i.e., engaging in an activity because it is perceived as personally important and useful), *integrated regulation* (i.e., engaging in an activity because it is perceived as coherent with his or her values and identity), and *intrinsic motivation* (i.e., engaging in an activity because of the inherent satisfaction it conveys) represent increasingly autonomous forms of motivation. In contrast, *introjected regulation* (i.e., engaging in an activity to avoid negative emotions, such as anxiety or guilt) and *external regulation* (i.e., engaging in an activity to obtain a tangible reward, to avoid a punishment, or to comply with an external authority) represent increasingly controlled forms of motivation. In addition to autonomous and controlled forms of motivation, SDT also considers *amotivation* (i.e., individuals see no relationship between behavior and outcomes), which represents the absence of motivation.[11]

While the differentiation between autonomous versus controlled motivation is central to SDT, *perceived competence* (i.e., individuals' feeling of efficacy with respect to the behavior) is an important variable of the theory presumed to facilitate autonomous motivation.[11] Furthermore, SDT suggests that the social context—in particular the degree of autonomy support provided by health care supervisors (i.e., active listening, collaboration, respect, and thorough support)—may improve patients' autonomous motivation, perceived competence, and health-relevant behaviors.[16] Research has shown that perceived *autonomy support*, *autonomous forms of motivation*, and *perceived competence* are related to positive health outcomes,[15] such as a reduction in BMI[17] and an increase in physical activity among obese or overweight patients.[17,18] In a study[19] evaluating the effect of a motivational interview (MI)-based intervention as an addition to a standard weight loss program on physical activity practice in obese adolescents over a 6-month period, the standard weight loss group with MI intervention had a greater BMI decrease and a greater physical activity practice increase over time. This group also reported greater autonomy support from medical staff at the end of the program, greater increase in integrated and identified regulations, and a decrease in amotivation. The determination was made that MI is an efficient counseling method as an addition to a standard weight loss program to promote physical activity in the context of pediatric obesity.[19]

A subtheory within the SDT is *cognitive evaluation theory* (CET), which, simply put, means that people engage

in activities to satisfy certain inherent needs as well as to gain intrinsic rewards and satisfaction. CET also proposes that if an individual who was previously intrinsically motivated to meet certain psychological needs but was then given extrinsic rewards for their behavior, by the very nature of the process (i.e., through cognitive rethinking), the individual would lose his or her "locus of causality" and move to being more extrinsically motivated.[20,21] Events or actions that occur and are affected by feedback, communication, and rewards and that elicit a sense of competence during the action will serve to enhance intrinsic motivation for those events or actions.[21] In this way, external sources may serve to either increase or decrease intrinsic motivation for action.

SDT suggests that humans have psychological needs for competence, relatedness, and autonomy that must be satisfied in a way that fosters immediate well-being and strengthens inner resources contributing to subsequent resilience. *Competence* pertains to the mastery and a need to control desirable outcomes. In this sense it is related to self-efficacy or the confidence in one's ability to achieve a certain outcome.[13] Goal setting and action planning are avenues that can serve to increase feelings of competence.

Relatedness refers to the universal need to feel connected to and experience caring from others. It is the need to be understood by important others in our lives.[22] Feelings of relatedness can influence motivation if one does not feel as if he or she is heard or if there is conflict within a social setting. For example, relatedness and thus motivation are enhanced via the empathetic listening of clinicians and during social interactions, such as during exercise group sessions.[22]

Autonomy or independence is the universal urge to act in harmony with and to be in control of one's own life. As clinicians it is essential not to impose one's thoughts or ideas but rather to incorporate clients/patients into important goals and decisions regarding their lives. Vansteenkiste and Ryan have noted that if these needs are not satisfied, subsequent feelings of frustration will heighten vulnerabilities and trigger defense mechanisms.[23]

Health Belief and Health Promotion Models: Theories of Reasoned Action and Planned Behavior

The health belief model includes the motivational, attitudinal, and self-efficacy components of various theories. The *theory of reasoned action* (TRA) and *theory of planned behavior* (TPB) as developed by Ajzen and Fishbein[20] and Ajzen[21] take into account the individual's attitude and social norms as well as the individual's perceived control as accurate predictors of behavioral intentions. TRA is most successful when applied to behaviors that are under an individual's voluntary control. If behaviors are not fully under voluntary control, even though individuals may be highly motivated by their own attitudes and subjective norms, they may not actually perform the behavior due to intervening environmental conditions. The TPB was developed to predict behaviors in which individuals have incomplete voluntary control. Taking self-esteem and self-efficacy into consideration, the TPB expands on the concept of perceived behavioral control. *Perceived behavioral control* indicates that an individual's motivation is influenced by how difficult the behaviors are perceived to be, as well as the perception of how successfully the individual can (or cannot) perform the activity. It is easy to see how this theory may relate to the concept of motivation and adherence to physical activity and/or exercise, especially in the rehabilitation setting. If a patient's perceived control or self-efficacy or self-esteem is low, the perception and belief that he or she can influence own behaviors in a positive manner is undermined. In a study assessing risk behavior following coronary heart disease diagnosis, planned behavior was found to be the main factor in predicting self-reported exercise and observed fitness levels.[24] When exercise intention and behavior were assessed in a sample of 225 older women aged 65 years and older, significant predictors of exercise intention were behavioral beliefs, normative beliefs, and perceived control beliefs.[25] In other words these women were more likely to exercise if they perceived more positive than negative consequences of performing the behavior (i.e., behavior beliefs), if they believed that people close or important to them approved versus disapproved of their behavior (i.e., normative beliefs), and, lastly, if they believed the difficulty of the task was manageable by them (i.e., perceived control belief).[25]

Humanistic Theory: Maslow's Hierarchy of Needs

This theory, as proposed by Abraham Maslow,[9] is one of the most popular theories of motivation. According to the theory, humans are driven to achieve their maximum potential and will always do so unless obstacles are placed in their way. This theory states that specific needs must be met in order to achieve ones' potential, which Maslow termed *self-actualization*, or a complete understanding of oneself and those around us. In essence, self-actualization includes focusing on problems, incorporating a continuous appreciation for life, concern about personal growth, and the ability to have peak and meaningful experiences. Needless to say, there are few, if any, individuals who have reached this level. Illustrated is Maslow's pyramid of needs (Figure 1-3).[26]

According to Maslow the obstacles put in our paths are reflective of basic needs, such as hunger, thirst, financial problems, safety, and time constraints, essentially anything that detracts from our pursuit of maximum growth. In this theory it is not possible to focus on the higher levels without first obtaining some mastery of the lower levels. Indeed, how can one concentrate on transcendence and actualization if basic needs for food, comfort, sleep, and safety are unmet? In the same vein, one can ask the question: How can one focus on the maintenance or improvement of one's health through physical activity and exercise if basic needs go unfulfilled?

Multidimensional Model: Transtheoretical Model and Stages of Change

The transtheoretical model (TTM) was first introduced by Prochaska and DiClemente[27] as a theoretical model of behavior change related to smoking cessation. This model has since been used for developing effective interventions to promote health behavior change across a variety of settings and individuals of varying ages. The TTM is an integrative model of behavioral change that incorporates a decisional balance, temptation, and self-efficacy scales.[27–30] The model describes stages of change, including precontemplation, contemplation, preparation, action, maintenance, and relapse (Figure 1-4; Table 1-1).

Precontemplation Stage. The hallmark of this stage is the person's lack of intention to take action. Individuals will have a variety of reasons for not being engaged in an activity. These reasons range from being uninformed or underinformed about the benefits of participation to having attempted the behavior previously and not being successful. The latter may often prove to be demoralizing to the individual attempting the behavioral change. For example, an obese patient may have tried unsuccessfully

TABLE **1-1**

Stages of Change Model

Stage	Characteristics
Precontemplation	Identified with individuals who do not intend to take action regarding the specific behavior (e.g., "I don't exercise, and I don't intend to start.")
Contemplation	Identified with individuals who intend to change their behavior within the next 6 months (e.g.,"I don't exercise, but I'm thinking about starting.")
Preparation	Identified with individuals who intend to take action in the immediate future (e.g., "I exercise once in a while but not regularly.")
Action	Identified with individuals who have made specific and explicit changes in their behaviors and lifestyle within the past 6 months (e.g., "I exercise regularly and have done so for the past 6 months.")
Maintenance	Identified with individuals who are actively working to prevent relapse into previous behaviors and habits (e.g., "I exercise regularly and have done so for longer than 6 months.")
Relapse	There is a resumption of old behaviors (e.g., "fall from grace"): • Evaluate trigger for relapse • Reassess motivation and barriers • Plan stronger coping strategies

to engage in an exercise program to lose weight and therefore has no thoughts or intentions of trying again.

Contemplation Stage. This stage is typical of the person who is thinking about engaging in the behavior or activity within the next 6 months. These people are usually open to receiving new knowledge and are interested in listening to the benefits that engaging in the behavior might accomplish. For some individuals, this is as far as they will progress. In this stage, the person is aware of the "pros" of changing their behavior as well as of the "cons" of not changing. This awareness may cause the person to become ambivalent, leading to inaction on their part, and there is a danger of becoming stagnant in the "information gathering" mode. Patients in this stage will say things such as, "I know I should be doing these exercises, but I don't have the _____ (e.g., time, money, equipment)."

Preparation Stage. Individuals in this stage are intending to take action within the immediate future (i.e., within 30 days) and are typified by both intentional and behavioral components. These individuals have taken some concrete action toward the behavior change. In essence, they have a plan of action that they have begun to implement. For example, they may have made an appointment with the clinician, or they have bought appropriate workout shoes.

Action Stage. Individuals are actively engaged in the behaviors and/or lifestyle changes that will promote improved health. Individuals within this stage are encouraged and taught relapse prevention strategies because the changes they have made are considered new and therefore tenuous. In this stage, relapse prevention is critical and there are criteria that have been established that qualify the change in behavior as sufficient for reducing the risk of disease. These strategies include making sure the individual is aware of occasional "slips" in commitment to routine. The person needs to be made aware that missing an occasional workout session or rehabilitation appointment does not doom one to failure or that "cheating" on diet does not mean that one cannot get back on task. Shifting the focus from failure to successes (e.g., "You did it for 6 days; what made that work?") promotes problem solving and offers encouragement.

Maintenance Stage. Engagement in the behavioral change for more than 6 months will classify individuals in this stage. Prevention against boredom and changing focus is essential during this stage. This can be accomplished through the establishment of creative, new supporting behaviors. Supportive behaviors include the continual addressing of barriers as they arise, reformulation of the rules of their lives as related to the behavior change, and acquisition of new skills (e.g., problem-solving and coping mechanisms) to deal with life and avoid relapses. Anticipating situations in which a relapse could occur and preparing coping strategies in advance should be emphasized to individuals who are in this stage. Being patient with themselves and recognizing that it often takes a while to let go of old behavior patterns and practice new ones needs to be encouraged and reinforced. Individuals in this stage will have recurring thoughts of returning to their old habits (e.g., not exercising, making poor dietary choices, skipping rehabilitation appointments), but they usually resist the temptation and stay on track because they have noted progress. As mentioned previously, the TTM encompasses an integrative schema for behavior change, including an examination of cost and benefits inherent in the decisional balance model. Using this model, individuals weigh the relative importance of the "cons" against the importance of the "pros" of engaging in any particular behavior change. In examining the stages of change in relation to healthy (e.g., exercise) and unhealthy (e.g., smoking) behaviors, Velicer et al.[31] found a predictable pattern in the "pros" and "cons" in relation to stages of change (Figure 1-5).[32] In precontemplation, the "pros" of smoking far outweigh the "cons" of smoking. In contemplation, these two scales are more equal. In the advanced stages, the "cons" outweigh the "pros." With healthy behavior and stages of change, the patterns are analogous across the first three stages with the pros of the healthy behavior remaining high.

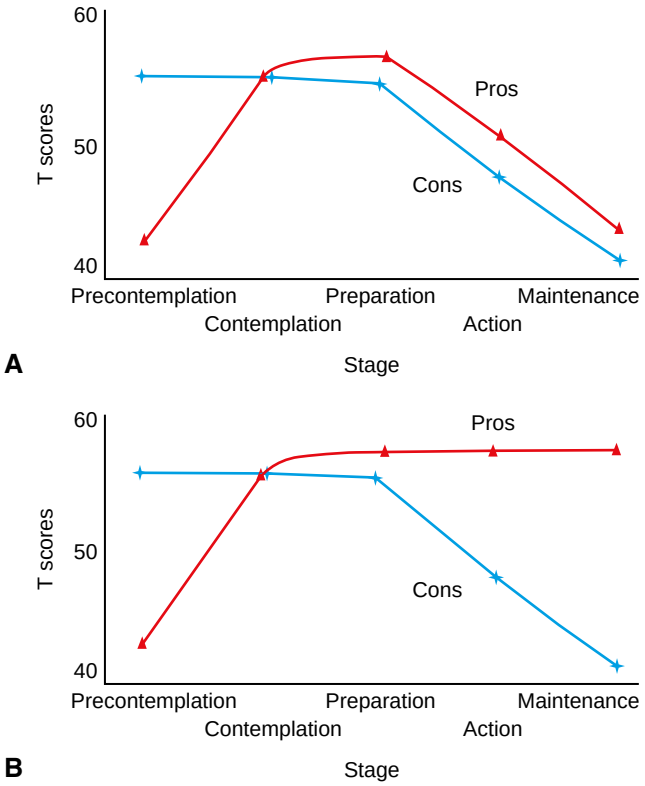

Figure 1-5 **A,** Stages of change and smoking. **B,** Stages of change and exercise. (From Velicer WF, Prochaska JO, Fava JL, et al: Using the transtheoretical model for population-based approaches to health promotion and disease prevention, *Homeostasis in Health and Disease* 40:174-195, 2000.)

Relapse Stage. Relapse is considered an important stage in the change process and commonly occurs during lifestyle changes. Relapse should be used as an opportunity to learn about sustaining maintenance of the behavior change over time. Clinicians can help to encourage their clients/patients by explaining that even though a relapse has occurred, the patient has learned something new about oneself and about the process of changing or maintaining the changed behavior.[33] For example, patients who have started an exercise program recognize that if they do not do it at a set time each day, they may not get it done at all. Patients with diabetes may learn that they can be successful in adhering to their diet if they order from a menu rather than going to an all-you-can-eat buffet. Discouragement over occasional "slips" may halt the change process and result in the patient giving up. However, most patients find themselves "recycling" through the stages of change several times before the change becomes truly established.[33]

Focusing on the successful part of the plan (e.g., "You did it for 6 days; what made that work?") shifts the focus from failure, promotes problem solving, offers encouragement, and allows the client/patient to get back on the "proverbial horse." The goal is to offer support and help clients/patients to renew and reengage their efforts in the change process. They should be left with a sense of realistic goals to prevent discouragement, and their positive steps toward behavior change should be acknowledged.[34]

Advocates of using the stage of change model have cited its advantages as a model to predict and promote healthy behavior. One advantage of using this model is that it is able to match the stage that each individual is in with the proper intervention. For instance, if a person has purchased a pair of gym shoes and has joined the local gym, it can be stated according to the stage of change model that the individual is in the preparation stage. Interventions can then be focused on providing positive support and encouragement in facilitating the individual to move into the action stage. Another advantage of this model is that it helps the health and exercise professional to identify individuals who are indeed ready to change their behavior, thereby saving time and resources that could be better used elsewhere. Both the clinician and the patient should anticipate recycling *through the stages*. Many patients will recycle several times through the stages before achieving long-term maintenance as progression through the stages is circular rather than linear. Professionals, patients, and programs that expect people to progress linearly through the stages of change are likely to gather disappointing results. Clinicians should, as mentioned previously, be prepared to help their clients/patient by including relapse prevention as part of the treatment, anticipate the probability of recycling for patients, and try to minimize guilt and patient shame over recycling through the various stages.[35]

In a study examining barriers to physical activity by general practitioners and practice nurses, results indicated that general practitioners in the action or maintenance stage of behavioral change were 3 times more likely to regularly promote the same behavior in their patients than those in other stages.[9] In a critical review of the literature examining activity promotion interventions in a variety of populations based on the TTM, 26 studies using written material, counseling, or both were found.[36] Based on the review the authors found some evidence of short-term benefit in terms of activity levels or stage of activity change. Longer term effects were harder to achieve and maintain. In 73% of the short-term studies, a positive effect of TTM-based interventions over control conditions was seen. This is in contrast to longer term studies that showed only a 29% increase or positive effect of TTM-based interventions over the control. The numbers are encouraging, however, as the review seems to suggest that even a brief intervention using the TTM will have an effect on behavior change and should be encouraged in other settings and studies. In a study assessing motivational readiness to change, aerobic capacity and reported participation in leisure activities were higher for men and women in the stages of contemplation, preparation, action, and maintenance. Additionally, men in the contemplation stage had a higher BMI and a greater percentage of body fat compared with men in the maintenance and action stages. Likewise, men who were randomized to an exercise intervention group and who were initially in the contemplation and preparation stages had a 14% and 15% increase, respectively, in aerobic capacity at follow-up, whereas men in the action and maintenance stages had a 5% increase in aerobic capacity. For women, those in the contemplation, preparation and action stages had a 16%, 14% and 10% increase, respectively, in aerobic capacity. This study also examined the baseline stage of motivational readiness for exercise and found that over a 9-month intervention period, there were no differences in baseline stages of motivational readiness for exercise for the subjects reporting an increase in activity. Of the men in this study who participated in the exercise intervention and met their exercise goals, 54% were in the contemplation stage, 69% were in the preparation stage, and 68% were in the action and maintenance stages. For women, 35% initially in the contemplation stage met their intervention goals, whereas 67% and 24% who were initially classified in the preparation and action stages met their goals. This surprising finding revealed that adherence did not differ by baseline exercise motivational readiness stage as was often found in other studies.[37] The most reliably predicted stage of change for exercise were maintenance (90.2%), precontemplation (73.8%), and contemplation (70.8) stages in a study assessing factors influencing exercise behavior in adults with physical disabilities.[36] As previously mentioned, the primary role of clinicians in the maintenance stage is to help to prevent the relapse in their clients. This can be done by helping clients to reengage in their efforts in the change process by focusing on successes

and promoting realistic goal setting to prevent discouragement and to help them to continue to uphold their positive steps toward the changed behavior. Clinicians attempting to help clients who are in the precontemplation stage should be empathetic while attempting to engage their clients in questions that require thoughtful insight into the behavior requiring change. Instilling hope and the identification of incongruities between goals and statements can play a large part in inducing change in individuals in this stage. For individuals in the contemplation stage, clinicians should attempt to develop and maintain a positive relationship with their patients. This can come in the form of helping the individuals personalize risk factors while posing questions that provoke thoughts about the risk factors and potentially negative outcomes if they indeed do not change their behavior.

Multidimensional Model: Socioecological Model

The socioecological model serves as a framework for understanding the multiple levels that influence behavior. Ecological models assume not only that multiple levels of influence exist but also that these levels are interactive and reinforcing. These models vary from individual behavioral and cognitive models that do not offer a thorough explanation of how and why behavioral change occurs.[38] What the socioecological model offers is a consideration of the far reaching influences on behavior that consists of both internal and external factors ranging on an individual level to a more global or societal level and the interaction of each upon one another (Figure 1-6).

Ecological models assume not only that multiple levels of influence exist but also that these levels are interactive and reinforcing.

There are several assumptions made by the socioecological model. The first is that behavior is influenced by a multitude of factors at several levels, including biological, individual, interpersonal, community, environmental, policy, and global. The second assumption revolves around the understanding that the human environment is complex, meaning that we do not pay attention to only the physical or actual environment but also to the social attributes and the perceived qualities of the environment.[39] A third assumption of this model is that those who are active participants within the environment are, like the environment, complex and should be observed on multiple levels from the individual to small groups to larger organizations and the broader population.[40] The key of this assumption is that the focus should not be on any one element but on a coordinated effort to address multiple elements. A fourth assumption of the socioecological model is that there are factors in any individual's environment that can encourage or encumber participation in healthy behaviors. This simply means that once a person makes a choice, it is independently influenced more or less, positively or negatively, by the social and environmental situation in which the person lives and works.[39]

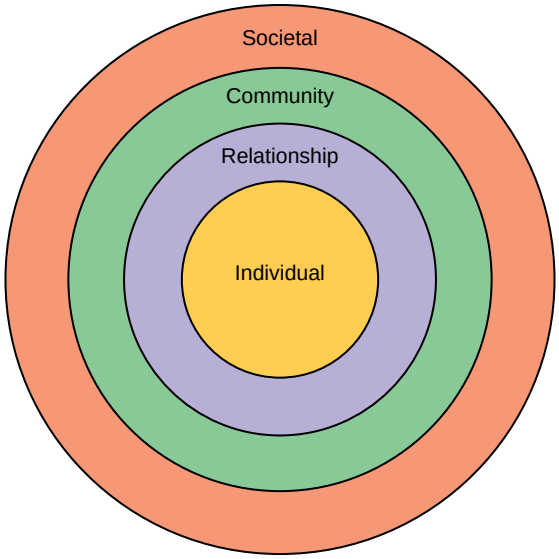

Figure 1-6 Socioecological model. (Redrawn from CDC: *The social-ecological model: a framework for prevention*, Centers for Disease Control and Prevention, National Center for Injury Prevention and Control, Division of Violence Prevention. Available at: http://www.cdc.gov/violenceprevention/overview/social-ecologicalmodel.html. Accessed December 5, 2014.)

A fifth assumption is that behavioral responses will vary from one person to the next even when viewed within a similar environmental context. Given two people within similar circumstance, the influence of familial norms, culture context, and emphasis as well as the influence of the physical environment (e.g., perceived safety, access) will play a role in whether either person engages in a behavior change.

The last assumption reflects that behavior as well as the environment is dynamic and fluid. Behavioral choices will be made in response to the ever changing environment. To put it another way, because the environment is not stable, behavioral choices will not always be the same; therefore flexibility on the individual's part is required.

THE PROFESSIONAL'S ROLE IN PHYSICAL ACTIVITY AND EXERCISE ADHERENCE

It is important to discuss the health care professional's role in motivating individuals to participate in physical activity and exercise. The importance of this role is particularly significant to the older adult population. In one study examining older adults who were frail and obese, lifestyle interventions associated with weight loss improved insulin sensitivity and other cardiac and metabolic risk factors, but continued improvement in insulin sensitivity was only achieved when exercise training was added to weight loss.[41] A study done by Schutzer and Graves[42] showed that individuals who were older

or chronically ill saw their physician at least once a year and preferred to receive advice about exercise from their physician or personal health care provider. Forty percent of older individuals on Medicare surveyed revealed participation in an exercise program was the result of their physician's advice.[43] In a study assessing long-term exercise adherence after rehabilitation for chronic low back pain, results revealed that physicians' and physical therapists' conveyance of the patient's capacity to perform the recommended exercises in spite of pain symptoms went a long way in reinforcing self-efficacy in the patient's ability to complete the exercises.[8] In assessing barriers to physical activity promotion for general practitioners and nurses, McKenna et al.[44] found that general practitioners in the action or maintenance stage of changing their own physical activity level were 3 times more likely to regularly promote the same behavior in their patients. It is in this way that professionals who exercise on a regular basis and "practice what they preach" will transfer these same beliefs, attitudes, behaviors, and action to their patients. In a study examining socioenvironmental exercise preferences among older adults,[45] results suggest that the perception of the exercise instructor as qualified, advice of the medical doctor to begin exercising, and evaluation by a health professional to monitor the physical effects of exercise were rated as most important in 320 adults 74 to 85 years of age living independently within the community. In addition, the health professional's ability to evaluate and demonstrate appropriate exercises and their ability to evaluate and monitor the physical effects of exercise were rated as very important. The latter finding is especially relevant to clinicians who treat older adults and who would like to encourage them to be active participants in their rehabilitation programs.

Dorflinger et al.[46] found that patients benefited from a biopsychosocial and patient-centered approach in the care of their low back pain. They found that patients were more likely to fully disclose when providers responded in an empathetic way. Sluijs et al.[47] found a relationship between positive feedback given to the patients by their physical therapists and noncompliance. It was inferred that if physical therapists did not give positive feedback to their patients, compliance to the rehabilitation program was decreased. The question remains, however, whether it was the positive feedback that facilitated compliance or compliance that facilitated the physical therapist to give positive feedback. It is presumed that it would be beneficial to give positive feedback so as to increase the likelihood that adherence to the rehabilitation program was obtained. Exercise professionals have the most influence over program factors when designing a plan for increasing client retention. Remembering to keep clients involved in designing their exercise programs is necessary because it will increase feelings of self-efficacy and greatly affect choice of exercise.

The author of a physical therapy blog quoted Albert Einstein stating "the definition of insanity is doing the same thing over and over and expecting different results." He also implied that even with this sage saying, clinicians continue to follow the same routine of creating patient exercise programs with diagrams and pictures of varying quality and expect them to go home and complete them without ensuring the exercises are understood and done correctly. He points out that practitioners do not change the routine when the patient does not comply with their directives. "We know that the majority of our patients aren't doing their exercises at home, and we aren't implementing strategies that affect change." He hypothesized that the reason clinicians do not do anything was because they believed that they did not have the capability to improve their patients' adherence. In turn, clinicians' low self-efficacy and perception of barriers translated into their patients having low self-efficacy and perceived barriers.[48]

Adherence

Adherence is defined by the World Health Organization (WHO) as the extent to which a person's behavior—taking medication, following a diet, participating in an exercise regimen, and/or executing lifestyle changes—corresponds to the recommendations of a health care provider.[49] *Exercise adherence* is the extent to which a patient acts in accordance with the advised interval, exercise dose, and exercise dosing regimen. The unit of measure for adherence is performed exercise doses per defined period of time reported as a proportion of prescribed exercise doses undergone at the prescribed time interval. *Exercise persistence* is the accumulation of time from initiation to discontinuation of therapy, measured by time metric (e.g., number of weeks or months to discontinuation). According to the WHO, adherence is simultaneously influenced by several factors, such as patient-related factors, social and economic factors, factors related to the health care team or system, condition-related factors, and therapy-related factors.[49]

Adherence can be assessed by subjective or objective methods or both. The subjective methods include physical activity questionnaires and diaries filled in by patients. Objective methods include the recording of data from pedometers, accelerometers, pulsometers (heart rate monitoring), and electrocardiogram (ECG) telemonitoring.[50]

FACTORS ASSOCIATED WITH MOTIVATION AND ADHERENCE TO PHYSICAL ACTIVITY, EXERCISE, AND REHABILITATION

As the reader has probably concluded, motivation and how it relates to adherence to physical activity and exercise is not an easy concept to explain. There are factors that have been identified and shown to be associated

with increased or decreased motivation and adherence to physical activity, exercise, and rehabilitation. Forkan et al.[51] found that exercise adherence following discharge from a physical therapy program was poor among older adults. It was also concluded that barriers, not motivators, were predictors of adherence across all factors associated with motivation and adherence to activity and exercise (Table 1-2).

Personal Factors

Characteristics that are considered inherent to the individual's personality fall into the category of personal factors that influence motivation and adherence. According to Whaley and Schrider,[52] how people view themselves from past experiences to current reality will greatly influence their choice for physical activity. A person's sense of self-perception plays a major role in whether one will start an exercise program. So even if, for medical reasons, one has been encouraged to exercise, the person's own self-perception may impede this from happening. These characteristics are referred to as being stable and representative dispositions of an individual's persona. These include concepts such as self-motivation, biomedical status, education, socioeconomic status (SES), age, ethnicity, and gender. Various studies have examined these concepts and how they relate to adherence and compliance in a variety of populations and as they relate to physical activity or exercise and rehabilitation adherence. The sport psychology literature covers other personal concepts, such as pain tolerance, task and ego involvement, and trait anxiety, as they influence rehabilitation adherence in the athletic population.

Personal Factors that Influence Motivation and Adherence

- Self-motivation
- Biomedical status
- Socioeconomic status
- Age
- Ethnicity
- Gender
- Marital status
- Education
- Smoking status

Self-Motivation

Self-motivation is the ability to persist in behaviors in spite of situational or environmental reinforcements[53] and has been found to be most consistently correlated with

TABLE 1-2

Characteristics Associated with Motivation and Adherence to Physical Activity, Exercise, and Rehabilitation

Factors	Description
Personal factors	Considered inherent individual's personality; stable and representative of the individual's persona
Self-motivation	Ability to persist in behaviors despite situational or environmental reinforcements
Biomedical status	Poorer health tends to lead to decreased adherence
Socioeconomic status	The individual's income bracket tends to influence the ability to access medical care as well as exercise equipment and venues
Age	In various studies, older individuals tend to adhere to exercise programs more than younger individuals
Ethnicity	Caucasians tend to participate in more physical activities than other racial or ethnic groups
Gender	Males tend to adhere to cardiac rehabilitation programs more than females; men report greater levels of total and vigorous activity than women
Marital status	Singles tend to have lower rates of adherence to physical activity and exercise than married couples
Education	Individuals with higher levels of education adhere to exercise programs more than those who are uneducated
Smoking status	Cigarette smokers tend to show less adherence to exercise programs
Situational and environmental factors	Social and physical environment in which the individual interacts will influence the positive or negative perception of the individual
Cognitive factors	What a person thinks about a situation or action influences the individual's emotional and behavioral responses
Behavioral factors	These factors are influenced by cognitive appraisal and by the person's belief that he or she can or cannot change his or her behavior

adherence to rehabilitation in athletes who have sustained a sport injury.[54,55] It stands to reason that individuals who are highly self-motivated will be more inclined to adhere to self-monitored exercise programs longer than those who are not as highly motivated. This being the case, increasing self-motivation would be advantageous for promoting adherence to various rehabilitation programs. Clinicians can help to improve one's ability to be self-motivated by assisting the person in building a history of success. For example, starting an individual with a task or exercise that is easily accomplished by the person and gradually increasing the level of difficulty will promote confidence and thereby inspire continued motivation to reach a particular goal. Allowing the individual to focus on successes rather than failures that may prevent the person from trying again is beneficial. To promote adherence to a self-pain management approach from a biopsychosocial perspective as well as a patient-centered approach has been successful.[46]

Biomedical Status

When a panel of geriatric exercise experts were asked to assess personal characteristics in regards to exercise behavior in older adults, biomedical status was rated as the most important factor in determining whether the older adult would initiate and adhere to exercise.[56] In other words, the determination of exercise participation is based on whether one perceives himself or herself to be in good health or not. This is important because health care providers can offer physical screens that would serve to reassure the individual that it is indeed safe and beneficial to exercise. This same panel also found that past exercise history and socioeconomic level were important for adherence in this population. Incorporating the individual's past exercise history will help identify strategies that will optimize future exercise behavior. This includes inquiring about what activities the individual liked or disliked in addition to soliciting information about perceived and real barriers and rewards.[43]

Questions to Ask to Determine Likelihood of Compliance with Exercise or Rehabilitation Programs

- Have you exercised or participated in a rehabilitation program in the past?
- What are some barriers that might prevent you from engaging in exercise and rehabilitation?
- What are some things that might help you to "stick" with the program?
- When you exercise, do you exercise alone or with others?
- Do you prefer to exercise alone or with others?
- What kind of activities and exercise do you like to do?
- What are your goals for participating in an exercise and rehabilitation program?

Socioeconomic Status

Interestingly, SES was found to be extremely relevant in the older population in promoting exercise adherence. As the income levels of individuals decrease or were fixed, the ability to pay for exercise advice, equipment, and an exercise facility became limited. For individuals who can no longer afford these expenses, adherence tended to decrease. Therefore it is essential for the health care provider to seek out information regarding income in order to best suit the needs of their clients and to increase the probability of adherence to an exercise and/or rehabilitation program.

Age

Age is another personal factor that has been found to be correlated with adherence to exercise and rehabilitation. In a group of church-going African Americans, older individuals tended to adhere to an exercise program more than younger individuals participating in an exercise intervention.[57] The researchers did note in this study that the exercise intervention was timed and coordinated to accommodate the schedules and needs of the older subjects, thereby potentially biasing the results. In a study assessing training levels and adherence in coronary heart disease patients between the ages of 30 and 67 years, it was found that older patients were more likely to sustain an exercise attendance schedule necessary to recoup therapeutic benefits.[58] In yet another study, participation and adherence to a physical activity program decreased in older individuals.[59] This decrease in participation might be attributed to an assortment of reasons, including poor health, lack of time, fear, and unsafe environment. In a more recent study, middle-aged women (40 to 62 years of age) stated that the most common barrier interfering with adherence to regular exercise was attributable to the demands inherently placed on them at this life stage, meaning demands at home and with others that led to lack of time to engage in regular exercise and menopausal symptoms associated with this life stage.[60]

Ethnicity

It has been found in the literature that Caucasians participate in more physical activities than other racial and ethnic groups regardless of age.[61] In a sample of African Americans, a 27% attendance rate to a church-based exercise program was noted, providing some support for the notion that minorities tend to adhere less to physical activity and exercise programs. In a study examining adherence to the Dietary Approaches to Stop Hypertension (DASH) diet, it was found that African Americans were less likely to be adherent to the dietary eating plan than Caucasians.[62] In a pilot study assessing irrational health beliefs as a predictor to cardiac rehabilitation adherence, it was found that adherence was lower among African Americans than Caucasians.[63]

Gender

Men have been found to be more engaged and adherent to physical activity or exercise and cardiac phase II rehabilitation programs than women.[64] In a study examining the effects of a 6-month home physical activity program on adherence, it was found that retention rates and adherence were higher for men than women.[65] In assessing the effect of tailored interventions on exercise adherence, Keele-Smith and Leon[61] found women to be more inactive than men and that more men than women were reported to have engaged in vigorous physical activity. When demographic and other variables were examined, assessing participation in American College of Sports Medicine and Center for Disease Control exercise guidelines in a cohort of adults 18 years and older, women were less likely to meet the guidelines as recommended by these groups. In addition, men reported greater levels of total and vigorous activity with women reporting engagement in low to moderate activities.[66] In a sample of college students, 92% of males versus 63% of females reported engaging in regular exercise.[67]

Marital Status

Another personal factor that may play an important part in determining level of motivation for physical activity or exercise and rehabilitation participation is marital status; those who were unmarried tended to have lower adherence,[61] which may be directly related to social support, which will be discussed later. A meta-analysis of the general medical literature concluded that adherence to medical recommendations was higher in married patients.[68]

Education and Smoking Status

Other personal factors include education, in which individuals who were not as educated adhered less to health-related programs,[56,61] and smoking status, in which cigarette smokers tended to be less committed to making healthy lifestyle changes[45] and were less able to maintain a consistent exercise program.[58]

Situational or Environmental Factors

Situational factors are representative of the social and physical environment in which the individual interacts. Therefore the presence of other people, including the health care or exercise specialist and other patients or clients, will influence whether the individual has a positive or negative perception and experience with physical activity, exercise, or rehabilitation.[69] Seguin et al.[69] emphasized that there was a significant relationship in a client/patient's exercise adherence with his or her personal trainer's leadership style. It was found that exercise leaders who were perceived to have a high mastery of exercise favorably influenced client exercise adherence. Thus exercise professionals may be esteemed role models for their clients.

Situationally, convenience of location of exercise facilities and convenience of exercise opportunities (e.g., research solicitations) will often facilitate adherence to exercise programs. In addition, the quality of the patient/client–practitioner interaction will either help or deter the quality of the participation on the individual's part.

Environmentally, the characteristics of the actual exercise or rehabilitation setting and time of day also are important to individuals and can, in part, determine adherence. Individuals have a preferred time of day and setting in which they will feel the most comfortable and be the most likely to follow through with established exercise and/or rehabilitation protocols. Therefore it is critical for the practitioner to establish an environment and situation to best suit the individual's need to best ensure adherence.

Cognitive Factors

What a person thinks about a situation or action will mediate emotional and behavioral responses to an event. If one perceives something to be out of one's control, then one will either not attempt to perform the behavior or will expect to fail in that behavior. This is especially relevant when trying to elicit changes in health behaviors. If individuals do not believe they will be successful in the tasks set forth by the exercise and physical activity guidelines, they may be more apt not to engage in the activity. It is in this sense that education is helpful in facilitating cognitive reappraisals and the belief that individuals can engage in behaviors conducive to positively affecting health.

Behavioral Factors

Whether individuals engage in behaviors is reflective, as stated previously, on the cognitive appraisal of the situational context. In rehabilitation, one's cognitive belief that he or she will not only be able to cope with the injury but also cope well will determine if he or she will exhibit behaviors conducive to recovery. Changing behaviors, especially health-related behavior, has proven to be difficult. Strategies in the form of behavioral modification (also known as behavioral interventions) are practiced in psychology and rehabilitation in order to encourage the desired change in individuals. For example, encouraging the individual to make a commitment in private by choosing and committing, and then later going public by announcing to others the decision to change is a powerful step toward behavior change. The public commitment is more powerful than the private decision. Another way to encourage behavior change is to have an individual sign a written contract. This contract is an agreement made between themselves and the clinician to engage in specific steps in order to reach mutually established goals.

BARRIERS ASSOCIATED WITH DECREASED MOTIVATION AND ADHERENCE, OR COMPLIANCE TO PHYSICAL ACTIVITY, EXERCISE, AND REHABILITATION

The factors discussed pertaining to motivation, adherence, and compliance to exercise and rehabilitation, although reflective of mainly theoretical manifestations of personality, situation, and cognition, do not adequately identify the perceived and real issue of individuals who are most at risk for health-related decline as a result of nonparticipation or inadequate participation. The following discussion will include an identification of barriers (Table 1-3), both perceived and real, and how health care providers and exercise specialists can help individuals overcome them.

Knowledge regarding patients' barriers for nonadherence and reasons for drop-out from cardiac rehabilitation programs may provide guidance for designing successful strategies to increase participation. The main barriers identified in a study examining adherence to exercise rehabilitation in patients with congestive heart failure ranged from patient-related (e.g., older age, low level of education, low SES, minority status, anxiety and depression, and lack of motivation, insight, and time) to health care system or team barriers (e.g., lack of expertise, lack of referrals) and condition-related barriers (e.g., severity of symptoms, level of disability, rate of disease progression, impact of co-morbidities). This same study also cited therapy-related barriers, such as lack of exercise relevance and difficulty of incorporating exercise into the patients' daily life.[70] There were several barriers to adherence that were found in a systematic review by Jack et al.[71] In this review there was strong supporting evidence that poor treatment adherence to outpatient physical therapy was associated with low levels of physical activity at baseline, low in-treatment adherence with exercise, low self-efficacy, depression, anxiety, helplessness, poor social support or activity, greater perceived number of barriers to exercise, and increased pain levels during exercise. An exploration of many of these barriers and possible strategies to overcome them follows.

TABLE 1-3

Barriers Associated with Decreased Motivation and Adherence or Compliance to Physical Activity, Exercise, and Rehabilitation

Barrier	Overview
Environment	Includes physical obstacles, access to and cost of health clubs and rehabilitation centers, and climate
Health	Includes unhealthy behaviors, such as smoking, perception of poor health, and individuals suffering from chronic illness
Supervision and direction	Lack of supervision and guidance for exercise has been a deterrent in initiation of and compliance to exercise
Time	Lack of time for exercise; exercise programs taking too much time
Family	Family responsibilities and obligations may take priority over rehabilitation and exercise
Occupation	Responsibilities and obligations of work may take priority over rehabilitation and exercise

Environment

The physical environment can be a detriment to some individuals when deciding if they should commit to an exercise and/or rehabilitative program. This is true across the lifespan, from the young to the older persons who would be well advised to change their exercise behavior. In a sample of African American women (18 to 64 years of age) with physical disabilities, the cost of joining a fitness center, lack of transportation, and being afraid to leave their home were ranked 1 through 3, respectively, as barriers to exercise.[72] When examining ways to overcome exercise barriers in older adults, identified environmental barriers included physician advice, access to and cost of health clubs and rehabilitation centers, and climate.[73] As mentioned previously, if physicians did not inquire about diet and exercise, the perception that they were not important on the part of the patient was high. In addition, lack of follow-up to monitor progress or goal achievement and busy schedules on the part of the health care provider and/or exercise specialist will often promote nonadherence in individual patients.

When one considers access and cost, many individuals, especially those living in low income areas and the elderly, do not have the monetary funds to join an area gym. Although there are some areas that will provide free access to fitness and recreational equipment, individuals may not be able to afford the transportation to these facilities. Similarly, walking may not be an option because some patients may live in dangerous neighborhoods where crime is high.[42,74] Finding a safe environment for patients and clients to exercise should be a priority for the health care provider and other exercise specialists.[75] It has been shown that older adults who do not live in the vicinity of recreational facilities often do not participate in regular exercise and are more sedentary.[75] For individuals living in the northern climates, weather

conditions may not be conducive to engaging regularly in outdoor activities.[42] In the same sense, individuals living in warmer climates may be impeded by high humidity and/or heat. In either case, extremes in the weather often will preclude individuals for up to 6 months from participating in a regular exercise routine.[73] In the rehabilitation environment, patients with physical disabilities often point to lack of adaptive space and/or accessible equipment, along with poor equipment maintenance, as barriers.[72] These individuals also revealed that they perceived fitness and recreational facilities to be unfriendly to individuals with physical disabilities.

Health

Unhealthy behaviors, such as smoking and leading a sedentary lifestyle, are contributors to both acute and chronic diseases in the general population. Abolishing or at the very least reducing these practices ideally should promote increased quality of life. Facilitating exercise and adherence to exercise programs is often encumbered by the individual's perception that poor health is limiting the ability to participate in exercise and rehabilitation programs. Older adults in particular will often cite poor health as the leading barrier to physical activity and exercise.[76] In a group of cardiac rehabilitation patients, gender and barrier efficacy were related to overcoming health barriers, such as fear of having another cardiac event, medication side effects, and angina or chest pain.[64] These investigators also found that men more than women tended to have higher barrier efficacy (i.e., they felt more capable of engaging the cardiac program without experiencing detrimental effects to their health). During the initiation and adherence stage of a study examining exercise behavior in older adults, biomedical status was implicated as the most important determinant of exercise adherence.[43] A panel of experts agreed that initiation and adherence to an exercise program in the older adult depended on their state of health.[56] When examining factors associated with physical activity participation in older adults in the population (≥65 years old), the most commonly reported barrier to increasing physical activity was health problems.[77] Sluijs et al.[47] reported in their review of the literature that characteristics associated with certain illnesses related to compliance: "When the illness causes more disabilities and handicaps and patients perceive the illness as very serious, they appear to be more compliant (with rehabilitation) than patients with less serious illness" (p. 772). They also reported that patients with chronic illnesses seemed to be less compliant than those with acute illnesses, suggesting that recovery from the illness is an incentive within itself to participate in the exercise regimen as dictated by their rehabilitation. In a group of middle-aged and older women participating in the Sedentary Women Exercise Adherence Trial (SWEAT), the most common reason stated for withdrawal from an exercise program was illness or injury.[78] Add to this, fear of injury or reinjury, and compliance to rehabilitation and other exercise programs decreases.[73]

Supervision and Direction

Individuals have reported that a lack of supervision and guidelines for exercise have been a deterrent in initiating and adhering to exercise. It is not unreasonable to think that those who have not had training in exercise prescription would want some assistance with the planning and implementation of an exercise program. This is especially relevant for some older adults and other individuals who may have significant health-related issues. It is also essential to monitor participants in any exercise program for excessive effort. If the activity is too intense for their comfort, they are more likely to drop out or sustain an injury. When examining exercise preferences in older adults, researchers found that those older individuals who had higher levels of reported pain were more likely to feel that their exercise should be monitored and evaluated by a qualified professional.[76] This finding is in alignment with other research that has reported a higher degree of noncompliance to exercise and rehabilitation in older individuals who have significant health problems and pain.[78] The literature supports the finding that adherence to exercise protocols is best established when the protocols are supervised. Morey et al.[79] conducted a study that investigated whether a supervised exercise program could predict adherence in the same group of individuals when transitioned over to a home-based program. They found that adherence to weekend home-based exercise as a preparation to transition to the home-based program during the supervised portion of the study was the strongest predictor of adherence to the home-based program. Of interest in this study was the fact that individuals who were assessed and determined to be adherers versus those determined to be nonadherers remained so throughout the study. It can then be surmised that adherence to exercise can be predicted at an early stage, say, for example, using the "stage of change model" of behavioral change.

Studies have indicated that marital status plays an important part in exercise preference and supervision. Cohen-Mansfield et al.[45] reported that unmarried participants rated supervision by an authority figure (i.e., providing advice, monitoring, and/or evaluation of the exercise program) to be highly important, suggesting that encouragement and direction were relevant for these individuals to initiate and adhere to the exercise program.

Time, Family, and Occupation

Time is often perceived as a barrier to engaging in physical activity, exercise, and rehabilitation. Cohen-Mansfield et al.[76] found that older individuals (74 to 85 years of age) preferred to exercise between 9 AM and 12 PM, with the oldest group preferring to exercise between 12 PM and

3 PM. Interestingly, these researchers also found that the group that had a preference for early exercise (between 9 AM and 12 PM) were healthier than the group that preferred exercise later in the day.[76] College-aged students regularly listed exercise taking too much time as a barrier.[67] Physical therapy patients also indicated that exercise in the form of rehabilitation required extra time that they did not have.[76] In a sample of Australian subjects (18 to 78 years of age), lack of time was cited as a barrier to exercise participation most frequently.[80]

For individuals with children and who work, child care and the responsibilities of the work environment may be prohibitive to incorporating exercise and physical activity into their daily or weekly routine. Accomplishment of work goals and tasks may be made a priority over participating in rehabilitation, physical activity, or exercise. If one is retired, other activities (such as volunteering and spending time with grandchildren) may supercede exercise or rehabilitation participation.[73,75]

As can be implied from these findings, rehabilitation and exercise specialists need to be flexible in scheduling patient/client appointments to increase the likelihood of these individuals participating in an exercise or rehabilitation program. In addition, physical therapy clinics, gyms, fitness centers, and other recreational environments should vary their hours of operation in order to accommodate individual's preferences and conflicts of other activities.

Psychological

As alluded to earlier, there are psychological factors that influence motivation to exercise and rehabilitation. Depression, anxiety, and helplessness have been found to significantly contribute to decreased adherence to rehabilitation.[71] A study examining adherence to exercise in older veterans found that participants with both depression and/or posttraumatic stress disorder (PTSD) had lower 1-month and 11-week exercise adherence rates compared with participants without these conditions. It was also found that veterans who were screened and found to have both depression and PTSD had the lowest rates of exercise adherence compared with those with only depression or those with neither PTSD nor depression.[81]

In another study looking at the effects of depression and anxiety on cardiac rehabilitation, it was found that individuals with the highest dropout rates also had higher depression and anxiety scores and lower quality of life.[82] It was also found that younger, female patients had higher dropout rates and that women had higher psychological distress, lower quality of life, and less distance walked than men.[82] In another study looking at the effects of depression and anxiety, improvement in adherence to medication, and health behaviors in acute depressed cardiac patients, it was found that improvement in depression was consistently and independently associated with superior self-reported adherence to medications and secondary prevention behaviors across a 6-month span, whereas improvement in anxiety was not.[71] Another study by Zen et al.[83] found that among patients with heart disease, those with PTSD were more likely to report physical inactivity, medication nonadherence, and smoking.

OVERVIEW OF ADHERENCE TO REHABILITATION IN THE CLINICAL POPULATION

Rehabilitation specialists, such as physical therapists, occupational therapists, speech language pathologists, and athletic trainers, use exercise as one component of their intervention in order to effectively treat their patients. Having a thorough understanding of the pathology of the injury and physiological demands of the exercise is presumed. However, when confronted with the unique physical impairments and disabilities that the injury may cause, the psychological or motivational impact, although intuitively important to the success of the exercise program, is often ignored.

In rehabilitation, successful outcome is often linked to attending clinic appointments and compliance with therapist-developed exercise programs.[70,80,84,85] This, however, is not always the case. Brewer et al.[54] found that outcomes in rehabilitation after anterior cruciate ligament reconstruction were not mediated by adherence to rehabilitation. Even so, encouraging individuals to actively participate in rehabilitation is important to increase the probability of recovery from injury. In a position paper introduced by a study group of the Heart Failure Association of the European Society of Cardiology examining exercise training adherence in persons with heart failure, it was found that increasing adherence to exercise often led to positive health benefits.[86]

In a study examining perceived barriers and motivators to exercise in patients who were receiving hemodialysis, adherence to exercise among these patients was low, with 38% stating that in a typical week, exercise did not reach 15 minutes.[87] The results also suggested that it was not health-related impairments that stopped these individuals from exercising but lack of motivation and barriers (see Table 1-3).

In a sample of African American women with physical disabilities as rated by the Americans with Disabilities Act (ADA), adherence to regular physical activity was found to be directly related to the number of barriers that existed in the individual's life.[72] These barriers included (in rank order) cost of the exercise program (84.2%), lack of energy (65.8%), transportation (60.5%), and not knowing where to exercise (57.9%). These have some implications regarding what strategies rehabilitation and exercise specialists will use to encourage these individuals to engage in habitual exercise and/or rehabilitation.

Short-term adherence to a pelvic floor muscle exercise program significantly predicted long-term adherence (i.e., 1 year post program) to the same program in a clinical population of women with urinary incontinence.[88]

This may be directly related to the severity of symptoms each individual experienced (i.e., the number of incontinence episodes on a weekly basis). It appeared that individuals with more frequent episodes were more adherent to the program and tended to maintain their adherence 1 year post program.[88] This may also be due to the social stigma and embarrassment that individuals may feel with this health problem.

A major health concern today, cardiovascular disease, results in the loss of independence and quality of life for individuals who have sustained a cardiac event. Because of this, cardiac rehabilitation programs have been developed to provide exercise, education, and assistance in a medically supervised environment to assist in behavioral changes, so as to enhance quality of life.[66] Facilitation of adherence to these programs by health care professionals is essential to help to bring about the behavioral changes needed to maximize function in these individuals. A few studies have examined adherence and motivation to participate in cardiac rehabilitation programs.[89,90] In a review of the literature, Beswick et al.[90] identified several themes that improved recruitment, adherence, and professional compliance to cardiac rehabilitation.

Identified themes that increased patient adherence to cardiac rehabilitation included (1) formal patient commitment via written contract, (2) spouse or familial involvement, (3) strategies to aid self-management, (4) educational intervention, and (5) psychological intervention via group psychotherapy. The themes identified had varying levels of success in improving adherence to the cardiac program and will be discussed later in this chapter. In yet another study, personal factors, such as health and work status, significantly impacted adherence to the cardiac program.[91] It was noted that individuals who were not working and categorized in the "high risk" group for health were found to have the lowest mean physical activity scores (i.e., participation) in the cardiac rehabilitation program at baseline and the conclusion of the study one year later.[91] When motivation in conjunction with health-promoting lifestyle was examined after a 12-week cardiac rehabilitation exercise program, it was found that individuals who participated in the program had higher motivation for a healthy lifestyle than those who did not participate. In addition, perceived benefits of exercise, barriers, and self-efficacy, as well as emotional well-being and health improved in the exercise group versus those in the comparison group.[92] A review of the U.S. National Exercise and Heart Disease Project[93] found that participation in a cardiac rehabilitation program had a compliance rate of 79.6% after 2 months of continuous, monitored training but that adherence decreased to 13% at 36 months.[94] In a study by Blanchard et al.,[89] barrier self-efficacy was shown to be associated with compliance in a phase II cardiac rehabilitation program. In essence, individuals who believed that they had sufficient abilities to overcome specific cardiac related barriers had better adherence to the rehabilitation program. Bray and Cowan[95] found that proxy efficacy had an effect on predicting exercise self-efficacy and post-program intentions in cardiac rehabilitation. Simply stated, proxy efficacy means the confidence that individuals had in their clinicians' communication, teaching, and motivating capabilities was predictive of exercise self-efficacy and post-program participation in cardiac rehabilitation. Considering that the research performed correlating increased physical activity and exercise with positive outcomes after a coronary event, the impetus to increase compliance and adherence in this population is great.

Methods of Increasing Patient Compliance

- Formal written contract
- Spousal or family involvement
- Strategies to aid self-management
- Educational intervention
- Group psychotherapy

Another clinical population that would warrant the benefits of an exercise program is the chronic obstructive pulmonary disease (COPD) population. This disease is the fourth leading cause of death in the United States for people ages 65 to 84 years and is the fifth leading cause of death for people ages 45 to 64 and those aged 85 and older.[96] In addition, COPD is a primary cause of disability among older adults.[74] There are many psychological as well as physical benefits to participation in an exercise program for individuals who have COPD. Major benefits as detailed in the literature include increased physical capacity, decreased anxiety about dyspnea, greater independence in activities of daily living, reduced fatigued, and improved overall quality of life.[97] Emery et al.[98] conducted a study examining cognitive and psychological outcomes in patients with COPD after 1 year and found that adherence to a regular exercise program in patients in COPD was associated with increased physical and cognitive performance and greater emotional well-being. Those who did not adhere to the program were found to have a decrease in both physical and psychological constructs.[98] The danger of noncompliance in any of these clinical populations, but with COPD most specifically, is that any benefits gained will diminish over time,[99] which makes increasing the likelihood of exercise participation and maintenance over time warranted.

INCREASING ADHERENCE AND MOTIVATION TO EXERCISE AND REHABILITATION

Theoretical approaches, models, and barriers notwithstanding, increasing motivation and subsequently adherence to exercise and/or rehabilitation is the goal of health care professionals, exercise specialists, patients, and clients in a variety of settings with a variety of health-related

TABLE 1-4

Examples of Strategies That Increase Compliance

Strategy	Effect
Solicit social support from family, significant others, children, friends	Family support is the most important type of social reinforcement. If possible, have the family participate in the exercise or take part in the patient's rehabilitation. Suggest fitness routines with children
Make the activity fun and enjoyable	In conjunction with the individual, target activities that he or she has enjoyed in the past and incorporate them into his or her exercise or rehabilitation routine
Increase the individual's knowledge about the activity and/or injury	Teach the patient about the benefits of exercise or rehabilitation and the dangers of not engaging in the suggested activities
Make the physical environment pleasant and appealing	Remove clutter; ensure décor is bright and cheery
Address perceived and real barriers	Compile a list of potential barriers and help the individual solve problems by identifying realistic alternatives

TABLE 1-5

Factors That Increase Motivation

Factor	Effect
Social support	High self-efficacy
Establishment of therapeutic rapport	Individual involvement in planning aspects of the exercise or rehabilitation program
Decreased perception of discomfort	Individual engagement in planning and establishing goals
Positive reinforcement by clinician	Increased knowledge about benefits of engaging in a regular exercise or rehabilitation program

issues. Based on this, there have been several factors identified across the rehabilitation, sport psychology, psychology, and sociology literature that have sought to identify ways to increase motivation and adherence to exercise and rehabilitation (Tables 1-4 and 1-5). Some of these strategies have been identified previously (e.g., behavior written contract, spouse or familial involvement, strategies to aid self-management, educational intervention, and psychological intervention via group psychotherapy). Others include self-efficacy, social support, education, and client–practitioner interaction.

Self-Efficacy

Self-efficacy can be defined as an "individual's beliefs in his or her abilities to execute necessary courses of action to satisfy situational demands" (p. 236).[100] It is often hypothesized to be a strong influence on behavior because higher levels of self-efficacy are related to a propensity to undertake more challenging tasks, expend more effort in pursuit of goals, and demonstrate greater resilience in the face of adversive stimuli.[101] Human motivation, well-being, and sense of personal accomplishment are based on self-efficacy beliefs. Unless people believe that their actions can produce the outcomes they desire, they have little incentive to act or to persevere in the face of difficulties. Therefore it is presumed that the development of self-efficacy will promote action to initiate and complete various tasks. The development of self-efficacy occurs through mastery of tasks or performance experience, vicarious or observational experiences of others successfully completing the task, verbal persuasion from a voice of authority (e.g., physician, physical therapist), emotional desire to perform the task (i.e., motivation), and physiological states (e.g., reduction in physical discomfort, such as pain or fatigue).[42,102] In a study examining self-efficacy and motivation in the prediction of short- and long-term adherence to exercise among patients with coronary heart disease, both self-efficacy and motivation significantly predicted exercise behavior at 6 months.[103] It has been determined that self-efficacy can be developed through supervised exercise training, peer support, and seeing peers undertake exercise, realistic goal setting, and support from family and friends.[104,105]

Self-efficacy may be increased through the following:

- Mastery of tasks
- Performance experience
- Vicarious or observational experience of successful task completion
- Verbal persuasion from a voice of authority (e.g., physical therapist)
- Emotional desire to perform the task (motivation)
- Physiological states (reduction of discomfort)

When individuals master a task(s), their success will contribute to their sense of personal efficacy. In the same sense, failure to master a specific task(s)—in this case, exercise—will undermine self-efficacy, especially if failures outweigh the successes.[106] In the general adult population, self-efficacy is often a strong indicator of physical activity engagement.[107,108] In populations with acute or chronic illness, improved self-efficacy has been predictive of long-term exercise compliance.[102]

In the health care setting, clinicians have often used the successful experience of patients to engage other patients

to increase participation in rehabilitation. The rehabilitation environment may be set up in such a way as to help patients view and translate the positive experiences of other patients with similar injuries or diagnoses, thereby increasing self-efficacy and facilitating positive outcomes for themselves.

Social Support

Whether in the beginning, middle, or end stage of an exercise or rehabilitation program, individuals have stated that social support from family, friends, significant others, peers, and/or health care providers is desired. Indeed not having the support of important persons in their lives has been cited as a barrier to participation or maintenance to exercise and rehabilitation programs. Studies have found that married individuals tend to adhere longer to physical activity and exercise programs than individuals who are not married[109] and that unmarried individuals were more likely to participate in exercise programs if there were social opportunities available,[45] thereby implying that the support provided by their spouse was important to them. In a study examining the role of social support and group cohesion on exercise compliance, Fraser and Spink[110] found group cohesion and social support to be contributory to the prediction of exercise session attendance. Social support was identified as a main motivator in a group of southern women participating in a walking intervention.[110] These women reported spouses, significant others, friends, coworkers, neighbors, as well as children, siblings, parents, and extended family members as sources of exercise support. Of interest was the finding of differences in support plans for people in different income groups. Nies et al.[111] found that high income women appeared to incorporate significant others (spouses, boyfriends, partners) and pets into their walking schedule more than women in a low income group. This is in contrast to a study assessing attendance to a community-based exercise program for an African American church congregation that reported increased adherence in those individuals who had a high sense of community affiliation.[57] In an attempt to predict long-term maintenance of physical activity in older adults, McAuley et al.[112] examined the role of social, behavioral, and cognitive factors and found an indirect correlation between increased levels of social support for exercise and pleasant effects mediated by high levels of self-efficacy at the end of the program. Scores on the social support subscale of the exercise motivation questionnaire (EMQ), although not statistically significantly, differentiated between individuals who exercised regularly and those who did not. Regular exercisers tended to have higher than average scores on this subscale.[112] Increased adherence to home-based rehabilitation programs may in part be due to the familiarity of the environment as well as the increased likelihood of support from family members, significant others, friends, neighbors, and/or peers.

As stated previously, significant others may play an important role in encouraging patients to increase daily physical activity and to reinforce the changes. Support interventions that focus on changing physical activity behavior through building, strengthening, and maintaining social networks that provide supportive relationships for behavior change (e.g., setting up a buddy system, making contracts with others to complete specified levels of physical activity, or setting up walking groups or other groups to provide friendship and support).[113] Higher social interaction either with family members or with others has been shown to have a positive impact on motivation and adherence to cardiac rehabilitation.[114,115] Although heart failure patients do not always have a strong social support system, they might be motivated to be active in an exercise group or with family members in order to be less isolated.[116] Recognizing the important role that social support plays in exercise and rehabilitation should inspire health care providers and other specialists to include people of importance in their patients' and clients' lives.

Education

Intuitively, the more knowledge one has about a topic, the more comfortable and confident he or she will feel in making a decision regarding that topic. This is also true for exercise. It has been suggested that education should be an integral part of any exercise or rehabilitation program.[56] When a panel of experts was asked to examine personal characteristics that may have an influence on exercise behavior in older adults, educational level was rated as the third most important determinant of whether older adults would initiate an exercise regimen.[56] In a sample of women experiencing urinary incontinence, the lack of information regarding sex was a significant predictor of long-term adherence to a regimen of pelvic floor muscle exercises given to them by a physical therapist.[88] This study found that women who did not have sex education in school and who attended school for fewer years tended not to adhere to their prescribed exercise program. Given the findings of these studies, delivery of information on what constitutes good exercise habits, parameters, and benefits is necessary.

Delivery of educational information about exercise and rehabilitation may be done through a variety of verbal and nonverbal interactions on the part of the health care professional or exercise specialist. Interactions can come in the form of telephone counseling, written materials, direct conversation between the therapist/exercise specialist and patient/client, as well as through committee liaisons.

The educational component should be composed of explanations regarding the impact or benefits engaging in exercise and physical rehabilitation will have on the individual's health status and symptoms. It should also include a general explanation on the major concepts of exercise based on the individual's past and current exercise behavior, health status, and baseline physical functioning. Relevant information to include is target heart rate, perceived exertion, and body composition, as well as

written handouts with pictures and that are appropriate for the educational level of the individual.

Other areas that need to be included in the educational component, especially for those individuals in rehabilitation, include an accurate explanation of the nature of the injury, treatment approach and rationale, and what constitutes realistic expectations for recovery.[85,117] In addition, delivery of the information, whether done verbally or nonverbally, should occur through a health care or exercise professional that the patient or client trusts and perceives to have a strong knowledge about exercise.

Patient/Client–Practitioner Interaction

Development of rapport between a patient and health care provider and effective communication is necessary for the promotion of motivation and adherence to rehabilitation.[118] Patients who were found to have effective communication with their physical therapists also were found to attend scheduled physical therapy appointments and comply with established rehabilitation activities during the sessions.[118] In the athletic population, it has been suggested that those athletes who felt that medical professionals who were honest, interested in their well-being, and showed an awareness of psychological symptoms relating to their injuries may be more likely to adhere to their rehabilitation program.[119] Having open lines of communication and fostering a collaborative atmosphere more often than not has a positive influence on adherence to treatment.[120] In addition, enhanced communication between the client and the health care practitioner will help to bring to light and resolve any issues that may affect adherence. Building a sound therapeutic relationship plays a major role in adherence, and both the clinician and patient must communicate in partnership in order to build trust.[121]

Another essential component to exercise and rehabilitation adherence is feedback. The health care and exercise professional should provide positive feedback to their patients and clients so as to improve adherence to any rehabilitation and exercise program. Studies have found that positive reinforcement increases the likelihood and maintenance of the activity.[122] Monitoring and supervision by a qualified health care professional has also been shown to improve compliance to exercise and rehabilitation programs.[47] In studying correlates of exercise compliance in physical therapy, Sluijs et al.[47] found that compliance was significantly related to the amount of positive feedback that the patients received. In addition, patients who perceived that their therapist were satisfied with how they were exercising were more compliant than those patients who were not aware of their clinician's feelings regarding their exercise. In the same study, patients who were more compliant with their exercises had therapists who frequently asked them to participate in establishing the exercise regimen and supervised them more often throughout its implementation. The findings from the previous studies again strengthen the association between the development of trust, communication, and caring as some of the most important factors in establishing a therapeutic relationship that fosters patient adherence.

MOTIVATIONAL INTERVIEWING (MI)

Ambivalence is often at the core of why people struggle to embark upon change. Patients faced with recommendations to make behavioral changes will often experience ambivalence, the simultaneous holding of contradictory feelings or attitudes, in other words, having both the desire to change and not change at the same time. When patients are ambivalent about making recommended changes (such as taking a prescribed medication, stopping smoking, or modifying their diet or physical activity level), clinicians may try to persuade them via the use of logic, problem solving, an emphasis on the importance of making the change as well through advice giving as to how the change might be implemented. When recommendations are not followed, as is frequently the case, clinicians may react in one of several ways. One reaction may be to state that their clients/patients are noncompliant and that helping to motivate their clients/patients toward behavior change is impossible. This assumes that patients will only make recommended behavioral changes when they are ready. Another reaction by clinicians may be to increase their advice-giving and problem-solving strategies by reiterating the importance of following the recommendations. This approach will typically not be successful and will serve to have the client/patient "tune out" or not return to the clinic. Yet another way may be to confront patients out of concern or frustration. These providers may simply present patients with a brief description of what is to be done and then hope for the best. Neither of these approaches is ideal and is ineffective in encouraging the client/patient toward behavior change.

Some important questions to be asked and answered are: How can clinicians help their clients/patients find motivation to progress toward their goals? Why are methods of persuasion and confrontation not useful for promoting change? Why is the threat of poor health not enough to persuade a patient to quit smoking, begin exercising, change his or her diet, or take medication? Is there a more effective way to evoke behavioral change?[123]

MI offers an alternative response to ambivalence. The approach is grounded in the assumptions that struggles with ambivalence are a normal part of the process of change. MI allows for a "collaborative, person centered form of guiding to elicit and strengthen motivation for change" (p. 137).[124] The MI approach was initially developed by Miller and Rollnick[125] to help problem drinkers reduce or abstain from alcohol use. Many of its principals and the techniques of MI are founded in the client-centered approach of psychologists Carl Rogers and Robert Carkauff,[124,126–128] although MI is perhaps more goal driven than classic Rogerian client-centered therapy.

MI has evolved into helping individuals commit to making positive behavior changes in a variety of areas, including health. In contrast to delivering simple advice, a practitioner using the MI approach helps the patient discuss the "pros" and "cons" of the target behavior; in turn, resolving the patient's ambivalence about the behavior. In a meta-analysis examining the effectiveness and applicability of MI as a treatment, it was found that MI was 10% to 20% more effective than no treatment and equal to other viable treatments for a wide variety of problems ranging from substance use (i.e., alcohol, marijuana, tobacco, and other drugs) in reducing risky behaviors and increasing client engagement in treatment.[129,130]

In patients with congestive heart failure it was found that in the short term (≤6 months), MI and other strategies that enhanced patient self-efficacy for exercise were successful in increasing exercise in intervention groups by 25% to 30% compared with the control groups.[70] For positive healthy behavior change to occur, there are an innumerable amount of things that need to happen. For instance, a discussion should ensue about the behavior in question that needs to change. The patient needs to be queried about lifestyle, for example, whether they require the use of an assistive device, other aids and/or medications, and if they are physically active. In this regard, patients are often ambivalent or unmotivated to change, and as clinicians, the response is to impart knowledge and advice as to what positive behavioral changes need to be made and how to approach making them. It is in this instance that clinicians may make a mistake and lose the therapeutic rapport that had been established with the patient. Advice giving using a directive style may generate resistance or passivity on the part of the patient. A way to reengage or prevent this disconnection from happening is to use an approach that has been developed to engage and encourage behavior change across a variety of settings.[131] MI is an alternative approach to discussing behavior change that fosters a constructive provider–patient relationship that leads to better outcomes for the patient because it allows for patients to say why and how they might change and is based upon a guiding style as opposed to a directing one.[132,133] In one systematic review that included 72 studies, it was found that using MI with its guiding style outperformed traditional advice giving in 80% of studies.[134] Meta-analyses show that MI is equivalent to or better than other treatments, such as cognitive behavioral therapy (CBT) or pharmacotherapy, and superior to placebo and nontreatment controls for decreasing alcohol and drug use in adults and adolescents.[135–137] MI has also been shown to be effective in health conditions, such as diabetes management.[138] Additional studies support the applicability of MI to human immunodeficiency virus (HIV) care, such as improving adherence to antiretroviral therapy.[139] Given the evidence, MI has been shown to be an important therapeutic intervention that has wide applicability within health care settings in motivating people to change.

Motivational Interviewing (MI) Framework

Prochaska and DiClemente[27] proposed readiness for change as a vital mediator of behavioral change. Their TTM of behavior change (stages of change) describes readiness to change as a dynamic process, in which the "pros" and "cons" of changing generate ambivalence. Ambivalence is a conflicted state in which opposing attitudes or feelings coexist in an individual who is stuck between simultaneously wanting to change and not wanting to change. Ambivalence is particularly evident in situations in which there is conflict between an immediate reward and longer term adverse consequences (e.g., substance abuse, weight management). For example, the patient who presents with serious health problems as a result of heavy drinking, shows genuine concern about the impact of alcohol on his health, and in spite of advice from his practitioner to cut back his drinking, continues to drink at harmful levels embodies this phenomenon.

It is important to note that MI is *not* based upon the transtheoretical stages of change. Both TTM and MI refrain from blaming the client or patient and do not accuse them of being unmotivated and instead focus on the clinician's role in helping to enhance motivation for change.[124] The stages of change model provided a rational way to think about the clinical role of MI, and MI in turn, provided a clear example of how clinicians could help people to move from precontemplation and contemplation to preparation and action. Miller and Rollnick noted that "TTM is intended to provide a comprehensive conceptual model of how and why changes occur, whereas MI is a specific clinical method to enhance personal motivation for change" (p. 131).[124] They stated that explaining the TTM stage of change model is not necessary when engaging in MI, but many practitioners have found it helpful in their work with clients and patients to change their behaviors because it helps to determine how ready these people are to make a change.[124]

Research globally supports the view that MI provides a promising framework for enhancing adherence to health behaviors. Meta-analyses report medium-to-large effects of MI on treatment adherence and small-to-medium effects on treatment outcomes (e.g., drug consumption, psychological well-being).[130,136] Regarding weight loss, MI has also been recognized as an efficient approach among adults to improve adherence to physical activity routines.[140] It has also been shown to be an effective treatment technique for weight loss in people who are obese.[141] A core theoretical assumption of MI is having the knowledge that people will often modify their behavior as a result of their interaction with others. Related to the previous assumption is having the knowledge that health professionals possess critical counseling skills that can help facilitate personal change in their clients and patients.[142]

Principals of Motivational Interviewing (MI)

Expressing empathy (i.e., the counselor's attitude of acceptance), developing discrepancy (i.e., amplifying discrepancy between the patient's present behavior and his or her important goals), avoiding argumentation (i.e., assuming that the patient is responsible for change), rolling with resistance (i.e., acknowledging and exploring the patient's arguments against changing), and supporting self-efficacy (i.e., helping the patient to find resources to implement new behaviors and overcome barriers) are the general principles upon which MI is based.[132,142] It is thought that if the clinician can get the client/patient to do anything toward changing his or her behavior for the better, the greater the chances are for continued forward movement and success. This is a major tenet in social psychology on which Rollnick and Miller base MI.[143] For example, the question that clinicians should ask themselves, according to Miller and Rollnick,[132] is how can I get my client/patient to take action on his or her own behalf? Another major tenet of social psychology relates to when one takes a position and defends it verbally, such as what occurs in a debate; that person then becomes committed to that position (whether he or she still believes it). As such, an MI principle, rolling with resistance, advocates for a nonconfrontational approach because people are more likely to grow and change in a positive direction if they are not engaged in a battle of wills with their clinician.

Principles of Motivational Interviewing

- Expressing empathy—the counselor's attitude of acceptance
- Developing discrepancy—amplify discrepancy between the patient's present behavior and his or her important goals
- Avoiding argumentation—assumption that the patient is responsible for change
- Rolling with resistance—acknowledgment and exploration of the patient's arguments against changing
- Supporting self-efficacy—helping the patient to find resources to implement new behaviors and overcome barriers

Key Strategies in Motivational Interviewing (MI)

The essence of MI lies in its spirit, and for a true understanding of MI to be had, it is vital to distinguish between the *spirit* of MI and the *techniques* that are used to manifest that spirit. Clinicians who become too focused on matters of technique may lose sight of the spirit and style that are central to MI.[143] There are four key strategies that are discussed that help the clinicians remain true to the spirit that is MI (Figure 1-7). They include (1) resisting the "righting" reflex, (2) understanding the patient's own motivations, (3) listening with empathy, and (4) empowering the patient.

Resisting the "Righting" Reflex

The "righting" reflex in the context of motivation describes the tendency of health professionals to advise patients about the right path for good health. This can often have a paradoxical effect in practice, inadvertently reinforcing the argument to maintain the status quo. Most people resist persuasion when they are ambivalent to change and will respond by recalling their reasons for maintaining the behavior. MI requires clinicians to suppress the initial "righting" reflex so that they can explore the patient's motivations for change. It is essential for the clinician to refrain from responding to the client/patient with questions or unsolicited advice. Questions can be biased by what the clinician may be most inclined to hearing, flavored by their worldview or prior experience, rather than by what the client wants or needs to explore to facilitate the change. Unsolicited advice can evoke resistance on the part of the client/patient. It is best that the direction of the intervention be driven by the client.

Understanding the Patient's Motivations

As alluded to previously, it is the patient's own reasons for change, rather than the clinicians, that will ultimately result in behavior change. When clients/patients are allowed to explore their own interests, concerns, and values with freedom and the clinician openly explores the patient's motivations for change, a better understanding of the patient's motivations and potential barriers to change will emerge.

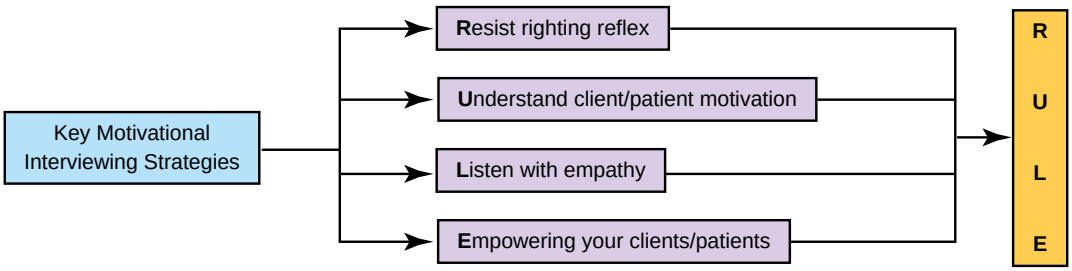

Figure 1-7 Motivational interviewing strategies.

Listening with Empathy

Effective listening skills are essential to understand what will motivate the patient, as well as the "pros" and "cons" of their situation. A general rule of thumb in MI is that equal amounts of time in a consultation should be spent listening and talking.

Empowering the Patient

Empowering one's client/patient involves the establishment of a collaborative therapeutic relationship that allows the patient to explore his or her own ideas about how one can make changes to improve his or her health. It permits patients to access personal knowledge about what has succeeded for them in the past.[131] Clients/patients will benefit from this relationship the most when the practitioner also embodies hope that change is possible.

SUMMARY

As is apparent from this chapter, the concepts of motivation, adherence, and compliance as they relate to physical activity, exercise, and rehabilitation are complex. There is no one factor that will help individuals want to engage in healthy habits. For behavior to change, a combination of factors needs to be incorporated to assist individuals in making decisions that will positively affect their quality of life. Health care practitioners and exercise professionals should make use of the many theories and models available in the literature, including the use of MI as an effective way to facilitate positive behavioral changes in their patients and clients. Listening and addressing the unique situations of each patient and client are needed to help empower and motivate patients and clients to be involved in their own care.

CHAPTER 2

The Skin and Wound Healing

HOLLIE KIRWAN, ROSE PIGNATARO

ANATOMY AND FUNCTION OF SKIN

Skin is the largest organ in the body and performs a wide variety of different functions. It is composed of a predominantly cellular epidermis and an underlying dermis, which is composed of fibers of connective tissue relatively sparsely populated with cells (Figure 2-1). Both the epidermis and dermis play roles essential to the skin's function and response to injury.[1]

The **epidermis** contains mostly keratinocytes, among which are interspersed melanocytes, Merkel cells, Langerhans cells, and other resident immune cells. *Keratinocytes* represent 95% of the cellular content of the epidermis. They migrate from the dermo-epidermal junction between the dermis and epidermis toward the surface of the skin. During this migration, they undergo progressive flattening and loss of cellular "machinery," giving rise to four distinct layers: stratum basale, stratum spinosum, stratum granulosum, and stratum corneum.[1,2] Keratinocytes are responsible for the production of keratin, a fibrous structural protein that contributes to the strength and waterproofing of skin. *Melanocytes* protect against ultraviolet (UV) light, producing melanin, the dark pigment that gives the skin its color. *Langerhans cells* are professional antigen-presenting cells and play critical roles in both protective immune responses in the skin and maintenance of immune homeostasis.[3] *Merkel cells* are perhaps the least well characterized of the cutaneous cells but have been associated with discrimination of light touch.[4] The epidermis also contains dermal appendages, such as hair follicles, sebaceous glands, eccrine sweat glands, and apocrine glands. The **pilosebacious unit** is composed of hair follicle, hair shaft, and sebaceous gland. The pilosebacious unit contains epithelial stem cells, which are critical to the reepithelialization process because they have a high capacity for self-renewal.[2]

The **dermis** is the layer between the epidermis and the subcutaneous tissue. It is made up of collagen, elastic fibers, and an extrafibrillar matrix. The dermis can be subdivided into a papillary layer and recticular dermis. The *papillary layer* interweaves with the epidermis through papillae, which are fingerlike projections with capillaries that help to nourish the epidermis. The *reticular layer* of the dermis contains a network of collagen fibers, which provides skin turgor and elasticity.

The dermis is a highly vascularized structure containing major vascular networks or plexuses, the deepest of which is the fascial plexus, located at the level of the deep muscle fascia. Overlying this, at the level of the superficial fascia, is the subcutaneous plexus. The next level is the subdermal plexus, an extensive vascular network situated at the junction between the reticular dermis and the subcutaneous tissue directly below, which has an important role in the distribution of blood to other regions of the cutaneous system. Superficial to the subdermal plexus is the subpapillary plexus, situated between the papillary and reticular dermis with capillary loops extending into the papillae. Blood flow between the subdermal and subpapillary plexus is achieved through a series of arterioles and venules and has an important role in regulation of body temperature and the metabolic supply of the skin.

WOUNDS AND HEALING

Wounds can be separated into open or closed wounds. In a **closed wound** the surface of the skin is intact, but the underlying tissues may be damaged. Examples of closed wounds are contusions, hematomas, or stage 1 pressure ulcers. With **open wounds** the skin is split or cracked, and the underlying tissues are exposed to the outside environment. In terms of open wounds, the depth of tissue damage may be broadly divided into the following categories: superficial, partial thickness, or full thickness. Wound healing can occur by primary, secondary, or tertiary intention (Table 2-1). If the edges of the wound can be readily approximated, wound healing of superficial or partial-thickness wounds (i.e., epidermis and dermis) will usually occur by **primary intention**.

Depth of Wound Damage in Open Wounds

Superficial	Involving only the epidermis and upper dermis
Partial thickness	Skin loss up to the lower dermis
Full thickness	Skin and subcutaneous tissue loss

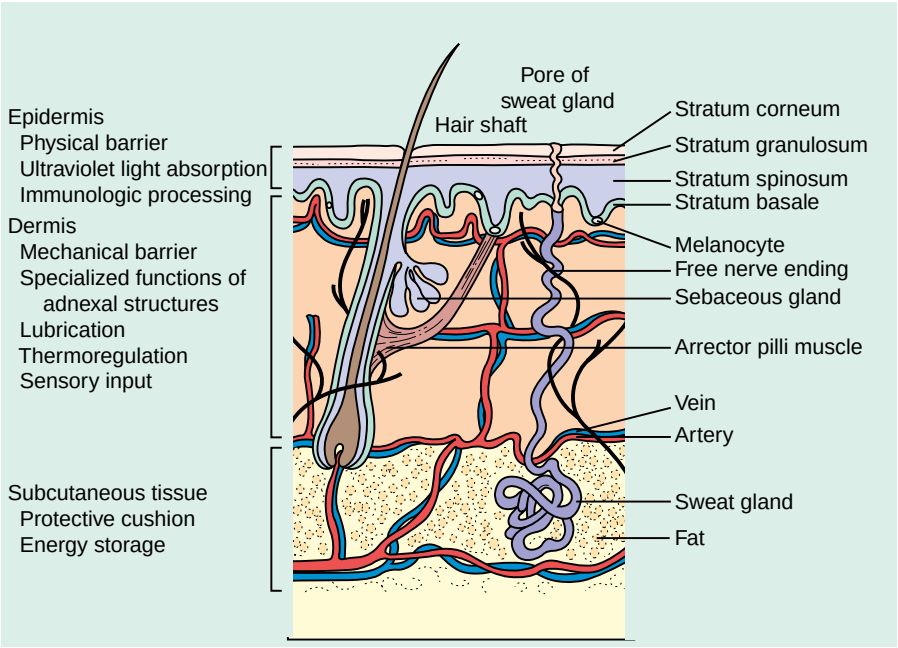

Figure 2-1 The anatomy of the human skin illustrating structures pertinent to wound repair. (From Cohen BA: *Pediatric dermatology*, ed 2, London, 1999, Mosby International Ltd.)

TABLE **2-1**

Types of Wound Healing

Primary Intention	Secondary Intention	Tertiary Intention
• Skin edges are approximated with sutures, staples, or adhesive • Enables quick closure with minimal scarring • Used when there is minimal epithelialization and new tissue	• Large, deep wounds in which edges cannot be approximated • Wound depth determines degree of new tissue matrix and epidermal surface needed for complete closure • Lengthier than healing by primary intention • Can be associated with substantial scarring	• Healing is promoted by leaving the wound open for a prescribed period before approximating the skin edges for primary closure • Used in infected or dehisced surgical wounds

Modified from Strodtbeck F: Physiology of wound healing, *Newborn Infant Nurs Rev* 1(1):43-52, 2001.

The wound will heal through the formation of granulation tissue and reepithelialization, and there should be little or no evidence of a scar. When the wound covers a larger surface area and the margins cannot be readily approximated and/or tissue damage extends deeper than the dermis and into the subcutaneous tissue, wound healing occurs by secondary intention. **Secondary intention** involves wound contraction, along with angiogenesis (i.e., formation of new blood vessels) and reepithelialization. Due to the presence of greater amounts of scar tissue for wounds that close by secondary intention, the regenerated tissues are not identical to the original tissues and only regain a portion of their original tensile strength, making them somewhat vulnerable to future injury. Wounds that heal by secondary intention should be monitored and protected until maturation of the scar tissue has occurred. In wounds that contain a large degree of tissue damage, necrosis, or foreign debris, treatment may include delayed closure to ensure removal of these materials before closure of the skin. This process is known as **delayed primary** or **tertiary healing**.

In adults, optimal wound healing should involve four continuous and overlapping phases: **hemostasis**, **inflammation**, **proliferation**, and **remodeling** (Table 2-2). The first-stage wound healing concentrates on achieving *hemostasis* (i.e., a relatively constant internal environment) and a provisional wound matrix. In open wounds, vascular constriction and fibrin clot formation will occur to prevent further blood loss. Damage to the tissues also stimulates vasodilation with an increase in capillary permeability due to the release of histamine by injured mast cells. This will influence the release of chemotactic factors leading to leukocyte infiltration and thus the release of cytokines and growth factors, which allow the tissues to progress to the inflammatory phase. When injury to the skin first occurs, keratinocytes release a store of interleukin-1 (IL-1). This proinflammatory cytokine is important in initiating the healing cascade.[5] Other cytokines released during the transition from hemostasis to

TABLE 2-2

Physiology of Healing

Phases of Healing		Timeline
1	Homeostasis	Within hours of injury
2	Inflammation	1 to 5 days post injury
3	Proliferation	4 to 21 days post injury
4	Remodeling	21 days to 1 yr post injury

the inflammatory phase include epidermal growth factor (EGF) and platelet-derived growth factor (PDGF), another important substance in stimulating growth and function of fibroblasts and the formation of new tissue.

Neutrophil infiltration and migration of macrophages, shortly followed by lymphocyte infiltration into the wound, signal the start of the *inflammatory phase*. Macrophages play a central role in tissue healing through their production of growth factors, cytokines, and chemokines, which are important in the modulation of the inflammatory response. As the process of phagocytosis cleanses the wound of debris, such as denatured matrix and damaged cells, there is a shift toward the *proliferative* or *granulation phase* of healing. The focus of healing during the proliferative phase is to cover the surface of the wound and restore the vascular network through the generation of granulation tissue. This stage is characterized by epithelial proliferation and migration over the provisional matrix within the bed of the wound. As blood cells enter the site of tissue injury, monocytes are converted to macrophages with the assistance of transforming growth factor beta (TGF-β), a substance released by degranulating platelets. The macrophages release basic fibroblast growth factor (bFGF), a substance that increases the proliferation and function of fibroblasts. It is thought that macrophages also release vascular endothelial growth factor (VEGF), which contributes to angiogenesis. During the proliferative phase, reduction in the number of macrophages or impairment in function can contribute to impaired wound closure and delayed formation of granulation tissue.[6] Fibroblasts and endothelial cells are the predominant cell types in the wound during this phase, and they support capillary growth, collagen formation, and the formation of granulation tissue. Collagen is the major component of acute wound connective tissues. During the proliferative phase, its molecules are cross-linked and organized into bundles. In addition to producing collagen, fibroblasts also produce glycosaminoglycans and proteoglycans, all of which are major components of the extracellular substance of granulation tissue. Keratinocytes and endothelial cells produce autocrine growth factors, and, in synchrony with endothelial expansion, new blood vessels are formed by angiogenesis. As the fibrin clot and provisional matrix are degraded, there is simultaneous deposition of granulation tissue. Epithelial cells migrate inward until the wound is covered. Fibroblasts are transformed into myofibroblasts through contact inhibition. Myofibroblasts are contractile cells, so wound contraction follows, leading to the final stage of wound healing, the remodeling or maturation phase.

The *maturation* or *remodeling phase* can last up to 1 year or longer post injury, particularly in full-thickness wounds and/or wounds involving larger surface areas of skin. During this time the formation of granulation tissue stops through the apoptosis (i.e., normal death of cells as part of the healing process) or exiting of macrophages, endothelial cells, and myofibroblasts. Therefore a mature wound can be classified as avascular and acellular. Collagen is remodeled into a more organized structure along lines of stress, thereby increasing the tensile strength of the healing tissues. Fibroblasts secrete matrix metalloproteinases. The enzymes facilitate remodeling of type III collagen to type I collagen, which is now organized in parallel bundles until the normal collagen ratio of 4 type III:1 type I is achieved.[7]

There are many factors that can affect tissue healing. These are listed in Table 2-3. Factors intrinsic to the patient can include age, nutrition, and hydration levels, location and depth of the wound, medications, and co-morbidities. Extrinsic factors include support surfaces, friction, and shear and effective repositioning schedules. Education of the patient and caregiver on factors that can affect wound healing is an integral part of the management strategy. More information on wound healing may be found in Chapter 1 - Injury, Inflammation, and Repair: Tissue Mechanics, the Healing Process and Their Impact on the Musculoskeletal System in *Scientific Foundations and Principles of Practice in Musculoskeletal Rehabilitation*, volume 2 of this Musculoskeletal Rehabilitation book series.

TABLE 2-3

Systemic and Local Factors Affecting Wound Healing

Systemic Factors	Local Factors
• Nutrition and hydration • Diabetes mellitus • Peripheral vascular disease • Gastroesophageal reflux disease • Collagen disease • End stage renal disease • Immunosuppression • Aging • Medications • Social and health habits • Functional status • Infection • Paresthesia • Perfusion • Incontinence • Psychological function (i.e., stress, memory)	• Hypergranulation • Perfusion and oxygenation • Infection • Edema • Pressure, friction, shear, moisture • Sensation, neuropathy • Hyperkeratosis • Epibole • Cellulitis • Nonviable tissue • Lack of growth factors • Cytokines • Matrix metalloproteinases

WOUND ASSESSMENT

As will be evident from the extensive list of parameters that may affect wound healing, wound assessment must be performed in the context of a thorough patient evaluation. In severe cases, such as large burns, evaluation is most effectively performed by an interdisciplinary team, which can include physicians, nurses, occupational therapists, and physical therapists. A detailed patient history, systems review, and general physical examination (including cardiopulmonary and vascular testing, in addition to a musculoskeletal assessment and overall view of the integument) should precede local evaluation of the wound itself. There are a variety of tools available for local wound assessment, and these tools should contain the categories of examination reviewed in the following section. Any nonhealing wounds or suspicious lesions should be referred to a specialist physician to check for signs of malignancy.

Wound Dimensions: Surface Area and Depth Measurement Techniques

Keeping a record of wound dimensions is necessary to monitor changes in wound size to identify whether an exacerbation or progression of healing has occurred. There are various methods that can be used to measure and describe the size, shape, and location of a wound.

Clock Method

The clock method is one of the most common methods of wound measurement. The wound is considered as a face of a clock with the position of the wound based on the standard anatomical position of the patient (Figure 2-2). For wounds on the torso and extremities, the patient's head is considered as the landmark for 12 o'clock and the feet are considered 6 o'clock, whereas for wounds located on the foot, the heel is considered 12 o'clock and the toes are 6 o'clock. Key characteristics that can be measured and described using the clock method are length, width, depth, and the presence of dead space. **Dead space** represents tissue damage that is not immediately evident when inspecting visible aspects of the wound. All forms of dead space must be properly addressed during local treatment of the wound to prevent the accumulation of pathogens and exudate. This can be prevented by using wound fillers, such as calcium alginate or amorphous hydrogel, or in deeper wounds using gauze strips. In addition, the use of wound fillers to occupy dead space ensures that the wound will heal from the base to the surface without abscess formation or opportunities for deeper infection and sepsis.

Categories of dead space include sinus formation, tunneling, and undermining. **Tunneling** is generally located in the wound bed or along the wound margins and can connect one wound to another or a wound to a body cavity. Tunnels can descend deeper into the wound or to the side of the wound bed. The deepest area of tunneling and its location on the clock should be recorded. **Sinus** formation may appear similar to tunneling but differs in that there is no exit point. Sinuses may extend beyond the visible margins of the wound and are often hidden beneath the surface of the skin. Both tunneling and sinus formation need to be carefully assessed due to possible infection, unrelieved pressure, or the presence of foreign bodies. **Undermining** is another category of dead space and can be described as a hidden shelf or ledge resting just beneath the wound margin but not visible from the surface of the skin. The presence of undermining can indicate shear or pulling at the wound bed and should be properly documented because the presence of preexisting damage to the subcutaneous tissues may later manifest as a visible increase in the length, width, or diameter of the wound. Undermining should be measured at each time of the clock, for example, 4 cm at 12 o'clock, 3 cm at 3 o'clock, 3 cm at 6 o'clock, and 2 cm at 9 o'clock.

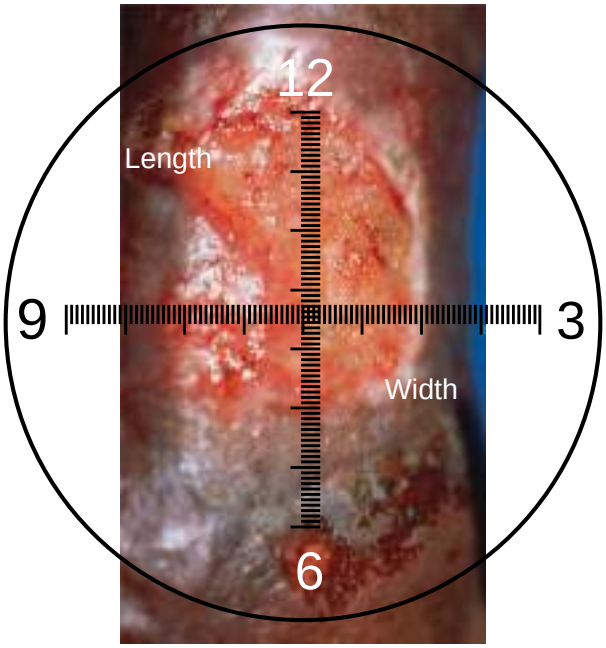

Figure 2-2 Demonstration of how the clock face method can be used to measure the size of a leg wound. (Modified from Morison M, Ovington LG, Wilkie K: *Chronic wound care*, St Louis, 2004, Mosby/Elsevier.)

Perpendicular Method

A quick method often used during brief patient encounters is a linear wound measurement. A perpendicular linear dimension is simple, reliable, costs little to implement, and is portable. However, it can have limited sensitivity to change in wound size, and limited information is gathered on wound shape. The perpendicular method assumes the wound is a simple shape, such as a circle or a rectangle. Using this method the size of the wound is estimated by measuring the maximum length and the maximum width perpendicular to the initial measurement, in centimeters

or millimeters using a paper or plastic ruler.[8] Next the two measurements (length×width) are multiplied and recorded as total surface area. Although the perpendicular method can overestimate total size of the wound, particularly when tissue damage involves an irregularly shaped area, research has demonstrated a high degree of interrater reliability and the ability to document changes in wound area over time using serial measurements taken using the same standard procedures.[9]

Planimetry

Planimetry (i.e., wound tracing) is a technique that is more sensitive to changes in wound size than the perpendicular method. The outline of the wound is drawn onto a clear plastic sheet then transferred onto metric graph paper with a 4- or 8-cm grid. A second clear plastic sheet is placed between the tracing sheet and the wound to manage wound contamination. This sheet is discarded after use. The wound tracings are kept for sequential comparison. Wound tracings rely on the precise location of the wound edges and have good intrarater reliability.[8,10] A study comparing wound tracing to other techniques, including photographic area quantification, reported that wound tracing was highly correlated with the other techniques ($r \geq 0.93$, $p \leq 0.001$).[11]

Deepest Wound Base (Swab Measuring Technique)

Measurement of wound depth or volume is more reliable in deep wound cavities and less reliable for shallow and irregularly shaped wounds. Depth can be measured using a sterile cotton swab or curette inserted into the maximum depth in a particular dimension and documented on the wound tracing (Figure 2-3). Care must be taken with this method to avoid iatrogenic injury (i.e., injury caused by treatment or diagnostic procedures).

Photographs

The use of photographs in wound documentation allows a permanent record of wound size as well as appearance to be maintained in records for future comparison. High-resolution photographs are preferable to identify epithelial growth at wound margins.[12] Photo quality, lighting, and angle must all be considered. A variation in camera angle can lead to an underestimation of wound area by up to 10%.[13] Therefore it is recommended that photos contain a small ruler or tape measure within the vicinity of the wound to indicate scale. In addition, effort should be made to maintain consistent distance from the camera to the wound when taking serial photographs. In some facilities, digital film does not meet legal requirements for documentation due to its nature of being easily altered. In these cases special film integrating graph lines can facilitate wound measurement and comparison over time. Circumferential wounds or those on curved body surfaces may lead to apparent wound size discrepancy due to the two-dimensional (2D) nature of photography. It is best to combine wound photography with other methods for assessing wound dimensions to obtain the most accurate results. Benefits of the photographic method include reduced risk of wound contamination, wound bed contact, and patient discomfort.

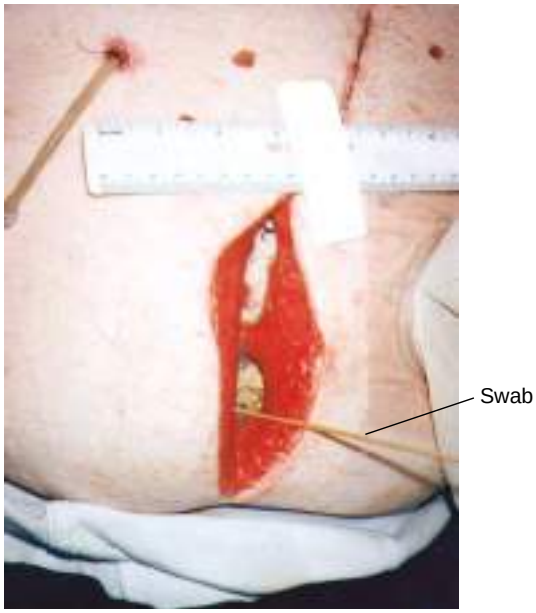

Figure 2-3 Demonstration of measuring wound depth using a swab. A sterile swab is inserted into the deepest portion of the wound and marked at surface level. The depth of the wound from the end of the swab to the mark is measured and recorded. (From Gallagher S, Gates JL: Obesity, panniculitis, panniculectomy, and wound care: understanding the challenges, *J Wound Ostomy Continence Nurs* 30(6):334-341, 2003.)

Photogrammetry

Computerized photogrammetry can give the practitioner precise objective information on wound size, shape, outline, area, color, and surrounding tissue changes.[8] The photogrammetry technique is based on color- and light-balanced computerized photographic image capture. A target plate is based in the same plane as the wound, and the software can extract dimensional and perspective information from the image (Figure 2-4). Marking a cotton swab showing the depth and placing the swab in the image allows calculation of wound depth.

Assessment of the Wound Bed

To determine the correct management and appropriate dressing selection, it is necessary to identify the shape and size of the wound and what types of tissue are present within the wound base.

Granulation tissue is the indication of healthy tissue—it can be yellow, red, or pink in color and will progress upward, filling in the base of the wound and providing a surface for the migration of new epithelial cells. It often has an appearance resembling cobblestones. **Unhealthy**

Figure 2-4 Digital photo-planimetry software for measuring wound size. This image displays output from PictZar software. (Images courtesy PictZar® Digital Planimetry Software. Available at: www.pictzar.com/PictZar%20Images.htm.)

granulation tissue is dark red in color, can bleed on contact, and may be indicative of wound infection. **Hypergranulation tissue** is red or pink in color and can rise above the wound bed. Evidence of hypergranulation can indicate that the cells contain excess fluid or have had contact with a caustic irritant causing chronic irritation and inflammation. It may also indicate the presence of an aerobic pathogen causing increased oxygen in the wound bed. **Slough** is nonviable, yellow or white, fibrous, necrotic tissue. It can vary from being loose and easily removed to being stringy and difficult to remove, as is often the case in chronic wounds. Slough is made up of fibrin, bacteria, dead cells, and wound fluid. It is necrotic tissue, and if left in the wound, healing cannot occur. Methods for debriding slough will depend on whether it is heavily adhered to underlying tissue. Slough that is loose and easily removed can be lifted from the wound bed using gentle mechanical debridement or through dressing choices that promote autolysis (i.e., enzymatic digestion of cells). Care must be taken because exposed tendons may be mistaken for slough. Tendons tend to be gleaming yellow or white and shinier than slough. In addition, upon close inspection, tendons contain a visible network of parallel fibers due to the presence of well-organized layers of collagen. **Eschar** is nonviable, hard, brown or black tissue. Sometimes the presence of eschar represents necrotic tissue that has remained in the wound and become desiccated, or dry. It may also represent necrotic tissue that has lost its blood supply. The presence of black eschar, slough, or any necrotic tissue will inhibit wound closure and may serve as a breeding ground for pathogens. Therefore removal of this tissue is usually required to promote full healing in most wounds. Black eschar and slough may be quantified as excessive (+++), moderate (++), minimal (+), or absent (–). The choice of an appropriate method of debridement, or removal of necrotic tissue from the wound bed, will depend on the type of necrotic tissue present, how firmly adhered the tissue is to the underlying layers of the wound, and the amount of necrotic tissue present relative to the presence of granulation tissue or new epithelium.

Epithelial tissue is the final visual sign of healing. Epithelial tissue is superficial, pink or pearly white tissue that migrates from the wound margins, hair follicle, or sweat glands.[14] As healing progresses, this new epithelial tissue will eventually cover the granulation tissue, resulting in full wound closure.

Assessment of Wound Edges

Examining the edges and margins of a wound may provide information on the wound etiology and assist in differential diagnosis. For example, venous leg ulcers often have sloping edges, irregular borders, and a shallow wound base. In contrast, arterial ulcers tend to be well demarcated with steep wound margins and greater depth. In some cases rolled or everted edges can indicate wound chronicity but may also raise suspicions of malignancy.[15]

Non-distinct wound edges occur when the wound bed is at the same level of the edges and can indicate that epithelialization is occurring. If the wound edges are calloused, it may indicate the presence of repetitive stresses, such as pressure or rubbing close to the wound. Callused edges are a strong characteristic in neuropathic foot ulcers, often seen in diabetic patients. In these cases, the wound may fail to close because callused tissue is not capable of epithelial regeneration. Rolled edges or epibole (i.e., wound edge rolls downward, and there is premature closure of wound) occur when the wound has been kept dry and the cells at the edges need moisture to continue healing. These rolled edges may also occur if there is a mechanical impediment to wound closure, such as the

presence of necrotic tissue, foreign debris, or the use of an improper dressing or topical agent within the wound bed. When rolling occurs, application of silver nitrate or surgical reopening of the wound edges is required to allow migration of new epithelial cells from the margins of the wound. If the wound margin is macerated (i.e., showing damp white edges with a mushy consistency), then a review of the wound dressing is required. If wound drainage is not adequately controlled, the areas of maceration may lead to further tissue breakdown, extending the size of the wound.[16] In many cases the onset of maceration can be effectively prevented through use of an absorptive dressing and the application of a petroleum skin protectant on intact tissues surrounding the wound.

Wound Site

The position and location of the wound can also provide information on differential diagnosis. For example, pressure wounds occur at or near bony prominences. **Arterial wounds** typically occur at the most distal portion of the impaired vascular supply, and **venous wounds** also tend to occur in the distal lower extremity, at locations where the return of blood to the systemic circulation is challenged by gravity and dependent positioning of the affected body part. The location of a wound also influences dressing and treatment choices. A wound over a joint capsule may leak synovial fluid, which could be mistaken for wound exudate. Exposed bone should be treated with care to reduce the risk of developing osteomyelitis. In addition, if a wound is in close proximity to or in close communication with an organ, body cavity, large blood vessel, or peripheral nerve, care must be taken to protect the exposed tissues during wound cleansing and irrigation and through the appropriate choice and application of topical agents, if any, as well as selection of a dressing that will guard against injury and infection without adhering or applying tension or excessive compression to the site. It should also be noted that if the wound meets the criteria noted earlier, the use of negative pressure wound therapy (NPWT) may be contraindicated.[14]

Wound Exudate

Consistency, color, odor, and amount of exudate should be recorded. Exudate can range from frank pus to serous, viscous, or blood-stained fluid. **Serosanguineous fluid** is a combination of blood and serous drainage that is thin, watery, and pale red or pink in color. Serous exudate is clear in color, and sanguineous is blood red. **Purulent exudate** can be thick or thin and yellow or brown or green in color. Purulent exudate is present in the inflammatory stage of healing due to the breakdown of blood cells, necrotic tissue, and other vascular constituents but can sometimes be indicative of infection, especially when found in conjunction with wound odor or other signs, such as warmth, redness, swelling, pain, or systemic symptoms, including fever, nausea, vomiting, and/or malaise. The amount of exudate may vary depending on the stage of wound healing. Wounds can produce exudate until the final stage of healing, epithelialization, is complete. The amount of moisture will determine the dressing choice. The quantity of exudate can be classified as heavy (+++ [dressing soaked]), medium (++ [dressing wet]), or minimal (+ [dressing dry]).[15] Wound infection or gross edema may cause excessive exudate, as may vascular congestion due to venous insufficiency. Each of these factors can lead to complications in wound healing if not properly addressed in the plan of care.

Tissue Classification Models

There are various models used in clinical practice to classify wound tissue or the extent of integumentary damage. These include, but are not limited to, pressure ulcer staging,[17] Wagner Wound Classification System for diabetic ulcers,[18] University of Texas classification for diabetic foot ulcers,[18,19] and Red-Yellow-Black (RYB) tissue color classification system.[20] In addition, there are objective tools and measures that can be used to document changes in wound status. These include the National Pressure Ulcer Association Pressure Ulcer Scale for Healing (PUSH) tool[21,22] and the Bates-Jensen Wound Assessment Tool (BWAT).[23]

Pressure Ulcer Staging

The National Pressure Ulcer Advisory Panel (NPUAP) redefined the definition of a pressure ulcer and the stages of pressure ulcers in 2007.[17] This definition is now considered the gold-standard system for staging or reporting pressure ulcers (Table 2-4). The original well-documented staging system was defined in 1975 by Shea[24] and was composed of four grades with each stage defined by the extent of soft tissue damage (I to IV and a closed pressure ulcer). When the NPUAP first developed its staging system, knowledge of pathology leading to pressure ulcers was very limited, and oftentimes, suspected deep tissue injuries were not considered and occasionally misclassified as stage I pressure ulcers. To help resolve this dilemma, the NPUAP has now defined deep tissue injury as the newest pressure ulcer stage in the current NPUAP staging system after examination of multiple clinical cases. Under the NPUAP system, the deep tissue stage has been defined as "purple or maroon localized area of discolored intact skin, or blood-filled blister resulting from damage of underlying soft tissue due to excessive pressure and/or shear."[17] The NPUAP acknowledged that deep tissue injuries could be more difficult to detect in individuals with dark skin tones. Therefore visual assessment should be augmented by additional observations, such as changes in skin temperature, texture, and turgor, as well as presence and degree of pain at the site of tissue damage.

TABLE 2-4

National Pressure Ulcer Advisory Panel Staging System for Pressure Ulcers

Stage	Definition
(Suspected) Deep Tissue Injury	Purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler as compared with adjacent tissue.
Stage I	Intact skin with nonblanchable redness of a localized area usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area.
Stage II	Partial-thickness loss of dermis presenting as a shallow open ulcer with a red-pink wound bed, without slough. May also present as an intact or open/ruptured, serum-filled blister.
Stage III	Full-thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon, or muscle is not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunneling.
Stage IV	Full-thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. Often include undermining and tunneling.
Unstageable	Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed.

Note: This staging system should be used only to describe pressure ulcers.

Modified from the National Pressure Ulcer Advisory Panel (NPUAP): NPUAP Pressure Ulcer Stages/Categories. Available at: http://www.npuap.org/resources/educational-and-clinical-resources/npuap-pressure-ulcer-stagescategories/. Accessed April 28, 2015

Stage I pressure ulcers are areas where skin damage exists but has yet to manifest as a break in the epidermis and visible exposure of subcutaneous tissues. Stage I pressure ulcers are identified as areas of nonblanchable erythema–areas of redness that do not turn white in response to gentle external pressure. Stage I pressure ulcers may also be more difficult to detect in patients with higher levels of skin pigmentation and may instead be characterized by a darker, almost violet discoloration. In stage I pressure ulcers the site may also be painful, firm, soft, warmer, or cooler when compared with adjacent tissue. **Stage II** pressure ulcers may present as a shiny or dry shallow ulcer with partial-thickness damage that extends through the epidermis and into, but not through, the underlying dermis. It is inappropriate to use this stage to describe skin tears, tape burns, perineal dermatitis, maceration, or denudement. **Stage III** pressure ulcer depth may vary depending on anatomical location. The bridge of the nose, ear, occiput, and malleolus lack subcutaneous tissue meaning that, even at stage III, ulcers in these areas may still be shallow. However, in areas with significant amounts of adipose tissue, extremely deep stage III ulcers may occur. Stage III pressure ulcers involve full-thickness damage to the epidermis and dermis, extending to, but not through, the subcutaneous tissues. **Stage IV** pressure ulcer depth will also vary depending on anatomical location. If over areas with little or no subcutaneous tissue, the ulcer may be shallow, but in areas with significant adipose tissue, the ulcer may extend into muscle and supporting structures, such as fascia, tendon, or joint capsule. This can lead to increased risk of osteomyelitis. In stage IV ulcers, bone and tendon may be visible or directly palpable.

There are some limitations in use of the NPUAP staging system that should be noted. The depth of a pressure ulcer cannot be properly assessed until sufficient amounts of slough or eschar have been removed such that the base of the wound may be seen. Therefore wounds that are covered with overlying necrotic tissue should be categorized as "unstageable" until an accurate determination of depth may be obtained. Another limitation in use of the NPUAP staging system is that a wound stage cannot be reversed; for instance, a stage III cannot become a stage II as wound closure occurs.

Pressure Ulcer Scale for Healing (PUSH) Tool

As an alternative to reverse staging, the NPUAP developed the PUSH tool (Appendix 2-1).[21,22] The PUSH tool represents a biologically accurate, easy-to-use, and clinically practical instrument for tracking pressure ulcer status over time. The NPUAP recommends use of the PUSH tool at regular intervals or if the condition of the patient or of the wound deteriorates. The PUSH tool is designed to monitor three critical parameters that are most indicative of healing: surface area (length×width, in centimeters squared), exudate (none, light, moderate, or heavy), and type of tissue present at the wound bed (i.e., closed or resurfaced, epithelial tissue, granulation tissue, slough, or necrotic tissue [eschar]). In addition, the NPUAP recommends assessment of additional parameters, such as odor, color of exudate, and the presence of undermining, tunneling, or sinus formation, as well as the condition of the periwound skin, to develop the most appropriate treatment regime.

Bates-Jensen Wound Assessment Tool (BWAT)

As an alternative to the PUSH tool, which is specifically designed for use in assessing pressure ulcers only, the BWAT is used to assess and monitor healing of all types of wounds. The BWAT was developed by Bates-Jensen in

the early 1990s and was initially called the Pressure Sore Status Tool (PSST). In 2001, the PSST was revised and renamed the BWAT—its new title reflecting its increasingly common use in wounds caused of various etiologies other than pressure (Appendix 2-2).[23] The BWAT is used to measure wound status at initial evaluation and then on at least a weekly basis or whenever a change in wound status occurs. It is more comprehensive than the PUSH tool and consists of 15 items (location and shape are not scored). The scored items are size, depth, edges, undermining, necrotic tissue type, necrotic tissue amount, exudate type, exudate amount, skin color, edema, induration, granulation, and epithelialization. Each item is scored from 1 to 5, with a lower score being preferable. The 13 subscores are totaled to get a total score. A BWAT score can be used to give an indication of the wound severity.

Bates-Jensen Wound Assessment Tool (BWAT) Score

13-20	Minimal severity
21-30	Mild severity
31-40	Moderate severity
41-65	Extreme severity

Wagner Wound Classification System for Diabetic Foot Ulcers

The well-established Wagner Wound Classification System for Diabetic Foot Ulcers (Table 2-5) has long been a popular tool for health care providers.[18] The Wagner system assesses ulcer depth and the presence of osteomyelitis or gangrene by using a grading system[25,26]; however, the disadvantage of this system is that it does not consider the presence of ischemia or infection of the ulcer.[27] Grading criteria for the Wagner system are as follows: Grade 0 signifies presence of bony foot deformities, callus formation, redness, or scar tissue indicative of a preulcerative or postulcerative state, but skin is intact. Grade 1 is used to describe a single, well-defined superficial ulcer. Grade 2 describes a deeper ulcer with exposure of the joint capsule or tendon. Grade 3 ulcers have involvement of deeper tissues, such as the muscle, fascia, or periosteum. Grades 4 and 5 involve more extensive tissue destruction with gangrene of the forefoot or more than two thirds of the foot, respectively.

The University of Texas San Antonio Diabetic Wound Classification System

The University of Texas classification system for diabetic foot ulcers is another commonly used tool. Similar to the Wagner Classification System, it uses four numeric stages focused on the depth of the wound, but within each stage, the University of Texas system also includes four letter grades based on the presence of infection and/or ischemia,[19] enabling better prediction of outcomes (Table 2-6).[18]

TABLE **2-5**

Wagner Wound Classification System for Diabetic Foot Ulcers

Grade	Description
0	Intact skin
1	Superficial diabetic ulcer
2	Ulcer extension involving ligament, tendon, joint capsule, or fascia. No abscess or osteomyelitis
3	Deep ulcer with abscess or osteomyelitis
4	Partial foot gangrene (i.e., forefoot)
5	Extensive or widespread gangrene (more than two thirds of foot)

Modified from Clayton W, Elasy TA: A review of the pathophysiology, classification, and treatment of foot ulcers in diabetic patients, *Clinical Diabetes* 27(2):54, 2009.

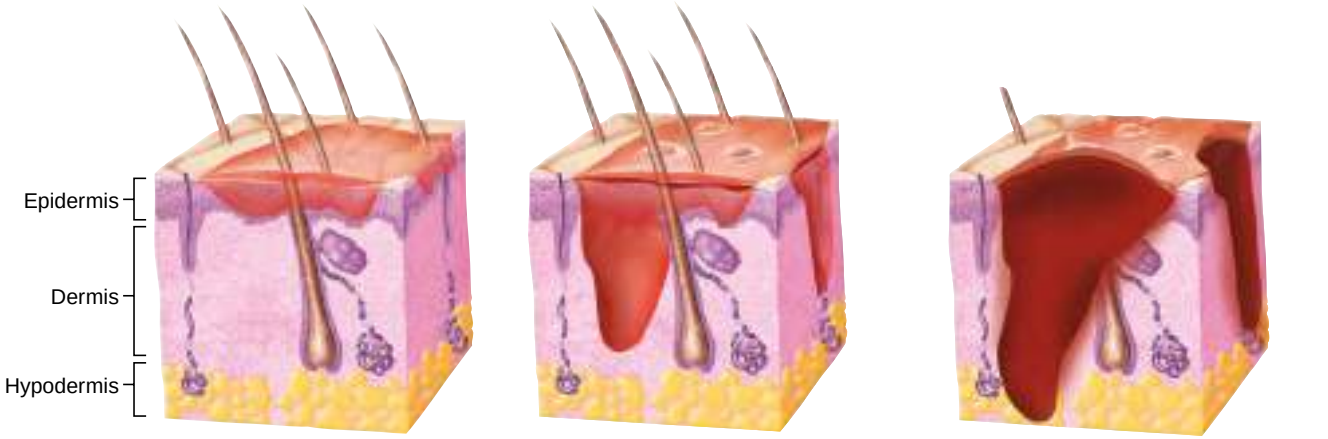
The Red-Yellow-Black (RYB) Color Classification System

The RYB tissue color classification system is a simple system for wound evaluation in chronic wounds or surgical sites. This system classifies wounds that are healing by secondary or delayed primary intention as red, yellow, black, or mixed. It can be applied to acute and chronic wounds. The classification is based on the continuum of the wound-healing process. Red wounds may be in the inflammatory phase, proliferation phase, or maturation phase of wound healing. Wounds that are not ready to heal are yellow wounds, which are infected or may contain fibrinous slough, and black wounds are those that contain necrotic tissue or eschar.[20]

Burns: Area and Depth Charts

There are three levels of burns: first, second, and third degree (Figure 2-5). In a first-degree burn, only the epidermis is affected, and pain, redness, and swelling may be present. With a second-degree burn (i.e., partial-thickness burn), the entire epidermis and upper layers of the dermis are affected, causing pain, redness, swelling, and blistering. Third-degree burns (i.e., full-thickness burns) destroy the entire epidermis and most of the dermis and will cause blackened and burned skin and may be accompanied by numbness or diminished sensation.[28] There are three methods that are commonly used to measure the size of a burn based on the amount total body surface area involved in the injury. These are the Rule of Nines, Palmar method, and Lund-Browder (LB) method.

Wallace Rule of Nines



The Rule of Nines was first developed in the 1940s but did not appear in the literature until the 1950s. It has now become a standard clinical method for determination of the percentage of the body affected by a burn (Table 2-7).[29] It is a quick way of estimating medium-to-large burns in adults, but it is not as accurate in children. Using a diagram, each region of the body is divided into regions

TABLE **2-6**

University of Texas Diabetic Wound Classification System

	Grade 0	Grade 1	Grade 2	Grade 3
Stage A	Areas of pressure which are sometimes called preulcerative lesion	Noninfected, nonischemic superficial ulceration not including tendon, capsule, or bone	Noninfected, nonischemic ulcer that penetrates to tendon or capsule	Noninfected, nonischemic ulcer that penetrates to bone or joint
Stage B	Infected, nonischemic epithelialized wound	Infected, nonischemic superficial ulceration	Infected, nonischemic ulcer that penetrates to tendon or capsule	Infected, nonischemic ulcer that penetrates to bone or joint
Stage C	Ischemic, noninfected epithelialized wound	Ischemic, noninfected superficial ulceration	Ischemic, noninfected ulcer that penetrates to tendon or capsule	Ischemic, noninfected ulcer that penetrates to bone or joint
Stage D	Infected and ischemic epithelialized wound	Infected and ischemic superficial ulceration	Infected and ischemic ulcer that penetrates to tendon or capsule	Infected and ischemic ulcer that penetrates to bone or joint

representing 9% of the total body surface. Due to differences in anthropometric proportions, separate diagrams are available for use in the adult and pediatric populations (Figures 2-6 and 2-7). Location of the burn is documented and size of the burn calculated based on affected regions of the body diagram.

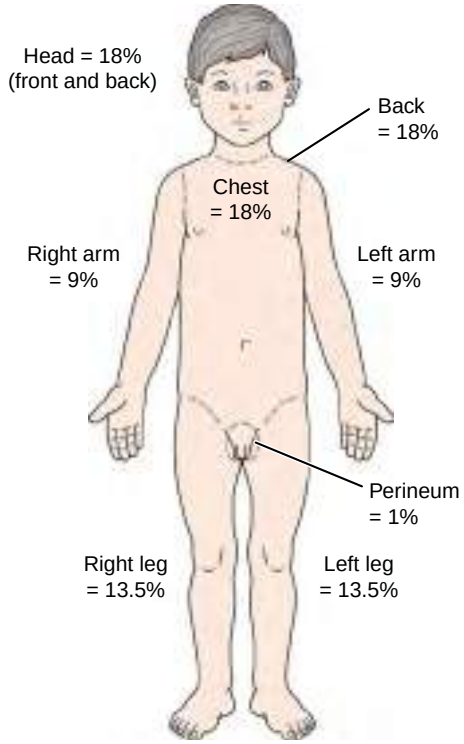

Figure 2-7 Child Rule of Nines.

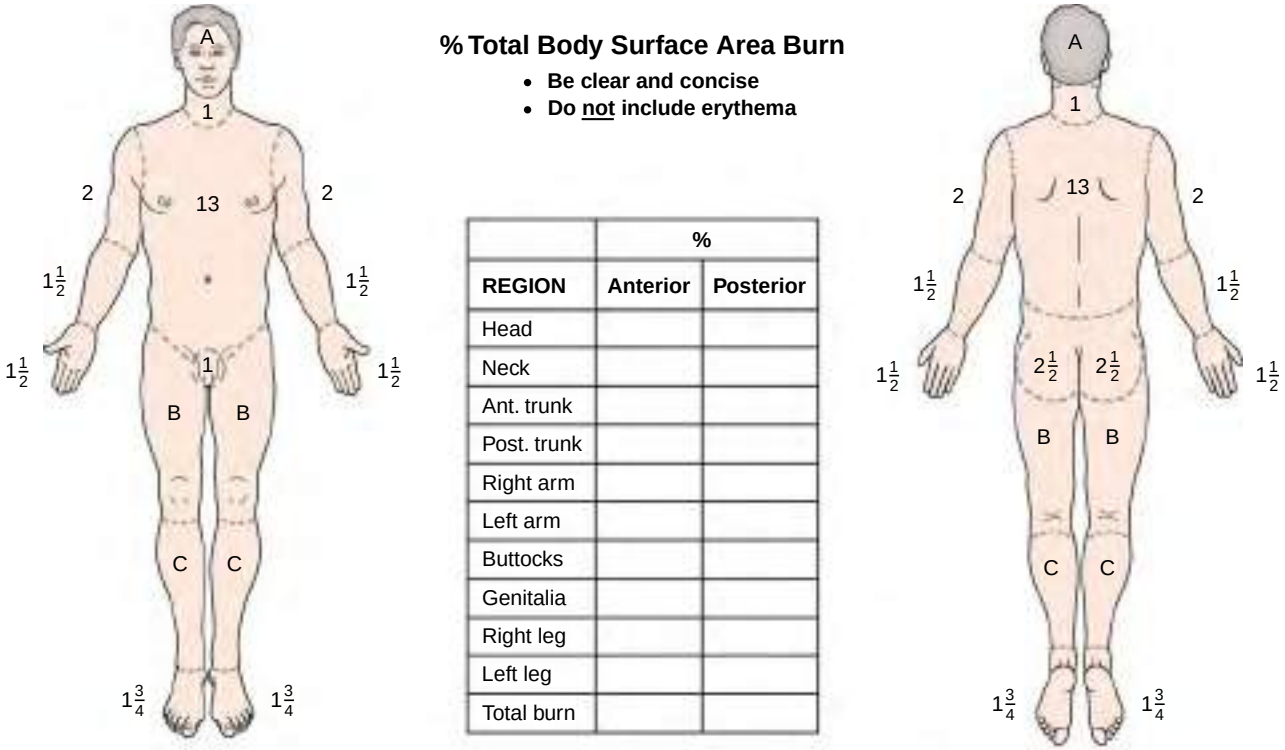
Lund-Browder (LB) Chart



The LB chart (Figure 2-8) is thought to be the most accurate assessment of a burn area when used correctly. It considers the body shape, size, and age of the patient when assigning total body surface area and therefore can be also used for children.[10] The LB chart consists of two drawings of the human body, one of the anterior body surface area and one of the posterior body surface area. The assessor draws the shape of the burn onto the chart, excluding simple erythematous areas. Each area is assigned a value of the body surface area percentage, which is entered into a table. The total body surface area affected by burn is then calculated.[30]

Palmar Surface Method

This method uses the surface area of the hand to estimate the surface area of a burn. The palmar surface area, including the fingers, represents roughly 1% of the total body surface area (Figure 2-9). Therefore the number of "palms" required to cover a burn injury can be used as an approximation of size. This method can be fairly accurate and reliable when evaluating smaller burns with irregular shapes or scattered distributions. However, accuracy and reliability steadily decline when measuring burns that involve more than 15% of total body surface area.[10]

Examination of Periwound Tissue

When caring for a patient with acute or chronic wounds, it is important to fully assess the area surrounding the wound. Skin surrounding a wound site is vulnerable, and

Factors Affecting Periwound Tissue

- Drainage from a fistula or stoma
- Excessive perspiration
- Increased wound exudate
- Removal of adhesive products
- Sensitivities, such as allergic reactions

periwound (i.e., skin surrounding the wound) problems are a frequent occurrence. Damage to periwound tissue may delay healing, increase the size of the original wound, and cause pain and discomfort that may adversely affect the patient's quality of life. Wounds such as venous leg ulcers, pressure ulcers, and diabetic foot ulcers may leave the periwound tissue more vulnerable due to the increased prevalence of maceration and exudate associated with these wound pathologies.[31] There are a number of wound-related factors that may also compromise the periwound skin, such as those listed in the following textbox.[32]

Examination of the periwound skin is performed by observation and palpation to determine whether there are any changes in skin characteristics (e.g., appearance, texture, temperature, or moisture content) with the skin being described in different ways (e.g., moist or dry, warm or cold, and rough or smooth).[33] If skin is devoid of hair, has a shiny appearance, and looks thin and fragile, it may indicate a chronic decrease in vascular supply. It is important to remember that skin lesions and inflammation may appear differently depending on the skin tone of the patient. Red or brown lesions on white skin may appear black or purple in people with darker skin pigment. It can also be difficult to identify areas of mild erythema (i.e.,

redness) in individuals with darker skin shades. The following items should be considered during the assessment of periwound tissue.

Callus (Hyperkeratosis)

Callus formation is most commonly observed on the soles of the feet or areas of increased pressure on the skin, uneven weight distribution, or friction on the skin.[33] The presence of excessive stresses on the upper layers of the epidermis may cause an increase in keratin production, leading to areas of skin that may be rough, thick, and yellow in color. Calluses tend to occur over bony prominences exposed to repeated pressure, friction, and shear. Although intended as a protective response to prevent damage to deeper tissue layers, when excessive callus formation occurs, the callus itself can lead to further problems in pressure distribution and may impair proper delivery of oxygen and nutrients to deeper tissue layers. In addition, the presence of callus may obscure underlying tissue damage, making it harder to identify areas of inflammation or infection. This is particularly true in patients with diabetic neuropathy in which damage to the autonomic nerve supply affects the function of sebaceous glands, leading to excessive dryness, cracking, and fissures at the sole of the foot. This increases the propensity toward callus formation and vulnerability toward tissue breakdown. Bony foot deformities resulting from the combined effects of motor and sensory neuropathy, as well as gait and balance impairments present in diabetic peripheral neuropathy, also contribute to excessive pressure and shear at the sole of the foot. These factors can also increase the likelihood of callus formation and subsequent tissue breakdown. Therefore, patients with a diabetic peripheral neuropathy should be advised to regularly apply emollient (a substance to soften tissue) to the heels and soles of the foot and have calluses regularly filed down or removed by a podiatrist.[31] Areas between the toes should be kept dry to decrease risk of fungal infection.

Color and Temperature

Warmth, increase in pain, and drainage at the wound site may indicate infection.[34] If capillaries in the periwound area around pressure ulcers have become damaged, the skin may become erythematous with the red color persisting despite removal of the pressure. This is more easily determined in white or lightly pigmented skin and is termed *unblanchable erythema*.[33] If the erythema persists after removing the pressure, it may signal a stage 1 pressure ulcer as defined by NPUAP.[17] Depending on the type of trauma, nonblanchable erythema may also indicate a superficial burn. If the skin tone of the patient makes it difficult to determine the presence of erythema, the clinician should compare the color on the opposite side of the body or ask the patient or family members, if appropriate, about color changes.

Induration (Hardening of the Tissue)

Presence of induration indicates excess fluid trapped within the tissue layers of the periwound skin and may signify a relapse to phase 1 of the inflammatory process. Induration may be described as an abnormal hardening of the tissue caused by consolidation of edema due to trauma or infection. Occasionally, induration will also be accompanied by visual changes including the appearance of small indentations or hollows in the skin resembling the peel or skin of an orange (i.e., *peau d'orange*).

Excoriation (Injury to Body Surface Caused by Trauma)

Excoriation is an abrasion of the superficial layers of the skin or linear erosion caused by itching, scratching, alteration of the natural moisture content, contact with topical irritants, presence of pathogenic microorganisms, or removal of adherent dressings. Repeated removal of adhesives in the same area can lead to a problem known as "skin stripping." Inflammatory skin damage, edematous changes, pain, and a negative effect on the skin barrier function may result.[35] Conditions that may predispose a patient to excoriation include urinary and/or fecal incontinence, excessive perspiration, use of harsh or caustic topical cleansers (which contribute to desiccation of the skin), and the presence of an artificial stoma, such as a tracheostomy or colostomy. In addition, older patients tend to be more vulnerable to both excoriation and stripping due to reductions in skin hydration, tissue turgor, and elasticity.

Fungal Infections

The alkaline nature of some wound fluid coupled with the increased humidity from the bandages can contribute to fungal growth.[36] Normally, the epidermis retains a slightly acidic pH. This "*acid mantle*" helps to protect against the excessive proliferation of surface bacteria and other pathogens. Alterations in the microenvironment of the skin due to illness or injury can lead to an increase in transient and resident flora, which are often the cause of mucocutaneous infections. Controlling the moisture content and temperature and maintaining normal pH balance will help to lower the risk of developing a fungal infection. It is prudent to have samples undergo laboratory analysis if fungal infection is suspected because incorrect treatment may lead to exacerbation of symptoms.[32]

Maceration (Skin Breakdown due to Prolonged Exposure to Moisture)

Prolonged exposure of the skin to moisture can lead to changes in the appearance of the skin, such as softening, swelling, and wrinkling of the epidermis. The moisture can be the result of wound exudate or body fluids, such as perspiration, urine, or fecal material. Macerated skin has been shown to be more sensitive to irritants[37] and may lead to breakdown of tissue in the periwound area leading to an enlarged wound. If the periwound tissue is white in color, it may mean there is maceration but little

inflammation. However, red and inflamed periwound tissue may indicate erythematous maceration, which may be accompanied by contact dermatitis or weeping.[38] Maceration of periwound tissue may result in excoriation, pain, and discomfort. Maceration can be avoided by appropriate selection of skin protectants and dressings.

Scarring

Scar tissue that is immature will be thin, flexible, and more susceptible to skin breakdown than healthy tissue. A new scar will appear light pink in color regardless of skin pigmentation. Thick and rigid scarring may lead to susceptibility of future skin breakdowns in addition to impairing motion, specifically if the wound is at or near a joint surface. Formation of **hypertrophic scarring** (Figures 2-10 and 2-11) appears to have a genetic component and is excess scar tissue within the boundaries of the wound. Hypertrophic scarring can sometimes also result from repeated or excessive stresses on the wound site during the proliferative phase of healing. The body responds to the excessive stress with an increase in collagen formation, leading to scar tissue that extends above the original wound dimensions. In addition to cosmetic concerns, this type of scarring may adhere to underlying layers, causing problems in soft tissue mobility and range of motion. Hypertrophic scarring is a major concern in burn injuries, particularly ones that involve excessive tissue depth or cross the surface of the joint. **Keloid scars**, which "spill out" beyond the wound margins, tend to be more common in people with intensely pigmented skin, have a female to male ratio of 2:1, and most commonly occur on the upper trunk (Figure 2-12; see Figure 2-10). The exact etiology behind keloid scars is unknown, but it is thought that estrogen and growth factors are important influences, in addition to immunological influences and genetic predisposition.[39] Prevention and management may include the use of splinting to prevent contracture, as well as compression garments to encourage remodeling.

Edema

Edema is an accumulation of fluid in the intracellular tissues and may be characterized as acute, subacute, or chronic. Immediately following an injury, the presence of edema is an early sign of inflammation, resulting from a transient increase in capillary permeability to large plasma proteins and other constituents of the blood. When large

plasma proteins leave the vascular bed, the oncotic pressure (a form of osmotic pressure) gradient is disrupted, causing excess fluids to follow. As the histamine reaction subsides, capillary permeability is restored to its usual level. These fluids are either reabsorbed into the local circulation or removed via the lymphatics. The presence of edema should be carefully evaluated before treatment. In patients with cardiovascular disease, localized edema (particularly within the extremities) may be indicative of cardiac pump failure. Care must be taken not to promote return of the fluid into the systemic circulation to avoid additional cardiac stresses. The same is true for patients with end-stage renal disease, in which the collection of excessive fluid within the abdomen (ascites) and extremities can indicate a protein imbalance and/or inability of the excretory system to remove fluids and toxins from the body. In certain cases the presence of excessive swelling can eventually lead to tissue breakdown because of increased pressures and secondary impairments in the delivery of adequate oxygen and nutrients to the affected area.[33] This is what often occurs in patients with venous insufficiency, in which chronic dependent edema in the lower extremities contributes to skin breakdowns in the gaiter area of the leg (i.e., the region that lies between the ankle and the knee, along the lower shin and calf area).

In closed traumas, such as fractures and crush injuries, excessive accumulation of fluid can cause compartment syndrome, resulting in the need for emergent surgery to alleviate pressures on the internal vasculature and nerve supply.

Hemosiderin Staining

Hemosiderin staining causes brownish discoloration of the legs and occurs when chronic venous stasis causes a change in skin elasticity and texture (Figure 2-13). The staining is caused by iron from hemoglobin leaking out of red blood cells, which have broken down due to increased venous pressure. Eventually the build-up of swelling in the area causes the skin to fail and break open, and a venous stasis ulcer results.[34] The leakage of proteins and accumulation of fibrin around the capillaries can lead to impaired circulation and sluggish lymphatic turnover.

Figure 2-13 Hemosiderin staining of the lower limbs occurs when iron from hemoglobin leaks out of red blood cells that have broken due to venous pressure. This causes brownish discoloration of the legs.

Infection

Infected wounds, such as pressure ulcers, can lead to delayed healing, temporary disability, and prolonged hospital stays, and in severe cases, the patient may develop septicemia (life-threatening infection), which causes thousands of deaths each year.[40] Infection is one of the greatest challenges in chronic wound closure. Many factors will influence healing in surgical, acute, and chronic wounds, and the most significant risk factor is the level of bacterial burden relative to the immune response of the patient or host. These risk factors are summarized in Table 2-8.[41,42]

TABLE 2-8

Risk Factors for Wound Infection[41,42]

Patient Factors	Surgical Factors	Anesthetic Factors	Other
• Diabetes • Nutrition • Smoking • Alcohol intake • Chronic renal failure • Liver function • Body mass index • Age • Medications • Chemotherapy • Radiotherapy	• Surgical classification • Skin preparation • Site and duration of surgery • Complexity of surgery • Presence of suture or foreign body • Suturing quality • Preexisting infection • Hematoma • Mechanical stress on wound	• Tissue perfusion • Normovolemia • Hypovolemia • Body temperature • O_2 saturation • Blood transfusion	• Wounds with necrotic tissue • Wound near areas of contamination, such as the groin • Microbial virulence and pathogenicity

Early identification of wound infection is vital for timely implementation of the appropriate treatment and for improved patient outcomes. Wound infection is one of the most common postsurgical complications and leads to significant mortality and morbidity.[43] Reports indicate that as many as 5% of patients who undergo surgery develop a surgical site infection (SSI).[44] Infection rates for SSIs are typically grouped according to surgical classification: clean, clean-contaminated, contaminated, and dirty wounds. Since the introduction of prophylactic antibiotics, infection rates of SSIs have been greatly reduced. Infection rates in the U.S. National Nosocomial (Hospital) Infection Surveillance system are reported to be: 2.1% clean, 6.4% contaminated, and 7.1% dirty.[45]

Wound infection is caused by pathogens establishing themselves within the host tissue, multiplying and causing a host reaction. Direct contact and poor hand sanitization methods of health care professionals are thought to be significant factors for common entry of pathogens into a wound. Some of the risk factors for infection can be avoided by use of modern surgical techniques and prophylactic antibiotics. In acute and chronic wounds, prevention also relies on proper cleansing and debridement, as well as careful attention to clean and sterile technique.

Ways in Which Microorganisms Gain Access to a Wound[46]

- Direct contact: transfer from hands of care givers or from equipment
- Airborne dispersal: deposited from the surrounding air
- Self-contamination: physical migration from the patient's skin or gastrointestinal tract

Infection may be localized to the wound site or systemic. The classic signs of infection are purulent or excessive exudate, heat, edema, erythema, cellulitis, pyrexia (increased temperature), delayed healing, wound breakdown, fragile granulation tissue, and presence of pus.[47] However, not all of these features are present in some patients with chronic wounds, particularly with microvascular or macrovascular disease, immunocompromise, or patients on anti-inflammatory medications, such as corticosteroids.[48] In these patients the only sign of infection may be failure of the wound to heal.

Contamination of a wound in the absence of active bacterial proliferation in a wound is not considered to be relevant to clinical practice. Due to the presence of resident flora on the surface of healthy, intact skin, all open wounds have some level of bacterial contamination. Instead, the presence of bacteria in a wound should be thought of as a continuum that may progress from contamination, to colonization, to critical colonization, in which replication of bacteria begins to overwhelm the immune response of the patient or host. Colonization in a wound (i.e., healing by secondary intention) is considered to be a healthy stable state even though the bacteria may be growing and multiplying. If a patient's immune response is efficient, a balance will be maintained and presence of bacteria in the wound will not lead to an infection.[49] However, if the patient's defense mechanisms are suppressed, then critical colonization may occur. *Critical colonization* is the state between colonization and infection when multiplication of bacteria delays wound healing but without some of the common signs and symptoms of infection.[41] Wound management involves prevention of bacterial invasion, with early detection and intervention to prevent progression of contamination to infection.[49] In a colonized but not infected wound, there is the risk of obtaining a false positive result in wound culture tests, which can lead to unnecessary treatment. To avoid inappropriate testing and treatment, it is important to use clinical judgment to distinguish between contaminated and infected wounds. Testing should only be performed when the presence of infection is suspected due to patient symptoms and/or

changes in the clinical presentation of the wound or the presence of delayed healing.

For patients with suspected infections, it is the current reference standard to perform a deep tissue biopsy. However, tissue biopsies are painful and invasive. Therefore most acute and chronic wounds are cultured using a wound surface swab. Use of wound cultures should be reserved for cases involving existing signs of infection or delayed healing due to the presence of surface bacteria in all open wounds and intact skin. The presence of bacteria alone does not indicate infection unless the number and virulence of the pathogen have overwhelmed or overburdened the immune response of the patient or host.

Three Techniques Commonly Used to Obtain a Wound Culture

- Tissue biopsy
- Needle aspiration
- Swab

Removal of a piece of tissue using a scalpel or punch biopsy is critical to achieve a quantitative culture of wound tissue, which is the gold standard for identification of wound infection.[50] Although tissue biopsies are considered the gold standard, they are time consuming, costly, and not within the scope of all wound care specialists. Swab culture is more cost effective and is noninvasive; therefore it is more commonly used in clinical settings. Quantitative swab culture technique is considered adequate by many to identify any bacterial species causing wound infection and can be used to guide antibiotic therapy.[51,52]

INTERVENTIONS

In the United States the Agency for Health Care and Policy Research (AHCPR, now known as the Agency for Healthcare Research and Quality [AHRQ]) recommends that initial pressure ulcer risk assessment be done on admission and reassessed at regular intervals.[53] The frequency of reevaluation will depend on the acuity of the individual and how rapidly a patient's condition changes over time.

Patients at higher risk of developing pressure-related wounds include older adults, patients with impaired mobility, under sedation, and having decreased motivation due to psychological overlay, and those with impaired cognition. Tools that can be used to assess the level of risk include the Norton[54] and Braden[55] Scales. The Norton Pressure Sore Risk Assessment Scale (Figure 2-14) was created in Britain in 1962 and examines five categories to calculate an overall score predicting likelihood of breakdown.[54] These categories include the patient's physical condition, activity level, mobility level, cognition, and presence of incontinence. Lower scores indicate individuals at higher risk. The Braden Scale (Figure 2-15) is the most commonly used pressure ulcer assessment scale in the United States.[55] The Braden Scale has six subscales: sensory perception, moisture, activity, mobility, nutrition, and friction or shear. It addresses the main etiological factors behind pressure ulcer development, intensity and duration of pressure and tissue tolerance for pressure.[55] A lower score indicates a patient at higher risk. Positioning and pressure redistribution are key factors in the prevention and management of pressure ulcers.

Positioning and Pressure Redistribution

For patients at risk, as well as those who have already developed a pressure ulcer, there are a number of interventions commonly used for redistributing pressure (Figure 2-16).

Interventions Commonly Used for Pressure Redistribution

- Modified support surfaces
- Reducing duration of loading by increasing frequency of turning and positioning
- Positioning devices and posture
- Weight shifting

The use of support surfaces in the treatment of pressure ulcers includes reactive and active surfaces. A reactive surface responds to the load placed upon it, whereas an active surface dynamically changes the body–support surface interface.[56] The effectiveness of a support surface can be measured by monitoring physiological responses, such as blood flow and tissue oxygenation, or by directly measuring the interface pressure. Support surfaces can be foam, air, water, or elastomeric mattresses, cushions, and overlays.[57]

Reducing the duration of loading is pertinent for patients who may be unable to reposition themselves independently or for patients who do not have the sensory feedback that would prompt repositioning. Using turning schedules and teaching weight-shifting strategies are necessary interventions for these patients.

Turning frequency is dependent on the support surface. Recommendations derived from research studies investigating optimal turning frequency range from every 2 to 6 hours depending on the support surface, stage of the ulcer healing, and mobility level of the patient.[58–60] When it comes to positioning of the patient, alternating between side lying and supine is common practice. In side lying, the greater trochanter, the malleoli, and medial femoral epicondyles are at increased risk, but the use of positioning devices, such as pillows or wedges, can effectively unload these bony prominences. In addition, rather than lying directly on the lateral aspect of the hip, pressure on the greater trochanter can be alleviated by slightly rotating the body 5° to 10° laterally. When lying in a supine position, care must be taken to avoid friction or shear in

Norton Scale for Assessing Risk of Pressure Ulcers*

Instructions: Complete the form by scoring each item from 1 to 4. Put 1 for low level of functioning and 4 for highest level functioning,

Name: _____ Date: _____

Criterion	Score
Physical condition	4 = Good 3 = Fair 2 = Poor 1 = Very bad
Mental condition	4 = Alert 3 = Apathetic 2 = Confused 1 = Stupor
Activity	4 = Ambulant 3 = Walk with help 2 = Chair bound 1 = Bed bound
Mobility	4 = Full 3 = Slightly impaired 2 = Very limited 1 = Immobile
Incontinent	4 = Not 3 = Occasionally 2 = Usually/Urine (catheter) 1 = Doubly (urine and feces)
TOTAL SCORE =	

Greater than 18 - Low risk
Between 18 and 14 - Medium risk
Between 14 and 10 - High risk
Less than 10 - Very high risk

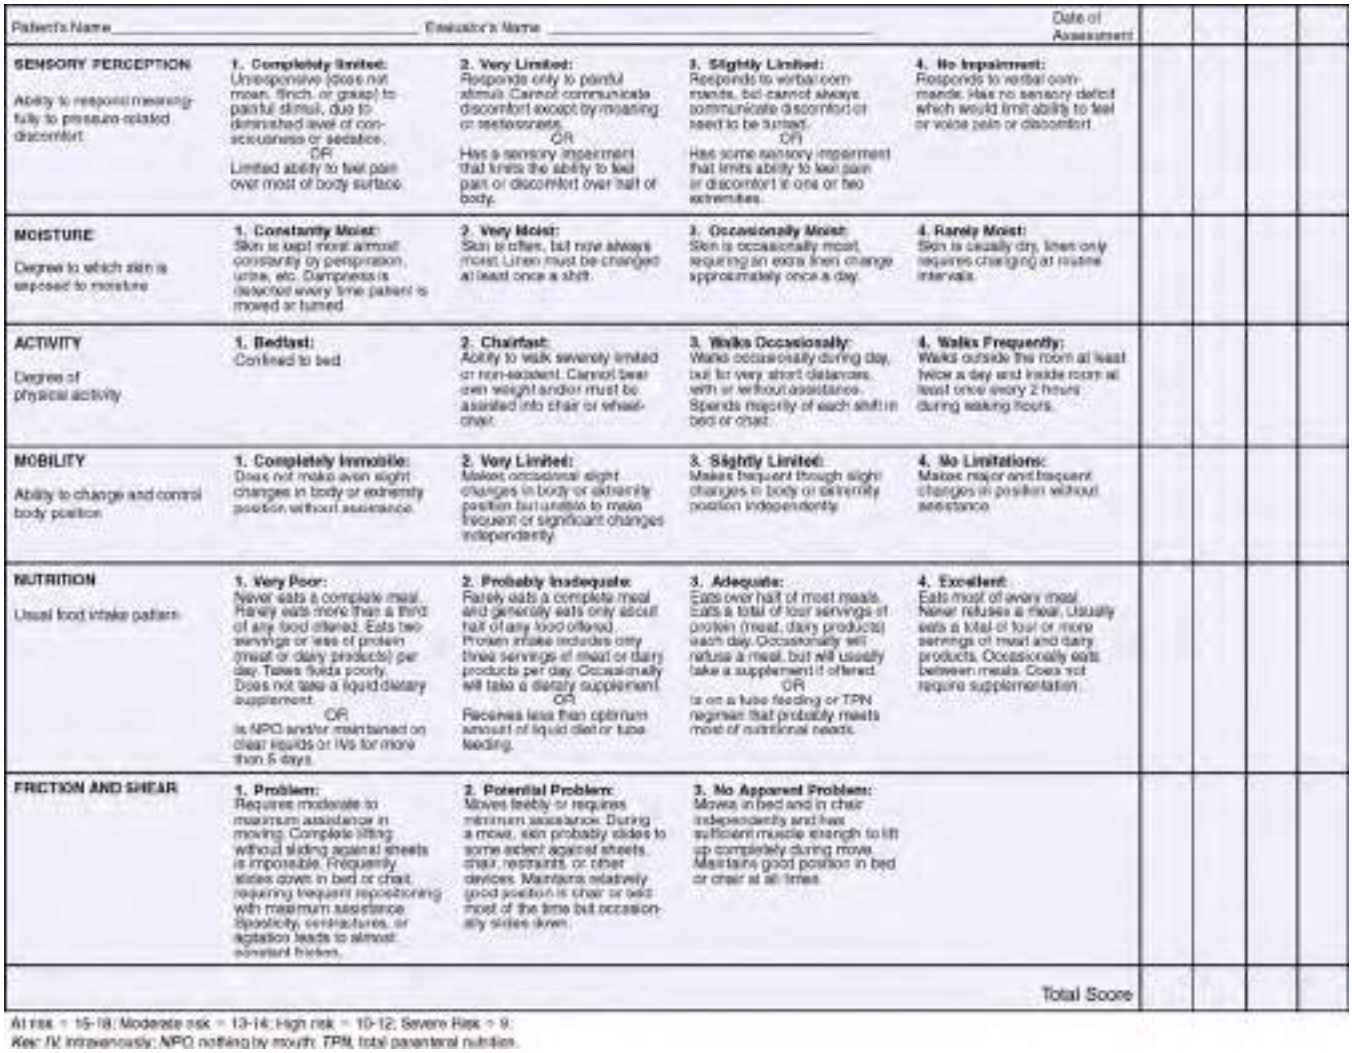

Figure 2-14 Norton Scale for Assessing Risk of Pressure Ulcers. (Modified from Norton D, McLaren R, Exton-Smith AN: *An investigation of geriatric nursing problems in hospital*, London, 1962, National Corporation for the Care of Old People.)

the buttocks. The amount of pressure and shear on the buttock is increased if the head of the bed is elevated; so although this is a more functional position for eating or drinking, it should not be used for extended periods. Keeping the head of the bed below a 45° angle and raising the foot of the bed can counteract the sliding motion, but there is still increased pressure on the sacral area.

Weight-shifting maneuvers can be taught to wheelchair users and patients with limited mobility. In bed, repositioning may be facilitated by the use of rails and/or installation of an overhead frame or trapeze.

Weight-Shifting Maneuvers for Wheelchair Users and Patients with Limited Mobility

- Pushing on the arms of the chair with the arms to lift the buttocks off the cushion
- Leaning forward to rest the trunk on the lower limbs
- Leaning over to one side and then repeat leaning over to the opposite side
- Using the powered tilt and recline function on powered wheelchairs to redistribute the pressure

Patient's Name _____ Evaluator's Name _____				Date of Assessment				
SENSORY PERCEPTION Ability to respond meaningfully to pressure-related discomfort	**1. Completely Limited:** Unresponsive (does not moan, flinch, or grasp) to painful stimuli, due to diminished level of consciousness or sedation. OR Limited ability to feel pain over most of body surface.	**2. Very Limited:** Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness. OR Has a sensory impairment that limits the ability to feel pain or discomfort over half of body.	**3. Slightly Limited:** Responds to verbal commands, but cannot always communicate discomfort or need to be turned. OR Has some sensory impairment that limits ability to feel pain or discomfort in one or two extremities.	**4. No Impairment:** Responds to verbal commands. Has no sensory deficit which would limit ability to feel or voice pain or discomfort.				
MOISTURE Degree to which skin is exposed to moisture	**1. Constantly Moist:** Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is detected every time patient is moved or turned.	**2. Very Moist:** Skin is often, but not always moist. Linen must be changed at least once a shift.	**3. Occasionally Moist:** Skin is occasionally moist, requiring an extra linen change approximately once a day.	**4. Rarely Moist:** Skin is usually dry, linen only requires changing at routine intervals.				
ACTIVITY Degree of physical activity	**1. Bedfast:** Confined to bed.	**2. Chairfast:** Ability to walk severely limited or non-existent. Cannot bear own weight and/or must be assisted into chair or wheelchair.	**3. Walks Occasionally:** Walks occasionally during day, but for very short distances, with or without assistance. Spends majority of each shift in bed or chair.	**4. Walks Frequently:** Walks outside the room at least twice a day and inside room at least once every 2 hours during waking hours.				
MOBILITY Ability to change and control body position	**1. Completely Immobile:** Does not make even slight changes in body or extremity position without assistance.	**2. Very Limited:** Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently.	**3. Slightly Limited:** Makes frequent though slight changes in body or extremity position independently.	**4. No Limitations:** Makes major and frequent changes in position without assistance.				
NUTRITION Usual food intake pattern	**1. Very Poor:** Never eats a complete meal. Rarely eats more than a third of any food offered. Eats two servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement. OR is NPO and/or maintained on clear liquids or IVs for more than 5 days.	**2. Probably Inadequate:** Rarely eats a complete meal and generally eats only about half of any food offered. Protein intake includes only three servings of meat or dairy products per day. Occasionally will take a dietary supplement. OR Receives less than optimum amount of liquid diet or tube feeding.	**3. Adequate:** Eats over half of most meals. Eats a total of four servings of protein (meat, dairy products) each day. Occasionally will refuse a meal, but will usually take a supplement if offered. OR is on a tube feeding or TPN regimen that probably meets most of nutritional needs.	**4. Excellent:** Eats most of every meal. Never refuses a meal. Usually eats a total of four or more servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation.				
FRICTION AND SHEAR	**1. Problem:** Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures, or agitation leads to almost constant friction.	**2. Potential Problem:** Moves feebly or requires minimum assistance. During a move, skin probably slides to some extent against sheets, chair, restraints, or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down.	**3. No Apparent Problem:** Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair at all times.					
								Total Score

At risk = 15-18; Moderate risk = 13-14; High risk = 10-12; Severe Risk < 9.
Key: IV, intravenously; NPO, nothing by mouth; TPN, total parenteral nutrition.

Splinting

Deciding on the appropriate splint for pressure relief, for protection, or to off-load a limb will depend on the mobility status of the patient. Factors to consider are whether the splint will be used while in bed only or if the patient will also be using the device for transfers and ambulation. The algorithm in Figure 2-17 displays some of the elements one needs to consider when providing a cast or splint.

Integumentary Repair and Protection Techniques

The presence of eschar or scab in dry wounds can delay epithelialization and wound contraction. Removal of impediments to healing can be done through cleansing or debridement. Cleansing typically uses fluid to remove debris and microorganisms on the wound surface.[61] Debridement (i.e., removal of damaged tissue or a foreign object from the wound[62]) involves the use of mechanical or chemical measures for the removal of adherent materials, such as necrotic tissue. There are numerous methods of cleansing, irrigating, and hydrating wound tissue. The size, location of the wound, and facilities available (e.g., inpatient versus outpatient clinic), as well as the knowledge, skill, and comfort level of the clinician, should all be considered when determining the appropriate method based on individual patient presentation.

Wound Cleansing

Prepackaged, single-dose, 8-psi, sterile irrigation can be used for simple cleansing. It is advisable to use splash guards during any irrigation procedures to avoid transfer of contaminated fluid to the treatment area. Sponges, cloths, or gauze may also be used for superficial cleansing when doused in saline or other cleansing detergents. The AHRQ has recommended avoiding use of antiseptic formulas or disinfectants on chronic wounds and limiting these agents to acute wound care.[63] The most commonly used irrigants are sterile water and sterile saline. Saline is preferred to maintain osmotic gradients within physiological tissues. The AHRQ guidelines[63]

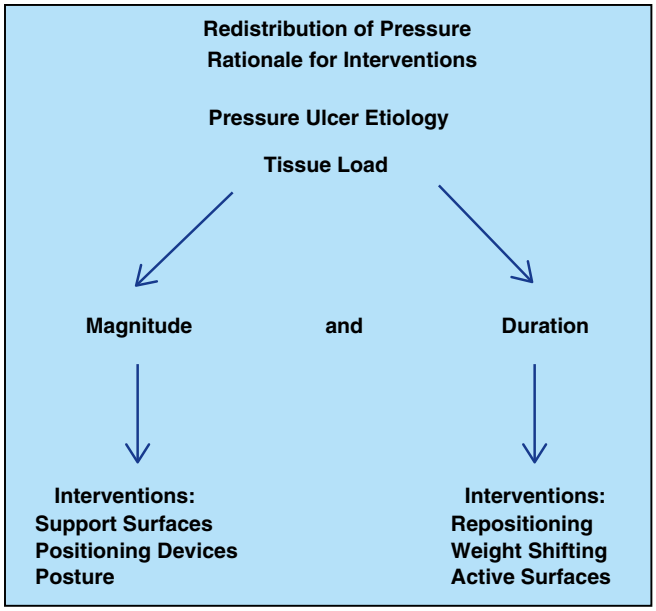

Figure 2-16 Redistribution of pressure: rationale for interventions. This model considers both magnitude and timing of loading to be important in pressure ulcer development. The magnitude of pressure can be controlled by strategies such as selection of support surfaces, and duration is addressed by turning and weight-shifting frequencies. (From Sprigle S, Sonenblum S: Assessing evidence supporting redistribution of pressure for pressure ulcer prevention: a review, *J Rehabil Res Dev* 48(3):203-213, 2011.)

also state that a pressure of less than 4 psi is unlikely to remove bacteria from the wound, and more than 15 psi might drive the bacteria or debris into the wound bed. Therefore, 4 to 15 psi is the recommended range for irrigation pressure.

Clinical Note

- When cleansing wounds, sterile irrigation should be between 4 and 15 psi

Debridement

Debridement is usually performed in conjunction with irrigation. Necrotic tissue may serve as a culture medium for bacteria, and often, wounds with necrotic tissue will not heal until the necrotic tissue is removed. The body may slough off the dead tissue on its own, but in cases in which this fails to happen, debridement may be necessary to facilitate wound healing. Debridement also allows removal of tissue samples for culture and sensitivity testing to confirm cases of suspected infection and to identify the best medication to facilitate recovery. For patients with intact neurological function, one of the negative side effects of debridement is pain. Use of topical anesthesia directly into the wound bed, regional anesthesia achieved

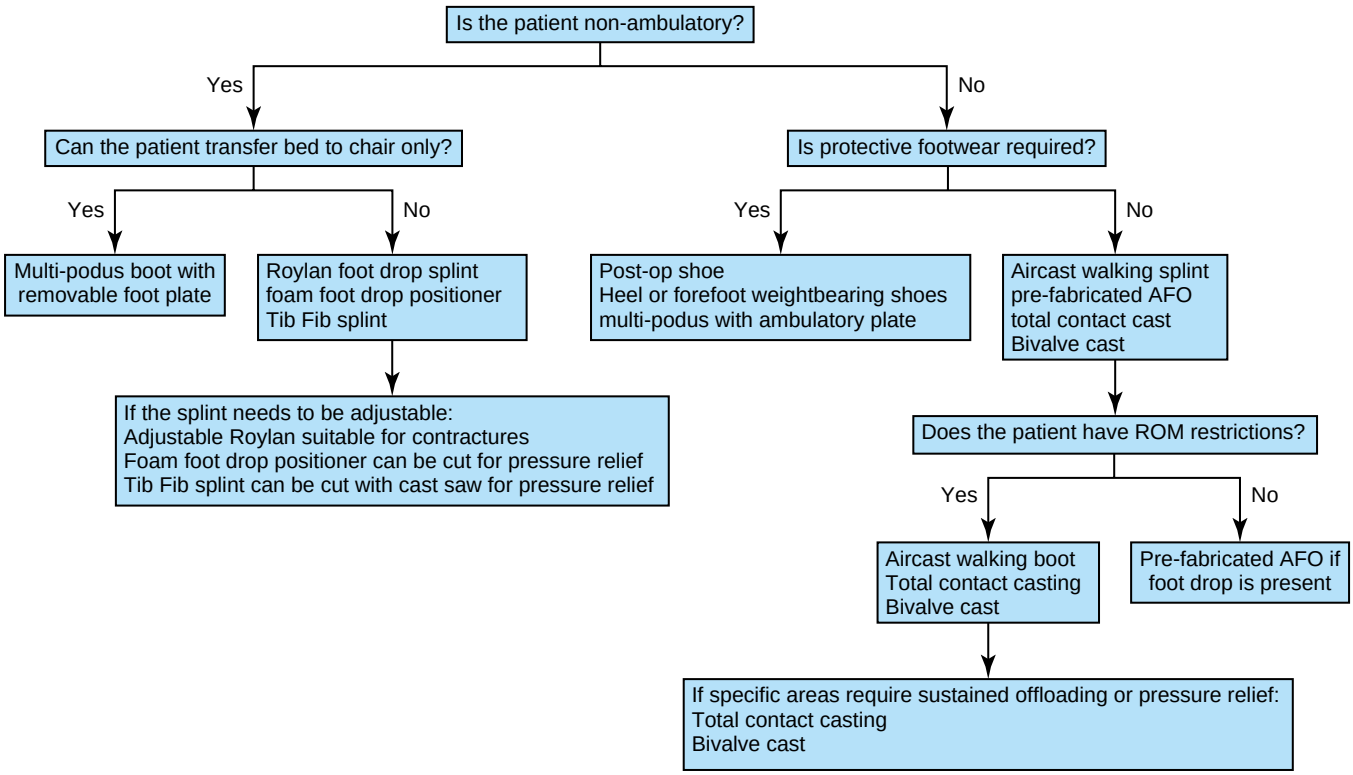

Figure 2-17 This algorithm for choice of splinting demonstrates the elements to consider when using a cast or splint for wound management. (Modified from Brigham and Women's Hospital: Standard of care: wound care/integumentary management. Physical Therapy management of the patient at risk for or with an integumentary disorder. Copyright © 2009 The Brigham and Women's Hospital, Inc., Department of Rehabilitation Services.)

by a nerve block, or in extreme cases, general, spinal, or epidural anesthesia may be required.[62]

As a rule, debridement methods (Table 2-9) may be divided into two distinct categories: selective and nonselective. Selective methods target only the necrotic tissue or debris and are preferred when a substantial proportion of the wound has already entered the proliferative phase, and care must be taken to protect the new granulation tissue and/or epithelial budding. Nonselective methods are used when the majority of the wound bed remains covered by necrotic tissue or debris or very little granulation tissue or new cell growth is present.

Surgical or Sharp Debridement. Surgical or sharp debridement is considered to be the gold standard for removal of necrotic tissue using selective methods. It is most commonly used when patients have increased risk of infection or gross contamination or for quick removal of large quantities of necrotic tissue. In surgical or sharp debridement, necrotic tissue and other foreign material can be removed using scalpels, scissors, and/or forceps. The clinician should use caution if sharp debridement is to be performed on patients on anticoagulant therapy or those with bleeding disorders. In addition, the clinician should be skilled in distinguishing necrotic tissue from underlying normal tissues because there is the risk of inadvertently removing viable tissue, such as a tendon, or other structures that may be mistaken as slough. Therefore clinicians should consider interprofessional consultation to identify the team member who is most skilled in performing this procedure. The choice of whether or not to use sharp debridement methods will also depend on the size and location of the wound, as well as the treatment setting and whether adequate support and resources are available in case of adverse events. Within the United States, physical therapists and other health professionals should consult their state practice acts to be sure this technique falls within their legal scope of practice.

TABLE 2-9

Types of Wound Debridement

Type	Description
Surgical or sharp	Necrotic tissue removed using scalpel, scissors, forceps, or curette
Biological	Maggot larvae: consume necrotic tissue and bacteria
Autolytic	Endogenous enzymes in wound fluid interact with moist dressings to soften and remove tissue
Enzymatic	Enzymes degrade and remove necrotic tissue
Mechanical	Wet-to-dry: moist dressings are allowed to dry on the wound and are then removed Hydrotherapy: flowing water removes loose debris Pulsed lavage: irrigation combined with suction

Biological Debridement. The use of fly larvae (i.e., maggots) to debride nonviable tissue was first introduced following anecdotal observation that maggots will only ingest nonviable tissue, making this a form of selective debridement.[64,65] Although the method remained unpopular due to concerns for safety and potential psychological stresses for the patient, a series of research studies conducted in the early 1990s affirmed that this method is highly effective in promoting debridement and accelerated wound closure. The efficacy of this method relies on three modes of action: debridement of necrotic tissue, removal of microorganisms and pathogens that may contribute to infection, and release of growth factors or cytokines to enhance formation of new tissue. The therapeutic use of maggots for tissue debridement should be distinguished from maggot infestation that sometimes accompanies neglect, poor sanitation, and/or limited access to care. Biological debridement, or biotherapy, is a well-controlled intentional process. Evidence-based information suggests a therapeutic dose of five to eight larvae per square centimeter (0.5 square inch) of wound surface area. Larvae are placed onto a piece of gauze netting, which is inverted over the wound. The wound is surrounded by a halo of hydrocolloid, which prevents migration of the larvae from the wound bed, and covered by a layer of nylon or Dacron netting and adhesive tape to secure its position. A light gauze bandage is then used as a secondary bandage to absorb exudates and liquefied necrotic tissue produced during this process. The maggots remain in place for approximately 48 to 72 hours and can be removed through irrigation or pulsed lavage. Maggots and associated materials should be handled as biological waste. This process may be repeated over several cycles, as indicated, until a clean, granulating wound bed has been achieved.[65] Biological debridement has been successfully employed in several types of chronic wounds, particularly neuropathic (diabetic) foot ulcers and chronic leg ulcers of vascular etiology. Most patients report little, if any, associated physical discomfort, and detailed patient education regarding safety and treatment rationale is usually sufficient to allay psychological concerns.[66,67]

Autolytic Debridement. This selective method of debridement uses the individual's endogenous enzymes to remove the necrotic tissue. This is achieved by placing a moisture-retentive occlusive or semiocclusive dressing over the wound and allowing the proteases within the wound to liquefy the necrotic tissue. In well-perfused wounds, this method is painless and has the benefit of being easy to perform. The patient should be closely monitored for signs of infection, especially patients who are immunocompromised. This method is contraindicated in infected wounds because it may lead to more severe infection. In addition, this method can be somewhat slower than other means of selective debridement

due to the time required for production and action of endogenous enzymes to occur. Therefore autolytic debridement is often used in combination with other methods, such as serial sharp debridement, whirlpool, or pulsed lavage.

Enzymatic Debridement. Use of topical enzymatic agents, such as papain or collagenase, is a popular treatment choice for nonviable or devitalized tissue.[62] Proteolytics, fibrinolytics, and collagenases act on necrotic tissue. However, papain urea debriding breaks down eschar and is the agent of choice in necrotic wounds. Cross-hatching or scoring the wound base allows for deeper penetration of the enzymatic agent. This method does not require a physician present and is relatively safe and effective without being cost prohibitive. Enzymatic debridement is often the selective debridement method of choice for patients who are not candidates for surgical debridement or for patients in long-term facilities and care homes where sharp debridement facilities are not available. Careful choice of dressings and cleaning substances is advised because metals, such as silver, may interfere with the enzymes, deactivating them. In addition, although this method is considered to be selective, repeated or prolonged exposure to enzymatic agents can damage viable tissue. Therefore specific application of topical ointments should be confined to areas of slough or eschar only. Topical antibiotic powder can be applied to the wound to prevent excessive bacterial growth on the liquefied material that can be produced during this method of debridement. In addition, a petroleum-based skin protectant can be used to reduce possible irritation of periwound tissues.

Mechanical Debridement. Mechanical debridement is nonselective because these methods target the entire wound bed as a whole. Mechanical methods can include wet-to-dry dressings, pulsed lavage, and whirlpool therapy.

Wet-to-dry dressings involve the placement of saline-soaked gauze on the wound surface. When the gauze is dry, it is removed, taking away devitalized tissue and debris on the gauze. However, because this method is notoriously painful and has a strong potential to damage viable tissue and underlying granulation tissue, it is rarely indicated and is no longer favored within clinical settings.[68]

Hydrotherapy or whirlpool therapy is one of the oldest therapies still in use in the modern era. Whirlpool therapy is jointly considered a method of wound cleansing as well as mechanical debridement. The agitation of water combined with injected air can remove necrotic tissue and foreign material and may dilute bacterial content. Care must be taken to control the pressure on the wound because excessive pressures or shearing forces may damage granulation tissue, extend the wound margins, or cause maceration.[69] Care must be taken to ensure the water and tank are clean before allowing the patient to receive treatment in the whirlpool tank. Cross-contamination is an issue if multiple patients are using the same tank, and although antibacterial agents in the water may help prevent this, these detergents may damage new tissues. In addition, even when care is taken to disinfect surfaces between patient use, it can be very challenging to properly cleanse and dry the internal mechanisms within the jets and turbines. However, the benefits of whirlpool therapy are numerous and beneficial in the following scenarios:

1. Patients for whom dressing changes are painful. The dressings can be soaked and removed gently by either the patient or the caregiver.
2. The warmth of the water promotes increased blood flow to the wound surface.
3. The resistance and buoyancy of the water can facilitate range-of-motion exercise, strengthening exercises, and functional exercises, such as aqua walking or jogging.

The frequency and duration of whirlpool sessions range from 20 to 30 minutes, 3 to 4 times per week.[69] Temperature of the water will vary and should be adjusted based on the stage of healing (e.g., avoid excessive warmth during the acute inflammatory stage or in the presence of excessive edema). The nature and presentation of the wound should also be considered because the affected limb will be in a dependent position throughout the treatment. For this reason, whirlpool therapy is generally deferred in patients with venous insufficiency, although when needed, parameters can be adjusted to include cooler temperatures and less exposure duration. Furthermore, to prevent infection or an increase in size of the wound, whirlpool therapy or soaking of the wound should be avoided in patients with stable, dry gangrene until restoration of necessary circulation has been achieved.

Pulsed lavage is the direct delivery into the wound of a cleansing solution or irrigant under pressure produced by a single-patient use, battery-powered device (Figure 2-18). This method has overtaken whirlpool treatment in popularity due to its portability, lower cross-contamination risks, and ease of use in patients with poor mobility or those being treated in isolation rooms. Like whirlpool, pulsed lavage is considered a wound cleansing method as well as a nonselective method of mechanical debridement. It is used to remove debris or infectious agents from the wound bed and surface. Pulsed lavage is particularly effective for neuropathic and venous ulcers, abscesses (pus in wound), or dehiscent (splitting open of wound)

Figure 2-18 Pulsed lavage device.

wounds. It is also useful following sharp or surgical debridement to remove the necrotic tissue that remains or develops after surgical debridement. However, it is not effective at removing hard eschar. Patients with widespread wounds or burns may be more effectively treated using whirlpool therapy. Use of the appropriate pressure will be the key determinant in how effective pulsed lavage will be for wound cleansing. Low pressures may be used for cleansing, and higher pressures often used when more of a debriding effect is desired. Pressures of between 5 and 10 psi have been found to be effective at removing loose necrotic tissue, wound exudate, and loose surface debris.[61] Using pressure of greater than 10 psi is more effective at preventing gross wound infection. Use of a splash guard and personal protective equipment for all personnel and any family members or visitors in the immediate vicinity of the treatment areas is necessary to minimize risks associated with splashing of contaminated fluid and bacteria that may be aerosolized during treatment. For these reasons, patients must also be treated in closed quarters. All intravenous sites, ports, and other potential areas for access of bacteria should be covered to prevent cross-contamination during treatment. Sterile saline is the most commonly used irrigant for pulsed lavage, although sometimes sterile water is also used. Most pulsed lavage devices come equipped with suction to collect fluids and materials removed from the wound bed. Such materials should be treated as biohazardous waste and disposed of accordingly.

Low-Intensity Phototherapy

There is an array of terms used to describe the use of light for therapeutic effect, including phototherapy, low-level laser therapy, low-power laser therapy, low-intensity laser therapy, cold laser, therapeutic laser, light-emitting diode, low reactive-level laser, and diode laser.[70] Low-intensity phototherapy has been described as highly effective in the treatment of tissue repair but with stronger evidence coming from experimental animal research than from human studies.[71] There are a small number of studies that have shown that laser therapy can be beneficial in the treatment of diabetic foot ulcers that have been unresponsive to conventional treatment.[72,73] The variables to consider when using low-intensity phototherapy are wavelength, power, power density, energy, energy density, treatment duration, chronicity of the wound, and the mode of treatment. The clinician must also consider elements of patient presentation, including wound size, patient history, presence of co-morbidities, and any concomitant treatment of the wound.[71] Energy density has been found to have a predictable dose-dependent treatment effect.[74] The mechanisms of action of phototherapy include promoting fibroblast proliferation, collagen synthesis, cellular and subcellular processes needed to augment formation of type I and type III procollagen pools of mRNA, ATP synthesis, and lymphocytic action.[71,74] The range of variables that need to be accounted for can make it complicated to compare studies, and there is a need for more well-controlled, blinded studies in clinical populations. There are few contraindications and side effects associated with this intervention, so, despite the controversy surrounding its effectiveness in humans, it remains a popular treatment modality.

Wound Dressings

There are numerous factors to consider when selecting an appropriate dressing for wounds. These factors are summarized in Table 2-10 and include the nature of the wound, level of moisture or hydration of the wound and surrounding tissues, location of the wound, and types of materials available.[75] Determining the main aims of dressing application will also influence the choice of dressings.

Function of Wound Dressings

- Facilitate the healing process by retaining warmth, moisture, cells, enzymes, and growth factors in the wound bed
- Promote autolytic debridement
- Fill dead space to prevent formation of hematomas, abscesses, and sinus tracts
- Manage odor and exudate by drainage, evaporation, or occlusion
- Reduce pain
- Prevent or manage infection
- Improve patient quality of life, achieved by minimizing distress or disturbance, or by hiding or covering wounds

Primary dressings typically refer to the dressing in contact with the wound itself or materials placed directly in the wound bed. Secondary dressings are used to cover and secure the primary dressing. The Center for Medicare and Medicaid Services (CMS) recognizes the categories of dressings listed in the following textbox.[76]

Types of Wound Dressings

- Hydrogel (sheets)
- Biological and synthetic membranes
- Impregnated
- Silicone gel sheets
- Contact layers
- Silver technology
- Elastic gauzes
- Transparent films
- Wound fillers
- Gauzes and nonwoven dressings
- Liquid skin protectants
- Hydrocolloids
- Moisture barriers
- Hydrogels (amorphous)
- Therapeutic moisturizers
- Hydrogels (impregnated dressings)
- Skin substitutes
- Oxygen reconstituted cellulose

From Irion G: *Comprehensive wound management*, ed 2, Thorofare, 2010, SLACK.

TABLE 2-10

Factors Influencing Wound Dressing Selection

Factor	Description
Wound type	• Superficial • Full thickness • Cavity
Wound description	• Necrotic • Sloughy • Granulating • Epithelializing
Wound characteristics	• Dry • Moist • Excessive exudate • Malodorous • Painful • Bleeds easily • Location
Bacterial profile	• Sterile • Colonized • Infected • Risk of serious cross-infection
Product-related factors	• Conformity and volume • Fluid-handling properties • Potential for sensitization • Ability to absorb odor • Antibacterial properties • Hemostatic properties • Permeability to fluid and microorganisms • Ease of use • Fiber-fast • Nontoxic
Patient-related factors	• Wound etiology • Continence • Sensitivity to medicated dressings • Fragile skin • Need to bathe or shower regularly • Compliance
Economic considerations	• Unit and treatment cost • Cost of alternative materials • Prescription required • Availability in stores or pharmacies • Availability in local formularies

Modified from Thomas S: *A structured approach to the selection of dressings*, World Wide Wounds, 1997. Available at: http://www.worldwidewounds.com/1997/july/Thomas-Guide/Dress-Select.html. Accessed April 28, 2015.

Transparent Film Dressings

Transparent films can be used as primary or secondary dressings. They are clear polyurethane membranes with a semipermeable adhesive surface. These dressings will accumulate liquid and exudate underneath because they have no absorption properties and can therefore be used to enhance autolytic debridement in noninfected wounds. However, if used with wounds having excessive exudate, there is a risk of leakage and maceration of the periwound tissue. The impermeable nature of the film means they protect the wound from contamination, and the transparency allows the patient, clinician, and caregivers to monitor the wound without disturbing the dressing. Films may also be used as a secondary dressing to hold wound fillers or primary dressings in place and are often used in conjunction with gauze and alginates (a salt or ester of alginic acid).

Hydrogels

Hydrogels are hydrative dressings that add moisture to a wound and may be indicated when wounds are dry (i.e., desiccated) or may be used to provide a soothing effect on burns and superficial abrasions.[76] Hydrogels are manufactured as sheets or amorphous material. The sheet form of hydrogels can be used on partial-thickness and full-thickness wounds, and due to the high moisture content, they are easily removed without causing additional trauma to the wound. Hydrogel sheets usually require a secondary dressing to hold them in place. Amorphous (lacking definite form) hydrogels come in a tube and can be applied using a cotton swab to hydrate dry wounds, loosen slough, and protect structures, such as tendons, nerves, and ligaments, from desiccation. The use of sheet hydrogels is discouraged in infected wounds, but amorphous hydrogels may instead be used, usually in combination with a carrier material, such as gauze or another secondary dressing.

Hydrocolloid Dressings

These dressings are moisture-retentive dressings made of pectin, carboxymethylcellulose, and adhesives. When the wound side of the dressings interacts with exudate or wound fluid, a gel is formed, leading to a moist environment.[77] The dressing in contact with the periwound skin will remain adhesive until the exudate soaks through and migrates toward the edges of the dressing. Often a layer of skin protectant will be applied to periwound skin to prevent rolling of the edges of the sheet and minimize skin injury during removal of the dressing. These dressings are worn for several days and on application allow for limited wound visualization. Hydrocolloid dressings are semiocclusive in nature, so they are not suitable for use in contaminated or infected wounds. These dressings are also not advised in wounds with subcutaneous defects, such as tracts or tunnels, unless used as a secondary dressing in combination with wound fillers, such as gauze roping, alginate, or hydrofiber.

Alginates and Hydrofibers

Alginates are a very versatile and absorbent dressing. They are made of nonwoven fibers derived from seaweed, composed of calcium salts of alginic acid, and typically absorb at higher rates than hydrocolloids. When they are

dry, alginates have a feltlike fibrous consistency, but when they absorb fluid, they turn into a gel. This gel conforms to the wound bed, maintaining a moist environment. Alginates can be combined with collagen, which promote wound healing as the combination is absorbed into the wound. Hydrofiber dressings are composed of sodium carboxymethylcellulose fibers, which have the ability to absorb large amounts of wound exudate. Alginates and hydrofiber dressings should not be used on dry dressings, hard eschar, or third-degree burns. They should also not be used in full-thickness wounds when tendon, nerve, or periosteum has been exposed. Removal of an alginate or hydrofiber dressing from a wound that has turned dry will have a similar effect to a wet-to-dry dressing, which can be painful to remove and cause trauma to the wound bed. Instead, the dressing should be moistened with saline before removal to prevent discomfort and associated tissue injury.

Foam Dressings

Foam dressings are typically made from a polyurethane base with a heat- and pressure-modified wound contact layer. They are highly absorbent, promote autolytic debridement, and are permeable to gases and water vapors. Foam dressings are used to provide a moist wound environment, most commonly in wounds with moderate-to-heavy exudate. They are very adaptable dressings and provide a cushioning effect, making them suitable for bony prominences or areas of increased friction. Not all foam dressings have adhesive edges, so they may need a secondary dressing to secure them in place. Foam dressings may be used in combination with enzymatic debriders and other agents, and newer-generation foams are available with ionic silver, a wide-spectrum antimicrobial. If changed daily, they can be used in the treatment of infected wounds, but the clinician should check the package insert before use.

Silver Technology

Silver has long been used in the management and treatment of wounds arising from burns, but the development of silver-containing dressings has led to a new interest in its use for wound management. It is the antimicrobial properties of silver that make it popular for use in nonhealing wounds. There are now ranges of proprietary silver dressings, which incorporate the metal into an alignate or hydrocolloid base, as well as fabric-based, silver-impregnated dressings.[78] It is thought that silver dressings provide immediate and sustained release of ionic silver and act as an effective barrier to bacterial penetration. In addition, silver ions are thought to interact with the cell membranes of bacteria, causing leakage, and apoptosis (i.e., cell death without release of harmful substances). Binding of the silver ions with proteins within the bacteria reduces the bacteria's ability to produce enzymes needed for replication.[79] For these reasons, silver dressings are often used in infected or highly colonized wounds and have proven effective in exerting antimicrobial effects in a variety of gram-positive and gram-negative pathogens, including methicillin-resistant staphylococcus aureus (MRSA), pseudomonas aeruginosa, and proteus.[80] Some reports have suggested that combining silver with suitable dressings may decrease some of the unwanted side effects, such as toxicity and staining, while increasing their antimicrobial efficacy.[81] Gradual, sustained release is thought to counteract some previous concerns associated with the use of silver, including studies that questioned whether silver might be cytotoxic to keratinocytes and fibroblasts.[82] In addition, due to concerns regarding the development of silver-resistant strains of bacteria, this intervention should be reserved for use in wounds showing overt signs of infection and should not be indiscriminately applied prophylactically unless there is evidence to suggest a high risk of contamination. In any case the use of silver should be reviewed at a 2-week minimum to ensure that effective progress is being made toward goals for appropriate wound management.

Honey Dressings

Honey has been used in the treatment of wounds for many years. Those typically used in the treatment of wounds are medical-grade honeys (MGHs) and are chosen for their bactericidal properties. *Leptospermum* honeys are the most widely studied, but local-regional honeys have also been reported in the literature. This presents a unique challenge in identifying which properties of honey are universal and those that are unique.[83] Honey has been used in the treatment of traumatic wounds, surgical incision sites, burns, sloughy wounds, and pressure ulcers.[84] It is also used for topical treatment of infected wounds or as a prophylactic treatment in patients susceptible to MRSA and other antibiotic-resistant bacteria.[85] Honey has been found to improve healing times in mild-to-moderate superficial and partial-thickness burns compared with conventional dressings; however, there is a conflicting report on its efficacy on other wound types.[86] The mechanisms of action of honey in promoting wound healing are summarized in Table 2-11.[87] The following practical considerations for the use of honey were described in a review by Molan.[85] The amount of fluid exudate will determine the amount of honey to be used. If the exudate is rapidly diluting the honey, then the frequency of application will need to be adjusted. It is preferable to apply the honey to an absorbent dressing rather than directly to the wound to prevent loss of honey from the wound before the dressing is applied. It may also be necessary to warm the honey to body temperature or to dilute it with 1 part water to 20 parts honey to facilitate soaking into the absorbent dressing. Depressions or cavities of wounds can be filled with honey to take advantage of the antibacterial components diffusing into the deeper

TABLE 2-11

Beneficial Effects of Medical-Grade Honey on Wound Healing

Effects	Description
Antibacterial activity	• Broad spectrum of activity, including antifungal • Effective against antibiotic resistant species • Effective against bacteria in biofilms
Debriding action	• Activates plasminogen which lyses fibrin-attaching slough • Prevents formation of eschar and scabs
Anti-inflammatory activity	• Clinical observation of reduced symptoms of inflammation • Biochemical and histological studies show decreased inflammation • Inhibits phagocytosis, the start of the inflammatory response
Antioxidant activity	• Contains plant phenolics from the nectar source • Scavenges reactive oxygen species • Decreases oxidative activation of proteases which destroy the matrix and growth factors
Increasing healing rate	• Stimulates leukocytes to release cytokines and growth factors that activate tissue repair • Acidity of honey allows for increased oxygen availability from the circulation for tissue repair • Osmotic action leads to outflow of lymph fluid

Modified from Molan P: The evidence and the rationale for the use of honey as a wound dressing, *Wound Pract Res* 19(4):215, 2011.

wound tissues. For practical purposes, treatment is usually applied using commercially available dressings consisting of pads that are preimpregnated with MGH. It is important to remember that honey designed for medical use differs significantly from culinary honeys. Most culinary honeys are heat pasteurized, a process that destroys the natural enzymes that contribute to its antimicrobial properties, making them less effective when used in the treatment of wounds.

Scar Management

Scar tissue is the end product of wound healing. It serves to restore tissue continuity, along with some tensile strength, and tissue function. However, scar tissue lacks the strength and elasticity of normal skin. Scar tissue also lacks some functions of normal skin, including melanization, sweating, and oil secretion. Scar tissue does not have hair follicles and the pigmentation differs from that of normal skin. If there has been a period of immobilization during the healing phases, the presence of scar tissue can increase risk of adhesions to subcutaneous structures, which may cause pain, and loss of range of motion. During the healing phases, controlling unwanted stresses and increasing stresses that produce a better quality scar should be considered when selecting splints or positioning patients.

Topical interventions, such as pressure garments, are often used as part of scar management, notably in burn patients.

Considerations when Choosing Pressure Garments or Devices for Scar Management[88]

- Healing time
- Size of the scar area
- Fragility of the healed skin
- Location of the scar

Scar mobilization can be used to increase range of movement around a joint that has been limited due to scar tissue. There is a three-point scale that can be used to describe the extent to which mobility is limited due to scar tissue.[76] A score of 3/3 indicates normal mobility that is the same as normal skin, 2/3 indicates mild hypomobility, and 1/3 indicates moderate hypomobility. When using this scale, the clinician should assess range of motion in all planes of movement that would normally be available at that joint.

Many patients require some desensitization before scar mobilization. Desensitization can include gentle tapping, massage, or rubbing the scar with different textures, such as soft clothes and coarser textures. To gain a prolonged increase in range, scar mobilization should be performed regularly for a number of sessions before significant improvement is observed. The scar tissue should be pushed and pulled in all directions in a slow and sustained manner. Skin blanching indicates the beginning of relevant stretching of the scar tissue. Other techniques, such as plucking and rolling, can be used by the clinician to mobilize adherent scar tissue. It should be noted that patients are less likely to be as aggressive as a clinician in their own self-mobilization techniques due to the discomfort the techniques can cause. The patient should be educated on how to perform stretches correctly, and if appropriate, a home exercise program of stretching exercises should be given to the patient. Gravity and assistive devices, such as pulleys and traction devices, may also be of help.

ADJUNCTIVE INTERVENTIONS IN WOUND MANAGEMENT

Therapeutic Ultrasound

Ultrasound uses sound waves, which are transferred into a tissue through a hydrated medium, such as a gel or

mist, through a treatment applicator. The depth of tissue reached by the ultrasound is dependent on the frequency. Typical therapeutic ultrasound frequencies used in wound management include frequencies of 1 and 3 MHz and noncontact low-frequency ultrasound (40 kHz). Because the frequency of the ultrasound device determines the depth of penetration, the approximate depth of penetration for a 3 to 3.3-MHz ultrasound is estimated at 0.5 to 1 cm beneath the surface of the skin, whereas a 1-MHz ultrasound is thought to penetrate 0.5 to 5 cm beneath the surface of the skin.[89] The benefits of therapeutic ultrasound can be classified into thermal or nonthermal effects. Thermal effects are achieved at intensities of 1.0 to 1.5 W/cm^2 and can improve scar or wound outcomes when used in the late stages of wound healing or during the remodeling phase. However, the frequencies at which therapeutic ultrasound is used by clinicians when treating open wounds tend to draw on the nonthermal effects. These effects are typically gained at intensities of 0.3 to 1.0 W/cm^2. The nonthermal effects include acoustic streaming, which is a unidirectional steady mechanical force, and cavitation. Cavitation is the production and vibration of small bubbles within the coupling medium and fluids within the tissues. The bubbles collect, condense, and are compressed. The movement and compression may lead to changes in cellular activities in the tissue. Both cavitation and acoustic streaming are thought to cause changes in cell membrane permeability and diffusion of cellular metabolites. Basic science and laboratory proof of the following effects of ultrasound have been reported in the literature.[69]

Beneficial Effects of Therapeutic Ultrasound on Wound Healing[69]

- Cellular recruitment
- Collagen synthesis
- Increased collagen tensile strength
- Angiogenesis
- Wound contraction
- Fibroblast stimulation
- Macrophage stimulation
- Fibrinolysis
- Reduction in inflammatory phase
- Promotion of proliferative phase

Research regarding the use of therapeutic, high-frequency ultrasound in wound management is sparse, and further studies using better methodology are required to reach a definitive decision on the effect of therapeutic ultrasound. When reviewing the use of therapeutic ultrasound for the treatment of venous leg ulcers, the Cochrane group reported that there was some available evidence suggesting accelerated wound closure with use of this modality.[90] A similar review of the use of therapeutic ultrasound for treatment of pressure ulcers failed to find any substantial evidence of benefit.[91]

In terms of clinical evidence of the benefits of therapeutic ultrasound, there have been some studies that use noncontact ultrasound therapy, in which low-frequency ultrasound (40 kHz) is delivered through a fine, sterile saline mist, which transmitted the ultrasound energy (also known as "MIST therapy"). These studies were using ultrasound to achieve wound healing via wound cleansing and removal of the yellow slough, fibrin, tissue exudates, and bacteria.[92] It is suggested that therapeutic ultrasound used in this way is indicated until slough is removed and healthy granulation tissue covers the wound bed. Other effects of this modality may include an increase in the synthesis and release of growth factors, improved blood flow, accelerated angiogenesis, and better collagen content and alignment during the proliferative phases of healing. MIST therapy has been shown to be effective in promoting accelerated rates of wound closure for a variety of chronic wounds, including diabetic foot ulcers and vascular ulcers.[93,94]

Electrical Stimulation

Electrical stimulation is the application of electrical current through electrodes placed on the skin near the wound or directly within the wound. It allows clinicians to deliver exogenous electrical signals into wound tissue, which mimics the underlying natural bioelectrical response to injury. It has been found that within 1 mm of the wound edge, there is a natural steady electrical field that can be manipulated through therapeutic electrical stimulation to accelerate the wound-healing process.[95] The resulting electrical fields can cause the stimulation of biomolecular signaling pathways and cell migration.[69] Electrical stimulation has been found to promote cellular activity in nearly all phases of experimental wound healing.[96] The effects of electrical stimulation are summarized in Table 2-12.

Current research focuses in the area of electrical stimulation are to develop new technologies, including dressings with embedded batteries, which will make the electrical stimulation devices more tractable for clinical uses, and the design of devices for use in the community, which may be a more cost-effective therapy than current standard therapies.

Compression Therapy

Compression therapy has long been a mainstay of treatment for vascular management and treatment of wounds arising from venous insufficiency. Benefits of compression therapy include edema management and improved venous return. However, many patients cannot tolerate the stockings and compression bandages that are commonly used. External pneumatic pressure therapy or intermittent compression therapy (ICT) can yield similar effects to compression bandages and stockings. ICT

TABLE 2-12

Effects of Electrical Stimulation on Wound Healing[69,96]

Negative Current	Positive Current	Both
• Decreases edema surrounding the electrode • Lyses necrotic tissue • Simulates growth of granulation tissue • Increases blood flow • Causes fibroblasts to proliferate and produce collagen • Causes epidermal cell migration • Attracts neutrophils • Stimulates directional growth of neurites	• Promotes epithelial growth and organization • Acts as a vasoconstrictor • Denatures protein • Aids in preventing postischemic lipid perioxidization • Decreases mast cells in healing wounds • Attracts macrophages	• Stimulate neovasculature • Have a bacteriostatic effect • Stimulate receptor sites for specific growth factors

uses an air pump to inflate and deflate an airtight bag wrapped around the limb, causing intermittent compression of the limb. ICT can cause a collapse of the superficial venous system, forcing blood into the deep venous system with an increase in subcutaneous pressure. This can prevent blood, fibrins, and protein from leaking out of the skin capillaries. Some studies have proposed that enhancement of fibrinolysis is yielded through ICT.[97] A Cochrane review summarized that ICT might increase healing compared with no compression and when used in conjunction with compression bandages. However, more studies are required to determine if ICT can be a substitute for compression bandages. Rates of application of external pneumatic pressure can vary. The ICT bags can be rapidly inflated and deflated. One study compared a rapid inflation protocol with a slow inflation protocol (0.5 seconds to inflate, 6-second plateau, 12-second deflation versus 60-second inflation, 30-second plateau, 90-second deflation) and reported that rapid ICT healed more venous leg ulcers than slow ICT.[98] The use of ICT is contraindicated in patients with deep vein thrombosis and peripheral vascular disease. Patients with congestive heart failure should be very closely monitored if an ICT protocol is used in their treatment plan.

Negative Pressure Wound Therapy (NPWT)

NPWT is also known as topical NPWT, vacuum-sealing technique, sealed surface wound suction, vacuum-assisted closure, or vacuum pack technique. It involves the application of subatmospheric pressure to a healing wound. A porous dressing will allow for an even distribution of pressure throughout the wound. This dressing is placed in direct contact with the wound with a drain attached to the vacuum device. A polyurethane covering should extend approximately 2 cm beyond the wound edges to provide an airtight seal. There are ongoing discussions regarding the intensity, intermittent or constant pressure, and the filler material to cover the wound.[99] Negative pressures of -50 to -150 mm Hg have been reported in the literature.[99,100]

Treatment Goals for the Application of Negative Pressure Wound Therapy (NPWT)[101]

- Provide a temporary wound cover
- Manage wound fluid and edema
- Accelerate patient mobility
- Improve pain management
- Prevent wound progression
- Increase dermal and wound perfusion
- Stimulate formation of granulation tissue
- Enhance wound bed reepithelialization
- Improve matrix material availability
- Reduce bacterial load
- Provide a moist wound environment that is preferable for wound healing
- Influence expression of genes involved in the wound-healing process, such as growth factors, TGF-β expression, and genes that elicit angiogenesis and cellular proliferation

NPWT is often used in the treatment of acute wounds in which healing by primary intention is unlikely or not possible. This includes grossly contaminated wounds and complex soft tissue injuries. NPWT is also used to treat chronic wounds, such as pressure ulcers, trophic, and vascular ulcers. The absence of well-designed studies makes it challenging to draw reliable conclusions regarding the efficacy of NPWT in the treatment of chronic wounds.[100] However, single studies have suggested that NPWT can lead to accelerated closure of diabetic foot ulcers when compared with current standards of care using moist wound-healing principles.[102,103] NPWT is contraindicated in wounds with exposed viscera, intestinal fistulas, in the presence of invasive soft tissue infection, wound necrosis, or active bleeding. Clinicians should be aware that NPWT can cause pain, pressure necrosis around the wound edges, hemorrhage, and infection when the patient is not properly monitored and treatment is not properly adjusted in light of these adverse responses.[69,101]

Hyperbaric Oxygen Therapy

Hyperbaric oxygen treatment has been used in the treatment of a myriad of medical conditions since the 1960s. It involves the patient breathing 100% oxygen while being exposed to increased atmospheric pressure. The

pressures in the chamber are typically 2 to 3 atmospheres absolute (ATA), and treatments can last 1 to 2 hours, 2 to 3 times daily depending on the reason for choosing this modality. A typical course may last 15 to 30 days.[104] Arterial oxygen tension can exceed 2000 mm Hg, and the pressure in tissues can reach 200 to 400 mm Hg during treatment.[105] It has been well established that breathing more than 1 ATA of oxygen will result in increased production of reactive oxygen species. This provides the molecular basis for the therapeutic benefits of this therapy through stimulation of pathways for growth factors, cytokines, and hormones. Wounds that should respond well to hyperbaric oxygen therapy include those with depletion of epithelial and stromal cells, chronic inflammation, fibrosis, and abnormalities in the components of the extracellular matrix and those with impaired keratinocyte function.[105] These characteristics are often seen in diabetic lower extremity wounds and delayed radiation injuries. However, it must be noted that reactive oxygen species can also cause detrimental effects on wound healing through damage to DNA and oxidation of lipids, amino acids, and enzymatic cofactors, leading to defective cellular functioning.[106] There is a lack of high-quality research reporting on the clinical benefits of hyperbaric oxygen therapy, with many of the studies demonstrating flaws in the study design and reporting. Therefore there is a need for further adequately powered research into the therapeutic and clinical benefits of hyperbaric oxygen therapy in acute and chronic wound healing.

TABLE 2-13

Types of Exercise Used in the Management of Patients with Wounds[107]

Type	Description
Therapeutic exercise	• Passive, active assisted, or active range of movement exercises in supine, sitting, or standing • Used for bilateral upper and lower extremities • Progression of intensity, duration, and frequency
Endurance training	• Increase out of bed tolerance • Progress time, distance, and frequency of ambulation • Develop an activity schedule with the patient, family, and caregivers
Gait training	• Preparation for gait • Education on weight-bearing restrictions and training of partial weight-bearing gait techniques • Gait retraining for patients with gait asymmetries • Assessment and prescription of assistive devices
Functional mobility	• Bed mobility • Transfers • Ambulation • Stair practice

Therapeutic Exercise

Therapeutic exercise can provide many benefits to patients with acute or chronic wounds. Exercise including gentle active or passive range of movement exercises can assist in edema management, increased perfusion, prevention of contractures, maintenance of mobility, and improved endurance (Table 2-13). It is thought that physical exercise may enhance cutaneous blood flow and accelerate angiogenesis due to its positive influence on production of vasoendothelial growth factor (VEGF).[108]

There are a very small number of studies that examine the effects of exercise on cutaneous wound healing. One such study[109] examined the effects of an exercise program on wound healing following a low-risk punch biopsy procedure in a group of older adults. This study found that the study participants assigned to the exercise group had a faster healing rate and increased cortisol secretion during stress testing following the intervention when compared with the participants assigned to the control group. The authors postulated that because exercise was associated with an enhanced neuroendocrine response, exercise might facilitate wound healing through neuroendocrine regulation and thus immune function changes. Another study,[110] which investigated the effects of exercise on subcutaneous wound healing in older mice, found that moderate exercise elicited an improved healing response. This might be attributed to decreased levels of proinflammatory cytokines and chemokines found in the wound tissue. There is a need for further investigation on the effects of exercise on wound healing, but the research available to date would indicate that exercise can lead to improved wound healing due to the exercise-induced anti-inflammatory response.

SUMMARY

The objective of successful wound management is to achieve a clean wound bed, protect the wound bed, prevent and eliminate infection, and provide an optimal wound-healing environment. As the chapter shows, there are numerous tools available to assist in objectively monitoring a patient with an acute or chronic wound. These tools will assist in identifying signs of infection and documenting efficacy of treatment techniques and wound-healing progression. Using these tools will also allow the clinician to determine which treatment techniques are most suitable. Pressure management, dressing selection, and use of adjunctive therapies must be considered for patients at risk of integumentary disruption or for patients presenting with an acute or chronic wound.

APPENDIX 2-1

Pressure Ulcer Scale for Healing (PUSH) Tool 3.0
(Copyright National Pressure Ulcer Advisory Panel (NPUAP), 2003 Reprinted with permission.)

Instructions for Using the Pressure Ulcer Scale for Healing (PUSH) Tool

To use the PUSH Tool, the pressure ulcer is assessed and scored on the three elements in the tool:
Length × Width –> scored from 0 to 10

Exudate Amount —> scored from 0 (none) to 3 (heavy)

Tissue Type —> scored from 0 (closed) to 4 (necrotic tissue)

In order to insure consistency in applying the tool to monitor wound healing, definitions for each element are supplied at the bottom of the tool.

Step 1: Using the definition for length × width, a centimeter ruler measurement is made of the greatest head to toe diameter. A second measurement is made of the greatest width (left to right). Multiple these two measurements to get square centimeters and then select the corresponding category for size on the scale and record the score.

Step 2: Estimate the amount of exudate after removal of the dressing and before applying any topical agents. Select the corresponding category for amount and record the score.

Step 3: Identify the type of tissue. Note: if there is ANY necrotic tissue, it is scored a 4. Or, if there is ANY slough, it is scored a 3, even though most of the wound is covered with granulation tissue.

Step 4: Sum the scores on the three element of the tool to derive a total PUSH Score.

Step 5: Transfer the total score to the Pressure Ulcer Healing Graph. Changes in the score over time provide an indication of the changing status of the ulcer. If the score goes down, the wond is healing. If it gets larger, the wound is deteriorating.

NATIONAL PRESSURE ULCER ADVISORY PANEL

Pressure Ulcer Scale for Healing (PUSH)
PUSH Tool 3.0

Patient Name_____ Patient ID# _____

Ulcer Location _____ Date _____

Directions:

Observe and measure the pressure ulcer. Categorize the ulcer with respect to surface area, exudate, and type of wound tissue. Record a sub-score for each of these ulcer characteristics. Add the sub-scores to obtain the total score. A comparison of total scores measured over time provides an indication of the improvement or deterioration in pressure ulcer healing.

LENGTH X WIDTH (in cm^2)	**0** 0	**1** < 0.3	**2** 0.3 – 0.6	**3** 0.7 – 1.0	**4** 1.1 – 2.0	**5** 2.1 – 3.0	**Sub-score**
		6 3.1 – 4.0	**7** 4.1 – 8.0	**8** 8.1 – 12.0	**9** 12.1 – 24.0	**10** > 24.0	
EXUDATE AMOUNT	**0** None	**1** Light	**2** Moderate	**3** Heavy			**Sub-score**
TISSUE TYPE	**0** Closed	**1** Epithelial Tissue	**2** Granulation Tissue	**3** Slough	**4** Necrotic Tissue		**Sub-score**
							TOTAL SCORE

Length x Width: Measure the greatest length (head to toe) and the greatest width (side to side) using a centimeter ruler. Multiply these two measurements (length x width) to obtain an estimate of surface area in square centimeters (cm^2). Caveat: Do not guess! Always use a centimeter ruler and always use the same method each time the ulcer is measured.

Exudate Amount: Estimate the amount of exudate (drainage) present after removal of the dressing and before applying any topical agent to the ulcer. Estimate the exudate (drainage) as none, light, moderate, or heavy.

Tissue Type: This refers to the types of tissue that are present in the wound (ulcer) bed. Score as a "4" if there is any necrotic tissue present. Score as a "3" if there is any amount of slough present and necrotic tissue is absent. Score as a "2" if the wound is clean and contains granulation tissue. A superficial wound that is reepithelializing is scored as a "1". When the wound is closed, score as a "0".

- **4 – Necrotic Tissue (Eschar):** black, brown, or tan tissue that adheres firmly to the wound bed or ulcer edges and may be either firmer or softer than surrounding skin.
- **3 – Slough:** yellow or white tissue that adheres to the ulcer bed in strings or thick clumps, or is mucinous.
- **2 – Granulation Tissue:** pink or beefy red tissue with a shiny, moist, granular appearance.
- **1 – Epithelial Tissue:** for superficial ulcers, new pink or shiny tissue (skin) that grows in from the edges or as islands on the ulcer surface.
- **0 – Closed/Resurfaced:** the wound is completely covered with epithelium (new skin).

BATES-JENSEN WOUND ASSESSMENT TOOL

Instructions for use

General Guidelines:

Fill out the attached rating sheet to assess a wound's status after reading the definitions and methods of assessment described below. Evaluate once a week and whenever a change occurs in the wound. Rate according to each item by picking the response that best describes the wound and entering that score in the item score column for the appropriate date. When you have rated the wound on all items, determine the total score by adding together the 13-item scores. The HIGHER the total score, the more severe the wound status. Plot total score on the Wound Status Continuum to determine progress.

Specific Instructions:

1. **Size**: Use ruler to measure the longest and widest aspect of the wound surface in centimeters; multiply length x width.

2. **Depth**: Pick the depth, thickness, most appropriate to the wound using these additional descriptions:
   - 1 = tissues damaged but no break in skin surface.
   - 2 = superficial, abrasion, blister or shallow crater. Even with, &/or elevated above skin surface (e.g., hyperplasia).
   - 3 = deep crater with or without undermining of adjacent tissue.
   - 4 = visualization of tissue layers not possible due to necrosis.
   - 5 = supporting structures include tendon, joint capsule.

3. **Edges**: Use this guide:

Indistinct, diffuse	=	unable to clearly distinguish wound outline.
Attached	=	even or flush with wound base, no sides or walls present; flat.
Not attached	=	sides or walls are present; floor or base of wound is deeper than edge.
Rolled under, thickened	=	soft to firm and flexible to touch.
Hyperkeratosis	=	callous-like tissue formation around wound & at edges.
Fibrotic, scarred	=	hard, rigid to touch.

4. **Undermining**: Assess by inserting a cotton tipped applicator under the wound edge; advance it as far as it will go without using undue force; raise the tip of the applicator so it may be seen or felt on the surface of the skin; mark the surface with a pen; measure the distance from the mark on the skin to the edge of the wound. Continue process around the wound. Then use a transparent metric measuring guide with concentric circles divided into 4 (25%) pie-shaped quadrants to help determine percent of wound involved.

5. **Necrotic Tissue Type**: Pick the type of necrotic tissue that is predominant in the wound according to color, consistency and adherence using this guide:

White/gray non-viable tissue	=	may appear prior to wound opening; skin surface is white or gray.
Non-adherent, yellow slough	=	thin, mucinous substance; scattered throughout wound bed; easily separated from wound tissue.
Loosely adherent, yellow slough	=	thick, stringy, clumps of debris; attached to wound tissue.
Adherent, soft, black eschar	=	soggy tissue; strongly attached to tissue in center or base of wound.
Firmly adherent, hard/black eschar	=	firm, crusty tissue; strongly attached to wound base and edges (like a hard scab).

© 2001Barbara Bates-Jensen

6. **Necrotic Tissue Amount**: Use a transparent metric measuring guide with concentric circles divided into 4 (25%) pie-shaped quadrants to help determine percent of wound involved.

7. **Exudate Type**: Some dressings interact with wound drainage to produce a gel or trap liquid. Before assessing exudate type, gently cleanse wound with normal saline or water. Pick the exudate type that is predominant in the wound according to color and consistency, using this guide:

Bloody	=	thin, bright red
Serosanguineous	=	thin, watery pale red to pink
Serous	=	thin, watery, clear
Purulent	=	thin or thick, opaque tan to yellow
Foul purulent	=	thick, opaque yellow to green with offensive odor

8. **Exudate Amount**: Use a transparent metric measuring guide with concentric circles divided into 4 (25%) pie-shaped quadrants to determine percent of dressing involved with exudate. Use this guide:

None	=	wound tissues dry.
Scant	=	wound tissues moist; no measurable exudate.
Small	=	wound tissues wet; moisture evenly distributed in wound; drainage involves $\leq$ 25% dressing.
Moderate	=	wound tissues saturated; drainage may or may not be evenly distributed in wound; drainage involves > 25% to $\leq$ 75% dressing.
Large	=	wound tissues bathed in fluid; drainage freely expressed; may or may not be evenly distributed in wound; drainage involves > 75% of dressing.

9. **Skin Color Surrounding Wound**: Assess tissues within 4cm of wound edge. Dark-skinned persons show the colors "bright red" and "dark red" as a deepening of normal ethnic skin color or a purple hue. As healing occurs in dark-skinned persons, the new skin is pink and may never darken.

10. **Peripheral Tissue Edema & Induration**: Assess tissues within 4cm of wound edge. Non-pitting edema appears as skin that is shiny and taut. Identify pitting edema by firmly pressing a finger down into the tissues and waiting for 5 seconds, on release of pressure, tissues fail to resume previous position and an indentation appears. Induration is abnormal firmness of tissues with margins. Assess by gently pinching the tissues. Induration results in an inability to pinch the tissues. Use a transparent metric measuring guide to determine how far edema or induration extends beyond wound.

11. **Granulation Tissue**: Granulation tissue is the growth of small blood vessels and connective tissue to fill in full thickness wounds. Tissue is healthy when bright, beefy red, shiny and granular with a velvety appearance. Poor vascular supply appears as pale pink or blanched to dull, dusky red color.

12. **Epithelialization**: Epithelialization is the process of epidermal resurfacing and appears as pink or red skin. In partial thickness wounds it can occur throughout the wound bed as well as from the wound edges. In full thickness wounds it occurs from the edges only. Use a transparent metric measuring guide with concentric circles divided into 4 (25%) pie-shaped quadrants to help determine percent of wound involved and to measure the distance the epithelial tissue extends into the wound.

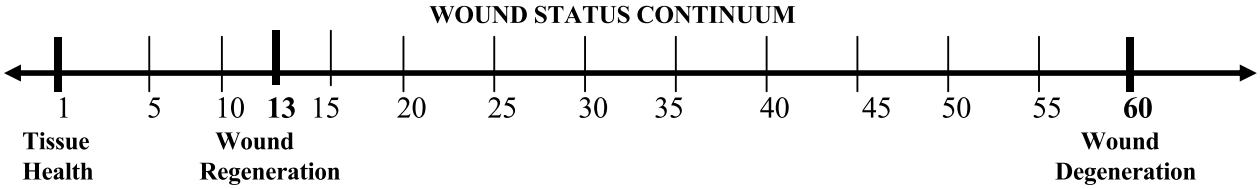
BATES-JENSEN WOUND ASSESSMENT TOOL NAME

Complete the rating sheet to assess wound status. Evaluate each item by picking the response that best describes the wound and entering the score in the item score column for the appropriate date.

Location: Anatomic site. Circle, identify right **(R)** or left **(L)** and use **"X"** to mark site on body diagrams:

____ Sacrum & coccyx ____ Lateral ankle
____ Trochanter ____ Medial ankle
____ Ischial tuberosity ____ Heel Other Site



Shape: Overall wound pattern; assess by observing perimeter and depth.

Circle and date appropriate description:

____ Irregular ____ Linear or elongated
____ Round/oval ____ Bowl/boat
____ Square/rectangle ____ Butterfly Other Shape

Item	Assessment	Date Score	Date Score	Date Score
1. Size	1 = Length x width <4 sq cm 2 = Length x width 4--<16 sq cm 3 = Length x width 16.1--<36 sq cm 4 = Length x width 36.1--<80 sq cm 5 = Length x width >80 sq cm			
2. Depth	1 = Non-blanchable erythema on intact skin 2 = Partial thickness skin loss involving epidermis &/or dermis 3 = Full thickness skin loss involving damage or necrosis of subcutaneous tissue; may extend down to but not through underlying fascia; &/or mixed partial & full thickness &/or tissue layers obscured by granulation tissue 4 = Obscured by necrosis 5 = Full thickness skin loss with extensive destruction, tissue necrosis or damage to muscle, bone or supporting structures			
3. Edges	1 = Indistinct, diffuse, none clearly visible 2 = Distinct, outline clearly visible, attached, even with wound base 3 = Well-defined, not attached to wound base 4 = Well-defined, not attached to base, rolled under, thickened 5 = Well-defined, fibrotic, scarred or hyperkeratotic			
4. Under-mining	1 = None present 2 =Undermining < 2 cm in any area 3 = Undermining 2-4 cm involving < 50% wound margins 4 = Undermining 2-4 cm involving > 50% wound margins 5 = Undermining > 4 cm or Tunneling in any area			
5. Necrotic Tissue Type	1 = None visible 2 = White/grey non-viable tissue &/or non-adherent yellow slough 3 = Loosely adherent yellow slough 4 = Adherent, soft, black eschar 5 = Firmly adherent, hard, black eschar			
6. Necrotic Tissue Amount	1 = None visible 2 = < 25% of wound bed covered 3 = 25% to 50% of wound covered 4 = > 50% and < 75% of wound covered 5 = 75% to 100% of wound covered			
7. Exudate Type	1 = None			

Item	Assessment	Date Score	Date Score	Date Score
	2 = Bloody 3 = Serosanguineous: thin, watery, pale red/pink 4 = Serous: thin, watery, clear 5 = Purulent: thin or thick, opaque, tan/yellow, with or without odor			
8. Exudate Amount	1 = None, dry wound 2 = Scant, wound moist but no observable exudate 3 = Small 4 = Moderate 5 = Large			
9. Skin Color Sur-rounding Wound	1 = Pink or normal for ethnic group 2 = Bright red &/or blanches to touch 3 = White or grey pallor or hypopigmented 4 = Dark red or purple &/or non-blanchable 5 = Black or hyperpigmented			
10. Peripheral Tissue Edema	1 = No swelling or edema 2 = Non-pitting edema extends <4 cm around wound 3 = Non-pitting edema extends ≥4 cm around wound 4 = Pitting edema extends < 4 cm around wound 5 = Crepitus and/or pitting edema extends ≥4 cm around wound			
11. Peripheral Tissue Induration	1 = None present 2 = Induration, < 2 cm around wound 3 = Induration 2-4 cm extending < 50% around wound 4 = Induration 2-4 cm extending ≥ 50% around wound 5 = Induration > 4 cm in any area around wound			
12. Granu-lation Tissue	1 = Skin intact or partial thickness wound 2 = Bright, beefy red; 75% to 100% of wound filled &/or tissue overgrowth 3 = Bright, beefy red; < 75% & > 25% of wound filled 4 = Pink, &/or dull, dusky red &/or fills ≤ 25% of wound 5 = No granulation tissue present			
13. Epithe-lializa-tion	1 = 100% wound covered, surface intact 2 = 75% to <100% wound covered &/or epithelial tissue extends >0.5cm into wound bed 3 = 50% to <75% wound covered &/or epithelial tissue extends to <0.5cm into wound bed 4 = 25% to < 50% wound covered 5 = < 25% wound covered			
	TOTAL SCORE			
	SIGNATURE			

Plot the total score on the Wound Status Continuum by putting an **"X"** on the line and the date beneath the line. Plot multiple scores with their dates to see-at-a-glance regeneration or degeneration of the wound.

CHAPTER 3

Cervical Spine

JIM MEADOWS, SUSAN L. ARMIJO-OLIVO, DAVID J. MAGEE

INTRODUCTION

The etiology of injury to the cervical spine and the causes of cervical spine pathology are numerous. They can be myogenic, mechanical, neurogenic, or psychosomatic in origin and can be further divided into acute and chronic states. Acute injuries may be due to trauma, unaccustomed activity, or a poor working or sleeping position. Chronic pathology usually is due to poor posture, poor muscle tone, or illness. In a young child, it may be the result of an idiopathic torticollis.

In young people, mechanical and myogenic types of cervical pathology are most commonly due to a ligament sprain or muscle strain, whereas in older adults, they are more commonly due to cervical spondylosis (disc degeneration). Spinal stenosis (narrowing of the spinal canal) also can lead to symptoms, as can facet syndrome (pathology in the zygapophyseal joints). Neurogenic neck pain is primarily due to facet impingement or disc degeneration or herniation, resulting in irritation of the cervical nerve roots and subsequent radicular pain into the shoulder and/or arm. Psychosomatic problems commonly are the result of depression, anxiety, hysteria, or, in some cases, malingering.

One reason the cervical spine is vulnerable to injury is its high degree of mobility with a heavy weight, the head, perched on top of it. The cervical spine is the most flexible and mobile part of the spine, with the intervertebral discs making up approximately 40% of its height.[1] However, neck pain tends to be less disabling than back pain.[2]

With regard to injuries, the cervical spine can be divided into two areas, the upper and lower cervical spine. Upper cervical injuries are associated with the vertebral segments CO (occiput) to C2; these injuries are referred to as cervicoencephalic injuries.[3,4] The term **cervicoencephalic** portrays the relationship between the cervical spine and the occiput. Cervicoencephalic injuries can be severe enough to involve the brain, brain stem, and spinal cord.[3,4] The symptoms of injury associated with these segments may arise from areas of the brain (cognitive dysfunction), autonomic nervous system (sympathetic dysfunction), cranial nerves (cranial nerve dysfunction), or vertebral and/or internal carotid artery (vascular dysfunction) and tend to be headache, fatigue, vertigo, poor concentration, and irritability to light.[3,4] This is important to understand because, once sympathetic system dysfunction, cognitive dysfunction, cranial nerve dysfunction, or vascular dysfunction is evident, the condition takes an inordinate amount of time to resolve, is more difficult to treat, and may have more severe consequences. Cognitive dysfunction includes altered mental functions of comprehension, judgment, memory, and reasoning. Sympathetic symptoms are a result of hypertonia of the sympathetic nervous system, affect emotions, and may include tinnitus, postural dizziness, blurred vision, photophobia, rhinorrhea, sweating, lacrimation, and weakness.[3,5] Cranial nerve dysfunction involves one or more of the cranial nerves, and vascular dysfunction involves either the vertebral, basilar, or internal carotid arteries. Patients with severe injuries often may also demonstrate numbness or pain, sharp reversal of the cervical lordosis, and restricted motion, especially at one particular vertebral level.

Sympathetic Symptoms Caused by Cervical Pathology

- Tinnitus (ringing in the ear)
- Postural dizziness
- Blurred vision
- Photophobia (intolerance to light)
- Rhinorrhea (runny nose)
- Abnormal sweating
- Lacrimation (tearing)
- Weakness

Symptoms of Cognitive Dysfunction

- From concussions, head injuries
- Memory dysfunction–retrograde amnesia, posttraumatic amnesia
- Concentration difficulties or difficulty remembering things
- Disorientation
- Balance problems or incoordination
- Dizziness
- Increased emotionality
- Feeling “in a fog”

Lower cervical spine injuries are associated with vertebral body segments C3 to C7; these injuries are referred to as **cervicobrachial** injuries. Pathology in this region commonly leads to pain in the upper extremity.[3,4] Neck pain or extremity pain may occur individually, or the two may occur together. One may be greater than the other, or they may be equal. In any case the clinician's main concern is whether the signs and symptoms are peripheralizing (i.e., moving more distally) or centralizing (i.e., moving more centrally). If they are peripheralizing, the condition usually is worsening. If they are centralizing, the condition is improving. Common signs of minor injury are neck stiffness and limited range of motion (ROM). Unfavorable signs of neck injury include the presence of paresthesia, muscle weakness into the upper extremity, radicular signs, and neurological deficit, all of which lead to longer recovery time.[5]

TORTICOLLIS

The term *torticollis* (wry neck) means scoliosis or "twisted neck" in the cervical spine. The condition may be acute or chronic. Congenital torticollis, seen in young children, involves the sternocleidomastoid (SCM) muscle. Congenital or infantile torticollis primarily affects females aged 6 months to 3 years. It results from unilateral contraction of the SCM muscle caused by ischemic changes in the muscle. The resulting deformity is side flexion to the same (affected) side and rotation to the opposite side (Figure 3-1). A lump, or pseudo-tumor, sometimes is felt over the muscle in the first month, but this disappears.[6] The contracture itself is not painful, but it can lead to developmental and cosmetic problems with altered head and neck posture and alignment.

The cause of congenital torticollis is unknown, but the condition may be related to abnormal blood supply to the SCM muscle, resulting in a structural abnormality in the muscle. Increased amounts of interstitial fibrous tissue are found in the muscle, and this fibrous tissue tends to contract over time, causing the deformity. If the condition is not corrected early, asymmetry of the face may develop, with the affected side not being as well developed. The asymmetry corrects itself if the condition is corrected early. However, the correction, which commonly involves repeated, painful stretching of the affected muscle, may take years. Torticollis often is associated with other cervical deformities, such as **Klippel-Feil syndrome**, which is characterized by shortness of the neck and fusion of two or three of the vertebral bodies.[6]

The treatment for congenital torticollis, from a rehabilitation standpoint, is stretching and overcorrection of the deformity at birth. Most cases of congenital torticollis can be corrected this way, provided the stretching is carried out diligently. The clinician must teach the parents how to do the stretching because it must be done 2 to 4 times a day for at least a year. Needless to say, the child will not like the stretching and will express herself or himself the only way she or he can— by crying. The clinician should prepare the parents for this so that they are not worried that the child is being injured.

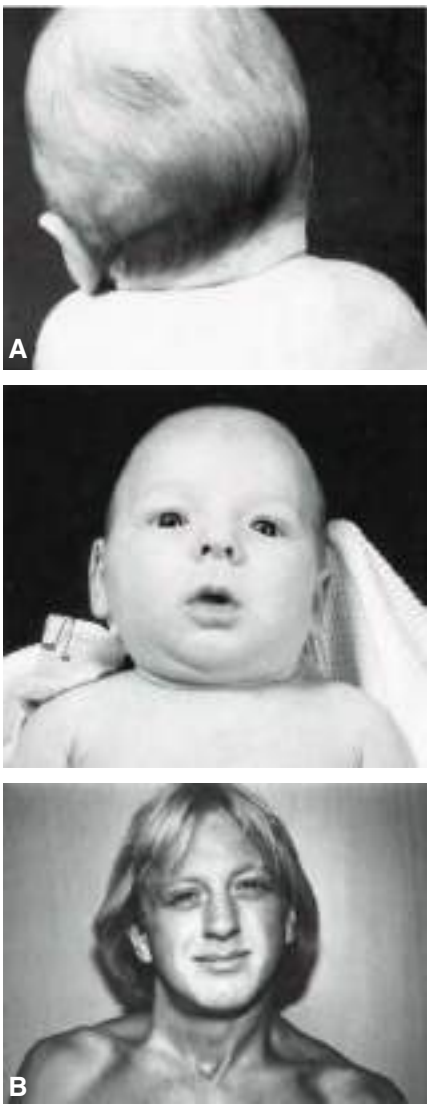

Figure 3-1 **A,** Congenital muscular torticollis on the left. The head is tilted to the left, and the chin is rotated to the right. **B,** Untreated right congenital muscular torticollis in a 19-year-old man. Note the asymmetry of the face. On the affected side, it is shortened from above downward and relatively wide from side to side. The level of the eyes and the ears is asymmetrical. (From Canale ST: *Campbell's operative orthopaedics,* St Louis, 2003, Mosby.)

Acute or acquired torticollis usually occurs in people 20 years of age or older. Spasm of one or more muscles (i.e., the SCM, splenius capitis, semispinalis capitus, or scalenus anterior) is commonly seen. The acute type of torticollis primarily is due to trauma or muscle strain; however, in some cases, it may be related to an upper respiratory tract infection, a viral infection, poor posture (with symptoms arising after the patient has been in an awkward posture for several hours), hearing problems, injury to the facet joints, dislocation, or even tumors.[6] Patients commonly awaken complaining of a "crick"

or pain in the neck, and they may relate the condition to "sleeping in a draft" or a similar circumstance. More commonly the real cause is poor neck position for several hours. The pain is unilateral; ROM is decreased, especially to one side; and severe pain is noted at the end range on active and passive movement testing.[6] In the neutral position, resisted isometric strength is strong but may be uncomfortable; however, the discomfort is not as great as that seen at the end of ROM in active and passive movement.

Acute or acquired torticollis usually resolves on its own within 7 days to 2 weeks.[6] This type of torticollis is treated primarily with rest and heat and/or ice, if the patient is seen within the first 24 hours. Muscle and joint mobilization and manipulation techniques may also be helpful, and pain-relieving modalities may be effective. The patient also should be treated with nonsteroidal anti-inflammatory drugs (NSAIDs) or muscle relaxants.

WHIPLASH (ACCELERATION INJURY)

Whiplash has been recognized as a significant public health problem in industrialized countries because it is an important cause of chronic pain disability.[7] According to Carrol et al.,[8] the incidence of whiplash-associated disorders (WADs) in Western countries has increased since the 1980s, with an estimated yearly incidence of at least 300 per 100,000 inhabitants. The economic impact of whiplash disorders has been reported to be incredibly high. For example, Joslin et al.[9] reported that whiplash personal injury claims exceeded £3 billion per year in the United Kingdom. Similar economic impact has been reported in the United States, with costs reaching U.S. $230 billion per annum in 2000.[10]

The term *whiplash* is derived from the "whipping of a lash," indicating a quick change in direction or movement, often with a snap. The head goes through a ROM involving flexion often combined with rotation, followed very rapidly by extension, or vice versa. Whiplash is also called a *cervical sprain* or *cervical strain* or an *acceleration-deceleration injury* of the neck. The extent of injury depends on the force of impact. If the injury is caused by an automobile accident, the position of the head at the time of impact, whether the patient was aware of the impending collision, and the condition of the neck tissues (e.g., effects of aging) are all factors that affect the severity of the injury.[11–13] Seventy percent of patients with whiplash report an immediate occurrence of symptoms, but many also report delayed symptoms.[5,14–17] Common signs include neck pain and headaches originating from the occipital area. If the condition is serious enough, the patient may complain of more severe symptoms (Table 3-1).[5,18]

The Quebec Task Force (QTF) on WADs[18] defines whiplash as "an acceleration-deceleration mechanism of energy transfer to the neck. It may result from rear end

TABLE 3-1

Grading System for Whiplash-associated Disorders

Grade 1	Grade 2	Grade 3	Grade 4
• Muscle strain • Neck stiffness • Neck pain/tenderness • No physical signs • Normal reflexes, dermatomes, and myotomes • X-ray film: Unnecessary • Accounts for approximately 43% of cases	• Muscle strain/ligament sprain • Neck and/or back stiffness • Neck and/or back pain • Paraspinal tenderness • Restricted ROM • Normal reflexes, dermatomes, and myotomes • X-ray film: No fracture/dislocation • Accounts for approximately 29% to 56% of cases	• Possible disc protrusion • Nerve root signs: Objective neurological signs (myotomes/dermatomes) • Neck or back pain • Restricted ROM • Abnormal reflexes (reduced), dermatomes (abnormal), and myotomes (weak) • Possible upper motor neuron signs • X-ray film: No fracture/dislocation • CT scan/MRI: May show area of nerve involvement • Accounts for approximately 3% to 2% of cases	• Cervical fracture/dislocation • Nerve root signs: Objective neurological signs (myotomes/dermatomes) • Neck pain • Restricted ROM • Abnormal reflexes (reduces), dermatomes (abnormal) and myotomes (weak) • Possible upper motor neuron signs (e.g., urinary incontinence, pathological reflexes) • X-ray film: Fracture/dislocation • CT scan/MRI: May show area of nerve/fracture/dislocation/spinal cord involvement • Accounts for approximately 6% of cases

Data from Spitzer WO, Skovron ML, Salmi LR et al: Scientific monograph of the Quebec Task Force on Whiplash-associated Disorders: redefining "whiplash" and its management, *Spine* 20:1S-73S, 1995.

TABLE 3-2

Quebec Task Force Classification of the Severity of Whiplash-associated Disorders

Grade	Clinical Presentation
0	No neck symptoms, no physical signs
1	No physical signs except neck pain, stiffness, or tenderness only
2	Neck symptoms and musculoskeletal signs, such as decreased ROM and point tenderness
3	Neck symptoms and neurological signs, such as decreased or absent deep tendon reflexes, weakness, and sensory deficits
4	Neck symptoms and fracture or dislocation

From Spitzer WO, Skovron ML, Salmi LR et al: Scientific monograph of the Quebec Task Force on "Whiplash-Associated Disorders: redefining "whiplash" and its management, *Spine* 20:8S-58S, 1995.

or side impact motor vehicle collision, but can also occur during other mechanisms. The impact may result in bony or soft tissue injuries to the cervical spine (whiplash injury), which in turn may lead to a variety of clinical manifestations called **whiplash-associated disorders (WADs)**." Chronic WADs usually are defined as symptoms or disabilities that persist for longer than 6 months.[18,19] The QTF established a system of five grades for classifying the severity of these disorders (Table 3-2).[18] WADs include aching or stiffness in the neck. These symptoms usually appear within a few hours after the accident. In some cases, the patient may have difficulty swallowing because of injury to the esophagus and larynx. Headache is common and usually occurs in the occipital area, but it may also radiate to the vertex of the skull or the temples. In some cases, the pain may be retroocular. The pain may also be referred into the interscapular area, chest, and shoulders. The head commonly is held in flexion (with a loss of the lordotic curvature) as a result of muscle spasm, and ROM, especially side flexion or rotation, is limited. In some cases, the person may suffer a concussion during the accident, leading to loss of consciousness, amnesia, nausea, vomiting, and cognitive dysfunction. Older patients because of preexisting degenerative changes and those who have a psychosocial response to the injury tend to have a poor prognosis. Symptoms associated with any preexisting degenerative changes seem to come on faster after an accident.[20] Research has indicated that even minor trauma, such as low-velocity collisions, can lead to prolonged symptoms.[21]

Rear-end impact (i.e., acceleration type) injuries tend to cause the greatest disability from the whiplash mechanism primarily because the victim is unaware of the impending impact. Impact from behind causes the lower portion of the body to move forward abruptly while the head momentarily remains in place. The head then arches backward through a path of extension because it is heavy and suspended on a thin, flexible support (the cervical spine). This quick movement catches the protective muscle reflex unprepared; consequently the limiting influence of the ligaments is exceeded, resulting in hyperextension, especially if the head is not stopped by a headrest. Backward shearing may also occur in the cervical spine, possibly resulting in spinal cord damage from subluxation or fracture of the vertical body.[22] The hyperextension is followed by a protective flexor muscle contraction that causes a rebound, combined with compression that pulls the head forward from its hyperextended position; the result is a compressive hyperflexion, which may stress the intervertebral disc and posterior structures.

The position of the head at the time of impact affects ROM and the severity of injury. Normal extension is approximately 70°, but extension is decreased when the head is rotated 45°. Therefore head rotation can increase the probability and severity of cervical injury because of the decrease in available ROM.

In front-end impact (i.e., deceleration type) injuries, the body moves forward and then comes to a sudden stop. Actually, the body stops, but the head, because of its weight, continues to move forward as a result of inertia. The impact is abrupt, may be unexpected, or overpowers the extensor mechanism, resulting in hyperflexion. Movement of the head is stopped by the chin hitting the chest wall. A rebound then occurs, causing hyperextension as a result of reflexive contraction of the extensor muscles.

A third type of whiplash mechanism is a rotation injury. For example, people with long hair can cause a rotational sprain of the ligaments or strain of the muscles, or possibly damage the facet joint, by whipping the head around to get the hair out of their eyes.

The influence of crash-related factors on outcome is the subject of debate. Some studies have found a relationship between factors,[23] whereas others have reported that crash-related factors were not important predictors of poor outcome.[7] The evidence is not conclusive in this matter. Higher-intensity neck pain and headache, as well as radicular symptoms and signs, have been strongly associated with delayed recovery.[24,25] Cassidy et al.[7] reported that patients who consulted a medical physician and a physical therapist or a medical physician and a chiropractor took longer to recover than those who did not seek a health care provider. These findings were corroborated by Gun et al.[20] No explanation was given for the difference, except that people in greater pain and discomfort would be more likely to seek help.

In some cases the same mechanism of injury that occurs with whiplash, if assisted by contact with the nonyielding surface, can lead to more severe cervical injuries, such as dislocation or fracture of a cervical vertebra, or a combination of these two injuries. The result can be neurological damage and paralysis. This might occur in an individual who falls forward, striking the chin, face, or forehead against an object, causing forceful hyperextension or backward thrust of the neck or an individual who falls backward, striking the head, causing forceful hyperflexion or forward thrust of the neck. Another

example is an individual who dives into shallow water, striking the head, causing forceful hyperflexion and compression of the cervical spine. Similar injury patterns can occur in football with spearing or in hockey when players are checked headfirst into the boards.

Although efforts have been made to classify and define WADs, the descriptive validity of the WAD classifications has been questioned because the two primary symptoms used to describe these conditions are nonspecific and prevalent in the general population.[26–29] Nederhand et al.[30] concluded that cervical muscle dysfunction was not specific to patients with grade 2 WAD and that it appeared to be a general sign of chronic pain. These findings do not support the validity of the WAD categories described by the QTF. Attempts have been made to modify this classification with no success due to the increase in complexity for classifying patients. Thus the QTF classification is still considered the criteria to classify WADs.[31]

According to Stovner[19] and Freeman et al.,[32] the estimated proportion of patients who report pain and disability 6 months after an accident ranges from 19% to 60%, and the percentage of patients who are absent from work after 6 months is 9% to 26%.[15,19] Styrke et al.[33] reported that 44% of subjects 5 years after suffering a whiplash presented with an inability to sustain previous workload and 43% fatigue at work. Only 39% of the sample were satisfied with their somatic health and 60% with their psychological health. Compared with healthy controls, the whiplash-injured individuals exhibited more symptoms and had lower life satisfaction, which could interfere with the recovery.

The natural course of whiplash disorders is unknown. Sterling et al.[34] have described three pathways to WAD recovery. The first is "good recovery," which involves people with initial mild-to-moderate disability after the accident. Generally 45% of patients follow this path. The second is characterized by initial moderate-to-severe pain-related disability, with "moderate recovery" at 12 months follow-up. Thirty-nine percent of people are predicted to follow this path of recovery. The last path is the "bad recovery." Subjects in this path start with moderate-to-severe disability and progress to some recovery with moderate-to-severe levels of disability at 1 year. Sixteen percent of the subjects follow this path.[34]

The area of prognostic factors for WAD has been of great interest because it is of paramount importance to recognize which patients will recover as well as the ones who will progress to high levels of disability, in order to target appropriate treatment strategies. Some prognostic factors have been described to distinguish between patients who are expected to experience either a normal or a delayed recovery. According to Stovner,[19] a causal link between trauma and chronic symptoms is not conclusive. Litigation issues have been related to the chronicity of symptoms. In countries where litigation appears to play a role in recovery, the disability of WADs is prolonged, and in countries where litigation is absent, the prevalence of chronic whiplash syndrome is low or nonexistent.[7]

It has been reported that long-term neck symptoms do not occur in any higher proportion in whiplash patients than in the general population.[27,35] However, 15% to 40% of whiplash patients may report persistent headaches and neck pain.[14] In a long-term longitudinal study of subjects with whiplash,[33] it was reported that the most common symptoms 5 years after whiplash injury were fatigue (41%), poor memory (39%), and headache (37%). These symptoms are typical of mild **traumatic brain injury (TBI)**; thus WAD patients can share some of the symptomatology of TBI, and as a result, assessment of these patients would be important to quantify TBI symptoms earlier in the rehabilitation process and target an appropriate treatment. Furthermore, it has been reported that subjects with WAD commonly present psychiatric disorders, such as posttraumatic stress disorder, major depressive episode, and generalized anxiety disorder, which can contribute to doubling the health care utilization and considerably greater time off work compared with those with physical injury alone.[31]

Clinicians can help patients understand the effect of the injury and reduce the impact of any disability by explaining the prognostic factors associated with these injuries. According to Scholten-Peeters et al.,[36] the physical prognostic factors associated with delayed recovery in WADs are decreased mobility of the cervical spine immediately after injury, preexisting neck trauma, older age, and female gender. Some psychological factors (e.g., inadequate cognition, fear-avoidance beliefs, catastrophizing, maladaptive copying strategies, depression, and anxiety) have been found to be related to delayed recovery in WADs, much as they have been in other pain conditions, such as low back pain.[20] More research is needed to develop a prognostic patient profile consisting of factors that predict outcome in whiplash patients.[35] Gun et al.[20] and others[37] found that patients who consulted a lawyer had a worse Neck Pain Outcome Score (NPOS); after 1 year, these patients had a sevenfold greater chance of still receiving treatment and a sevenfold lesser chance of claim settlement. For individuals with a history of a previous motor vehicle accident claim, improvement after 1 year in the NPOS was 10 points lower and improvement on the Visual Analogue Scale (VAS) was 1 point lower.

Factors Associated with Delayed Recovery in Whiplash-associated Disorders

- Decrease in cervical spine mobility immediately after injury
- Preexisting neck trauma
- Older age
- Female gender
- Psychological factors
- Pending litigation

According to a systematic review of prognostic factors in whiplash by Cote et al.,[24] reliable information on whiplash is still scarce, and the methodological quality of studies needs to be improved. Based on the reviewed studies, these researchers concluded that consistent evidence indicated that older age and female gender were associated with delayed recovery from whiplash. No consistent evidence was found for marital status, number of dependents, income, work activities, or education as predictors of recovery. No strong evidence was associated with a past history of headaches or neck pain with recovery. However, the studies that reported these associations lacked control of the confounders.

Cote et al.[24] also found that compensation or litigation issues could have an influence on claimants' behavior and recovery. The differences in the rating of prolonged symptoms between systems with and without compensation raises questions about the real incidence of chronic WADs.[19] In a meta-analysis by Walton et al.,[38] 12 prognostic factors were identified as related to persistent problems following WAD. The significant variables included high baseline pain intensity (greater than 5.5/10), report of headache at inception, less than postsecondary education, no seat belt in use during the accident, report of low back pain at inception, high Neck Disability Index (NDI) score (greater than 14.5/50), preinjury neck pain, report of neck pain at inception (regardless of intensity), high catastrophizing, female sex, WAD grade 2 or 3, and WAD grade 3 alone. In addition, they reported that catastrophizing but not depression was found to be an important risk factor for chronicity of WAD.[38] Psychological factors have been found to be more relevant than collision severity in predicting duration and severity of symptoms in WAD.[39] Helplessness, older age, and poor preinjury work status were found to predict poorer health and nonrecovery.[38,40] A study in a Swiss cohort[41] has partially corroborated these findings. They found that relief of depression and low baseline depression were highly associated with improved physical function in subjects with whiplash after a rehabilitation program (especially at the 6-month follow-up: 20.5% explained variance). In addition, low baseline catastrophizing and reduction of catastrophizing were associated with improvements in pain relief, physical function, and working capacity. For improved function at discharge, reduction of catastrophizing was the most important predictor (19.4% explained variance). Low baseline pain and relief of pain were associated with improvement of function and vice versa. Thus improved coping (i.e., decreasing catastrophizing and ability to decrease pain) and reduced depression may act as important predictors for pain relief and improved function in subjects with WAD. These findings shed light on the interrelation among psychological factors that could potentially affect recovery in subjects with WAD. These prognostic factors should be taken into consideration when planning therapy for subjects with chronic WAD. According to Sterling,[34] most of the studies investigating prognostic factors lacked validation, and thus more research is needed to develop a prognostic patient profile consisting of factors that predict outcome in whiplash patients.[24,29] Results from systematic reviews of prognostic factors' evidence were summarized by Sterling[34] and presented in Table 3-3.

A complete history of the whiplash patient should be taken. This should include details about specific symptoms (especially those related to cognitive, sympathetic, cranial nerve, and vascular dysfunction), preexisting symptoms, disabilities, participation problems, accident-specific information (e.g., velocity of the car, type of collision), recovery time, previous diagnostic tests and procedures, success of treatment (medical or other), attitude, cognition, present severity of symptoms, psychosocial issues, and medications used. This information can indicate the degree of compromise suffered by the patient and how the WAD affects his/her life. Some assessment tools are available for evaluating pain (VAS) and neck disability (NDI) (see *Orthopedic Physical Assessment,* volume 1 of this series). However, it should be pointed out that according to Stenneberg et al.,[42] these measurements do not cover important limitations for patients with WAD. For example, out of the

TABLE **3-3**

Prognostic Indictors of Poor Functional Recovery Following Whiplash Injury Based on Findings of Systematic Reviews

Factors Showing Consistent Evidence for Being Prognostic Indicators for Poor Recovery	Factors Showing Consistent Evidence of Not Being Prognostic Indicators	Factors with Inconsistent Evidence
• Initial pain levels: > 5.5/1 • Initial disability levels: NDI>29% • Symptoms of posttraumatic stress • Negative expectations of recovery • High pain catastrophizing • Cold hyperalgesia	• Accident-related features (e.g., collision awareness, position in vehicle, speed of accident) • Findings on imaging • Motor dysfunction	• Older age • Female gender • Neck range of movement • Compensation related factors

From Sterling M: Physiotherapy management of whiplash-associated disorders (WAD), *J Physiother* 60(1):7, 2014.

40 limitations most important to patients with WAD, the NDI covers only six items.[43] In addition, Hoving et al.[44] concluded that the NDI and Northwick Park Neck Pain Questionnaire (NPQ) did not fully reflect the full spectrum of disabilities judged to be important by patients with WAD. Only three of the most important problems were included in the NDI, and only four were included in the NPQ.[44] Therefore, Stenneberg et al.[42] and Schmitt et al.[43] created a new scale to assess activity limitation and participation restriction in patients with WAD: the Whiplash Activity and Participation List (WAL). The WAL is a self-assessment instrument that is based on the International Classification of Functioning, Disability and Health (ICF) framework. The WAL is primarily developed for the Dutch language and consists of 35 activity and participation items, scored on a 5-point scale according to the ICF (World Health Organization [WHO], 2001). A sum score is calculated ranging from 0 (no limitations) to 140 (extremely limited). The development process involved a Delphi technique with experts as well as patients with subacute or chronic WAD. The validation study found excellent properties for this tool, which makes it a promising tool to be used specifically in subjects with WAD. Cronbach's alpha was high (0.95), and test-retest reliability was excellent (0.92, 95% confidence interval [CI] 0.87; 0.95). In addition, construct validity was supported by 14 out of 15 confirmed hypotheses, and the WAL showed statistically significant differences between known groups. The minimal detectable change (MDC) was 16 points, and the minimal clinically important change (MCIC) was 18 points (Table 3-4).

A study by Nederhand et al.[45] in 2000 demonstrated that patients with grade 2 WADs had higher activity of the upper trapezius than healthy controls and that they also were unable to relax these muscles after a dynamic task. These findings indicated that patients with grade 2 WADs exhibited abnormal muscle activation in situations in which no biomechanical demand for the activation existed. One of the symptoms described in the QTF WAD classification system[17,18] coincides with the description of "musculoskeletal signs." Nederhand et al.[45] considered the criteria used to determine musculoskeletal signs (e.g., the presence of "point tenderness" and "muscle spasm") to be inaccurate because assessment commonly is performed in the sitting or standing position, which results in only small differences in electromyography (EMG) levels between patients and controls. According to these authors, surface EMG may be a useful tool for differentiating patients with grade 2 WADs because it helps to determine the hyperactivity of the cervical muscles.

TABLE **3-4**

Items Included in the Whiplash Activity and Participation List

Item	Rating*	Item	Rating*
Focusing attention	_____	Shopping	_____
Reading	_____	Preparing meals (such as slicing, cooking)	_____
Solving complex problems	_____	Doing housework (such as cleaning, washing clothes, window cleaning)	_____
Undertaking multiple tasks	_____	Using household appliances (such as vacuum cleaners)	_____
Handling stress	_____	Gardening	_____
Conversing	_____	Interacting with people (such as friends, coworkers, partner, and children)	_____
Using a desktop computer or laptop	_____	Maintaining relationships	_____
Bending over	_____	Sexuality	_____
Maintaining a sitting position	_____	Following education or training	_____

Modified from Schmitt MA, Stenneberg MS, Schrama PPM et al: Measurement of clinically relevant functional health perceptions in patients with whiplash-associated disorders: The development of the whiplash specific activity and participation list (WAL), *Eur Spine J* 22(9):2103, 2013.

For treatment of WADs, the advice to stay active as well as follow a program of exercise has been advocated as a good choice to manage this condition. However, the evidence is not consistent as to which type of exercise might yield the best results (a general program of exercise to treat neck pain and associated disorders is described later in this chapter). It seems that no specific exercise is better than the advice to stay active for acute and chronic WAD. Nevertheless, what is clear from the synthesis of the best evidence is that activity and exercise are superior to restricting movement with a soft collar, which has shown to be ineffective for the management of acute WAD.[46] Furthermore, interdisciplinary approaches have been found to be beneficial for some patients. However, no clear conclusions can be established for all cases due to the limited evidence found in randomized controlled trials (RCTs). Thus future directions for the research process are to target factors associated with recovery after WAD because many of them are potentially modifiable with more specific interventions.[46]

CERVICAL SPONDYLOSIS

Cervical spondylosis is an age-related, degenerative condition sometimes referred to as *cervical arthritis*, *segmental instability*, *hypertrophic arthritis*, *degenerative spondylosis*, *cervical arthrosis*, or *degenerative disease*.[3] It is believed to be part of the normal aging process of the vertebral column and is commonly seen in people after the age of 40.[47] Radiological investigation of asymptomatic individuals has shown spondylotic changes of greater than 50% by age 50 and up to 90% by age 65.[48–50] Spondylosis has both an inflammatory component and a degenerative component, which eventually lead to arthritis of the cervical spine. The term *cervical spondylosis* implies a loss of mechanical integrity of a cervical intervertebral disc, leading to instability of the affected segment and, later on, nerve root or cord compression symptoms caused by stenosis in either the intervertebral foramen or the spinal canal (Table 3-5).[51] Although spondylosis appears most obviously in the cervical spine because of its mobility, it may occur in other areas of the spine, especially the lower lumbar spine. The condition begins with intervertebral disc degeneration, which can occur as a result of damage to the disc or poor nutrition. A state of poor nutrition may result from changes at the cartilaginous end plate between the disc and the vertebral body, resulting in lack of nutritional interchange.

As the disc degenerates and loses bulk, a reduction of the mucopolysaccharides in the nucleus pulposus occurs, leading to an increase in collagen in the nucleus pulposus. These changes result in the loss of turgor in the disc[52,53] and a loss in the disc's ability to resist compressive forces. In time, the annulus, because it starts to act like an underinflated tire, begins to protrude beyond the margins of the vertebral body. This results in a loss in the buffer qualities of the nucleus pulposus. Shock absorption is no longer spread or absorbed evenly by the annulus or the cartilaginous end plate. The increased mobility (because of the "underinflated tire" of the disc) leads to greater shearing, rotation, and traction stress on the disc and adjacent vertebra. The result of these actions is approximation of the vertebral bodies and loss of the normal lordotic curvature in the cervical spine. In addition, the pedicles begin to approximate, resulting in an overriding or subluxation of the facet joints, which leads to approximation of the lamina. This in turn can lead to possible infolding of the ligamentum flava, especially when the cervical spine is in the neutral position or extension, along with degeneration of the joints of von Luschka. These changes subsequently lead to decreased ROM, shortening of the cervical spine, and loss of spinal stiffness.[53,54]

As previously stated, as the disc degenerates, the nucleus pulposus begins to lose its turgor, and its gel-like tissue, which normally is under pressure, begins to fibrose and take on an appearance similar to the annulus. The disc also begins to lose height, causing slight overriding of the zygapophyseal joint articular surfaces; this in turn leads to translational instability (i.e., loss of arthrokinematic control). Over time this instability leads to the formation of protective osteophytes and limitation of movement.[51,53] Radiological evidence shows that these changes are found in 60% of patients over age 45 and 85% of those over age 65, even if symptoms are not present.[51,53–55] In the cervical spine, the areas most commonly and most severely affected are reported to be C5-6 and C6-7.[3] If symptoms are going to develop, they tend to appear between 35 and 55 years of age. A cadaveric study by Lee and Riew[56] found that the upper cervical specimens appeared to be affected by facet arthrosis more frequently than the lower levels. In the same study, it was found that in the older population, the prevalence of facet arthrosis was as high as 29.87% for the C4-C5 level, which was the segment affected most frequently, followed by the C3-C4 level, then C2-C3, C5-C6, and C6-C7.[3,55] If symptoms are going to develop, they tend to appear between 35 and 55 years of age.

Kirkaldy-Willis[55] divided spondylosis into three stages: dysfunctional, unstable, and stabilization. Although he developed these stages for the lumbar spine, they are equally applicable to any area of the spine. Based on Kirkaldy-Willis's description, these stages begin when the

Synonyms for Spondylosis

- (Cervical)* disc disease/degeneration
- Segmental instability
- Hypertrophic arthritis
- Degenerative spondylosis
- (Cervical)* arthrosis

*Also occurs in other areas of the spine

TABLE 3-5

Assessment of Aging and Degeneration of the Human Intervertebral Disc

Disc Grade	Nucleus Pulposus	Annulus Fibrosus	End Plate	Vertebral Body
Assessment by Gross Morphology*				
I	Gel-like, bulging; blue-white	Discrete lamellae; white	Hyaline; uniform thickness	Margins rounded
II	Fibrous tissue band extending from the annulus fibrosus	Chondroid or mucinous material between lamellae	Irregular thickness of cartilage	Margins pointed
III	Consolidation of fibrous tissue	Extensive chondroid or mucinous material; loss of annulus-nucleus demarcation	Focal defects in cartilage	Early chondrophytes or osteophytes at margins
IV	Horizontal clefts parallel to end plate	Focal disruptions	Fibrocartilaginous tissue extending from subchondral bone; irregularity and focal sclerosis of subchondral bone	Osteophytes <2 mm
V	Clefts extending throughout	Clefts extending throughout	Diffuse sclerosis	Osteophytes <2 mm
Assessment of Magnetic Resonance Imaging Findings†				
I	Homogeneous; bright; demarcation distinct	Homogeneous; dark gray	Single dark line	Margins rounded
II	Horizontal dark bands extend across the annulus fibrosus centrally	Areas of increased signal intensity	Increase in central concavity	Tapering of margins
III	Signal intensity diminished; gray tone with dark and bright stippling	Indistinguishable from nucleus pulposus	Line less distinct	Small dark projections from margins
IV	Proportion of gray signal reduced; bright and dark regions larger	Indistinguishable from nucleus pulposus; some bright and dark signals contiguous with nucleus pulposus and annulus fibrosis	Focal defects in line	Projections <2 mm with same intensity as marrow
V	Gross loss of disc height; bright and dark signals dominant	Signals contiguous with nucleus pulposus	Defects and areas of thickening	Projections <2 mm with same intensity as marrow

patient complains of symptoms. However, the condition begins long before symptoms are evident. Initially spondylosis develops insidiously (silently) and is asymptomatic.[6]

In the **dysfunctional stage**,[55] the patient complains of nonspecific neck pain with localized tenderness (Table 3-6). On radiographic examination, the disc degeneration is obvious, as seen in the loss of height and the bulging of the annulus beyond the vertebral margins. Abnormal function of the facet joints (i.e., subluxation caused by disc degeneration) and synovitis may occur, along with protective muscle spasm, although this subluxation is seldom seen on x-ray films. Side flexion or rotation commonly is limited or stiff and painful, especially to one side. The same is true for cervical extension. A neurological examination at this stage frequently is negative. In some cases symptoms may be attributed to a recent injury, such as a car accident, when in fact they already were present, even though the patient did not complain of symptoms.

TABLE 3-6

Signs, Symptoms, and Radiological Changes in the Dysfunctional Stage of Spondylosis

Signs	Symptoms	Radiological Changes

• Local tenderness
• Muscle contraction
• Hypomobility
• Pain on extension
• Neurological exam usually normal
	• Low back pain:
	  ○ Often localized
	  ○ Sometimes referred
	• Pain with movement
		• Abnormal decreased movement
		• Malalignment of spinous processes
		• Irregular facets
		• Early disc changes

From Kirkaldy-Willis WH: *Managing low back pain*, p 79, New York, 1983, Churchill Livingstone.

The **unstable stage**[55] is marked by increased zygapophyseal or facet capsular laxity (Table 3-7). An abnormal "spinal rhythm" or "instability jog" (i.e., a flickering of the skin over the spine during movements) may become evident. This instability jog is an indication of lack of arthrokinematic motion control (i.e., a motor control deficit exists) as the patient moves the neck and head. The disc continues to degenerate and in some cases may herniate, and more bulging can occur in unstable stages and lead to hypermobility. This leads to segmental hypermobility (i.e., translational instability). Progressive degeneration of the facet joints is seen, which may lead to facet joint syndrome.[56] Radicular pain also may be seen because the lateral nerve roots can become trapped in the intervertebral foramen.[57] Traction spurs (usually found anteriorly) are sometimes seen on radiological examination.[58] Traction spurs are caused by abnormal stresses on the outermost attachments of the annulus and are thought to be related to the excessive mobility caused by the degenerative disc.[51,59] Traction spurs generally are seen 2 to 3 mm from the discal edge of the vertical body and project horizontally.

Traction spurs are not true claw, or marginal, osteophytes, which occur at the edge of the vertebral body (Figure 3-2). A claw osteophyte is commonly related to loss of disc height and annular bulging, which lifts the

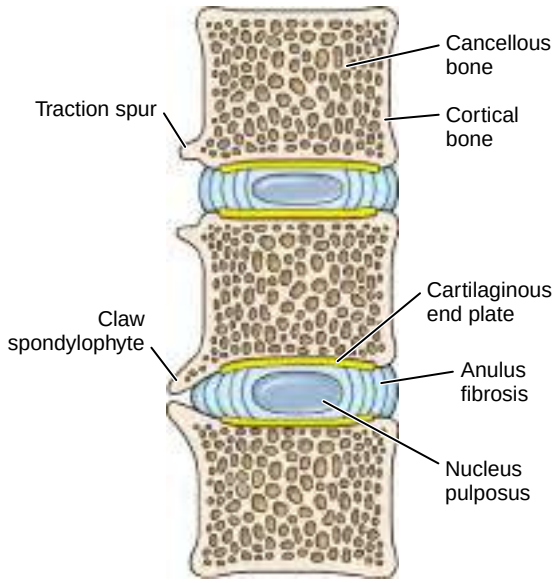

Figure 3-2 A traction spur projects horizontally from the vertebral body approximately 1 mm from the discal border. Traction spurs are indicators of segmental instability. In contrast, the common claw spondylophyte extends from the rim of the vertebral body and curves as it grows around the bulging intervertebral disc. Claw spondylophytes are associated with disc degeneration; they are *not* radiological manifestations of osteoarthritis. (Redrawn from Wong DA, Transfeldt E: *MacNab's backache*, ed 4, Philadelphia, 2007, Lippincott, Williams & Wilkins.)

TABLE 3-7

Signs, Symptoms, and Radiological Changes in the Unstable Stage of Spondylosis

Signs	Symptoms	Radiological Changes
• Detection of abnormal movement (inspection, palpation) • Observation of "catch" in the back (on movement) • Pain on coming to standing position after flexion	• Symptoms of dysfunction • Giving way of back (i.e., "catch" in back on movement) • Pain on coming to standing position after flexion	Anteroposterior view: • Lateral shift • Rotation • Abnormal tilt • Malaligned spinous processes Oblique view: • Opening of the facets Lateral view: • Spondylolisthesis (in flexion) • Retrospondylolisthesis (in extension) • Narrowing of the foramen (in extension) • Abnormal opening of the disc • Abrupt change in pedicle height CT changes

From Kirkaldy-Willis WH: *Managing low back pain*, p 81, New York, 1983, Churchill-Livingstone.

periosteum from the vertebral edge, causing new bone to be laid down. A claw osteophyte or spur may also hook over the disc at the discal margin. Osteophytes are a physiological response to a compression load that reflects the body's attempts to stabilize the spine.[59,60]

With disc degeneration in the cervical spine, the joints of von Luschka, also called uncovertebral joints, are approximated, leading to a third location of osteophyte formation. Intraforaminal osteophytes encroach on the intervertebral foramen and possibly the vertebral artery, resulting in neurological symptoms and an increased possibility of vertebral artery syndrome.[61] The anterior spinal artery may thicken, leading to vascular insufficiency, or compression of the nutrient vessels may occur. Silberstein[61] contends that the joints of von Luschka are actually formed by this degeneration and rubbing and that they are not true synovial joints. Intraforaminal osteophytes limit movement and eventually stabilize the joint containing the fragmented disc.

In the unstable stage, patients complain primarily of neck dysfunction (see Table 3-7). They also commonly complain of a "catch" or sudden pain in the neck in part of the ROM during movement.[54] Greater restriction of movement is seen in this stage than in the dysfunctional stage, as well as uncoordinated movement (i.e., abnormal movement patterns) caused by dysfunction of the functional spinal unit (i.e., the disc and two apophyseal joints). Circumferential tears of the annulus fibrosus and radial tears extending from the annulus fibrosus to the nucleus pulposus may also be seen in this stage.

In the final stage, or **stabilization stage**,[55] fibrosis of the facet joints occurs, along with even greater disc degeneration and osteophyte formation (Table 3-8). Osteophytes form along the edges of the facet joints, leading to enlarged facets. Lateral nerve root entrapment becomes more common in this stage, leading to radicular signs and lateral stenosis in the intervertebral foramen. At the same time, osteoarthritis (OA) of the facet joints becomes more obvious.

Narrowing of the degenerating disc through the different stages of spondylosis can lead to anterior impingement by the uncovertebral spurs, anterior impingement by the annular bulging, and posterior impingement by the osteophytes of the facet joints and fibrosis of the epidural nerve sleeves.[51,57] Facet joint degeneration leads to erosion of the joint cartilage and lipping around the joint edge, with formation of facet osteophytes. The synovial membrane thickens, and this, combined with the formation of facet osteophytes, leads to a decrease in the size of the intervertebral foramen and a greater possibility of radicular signs and symptoms. Nerve root fibrosis may also result from disc degeneration, leading to inflammatory changes, rubbing of the nerve root and sheath against the rough pedicles during movement, or injury to the nerve root. The cartilaginous end plate of the vertebral body degenerates throughout the development of spondylosis, showing thinning, fibrillation, and fissuring. The fissuring may extend the whole thickness of the end plate, and granulation tissue may grow through into the disc, adding to the fibrosis of the disc.[54]

The signs and symptoms of cervical spondylosis are mainly pain, restriction of motion, and in later stages, radicular signs. Cervical radiculopathy is the most common symptom of cervical degenerative disease that leads patients to seek treatment.[62] This occurs due to a combination of degenerative changes in the cervical spine, such as disc herniation, OA of uncovertebral and facet joints, decreased intervertebral height, and spondylolisthesis of cervical vertebrae. In some cases, the spinal cord or anterior spinal vessels may be compressed, leading to myelopathic symptoms.[63,64] It has been reported that cervical spondylotic myelopathy is the most serious and disabling progression of this disease.[48] The pain may be vague or ill defined, or it may be a dull, aching pain that increases over time and then tends to be referred to the shoulder or arm rather than the neck. Pain tends to be accentuated by movement and more often is evident toward end range. Radicular pain is referred into the appropriate dermatome initially, and the myotomes are affected later. Radiographic examination shows narrowing of one or more of the intervertebral discs and osteophyte spurring and irregularity, along with sclerosis of the vertebral body.[54,64,65]

Kellgren and Lawrence[66] developed a set of criteria to classify degenerative spondylosis based upon lateral cervical spine radiographs in a normal population sample. The classification is qualitative and has been extensively used to describe radiological changes in the cervical spine. This classification is a five-grade scale, ranging from "0" (absence of degeneration) up to "4" (severe narrowing of the disc space with sclerosis and large osteophytes). Gore et al.[67] added some criteria regarding the disc space narrowing, end plate sclerosis, and anterior and posterior osteophytes. According to a study by Ofiram et al.,[68] although the classification postulated by Kellgren and Lawrence has been shown to be reliable, it provides only a qualitative and general description of the degenerative changes. Therefore they created a quantitative radiographic index: the Cervical Degenerative Index (CDI) to measure cervical

TABLE 3-8

Signs, Symptoms, and Radiological Changes in the Stabilization Stage of Spondylosis

Signs	Symptoms	Radiological Changes
• Muscle tenderness • Stiffness • Reduced movement • Scoliosis	• Low back pain of decreasing severity	• Enlarged facets • Loss of disc height • Osteophytes • Small foramina • Reduced movement • Scoliosis

TABLE 3-9

Cervical Degenerative Index (CDI) and Scoring System

FACTOR	CDI SCORE			
	0	1	2	3
Disc space narrowing (%)	None-25	25-50	50-75	75-100
Sclerosis	None	Minimal	Moderate	Severe
Osteophytes	None	Small, less than 2 mm	Moderate, 2-4 mm	Large, more than 4 mm
Olisthesis	None	Less than 3 mm	3-5 mm	More than 5 mm

From Ofiram E, Garvey TA, Schwender JD et al: Cervical degenerative index: a new quantitative radiographic scoring system for cervical spondylosis with interobserver and intraobserver reliability testing, *J Orthop Traumatol* 10(1):22, 2009.

spondylosis.[68] The CDI includes four factors: disc space narrowing, end plate sclerosis, osteophyte formation, and olisthesis (either anterior or posterior), which makes the index more specific. The index is calculated based on a standard four-view cervical radiograph series (anteroposterior, lateral, flexion, and extension views), summing the four factors to achieve the final score for the CDI. A low score represents normal or very few signs of degenerative changes, and a high value represents more degenerative spondylytic changes of the cervical spine on the radiograph. Details of the scoring system can be found in Table 3-9. The overall CDI is thus calculated as the sum of the factor scores at all levels (equivalent to the sum of the level scores across all factors), resulting in a possible CDI score ranging from 0 (normal appearance) to 60 (most severe degeneration at each level). This index is innovative and can provide a score per cervical spine level, per independent factor, and a total for the entire cervical spine. It has been reported to have good intra-rater (0.87-0.89) and inter-rater (0.86) reliability, especially for senior raters. Thus, this index is useful and clinically relevant for the assessment of cervical spondylosis and can have a direct applicability for longitudinal studies of cervical spondylosis.

CERVICAL OSTEOARTHRITIS (OA)

OA in the cervical spine is in effect the later stage of spondylosis, marked by progressive degeneration of the intervertebral disc and especially the zygapophyseal joints (trijoint complex). Although the condition commonly is silent and asymptomatic, osteoarthritic changes can include osteophyte formation, hypertrophy of the synovial membrane, and in some cases a chronic inflammatory response (Figure 3-3). OA involves the zygapophyseal (facet) joints, which show degeneration of the articular surfaces and increased stiffness of the subchondral bone.[6] These changes lead to a decrease in the intervertebral disc space, osteophyte encroachment into the intervertebral foramen, hypertrophy of soft tissue (e.g., the ligamentum flava), and in some cases, encroachment on the spinal cord or vertebral artery.

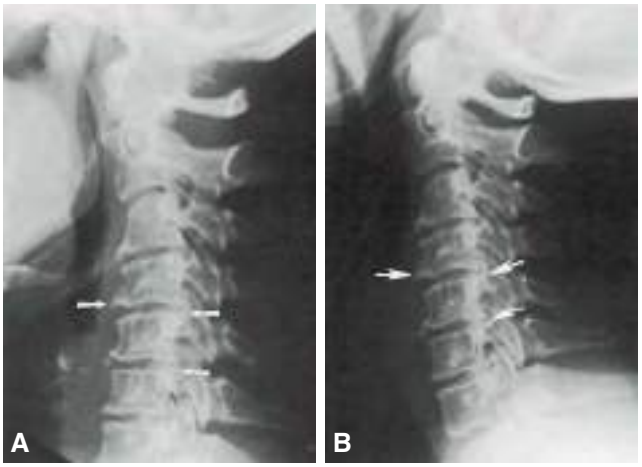

Figure 3-3 X-ray films of a 68-year-old man with multiple radiological signs of cervical osteoarthritis (*arrows*). **A,** The cervical spine in flexion, which is very limited. Note that the atlas tips up, compared with the one shown in **B.** All intervertebral disc spaces below C2-3 are very narrow, and anterior and posterior osteophytes are apparent (*arrows*). The spine extends very little in **B** and is quite straight in **A** (i.e., no significant flexion). (From Bland JH: *Disorders of the cervical spine,* p 213, Philadelphia, 1994, WB Saunders.)

Because of the structures involved and their proximity to the spinal cord, nerve roots, peripheral nerves (especially the sinuvertebral nerve), and in some cases, components of the autonomic system, symptoms can vary widely. They can range from relatively benign effects (e.g., limited ROM with minimal pain) to more severe symptoms involving the spinal cord (myelopathy), nerve roots (painful radiculopathy, sometimes without a predictable pattern), severe pain and muscle spasms, and in some cases, autonomic and brain stem responses.[6] Symptoms commonly are aggravated by movement.

CERVICAL SPINE INSTABILITY

According to Cook et al.,[69] "instability associated with active and neural cervical subsystem failure is identified as clinical cervical spine instability (CCSI)" (p. 896). It also has been called minor cervical instability.[70] Loss of

cervical spine stability may be a significant factor in neck pain in many cases.[71–74] Cervical instability has not been fully defined, and many of the concepts used to describe it are extrapolated from work done on the lumbar region.[75] Panjabi et al.[76] defined clinical stability as "the ability of the spine, under physiological loads, to limit patterns of displacement so as not to damage or irritate the spinal cord or nerve roots, and, in addition, to prevent incapacitating deformity or pain due to structural changes" (p. 313). When the cervical spine demonstrates instability, failure to maintain correct vertebral alignment has occurred,[77] a result either of bony changes or of neuromuscular pathology. The essential feature of stability is therefore the ability of the body to control the full range of joint motion.[78] Thus normally the limits of the stability should provide sufficient support yet allow for the flexibility of normal activities.[54,79–82]

Clinical instability of the spine occurs when the neutral zone increases relative to the total ROM (Figure 3-4). The neutral zone has been shown to increase with intersegmental injury and intervertebral disc degeneration (see the Cervical Spondylosis section)[80,83–85] and to be decreased by the activation of the stabilizing muscle forces across the motion segment. Degeneration and mechanical injury of the cervical stabilization components (e.g., discs, ligaments, and muscles) are the primary causes of increases in the neutral zone.[86]

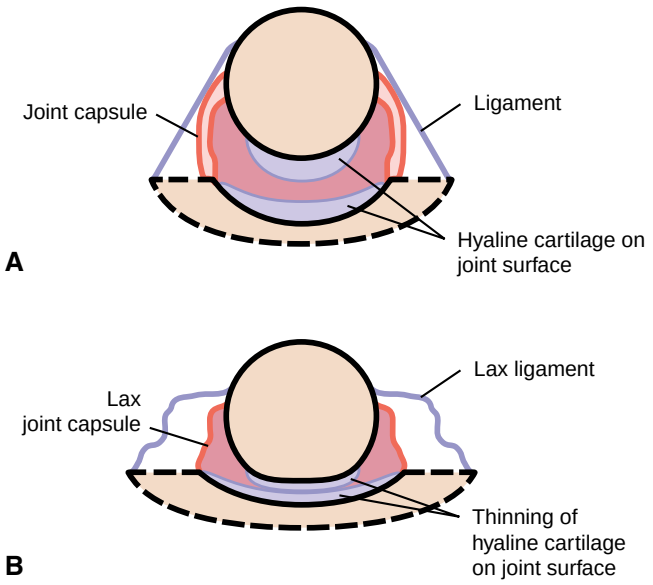

Figure 3-4 Articular instability. **A,** Normal joint with normal stability. Glides and nonphysiological mobility are limited by the joint surfaces and tension in the ligaments and joint capsules. **B,** Degenerative joint with articular instability. Note that the degeneration permits the bone ends to move closer to each other and thereby slacken off the capsule and ligaments. This allows increased nonphysiological motion on stability testing with a normal end feel. Glides and nonphysiological mobility are less limited by the flattened joint surfaces and slackened ligaments and joint capsules. (Modified from Panjabi M: The stabilizing system of the spine. Part II. Neutral zone and instability hypothesis, *J Spinal Disord* 5:390–396, 1992. In Magee DJ, Zachazewski JE, Quillen WS: *Scientific foundations and principles of practice in musculoskeletal rehabilitation*, p 516, St Louis, 2007, Mosby.)

Cervical instability can be secondary to several cervical spine conditions, such as chronic whiplash dysfunction, rheumatoid arthritis, OA, and segmental degeneration, situations involving trauma, genetic predisposition, disk degeneration, cervicogenic headache, systemic disease, or tumors. However, most patients diagnosed with cervical instability suffer from degenerative changes to the motion segment. Niere and Torney[70] defined minor cervical instability as "an increase in the neutral zone associated with one or more segments within the cervical spine. This condition may be associated with a number of signs and symptoms but does not include severe incapacitating pain nor symptoms indicative of spinal cord compression or vertebral artery disruption" (p. 145). It has been proposed that cervical instability may exist where pain and disability occur as a result of lack of control of the neutral zone motion, without compromise of the vascular or neural structures.[70] Minor cervical instability can be demonstrated only through clinical features that make the diagnosis more difficult (Table 3-10).[70]

Unfortunately, there is no gold standard for diagnosing minor cervical instability, nor even an accepted set of associated clinical signs and symptoms.[70] Clinical reasoning plus certain clinical characteristics could help with an approximated diagnosis. Clinical tests have been described to determine cervical instability. However, they have been considered unreliable,[87] or they have been reported to be uncommonly used by practitioners for diagnosing cervical instability.[88] According to Niere and Torney,[70] clinicians have described traction spurs, hypermobility, and anterolithesis on x-rays and clinical signs similar to those seen in Kirkaldy-Willis' unstable phase of cervical spondylosis as a sign of minor cervical instability. Poor motor control has been recognized as a major component of clinical instability.[70] Studies on the lumbar spine have demonstrated that this alteration in motor control can be a factor in the development of lumbar instability.[89–93] It has been hypothesized that aberrant motion (i.e., an instability jog), which is seen with sudden acceleration or deceleration that occurs outside the intended plane of movement in the midranges of active cervical movement, is a cardinal sign of instability.[94]

Other signs of clinical instability are reported to be general tenderness in the cervical region, referred pain to the shoulder and parascapular area, cervical radiculopathy, cervical myelopathy, occipital and frontal or retroorbital headaches, paraspinal muscle spasm, decreased cervical lordosis, and pain with sustained postures.[70,95] According to Niere and Torney[70] and Swinkels et al.,[96] clinical findings associated with cervical instability include neck pain, complaints of catching or locking in the neck, weakness, altered ROM, a history of major trauma or repetitive microtrauma, neck pain and headaches that are provoked by a sustained weight-bearing posture (e.g., sitting) and

TABLE 3-10

Signs and Symptoms of Minor Clinical Cervical Instability

Main Signs and Symptoms	Secondary Signs and Symptoms	Other Signs and Symptoms
• History of major trauma • Catching/locking/giving way • Poor muscular control • Excessively free end feel on palpation • Signs of hypomobility on x-ray film • Unpredictability of symptoms • Spondylolisthesis	• History of repeated microtrauma • Neck weakness (subjective) • Traction spurs • Altered ROM • Neck pain • Muscle spasms • Muscular atrophy • Headaches	• Apprehension when moving into neck extension • Feeling of "heavy head" • Feeling as if the head is dropping off • Episodes with no precipitating cause • Crepitus • Feeling of a lump in the throat • Difficulty returning from extension • Poor response to previous treatment and good response to stabilizing treatment • Shoulder girdle weakness and atrophy

Modified from Niere KR, Torney SK: Clinicians' perceptions of minor cervical instability, *Man Ther* 9:144-150, 2004; and Cook C, Brismée JM, Fleming R et al: Identifiers suggestive of clinical cervical spine instability: a Delphi study of physical therapists, *Phys Ther* 85(9):895-906, 2005.

relieved by non–weight-bearing postures (e.g., lying supine), hypermobility with a soft end feel during passive intervertebral motion testing, and poor cervical muscle strength (e.g., the multifidus, longus colli, and longus capitis).[69] Shaking and poorly controlled (aberrant) motion during active cervical ROM also have been mentioned.[71] Cook et al.[69] used similar signs and symptoms when describing cervical spinal instability when questioning practitioners about key features of cervical instability. For example, they found that "intolerance to prolonged static postures" was the symptom identifier that was most related to cervical instability. "Fatigue and inability to hold head up" ranked second, followed by "better with external support, including hands or collar." Regarding physical examination findings, clinicians thought that "poor coordination and neuromuscular control, including poor recruitment and disassociation of cervical segments with movement" were the most related physical examination findings to cervical instability followed by "abnormal joint play."[69] In a survey conducted in Australia on upper cervical instability, practitioners felt that increased mobility on passive testing, dizziness, headaches, upper cervical pain, nausea and/or vomiting, suboccipital pain, and bilateral or quadrilateral paresthesia were signs and symptoms that characterized this condition.[9] According to Paris,[97] instability exists only when an aberrant motion, such as a visible slip, catch, or shaking, occurs (i.e., an instability jog) or when a palpable difference in bony position can be noted between standing and lying supine. Poor motor control and an inability to initiate cocontraction of the local muscle system in the neutral zone have been observed in many patients.[93]

Generally patients with cervical instability develop compensatory movements to stabilize the motion segment. Because the patient does not have good control of deep spinal muscles (e.g., the multifidus, intertransversarii, and longissimus), the body tries to recruit global muscles to maintain segmental stability. This action also has been seen in patients with neck pain and whiplash.[98–100] Tables 3-11 and 3-12 present summaries of the variables and factors related to minor cervical instability as described by Niere and Torney.[70]

The lack of specific or sensitive diagnostic tools complicates the diagnosis of cervical instability. O'Sullivan[92] maintains that radiological evidence of intersegmental motion of a single motion segment is significant only if this finding is supported by clinical evidence of segmental instability at the corresponding segmental level. The diagnosis still relies on clinical findings: history, subjective complaints, visual analysis of the active motion quality, and manual examination.[71]

Upper cervical instability is a controversial topic, and the literature lacks consensus on its clinical aspects.[96] However, instability in the upper cervical spine is a major concern for clinicians because inappropriate treatment in this area can have severe consequences (i.e., paralysis or death).[71,101] According to Swinkels and Oostendorp,[102] upper cervical instability should be considered a special subcategory of general cervical instability because it is doubtful whether upper cervical instability occurs in patients without an inflammatory process (e.g., rheumatoid arthritis) or congenital problems (e.g., Down's syndrome). In fact atlantoaxial instability and hypermobility occur more frequently and most clearly in patients with rheumatoid arthritis, and in most cases without neurological signs.[102] Muscle action compensation could be argued to be a response of upper cervical instability without symptoms. A case study of upper cervical instability secondary to rheumatoid arthritis was published showing typical signs and symptoms of this condition.[103] This highlighted the importance of a good physical assessment performed by first contact practitioners to be able to recognize upper cervical instability, a condition which contraindicates manual treatment and requires immediate referral and further investigation of symptomatology. Practitioners working with manual techniques must be

TABLE 3-12

Factors Related to Cervical Instability

Passive Dysfunction	Active Dysfunction	Cervical Pattern	Movement Abnormality
• Traction spurs • Signs of hypomobility on x-ray films • Spondylolisthesis • History of repeated microtrauma • History of major trauma	• Poor motor control • Neck weakness (subjective) • Unpredictability of symptoms • Catching/locking/giving way, as well as muscular atrophy	• Headaches • Neck pain • Muscle spasm • Muscular atrophy	• Excessively free end feel on palpation • Altered ROM • History of major trauma

From Niere KR, Torney SK: Clinicians' perceptions of minor cervical instability, *Man Ther* 9(3):144-150, 2004.

aware of this condition and have the skills to detect it to avoid negative outcomes.

Atlantoaxial subluxation is the most common type of cervical spine instability in patients with rheumatoid arthritis, with a quoted incidence of 50% to 70%.[104] Inflammation and pannus formation in and around the transverse and alar ligaments cause the instability seen in rheumatoid arthritis. Other conditions associated with upper cervical instability are ankylosing spondylitis, psoriatic arthritis, and Reiter's syndrome.[104]

Suspicion of upper cervical instability is based on clinical signs, such as neck pain, the most common symptom (Table 3-13). Seventy percent of patients have pain in the upper cervical or suboccipital area, with variable radiation to the mastoid, occipital, temporal, or frontal region. Other signs that may be present include limitation of neck movements, torticollis (a cardinal sign in the early phase), and neurological signs (e.g., hyperreflexia, paresthesia, coordination problems when walking, and spasticity or pareses). Hypoesthesia is seen less frequently.

Upper cervical instability is commonly diagnosed using a radiological criterion known as the **Atlas-Dens Interval (ADI)**.[105] A consensus meeting of the American Roentgen Ray Society[106,107] set the upper limit for the ADI at 2.5 to 3 mm for adults and 4.5 to 5 mm for children. X-ray examinations have some restrictions, and other concerns include standardization of techniques, faults in measurements, and problems with standards of normalization. Thus a conventional x-ray study can fail to provide adequate information about atlantoaxial stability. According to some radiographic studies, no correlation has been found

TABLE 3-13

Signs and Symptoms of Upper Cervical Instability

Neurological Signs	Clinical Symptoms	Radiological Signs

• Hyperreflexia
• Paraesthesia
• Coordination problems in walking
• Spasticity or pareses
• Hypoesthesia in the area of the occipitalis major nerve (less frequent)
	• Pain in the upper cervical or suboccipital areas (70%)
	• Variable radiation to mastoid, occipital, temporal, or frontal regions
	• Limitation of neck movement
	• Torticollis
		• Atlas-Dens Interval (ADI):
		  • Adult limit: 2.5-3 mm
		  • Child limit: 4.5-5 mm

Modified from Swinkles R, Beeton K, Alltree J: Pathogenesis of upper cervical instability, *Man Ther* 1:127-132, 1996; and Swinkles RA, Oostendorp RA: Upper cervical instability: fact or fiction? *J Manip Physiol Ther* 19:185-194, 1996.

between the amount of atlantoaxial dislocation and the presence of neurological symptoms.[105,106] Most patients with rheumatoid arthritis tolerate atlantoaxial instability without neurological symptoms because the spinal cord tolerates gradually applied pressure surprisingly well.[98]

Clinical tests to detect upper cervical instability, such as the lateral shift test of C1, upper cervical flexion test, Sharp-Purser test, rotation test of C2 coupled with side flexion of the head, and anterior shift of the atlas compared with the dens axis,[107] are disputable, and according to Swinkels and Oostendorp,[102] no information is available about the reliability and validity of these tests. Surgical treatment for cervical instability is reserved for patients with severe neurological involvement. The objective of conservative treatment of clinical cervical instability is to increase the function of the muscular and neural systems so as to decrease the stress on the spinal segments.[77,81] Slater et al.[103] recommended cervical isometric stabilization exercises, controlled soft tissue stretches within the pain-free range, advice on the use of active ROM rotational and side flexion exercises, and information about symptoms that could prompt a patient to seek further assessment to treat cervical instability.

The objective of the stabilization exercises commonly incorporated into rehabilitation programs is to restore (i.e., reduce) the size of the neutral zone in order to restore the normal arthrokinematic motion that occurs when minimal forces are imposed on the spine.[104] The methods of restoring the neutral zone in rehabilitation are evident, and they include reeducation of the neurofeedback loop system, which includes muscles, tendons, and receptors.[104]

FACET (APOPHYSEAL OR ZYGAPOPHYSEAL) JOINT SYNDROME

The posterior joints of the vertebrae have a surface area that is approximately two thirds the size of the surface area of the intervertebral disc; they also have relatively lax and richly innervated capsules, and they are covered with hyaline cartilage.[6] The joints aid stability but are not primarily weight bearing.[6] As a result of disc degeneration or trauma, the mechanical load on the facet joints can be increased. This increased load may cause a synovial reaction, cartilage fibrillation, erosion of the joint surface, and in rare cases loose bodies. In most cases facet joint syndrome is believed to be the result of a synovial reaction that manifests itself symptomatically as muscle spasm and pain. These symptoms (i.e., pain and spasm) may be referred into specific areas, depending on the facet joint involved (Figure 3-5). This pattern of symptom referral is different from normal dermatome patterns.[108,109] Similarly ROM may be decreased. In some patients the condition is thought to be an early case of OA of the facet joints.

DISC HERNIATION

Disc herniation can occur in the cervical spine, although it is much less common than in the lumbar spine. The condition seems particularly to affect males in their 30s, and the discs most commonly affected are those between

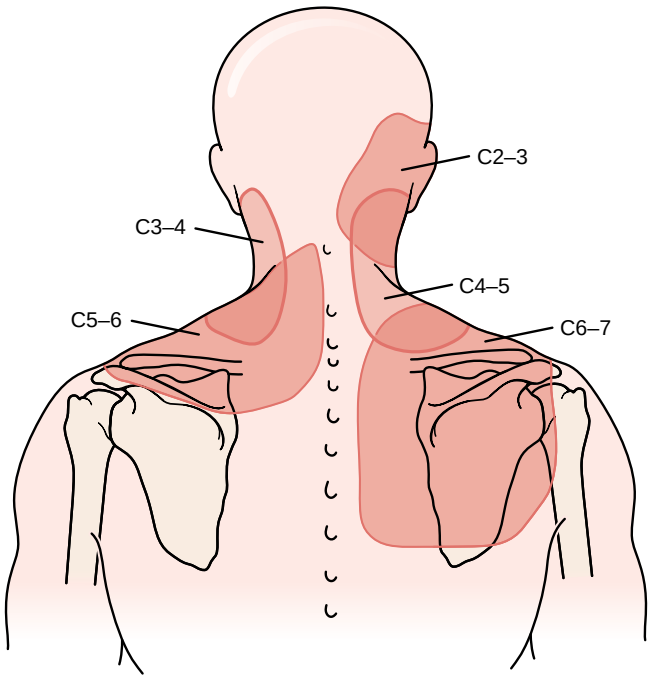

Figure 3-5 Referred pain patterns that can occur with pathology of the zygapophyseal joints. (Redrawn from Porterfield JA, DeRosa C: *Mechanical neck pain: perspective in functional anatomy,* p 104, Philadelphia, 1995, Saunders; modified from Dwyer A, Aprill C, Bogduk N: Cervical zygapophyseal joint pain patterns, *Spine* 15:453-457, 1990.)

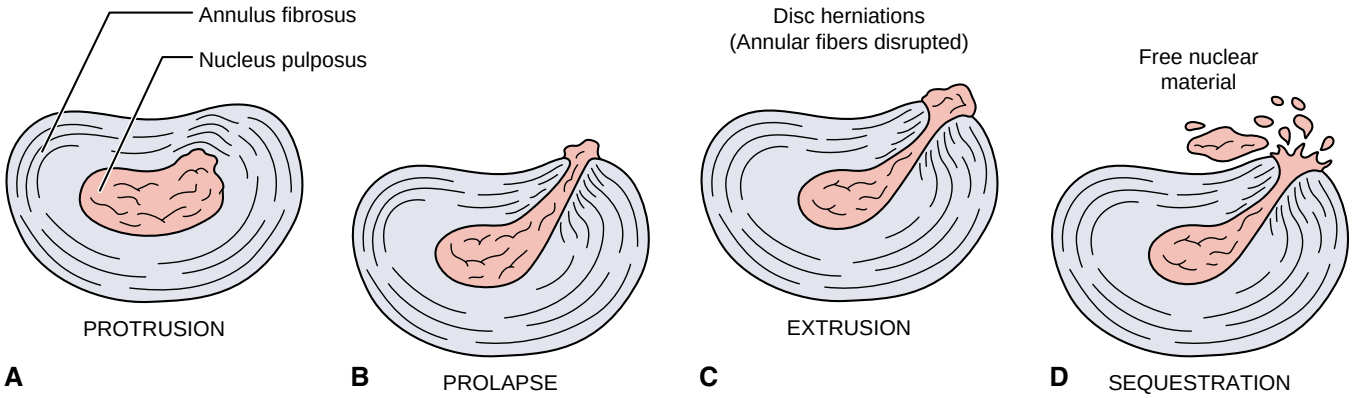

Figure 3-6 Types of disc herniations. **A,** Protrusion. **B,** Prolapse. **C,** Extrusion. **D,** Sequestration. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 553, St Louis, 2014, Elsevier/Saunders.)

C5-6 and C6-7.[110] Disc herniations can range from protrusion and bulging of the disc without rupture of the annulus fibrosus to sequestration of the disc, which results in discal fragments from the annulus fibrosus and nucleus pulposus outside the disc proper (Figure 3-6).[107–111] Between these two extremes are disc prolapse, in which the outermost fibers of the annulus fibrosus contain the nucleus, and disc extrusion, in which the annulus fibrosus is perforated and discal material moves into the epidural space.[107,111]

Disc herniations may occur in any direction, but posterior and posterolateral herniations produce the greatest number of clinical signs and symptoms. Central posterior herniations lead to pain that radiates into the limbs bilaterally and to myelopathic symptoms (Table 3-14).[3] However, because of the strength of the posterior longitudinal ligament, patients more commonly present with posterolateral protrusions that cause unilateral symptoms (radicular pain) in the upper extremity.[3] In most cases cervical disc herniations are acute, and the patient complains of pain or aching

TABLE **3-14**

Signs and Symptoms of Motor and Sensory Changes in Cervical Myelopathy

Initial Symptoms (Predominantly Lower Limbs)	Later Symptoms (In Order of Occurrence)
• Spastic paraparesis • Stiffness and heaviness, scuffing of the toe, difficulty climbing stairs • Weakness, spasms, cramps, easy fatigability • Decreased power, especially of flexors (dorsiflexors of ankles and toes; flexors of hips) • Hyperreflexia of knee and ankle jerks, with clonus • Positive Babinski's sign, extensor hypertonia • Decreased or absent superficial abdominal and cremasteric reflexes • Drop foot crural monoplegia	• Various combinations of upper and lower limb involvement • Mixed picture of upper and lower motor neuron dysfunction • Atrophy, weakness, hypotonia, hyperreflexia to hyporeflexia, and absent deep tendon reflexes • Headache and head pain • Neck, eye, ear, throat, or sinus pain • Sensory symptoms in the pharynx and larynx • Paroxysmal hoarseness and aphonia • Rotary vertigo • Tinnitus synchronous with pulse or continuous whistling noises • Deafness • Oculovisual changes: Blurring, photophobia, scintillating scotomata, diplopia, homonymous hemianopsia, and nystagmus • Autonomic disturbance: Sweating, flushing, rhinorrhea, salivation, lacrimation, nausea, and vomiting • Weakness in one or both legs, drop attacks with or without loss of consciousness • Numbness on one or both sides of the body • Dysphagia or dysarthria • Myoclonic jerks • Hiccups • Respiratory changes: Cheyne-Stokes respiration, Biot's respiration, or ataxic respiration

Data from Bland J: *Disorders of the cervical spine: diagnosis and medical management*, Philadelphia, 1994, Saunders.

and has limited functional ROM of the cervical spine.[112] Although the pain may be referred, it does not always follow a normal dermatomal pattern because more than one nerve root tends to be involved.[112] If the upper nerve roots are involved, the patient may also complain of headaches.[112]

SPINAL STENOSIS

Spinal stenosis generally is an uncommon problem in the cervical spine except as a secondary (i.e., acquired) result of degeneration or trauma. However, with a developmental stenosis (i.e., present at birth) of the spinal canal, degenerative symptoms may appear sooner because congenital spinal stenosis has been combined with the acquired spinal stenosis from spondylosis or trauma (Table 3-15).[113,114] With activities that put stress on the head, resulting in spinal compression, unilateral or bilateral neurological signs may result.[115] Spinal stenosis is diagnosed if the sagittal diameter of the spinal canal is less than 13 mm.[6] Acquired spinal stenosis may be due to disc herniation (all four types), hypertrophy of the ligamentum flava, osteophytes, an inflammatory response, or hypertrophy of the lamina or facet joints. Differential diagnosis of spinal stenosis must include elimination of other conditions (see the following sections). If the problem is due to an inflammatory response, physical therapy may be useful. If the problem is due to structural change, surgery may be indicated.

Differential Diagnosis of Central Spinal Stenosis

- Vascular claudication
- Diabetic neuropathy
- Other peripheral neuropathies
- Motor neuron disease
- Multiple sclerosis
- Other central nervous system lesions
- Spinal infections (acute, subacute, and chronic)
- Neoplasms (involving the cauda equina, spinal nerves, or vertebrae)

From Kirkaldy-Willis WH: *Managing low back pain*, p. 103, New York, 1983, Churchill-Livingstone.

TABLE 3-15

Classification of Spinal Stenosis

Congenital/Developmental
Acquired
• Degenerative (central, lateral, or both)
• Combined (with disc herniation, with developmental stenosis, or with both)
• After laminectomy (scarring)
• After fusion (above the fusion, beneath the fusion)
• Trauma (early and late changes)
• Paget's disease
• Fluorosis

From Kirkaldy-Willis WH: *Managing low back pain*, p 103, New York, 1983, Churchill Livingstone.

CERVICAL MYELOPATHY

In cervical myelopathy, the spinal cord is compromised as a result of compressive, tensile, or torsional forces being applied to the spinal cord, which are caused by stenosis, spondylosis, disc herniation, or trauma.[116,117] These forces lead to compression and ischemia of the anterior and sometimes the posterior aspect of the spinal cord.[6,51] Cervical myelopathy is most commonly seen as a spinal cord "disease" after middle age. This syndrome is the result of something disrupting or interrupting the normal transmission of neural signals along the spinal cord, resulting in the arms, hands, legs, and/or bowel and bladder being affected. This "something" may include trauma, inflammatory and autoimmune disorders, tumors, viral infections, or degenerative processes. The condition usually has an insidious onset, and the signs and symptoms can be quite variable depending on the spinal level involved and the pattern of involvement. These signs and symptoms are highly variable (see Table 3-14) and may be progressive and unrelenting or intermittent and steplike. They may also be associated with multiple remissions.[116] Cervical pain and signs related to cervical movement are not common.[116] This variability of symptoms often results in confusing diagnoses; consequently, the interval between the development of initial symptoms and final diagnosis can be as long as 1.5 to 4 years.[6] Decompression surgery is commonly performed to prevent progression of symptoms by removing the structures causing the pressure, although it should be noted that the surgery may not result in a clinical improvement.

VERTEBROBASILAR ARTERY INSUFFICIENCY

Vertebrobasilar artery insufficiency is not a common condition. However, both vertebrobasilar artery insufficiency and internal carotid artery insufficiency can lead to significant problems.[6] Injury to the lining of the vessels can lead to thrombotic occlusion, artery dissection, pseudoaneurysm, or subintimal hematoma from manipulation of the spine, overhead work, or traction.[118] Normally the vertebral artery, which supplies approximately 20% of the blood to the brain (the internal carotid supplies approximately 80%), runs cephalically through openings in the transverse processes of the cervical spine. Once past the transverse processes of C2, the course that the arteries must take to enter the skull en route to the brain causes them to "kink." As a consequence of this route and because the artery is tethered at the atlantooccipital membrane, at the C1 transverse foramen and at the C2 transverse process along with the kinking, these arteries are at risk from forces that cause excessive traction or compressive stress on the vessels. Excessive force or motion in rotation and extension can reduce the circulation and potentially injure the vessel lining of these arteries.[6,118,119] If this reduction in circulation with movement, which is normal, especially

in rotation or extension, is combined with degenerative or other changes in the area, the circulation to the brain stem may be further compromised; this can lead to signs and symptoms of vertebrobasilar artery insufficiency (Tables 3-16 and 3-17) or internal carotid artery insufficiency (Table 3-18), resulting from ischemia of the brain stem, cerebellum, cerebrum visual cortex, and vestibular apparatus.[6,119] Injury to the vessels can lead to quadriplegia or death.[119] Although injury to the vertebral artery and internal carotid artery is rare, clinicians treating the cervical spine should always have an understanding of possible accompanying risk factors as well as what factors should be assessed when looking for vascular problems.

Vascular Risk Factors

- Hypertension
- Hypercholesterolemia (high cholesterol)
- Hyperlipidemia (high fat)
- Hyperhomocysteinemia (hardening of the arteries)
- Diabetes mellitus
- General clotting disorders
- Infection
- Smoking
- Direct vessel trauma
- Iatrogenic causes (surgery, medical interventions)

Data from Kerry R, Taylor AJ: Cervical arterial dysfunction assessment and manual therapy, *Man Ther* 11:243-253, 2006.

TABLE **3-16**

Classic Signs and Symptoms of Vertebrobasilar Insufficiency with Associated Neuroanatomy

Sign or Symptom	Associated Neuroanatomy
Dizziness (vertigo, giddiness, lightheadedness)	Lower vestibular nuclei (vestibular ganglion = nuclei of CN VIII vestibular branch)
Drop attacks (loss of consciousness)	Reticular formation of midbrain Rostral pons
Diplopia (amaurosis fugax; corneal reflux)	Descending spinal tract, descending sympathetic tracts (Horner's syndrome); CN V nucleus (trigeminal ganglion)
Dysarthria (speech difficulties)	CN XII nucleus (medulla, trigeminal ganglion)
Dysphagia (+ hoarseness/hiccups)	Nucleus ambiguous of CN IX and X, medulla
Ataxia	Inferior cerebellar peduncle
Nausea	Lower vestibular nuclei
Numbness (unilateral)	Ipsilateral face: descending spinal tract and CN V Contralateral body: ascending spinothalamic tract
Nystagmus	Lower vestibular nuclei + various other sites depending on type of nystagmus (at least 20 types)

From Kerry R, Taylor AJ: Cervical arterial dysfunction assessment and manual therapy, *Man Ther* 11:245 2006.

TABLE **3-17**

Presentations of Vertebral Artery Dissection

Nonischemic (Local) Signs and Symptoms	Ischemic Signs and Symptoms
• Ipsilateral posterior neck pain/occipital headache • C5-6 cervical root impairment (rare)	• Hindbrain transient ischemic attack (dizziness, diplopia, dysarthria, dysphagia, drop attacks, nausea, nystagmus, facial numbness, ataxia, vomiting, hoarseness, loss of short-term memory, vagueness, hypotonia/limb weakness [arm or leg], anhidrosis [lack of facial sweating], hearing disturbances, malaise, perioral dysthesia, photophobia, papillary changes, clumsiness and agitation) • Hindbrain stroke (e.g., Wallenberg's syndrome, locked-in syndrome) • Cranial nerve palsies

Nonischemic symptoms may precede ischemic events by a few days to several weeks.

From Kerry R, Taylor AJ: Cervical arterial dysfunction assessment and manual therapy, *Man Ther* 11:245, 2006.

TABLE **3-18**

Clinical Features of Internal Carotid Artery Dissection

Nonischemic (Local) Signs and Symptoms	Ischemic (Cerebral or Retinal) Signs and Symptoms

• Head/neck pain
• Horner's syndrome
• Pulsatile tinnitus
• Cranial nerve palsies (most commonly CN IX to XII)
• Less common local signs and symptoms include:
  • Ipsilateral carotid bruit
  • Scalp tenderness
  • Neck swelling
  • CN VI palsy
  • Orbital pain
  • Anhidrosis (facial dryness)
	• Transient ischemic attack (TIA)
	• Ischemic stroke (usually middle cerebral artery territory)
	• Retinal infarction
	• Amaurosis fugax

Nonischemic signs and symptoms may precede cerebral/retinal ischemia by anything from a few days to over a month.

From Kerry R, Taylor AJ: Cervical arterial dysfunction assessment and manual therapy, *Man Ther* 11:248, 2006.

Assessing for Vascular Problems

- Risk factors
- Position testing (especially rotation and extension) for symptoms
- Cranial nerve examination
- Eye examination
- Blood pressure examination
- "Headache like no other"
- Autonomic nervous system examination

Data from Kerry R, Taylor AJ: Cervical arterial dysfunction assessment and manual therapy, *Man Ther* 11:243-253, 2006.

Barré-Léou syndrome, also known as *posterior cervical sympathetic syndrome*, involves both the sympathetic nervous system and the vertebral artery. It causes a widespread and diverse combination of signs and symptoms.[6] Basically, the symptoms are the result of compression on the posterior cervical sympathetic system and its innervation of the vertebral artery, which lies close by.

CERVICAL ANOMALIES

Although relatively rare, congenital anomalies can be found in the cervical spine. They are not usually found in isolation but are associated with other developmental skeletal defects, such as dysplasia.[6,120] Many anomalies cause no signs or symptoms and are discovered on a cervical x-ray film taken for other reasons. Some patients present with signs and symptoms later in life as degeneration contributes to the effect of the anomaly; other anomalies, although rare, may be incompatible with life.[6]

Cervical anomalies may combine bone and nerve defects.[121–124] Bony anomalies are of concern primarily in terms of their effect on cervical stability, especially in the upper cervical spine, as well as the narrowing (stenosis) of the spinal canal and the effect this narrowing may have on the neural structures.[120,122,123]

As mentioned previously, Klippel-Feil syndrome (Figure 3-7) is a condition in which two or more vertebral bodies are fused, which occurs during embryological development.[124] Approximately 50% of patients with Klippel-Feil syndrome have a low posterior hairline, limited ROM, and an apparent short neck,[124] although some may appear normal.

Cervical ribs (Figure 3-8) are another anomaly that may be related to the cervical spine, and this condition is often grouped with a number of conditions under thoracic outlet syndrome. These anomalous ribs, which may be bony or cartilaginous, arise from the costal processes of the vertebral bodies. They usually are asymptomatic but may cause brachial plexus symptoms, especially of the lower nerve roots (C7, C8, and T1), as well as evidence of nervous or arterial compression.[6]

CERVICOGENIC HEADACHE

Cervicogenic headache is pain referred to the head from a source in the cervical spine.[125] Although the International Headache Society recognizes cervicogenic headache as a distinct disorder,[126] the concept of cervicogenic headache has not been fully accepted. The prevalence of cervicogenic headache is variable depending on the population and diagnosis criteria used to make the diagnosis. It has been reported to be 1%, 2.5%,[127] or 4.1%[128] in the general population when the clinical criteria has been used and as high as 17.5% among patients with severe headaches.[128] Patients after WAD present a prevalence of cervicogenic headache as high as 53%.[129] In fact the presence of trauma has been considered one of the distinct criteria for cervicogenic headache because all studies that have implicated the C2-3 zygapophyseal joint as a source of cervicogenic headache have been conducted in patients with a history of trauma.[125] As occurs in most headache forms, the incidence of cervicogenic headache is more prevalent in females.[130] The onset of cervicogenic headache is not age specific and can be associated with degenerative joint disease or a sedentary lifestyle. The history is often prolonged.[130] According to Andersen et al.,[131] cervicogenic headache is a complex syndrome, and its pathophysiology is far from simple. The involvement of musculoskeletal structures (i.e., nociceptive pain), sensory nerves and nerve roots (i.e., neuropathic pain), and referred pain can be implicated. Even if no definitive damage can be found in patients with cervicogenic headache, the presence of some axonal dysfunction cannot be excluded. Also, central sensitization of the central nervous system (CNS) may explain the chronicity of this syndrome.

The pathophysiological mechanisms underlying cervicogenic headache have not been clearly demonstrated; however, there is some evidence that the fundamental mechanism must be convergence.[64,132,133] The neuroanatomic relationship between the cervical spine and craniofacial pain is provided by the interconnection between the trigeminal nerve and first cervical nerve roots. Studies in animals have supported this connection.[134–137] The communication between the trigeminal nerve and first three levels of the cervical spine is so close that they merge into a single column of gray matter, and, as a result, they are not differentiated anatomically, functionally, or pathologically.[127] This convergence is the foundation of referred pain in the head and upper neck. Nevertheless, the reference pattern is more common in the region innervated by the ophthalmic branch of the trigeminal nerve than in the maxillary or mandibular branches because the maxillary and mandibular afferents in the spinal tract of the trigeminal nerve do not extend as far caudally into the cervical segments as do the ophthalmic afferents.[138,139]

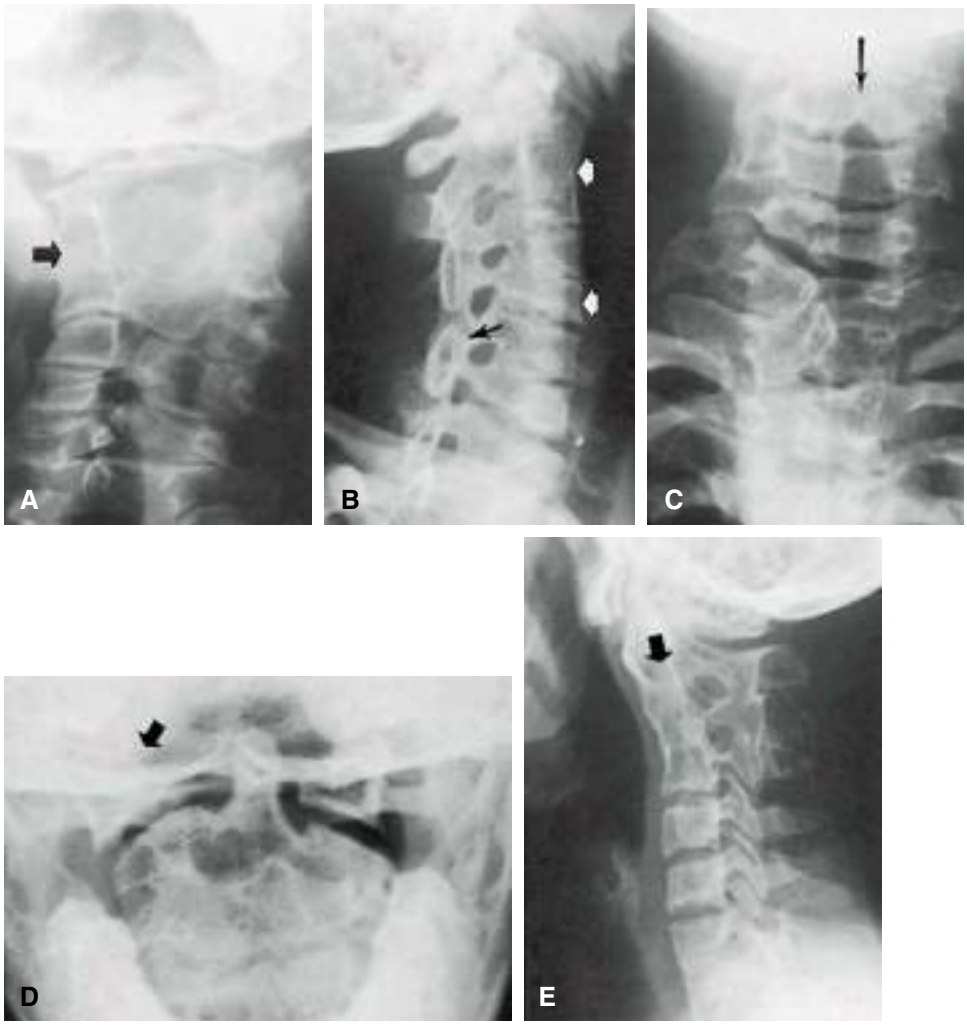

Figure 3-7 **A,** Anteroposterior view of the cervical spine of a 31-year-old man with Klippel-Feil syndrome shows fused C2 and C3 vertebrae (*arrow*), a hemivertebra at C5, spina bifida, and scoliosis of the cervical spine. The patient was asymptomatic and had an incidental radiological study for an injury. **B,** Lateral view of the cervical spine of a 12-year-old boy with Klippel-Feil syndrome shows fusion of the C2 and C3 vertebrae (*upper white arrow*) and only partial fusion with poorly developed disc spaces at C3-4, C4 to C6, and C6-7. A hemivertebra is seen at C5 (*lower white arrow*). The zygapophyseal joint is fused at C3-4 and C5-6 (*black arrow*). **C,** Anteroposterior view of **B** shows a butterfly vertebra (C3 and C4, *arrow*) and hemivertebrae (C7 to T1). T2 and spina bifida are seen just above the level of the first rib. In other views, a surprising amount of remodeling and osteophytosis is seen. **D,** Open-mouth view of **B** shows deviation of the odontoid process to the right, the result of having two sets of posterior elements on the left (*arrow*) and only one on the right. **E,** Lateral view of the cervical spine of a 15-year-old girl with Klippel-Feil syndrome shows fusion of the C2-3-4 vertebrae (*arrow*) and a kyphotic deformity of the cervical spine. Fusion also occurred at C7 through T3, and a hemivertebra is seen at C7. The neck was not short, and no evidence of basilar impression or occipitalization of the atlas was noted. The patient was asymptomatic. (From Bland JH: *Disorders of the cervical spine,* p 425, Philadelphia, 1994, Saunders.)

Another source of referred pain from the cervical spine to the head is provided by the innervation coming from the upper cervical nerve roots (Table 3-19).[138,140–142] The atlantooccipital joint is innervated by the C1 ventral ramus and the lateral atlantoaxial joint by the C2 ventral ramus; the C2-3 zygapophyseal joints are innervated by the C3 dorsal ramus. All three nerves of the upper cervical spine intermingle at multiple segments and converge with the trigeminal afferents on cells in the dorsal gray column of the C1 to C3 segments. Because of this convergence, pain from any of the upper three cervical synovial joints could be perceived in the same region and referred to the occiput and to regions innervated by the trigeminal nerve.[142–149]

The Quebec Headache Study group has stated that cervical facet dysfunction is probably the most important clinical source of cervicogenic headache.[150] In addition, the best available evidence indicates that the C2-3 zygapophyseal joints are the most common source of cervicogenic headache[129,145,151,152] accounting for approximately 70% of cases.[147] Some investigators have proposed the idea that cervicogenic headache can be caused by dysfunction of the lower cervical segments based on the evidence that some patients with lower cervical radiculopathy also have headache and were relieved of their headache pain after the radiculopathy had been treated surgically.[153] Although these data show an association between headache and lower cervical segments,

Figure 3-8 Anteroposterior view of the cervical spine of a 21-year-old man whose incidentally discovered cervical ribs became typically symptomatic after an automobile accident resulted in a neck injury (*arrows*). (From Bland JH: *Disorders of the cervical spine,* p 427, Philadelphia, Saunders, 1994.)

neuroanatomically, there is no direct link between lower cervical afferents and the trigeminocervical nucleus, and thus it does not seem plausible that cervicogenic headache can be caused by the lower cervical segments.

Another origin of cervicogenic headache may be the dura mater; headache can occur as a result of tension and/or pressure on the dura mater. The cranial dura mater is innervated by the trigeminal, vagus, and hypoglossal nerves and the upper cervical nerves. Hack et al.[154] found that an anatomical connection existed between the rectus posterior minor muscle and the dura mater, and as a result contraction of the rectus posterior muscle might cause tension on the dura mater, leading to a headache. Several cervical structures, such as the skin, the cervical muscles and their attachments, the capsules of the cervical joints, and discs, ligaments, nerves, and nerve roots, are thought to be possible origins of cervicogenic headache.[142]

According to Pereira Monteiro,[155] the clinical limits of cervicogenic headache have not yet been well defined. Cervicogenic headache is estimated to account for 15% to 20% of all chronic and recurrent headaches,[156,157] and cervicogenic headache is the most common persistent symptom following neck trauma.[144,145] According to Sjaastad et al.,[158] cervicogenic headache is characterized by predominantly unilateral symptoms, always on the same side, that are precipitated by neck movement or sustained neck postures or by pressure on certain tender spots in the neck. There is a variable presence of pain, stiffness, and decreased ROM of the neck and ipsilateral shoulder or arm pain.

From a classification standpoint, the implication of unilateral signs and symptoms in cervicogenic headache is fundamental.[159–161] However, Watson and Trott[162] have reported that cervicogenic headache can be bilateral with one side predominant. Side consistency is evident with cervicogenic headache; this means that the side on which the signs and symptoms appear should not change with different attacks, as occurs with migraine headaches. Although unilaterality has been used as diagnostic criteria, Sjaastad and Bakketeig,[163] the authors of the diagnosis criteria, have recognized that unilaterality is rare and generally is seen only in mild cases of cervicogenic headache. When the headache is severe, bilateral pain is present. Cervicogenic headache headache is typically associated with pain in the neck or suboccipital region.[164] By definition, the pain can be mechanically provoked or intensified, and it radiates in

TABLE **3-19**

Innervation Provided by Upper Cervical Nerves (C1, C2, and C3) to Different Structures

Structures	C1	C2	C3
Tissues	Sensory information to deep suboccipital tissues Vertebral internal carotid Paramedian dura of the posterior cranial fossa	Skin of the occiput, transverse ligament of Atlas, and membrane tectoria Vertebral internal carotid Paramedium dura (through its sinuvertebral nerve itinerates)	Atlantoaxial ligaments and the dura matter of the spinal cord and clivus Vertebral internal carotid
Muscles	Sensory of cervical prevertebral muscles (longus capitis, longus cervicis, rectus capitis anterior, lateralis, ECM, and trapezius)	Major part of the upper neck muscles, splenius capitis, semispinalis capitis, and longissimus capitis	Splenius capitis, splenius cervicis, and longissimus capitis Deeper branch supplies semispinalis cervicis and multifidus Superficial branch innervates semispinalis capitis
Joints	Atlantooccipital joint Median atlantoaxial joint	Atlantoaxial joint; through its sinuvertebral nerve innervates the median atlantoaxial joint	C2-C3 zygapophyseal joint C2-C3 disc

From Bogduk N: Cervicogenic headache: anatomic basis and pathophysiologic mechanisms, *Curr Pain Headache Rep* 5:382-386, 2001.

an atypical distribution from the occipital to the frontotemporal and orbital regions. In some cases, the face and ipsilateral shoulder and arm, without any definitive radicular pattern, are also affected. Nausea, vomiting, phonophobia and photophobia, and ipsilateral visual blurring may occur, as well as dizziness and difficulty swallowing.[165]

The intensity of cervicogenic headache can be mild, moderate, or severe, but it most commonly is moderate. It can fluctuate in intensity between headache periods and even within a single headache period. Lying down and resting may help, as does simple analgesia for some patients. Table 3-20 presents Sjaastad's diagnostic criteria[160,161] for cervicogenic headache. Alteration of the neck ROM generally is seen with cervicogenic headache, and it has been defined as a distinctive feature in the diagnosis of these patients.[151,155] Impaired neck mobility in the cardinal plane is a diagnostic criterion of cervicogenic headache.[161–166]

A systematic review[167] and meta-analysis about cervical impairments in cervicogenic headache supported the statement that patients with cervicogenic headache presented with altered ROM in all planes when compared with normal subjects. Moreover, it was found that cervical rotation movement with cervical flexion (i.e., the cervical flexion-rotation test) was very limited in patients with cervicogenic headache, supporting the finding that patients with cervicogenic headache have limited function in the upper cervical segments.[142] When all studies were added together for the meta-analysis,[168–171] it was found that patients with cervicogenic headache had a reduced ROM in all directions (i.e., flexion-extension, lateral bending, and rotation) when compared with a control group. Complete cervical rotation and flexion-extension movements were the most affected in patients with cervicogenic headache when compared with control subjects. When pooling the results of two studies[169,172] investigating the cervical ROM of rotation with cervical flexion, it was found that patients with cervicogenic headache presented with reduced ROM when compared with control groups. This information has been confirmed by a systematic review performed by Snodgrass et al.[173] Restricted cervical extension and altered cervical rotation test appeared to

TABLE 3-20

Major and Minor Criteria for Cervicogenic Headache

Major Criteria	Symptoms and signs of neck involvement. One or more of the following three phenomena must be present:
	• Precipitation of head pain similar to that which usually occurs by:
	  ○ Neck movement and/or a sustained, awkward head position, and/or
	  ○ External pressure over the upper cervical or occipital region on the symptomatic side
	• Restriction of ROM in the neck
	• Ipsilateral neck, shoulder, or arm pain of a rather vague, nonradicular nature or occasionally arm pain of a radicular nature
	Confirmatory evidence by diagnostic anesthetic blockages
	Unilateral head pain without side shift
	Head pain characteristics:
	• Moderate-to-severe, nonthrobbing pain that usually starts in the neck
	• Episodes of varying duration or fluctuating, continuous pain

Minor Criteria	Other characteristics of some importance:
	• Only marginal effect or lack of effect of indomethacin
	• Only marginal effect or lack of effect of ergotamine and sumatriptan
	• Female gender
	• Not infrequent head or indirect neck trauma by history, usually of more than moderate severity
	Other features of lesser importance:
	• Various attack-related phenomena that are only occasionally present and/or moderately expressed when present:
	  ○ Nausea
	  ○ Phonophobia
	  ○ Photophobia
	  ○ Dizziness
	  ○ Ipsilateral blurred vision
	  ○ Difficulty swallowing
	  ○ Ipsilateral edema, mostly in the periocular area

Modified from Sjaastad O, Fredriksen T, Bono G et al: *Cervicogenic headache: basic concepts*, European Headache Federation, p 43, London, 2003, Smith-Gordon; and Pikus H, Philips J: Characteristics of patients successfully treated for cervicogenic headache by surgical decompression of the second cervical root, *Headache* 35:621-629, 1995.

be useful when classifying individuals with cervicogenic headache if the patient also exhibited pain during manual examination of the upper cervical spine.[174] Thus ROM evaluation may be a useful tool in clinical practice to identify individuals with this disorder. In addition, this information could be used to determine appropriate treatment options and subjects who could benefit from therapies targeted to increase ROM because it has been shown to be effective in this population. However, several earlier studies have found that active cervical mobility is unreliable in differential diagnosis.[169,174–176]

In addition, the onset of cervicogenic headache may be related to a traumatic incident. Whiplash is among the first diagnostic criteria for cervicogenic headache,[157,162,168,169] but cervicogenic headache can be present in individuals without a history of tra uma.[157,162,169,177–179] As with most forms of headache, the incidence of cervicogenic headache is higher in females.[180] The onset of cervicogenic headache is not age specific, and the condition can be associated with degenerative joint disease or a sedentary lifestyle. The history often is prolonged.[180]

Despite efforts to clarify the clinical diagnosis of cervicogenic headache, diagnosis is still a problem because of the overlap of symptoms with other types of headaches, such as migraine and tension-type headaches (Table 3-21). Furthermore, the validity of the clinical diagnosis of cervicogenic headache has been questioned. According to several experts in cervicogenic headache, making the diagnosis of cervicogenic headache remains problematic and cervicogenic headache remains a controversial topic.[125,181] Because the clinical diagnosis of cervicogenic headache has not been completely validated, diagnostic blocks of cervical joints or nerves have been the most accepted method used to diagnose cervicogenic headache by practitioners of interventional pain medicine.[125] Without other evidence, controlled diagnostic blocks become the only means of establishing the diagnosis. However, this way to diagnose cervicogenic headache is impractical for clinicians working with these patients, and still the clinical criteria are commonly used to diagnose it in general practice.

Although Jull and Stanton[182] did not find any consistent pattern of predictors for improving cervicogenic headache, Fleming et al.[183] found that increased patient age, provocation or relief of headache with movement, and being gainfully employed were all patient factors that were found to be significantly related to improved outcomes.

TABLE **3-21**

Diagnosing Different Headaches

Cervicogenic Headache	Migraine	Tension-type Headache
Unilateral pain; never changes sides	Unilateral pain but may be bilateral and can change sides with different attacks	Usually bilateral pain
Throbbing pain	Throbbing pain	Pressing, tightening pain
Moderate-to-severe intensity	Moderate-to-severe intensity	Mild-to-moderate intensity
Autonomic symptoms	Autonomic symptoms	Not accompanied by autonomic symptoms
Pain starting in the neck and pain triggered by neck movement and/or sustained awkward position	Pain is not triggered by neck movement	Pain usually is not triggered by neck movement
Affecting mainly females	Affecting mainly females	Affecting mainly females
Requires individual to lie down to feel better	Aggravation by routine physical activity	Does not worsen with routine physical activity
Reduced ROM in the cervical spine	No reduced ROM in the cervical spine	No remarkable unilateral restriction of neck motion
No precipitant mechanism	Precipitant mechanism (i.e., food, light, stress)	Not attributed to some other disorder
No response to medications	Response to ergot/sumatriptan treatment	Presence of trigger points; tenderness extending to shoulders and cervical muscles and also present in pericranial muscles
Good response to blockage of cervical joints or nerves	No response to blockage of cervical joints or nerves	Blockage of greater occipital nerve reduces pain only in area of blockage; does not abolish headache

Modified from Bono G, Antonaci F, Ghirmai S et al: Unilateral headaches and their relationship with cervicogenic headache, *Clin Exp Rheumatol* 18(suppl 19): S11-S15, 2000; and Vincent MB, Luna RA: Cervicogenic headache: a comparison with migraine and tension-type headache, *Cephalalgia* 19:11-16, 1999.

In addition, in a recent survey conducted in Australia regarding factors associated to nonresponsiveness to treatment in subjects with cervicogenic headache, clinicians considered a history of trauma, minimal mechanical signs, family history of headache, genetic predisposition, neural sensitivity, and the presence of co-morbidities to be features associated with nonresponsiveness to cervicogenic headache management.[184] Thus it is important that clinicians consider these factors when evaluating and treating patients with cervicogenic headache, especially those which are modifiable. Therefore relying on the patient's history and symptoms may not be the best way to reach an accurate diagnosis. Also, patients can suffer a "mixed" headache form or two types of headaches concurrently.[180] The differences between the available classifications for headaches of cervical origin make the study of cervicogenic headache confusing and the diagnosis of this condition more difficult.[158]

According to Jull,[130] evaluation of physical impairments of the cervical spine can help in the diagnosis of cervicogenic headache. Also, treatment of the musculoskeletal impairments associated with cervicogenic headache has been proposed as an essential part of the condition's overall treatment.[130,185] This means that the physical examination is crucial. Deep flexor muscles, including the longus capitis and longus colli, are important for cervical segmental and postural control. Alteration of the strength and endurance of the deep flexor muscles has been found in patients with neck pain and those with cervical dysfunction.[130] Dumas et al.[168] and Watson and Trott[162] investigated the relationship between strength of the upper neck flexor muscles and endurance of the same group of muscles in patients with cervicogenic headache. Both studies concluded that strength of the upper neck flexors was significantly different between patients with nontraumatic cervicogenic headache compared with controls. In both studies, patients with nontraumatic cervicogenic headache had smaller values of endurance compared with normal subjects.

The treatment of cervicogenic headache involves many specialists, including physicians, neurologists, orthopedic surgeons, rheumatologists, neurosurgeons, physical therapists, chiropractors, and osteopaths. Conservative therapies are recommended as the first choice. According to Jull,[130] the physical therapy approach to cervicogenic headache should include treating the patient's physical impairments not only to reduce symptoms but also to provide preventive maintenance. In addition, education of the patient in the predisposing and precipitating factors that aggravate the condition is essential for the overall management of these patients. There is some evidence from randomized controlled trials (RCTs) that supports the use of both manipulative therapy and specific exercise to reduce the frequency and intensity of the headaches and neck pain in a 1-year follow-up period. However, the combined therapy was not superior to either therapy alone.[186] Exercise therapy consisted of exercises directed toward improving motor control of the deep and superficial cervical muscles and training of the scapular muscles. Stretching and postural exercises were also recommended to improve body mechanics.[187] A study by Sharma et al.[188] also provided evidence in favor of stabilization exercises for the cervical spine to reduce headache dysfunction and improve proprioception of the neck.[188]

Five systematic reviews regarding the effectiveness of manipulative therapy in cervicogenic headache have shown some evidence supporting its effectiveness.[189–193] Bronfort et al.[190] reported that spinal manipulation appeared to have a better effect than massage for cervicogenic headache. It also appeared that spinal manipulation has an effect that is comparable to commonly used, first-line, prophylactic prescription medications for tension-type headache and migraine headache. Although Posadzki and Ernst[192] found that the majority of the RCTs showed that spinal manipulation was more effective than physical therapy, gentle massage, drug therapy, or no intervention, three out of nine RCTs showed no difference in pain, duration, or frequency of headaches compared with placebo, manipulation, physical therapy, massage, or wait-list controls. From all of these trials, only one was able to adequately control for a placebo effect, and this trial showed no benefit of spinal manipulations beyond a placebo effect. Thus the authors concluded that, based on these studies' methodological quality, the evidence cannot be conclusive regarding the use of spinal manipulation to treat cervicogenic headache. However, another systematic review[191] investigating the effect of physical therapy and manual therapies for cervicogenic headache found positive results. They concluded that physical therapy and spinal manipulation might be an effective treatment in the management of cervicogenic headache, although the patients included had infrequent cervicogenic headache and there was a lack of a true control group. These results were supported by the systematic review by Raciki et al.[193] They found that a combination of therapist-applied cervical manipulation and mobilization with cervicoscapular strengthening was most effective for decreasing pain outcomes in those with cervicogenic headache. However, due to the limited number of included studies in these reviews, more research is necessary investigating the effect of physical therapy and manipulative therapy treatment in patients with cervicogenic headache to be supported clinically.

In the early stages, conservative treatment through medication, change of lifestyle, physical therapy modalities, and acupuncture can be used. If the symptoms persist, blocks or radiofrequency treatment of the facet joints may be useful. More aggressive procedures, such as surgical cervical stabilization (e.g., foraminectomy, laminectomy, and unectomy), are reserved for patients with severe symptoms.

ASSESSMENT OF THE CERVICAL SPINE

The assessment of the cervical spine follows the method presented in *Orthopedic Physical Assessment* (volume 1 of this series). However, if the examiner is assessing primarily for hypomobility, then an understanding of the biomechanics in the cervical spine becomes important. In this context, *coupling* becomes an important factor in the assessment of the cervical spine. In effect, coupling is the conjunct rotation of a spinal segment. Side flexion and rotation have very small amounts of pure movement, and for all practical purposes, the two movements are combined. If side flexion initiates coupled movement, a small amount of rotation is combined with it. Similarly, if rotation initiates a movement, a small amount of side flexion accompanies it. In this context, rotation implies rotation and side flexion occurring together, not separately. Experts have many opinions about how a spinal segment couples, whether ipsilaterally (right rotation with left side flexion) or contralaterally (right rotation with right side flexion). For the most part, no one really knows the exact coupling action. Fortunately, with regard to the cervical spine (unlike with the lumbar spine), most of the opinions about coupling are convergent, which strengthens their validity. That being said, the reliability and validity of these tests have not been confirmed. The following section is based on the clinical experience of the chapter's first author, Jim Meadows.

Atlanto-occipital Segment

Considerable motion occurs at the atlanto-occipital joint, certainly enough for the movement to be appreciated and not just the end feel. Table 3-22 outlines the movement and ROM that occur at the left occipital joint.

As with most of the cervical spine, the key to understanding the function of the atlanto-occipital joint is to remember that it is primarily capable of flexion and extension. A considerable degree of rotation and side flexion is also available. The second point to keep in mind is that the arthrokinematics are the reverse of those in the other zygapophyseal joints, and they occur in a different plane (i.e., horizontal). Although clinicians may know this intellectually, intuitively it "goes against the grain," and practitioners have a tendency to forget this point.

TABLE **3-22**

Movement and Range of Motion of the Left Atlanto-occipital Joint

Movement	Range (Degrees)
Flexion	3.5
Extension	21.0
Right side flexion	5.4
Left side flexion	5.6
Right rotation	6.6
Left rotation	7.9
Combined flexion-extension	24.5
Combined side flexions	11.0
Combined rotations	14.5

Mobility Tests

With the patient supine, the patient's head is extended around the axis for the atlanto-occipital joint (an axis approximately common with that of the atlantoaxial joint and running through the external auditory meatus). The head then is side-flexed left and right around a common craniovertebral axis running roughly through the nose. As the side flexion is performed, a gradual translation force is applied in the opposite direction to the side flexion. The translation is economical in that it maintains the axes of motion, reduces the degree of angular displacement necessary to obtain full ROM, and allows the clinician to detect an end feel. The ROM of side flexion is assessed from side to side, as is (more important) the end feel of the translation. The end feel allows the barrier to be assessed and can be muscular, capsular or tissue stretch (pericapsular tissue), or pathomechanical (subluxation or "jamming" of the joint). The side flexion procedure is then repeated for flexion.

During extension, the occipital condyles glide anteriorly to the limit of their symmetrical extension range. During side flexion and right translation, the coupled right rotation is produced. As rotation causes the right occipital condyles to retreat toward a neutral position, the left condyle must advance into the extension barrier. If side flexion is limited, the limiting factor must be on the left side of the segment (i.e., ipsilateral to the side flexion), preventing the advance of the condyle into its normal position (or with hypermobility, allowing it to advance too far).

An alternate method is to extend the segment and then rotate it rather than side-flex it. This method may be preferable because it eliminates the need to consider the coupling motion. Right rotation must flex the right joint and extend the left, but in practical terms this is problematic. Limiting the rotation to the atlantoaxial segment is quite difficult, and the examiner cannot be confident that any range restriction is a result of hypomobility at the atlanto-occipital joint rather than the segment below.

During flexion, the occipital condyles move posteriorly. The right rotation that occurs as a consequence of the left side flexion causes the left condyle to move away from the flexion barrier toward the neutral position while the right condyle is moved posteriorly into the flexion barrier. Therefore the limiting factor must lie on the right side of the segment that is contralateral to the side flexion. Again, rotation of the segment can be used instead of side flexion, but the practical difficulties remain.

It is apparent that the arthrokinematic and osteokinematic movements occur simultaneously. In fact the

arthrokinematic movement in itself does not afford as much information about the type of hypomobility in these craniovertebral segments as it does elsewhere. This is due to the orientation of some of the suboccipital muscles that are oriented parallel to the plane of the joint so that they can restrict the glide of the joint and the bone movement. Consequently whether the hypomobility is myofascial, pericapsular, or pathomechanical in nature must be determined by other means. End feel would be the obvious answer to this question, but hypertonic muscles sometimes alter the axis of rotation in such a manner as to cause a false pathomechanical end feel. The more useful approach is to try a hold-relax technique and determine how much improvement occurs. If substantial improvement is seen, an extraarticular restriction is playing a major role; if little improvement is noted, an articular restriction is present.

It is important for the clinician to determine the side that is affected. If manipulation is used, the force must be as local as possible. The side of hypomobility is less important if mobilization is used because the direction of the mobilization is into the hypomobility.

Atlantoaxial Segment

Although rotation is the main movement at the atlantoaxial joints, a surprisingly large amount of flexion, extension, and side flexion also occurs at the segment (Table 3-23).

Mobility Tests

The atlantoaxial joints can be tested using the coupled movements of rotation and side flexion. According to cadaveric and in vivo studies, this segment has considerable ROM (see Table 3-23).

Rotation. The advantage of using rotation to assess ROM is that coupling is not an issue. The disadvantage is that many clinicians find this a less sensitive means of testing. (*Sensitive* here means being able to feel the movement.)

TABLE **3-23**

Movement and Range of Motion of the Left Atlantoaxial Joints

Movement	Range (Degrees)
Flexion	11.5
Extension	10.9
Right side flexion	9.4
Left side flexion	4.0
Right rotation	39.5
Left rotation	38.3
Combined flexion-extension	22.4
Combined side flexions	13.4
Combined rotations	77.8

The patient sits with the clinician standing to one side. C2 is stabilized with a wide pinch grip, and the clinician's other hand reaches around the head to hold the occiput and C1. The patient's head is held against the clinician's chest, and a very light compressive force is applied as the head is rotated toward the clinician. The compressive force allows the descent of the head that normally occurs as the C1 facets descend on those of C2. The ROM is assessed and the end feel evaluated (Figure 3-9).

Side Flexion. With the patient lying supine, the clinician reaches under the neck such that a finger wraps around the spinous process of C2, compressing the soft tissue against the process. The clinician side-flexes the occiput around the craniovertebral axis while palpating the movement of the C2 vertebra via the motion of its spinous process (Figure 3-10). The movement is in the opposite direction to the side flexion, indicating rotation of the C2 vertebra to the same side with consequential rotation of the segment to the opposite side. For example, if the head is side-flexed to the right, the spinous process of C2 moves to the left as the vertebral body rotates to the right. Because by convention segmental movement is named by the movement

Figure 3-9 Atlantoaxial mobility test in rotation.

Figure 3-10 Atlantoaxial mobility test in side flexion.

of the superior vertebra, the C1-2 segment is rotated to the left. As the head is side-flexed, the clinician assesses the amount of spinous process displacement to gain an idea of the range of C2 rotation. The clinician stabilizes the head when all movement has ended and then pulls the C2 spinous process further into its passive range to gain the end feel of rotation. When right side flexion is produced, the clinician assesses left rotation and vice versa.

Flexion and Extension. These movements are most easily assessed in the sitting position when a rocking motion is produced and no glide is available. However, given that combined rotation has approximately 4 times the range of combined flexion-extension (see Table 3-23), if rotation is restored at the zygapophyseal joint, flexion and extension must also be restored, and this precludes the need to test the motion except in the extremely unlikely event that scarring has occurred in the flexor or extensor muscles. In trauma patients, who may have such scarring, flexion or extension is likely to be much more limited than rotation and side flexion. In addition, isometric testing reasonably can be expected to be either weak or painful (in the acute case, painfully weak) and the muscle to be tender to palpation. In such cases, stretching techniques must be undertaken for these muscles.

There also is no forward or backward translation because the dens and the transverse ligament severely restrict this motion; therefore no deductive determination of the side of the hypomobility can be made. Complex and very careful testing by a skilled practitioner may elicit this information, but in reality it is not necessary for treatment.

Cervical Segments (C2 to C7)

The cervical spine proper is more complicated to assess than the craniovertebral articulations because it has not only muscles and zygapophyseal joints but also discs and uncovertebral joints (i.e., joints of von Luschka). Consequently this examination needs to be somewhat more detailed and complex to obtain information on these additional structures.

Segmental Screening Test

As with any other screening tests, the purpose of the segmental screening test is to demonstrate quickly the need for more exhaustive testing and to focus the clinician's attention on a specific level or levels and specific movement or movements. However, it also can be used to determine the direction of treatment without concern about which structure is limiting the movement. This is particularly true for mobilization, but the information gained from the screening test may also be used with certain types of manipulation.

The segmental screening test is performed in a fashion similar to mobility testing of the atlantooccipital joint. The segment is extended, which lifts the superior vertebra forward (eliminating the need to extend the entire cervical spine). While the extended position is maintained, the segment is side-flexed left and right around its axis of motion and simultaneously translated contralaterally (Figure 3-11). During left side flexion, the left side of the segment is maximally extended while the right side is moving toward its neutral position. The ROM of the side flexion and the end feel of the translation are evaluated for normal, excessive, or reduced motion. If left side flexion is restricted, extension of the flexor muscles or one of the joints on the left likely is the problem. If the end feel of the translation is normal but side flexion is restricted, the hypomobility is extraarticular (i.e., myofascial). If left side flexion is restricted in flexion, then the right side of the segment is not flexing normally.

Figure 3-11 Segmental screening test for cervical segments C5 to C7.

Occasionally side flexion appears to be normal but translation is restricted in all three positions. The likeliest cause of this restriction is uncovertebral joint dysfunction because these "joints" are involved in (or are the result of) side flexion and rotation and are largely unaffected by flexion or extension.

Deduction within the limits of theoretical knowledge can be used to determine the dysfunction, but direct testing, of course, is better. To this end, the arthrokinematics of the zygapophyseal and uncovertebral joints are evaluated.

Zygapophyseal Arthrokinematic Tests: Posteroanterior Intervertebral Movements (PAIVMs)

The orientation of the zygapophyseal joints is craniocaudal, mainly in the coronal plane. The patient lies supine. If extension is to be tested, the clinician lifts the superior vertebra of the segment by using the hand to gain extension, and the fingers are placed over the inferior processes of the superior vertebra (the superior facet). The two facets of the hypomobile side are compressed against each other by lifting upward while the superior facet is pushed caudally (Figure 3-12). The end feel is assessed by comparing it with the other side and/or the joints above and below.

For flexion, the segment is flexed and the superior facet of the suspected hypomobile joint is pulled cranially, again to assess the end feel. To do this the clinician must move the bone and not the overlying soft tissue; therefore it is useful for the clinician to attempt to put the fingertips between the two facets (Figure 3-13).

Figure 3-12 Posteroanterior intervertebral movement in extension.

Figure 3-13 Posterior intervertebral movement in flexion.

Uncovertebral Arthrokinematic Tests: Posteroanterior Intervertebral Movements (PAIVMs)

The uncovertebral joints are oriented inferomedially and superolaterally in a mainly sagittal plane. Hypomobility of the joint restricts translation with or without perceptible limitation of side flexion itself. The restriction is felt in flexion, extension, and neutral; flexion generally is the least affected. The patient lies supine. If left translation is restricted, the right joint's inferomedial glide is tested by pushing inferomedially on the right superior transverse process while the inferior bone is stabilized by holding the left inferior transverse process (Figure 3-14). Superolateral glide of the left joint is tested by pushing the left inferior transverse process inferomedially while the superior bone is stabilized via the right superior transverse process.

Analysis of the Assessment Results

The assessment can yield information about the severity of the pain, the onset of the pain relative to the onset of tissue resistance (i.e., simultaneously, before, or after), and the type of tissue resistance (e.g., normal or abnormal, muscle spasm, capsular, or pathomechanical). Knowing these results and correlating them with the history findings enable the clinician to determine the degree of inflammation, if any, and the direction and type of hypomobility (i.e., flexion or extension, pathomechanical, pericapsular, extraarticular, or subacute inflammatory) and thus establish a viable treatment plan. Table 3-24 outlines the vertebral segments and the hypomobility diagnoses based on hypomobility findings.

Figure 3-14 Uncovertebral arthrokinematic testing.

Cervical Spine Hypomobility Considerations

- Limited motion with a spasm end feel plus a history of relatively severe pain and a proportional amount of irritability is strongly indicative of arthritis (systemic or traumatic), the treatment of which must be rest from adverse stress. This may mean mobilizing a nearby hypomobile segment that is putting undue stress on the painful joint.
- Limited motion with a hard capsular end feel requires rhythmical oscillations that stretch the capsular tissues. The joint may or may not be painful but is almost certainly contributing to the patient's neck pain by stressing a painful joint.
- Limited motion with a pathomechanical end feel (i.e., abrupt and lightly springy) requires nonrhythmical techniques, such as high-velocity, low-amplitude thrusts (manipulation) or minithrusts (oscillations).
- Minor pain or discomfort, which usually occurs when the barrier is stretched (i.e., pain after resistance), requires true grade 3 or grade 4 techniques; that is, near–end range oscillatory mobilizations that do not reproduce the pain but also do not retreat to the beginning of the range.
- Acute and subacute pain states (i.e., pain before or with the onset of resistance) require grade 1 or grade 2 oscillations for neurophysiological pain modulation.
- Any technique that provokes spasms should be avoided. If an alternative cannot be found, manual treatment should be abandoned until the pathology subsides.

Inflammation of the joint is characterized by relatively intense, continuous pain with high levels of irritability. In deeper joints, such as the vertebral articulations, other characteristics of inflammation, such as heat and swelling, cannot be observed. However, in the neck swelling may be palpated, and any redness is an indication of a systemic arthritis or infection (Table 3-25).

TREATMENT

Treatment of the cervical spine revolves primarily around patient complaints of pain, weakness, and restricted ROM. Several systematic reviews have been conducted to determine the best-quality evidence to treat neck pain and related disorders. Most of these reviews have found

TABLE **3-24**

Cervical Segment, Hypomobility Findings, and Subsequent Hypomobility Diagnosis

Segment	Hypomobile Findings	Hypomobility Diagnosis

†No physical stress or rest changes the intensity of the pain.

‡High-intensity rest pain that worsens with mechanical stress.

limited-to-moderate evidence regarding the effectiveness of manual therapy alone or in combination with physical modalities or exercises to decrease pain.[194–196] For example, Gross et al.[194] found moderate-quality evidence that cervical manipulation and mobilization had similar beneficial effects on pain, function, and patient satisfaction. In addition, they found low-quality evidence suggesting that cervical manipulation might provide greater short-term pain relief than a control group (standardized mean difference [SMD]: -0.90; 95% confidence interval [CI]: -1.78 to -0.0]). Miller et al.[196] concluded that the combination of manual therapy and exercise for treating neck pain was better than no treatment or exercise alone. When compared with no treatment, manual therapy plus exercises showed a clinically important long-term improvement in pain (SMD: -0.87 [95% CI: -0.69 to 0.06]), function and disability, and a global perceived effect. In addition, the combination of these two treatment modalities was superior to exercises alone or manual therapy alone for improving pain and quality of life for chronic neck pain sufferers. Yamato et al.[197] also investigated the use of therapeutic exercise in managing neck pain. They found that exercises in the form of strength training, stretching, deep muscle activation and coordination, endurance, and dynamic and postural exercises help to reduce pain in short (i.e., up to 1 month) and intermediate (i.e., 1 to 6 months) time periods. The effect sizes obtained ranged from 0.45 to 0.53, which are considered moderate effect sizes according to Cohen guidelines.[198] Another systematic review[199] that looked at exercises for neck pain found similar results. However, these authors' recommendations were more precise for different disorders. For example, they found that exercises, such as supervised qigong (a traditional Chinese practice of aligning body, mind, and breathing for health, meditation, and martial arts) and combined strengthening, ROM, and flexibility exercises, were more beneficial than a waiting list for subjects with persistent neck pain and a WAD grade 1/2. However, unsupervised exercise had no more superior effect than nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, nor was manual therapy for acute neck pain or WAD, or a supervised high-dose strengthening superior to home exercises or advice. For acute neck pain grade 3, supervised graded strengthening was more effective than advice but was equally effective as a cervical collar in the short term.

Patient education for neck pain has also being investigated. Two systematic reviews[200,201] found that trials looking at different types of education, such as advice on how to activate certain muscles, advice on stress coping skills, and neck school, were not superior to other treatments, such as therapeutic exercise, manual therapy, or cognitive behavioral therapy. These results contrast to the results of Sutton et al.,[202] who found that multimodal care involving manual therapy, education, and exercise might benefit patients with grades 1 and 2 WAD, neck pain, and associated disorders. The systematic review by Yu et al.[201] found that structured patient education might provide small benefits when combined with physical therapy regardless of the mode of delivery (i.e., oral or written education). The differences between these reviews was that the Haines et al.[200] and Yu et al.[201] reviews looked at education as a single modality; however, Sutton et al.[202] looked at education as part of a multimodal treatment. Based on these findings, it is recommended that clinicians reassure patients to stay active and carry on regular activities for the early management of WAD grades 1 and 2 as part of a multimodal management program. In addition, clinicians should not provide high levels of treatment for patients with WAD, neck pain, and associated disorders because these patients had demonstrated poorer outcomes than those who receive fewer treatments. According to Jull and Richardson,[203] it is not wise to think that the "one-size-fits-all" approach is the solution for treating neck disorders. Rather, a tailored program of exercise should be planned because of the great variability of motor control impairment found in subjects with spinal pain.

The remainder of the chapter discusses treatment methods used in the cervical spine to increase ROM, improve strength, and provide relief of pain. However, before beginning the treatment, the clinician must clear any cautions or contraindications to such treatment (Table 3-26).

TABLE 3-26

Cautions and Contraindications to Joint Play Mobilization of the Cervical Spine

Cautions	Contraindications
• Osteoporosis • Bone disease • Congenital anomalies • Coagulation problems • Dizziness/vertigo • Nonmechanical reason for hypomobility • Atypical patterns of restriction • Neurotic patient • Acute inflammation • Pending litigation • History of cancer in the area • History of poor response to manual techniques	• Vertebral artery symptoms • Spinal cord lesions • Multiple nerve root involvement • Active collagen disease • Active rheumatic disease • Joint instability • Ankylosed joint • Hyperacute pain

Exercise Therapy

Exercise therapy is one of the most commonly used approaches to treat neck pain and associated disorders. Therapeutic exercise has grown enormously in physical therapy due to its benefits in chronic conditions.[204–207] Physical exercise represents a relevant component of rehabilitation for subjects suffering from musculoskeletal pain. Therapeutic exercise has been widely used in a variety of painful musculoskeletal conditions, such as low back pain, shoulder pain, neck pain, patellofemoral pain syndrome, and OA, to reduce pain and improve function of the musculoskeletal system.[204–207] Besides its effects on function and health, therapeutic exercise is known to have some pain-relieving effects,[208,209] and specific exercises targeted at the neck can enhance the neural control of the cervical spine in patients with neck pain.[210] According to Jordan and Ostergaard,[211,212] the goal of any rehabilitation protocol using exercises is to restore lost functional capabilities, such as ROM and muscular strength and endurance, as well as the ability to manage daily tasks at home and in the workplace. O'Leary et al.[213] have highlighted that regardless of the approach, "the focus underlying all exercise strategies is towards the restoration of the patient's key functional deficits, and this should be reflected in all exercise prescription. This function-oriented approach is meaningful to the patient and encourages patient compliance" (p. 329). Exercise should be implemented early in the rehabilitation process and has to be free of pain to avoid exacerbation of symptoms and fear avoidance behavior.[213] Although evidence supports the use of exercise to treat neck pain conditions, successful treatment relies on clinician skills and abilities to optimally assess and treat cervical muscle function and respond to requirements of each patient.[213]

Exercise therapy trials have shown that certain parameters are important for a successful outcome. Richardson and Jull[214] and Bird et al.[215] have reported that appropriate exercises must ensure proper motor control, performance, and endurance of a certain part of the body. Furthermore, it has been found that specific types of training, such as resistance, coordination, or mobility, improve motor performance domains specifically, without improving other domains.[216] Therefore the clinician must decide on the type of muscle contraction (i.e., concentric, eccentric, or isometric), patient's body position (i.e., supine, prone, or standing), level of resistance or load (i.e., high or low intensity), number of repetitions, and method of progression.[217]

Type of Muscle Contraction

Based on the biomechanical and physiological characteristics of local cervical muscles, isometric exercises are more beneficial for reeducating the stabilization role of the deep muscles in the spine because these muscles support low loads for longer periods and work to control fine movement. However, in later stages, isometric exercises can be combined with dynamic and global exercises.

Exercises involving a coordinated contraction between deep anterior and posterior muscles (the multifidus posteriorly and the longus colli and longus capitis anteriorly) are also part of the protocol requirements. In the cervical spine, stability is obtained by the coordinated activity of deep muscles.

Tonic motor units and tonic fibers work best in a stabilization function. Disuse and reflex inhibition are shown to affect the slow twitch and tonic fiber function. A good training program focuses on improving the holding capacity (i.e., endurance) of these muscles; therefore prolonged tonic isometric contractions using a percentage of the maximum voluntary contraction (MVC) (approximately 30%) are most effective in retraining the stability in the affected muscles.[218] In addition, specific exercises that isolate the local muscles from the global muscles are preferred because they have been shown to obtain a better result in posture control and symptomatology.[186,203] These suggestions are in agreement with those postulated by Bird et al.[215] and Falla et al.[217] According to Bird et al.,[215] low loads are used for muscular endurance in the range of 20 or more repetition maximum (RM) (i.e., the greatest amount of weight lifted with a correct technique for a specific number of repetitions).

Body Position and Level of Resistance

In general, the body positions used depend on the objectives of treatment. Because the required level of resistance is low, to obtain a focused reeducation of the muscles, positions such as supine, prone, or kneeling have been suggested to help better obtain motor control in the spinal segments.[214] Therefore reduced loads to the local muscles should be used as much as possible, along with positions

and exercises involving minimal external loading to reduce the possibility of pain and reflex inhibition. Thus high-intensity exercises are not appropriate in the early stages of rehabilitation or when the objective is reeducation of specific muscles.

Low loads also help to restore tonic function in the spinal muscles. Muscle contractions below 30% to 40% of MVC can be used to restore this function.[218] Loads as low as approximately 25% of the MVC have been shown to develop increased muscle stiffness to stabilize the spine. It has been shown that exercise at low load (20% MVC) facilitated a more selective activation of the deeper cervical muscles compared with exercise at moderate (50% MVC) and maximal (100% MVC) intensities.[219] At higher intensities, superficial muscles that are not stabilizers of the cervical spine increase their activity. However, if the patient requires a higher level of training due to his or her activity demands, high-load training should be implemented mainly in later stages of training. However, the load has to be tailored to each patient and based on symptom control. In this way, improved function without increasing symptoms can be attained.

In summary, low loads used with positions and exercises that involve minimal external loading are the ideal combination for rehabilitating local muscles in any spinal stabilization program.[203,213,213]

Number of Repetitions

To rehabilitate motor control and coordination among muscles in the cervical spine, the local (deep) muscles must be isolated. Therefore, to gain maximum benefit, the exercise must be repeated as many times as possible during the day until the patient acquires the desired control of the muscle. In addition, the patient must be able to hold the determined position before progressing to advanced stages. According to Bird et al.,[215] to improve endurance, a repetition of four to six sets per exercise, with rest periods of 30 to 60 seconds between sets, is appropriate.

Methods of Progression

According to Richardson and Jull[214] and corroborated by others,[213,220] progression proceeds in the following stages: first, the hold time of a determined action (isometric cocontraction) is increased. This is followed by increasing the number of repetitions of this holding activity (i.e., static stabilization). Ideally patients should be able to stabilize and isolate the correct muscle action in all exercise positions and develop this holding activity. As patients progress, they should be able to reproduce and maintain the contraction during dynamic functional movements. The time taken to achieve this varies from patient to patient and with the severity of the dysfunction. The first treatment sessions commonly focus on teaching the patient the correct contraction procedure, which can take several weeks.

Duration

According to Jordan and Ostergaard,[211,212] supervised instruction should be provided for a minimum of 2 months, with two or three sessions per week. To ensure compliance with the treatment, sessions should last no longer than 1 hour. Home exercises must be performed in addition to these supervised exercises.[213,220–224]

Cervical Muscle Retraining

It has been shown that motor dysfunction appears early after injury and does not automatically resolve with pain reduction.[225] Therefore therapeutic exercises have an important role to play in improving motor function because pain reduction alone does not seem to restore motor function fully. In addition, early intervention is preferred in patients suffering from pain and cervical dysfunction to prevent chronicity and perpetuation of symptoms and dysfunctional patterns.[213,217]

According to O'Leary et al.[213] and Falla et al.,[217] two basic approaches can be used to treat neck pain conditions with exercises. One exercise regimen consists of general strengthening and endurance exercises for the neck flexor muscles.[211,226,227] This exercise program involves high-load training and recruiting of all synergist muscles (i.e., deep and superficial muscles).

The other exercise approach focuses on the muscle control aspects, and its objective is to improve coordination and control of the muscles (e.g., during a controlled flexion movement).[213,218] With this approach, low-intensity contractions of the deep cervical flexors are used during the craniocervical flexion (CCF) movement. After the patient acquires control between the deep and superficial muscles, through training of the CCF movement holding capacity and progression, general strengthening exercises can be added.

O'Leary et al.[213] highlighted that both regimens could be used, but they must be applied at different times. Low-intensity exercises and control pattern movements must be applied in the initial stages when the subjects' pain and disability might impede high-load exercises, whereas global exercises involving a greater number of muscles must be used after reeducation of and coordination between the deep and postural neck muscles have been established.[217,221] Both approaches have been found to have successful outcomes.[213]

Evidence supports the use of exercises that address neck muscular impairments to reduce symptoms and to improve functionality in the cervical spine in conditions such as chronic neck pain, WAD, and cervicogenic headache.[186,228–230] Several clinical trials have been conducted to address muscular impairments in patients with cervical involvement. Training the endurance capacity of these muscles as well as exercises focused on fine motor control through the reeducation of normal patterns of contraction have obtained good results in reducing pain and improving function in these subjects.[186,228,230–232] Deep flexor

training in patients with cervicogenic headache has been shown to decrease pain and the frequency of headaches.[186] The same findings were corroborated by van Ettekoven and Lucas[233] in a sample of subjects with tension-type headache using craniocervical (i.e., deep flexor) training, by Dusunceli et al.,[234] who found positive results at long-term follow-up (i.e., 12 months) in a group of subjects with neck pain, and by Deep Gupta et al.[230] in a group of dentists with neck pain. In addition, subjects participating in a training program involving CCF and cervical flexion exercises improved endurance as well as strength in the cervical flexor muscles after training.[219] Furthermore, an endurance program targeting the cervical flexor muscles found that subjects who underwent this type of training improved cervical flexor strength and showed reduced myoelectric manifestations of fatigue of the cervical flexor muscles, along with a decrease in pain and disability of the neck.[228] The same effects were found when training the endurance of the cervical extensor muscles in a group of patients with neck pain and cervical disk disease after anterior cervical decompression and fusion.[235] According to Falla et al.,[228] the improvements in strength and endurance capacities after treatment could have been responsible for the reported efficacy of this type of exercise program in musculoskeletal pain conditions. They reported that this type of exercise program decreased pain intensity and improved function of the neck.[228] The effects of this program were attributed to an increase in stabilization, improvement in motor control of the cervical spine, and an afferent input produced by joint mobilization during the exercises, which, in turn, modulated pain perception at different levels of spinal cord.[236] Although the majority of studies looking at these exercises found positive results, Griffiths et al.[237] in an RCT did not find any statistical difference between a specific neck stabilization exercise program when compared with general neck advice and an exercise program for subjects with chronic neck pain. Nevertheless, subjects receiving a specific exercise program showed clinically significant improvement at 6 months and also reduced the use of pain medications at 6 weeks.

It has also been shown that exercises addressing the neck extensor muscles increased the total neck cross-sectional area (CSA) by approximately 13%. The hypertrophy obtained after 12 weeks of training was mainly due to increases in CSA for the splenius capitis (24%), semispinalis capitis (24%), and semispinalis cervicis and multifidus muscles (24.9%).[238] A positive training effect for the cervical muscles was demonstrated by an increased CSA of the SCM and trapezius muscles as well as decreased fatigability of the cervical muscles after 8 weeks of training.[239] It is known that an increase in neck muscle size is expected to stabilize the cervical spine and prevent or reduce the severity of cervical impairments and cervical pain.

Jull et al.[221] proposed a treatment protocol for training dysfunctional cervical muscles, which has been used successfully in several trials to treat both patients with cervicogenic headache and those with painful neck conditions.[186,234,239,240] The protocol emphasizes motor control rather than muscle strength. The same principles have been stated by O'Grady and Tollan.[241] Both groups of researchers divided the treatment into two phases: retraining the cervical muscles and retraining the scapular muscles. The following sections describe retraining of the cervical muscles.

Reeducation of the Craniocervical Flexion Movement. According to Jull et al.,[221] the reeducation of the correct CCF movement is the first indispensable component of the exercise program. The clinician must teach the patient to perform the movement correctly and to control and to eliminate any compensation strategy, such as neck retraction, excessive cervical flexion, and/or jaw clenching. For the treatment to progress, the CCF movement must be performed correctly. Emphasis on the precision of the movement, rather than the number of repetitions, is essential.[213,217,221,240]

Training of the Holding Capacity of the Deep Neck Flexors. Once the patient can correctly perform the CCF movement, training to improve the holding capacity of the deep flexors is begun. A preinflated, air-filled pressure sensor is used to guide and control the training of deep neck flexor muscles (Figure 3-15). This sensor, which has a visual feedback device (a pressure gauge), is essential to guide the patient in controlling the level of pressure and the desired level of muscle contraction. In addition, the feedback device helps motivate the patient and provides quantification of the degree of improvement.[217,221,240]

The starting point for holding capacity training (HCT) usually is the pressure level the patient has reached and

Figure 3-15 Craniocervical flexion test and craniocervical flexion training. Patients are instructed to perform a gentle nodding movement (craniocervical flexion) and practice progressive targeting using the air-filled pressure sensor at five incremental levels with the aid of a visual feedback device.

can hold without compensation for at least 10 seconds.[214,221,241] Patients commonly start at 22 or 24 mm Hg. The training consists of teaching the patient to achieve the determined pressure level and then to hold it for a time without evidence of compensation or poor motor patterns. Ideally the patient is asked to practice the exercise at least twice a day, as long as it does not interfere with daily activities. For each pressure level, the patient holds the position for 10 seconds and repeats this 10 times. Reaching an ideal pressure level between 28 and 30 mm Hg may be somewhat difficult for patients.[221] The duration of training needed to acquire holding capacity for the deep flexors varies from patient to patient; however, according to Jull et al.,[221] an average of 4 to 6 weeks is necessary to obtain a good performance (i.e., holding 28 to 30 mm Hg for 10 seconds, 10 times), but some patients with major muscle dysfunctions could take up to 12 weeks. The patient can use the feedback device at home to practice the training, and once the correct performance is achieved, the individual can be weaned from the visual feedback. Beer et al.[242] have tested the training of the CCF movement in the sitting position. They asked subjects to gently lift the base of the skull from the top of the neck as if lengthening the cervical spine. This type of exercise has been demonstrated to activate the longus colli muscle. Subjects were asked to perform the exercise holding the position for 10 seconds, ideally every 15 to 20 minutes throughout the day, as a daily routine. They found that this simple exercise improved performance in the CCF and decreased the EMG activity of the SCM. Thus these authors recommended the inclusion of this type of exercise in training programs because it is an easy and convenient exercise that can be performed during the day and does not interfere with daily routine.

Retraining of Cervical Spine Extension in the Upright Position. Once the patient is able to perform the CCF movement in the supine position without compensations, the movement is progressed to the sitting and standing positions. The first part of this next stage consists of moving the head and cervical spine into an extension movement in the sitting or standing position. The patient is instructed to first lift the chin and then look up to the ceiling and to continue this movement, trying to look farther along the ceiling, until the end of the comfortable range of extension is reached. The patient then returns to the neutral position (i.e., natural head position). The first part of this exercise trains the cervical flexor muscles to contract eccentrically. Any compensation, such as chin retraction or cervical retraction, should be discouraged.

The second part of the exercise is the return to the upright position by concentric contraction of the cervical flexors muscles. The movement must be started with CCF. It is important that the movement be performed mainly at the level of the craniocervical region rather than having dominant action of the SCM (Figure 3-16).

These exercises can be progressed in two ways: first, by increasing the range of the head extension movement as control improves and second, by adding isometric hold exercises in different parts of the range of cervical returning movement (i.e., concentric flexion) to improve the cervical flexion synergy through functional ranges of extension. The exercises consist of performing neck extension in a comfortable (i.e., pain-free) range and then initiating the CCF movement toward the standing position, without reaching the full upright position, and holding it for 5 seconds. These exercises should be repeated and progressed according to the patient's tolerance because they are potentially high-load exercises.

Retraining of the Extensors of the Craniocervical Spine. To retrain the extensors of the cervical spine along with the training of the deep flexor muscles, exercises are started

Figure 3-16 Retraining of cervical spine extension in the upright posture.

with the patient in the sitting or standing positions, with progression to the prone and four-point kneeling positions. In the sitting position, for example, the patient is instructed to perform slow head flexion, controlling the speed against gravity and working the extensors eccentrically, and then to return to the neutral position without any compensation. Chin poking, for example, is one of the most common compensations seen with this movement, and it indicates excessive craniocervical extension, which usually is caused by dominance of the superficial muscles (e.g., semispinalis capitis). This exercise can be progressed by asking the patient to alternate small ranges of craniocervical extension and flexion while maintaining the cervical spine in the neutral position in the prone on elbows position or the four-point kneeling position (Figure 3-17). In addition, isometric holds during this movement in the intermediate ranges can be encouraged. The objective of these exercises is to train the coordinated movement among the deep cervical extensor muscles (e.g., the semispinalis cervicis and multifidus), deep craniocervical extensors (e.g., rectus capitis and the suboccipital muscles in the upper cervical levels), and deep flexor muscles (e.g., longus colli and longus capitis). In this exercise, semispinalis and multifidus help to control the cervical spine in the neutral position and the deep flexor muscles (especially longus colli) stabilize the neck,[243] while the deep small craniocervical extensor muscles perform controlled eccentric, concentric, or isometric contractions.[217,221,240]

Co-contraction of the Neck Flexors and Extensors. This exercise is started once the patient has achieved control of the correct pattern of contraction for the cervical flexor and extensor muscles. The exercise consists of a self-resisted isometric rotation in the supine, correct sitting, or standing position. The resistance must be gentle (approximately 10% to 30% of the MVC) (Figure 3-18). The patient alternates the resistance as an alternating rhythmic stabilization exercise. The exercise must be done smoothly and slowly, with the focus on control rather than speed. This exercise is easy to perform and can be done throughout the day.[213,217,221,240]

Murphy[222,223] has proposed a progression for retraining of the cervical muscles through retraining of the cervical flexors and extensors in the four-point ("all fours" or "bird dog") kneeling position. This method is designed to help the dynamic stability system of the cervical spine work functionally and optimally. The first step is a maneuver called **cervical bracing**, which consists of training the cocontraction of the deep cervical flexors and lower cervical and upper thoracic extensors. While in the four-point kneeling position (Figure 3-19, *A*), the patient first protracts the head and then performs upper cervical flexion, while keeping the lower cervical spine in a neutral position. This configuration is maintained by the patient, who is encouraged to keep the spine and the rest of the body stabilized.[223] When this movement can be performed correctly and held for at least 10 seconds, the patient progresses to the next stage in which the patient combines head and neck control movement with arm and leg movements (Figure 3-19, *B* and *C*). The patient raises an arm and maintains the stability of the body, as well as the stability of the cervicothoracic system. The patient then raises a leg. These movements are alternated (right arm, left leg; then right leg, left arm) until the patient can maintain and perform the correct movement pattern. In addition, the patient can balance a light weight

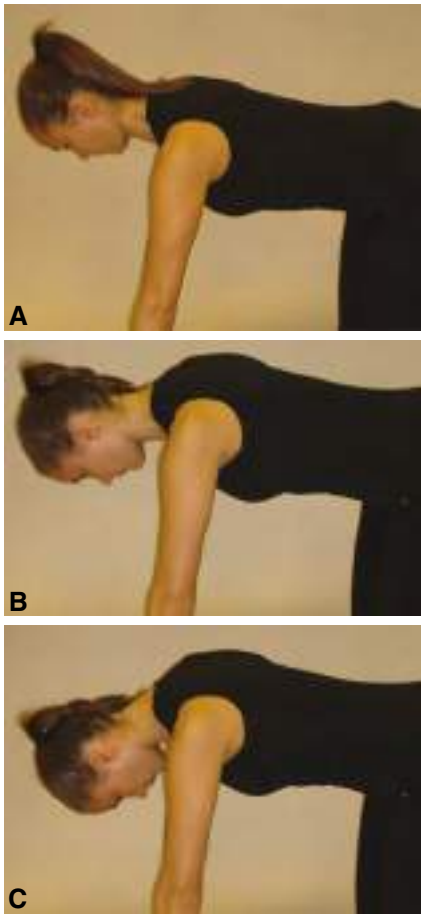

Figure 3-17 Retraining of the extensors of the cervical spine. **A,** Neutral position. **B,** Nod. **C,** Flexion.

Figure 3-18 Co-contraction of the neck flexors and extensors using self-resisted isometric rotation contraction in a correct upright position.

(e.g., a book) on the head to increase the difficulty of the exercise and to retrain stability in the same sequence (Figure 3-19, *D*).[222–224]

O'Grady and Tollan[241] have proposed a further progression of these exercises using foam rolls or a gym ball. The exercises performed with these tools are advanced-stage exercises of increased difficulty, as they are two- and three-dimensional, unstable exercises, so they must be performed with care. The patient co-contracts the deep cervical flexors and extensors while balancing on the foam rolls or gym ball (Figure 3-20). These exercises can be made more challenging by having the patient contract the neck (i.e., cocontraction) in different positions.

Retraining of Scapular Orientation and Position. The position of the scapula commonly is altered in patients with cervical pain resulting in tight and weak muscles. The altered muscular patterns contribute to increased vertical compressive loads on the joints of the cervical spine.[184] Retraining of the scapular position is a very complex and difficult task because patients have difficulty understanding the position of the scapula and cannot correct it through visual cues; they must be taught to feel the correct position and movement.[207,221,240]

The scapula generally is seen to be protracted and downwardly rotated (inferior angle moves toward the

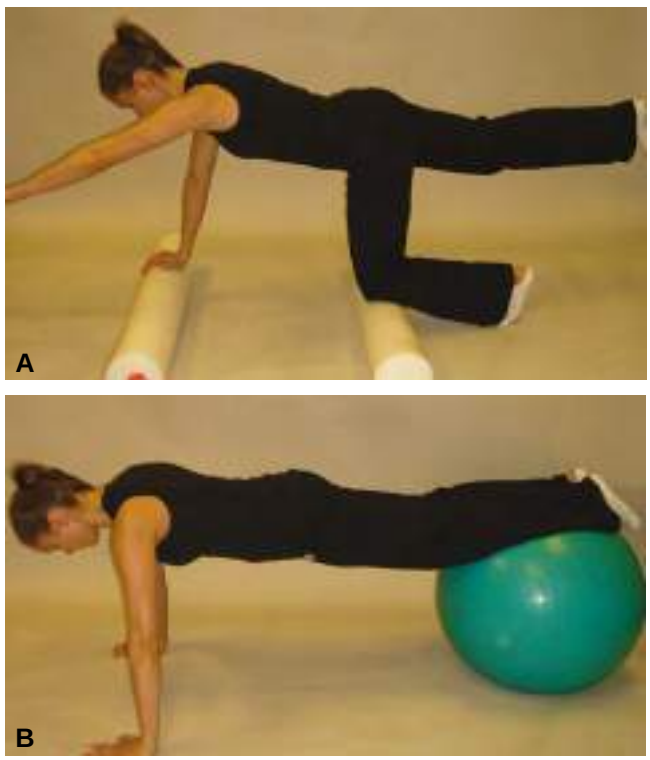

Figure 3-20 Advanced cervical stabilization exercises. **A,** Two-dimensional exercises. **B,** Three-dimensional exercises.

spine) leading to rounded shoulders accompanied by a poking chin in patients with cervical problems. Exercises are performed to bring the head back into neutral and to try to bring the coracoid upward and the acromion backward to retract and put the scapula in the normal resting position. This action results in a slight retraction and lateral rotation of the scapula. The objective is to activate all of the muscles that control the scapular position (i.e., the three parts of trapezius, serratus anterior, levator scapulae, and rhomboids). However, before retraining can begin, lengthening and relaxation of the hyperactive and tight muscles, such as the upper trapezius (Figure 3-21) and the levator scapulae, pectoralis minor, pectoralis major, and SCM (Figure 3-22), must be promoted.[217,221,240] Teaching the patient to actively control the orientation of the scapula is a priority when reeducating axioscapular muscles.[213] (More information on scapular stabilization may be found in Chapter 6.)

Training of the Endurance Capacity of the Scapular Stabilizers. Increasing scapular muscle endurance is the next step. It consists of maintaining the correct position of the scapula for at least 10 seconds and then progressing to holding longer based on the patient's tolerance. These exercises can be progressed from the side-lying position to the prone position using gravity resistance to train the endurance of the scapular muscles. The exercise is similar to the retraction and depression test. The clinician usually needs to facilitate this training until the patient is able to perform the movement and hold it for the required time.[217,221,240]

Retraining of Scapular Control with Arm Movement and Load. The objective of this stage is to maintain the position of the scapula (i.e., "locking" it) while performing movements of the arm (i.e., "loading" it). The patient accomplishes this by doing exercises within a small ROM (60° or less) while holding the correct position of the scapula. Closed chain exercise can be used to progress the difficulty of these exercises. For example, in the four-point kneeling, "prone on elbows" position, the patient can perform concentric and eccentric scapular control exercises of the scapula while maintaining the cervical spine in the neutral position. The objective is to improve the holding capacity of serratus anterior by holding set positions in the intermediate ranges for 10 seconds; this is repeated 10 times (Figure 3-23).

Figure 3-21 In addition to having the patient perform active exercises, the clinician stretches the cervical and shoulder girdle muscles (here, the upper trapezius) to maintain the biomechanical environment and to allow reeducation of muscular function.

Figure 3-22 Stretching of the cervical and shoulder girdle muscles (here, the sternocleidomastoid).

Postural Re-education. Postural retraining is one of the main objectives of treatment of patients with neck pain. Correcting the patient's posture and alignment ensures a regular reduction in harmful loads applied to the cervical joints by the poor postural pattern of the head, cervical spine, and scapula and is especially useful in patients having postural alterations as an aggravating factor.[213] In addition, postural correction helps retrain the deep and postural stabilizing muscles during functional postures. Postural training should be performed repeatedly during the day so that it becomes a habit for the patient and also to give constant positive feedback to the muscles needing to be activated. Postural training is performed first in the sitting position and then in the standing and functional positions (Figures 3-24 and 3-25). This retraining cannot just concentrate on the cervical spine and head and their relation to the trunk and pelvis. It must involve training of the thoracic spine, scapula, and especially the pelvic core. The complete kinetic chain must be trained. An interesting postural exercise, the action of lifting the occiput from the atlas, has been shown to activate the longus colli, an important postural muscle.[244]

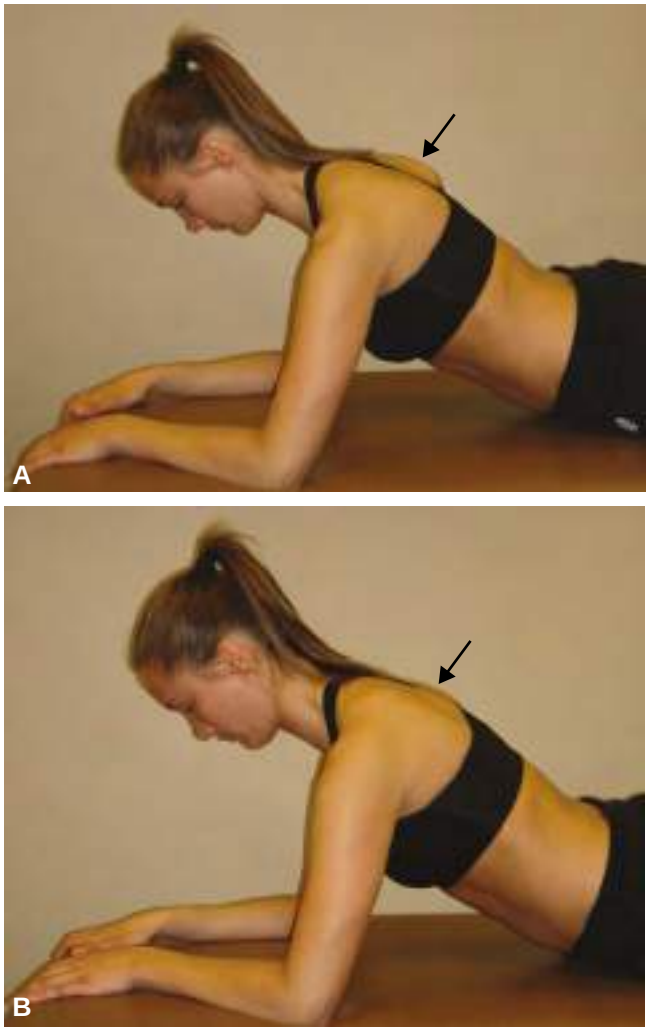

Figure 3-23 Training of the scapular stabilizing muscles. The patient is positioned with the elbows supported in the bed. She then trains the scapulae in both eccentric and concentric control and in holding capacity. The head and neck must maintain a neutral position to retrain the capacity of the cervical extensors. **A,** Scapular winging. **B,** Scapula engaged.

Treatment of Postural Control Disturbances

In some patients, especially those with chronic WADs, dizziness and unsteadiness are common symptoms.[220] Patients with idiopathic chronic neck pain and those with acute and persistent WADs also have been found to have greater cervical joint position errors.[245–248] In addition, patients with whiplash who complain of dizziness have a greater joint position deficit than those who do not have these symptoms.[221] Deficits in standing balance have been demonstrated in people with persistent neck pain of both idiopathic and traumatic origin.[221] According to Humphreys and Irgens,[247] "*There is a dissociation or dysfunction in the integrated visual, vestibular and proprioceptive systems of the neck due to trauma and/or continuing mechanical problems in chronic neck patients* (p. 100)." Most of the time these symptoms (i.e., dizziness and unsteadiness) are related to altered joint position error or disruptions of balance or eye movement control.[247–249] The treatment should include exercises to address these conditions (although research into the effectiveness of these exercises is needed). According to Kristjansson and Treleaven,[220] specific programs targeting cervical joint position sense, eye-neck coordination, and gaze stability have demonstrated a better success at improving pain, neck disability, and ROM in subjects with neck pain than other nonspecific programs. For example, Hansson et al.[250] showed that a specific vestibular rehabilitation program improved balance and dizziness in patients suffering from whiplash injury. Thus, subjects with neck pain need to be evaluated for these disturbances to provide a more focused management to obtain better results.

Figure 3-25 Postural training in the upright position using a gym ball. The patient is encouraged to lift the occiput from the atlas and to maintain the shoulder girdle in neutral position. Scapula position also is encouraged.

The following section focuses on the retraining of these impairments.

Retraining Exercises for Repositioning the Head in Natural Head Posture. These exercises are applied only if the patient has an impairment of the joint position sense of the head and the patient is able to hold the neutral head position.[251,252] The patient practices relocating the head to the natural head posture and to specific positions through the ROM. The patient trains first with the eyes open and then with the eyes closed. All movements (i.e., flexion, extension, rotation, and side flexion) are used to retrain the head position.[221,247]

Retraining Balance. Training of balance is important and depends on the level of impairment. The positions and exercises commonly use unstable positions or surfaces to train body balance first in "low" positions (e.g., lying down) and then progress to the sitting and standing positions.

Oculomotor Exercises. Ocular exercises progress through several stages. They start with the head stationary and progress to head movements but with the eyes fixed on a target.[221,247,248] These exercises cannot be performed if the patient is in pain, and they should be stopped if symptoms, such as dizziness and unsteadiness, appear. According to Fitz-Ritson,[249] the exercises must begin slowly, and the patient must focus on different components of each exercise. Some exercises for eye and head coordination are also used. For these, the patient must combine eye movements and head movement in a synchronized fashion. For example, the patient first rotates the head and the eyes at the same time in the same direction; then, progressively, the patient moves the eyes first to the target and then rotates or moves the head toward the target. Movement in opposite directions (i.e., the eyes look in one direction and the head moves in the opposite direction) is trained at the end of the progression (Figure 3-26). All these exercises can be progressed using different surfaces and positions (e.g., the patient sits on a therapy ball, wobble board, or foam roll or walks while doing the exercises).[247] Kristjansson and Treleaven[220] have provided a detailed example for an exercise program for cervicogenic dizziness or unsteadiness and an example of progression of exercises to improve sensorimotor control in neck disorders (Table 3-27). This type of treatment can be embedded with the general multimodal approach to treat neck disorders.

Fitz-Ritson[249] used these types of exercises in an RCT to evaluate the effect of "phasic exercises" plus chiropractic treatment compared with standard exercise treatment plus chiropractic treatment in patients with chronic WADs. The Neck Disability Index (NDI) was used as an evaluation tool. The study found that patients treated with phasic exercises plus chiropractic treatment improved 48.3% compared with the baseline evaluation. The author recognized that in the past these phasic exercises were applied to patients with acute and chronic neck pain or WADs, which led to poor results. Therefore Fritz-Ritson[249] suggested that tonic exercises be performed first, before the patient is progressed to phasic exercises.

Humphreys and Irgens[247] obtained the same results using oculomotor exercises. They found that these exercises reduced pain intensity and improved the accuracy of repositioning of the head after 4 weeks of treatment in patients with chronic neck pain compared with patients who did not receive treatment. However, even with these good results, the authors recognized that a link still had to be established connecting cervicocephalic kinesthesia, head reposition accuracy (HRA), and neck pain.

Figure 3-26 Oculomotor training. The patient trains the coordination between head and eye movements.

TABLE 3-27

Example of Task and Progression to Improve Sensorimotor Control in Subjects with Neck Disorders and Postural Disturbances

Aim	Task	Progression
Cervical position sense	With laser on headband for feedback, relocate back to neutral head position from all head movements with eyes open	• Eyes closed, check eyes open • Relocate to points in range place on a wall, eyes closed, check eyes open • Increase in speed • Perform in standing • Perform on unstable surfaces
Cervical movement sense	With laser mounted on headband practice trace over a pattern placed on the wall, eyes open	• Increase in speed • More difficult and intricate pattern • Small finer movements
Eye follow	Sit in a neutral neck position, keeping the head still and the hands in the laps. Move the laser light back and forth across the wall, while following the laser with the eyes	• Sit with neck in a relative neck torsion position • Eyes up and down, H pattern • Increase in speed • Increase range of movements • Perform in standing • Perform on unstable surfaces
Saccades	Quick simultaneous movement of both eyes to focus on selected dots on a wall	• Increase distance • Add busy background, such as stripes
Gaze stability	Maintain gaze on a dot on the wall as therapist passively moves the patient's trunk and/or the head/neck Maintain gaze on a dot placed on the wall or ceiling as patient actively moves the head/neck in all directions	• Fix gaze, close eyes, move head and open eyes to check if gaze was maintained • Check the background of the target, plain, stripes, checks • Change focus point to words or a business card • Increase in speed • Increase range of movements • Perform in standing • Perform on unstable surfaces
Eye-head coordination	Move eyes to a new focus point and then move head in the same direction and return to neutral	• Actively move head and eyes together same direction • Move eyes one direction and head opposite direction • Move eyes and head together when peripheral vision restricted • Move eyes, head, neck, and arm with or without vision restricted • Rotate eyes, head, and trunk looking as far behind as possible with or without vision restricted • Hold a target, keep eyes fixed and move target, head and eyes move together
Balance	Maintain standing position for 30 seconds	• Eyes open then closed • Firm then soft surface • Different stances: comfortable, narrow, tandem, single limb • Walking with head movements-rotation, flexion, and extension-maintaining direction and velocity of gait • Performing oculomotor or movement or position sense exercises while balance training

Traction

Traction is used in the cervical spine to distract the zygapophyseal joints, increase the space between the vertebrae, and enlarge the intervertebral foramina. Traction may also be used to stretch joint capsules and ligaments that are hypomobile, reduce muscle spasm and pain by reducing α-neuron excitability and improve blood supply through use of intermittent traction.[253,254] Although traction is commonly used in the treatment of the cervical spine and has been found clinically effective in some cases

(e.g., nerve root irritation), there are some who have questioned its effectiveness.[255–258]

Manual traction usually is the first form applied. It is used to relax the patient, test the tissues' reaction to traction, and test the reaction of the patient's signs and symptoms to traction.

Specific manual traction involves applying longitudinal traction to a segment while stabilizing the segments above and below to safeguard them from the effects of the treatment. This technique generally is used to reduce pain and muscle spasm and thereby indirectly increase the ROM. The technique also is used to reduce the mechanical effects of traction when pain relief is not the primary response required. For example, in certain patients with multiple levels that are unstable or painful or in a patient who is unable to tolerate lying down, mechanical traction may be difficult or even contraindicated.

Manual traction may be used with the patient in either the sitting or the supine lying position (the sitting position is described). The patient is seated comfortably at a height suitable for the clinician (the top of the patient's head should be approximately level with the clinician's humerus when the arm is held at 90° of elevation). To achieve this, the patient may have to slump in the seat if the chair is not adjustable. The clinician stands just behind the patient's shoulder on either side, depending on which is more comfortable for the clinician. The clinician cradles the patient's forehead with the arm that is anterior with respect to the patient, reaching around the patient's head to hold the occiput. The clinician's other hand holds across a posterior aspect of the inferior bone of the segment to be treated in a lumbrical grip. The segments above are now locked by a sequence of movements that, all else being equal, are at the discretion of the clinician (Figure 3-27). This sequence includes flexion, rotation, and side flexion or extension, and rotation and side flexion to the left or right, depending on whether instability is present above the target segment.

Mechanical traction usually is applied to the cervical spine with the patient in the supine position on a traction table (Figure 3-28), although seated traction may be used in some cases, especially if the patient has respiratory difficulties.[259] This is often an effective technique for patients with cervical spondylosis or those showing radicular signs. The patient is placed in a relaxed position with pillows under the head, shoulders, and knees.

The amount of traction applied to the cervical spine will vary; the minimum is 1.8 to 4.5 kg (4 to 10 lb). Gentle, sustained traction of 4.5 to 7 kg (10 to 15 lb) for 3 to 5 minutes is appropriate for relieving muscle spasm; intermittent traction of 7 to 14 kg (15 to 30 lb) is appropriate for causing a "pumping action" to aid circulation and to relieve pressure on the nerve and nerve roots by separating the joint structures. Traction increases the pressure in a normal disc, and machine traction has a greater effect than manual traction.[260]

Figure 3-27 Specific manual traction.

Figure 3-28 Mechanical traction using the Saunders device with the patient in the supine position.

Sustained, or **static**, mechanical traction is traction that is applied continuously for a number of minutes. Sustained traction is indicated for patients with high joint and/or nerve root irritability, those with recent or developing neurological signs that have been associated with irritability, and patients with severe arm pain combined with reduced neck movement toward the painful site.

Intermittent, or **rhythmic**, mechanical traction is probably the most common form of cervical traction used by clinicians because it enables patients to tolerate greater traction forces.[261] This type of traction is applied for short periods (i.e., seconds or minutes) with equal or longer rest periods (i.e., seconds or minutes) in between. Intermittent traction is indicated for patients with an acute joint derangement (less than 6 weeks), unless joint or root irritability is high, and for those needing generalized joint mobilization (facet OA), or suffering from spondylosis, cervical problems that do respond to

mobilization, nonirritable neurological (radicular) signs, headaches coming from the neck, muscle spasm, or pain. Intermittent traction is reported to produce twice as much separation as sustained traction.[261]

Studies have shown that 24° to 35° of cervical flexion allows maximum separation of the zygapophyseal joints, providing maximum enlargement of the intervertebral foramina.[261–265] In the supine lying position, the most effective angle of pull for treating the cervical spine is approximately 60° from the horizontal. Researchers also have found that approximately 11.3 kg (25 lb) is necessary to separate the cervical vertebrae, with maximum separation occurring with 20.4 kg (45 lb); at these weights, separation occurred within 7 seconds.[266] Ten to 4.5 to 6.8 kg (15 lb) may be necessary to overcome the weight of the head and the force of gravity if the head is upright. In the lying position, the force is reduced. However, the clinician must keep in mind that the head accounts for approximately 7% of the total body weight.

It has been shown that 9.1 to 11.3 kg (20 to 25 lb) is necessary to straighten the lordotic curvature of the cervical spine.[267,268] Table 3-28 provides a traction guide that is based on signs and symptoms as an indication of when the duration (time) or weight should be altered. Normally, the clinician starts with a weight approximately equivalent to the weight of the head (i.e., 3.6 to 4.5 kg [8 to 10 lb] or less) and increases or decreases either the duration or the load, depending on the reaction of the signs and symptoms.[261] Treatment usually is given for 20 to 30 minutes daily or every second day for 2 to 3 weeks.[262]

Cervical traction must be applied with caution in patients whose history indicates osteoporosis, hypertension, cardiovascular disease, congenital anomalies, evidence of instability, vertigo, "drop attacks," possible arteriosclerosis of the vertebral or carotid arteries, or claustrophobia, as well as in patients with respiratory problems or coughing. The immediate disappearance of nerve root pain on the first application of traction may indicate a high probability of severe pain occurring when the traction is removed. It has been reported that intermittent cervical traction may lead to lumbar radicular discomfort in some cases.[180]

Manual Traction with a Locking Technique

To apply manual traction with locking, the clinician flexes or extends (depending on the clinician's preference or the patient's requirement) the segments from the occiput down to the superior bone of the segment of interest while palpating a superior vertebra for movement. As soon as any movement is felt, the flexion or extension is backed off slightly to ensure that the target segment remains in neutral. The superior segments then are sideflexed away from the clinician, who ensures by palpation of the superior vertebra that the side flexion is not carried into the target segment. At this point, the levels above the target segment are locked into flexion, side flexion, and rotation, whereas the levels below it are stabilized by the clinician's lumbrical grip (see Figure 3-27). Traction is produced by slight straightening of the clinician's legs at the knees, to the degree required. When only neurophysiological effects are required, very little lifting is necessary. If a mechanical effect is required, the clinician provides more knee extension.

Cervical Orthosis

Cervical collars are used primarily to treat muscle spasm, provide stabilization, and limit ROM. The physiological effectiveness of these devices has been questioned, but they can limit movement, depending on the collar chosen.[6,269–272] No studies have been performed to determine the clinical effectiveness of these devices or the outcomes when they are used. The clinician must also be aware that the patient may become dependent on the device, which is visible and may contribute to a sympathy factor. In most

cases, except when bony or ligamentous instability has been diagnosed, the patient should be weaned off the collar as soon as possible.

Mobilization of the Cervical Spine

The results of the segmental examination, leading to treatment and the assessment described previously, can be used as the basis for treatment of both acute pain states in which a neurophysiological but nonmechanical effect is desired and for nonacute conditions in which primarily a mechanical effect is needed. The advantage of using the assessment technique for mobilization is that it requires no "levering" through a proximal segment, and therefore there is no need to lock the cervical spine segments above and below the segment of interest. This means that minimal risk of stressing either the other segments or the vertebral arteries at levels different from that being treated is incurred. The assessment approach is also a simpler technique and consequently easier to master. The following section is based on the clinical experience of the chapter's first author, Jim Meadows.

Treatment of the Non-acutely Painful Segment

When the cervical spine is treated with manual techniques for nonacute or nonpainful hypermobilities for which a mechanical effect on the barriers is required, multiple barriers are likely to be encountered during the treatment, and each barrier must be dealt with as it becomes evident. Muscle resistance usually is the first barrier the clinician meets, and this resistance can be reduced or eliminated by using very light hold-relax (10% to 30% MVC contraction) techniques or muscle energy techniques.[273–275] The patient is asked to produce resistance that matches the clinician's light push into the direction to be mobilized, holds the contraction for approximately 10 seconds to allow inhibition of the muscle spindle, and then relaxes. The clinician then takes up the slack, and the sequence is repeated until a new barrier is met or until no new range is achieved with each contraction. If full range and normal end feels are found after this, the barrier was entirely increased muscle tone (e.g., muscle spasm). If motion is still restricted and the end feel changes from a muscular end feel, different techniques may be required. For example, the next barrier may be mild pain or discomfort, for which grade 4 Maitland oscillatory techniques may be used until the discomfort is abolished.[276] If the grade 4 techniques provoke pain, the clinician should perform grade 3 techniques. If an early collagen end feel is detected, a technique specific to that barrier is used, such as grade 4+ oscillatory techniques for pericapsular extensibility or minithrust or manipulation for pathomechanical problems. Treating each barrier as it appears, with the appropriate technique, makes the entire treatment more effective and economical.

The duration of mobilization treatment varies and depends on the effect required, irritability of the patient's tissues, and patient's response during treatment. If the patient's tissues or joints are all irritable, the additional treatment should be relatively short, especially if it is performed at the same session as the extensive assessment. Once the clinician knows that the treatment responses are good or at least neutral, the dose (i.e., the duration) can be increased. If the clinician hears a click or other noise or feels the vertebra shift, the treatment should be stopped and the segment and regional movements should be reassessed. Before the segment is taken out of its end-range position, four or five isometric contractions should be performed by the agonist muscles. This tends to reduce the amount of relapse between treatment sessions.

Mobilization Sequence of Progression

1. Hold-relax or muscle energy techniques for muscle spasm
2. Maitland grades 2-4 mobilization techniques for pain modulation (depending on acuteness); grades 3-4 techniques for mobilization
3. Maitland grade 4+ mobilizations or minithrusts for end-range mobilization
4. Isometric contractions for reeducation

Neurophysiological Techniques for Pain

Midrange Techniques. For the purposes of this chapter, midrange is the biomechanical neutral or resting position of the joint. It is the point where the joint capsule has maximum laxity, the volume of the joint is at its greatest, and as a result the joint is in its least irritable position.[109] Therefore as a starting point, this position is ideal for techniques that are not intended to stress the barrier and that are intended to avoid causing pain and increasing inflammation.

Using the starting point, a **grade 1** Maitland technique can be defined as a small-amplitude technique (approximately 25%) at the beginning of the available range; a **grade 2** Maitland technique is a large-amplitude movement in the middle of the ROM (i.e., the middle 50%); a **grade 3** Maitland technique is a large-amplitude movement at the end of the ROM (i.e., the last 50%); and a **grade 4** Maitland mobilization is a small-amplitude movement at the end of the ROM (the last 25%).[276] Although grades 3 and 4 are not primarily intended to stress the barrier, but just to reach it, in practice most clinicians do stress the barrier with these techniques; therefore properly speaking, they should be described as grade 3+ and grade 4+ mobilizations. A **grade 5** mobilization generally is referred to as exceeding the barrier and is in fact a manipulation; however, for most models of biomechanical dysfunction, this definition is lacking in accuracy; therefore in this chapter, it is defined as a grade 4+ mobilization.

With the exception of traction or distraction, techniques that work at the beginning of joint play are intended to reduce pain by achieving a neurophysiological modulation of the pain rather than by exerting a mechanical effect on the abnormal movement barrier.

Neutral Side Glide Techniques. Neutral side glide techniques may be general or specific. For the general techniques, the patient lies supine, and the clinician stands at the head of the bed. The clinician lifts the patient's head slightly off the pillow using both hands and then side glides the head, keeping it parallel with the shoulders (Figure 3-29). This causes a side translation in the whole cervical spine.

With regard to specific techniques, those described in the following sections can be used for pain modulation. When they are used for this purpose, no flexion or extension is added to the technique for the atlantooccipital joint and the C2 to C7 segments, and very low amplitude translation oscillations are used. For the atlantoaxial segments, the supine techniques work well when grade 1 or grade 2 techniques are required.

Common Requirements for a Safe, Effective, and Economical Mobilization Treatment

- Most importantly, all cautions and contraindications must be recognized and respected
- A precise and accurate diagnosis is essential
- The mobilizing force must be focused at the affected segment
- Each barrier must be recognized as it is encountered and treated appropriately
- The mobilization technique must be appropriate for the direction, grade, and type of mobilization; this will depend on the barrier met.
- All other segments must be safeguarded from the force of the mobilization as much as possible
- Definitive therapeutic exercise and patient instruction must follow up manual therapy for both hypomobility and instability (hypermobility) if long-term results are to be accomplished

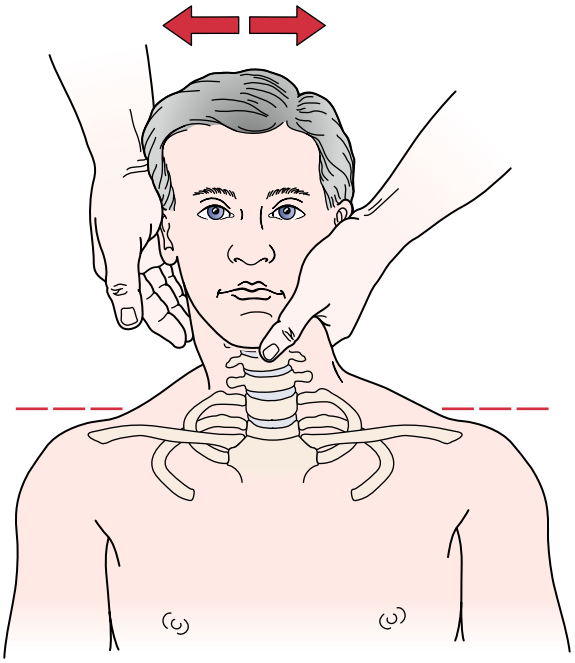

Figure 3-29 Side glide of the cervical spine: Glide to the right. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 204, St Louis, 2014, Elsevier/Saunders.)

Treatment of the Atlanto-occipital Joint

The first technique to treat the atlanto-occipital joint simply takes the assessment and, using grades, converts it into a treatment method. The techniques described are for the right side of the segments; therefore when the joints on the left are treated, the patient's and clinician's positions, the hand positions, and the directions of forces must be reversed.

Treatment of Right Flexion Hypomobility in the Supine Position. The patient lies supine, and the clinician sits or stands at the head of the bed. Both of the clinician's hands are placed on top of the patient's head, slightly forward of midline (Figure 3-30, *A*). The clinician flexes the patient's head by pushing down on the head so that the chin tucks in. Hold-relax or muscle energy techniques then are used to relax the muscles, and any discomfort that may be present is dealt with using grade 4 oscillations. Then mobilization is performed using either grade 4+ techniques or minithrusts to the barrier. The clinician then side-flexes the head to the left, trying to take the left ear onto the

Figure 3-30 **A,** Axially specific mobilization of extension of right flexion atlantooccipital joint. **B,** Supine side flex of the right atlantooccipital joint.

neck and simultaneously translating the head to the right until the barrier is felt (Figure 3-30, *B*). Mobilization is performed using either grade 4+ techniques or minithrusts to the barrier. After mobilization the patient is asked to contract the agonist and antagonist muscles isometrically for short-term re-education.

Treatment of Right Flexion Hypomobility in the Sitting Position. The patient is seated, and the clinician stands slightly behind the patient's right shoulder. The clinician stabilizes the atlas by applying a wide lumbrical grip with the left hand. The clinician's other hand reaches around the patient and lightly grasps the occiput. The clinician flexes the occiput around its own sagittal axis (i.e., through the ear) and then side flexes it to the left around its coronal axis (i.e., through the nose) and simultaneously translates it to the right, being careful to minimize movement in the adjacent segment (Figure 3-31). When the abnormal end feel is felt, the clinician performs the sequence for muscle relaxation (i.e., hold-relax or muscle energy techniques) or pain modulation (i.e., grades 2 to 4 mobilizations); when the definitive barrier of translation is encountered, the clinician applies either grade 4+ mobilizations or minithrusts. Afterward, the patient performs isometric contractions using the antagonist and agonist muscles to move the joint actively through the available ROM.

Treatment of Right Extension Hypomobility in the Supine Lying Position. The patient lies supine, and the clinician sits or stands at the head of the bed. The patient's head is extended. Both of the clinician's hands are placed on top of the patient's head, slightly behind the midline. The clinician extends the patient's head by pushing it down so that the chin is lifted up and back. The clinician then side-flexes the head to the right, trying to tuck the right ear onto the neck and simultaneously translating the head to the left until a barrier is felt (Figure 3-32). The muscles are first relaxed using hold-relax or muscle energy techniques, and any discomfort that may be present is dealt with using grades 2 to 4 oscillations. Mobilization is then performed with either grade 4+ techniques or minithrusts to the barrier. After mobilization the patient is asked to contract the agonist and antagonist muscles isometrically for short-term re-education.

Figure 3-31 Treatment of right flexion hypomobility in the sitting position.

Figure 3-32 **A,** Axially specific mobilization of extension of right flexion atlantooccipital joint. **B,** Extension of the right atlantooccipital joint.

Treatment of Right Extension Hypomobility in the Sitting Position. The patient is seated, and the clinician stands slightly behind the patient's left shoulder. The clinician stabilizes the inferior vertebra of the segment to be treated by applying a wide lumbrical grip with the right hand. The clinician's left hand reaches around the patient's head and lightly grasps the segments above the target segment, making sure that the hypothenar eminence contacts the neural arch and the tip of the transverse process of the segment to be treated. The clinician extends the target segment around its sagittal axis and then flexes the right side around its coronal axis while simultaneously pulling the vertebra toward the left, causing left translation (Figure 3-33). Once an abnormal end feel or restriction is felt, the clinician carries out the sequence of muscle relaxation (i.e., hold-relax or muscle energy techniques) until no further relaxation is produced (usually 4 to 5 contractions). If necessary, pain modulation can be

Figure 3-33 Treatment of right extension hypomobility in the sitting position.

achieved using oscillatory mobilization graded according to the degree of pain (i.e., grades 1 to 4) until the pain is relieved, at which point the definitive restricted end feel (i.e., capsular or pathomechanical) is encountered. This definitive barrier or abnormal end feel can then be treated with grade 4+ mobilizations, minithrusts, or a manipulation technique. The mobilizations are continued as long as the clinician feels necessary or prudent. Afterward the patient performs agonist and antagonist isometric contractions at the end of the newly gained range.

Note: In the preceding descriptions, side flexion is always away from the clinician, and translation is always toward the clinician. The clinician can stand on the other side of the patient and side-flex toward and translate away, but the method described is the easiest one.

Treatment of Bilateral or Symmetrical Hypermobilities. Bilateral hypermobilities can be treated with unilateral techniques performed to each side, and this approach is preferable when only the last part of the range of movement is absent. However, a bilateral technique for symmetrical dysfunction can also be used and may save time and effort. Such symmetrical restrictions can be due to scarring or adhesions resulting from trauma or to adaptive shortening; that is, structural shortening that results when the tissue does not go through its full ROM frequently enough.

Treatment of Bilateral Flexion Hypomobility. The treatment for bilateral flexion hypomobility can be performed with the patient either seated or lying down. If the patient is seated, the clinician stands to one side of the patient (in this case description, the clinician stands on the right). The clinician's left hand stabilizes the atlas with a wide lumbrical pinch grip around the neural arch; the right hand reaches around the patient's head and the fingers wrap around the lower occiput, so that the fingers of both hands touch each other. The occiput is flexed around the craniovertebral sagittal axis and simultaneously glided posteriorly (Figure 3-34). Hold-relax or muscle energy techniques are used to reduce muscle tone or spasm, and grades 2 to 4 oscillations are performed to reduce any discomfort that may

Figure 3-34 Treatment of bilateral flexion hypomobility in the sitting position.

be present. Then grade 4+ techniques are used to stretch the abnormal barrier to posterior gliding.

If the lying position is preferred, the patient is placed in the supine lying position with the head on a pillow, and the clinician stands at the head of the bed. The clinician uses both hands to hold the patient's head slightly forward of midline. The chin is tucked into the throat until the clinician detects the end feel. Muscle spasm and pain are dealt with first as noted previously (Figure 3-35). Using 4+ mobilizations, the glide is increased by applying further pressure into the end feel.

If a locking technique is desired (some clinicians feel that it is more specific), only one hand is placed on the head, and the other hand stabilizes the atlas in the same wide lumbrical grip described for the sitting technique.

Treatment of Bilateral Extension Hypomobility. The treatment for bilateral extension hypomobility can be performed with the patient either seated or lying down. If the patient is seated, the clinician stands to one side of the patient (in this case description, the clinician stands on the right). The clinician's left hand stabilizes the atlas with a wide lumbrical pinch grip around the neural arch,

Figure 3-35 Treatment of bilateral flexion hypomobility in the supine lying position.

Figure 3-36 Treatment of bilateral extension hypomobility in the sitting position.

Figure 3-37 Treatment of bilateral extension hypomobility in the supine lying position.

if possible coming a little anterior around the transverse process; the right hand reaches around the patient's head and the fingers wrap around the lower occiput, such that the fingers of both hands touch each other. The occiput is extended around the craniovertebral sagittal axis and simultaneously glided anteriorly (Figure 3-36). The clinician then applies the appropriate mobilization technique, which depends on the barrier encountered. The technique using grade 4+ mobilizations to stretch the abnormal barrier to posterior gliding is a little more difficult because the atlas must be prevented from moving forward during the mobilization.

If the lying position is preferred, the patient is placed in the supine lying position with the head on a pillow, and the clinician stands at the head of the bed. The clinician uses one hand to reach under the patient's head to stabilize the atlas, using the usual wide lumbrical grip, by holding the head back; the other hand reaches around the chin so that the head rests in the crook of the clinician's arm. The head is extended and glided anteriorly on the stabilized atlas until an end feel is appreciated (Figure 3-37). Grade 4+ mobilizations are applied in the manner described previously.

Treatment of the Atlantoaxial Segment

As with the treatment techniques for the atlanto-occipital segment, the techniques for the atlantoaxial segment are simply modifications of the assessment techniques. Right hypomobility restriction is described. Similar techniques can be used for left hypomobility restriction but in the opposite direction.

Treatment of Right Rotation Hypomobility Using Side Flexion. With the patient lying supine with a pillow supporting the head, the clinician stands or sits at the head of the bed. The clinician reaches under the patient's neck with the right hand such that his or her finger wraps around the spinous process of C2, compressing the soft tissue against the spinous process; the other hand holds the top of the patient's head. The clinician left side-flexes the occiput around the craniovertebral coronal axis (i.e., through the nose) while pulling on the spinous process of the C2 vertebra until an end feel is appreciated. At this point, C2 is rotated to the left, but the segment is rotated to the right as C1 is relatively right rotated (Figure 3-38, *A*). As mentioned previously, convention dictates that the segmental movement be named by the relative or absolute movement of the superior vertebra.

The clinician stabilizes the head when all movement has occurred and the end feel has been reached, and then starts to mobilize into right rotation (Figure 3-38, *B*). Muscle relaxation consists of hold/relax or muscle energy techniques to the right side flexors; left side-flexion slack is taken up in the relaxation phase. If soreness intervenes, grades 2 to 4 mobilizations are performed by oscillations to the spinous processes, and the barrier then is mobilized by grade 4+ mobilizations or minithrusts. Isometric exercises of the right and left side flexors are performed to produce some short-term re-education.

Treatment of Right Rotation Hypomobility Using Rotation. The patient is seated, and the clinician stands on the right side, slightly behind the patient. The clinician's left hand holds C2 in a wide lumbrical grip around its neural arches so that the thumb stabilizes the posterior aspect of the right transverse process. The clinician's right hand wraps around the occiput, with the little finger lying over the left neural arch of C1. Care must be taken that the clinician's arm does not compress the patient's nose or face. One of two things now must be done to take the slack off the alar ligament and allow rotation to occur; either the occiput must be side-flexed to the left or a light compressive force must be imparted so that when rotation starts, C1 can descend onto C2. The clinician achieves compression by allowing a small amount of his or her weight to fall onto the patient's head, so that the head is not being

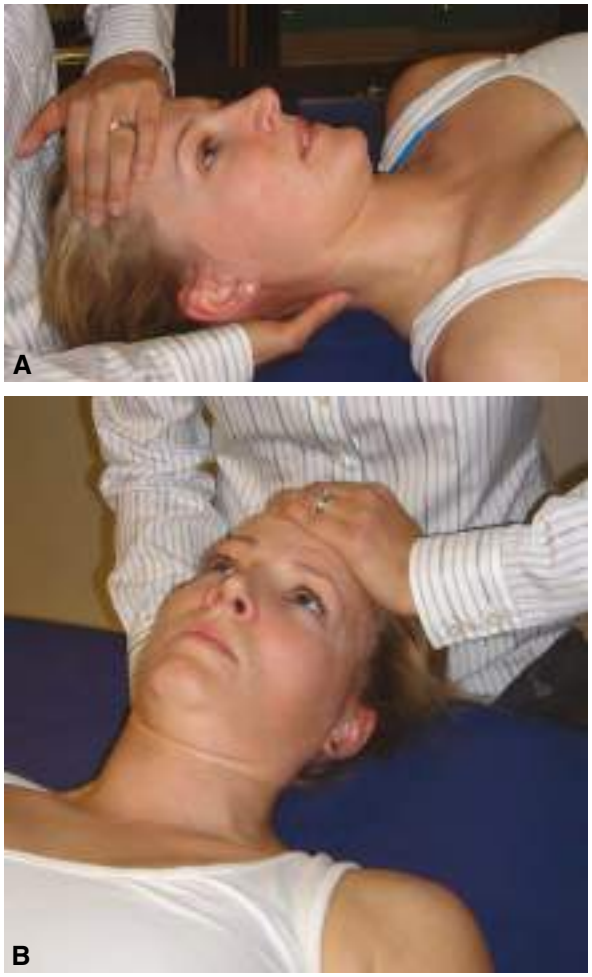

Figure 3-38 Right rotation assessment and mobilization of the atlantoaxial joints. **A,** Side view. **B,** Overhead view.

Figure 3-39 Assessment and mobilization for right rotation of the atlantoaxial joint in the sitting position.

Figure 3-40 Treatment of flexion hypomobility of the atlantoaxial joint.

inadvertently held up by the clinician (Figure 3-39). The appropriate mobilization technique is used for the type of barrier encountered, followed by the appropriate isometric contractions.

Treatment of Flexion Hypomobility. On the rare occasion that the posterior muscles are structurally shortened and require stretching, the following technique may be useful. The patient is seated, and the clinician stands on either side of the patient (for the purpose of this description, the clinician is on the right side). The clinician's left hand stabilizes the axis (i.e., C2); the right hand reaches around the occiput and atlas (i.e., C1), as low as possible, such that both hands are touching. Care must be taken that the clinician's forearm does not compress the patient's face. The clinician flexes the occiput and atlas around the craniovertebral sagittal axis until the end feel is appreciated (Figure 3-40). The appropriate mobilization technique is then performed. These mobilizations are *osteokinematic* (i.e., they follow a normal ROM), rather than arthrokinematic, and they consist of a rollover movement because the dens-transverse ligament complex, when intact, prevents anterior and posterior gliding at this segment.

Treatment of Extension Hypomobility. The patient and clinician positions, as well as the positions of the clinician's hands, as described in the previous section, are adapted for the flexion technique, except that the occiput and atlas are extended around the craniovertebral sagittal axis, and extension osteokinematic mobilizations are applied at the appropriate barrier (Figure 3-41).

Minithrusts are not indicated for either flexion or extension hypomobility because neither type of hypomobility is a pathomechanical dysfunction.

Treatment of C2 to C7

Treatment of Right Side Flexion/Flexion Hypomobility in the Supine Lying Position. The patient lies supine, and the clinician sits or stands at the head of the bed. The patient's head and neck are fully flexed and resting on a pillow or the clinician's abdomen. The clinician uses the middle fingers of both hands to hold the superior vertebra of the target segment under the neural arches; the pads of the index fingers are pressed gently against the transverse

Figure 3-41 Treatment of extension hypomobility of the atlantoaxial joint.

Figure 3-42 Treatment of right side-flexion hypomobility of C2 to C7 in the supine lying position.

process tips (Figure 3-42). As an alternative, especially for those with smaller hands or when a lower segment is treated, the index fingers reach around the neural arches and the first metacarpal head is pressed against the transverse process tip. The first technique is likely to be more sensitive for most clinicians.

With either grip, a small amount of left side flexion is applied to fix the axis and then combined with rotation to the right until an end feel is appreciated. The barrier to the translation is then addressed with the appropriate mobilization technique, as determined by the end feel. As more range becomes available as a result of the treatment, the slack is taken up. The maximum duration of the treatment has been reached when no further improvement in movement is noted or when the technique can no longer be controlled because of clinician limitations (e.g., fatigue).

Treatment of Right Side-Flexion/Flexion Hypomobility in the Sitting Position. The patient is seated, and the clinician stands slightly behind the patient's right shoulder. The clinician uses the left hand to stabilize the lower vertebra of the target segment, using a wide lumbrical grip around its neural arches. The clinician's right hand reaches around the patient to lightly grasp the segment above the level to

Figure 3-43 Treatment of right side-flexion hypomobility of C2 to C7 in the sitting position.

be treated, making sure that the little finger wraps around the right neural arch of the superior vertebra of the target segment and that the hypothenar eminences are over the left transverse process tip. The clinician flexes the segment around its own sagittal axis and then side-flexes it to the left around its coronal axis while simultaneously translating it to the right, taking care to minimize movement in the adjacent segments (Figure 3-43). When the abnormal end feel is appreciated, the clinician applies the appropriate mobilization technique, followed by the appropriate isometric contractions.

Treatment of Right Extension Hypomobility in the Supine Position. The patient lies supine with the head supported on a low pillow, and the clinician sits or stands at the head of the bed. The clinician uses the middle fingers to hold the superior vertebra of the target segment under the neural arches; the pads of the index fingers are pressed gently against the transverse process tips (Figure 3-44). As an alternative, especially for those with smaller hands or when a lower segment is treated, the index fingers reach around the neural arches and the metacarpal head

Figure 3-44 Treatment of right side-extension hypomobility of C2 to C7 in the supine position.

of the second finger is pressed against the transverse process tip. Using either grip, the clinician lifts the vertebra so that the segment extends. A small amount of right side-flexion is applied to fix the axis and then combined with left translation until an end feel is felt. The barrier to the translation is then addressed with the appropriate mobilization technique, as determined by the end feel. As more range becomes available as a result of the technique, the slack is taken up.

Treatment of Right Extension Hypomobility in the Sitting Position. The patient is seated, and the clinician stands slightly behind the patient's left shoulder. The clinician stabilizes the lower vertebra of the target segment with the right hand, using a wide lumbrical grip around the neural arches. The clinician's left hand reaches around the patient to lightly grasp the segments above the level to be treated, making sure that the little finger wraps around the right neural arch of the superior vertebra of the target segment and that the hypothenar eminence is over the right transverse process tip (Figure 3-45). The clinician extends the segment around its own sagittal axis and then side-flexes it to the right around its coronal axis while simultaneously translating it to the left, taking care to minimize movement in the adjacent segment. The barrier to the translation is then addressed with the appropriate mobilization technique, as determined by the end feel. This is followed by the appropriate isometric muscle techniques.

Note: In the preceding descriptions, side flexion is always away from the clinician, and translation is always toward the clinician. To treat hypomobility to the left, the same techniques are used, but in the opposite direction.

Treatment with a Flexion, Extension, or Rotation Locking Technique. The segments from the occiput down to the superior bone of the segment of interest are flexed or extended (depending on the clinician's preference or the patient's requirement) while the superior vertebra is palpated for movement. As soon as any movement is felt, the clinician backs off the flexion or extension to ensure that the target segment remains in neutral. The superior segments then are side-flexed (the clinician palpates the superior vertebra to ensure that the side flexion is not carried into the target segment) (Figure 3-46). At this point, the levels above the target segment are locked into flexion, side flexion, and rotation while the levels below are stabilized by the clinician's lumbrical grip. If flexion is mobilized, the spine must be locked into extension, and if extension is mobilized, the spine must be locked into flexion; otherwise, the mobilizing force will extend to unlock the superior segments. The clinician provides flexion by flexing the head and spine while holding the locked position. Extension is performed in a similar fashion. The clinician provides rotation by rotating the head and spine while holding the locked position.

Summary of Mobilization Techniques

Specific manual mobilization techniques are many and varied. They may include complex locking techniques that allow the clinician to lever through unaffected segments, or they may be simple techniques with no preparatory locking if direct force to the affected vertebra is intended. Passive mobilization is an effective and satisfying method of treating mechanical segment dysfunction, but it is only part of the treatment, and it opens a window of opportunity for rehabilitation. Passive mobilization is not a definitive treatment in and of itself. Nonetheless, it is perhaps the most effective way to control the sequencing of other interventions because it results in rapid improvement in pain intensity, ROM, willingness to move, and patient compliance, and it allows the clinician to dictate when rehabilitation of movement begins.

CHAPTER 4

Temporomandibular Disorders

SUSAN L. ARMIJO-OLIVO, INAE C. GADOTTI*

INTRODUCTION

Temporomandibular disorders (TMDs) consist of a group of pathologies that affect the masticatory muscles and the temporomandibular joint (TMJ) and related structures. TMDs interfere greatly with daily activities and can significantly affect the patient's lifestyle, diminishing the individual's ability to work and interact in a social environment. In the United States alone approximately $2 billion is spent each year on direct care for TMDs.[1]

Chronic pain caused by TMDs has been shown to produce the same individual impact and burden as back pain and severe headache. TMDs are commonly associated with other conditions of the head and neck region, such as headache, neck pain, and neck muscular dysfunction. To date, studies have shown a clinical association between cervical spine dysfunction and TMD.[2–8]

Research supports the use of conservative and reversible treatments to treat most patients with TMDs.[9,10] A TMD is recognized as a complex disorder, and the treatment of these patients involves many health care professionals, such as dentists, speech pathologists, physicians, psychologists, and physical therapists. Occlusal splint therapy, medications, psychotherapy, behavioral therapy, acupuncture, and physical therapy have been used to improve patients' symptomatology. The effectiveness of the treatment also depends on the patient. Most treatments have not been researched, and their use depends on the experience of the clinicians.

Physical therapy does not escape the rigor of scientific evaluation. The procedures of physical therapy intervention are not well described in the literature in this area. Basically, physical therapy treatment is used to relieve pain, improve range of motion (ROM), and improve the function of the masticatory system through physical modalities, exercises, and manual techniques. Physical therapy also addresses the craniocervical system as a whole, improving the balance between various muscles to maintain the equilibrium of the craniomandibular system (CMS) (i.e., postural equilibrium) and to prevent additional problems sometimes seen in patients with TMDs, such as spasm of the cervical muscles, cervical pain, and referred pain from the cervical spine to the masticatory system.

From a physical therapy perspective, clinicians work with patients who require treatment of the TMJ and its surrounding structures. Treatment goals are the same as for any other musculoskeletal structure. However, the clinician must always keep in mind that this is a special joint: bilateral in nature and having structural and anatomical features that are different from the other joints in the body.[11] Pain is the most common symptom and the one that usually causes the patient to seek help in the first place. For this reason any clinician treating patients with TMDs must address pain management in addition to possible causes or factors associated with pain.

If the TMJ is hypomobile, normal mobility should be restored through mobilization and exercise and then should be maintained through exercise and function. If the TMJ is hypermobile, the hypermobility must be restricted through patient education, modification of use, and exercises to restore normal function. If muscle spasm is present, the spasm has to be reduced through mobilization, exercise, or perhaps with the assistance of physical agents. If inflammation is a factor, the effects of the inflammation must be controlled with rest, change of function, an increase in the blood supply to the area, and adjunctive pharmaceutical therapy.

This chapter provides a general overview of the etiology, epidemiology, classification, and treatment of TMDs. It deals only with disorders that are commonly presented or referred for rehabilitation (usually to a physical therapy department). The reader interested in more in-depth knowledge about TMDs is encouraged to refer to more specific references.[12,13]

TEMPOROMANDIBULAR DISORDERS (TMDS)

Definition

TMDs is a broad, nonspecific term that encompasses several clinical problems involving the stomatognathic

*The authors, editors, and publisher wish to acknowledge Martin Parfitt for his contributions on this topic in the previous edition.

system (which is responsible for speech, swallowing, breathing, and mastication functions), TMJ, masticatory muscles, and craniocervical system.[14] Use of the term **temporomandibular joint (TMJ) dysfunction** as an overall descriptor of TMDs has been discontinued because it is considered misleading and inaccurate, implying structural conditions when in fact most of the time these conditions are not the cause of the dysfunction.[15] TMDs usually are manifested by one or more of the following signs or symptoms: pain, joint sounds, limitation of jaw movement, muscle tenderness, and joint tenderness.[16] In addition, TMDs are commonly associated with other symptoms affecting the head and neck region, such as headache, ear-related symptoms (e.g., tinnitus [ringing in the ear] and otalgia [pain in the ear]), and cervical spine disorders (e.g., fatigue of the masticatory, cervical, and scapular muscles).[17–20] TMDs are considered musculoskeletal disorders of the masticatory system, and they affect more than 25% of the general population.[17] According to Goldstein "chronic TMD is considered as a psychophysiologic disorder of the central nervous system that modulates emotional, physiologic, and neuroendocrine responses to emotional and physical stressors" (p. 380).[15]

Epidemiology

According to a study by Drangsholt and LeResche,[1] TMDs affected approximately 20 million adults in the United States and 450 million adults worldwide in 1998. One in three adults will develop TMD pain.[21] Therefore TMDs are very common conditions. However, only 1% to 3% of the population seeks care for their TMDs, and 3.6% to 7% of the general population is in need of treatment.[21] Various studies demonstrate that 50% to 75% of adults have at least one sign and/or symptom related to TMD.[22] According to Auvenshine,[23] approximately 10% of the adult population has pain in the temporomandibular region. Some signs seem to be more common in the healthy population than others; for example, joint sounds or mandibular deviation occurs in 50% of the population.[17,24,25] Limitation of mouth opening is thought to be rare (seen only in 5%).[23]

In a representative urban sample of 1230 subjects from the Brazilian population, at least one TMD symptom was reported by 39.2% of the individuals and pain related to TMD was noted by 25.6% of the population. The most common symptom was TMJ sound, followed by TMJ pain and masticatory muscle pain.[26] All symptoms were more prevalent in women than in men. In a prospective study a cohort of 2737 TMD-free subjects were followed for up to 5.2 years.[27] According to the study, 260 people developed first onset of TMD, which indicates an annual incidence rate of 4%. Although the literature about the natural course of TMD is limited, evidence shows that progression to chronic condition is uncommon.[28]

Some studies have found that signs and symptoms of TMD in the general population occur twice as often in females as in males (2:1).[29–32] However, other studies have found the ratio of females to males to be approximately the same[33] or 3:1.[34] For example, one study found that more than 70% of patients with TMD were women, and the ratio of affected females to males was 2.4:1 for arthralgia, 2.5:1 for osteoarthritis, 3.4:1 for myofascial pain, and 5.1:1 for disc displacement (DD).[35] The literature supports the fact that women are more sensitive to pain conditions and that they report pain that is more severe, more frequent, and of longer duration than that reported by men.[36–43] In addition, women are more likely to seek help than men.[1]

Women have also been found to have more TMJ clicking and tenderness, headaches, and muscle tenderness than men.[44] According to data presented by LeResche,[45] only 25% of the community cases met the criteria for a diagnosis of myalgia or myofascial pain; 3.3% met the criteria for a diagnosis of internal derangement; and 4.2% met the criteria for a diagnosis of an arthrogenic condition. Most subjects presented with a mixed diagnosis and were classified into more than one group. Muscle and disc diagnoses were made in 8.3%; myogenic and arthrogenic diagnoses were made in 21.7%; and myogenic, arthrogenic, and DD diagnoses were made in 7.5%.

Etiology

The etiology of TMDs has been hypothesized to be multifactorial. As stated by Goldstein,[15] the medical cause of most TMDs has not yet been established or is unknown (idiopathic). Some factors, such as bad posture, bruxism, anatomical factors (related to dental occlusion alterations that can cause internal derangement of the TMJ), occlusal disharmony, malposition or malformation of the condyle or fossa, trauma, orthodontic treatment, and psychological factors (e.g., stress),[46] have been hypothesized to initiate or precipitate TMD or to increase a person's predisposition to develop these disorders.[47] However, most of these factors are not based on solid scientific grounds. According to Drangsholt and LeResche,[1] factors associated with female gender, the number of preexisting pain conditions, and depression appear to be strongly associated with TMDs. The remaining factors mentioned previously have failed to demonstrate a strong relationship with TMDs, and more research is needed to clarify their role in causing or perpetuating TMD pain.

It is unknown why people develop TMDs and why they progress to chronicity. A variety of physical and psychological factors could be implicated in chronic TMDs, such as oral habits, secondary gain, and higher levels of pain and disability. Such factors are also seen in other chronic pain conditions, including low back pain, headache, and neck pain. Thus, the most accepted theory related to the etiology, assessment, and management of TMD is supported

by the biopsychosocial model.[48] Therefore TMD is recognized as a multidimensional disorder that is a result of biological, psychological, and social alterations.

CLASSIFICATION OF TEMPOROMANDIBULAR DISORDERS

Various professional organizations have classified TMDs in various ways. The American Academy of Orofacial Pain has established a set of diagnostic criteria that has been presented as an addendum to the classification of and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain.[49] A number of classification schemes used in epidemiological studies of TMDs include clinical signs. The differential diagnosis of TMD is based on the patient's chief complaint, clinical evaluation of the patient's signs and symptoms, and TMJ imaging, when necessary. Most of the tools have been based on clinical experience and patients' reports.

Several classification systems have been used in epidemiological studies to define TMDs. However, not all of them have been validated or tested for reliability and responsiveness. The *Research Diagnostic Criteria for Temporomandibular Disorders* (RDC/TMD)[1] for diagnosing TMDs developed by the Department of Oral Surgery, University of Washington has been the accepted criteria to diagnose TMDs. The RDC/TMD is a guide that provides clinical researchers with a standardized system for examining, diagnosing, and classifying the most common subtypes of TMDs with clear face and criterion validity.[1] It was introduced in 1992 and has been widely used in clinical research settings around the world where TMD and facial pain are managed. Some studies have demonstrated good reliability of the RDC/TMD in different settings, not only for determining signs and symptoms[50] but also for making reliable diagnoses.[51] Wahlund et al.[52] found good to excellent reliability ($\kappa > 0.78$) for each of the RDC/TMD major groups. This guide has been recommended as a model system for standardizing the investigation into the diagnosis and classification of any chronic pain condition. The guide is divided into two sections—axis I: clinical TMD conditions and axis II: pain-related disability and psychological status.[53] The axis I diagnosis classification will be described in this section of the chapter. The axis II classification will be discussed later.

Although the RDC/TMD has been used extensively in the TMD area since its inception in 1992, several researchers have revised it, and several studies have been performed to improve its psychometric properties as well as its usability for clinical practice and research.[54–59] Steenks and de Wijer,[60] for example, felt that the RDC/TMD criteria were unbalanced in the number of muscular and articular palpation sites which could lead to an overrepresentation of muscular conditions at the expense of articular pain conditions when determining TMD diagnoses. In addition, the use of some unreliable muscle palpation sites, such as intraoral muscles and submandibular muscles, and the arbitrary cutoff of three painful palpation sites could increase the probability of false positive results for myogenous muscular pain as well. Furthermore, the algorithm to determine articular compromise from the RDC/TMD was only based on ongoing pain. Compression, retrusion, and joint play (i.e., a traction test) were not included in the examination protocol used by the RDC/TMD. Thus these suggestions were compiled as well as other suggestions from several experts, and a new version of the RDC/TMD has been launched.[61]

Now it is called *Diagnostic Criteria for Temporomandibular Disorders* (DC/TMD). This new diagnostic classification is intended to be used in clinical as well as research settings. It includes 12 common diagnoses of TMD: arthralgia, myalgia, local myalgia, myofascial pain, myofascial pain with referral, four disc displacement (DD) disorders (i.e., DD with reduction [DDwithR], DDwithR with intermittent locking, DD without reduction [DDwithoutR] with limited opening, and DDwithoutR without limited opening), degenerative joint disease (DJD), subluxation, and headache attributed to TMD. A complete outline of the main diagnoses proposed by the DC/TMD can be found in Table 4-1. Several new diagnoses were created and some of the old diagnoses were deleted because their clinical applicability was minimal.[53,62] For instance, because the terms osteoarthrosis and arthritis are not used consistently in medicine, there is a change in nomenclature and these terms are considered to denote subclasses of DJD according to the new DC/TMD. If pain co-occurs with DJD, the diagnosis of arthralgia can be used as well. Thus, the previous diagnosis of osteoarthritis is now called DJD and arthralgia. This new classification has been found to be valid for differentiating the most common pain-related TMDs, such as myalgia with a sensitivity of ≥0.90 and a specificity of 0.99. Myofascial pain with referral showed a sensitivity of ≥0.86 and a specificity of ≥0.98. Arthralgia had a sensitivity of 0.89 and specificity of 0.98. In addition, DDwithoutR with limited opening had a sensitivity of 0.80 and specificity of 0.97. The diagnostic accuracy of the rest of the classifications was poor. Interexaminer reliability for myalgia was found to be excellent ($\kappa = 0.94$) as well as for myofascial pain with referral ($\kappa \geq 0.85$) and arthralgia ($\kappa = 0.86$), which is considered excellent. Nevertheless, other intracapsular diagnoses had poor reliability.

Some authors classify TMDs as **arthrogenic TMDs**, which involve an alteration in the TMJ (e.g., congenital disorders, DD, fracture, dislocation, inflammation, hypermobility, ankylosis, and osteoarthritis) and **myogenic TMDs**, which involve the masticatory muscles (e.g., myalgia [local muscle soreness], myofascial pain, myositis, myospasm [protective co-contraction], myofibrotic contracture, and centrally mediated myalgia).[9,23,63]

Because the classification proposed by the new DC/TMD is the most up to date and accepted, it will be described in more detail in this chapter. In addition, only

TABLE **4-1**

Expanded Taxonomy for Temporomandibular Disorders Proposed by the New Diagnostic Criteria for Temporomandibular Disorders (DC/TMD)

I. TEMPOROMANDIBULAR JOINT DISORDERS
- 1 Joint pain
  - A Arthralgia
  - B Arthritis
- 2 Joint disorders
  - A Disc disorders
    - 1 Disc displacement with reduction
    - 2 Disc displacement with reduction with intermittent locking
    - 3 Disc displacement without reduction with limited opening
    - 4 Disc displacement without reduction without limited opening
  - B Hypomobility disorders other than disc disorders
    - 1 Adhesions/Adherence
    - 2 Ankylosis
      - a Fibrous
      - b Osseous
  - C Hypermobility disorders
    - 1 Dislocations
      - a Subluxation
      - b Luxation
- 3 Joint diseases
  - A Degenerative joint disease
    - 1 Osteoarthrosis
    - 2 Osteoarthritis
  - B Systemic arthritides
  - C Condylysis/idiopathic condylar resorption
  - D Osteochondritis dissecans
  - E Osteonecrosis
  - F Neoplasm
  - G Synovial Chondromatosis
- 4 Fractures
- 5 Congenital/developmental disorders
  - A Aplasia
  - B Hypoplasia
  - C Hyperplasia

II. MASTICATORY MUSCLE DISORDERS
- 1 Muscle pain
  - A Myalgia
    - 1 Local myalgia
    - 2 Myofascial pain
    - 3 Myofascial pain with referral
  - B Tendonitis
  - C Myositis
  - D Spasm
- 2 Contracture
- 3 Hypertrophy
- 4 Neoplasm
- 5 Movement Disorders
  - A Orofacial dyskinesia
  - B Oromandibular dystonia
- 6 Masticatory muscle pain attributed to systemic/central pain disorders
  - A Fibromyalgia/widespread pain

III. HEADACHE
- 1 Headache attributed to temporomandibular disorders

IV. ASSOCIATED STRUCTURES
- 1 Coronoid hyperplasia

From Peck CC, Goulet JP, Lobbezoo F et al: Expanding the taxonomy of the diagnostic criteria for temporomandibular disorders, *J Oral Rehabil* 41(1):6, 2014. In consultation with Schiffman E, Ohrbach R, Truelove E et al: Diagnostic criteria for temporomandibular disorders (DC/TMD) for clinical and research applications: recommendations of the International RDC/TMD Consortium Network and Orofacial Pain Special Interest Group, *J Oral Facial Pain Headache* 28(1):6-27, 2014.

common TMD alterations are described. For a more detailed description of other less common disorders, the reader is encouraged to review the expanded taxonomy of DC/TMD elaborated by Peck et al.[64]

Joint Pain

Temporomandibular Joint (TMJ) Arthralgia

TMJ arthralgia is pain of joint origin. It is characterized by pain and tenderness in the TMJ capsule and/or the synovial lining. Pain is present in one or both joints during palpation, and the patient has at least one of the following symptoms: pain in the joint region, pain during maximum unassisted opening, pain during assisted opening, or pain during lateral movements. Crepitus should not be present with a diagnosis of simple arthralgia.[53] Capsulitis commonly is present in patients with TMJ arthralgia. Pain occurs with provocation testing of the TMJ. Patients report familiar pain (i.e., reproduction of the patient's pain) in the TMJ on palpation at the lateral pole or around the lateral pole or with jaw movements.[64]

Arthritis (Synovitis, Capsulitis)

Patients will complain of pain of joint origin with clinical characteristics of inflammation or infection over the affected joint (i.e., edema, erythema, and/or increased temperature). Arthritis is also called synovitis or capsulitis, but these terms limit the sites of pain perception; thus the term *arthralgia* is more global and involves them both. Pain on palpation over the superior pole and/or posterior part of the TMJ is thought to indicate a capsulitis of the joint. This can be present in an acute stage (e.g., after trauma, such as a blow to the jaw) or in a chronic stage, after repeated minor trauma or insults to the joint itself

(e.g., with bruxism in the presence of a class II malocclusion).* The clinician should keep in mind that capsulitis also may be present in the first stages of some general systemic diseases (e.g., rheumatoid arthritis, ankylosing spondylitis) and with local or systemic infection, although cases involving infection are rarely seen in the private practice setting.

Along with pain on palpation, the patient may have some swelling within the joint (although this is rarely seen except in cases of direct acute trauma). Patients often complain of swelling or a sense of fullness over the temporomandibular region. However, this is not often seen clinically unless the area has suffered a severe degree of trauma. Patients are likely to have pain on occlusion and to complain of discomfort with mastication (which of course causes compression within the joint and distention of the joint capsule). The capsular pattern of the TMJ is thought to be reduction of mandibular opening. Sometimes the patient also reports having pain with activities such as yawning or opening wide to bite, which involve stretching of the joint capsule. Capsulitis can be accompanied by spasm of the muscles of mastication, particularly the masseter and the medial and lateral pterygoid muscles. Muscle spasm is present on the ipsilateral side, and during the assessment the examiner will note deviation of the mandible to that side on opening. Condylar translation (i.e., the movement of the condyle forward within the joint) is likely to be present, and this clinical finding is one of the differential diagnostic indicators that distinguish an isolated capsulitis from other internal derangements of the TMJ.

In the acute stage, treatment is aimed at reducing the inflammation and resultant swelling, resting the involved structures, and reducing any muscle spasm. Pain reduction should follow as a result of these measures.

Three of the four basic principles represented by the acronym RICE (rest, ice, and compression; elevation is not really possible with the TMJ) can be used in the treatment of acute capsulitis. The patient should be instructed to eat only soft foods to avoid compressing the joint and aggravating the muscle spasm. The use of an occlusal splint to rest the joint sometimes is effective; however, if the surrounding muscle spasm is severe, a splint can actually increase the spasm because it increases the vertical dimension, thus stretching the contracted muscles. Ice can be applied to the side of the face over the TMJ region to reduce any heat caused by an acute inflammation, as well as the effects of the inflammation and swelling. The authors' experience has been that, apart from cases involving an acute traumatic inflammatory problem, patients usually find moist heat more comfortable and efficacious. As mentioned, elevation is not possible for cases involving the TMJ; however, symptoms can be controlled through use of the usual principles for treating an acutely traumatized musculoskeletal joint. Nonsteroidal anti-inflammatory drugs (NSAIDs) may be prescribed to reduce pain and/or inflammation.

*Details on malocclusion, internal derangement, clinician observation, and the patient history can be found in volume 1 of this series, *Orthopedic Physical Assessment,* Chapter 4.

Joint Disorders

Temporomandibular Joint Disc Displacements

Internal derangement of the TMJ is defined as an abnormal relationship between the mandibular condyle and the disc. This abnormal relationship may involve DDwithR or DDwithoutR. Patients with DD can present with a clinical sign, such as clicking, that is characteristic but not necessarily confirmation of a reducing DD.[65]

Disc Displacement with Reduction (DDwithR)

DDwithR is an intracapsular biomechanical disorder involving the condyle-disc complex. DD can occur anteriorly, medially, anteromedially, or (the most rarely seen) posteriorly. The etiology of DD can be either direct trauma to the mandible (e.g., a blow during a motor vehicle accident [MVA] or contact sports) or indirect trauma. Some researchers postulate that small, repeated episodes of trauma to the joint eventually can cause enough internal tissue damage to produce displacement.[66] It is thought that microtrauma occurs to the structure of the disc itself and/or in some cases to the posterior ligament attached to the disc. This damage causes histological changes within the cell structures of the disc and reduces the disc's load-bearing or compression capacity.

Repeated microtrauma eventually leads to macrotrauma and a further breakdown in tissue and in the disc's ability to function properly. Eventually the disc begins to sublux off the head of the condyle; clinically this produces a click, which can be heard by the patient (and sometimes by others) or can be felt by the clinician during palpation over the poles of the joint during mandibular movement. The patient may present with a reducing disc (i.e., a disc that is displaced and reduces back to its proper position on the condyle), which the patient and clinician may or may not be able to feel. According to the new DC/TMD, to diagnose a DDwithR, clicking or popping and/or snapping noise is detected during both opening and closing with palpation during at least one of three repetitions of jaw opening and closing or clicking or popping and/or snapping noise with palpation during at least one of three repetitions of jaw opening or closing or lateral or protrusive movements. A confirmatory diagnosis of subluxed or dislocated disc can be made only with the backup of an appropriate radiological examination (i.e., MRI). In this case, in the maximum intercuspal position, the posterior band of the disc is located anterior to the 11:30 position

and the intermediate zone of the disc is anterior to the condylar head, or on full opening the intermediate zone of the disc is located between the condylar head and the articular eminence.

In the initial stage of DD, the click during displacement is present early in the opening phase. As the disc and posterior ligament become further traumatized and further displaced, the click is noted later in the opening phase. Therefore a patient who has a click after opening the mandible at least 5 mm of intraincisal distance is likely to have a fairly recent dysfunction, whereas a patient who does not have a click until 45 mm of opening is likely to have had a dysfunction for a longer time (Figures 4-1 and 4-2). In the dental profession a click that is felt during both the opening and closing phases is called a **reciprocal click**; in other cases a click at the joint may be felt either during opening or during closing. When the DD with reduction is unilateral, the mandible can deviate to the affected side during mouth opening.[67]

Figure 4-1 MRI of disc displacement with reduction. *Arrows* indicate disc. (Courtesy Dr. L. Kamelchuk, Calgary, Alberta.)

Figure 4-2 MRI of disc displacement with reduction showing reduced disc opening. (Courtesy Dr. D. Hatcher, Sacramento, California.)

Patients with DDwithR can have symptoms of joint tenderness on palpation, joint pain that is increased with function, and aberrant mandibular movement with opening.[67]

From a clinical standpoint, it is important to make the patient aware of the likely biomechanical dysfunction occurring in the joint and to emphasize the fact that no form of treatment is likely to reduce the displaced disc. Patients tend to focus on the click, and it is vital to explain as an educational part of the treatment that it is possible to have a clicking joint that is pain free and functional. Indeed, because the disc is crucial to lubrication and nutrition of the structures within the joint,[11] a joint with a clicking disc is preferable to one that is silent and displaced.

Treatment should focus on attempting to produce a symmetrical opening so that the heads of the mandibular condyles translate equally during opening. Making sure that muscle activity is symmetrical also is necessary. As part of the education process, the clinician must teach the patient to avoid any activities that might cause additional trauma to the involved joint or even to the opposite joint. As a result of the dysfunction or the pain caused by the dysfunction, patients not uncommonly isolate any mastication to the side away from the dysfunction. Patients must be coached to chew equally on both sides. They also must be taught to avoid any habit that might increase trauma to the joint, such as nail biting, chewing on toothpicks, bruxing, or chewing gum; these activities can adversely affect the TMJ.

Disc Displacement Without Reduction (DDwithoutR)

DDwithoutR (also called a **clinical closed lock**) (Figures 4-3) is an intracapsular biomechanical disorder involving the condyle-disc complex. In some cases DDwithR causes enough trauma to the disc and its attached

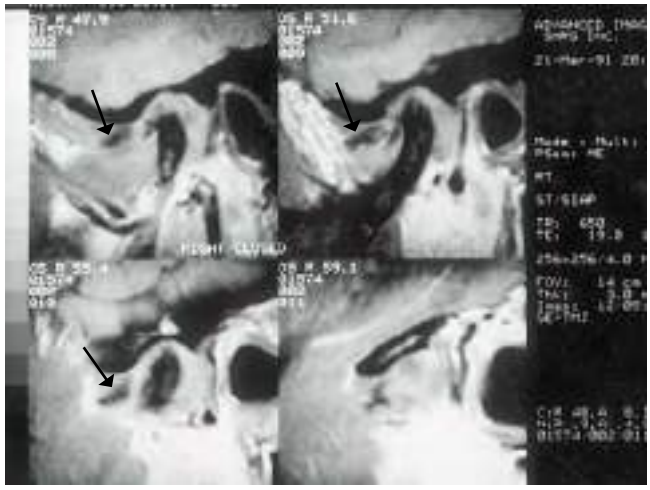

Figure 4-3 MRI of disc displacement without reduction. *Arrows* indicate disc. (Courtesy Dr. L. Kamelchuk, Calgary, Alberta.)

ligaments that the disc does not slide back into its normal position over the pole of the condyle. This can happen asymptomatically, although classically patients present with a history of a clicking functional joint that suddenly changes to a nonclicking, reduced opening joint (e.g., "My jaw clicked for 5 years, and then all of a sudden I woke up [or bit down on some popcorn or yawned], there was a big crack, and my jaw did not click any more, but I couldn't open my mouth as far."). In a study by Stegenga and De Bont,[65] 9% of patients with reducing DD progressed to nonreducing DD within 3 years. The main complaint of these patients is inability to open the mouth wide, and it does not resolve with the clinician or patient performing a specific manipulative maneuver. In the case of a unilateral problem, the mandible is deviated to the affected side during attempted opening without returning to the midline.[67] In the closed-mouth position, the disc is in an anterior position relative to the condylar head, and the disc does not reduce with opening of the mouth. Medial and lateral displacement of the disc may also be present. Presence of TMJ noise (e.g., click with full opening) does not exclude this diagnosis.[64]

As previously noted, the closed lock can be present with or without symptoms; however, a person with a clinical closed lock is more likely to have accompanying symptoms, such as pain, muscle spasm, and reduced function. If the pain is from the TMJ itself, the patient probably will point to the joint and indicate that it hurts there. Sometimes pain can be referred from the TMJ to other areas. It often manifests as a parietal headache on the same side or as pain under the angle of the jaw, or both. Pain also can be referred to the temporomandibular area from other structures; for example, a trigger point in the midbelly of the sternocleidomastoid muscle refers pain directly over the TMJ. Therefore, it is very important that the clinician perform a complete musculoskeletal assessment, which includes not only the masticatory system but also other structures that could be involved, especially the cervical spine.

Treatment of a clinical closed lock is aimed at restoring more normal function. Because of the kinematics of the joint, a degree of opening can be achieved with the disc in a displaced position. Opening produces condylar translation and rotation. In the first movement, which takes place in the superior part of the joint, the mandibular condyle articulates with the disc; in the second movement, which takes place in the inferior part of the joint, the disc and condyle articulate with the temporal fossa. With the disc displaced, translation is reduced; this can be seen during the examination, and it differentiates the clinical closed lock from a straightforward capsulitis. Unless a large amount of muscle spasm disrupts the normal condylar movement, when capsulitis is present without DD, the head of the condyle is still able to translate forward during mandibular opening. In both disorders the condyle can still rotate, and an opening of up to 30 mm of intraincisal distance can be achieved using only condylar rotation.

In most cases if the joint is left untreated, the structures in the joint gradually are stretched so that eventually a more functional opening is achieved. However, secondary adaptive changes can occur in the masticatory structures and can cause other dysfunctions. For example, a joint with a clinical closed lock (a hypomobile joint) stresses the contralateral mandibular joint and causes hypermobility of that joint, which may become symptomatic. For this reason, one of the aims of treatment should be to speed up the stretching that normally occurs in the dysfunctional joint to alleviate the stress on the opposite joint. Thus mobilization of the hypomobile joint becomes vital to restoration of a more symmetrical opening. The patient should be informed that the clinician is not actually trying to relocate the disc but rather to speed up what the body eventually would achieve anyway; that is, a stretching out of tight structures to obtain a more normal function.

Estimates are that 9% to 13% of asymptomatic joints have some type of TMD-related problem. However, not all patients with pain over the TMJ region have an internal derangement; likewise the absence of pain in the TMJ region does not necessarily mean that no internal derangement is present. It has been shown that in so-called normal, symptom-free populations, a certain percentage of joints actually have internal derangements. This fact emphasizes the importance of the history, musculoskeletal assessment, and radiological survey in determining the condition present.

The clinician cannot determine the type of pathology taking place in the joint by using just one type of diagnostic imaging. In the past some practitioners thought that a lateral x-ray film of the TMJ was enough to allow determination of the pathological condition at the TMJ and even the position of the condylar head in the temporal fossa. However, it has since been shown that a full set of diagnostic images is needed to ascertain properly what is going on in the joint. Many practitioners now require a Panorex (a radiograph that gives an overall impression of the maxilla-mandible structure) (Figure 4-4), tomograms that show both the opening and resting positions of the condyle, and cephalograms, which orthodontists use to define growth patterns, particularly the skull structure (Figure 4-5). Magnetic resonance imaging (MRI) of the joint demonstrates the state and position of the disc and surrounding soft tissues in much greater detail (Figure 4-6) than an x-ray film.

Disc Displacement Without Reduction Without Limited Opening

Similar to DDwithoutR, this condition is an intracapsular biomechanical disorder involving the condyle-disc complex. The only difference with the DDwithoutR is that this kind is *not* associated with limited mandibular opening.[64]

Joint Diseases

Degenerative Joint Disease (DJD)

DJD is a degenerative disorder characterized by deterioration of articular tissue of the joint with concomitant osseous changes in the condyle and/or articular eminence. DJD can be subclassified: DJD without arthralgia is defined as osteoarthrosis and DJD with arthralgia is defined as osteoarthritis.

As mentioned previously, the disc is an important structure in the lubrication and nutrition of the joint. When the disc stops functioning properly (e.g., immobile, disc in the anterior position), changes occur in the joint structures that can be seen with diagnostic imaging. The hypomobility affects the pumping action that delivers nutrients from the synovial fluid to the articular cartilage. The deficiency in lubrication and nutrients may induce or aggravate degeneration.[65] Changes that occur in the joint structures include erosion, cavitation, osteophyte formation, and a reduction in the normal joint line (Figure 4-7).

TMDs that arise from degenerative joint changes most often are seen after age 40.[68] Some small x-ray changes usually can be seen in a joint that has DDwithR, such as flattening of the condylar head, subchondral sclerosis, and slight remodeling; however, the major degenerative changes do not occur until the disc is displaced and is not reducing. According to the new DC/TMD classification, flattening and/or cortical sclerosis are considered indeterminant findings for DJD and may represent normal variation, aging, remodeling, or a precursor to frank DJD. All these changes can occur without symptoms. When symptoms do occur, they usually include pain, muscle spasm, headaches, and a change in function of the masticatory system. For example, the patient is unable to chew hard foods, or crepitus is experienced at the TMJ with function. The main aim of treatment for DJD of the TMJ is to restore the area to normal function. In addition, it bears repeating: "*as part of the educational process, the clinician must emphasize to the patient that the treatment is not about restoring the disc or disc function, but more about speeding along what the body would normally do.*"

Based on the new DC/TMD, DJDs include TMJ osteoarthritis and osteoarthrosis.

TMJ Osteoarthritis and Osteoarthrosis. Osteoarthritis is an inflammatory condition in the joint, and it can manifest in different forms, such as osteoarthritis and rheumatoid arthritis (RA). Osteoarthritis results in erosion and fibrillation of the cartilage and degeneration of subchondral bone. Symptoms of osteoarthritis include pain, restricted jaw movement, and joint sounds (crepitus). RA is a chronic systemic inflammatory disease that involves the synovial joints, including the TMJ. RA produces symptoms such as fatigue, fever, anemia, and neuropathy.[69]

According to the new DC/TMD, a diagnosis of osteoarthritis requires the presence of arthralgia plus either crepitus in the joint or imaging evidence of at least one degenerative characteristic, specifically subchondral cyst, erosion of normal cortical delineation, generalized sclerosis of the condyle and articular eminence, or osteophyte formation.[64] TMJ osteoarthrosis is a degenerative disorder in a joint with an abnormal joint structure. For this diagnosis, the same characteristics must be present as for the osteoarthritis diagnosis, but the arthralgia symptoms must be absent.[53,64]

Osteoarthrosis presents degenerative changes similar to those seen with osteoarthritis, but it is a noninflammatory condition.

Masticatory Muscle Disorders

Myalgia

Myalgia is an acute, local, noninflammatory pain in the masticatory muscles that is the result of protective

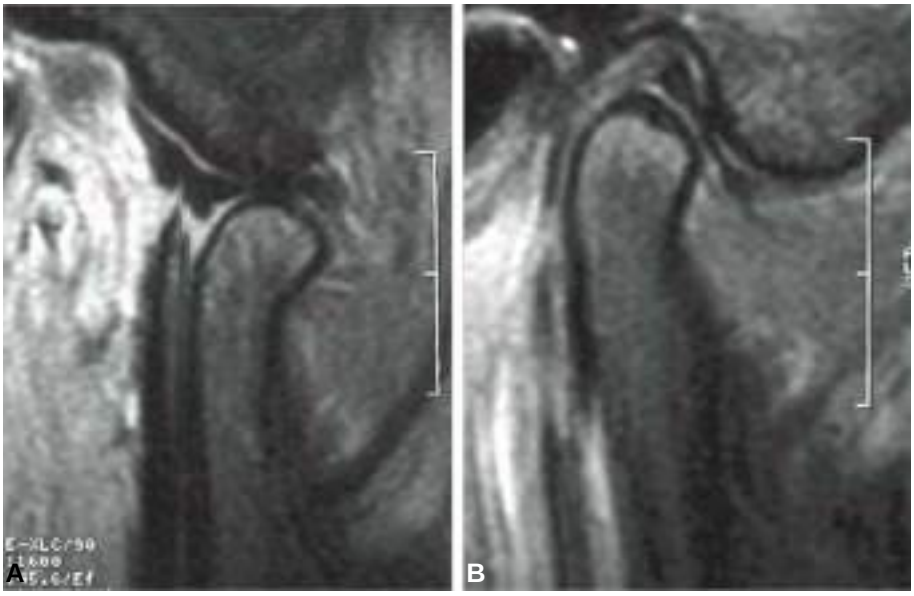

Figure 4-6 MRI studies of a normal temporomandibular joint. **A**, Open. **B**, Closed. (Courtesy Dr. D. Hatcher, Sacramento, California.)

muscle splinting, postexercise muscle soreness, muscle fatigue, trauma, and/or pain from ischemia. It is a pain of muscle origin affected by jaw movement, function, or parafunction, and replication of this pain with provocation testing of the masticatory muscles. Limitation of the mandibular movement(s) secondary to pain may be present.[61] Its causes and pathology are not clearly defined.[62] It is called "local myalgia" when the localization of pain is only at the site of palpation (i.e., localized to the area of the palpating finger) when using the examination protocol stated by the DC/TMD.[61,64] According to Okeson,[70] it is characterized by changes in the local environment of the muscle tissues, mainly through release of algogenic substances that produce pain.

The diagnosis of myalgia is made based on examination of the masseter and temporalis muscles. However, a positive finding with the specified provocation tests when examining the other masticatory muscles can help to corroborate this diagnosis. Based on the new DC/TMD classification scheme, there are three subclasses of myalgia: local myalgia, myofascial pain, and myofascial pain with referral, which are described later. When myalgia is further subclassified as local myalgia, myofascial pain, or myofascial pain with referral, the latter diagnoses are based on using only the examination findings from palpation protocol stated by the DC/TMD. The palpation pressure being held over the site being palpated for myofascial pain with referral is 5 seconds compared with 2 seconds for myalgia.

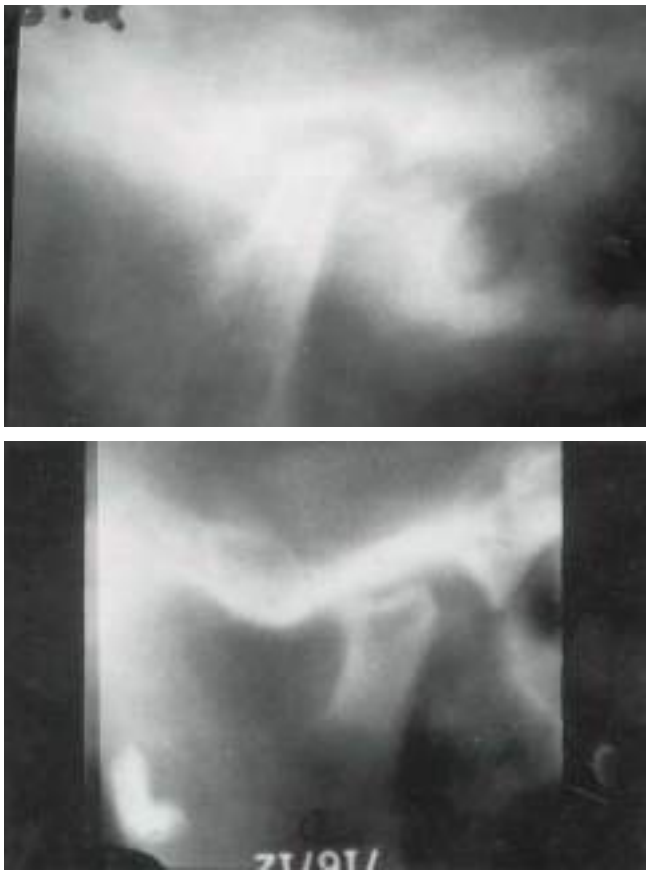

Figure 4-7 CT scans of degenerative joint disease. (Courtesy Dr. L. Kamelchuk, Calgary, Alberta.)

Myofascial Pain

According to the new classification scheme from the DC/TMD, the term "myofascial pain" can be divided in two new subclassifications: **myofascial pain** and **myofascial pain with referral**. Myofascial pain is defined as pain of muscle origin as described for myalgia with pain spreading beyond the site of palpation but within the boundary of the muscle at palpation. Myofascial pain with referral describes the pain that is characterized by referral of pain beyond the muscle being palpated when using the examination protocol described by the DC/TMD.[61,64] It can be characterized by stiffness, muscle pain that increases with function, and the possible presence of trigger points.[53,62] The recommended treatments include manual therapy (e.g., therapeutic massage, acupressure, and acupuncture) and osteopathic manipulation. Some of these treatments are discussed in detail later in the chapter.

Myospasm

Myospasm is a rare, acute condition of the masticatory muscles. It is a sudden, involuntary, and reversible muscle contraction characterized by localized pain and limited ROM of the jaw.[62] It usually is of short duration.[70] It may affect any of the masticatory muscles.[64]

Contracture

Contracture is a painless shortening of a masticatory muscle as a result of fibrosis in muscles and surrounding tissues, such as tendons, ligaments, or muscle fibers.[62] It is usually not painful unless the muscle is overstretched. Contractures are generally the result of radiation therapy, trauma, or infection. Masseter and medial pterygoid muscles are most commonly affected.[64]

Other Temporomandibular Joint Problems

Hypermobility

Hypermobility can be viewed in two ways: as a joint dysfunction entity in itself or as an end process in the natural history of joint dysfunction, which progresses from capsulitis to DDwithR to DDwithoutR to DJD and eventually to hypermobility.

For a joint to be labeled hypermobile, radiological hypermobility must be present. Normally the head of the condyle can be seen to translate to the tip of the articular eminence; however, with radiographic hypermobility, the condylar head translates beyond the articular eminence (Figure 4-8). This often is accompanied by a change in the normal biomechanics of the joint, which means the examiner would see an increase in condylar translation and a reduction in condylar rotation. As mentioned previously, rotation normally takes place at the beginning of mandibular opening; midopening requires a degree of rotation and some translation; and the final phase of opening involves mainly translation of the condyle. In a hypermobile joint, posterior disc structures usually are stretched and the posterior ligament frequently is perforated. Because of the soft tissue laxity, a great deal of translation can occur at the beginning of opening, and very little rotation is felt at all. This is almost a reversal of the normal articular mechanics of the joint.

If the hypermobility is the result of stiffness in the opposite joint, treatment obviously includes mobilization of the hypomobile joint. If the hypermobility is the end result of degenerative changes within the joint, treatment focuses more on restricting the extra mobility within the joint. If the biomechanics of the joint have been changed, part of the treatment should include exercise to try to return joint movement to a more normal form. For example, some hypermobility can cause increased translation and reduced rotation. One way to restrict translation is to coach the patient in using the tongue to control movement. The tip of the tongue is placed behind the top teeth, the lips are placed together, and the teeth are left in their resting position in slight dysocclusion (the upper and lower teeth have a slight distance between them [1 to 3 mm at rest]; this is called the *free way space*). Then the patient is instructed to keep the lips together and drop the jaw. By placing an index finger over the head of the condyle, the examiner can feel a reduction in the condylar translation and a return to some rotation. The patient is instructed to repeat this exercise once an hour so that the different movement

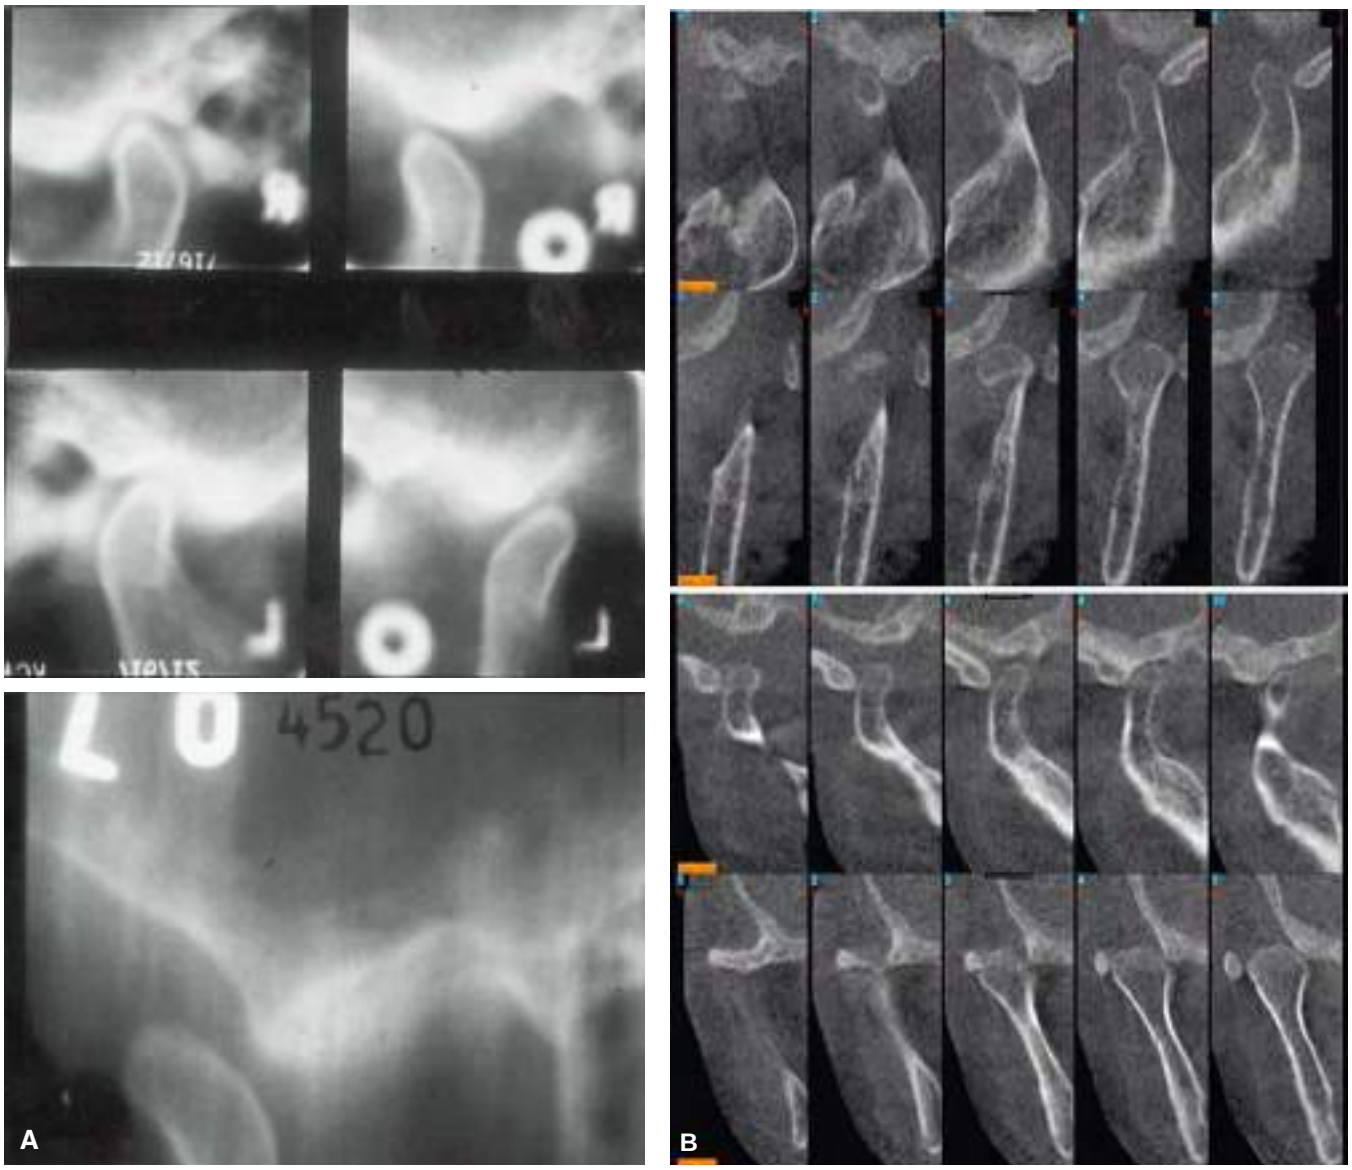

Figure 4-8 **A,** Tomograms showing hypermobility of the temporomandibular joint (TMJ). **B,** Tomograms of a hypermobile TMJ showing dislocation of the condyle. (**A**, Courtesy Dr. L. Kamelchuk, Calgary, Alberta. **B**, Courtesy Dr. D. Hatcher, Sacramento, California.)

patterns produced by the motor units are reprogrammed as a new engram into the motor cortex.

The tongue can also be used to restrict hypermobility. If the patient is instructed to keep the tip of the tongue behind the top teeth and to open the mouth as far as possible with the tongue in place, in most cases the joint will not be stretched into its hypermobile range. In some cases a patient with a long tongue will not be able to restrict the opening sufficiently; the individual should then be instructed to place the tip of the tongue in the roof of the palate. If this still does not restrict the opening movement sufficiently, the patient can be coached to fold the upper one third of the tongue into the roof of the mouth. Normal opening should be assessed as 40 to 50 mm interincisal distance. Opening past 50 mm frequently can be present with normal joint biomechanics, indicating laxity. Increased translation also can occur at the cost of lost condylar rotation (less than 50 mm), which often is seen in individuals with Asian features.

Patient Education to Limit Hypermobility

- Control opening wide (hypermobility)
- Put the tip of your tongue against the back of your upper teeth. Keeping your tongue in this position, open your mouth as far as the tongue will allow. This is as far as you should allow yourself to open, so that the soft tissue around the jaw is not overstretched and is allowed to rest
- Cut your food into bite-sized (i.e., small) pieces. Do not take big bites out of hamburgers or other foods
- When you feel a yawn coming on, make sure to control the amount of mouth opening, using the tongue positioning technique described in the second point

Temporomandibular Joint Ankylosis

Ankylosis of the TMJ is a complete fusion of the condyle to the temporal fossa (true ankylosis). Ankylosis is classified as congenital, traumatic, inflammatory (i.e., RA), systemic (e.g., ankylosing spondylitis), or neoplastic (e.g., osteochondroma).[67]

TMJ ankylosis causes restriction of opening and stress on the opposite joint; in fact patients often present with symptoms arising from the joint opposite the ankylosed joint. In children, TMJ ankylosis impairs mandibular growth and can result in mandibular micrognathia (underdevelopment). This condition has functional and aesthetic implications. It also causes difficulties related to nutrition and oral hygiene. Treatment (i.e., surgical correction) should be initiated as soon as the condition is recognized. The main objective is to reestablish joint and jaw functions.[71]

During mobilization as part of the physical therapy treatment, no distraction of the condyle on the ankylosed side occurs, and radiographic restriction also is noted. Apart from treating the opposite joint symptomatically, therapy is not effective in improving movement (Figure 4-9).

TEMPOROMANDIBULAR DISORDER-RELATED FACTORS

Any discussion of TMDs must include factors and dysfunctions associated with TMDs. As mentioned previously, bruxism, forward head posture, whiplash injury, cervical spinal dysfunction, alterations in occlusion, and psychosocial stress have been hypothesized to initiate or precipitate a TMD or to increase a person's predisposition to developing a TMD. These factors will be described briefly in this chapter.

Bruxism

Parafunctional (abnormal) habits, such as bruxism, teeth clenching, jaw thrusting, gum chewing, and jaw testing (repeatedly moving the jaw to cause a click or moving the jaw into a painful position to see if the click or pain is still present), can add repetitive strain to the masticatory muscles and cause tenderness and pain.

According to Lobbezoo and Naeije,[72] the etiology of bruxism is related to morphological, pathophysiological, and psychological factors. Pathophysiological factors in the etiology of bruxism are increasingly related to sleep disturbances, chemical alterations in the brain, use of medication, and use of cigarettes and alcohol. Bruxism can cause muscle pain, TMJ noise, limited jaw movements, and headache.

One of the most common characteristics seen in patients with myogenic TMDs is the hyperactivity of the masticatory muscles that can be caused by bruxism. This hyperactivity is caused by the dynamic imbalance of the masticatory system,[74] and it can contribute to internal derangement.[68]

In 1997, Kampe et al.[74] investigated subjects between 23 and 68 years of age with more than 5 years of bruxism. The authors suggested a causal relationship between the bruxism and TMD signs and symptoms, including headache and pain in the neck and shoulder. People with TMDs commonly have parafunctional habits (e.g., bruxism, clenching the teeth, and nail biting [neuromuscular factors]). However, the relationship between bruxism, stress, and TMDs is unclear. Some studies have found that bruxism is not always present in people with a TMD; therefore a causal relationship cannot be claimed.[48]

Bruxism (clenching the teeth) often can be done unconsciously and may be the body's response to an aggravating stimulus (e.g., a high restoration on a tooth, malocclusion, stress, habit, or a combination of factors). Some authors believe that bruxing can trigger problems within the TMJ apparatus, whereas others deny such a claim.[15,75] Either way, bruxing definitely can aggravate TMDs and hinder treatment and recovery.

Because bruxism often is an unconscious habit, it can be very difficult to control. Sometimes just pointing out the habit to patients can be enough to make them aware of the problem and prompt them to take steps to control it themselves. In other cases some form of relaxation technique, biofeedback, or stress management might be necessary to help control the problem. Exercise that promotes the contraction of muscles antagonistic to the masseters and temporalis can help (e.g., a resisted mandibular opening). If the bruxing is aggravated by gum chewing or holding a toothpick between the teeth, removal of the offending object often is enough to control the symptoms.

Signs and Symptoms of a "Bruxer"

- The patient regularly and consistently clenches and relaxes the masseters
- A masseter "bump" is present. (The clinician lightly palpates the masseters as the patient opens and closes the mouth. Normally, on closing, the teeth lightly come together before resting. A "bruxer" shows a definite and obvious overcontraction as the teeth occlude)
- Hypertrophy of the masseters is obvious (this may give the patient a heavyset jaw)
- The patient regularly and consistently purses the lips or squeezes them together
- The teeth show facet wearing
- The tongue shows scalloping (this occurs as a result of the teeth constantly biting on the edges of the tongue)

Patient Management Program: Controlling Bruxism

- One of the most important steps in breaking the habit of clenching and grinding the teeth (bruxism) is to become conscious of when it occurs and then to stop doing it. Many people are unaware they have the habit until it is pointed out to them. This awareness must occur before you can control the habit. An excellent way to avoid clenching the teeth is to learn to keep your lips together and your teeth apart. This simple step makes clenching the teeth impossible; even more important, it relaxes the muscles that become tense and taut. As an extra dividend, this relaxation technique improves your facial expression and appearance. It also promotes a more normal resting position of the TMJs.
- The more conscious you become about this basic procedure of relaxing the jaw muscle, the greater control you will have in overcoming this harmful habit. First, you need to identify when you are most likely to clench or grind your teeth during waking hours, such as while driving on the freeway, during physical exertion or sports, or when you are under emotional tension or stress. At these times you should repeat to yourself, "lips together, teeth apart."
- By sealing your lips and gently blowing or puffing air, you will automatically separate your teeth and simultaneously relax your jaw and facial muscles.
- Remember, you probably have had this habit for a long time, and it will not vanish overnight. You must persevere and practice this exercise each time you find your teeth clenched.

Forward Head Posture

According to some researchers, forward head posture can cause TMDs.[76–78] Head posture and its relation to occlusion, to the development and function of the dentofacial

structures, and to TMDs have been studied. Head posture alterations have been associated with changes in the stomatognathic system, influencing the biomechanical behavior of the TMJ and associated structures. Some have suggested that the position of the head affects the resting position of the mandible,[78,79] produces greater muscular activity in the temporal and masseter muscles,[76,78–85] and alters the TMJ internal relationships.[86] This can be explained by the relationship between the masticatory system and the cervical spine, as a result of neurophysiological, anatomical, and biomechanical interactions.[73]

The association between cervical and head posture in the presence of TMDs has been a matter of debate for many years. Physical therapists have commonly used cervical-head posture reeducation techniques to address postural abnormalities in patients with neck involvement.[87] Postural alterations have been associated with changes in the distribution of loads between the anterior and posterior cervical segments as well as with changes in cervical muscular length.[78]

A systematic review done in 2006 studied the association between the head and the cervical posture and TMD.[88] Of the 12 papers included in the study, nine concluded that postural alteration could be associated with TMD. However, the studies included in the review were of poor methodological quality. According to the authors, it was not clear that head and cervical posture were associated with TMD because of the level of evidence in the studies.

A study investigating head and neck posture in subjects with TMD[89] found that subjects with TMD had neither statistically nor clinically significant differences in most of the head and cervical posture variables when compared with pain-free subjects. According to the results of this study along with a systematic review,[90] there is a lack of a scientific validation of a correlation between postural alteration and TMD. The study results indicated that static posture of the craniocervical system in patients with TMD (evaluated through the tragus-C7-horizontal, pogonion-tragus-C7, eye-tragus-horizontal, and tragus-C7-shoulder angles) was not significantly altered and thus static posture evaluation of the craniocervical system was not recommended for these patients. However, it is still unknown whether dynamic posture (i.e., posture that subjects adopt when performing functional activities) is significantly different in subjects with TMD when compared with healthy subjects. Falla et al.[91] evaluated posture when subjects were performing a functional activity. They found that subtle changes in head and cervical posture over time (approximately 4°) could reflect poor muscle control of the deep cervical flexor muscles when evaluating sustained postures in patients with pain in the upper quarter. Thus, a more functional evaluation of posture between patients with TMD and healthy controls could provide a better understanding of the muscular impairments of these patients and also explain more accurately the symptomatology in these patients.

Although there is a lack of a scientific validation of an association between postural alteration and TMD, a systematic review that focused on the effectiveness of physical therapy interventions for TMD found that postural training was one of the interventions recommended to restore or optimize the alignment of the CMS and to reduce pain in patients who have TMDs with muscular involvement (i.e., myogenic TMD).[92] According to O'Leary et al.,[87] postural evaluation and treatment could be considered based on individual needs. For example, patients who reported posture as an aggravating factor and who reported an improvement of symptoms when performing postural corrections could use postural correction to improve their symptoms. Thus clinicians who work with patients with TMD having postural abnormalities as an aggravating factor could consider these recommendations for treating these subjects in clinical practice.

Occlusal Alterations

Dental occlusion is very important for masticatory function. It has been suggested that a significant relationship exists between alterations in the masticatory system and dental occlusion. Occlusion relationships should be routinely considered as part of the examination in patients with TMD.[93]

Occlusion alterations influence the TMJ and the functions of the masticatory muscles. According to Okeson,[63] occlusion alterations can be associated with parafunctional habits, such as squeezing, bruxism, and clenching the teeth, which lead to muscle spasm and hyperactivity. Celic et al.[94] investigated the prevalence of TMD and relationship between dental occlusion and parafunctional habits using clinical assessment and patient histories. They found a significant correlation between occlusion alterations, parafunctional habits, and TMD. Another study[95] found that the electromyographic (EMG) responses of the temporal and masseter muscles were modified in subjects with a class II occlusion alteration (Angle classification). Subjects with a class II occlusion showed hyperactivity of the temporal muscles, which altered the normal EMG pattern between the temporal and masseter muscles and also led to a higher occurrence of forward head posture. Conversely, many clinical studies have failed to demonstrate any significant differences between patients with TMD and controls in terms of occlusal variables.[96–98] For example, a study that evaluated 4310 subjects did not find any association between any occlusal variable and subjective TMD symptoms.[97] Neither convincing nor powerful evidence supports the theory of occlusal alterations as an important factor in TMD.[15]

Stress, Anxiety, and Depression

Psychological factors, such as stress and anxiety, can play a significant role in TMDs—they can either initiate problems or aggravate an existing dysfunction. The clinician

should include an explanation of the effects of stress in the initial history and interview process because if stress appears to be a major concern, it may be necessary to involve a health professional (e.g., a clinical psychologist) who is experienced in stress management techniques, relaxation techniques, biofeedback, and counseling. The authors have found that a patient is much more willing to accept a referral to a clinical psychologist if this is brought up as a possibility before any therapy is initiated. If the whole concept of stress as a factor in the pathology and treatment of the condition is left until after therapy has been initiated, the patient is more inclined to believe that the clinician thinks the problem is all in the patient's head; patients can be very averse to referral to a clinical psychologist after therapy has been unsuccessful or only partially successful.

Discussions with clinical psychologists have revealed that people commonly are able to cope with a severe life stress at the time of the event and that symptoms become apparent approximately 6 months after the stressful period. Therefore when taking the history, the clinician should ask about previous life stressors to determine whether they are coincident with the latest exacerbation of symptoms. Clinically, some patients have been found not to be *psychologically aware;* that is, they are unable (or unwilling) to comprehend the effects of the psyche on the body and on an individual's well-being. Involvement in the psychological side of therapy might not be practical. Similarly the clinician may have encountered people who are not *body aware;* that is, they seem to have no awareness of the physical functioning of the body or its specific control. This can make treatment for certain individuals challenging.

To help a patient understand the problem and identify some of the initiating factors, the clinician may find it worthwhile to get the patient to keep a daily diary of the symptoms or pain. The myofascial pain caused by stress and fatigue can occur not only in the region of the masticatory muscles but also in the neck and shoulder region. This symptom is commonly present in patients with TMD. The sternocleidomastoid and trapezius muscles often are affected. Stress also can cause the patient to develop parafunctional habits, such as bruxism and clenching the teeth, which contribute to the hyperactivity of the masticatory muscles and consequently cause pain in this region.

A group of patients with TMD have been differentiated from a control group by levels of pain, anxiety, depression, and sleep disturbances.[99] Patients with TMD frequently have symptoms of fibromyalgia, chronic fatigue syndrome, headaches, panic disorder, irritable bowel syndrome, and posttraumatic stress disorders.[100]

In a multicenter study[101] including 1149 patients seeking for TMD treatment, a strong relationship of depression and somatization levels with pain-related disability was found ($p<0.001$). In addition, pain lasting more than 6 months (i.e., chronic conditions) was found to be significantly correlated with high scores of pain-related disability in subjects with TMD ($p<0.001$). In another study,[102] chronic female patients presented significantly higher depression and somatization scores in comparison with acute patients. In addition, acute patients self-perceive higher levels of anxiety in relation to the control group (healthy females). Patients reporting higher levels of depression were more inclined to somatization and had experienced a greater number of stress events in the past 6 months.

The presence of mood and panic-agoraphobic symptoms in different groups of TMD patients has been investigated.[103] Patients classified as having myofascial pain differed from those with DD, joint disorders, and no TMD in relation to some psychopathological symptoms. A higher prevalence of both mood ($p<0.001$) and panic-agoraphobic ($p<0.01$) symptoms was found in this group classification.

In a large prospective cohort study (Orofacial Pain: Prospective Evaluation and Risk Assessment, OPPERA) designed to discover causal determinants of TMD pain,[104] 3263 TMD-free subjects completed several psychological tests assessing general psychological adjustment and personality, affective distress, psychosocial stress, somatic symptoms, and pain coping and catastrophizing. The follow-up data (after 2.8 years) from 2737 subjects revealed that several psychological variables predicted increased risk of first-onset TMD, including reported somatic symptoms, psychosocial stress, and affective distress.

In summary, physiological factors, such as stress, depression, and anxiety, may play a predisposing role in the etiology of TMD. Therefore these factors should be taken into account in the management of these patients. Because patients with TMD present with cognitive, emotional, and behavioral responses to pain, the new DC/TMD recommended assessing the psychosocial functioning of these subjects by applying the questionnaires described in Table 4-2. These tools can be used when indicated by clinicians or researchers. These tools follow the Initiative on Methods, Measurements, and Pain Assessment in Clinical Trials (IMMPACT) recommendations. The axis II screening instruments consist of 41 questions from the Patient Health Questionnaire 4 (PHQ-4), Graded Chronic Pain Scale (GCPS), Oral Behaviors Check List (OBC), and Jaw Functional Limitation Scale (JFLS, short form), as well as pain drawing. It was strongly recommended that these instruments be used in patients with a history of pain longer than 6 months and presence of previous unsuccessful treatments.[61] The JFLS (short and long versions) is described here because this tool is generally used to determine dysfunction associated with TMDs and can be used to test effectiveness of treatments in clinical practice as well as research. The remaining tools are described in detail elsewhere.[105]

The JFLS is a valid and reliable tool comprising 8 and 20 items (short and long forms, respectively) clustered in three domains. These three constructs (mastication, vertical jaw mobility, and emotional and verbal expression) were obtained through a complete validation process

TABLE 4-2

Diagnostic Criteria for Temporomandibular Disorders (DC/TMD) Axis II Recommended Tools to Assess the Psychosocial Functioning of Subjects with TMD

Domain	Instrument	Number of Items
Pain intensity	Graded Chronic Pain Scale (GCPS)	3
Pain locations	Pain Drawing	1
Physical function	Graded Chronic Pain Scale (GCPS)	4
Limitation	Jaw Functional Limitation Scale (JFLS)—short and long form	8 and 20 items, respectively
Distress	Patient Health Questionnaire 4 (PHQ-4)	4
Depression	Patient Health Questionnaire 9 (PHQ-9)	9
Anxiety	General Anxiety Disorder-7 (GAD-7)	7
Physical symptoms	Patient Health Questionnaire-15 (PHQ-15)	15
Parafunction	Oral behaviors Checklist (OBC)	21

Modified from Schiffman E, Ohrbach R, Truelove E et al: Diagnostic criteria for temporomandibular disorders (DC/TMD) for clinical and research applications: Recommendations of the International RDC/TMD Consortium Network and Orofacial Pain Special Interest Group, *J Oral Facial Pain Headache* 28(1):6-27, 2014.

using expert consensus as well as psychometric testing by a Rash analysis. A global functional limitation score is obtained from both versions (short and long). In addition, both scales can be administered independently, which allows the clinician or researcher to tailor the administration of this scale. The tool has exhibited excellent psychometric properties with respect to modeled variance, item fit, reliability, and internal consistency.[106] The items for short and long versions can be found in Table 4-3.

Whiplash Injury

Whiplash injury may cause symptoms associated with TMDs in addition to other symptoms, such as neck pain,

TABLE 4-3

Jaw Functional Limitation Scale (JFLS)

Items 1 to 6 represent mastication, items 7 to 10 represent mobility, and items 11 to 20 represent verbal and emotional communication. Items with an asterisk (*) are those used for the JFLS-8 (short form). Responses used a 0 to 10 NRS, with 0 anchored as "no limitation" and 10 anchored as "severe limitation."

For each of the items below, indicate the level of limitation during the past month. If the activity was completely avoided because it is too difficult, indicate "10." If you avoid an activity for reasons other than pain or difficulty, then leave the item blank.

1* Chew tough food
2 Chew hard bread
3* Chew chicken (e.g., prepared in oven)
4 Chew crackers
5 Chew soft food (e.g., macaroni, canned or soft fruits, cooked vegetables, fish)
6* Eat soft food requiring no chewing (e.g., mashed potatoes, apple sauce, pudding, pureed food)
7 Open wide enough to bite from a whole apple
8 Open wide enough to bite into a sandwich
9 Open wide enough to talk
10* Open wide enough to drink from a cup
11* Swallow
12* Yawn
13* Talk
14 Sing
15 Putting on a happy face
16 Putting on an angry face
17 Frown
18 Kiss
19* Smile
20 Laugh

From Ohrbach R, Larsson P, List T: The jaw functional limitation scale: Development, reliability, and validity of 8-item and 20-item versions, *J Orofacial Pain* 22(3):219-230, 2008.

headache, and cognitive disturbances. TMDs following a motor vehicle accident (MVA)-related whiplash may result from direct trauma to the orofacial region, or symptoms could also occur later following the accident.[107]

Salé and Isberg[108] found the incidence of new symptoms of TMD among patients who suffered whiplash due to MVA was 5 times that found in a control group. TMD was reported as the primary complaint by 5% of the patients at the first visit and by 19% at 1-year follow-up. Delayed onset of new symptoms of TMDs was seen in a third of patients with whiplash-associated disorder (WAD) versus 7% of the control group.[108] Therefore approximately 33% of people with whiplash history are at risk of developing TMD.[107]

According to a systematic review, the prevalence of whiplash trauma is higher in patients with TMD compared with non-TMD controls.[109,110] TMD patients with history of whiplash present with more jaw pain and more severe jaw dysfunction compared with TMD patients without a history of head-neck trauma. Symptoms such as limited jaw opening, TMD pain, headaches, and stress were reported more by TMD patients with history of whiplash. According to the authors of the papers, whiplash trauma may be an initiating and/or aggravating factor as well as a co-morbid condition for TMD.

According to Epstein et al.,[107] TMDs may represent a component of the whiplash symptom cluster, and therefore the masticatory region should be evaluated not only at the beginning but also later during the treatment for neck pain due to whiplash injury.

Cervical Spine Dysfunction

Some clinical evidence of the interconnection between the cervical spine and TMDs has been demonstrated, and thus cervical spine dysfunction (CSD) has been associated with TMD.[18,20,111,112] De Wijer et al.[18–20,113] concluded that symptoms of the stomatognathic system overlap in patients with TMD and CSD, and symptoms from the cervical spine overlap in the same group of patients (TMD and CSD). It has also been found that patients with chronic TMD more often suffered from cervical spine pain than those without this disorder[111] and asymptomatical functional disorders of the cervical spine occurred more frequently in patients with internal derangement of the TMJ than in a control group.[114] Sipila et al.[115] found that facial pain was associated with reported neck pain and clinical pain resulting from palpation in the muscles of the neck-occiput area. Ciancaglini et al.[116] demonstrated that patients suffering from TMD had more than double the risk (odds ratio [OR] = 2.33) of suffering neck pain than patients without TMD (OR = 1). Plesh et al.[117] in a population study from the United States found that TMD-type pain was most often associated with other common pains and seldom existed alone (only 0.77% overall reported TMJ and muscle disorders [TMJ/MDs] without co-morbid headache and migraine, neck, or low back pain). In addition, almost 55% of those who reported TMJ/MD-type pain also reported neck pain versus 13% of those who did not report TMJ/MD-type pain (OR = 7.9, $p < 0.001$). Thus neck pain was most strongly associated with TMJ/MD-type pain, followed by headache and migraine pain, low back pain, and then joint pain. Armijo-Olivo and coworkers investigated the relationship between cervical impairments and TMD.[3,4,118] They found a strong relationship between neck disability and jaw disability ($r = 0.82$). No statistically significant differences were found in EMG activity of the sternocleidomastoid or the anterior scalene muscles in patients with TMDs when compared with healthy subjects while executing the craniocervical flexion test ($p = 0.07$). However, clinically important effect sizes (0.42 to 0.82) were found.[3] Subjects with TMDs presented with reduced cervical flexor as well as extensor muscle endurance while performing the flexor and extensor muscle endurance tests when compared with healthy individuals.[3] Therefore subjects with TMD presented with impairments of the cervical flexors and extensors muscles. Based on these results, they suggested that an association between neck pain and TMD may be possible and a systematic clinical examination of cervical spine areas could be important in identifying possible causes of craniofacial pain and guide possible treatments. These results could help guide clinicians in the assessment and prescription of more effective interventions for individuals with TMD.

PHYSICAL THERAPY TREATMENT

The American Academy of Craniomandibular Disorders (AACD) and the Minnesota Dental Association (MDA) have cited physical therapy as an important treatment for TMD.[119] The role of physical therapy has been shown to be one of the most effective conservative treatments for TMDs.[120] The most important contribution by physical therapists is the identification of the musculoskeletal components that contribute to the symptoms of the patient.[9] Because the TMJs are synovial joints, physical therapists can treat the joints with similar interventions as they would most other joints in the body. Physical therapy includes a large number of modalities to treat TMDs secondary to inflammation, hypermobility, DD, masticatory muscle pain, bruxism, and fibrous adhesion, among other conditions.[9] Physical therapy is prescribed with the intent to relieve musculoskeletal pain, reduce inflammation, and restore oral and neck motor function.

Numerous therapeutic interventions may prove effective in the treatment of TMDs, including electrophysical modalities, acupuncture, exercises, and manual therapy techniques. Electrophysical modalities include ultrasound (US), microwave, laser, and electroanalgesic techniques (e.g., transcutaneous electrical nerve stimulation [TENS]),

interferential current, and biofeedback. Interventions often include therapeutic exercises for the masticatory and/or cervical spine muscles to improve strength, coordination, resistance, and mobility in the region.[121] Manual therapy techniques are commonly used to reduce pain, restore mobility, or both. Interventions may also include or focus on associated impairments of the craniocervical system, such as poor posture, cervical muscle spasm, cervical pain, and referred pain from the cervical spine,[121] because a connection between cervical spine dysfunction and TMDs has been seen clinically.[2,3,5,7,122]

Several systematic reviews have been conducted regarding the effectiveness of physical therapy interventions in subjects with TMDs.[92,123–125] The information has expanded in the past 10 years, and new randomized clinical trials have been performed. However, the quality of the current evidence supporting the effectiveness of physical therapy in TMDs is still limited.[126] Because of the lack of published research on the efficacy of physical therapy in the treatment of TMDs, only limited evidence is available upon which to base practice guidelines. Consequently, clinical decision making must still be based on empirical evidence. For this reason the information about treatment interventions that follows is based on evidence and on the authors' clinical experience. For practical reasons, the information is divided into three general categories:

1. *Exercise,* including isotonic and isometric exercises to reestablish the correct working postures of the masticatory, cranial, and cervical systems, along with exercises to improve strength, resistance, and motor control of the masticatory and cervical muscles
2. *Manual therapy,* including various mobilization techniques to improve ROM, reduce muscle spasm, and diminish pain
3. *Electrophysical modalities*, including heat sources (e.g., hot packs), US, TENS, and acupuncture

Clinicians practicing in this area can use any combination of these treatments that they feel suits their needs. However, after a stringent search of the literature, the authors must emphasize that the methods and combinations chosen are purely a matter of preference; there is no "gold standard" physical therapy treatment for any particular TMJ condition.

Exercise

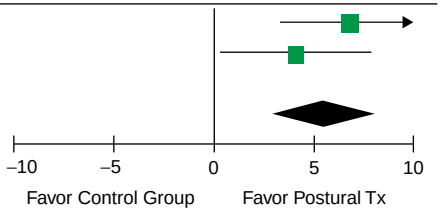
Therapeutic exercises are prescribed to address specific TMJ impairments and to improve the function of the TMJ.[127] The most useful techniques for reeducation and rehabilitation of the masticatory muscles have been reported to be muscle stretching and strengthening exercises.[128] Passive and active stretching of muscles and/or ROM are performed to increase oral opening and reduce pain.[128] Postural exercises also are recommended to restore or optimize the alignment of the CMS.[121]

All of the systematic reviews published[92,123,125] provided evidence in support of postural exercises and active and passive oral exercises to reduce pain and improve mouth opening in people with TMD due to DD, acute arthritis, and chronic myofascial pain. Effectiveness of different types of exercise therapy by specific TMD conditions bringing together the results of these systematic reviews plus up-to-date information of physical therapy interventions used to manage TMDs will be discussed later. A summary of the results found in the latest systematic reviews are described in the following section.[125]

Posture Correction Exercises in Myogenous Temporomandibular Disorders

Two studies[129,130] evaluated the effectiveness of posture correction exercises for patients with myofascial pain. One of them[130] compared posture correction exercises with self-management instructions, and the other[129] assessed the postural exercises plus behavioral therapy versus behavioral therapy alone and versus a control group. Both studies found positive results of postural exercises for improving symptoms of muscular TMDs. Based on the results of Armijo-Olivo et al.[125] when pooling the data from both studies, it was found that maximum pain-free opening significantly increased in patients receiving postural training when compared with a control group. The mean difference in maximum pain-free opening was 5.54 mm (95% confidence interval [CI] = 2.93, 8.15) (Table 4-4). This difference has been found to be clinically significant.[131] Furthermore, patients treated with postural training had significantly fewer symptoms and disturbance with daily living when compared with a control group. The standardized mean difference (SMD) in symptoms and disturbance of symptoms with daily life was 1.13 (95% CI = 0.48, 1.78) which indicated a big effect size for this pooled outcome.

These results are encouraging and support the use of physical therapy interventions including exercises to correct head and neck posture to relieve musculoskeletal pain and to improve oral motor function[129,130] in subjects with myogenous TMDs. More information is required, however, on the optimal exercise prescription. In particular, details on frequency, intensity, time, and type of the specific exercise used in treatment protocols are essential to allow for replication in the clinical setting.



General Exercise Program in Myogenous Temporomandibular Disorders

Seven studies[132–138] looked at the effect of exercises alone or combined with other therapies for myogenous TMDs. When pooling the data from all of these studies, there was a trend to favor exercise therapy for pain-free maximum opening and pain intensity when compared with a control group. The mean difference for pain-free maximum opening was 5.94 mm (95% CI = −1.0, 12.87), which is clinically significant (Table 4-5).[131] The SMD for pain

intensity was 0.43 (95% CI = −0.02, 0.87) with a moderate effect size based on Cohen guidelines.[139] Although these results show a nonsignificant difference between general exercises and other treatment modalities, they do highlight a clinical trend to favor the use of therapeutic exercise to improve ROM and decrease pain in this patient group. However, it is important to highlight that all of the studies analyzed used a very general exercise program for the TMJ and orofacial region, and it is uncertain if more specific types of exercises could be more beneficial for treating myogenous TMDs. Additional research studies are needed to clarify the benefits of a specific physical therapy treatment for the treatment of jaw pain over other forms of treatments in subjects with myogenous TMDs.

Exercises Alone or as Part of a Conservative Regime in Arthrogenous Temporomandibular Disorders

Nine studies[135,140–147] looking at subjects with arthrogenous TMDs focused on exercises alone or combined with other therapies, such as medications, surgery, or self-care recommendations. Most of the studies tended to favor exercises to improve ROM and decrease pain intensity in patients with arthrogenous TMDs. When the results of the studies investigating the effectiveness of exercise alone or in combination with other conservative therapies on pain intensity at 4 to 6 weeks of treatment were pooled, it was found that there was no statistically significant difference in pain between the exercise and control groups. Nevertheless, there was a trend to favor the exercise group when compared with the control group. The SMD for pain intensity was 0.68 (95% CI = −0.04, 1.40) with a moderate effect size favoring exercise therapy based on Cohen guidelines.[139] Regarding active mouth opening, a nonsignificant effect was found between general exercise and the control group. The mean difference for active mouth opening was 3.13 mm (95% CI = −1.96, 8.23), although a trend to favor exercises was observed.

When pooling the studies that looked at exercises plus arthrocentesis or arthroscopy versus conservative therapy including exercises alone on active mouth opening at 6 months, it was found that no differences between these approaches existed. The mean difference was −1.01 mm (95% CI = −5.43, 3.42), implying that conservative treatment plus exercises is appropriate to treat DDwithoutR or restricted mandibular movement. In addition, these results highlight that arthrocentesis or arthroscopy, procedures that are more invasive than conservative treatment, should not be conducted as a routine treatment for these patients.

Exercise in Mixed Temporomandibular Disorders

Several studies[148–160] looked at exercises alone or as part of a general conservative therapeutic regime to treat subjects with mixed TMDs. When the results of studies with available data were pooled, it was found that exercises in the form of general jaw exercises plus conventional treatment or with the addition of an oral device[156] were equally effective when compared with other treatment modalities, such as splint therapy, global reeducation posture, splint plus counseling, acupuncture, or standard conservative care, to improve pain intensity. The SMD for pain intensity was −0.06 (95% CI = −0.50, 0.38) with a very small effect size based on Cohen guidelines.[139]

When the results for mouth opening were pooled, nonsignificant differences were obtained between general exercises and splint therapy, global reeducation posture, splint plus counseling, or standard conservative care. The mean difference for mouth opening was 0.4 mm (95% CI = 1.64, 2.51).

In summary, evidence exists that supports the use of oral and postural exercises to reduce pain and improve ROM in people with TMDs. In addition, exercise therapy is equally as effective as other more costly modalities, such as splint therapy or surgery. This can guide clinicians in making the best choice for treating TMD patients. Exercises can help reduce muscle spasm, restore muscle function, improve muscle strength and resistance, diminish pain, and aid muscle motor control. Different types of exercises can be performed to the jaw and cervical region. (Information on cervical spine exercises can be found in Chapter 3.) Evidence supports the use of cervical and postural exercises to improve TMD symptoms. The following exercises focus on the TMJ and masticatory muscles.

Isotonic, isometric, and resistive exercises can be used, depending on the patient's condition. For example, the patient can actively perform exercises to improve ROM by moving the jaw in all directions (open-close and lateral movements) to the end of ROM. These types of exercises stimulate lubrication of the TMJ, improve the proprioceptive information to the joint receptors, and help control pain.[161–163] In addition, these active exercises can be assisted by the clinician or self-assisted by the patient at the end of opening ROM. Mandibular opening can be achieved by placing the thumbs and forefingers between the teeth and causing a passive stretch against the mandible and maxilla (Figure 4-10). The stretch should be held for at least 30 seconds to cause changes in the soft tissues.[164]

Figure 4-10 Passive stretch of the mouth opening.

Active exercises also have been used to improve coordination and retraining of the jaw muscles. As mentioned previously, patients with TMD usually present with impaired masticatory muscle contraction patterns. These impaired patterns can cause abnormal distribution of loads to the TMJ and reinforce abnormal equilibrium between muscular groups. The objective of active coordination exercises is to train the patient to open and close the mouth and to perform lateral movements smoothly, trying to avoid abnormal patterns of contraction. This often can best be done if the patient works in front of a mirror. The patient opens and closes the mouth and performs lateral movements using the visual feedback on the position of the jaw (Figure 4-11).

A mastication device can be used to improve coordination of jaw movements and muscle strength during the movements. The hyperboloid is a mastication device invented by a Brazilian dentist (patent no. 8901216-0) that has a hyperbolic shape and is made of soft, nontoxic, odorless, tasteless silicone (Figure 4-12).[165] Its hardness and texture are compatible with the ideal force applied during mastication.[166] This device is used to assist with the treatment of patients with TMD.[167] The propioceptive mechanism of excitation is the explanation for the effectiveness of the hyperboloid device.[165,167] This device has also been used to treat abnormal orodental development, abnormal occlusion, and bruxism.[165]

Figure 4-11 Visual feedback on jaw movement using a mirror.

Few studies have investigated the effect of the hyperboloid. Its effect on EMG activity in the jaw-closing muscles and on the reduction of sleep bruxism in a child with cerebral palsy was investigated by Giannasi et al.[166] They found that 9 months of treatment using specific exercises with the hyperboloid (6 times a day for 5 minutes) resulted in an improvement of EMG activity of the jaw-closing muscles and a reduction of sleep bruxism. The authors concluded that the mastication device positively affected the processes of chewing and swallowing, improving oral function associated with improvement of muscle tone. The hyperboloid was also included in a physical therapy program of a patient with TMD.[168] Treatment also included exercises, manual therapy, massotherapy, laser, and US. Results indicated a reduction of pain in the masticatory muscles and cervical region, parafunctional habits (i.e., habitual use of the mouth, tongue, or jaw for activities unrelated to eating, drinking, or speaking—e.g., bruxism [tooth clenching or grinding], tongue thrusting, fingernail biting, pencil or pen chewing, mouth breathing), improvement of posture, and better coordination of jaw movements. The effectiveness of physical therapy, including the use of the hyperboloid, was also evaluated in 11 patients suffering from oral cancer and TMDs.[169] Exercises for proprioception using the hyperboloid are performed at the end of treatment after a series of treatment techniques, including muscle relaxation, cervical spine, and TMJ mobilization. The results showed an increase of mouth opening and relief of symptoms, such as pain and difficulty to chew and talk. Figures 4-13 and 4-14 show some exercises of coordination and proprioception with the hyperboloid. The patient is asked to place the device between central incisors and perform deviation of the mandible to the side (see Figure 4-13, *A*). The same can be done by asking the patient to perform

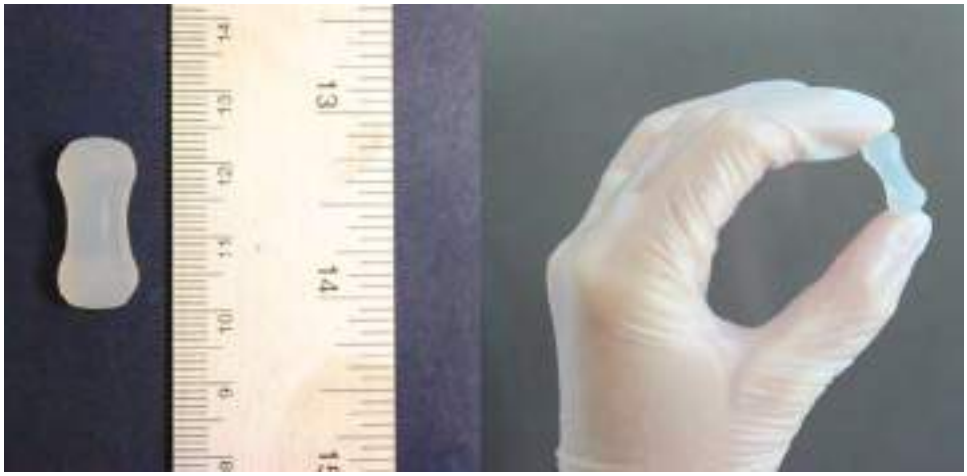

Figure 4-12 Hyperboloid: mastication device.

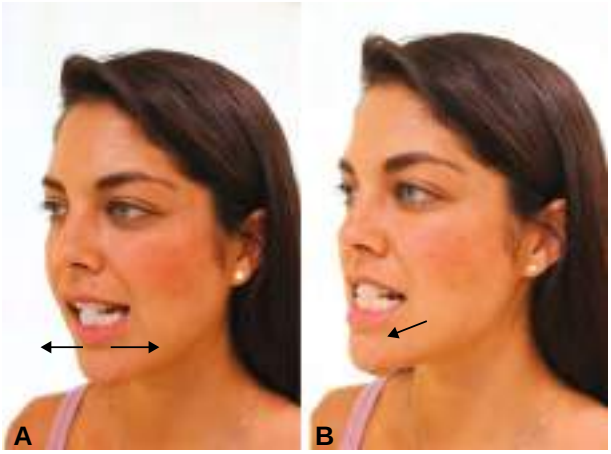

Figure 4-13 Exercises using the mastication device. **A,** With mandible side movement. **B,** With mandible protrusion.

protrusion (see Figure 4-13, *B*). The exercises can be performed with the patient positioned in front of a mirror for visual feedback (see Figure 4-14).

The other exercise used for coordination of jaw movements is to ask the patient to open and close the mouth in front of a mirror using a paper covering half of the patient's face (Figure 4-15). The edge of the paper will guide the jaw to a more straight down movement during opening.[63] The tongue positioned on the palate during this exercise can also be added to help the jaw to achieve a straight movement and to limit excessive opening in patients with TMJ hypermobility.

Figure 4-14 Exercise using the mastication device in front of the mirror for visual feedback.

As mentioned earlier, in patients with hypermobility, the active exercises can be controlled with the tongue positioned in the roof of the palate (Figure 4-16). If strengthening is the aim, gentle resistance can be provided in all directions (Figures 4-17 and 4-18). Sensory input can be achieved by the clinician placing the fingers lightly beneath or on the side of the mandible and having the patient push into the slight resistance to get the muscles to contract and achieve the required movement. As an alternative, the clinician can have the patient use his or her own fingers to supply the necessary light resistance. Jaw strengthening is performed with low loads (i.e., low resistance). The clinician must always keep in mind the patient's symptoms. If the patient is in an acute phase or if pain is intense, strengthening exercises should be delayed and treatment should begin with only gentle active or passive exercises.

Proprioceptive neuromuscular facilitation (PNF) techniques are another type of active-assisted exercises that physical therapists commonly use to reduce muscular activity in the jaw (e.g., the masseter and pterygoid muscles).[170] The patient is asked to open the mouth within a comfortable range; this takes pressure off the inflamed or painful posterior structures and prevents condylar loading when resistance is applied. The clinician then places the hands under the mandible and, using light, gradually increasing pressure, attempts to close the mandible while the patient resists the closure (Figure 4-19). This causes contraction of the hyoid muscles and produces a reciprocal inhibition of the masseter, temporalis, and pterygoid muscles. Resistance is applied for a number of seconds and then slowly withdrawn, and the sequence is repeated a number of times, as required. Pain and fatigue are limiting factors and should guide the clinician in the number of repetitions to be performed. By placing one hand on the side of the mandible and producing a pressure to the opposite side, the clinician can encourage lateral glide and

Figure 4-15 Using a piece of paper as a guide to opening and closing jaw in a straight line. **A,** Oblique view showing mirror. **B,** Front view.

Figure 4-17 Resistive exercise for lateral excursion.

Figure 4-18 Resistive exercise for protrusion.

exercise of the muscles. Again using the PNF technique of reciprocal inhibition, the muscles on the side of the resistance contract and the muscles on the opposite side relax. Even though these exercises are effective at improving ROM of the jaw and probably improve the flexibility of the relaxed muscles, the mechanisms of that improvement are still under study.[170,171]

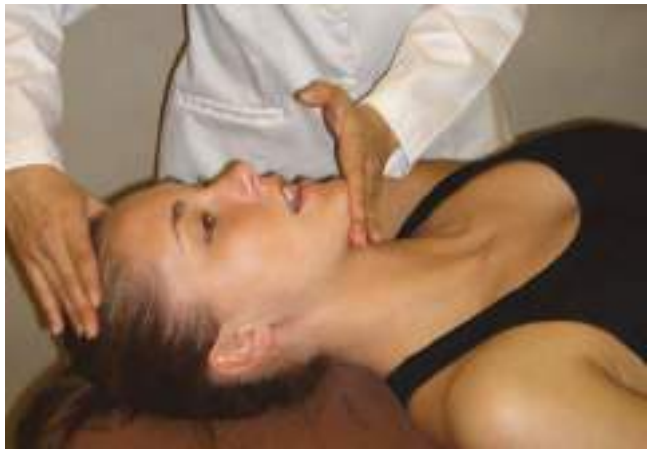

Figure 4-19 PNF technique for inhibition of closing of the masticatory muscles.

Clinicians must keep in mind that exercise and/or mobilization can easily be overdone in the treatment of the temporomandibular region. This is a sensitive area, which is made more sensitive by any dysfunction within it. Instead of exercising once or twice a day for 5 minutes at a time, a far more effective approach is to exercise a little bit and often. Some clinicians, such as Rocabado,[172] have instituted a 6×6×6 exercise routine: six exercises performed six times a day, with six repetitions of each exercise. This is easy for the patient to remember and to follow. Other clinicians prefer to have the patient perform one or two exercises each hour, using a few repetitions of each exercise. Either way, the patient must be continually reminded to perform the exercises, not only to maintain any restored function but also as a reminder to avoid performing any movements or habituations that might aggravate the condition. A home exercise program is described in Box 4-1.

Manual Therapy

Kalamir et al.[173] stated that, "the biopsychosocial health paradigm emphasizes a reversible and conservative approach to chronic pain management. Manual therapy for TMD claims to fulfill these criteria." Mobilization of the mandible aims to restore the normal ROM, reduce local ischemia, stimulate proprioception, break fibrous adhesions, stimulate synovial fluid production, and reduce pain.[173] Manual therapy has been used for many years as an adjunct treatment, along with exercises, physical modalities, and splint therapy. Evidence suggests that manual therapy is a legitimate treatment for TMDs, superior to splint therapy and even more effective when combined with exercises.[174]

Before the TMJ can be mobilized (Figure 4-20), any inflammation and local muscle spasm in the area must be reduced because both of these conditions can be aggravated by attempts to stretch the affected joint. Unless the dysfunction is fairly recent (fewer than 6 weeks), the

BOX 4-1

Home Exercise Program for the Temporomandibular Patients

Do all of the exercises (or those assigned) hourly or as instructed, with a repetition of 5 times each. The five repetitions of each exercise should take 1 minute or less. Doing these exercises throughout the day will take only a few minutes of your time. Do the exercises for 1 month or longer if so instructed. Do them at home, at work, in the car, and so on. However, if any exercise causes you pain, discontinue it immediately and consult your therapist.

Exercise 1: Place the top of your tongue against the roof of your mouth, and make a clucklike sound. Your lower jaw will drop downward to a comfortable position, and your upper and lower teeth will be apart. Return the top of your tongue to the position it was in immediately before you made the sound, exerting slight upward pressure with the tongue; your teeth are still apart. Place the palm of your left hand just below your navel, and breathe in and out through your nose 5 times using only your stomach muscles to breathe. Feel your stomach rise and fall the 5 times. Do not use the muscles of your chest or shoulders to breathe.

Exercise 2: Return the top of your tongue to the position against the roof of your mouth as in exercise 1, exerting slight upward pressure. Continue to breathe through your nose using your stomach muscles. Now, open and close your mouth farther 5 times without moving your tongue. At the end of the second week, chew all your food this way.

NOTE: Do all repetitions of the following exercises with your tongue elevated against the roof of your mouth; breathe through your nose using your stomach muscles.

Exercise 3: Grasp the back of your neck with both hands with your elbows pointing forward. Holding your neck rigid, nod your head, trying to touch your chin to your Adam's apple. If you do this correctly, your head will be able to move only about 2.5 to 3.8 cm (1 to 1.5 inches). Do not flex your neck forward. Your head should just rotate forward at the very top of your neck. Hold this position for a few seconds. Feel the muscles stretch at the top of the back of your neck, just beneath your skull. Repeat 5 times. Continue breathing through your nose using your stomach muscles and with your tongue against the roof of your mouth.

Exercise 4: Move your face straight backward keeping your chin down and your face perpendicular to the floor (i.e., as if you were bracing at attention). Do not raise your head while doing this exercise. Continue to breathe through your nose. Pause for a few seconds when your head is in the backward position, as far back as you can get it, and then relax. To help maintain the head in the correct position, you can focus your eyes on a point directly in front of you while performing the exercise. Repeat 5 times. Continue correct breathing.

Exercise 5: Repeat the position in exercise 4. With your head braced back, rotate your head forward, and try to touch your chin to your Adam's apple. You do not need to immobilize your neck with your hands, but do not bend your neck forward. Hold for a few seconds. Repeat 5 times.

Exercise 6: Grasp your hands behind your waist. Roll your shoulders backward as far as they will go. Mentally picture your left and right shoulder blades touching each other. Hold for a few seconds and then relax. Repeat 5 times. Continue correct breathing.

Exercise 7: Simultaneously elevate your left and right shoulders upward, attempting to touch your ears. Hold for a few seconds and then relax. Repeat 5 times.

Exercise 8: Without elevating your left shoulder, bend your head to the left and attempt to touch your left ear to your left shoulder. Hold for a few seconds and then relax. Repeat 5 times.

Exercise 9: Without elevating your right shoulder, bend your head to the right, and attempt to touch your right ear to your right shoulder. Hold for a few seconds, and then relax. Repeat 5 times.

Exercise 10: With your head in a neutral position, place the heel of your right hand against your right temple, and gently press to your left so that your head bends an additional 1.3 cm (0.5 inch) toward your shoulder. Repeat 5 times.

Exercise 11: With your head in a neutral position, place the heel of your left hand against your left temple, and gently press to your right so that your head bends an additional 1.3 cm (0.5 inch) toward your shoulder. Repeat 5 times.

Exercise 12: With your head braced back and your chin rotated toward your Adam's apple, intertwine the fingers of your hands, and place them so that they cup the back of your head. Gently press forward to rotate your chin an additional 1.3 cm (0.5 inches) toward your Adam's apple. Feel this additional stretching pressure at the top of your neck just beneath your skull. Hold for a few seconds, and then relax. Repeat 5 times.

Exercise 13: This is an *isometric* exercise; that is, the muscles contract, but you will not see or feel any appreciable movement of the head. Throughout this exercise, *do not* let the position of your head change.

a. With your head bent forward 30°, place the heel of either your left or right hand against your forehead and press upward with 0.45 kg (2 lb) of pressure. Resist this upward pressure with your neck muscles so that your head does not move. Hold for a few seconds, and then relax. Repeat 5 times.
b. With your head upright, place the palm of your left or right hand against the back of your head, and press forward with 0.45 kg (2 lb) of pressure. Resist this pressure for a few seconds, and then relax. Repeat 5 times.
c. With your head upright, place the heel of your left hand against your left temple, and press to your right with 0.45 kg (2 lb) of pressure. Resist this pressure for a few seconds, and then relax. Repeat 5 times.
d. With your head upright, place the heel of your right hand against your right temple, and press to your left with 0.45 kg (2 lb) of pressure. Resist this pressure for a few seconds, and then relax. Repeat 5 times.

Exercise 14: Place the top of your tongue in the same position against the roof of your mouth as in exercise 1, exerting slight upward pressure. Continue to breathe through your nose using your stomach muscles. The upper and lower teeth are still apart. Throughout this exercise, *do not* let the position of your jaw move.

a. This is an isometric exercise. Place your thumbs beneath your chin and push upward with 170 g (6 oz) of pressure to close your mouth. Resist this closing force with an equal opening force so that your jaw does not move from its original position. Hold for a few seconds. Repeat 5 times.
b. Resume the tongue and jaw positions described in exercise 1. Place the ends of the index and middle fingers of your right hand against the right side of your lower jaw and push to your left with 170 g (6 oz) of pressure. Resist this by holding your jaw steady with an equal force so that your jaw does not move. Hold for a few seconds. Repeat 5 times.
c. Repeat exercise 14b using the index and middle fingers of the *left* hand against the *left* side of your lower jaw and pushing to the *right* with 170 g (6 oz) of pressure. Do not let your jaw move. Hold for a few seconds. Repeat 5 times.

Box 4-1—Cont'd

Exercise 15: Throughout this exercise, *do not* let the position of your tongue change.

a. Place the index finger of your right or left hand on top of your tongue with your finger pointing toward your throat. Press downward with approximately 170 g (6 oz) of pressure and simultaneously lift your tongue with an equal force so that the index finger does not press the tongue down. Hold for a few seconds, and then relax. Repeat 5 times.
b. Place your index finger under your tongue with your fingernail upward. Press upward against the undersurface of your tongue with 170 g (6 oz) of pressure and simultaneously press down with your tongue with an equal force so that the index finger does not push the tongue up. Hold for a few seconds, and then relax. Repeat 5 times.
c. Place your left index finger against the left side of your tongue. Press to your right with 170 g (6 oz) of pressure and simultaneously resist this pressure with an equal force so that your tongue does not move. Hold for a few seconds, and then relax. Repeat 5 times.
d. Place your right index finger against the right side of your tongue. Press to your left with 170 g (6 oz) of pressure and simultaneously resist this pressure with an equal force so that your tongue does not move. Hold for a few seconds, and then relax. Repeat 5 times.

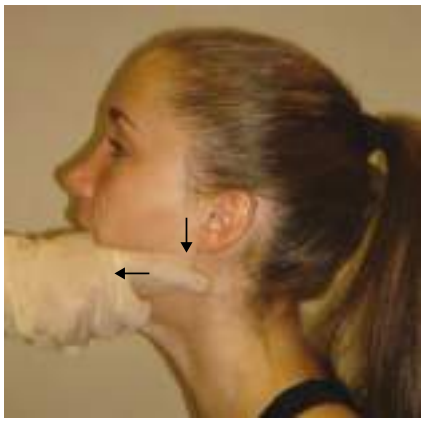

Figure 4-20 Mobilization to reduce acute disc displacement without reduction.

clinician should not look to mobilization to restore the disc-condyle relationship to normal. Rather, mobilization should be used to achieve what the body would do on its own over an extended period; that is, stretch out the tight structures to restore a more functional movement. The clinician must be sure to explain this so that the patient does not get the idea that mobilization will cure the clicking or tight joint by "getting everything back to normal." In addition to restoring function, mobilization attempts to prevent the development of adaptive problems elsewhere. For example, stiffness in the affected joint causes torsion of the unaffected joint on the opposite side, which eventually could cause hypermobility of that joint.

To mobilize the joint, the clinician asks the patient to open the mouth and then places the thumb along the superior surface of the lower teeth on the side of the joint to be mobilized (Figure 4-21). The index finger is curled under the angle of the mandible so that the bone is cupped by the finger. The index finger of the opposite hand can be used to palpate the joint. Mobilization is brought about by exerting pressure on the teeth with the thumb; this causes a distraction of the head of the condyle meeting the head of the mandibular joint. If some condylar translation is lost, this can be restored by performing an anterior glide of the condyle after some distraction of the joint.

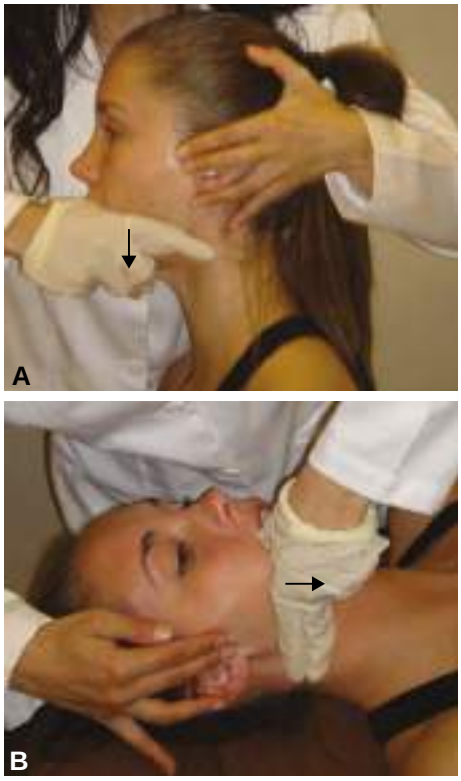

Figure 4-21 **A,** Axial intraoral mobilization in the sitting position. **B,** Axial intraoral mobilization in the supine position.

Jaw mobilization can also be performed in the lateral and medial directions to provide joint stretching in all structures. For lateral mobilization the clinician positions the thumb in the lateral aspect of the last molar and pushes the condyle in a lateral direction. For medial mobilization (i.e., internal mobilization of the condyle), the clinician positions the second and third fingers outside the mouth and pushes the condyle in a medial direction. Sometimes the clinician can guide the lateral or medial movements using intraoral mobilization (Figure 4-22).

Patients can be taught to perform self-mobilization of the joint according to the techniques just described (Figure 4-23). It is important to teach the patient to perform these mobilizations appropriately and to hold the

Figure 4-22 Guided jaw mobilization.

Figure 4-23 Patient self-mobilization of the TMJ.

positions for the amount of time required to achieve a positive effect on the TMJ.

Patients with a hypomobile joint on one side and a symptomatic hypermobile joint on the other side frequently complain that mobilization on the hypomobile side causes pain on the hypermobile side because of stretching of symptomatic tissue. This is a problem that requires graduated mobilization to lessen the effects of any torsion of the opposite mandible. In these cases Maitland-type graduated mobilization can be used. The regimen starts with mobilization grade 1 techniques and progresses through grades 2 and 3 to a strong grade 4 (4+). Oscillation at the end of the available range can be added to reduce spasm and to add more proprioceptive input, thereby reducing pain.[175] Although mobilization is used primarily to restore movement, the clinician should keep in mind that the lighter grades (1,2) can be used on a hypermobile joint to reduce muscle spasm and for proprioceptive effect. The stronger grades of mobilization should not be used on a hypermobile joint because they would stretch tissue that already is in a lax state.

Once a joint has been mobilized, the patient should be instructed to perform some regular exercises to maintain the regained mobility. Opening the mouth to the end of the newly acquired range, repeated a few times every hour, is one such exercise. The patient might need the visual feedback afforded by performing the exercise in front of a mirror to ensure that the mandibular motion can be produced symmetrically in the midline. Unless the patient is coached properly, maintenance exercises will not return the mandible to its normal function. For example, an anteromedially displaced disc on one side will stop condylar movement during opening and also during lateral glide. If mobilization has succeeded in stretching out the tight tissue, more opening should be available, together with more lateral glide. However, if the patient has not been able to achieve a lateral glide because of the joint dysfunction, she or he will need visual feedback (i.e., doing the exercise in front of a mirror) to see what happens to the mandible when she or he performs the movement.

Manual Therapy Targeted to the Orofacial Region in Myogenous Temporomandibular Disorders

Four studies[176–179] looked at manual therapy techniques, such as facial manipulation versus botulinum toxin[176] or intraoral myofascial therapy versus waiting list, and self-care education and exercises for subjects with myogenous TMDs.[177–179] The results of these studies supported the use of manual therapy to treat myogenous TMDs because subjects treated with all of these approaches improved mouth opening and reduced jaw pain related to their baseline. Although intraoral myofascial therapy and exercise groups were superior to a waiting list control group, they did not have any statistically significant difference between them. In addition, facial manipulation had the equivalent effect as botulinum toxin. However, fascial manipulation was slightly superior in reducing subjective pain perception, and botulinum toxin injections were slightly superior in increasing jaw ROM at 3 months following treatment. When pooling the results from three of these studies,[176,178,179] it was found that there was a trend in favor of manual therapy to improve pain at 4 to 6 weeks of treatment when compared with an exercise waiting list group. However, the difference was not clinically relevant. The mean difference for pain intensity was 0.95 cm (95% CI = –0.07, 1.83).

Manual Therapy Targeted to the Cervical Spine and Cervical Exercises in Myogenous Temporomandibular Disorders

A randomized controlled trial (RCT) conducted by La Touche et al.[180] testing a more specific approach directed to the cervical spine to treat patients with cervicocraniofacial pain of myofascial origin was performed. They investigated the effects of anterior-posterior upper cervical mobilization (APUCM) when compared with placebo on pressure pain thresholds (PPTs) in the craniofacial and cervical regions and pain intensity after three sessions of treatment. This preliminary study found that

mobilizations targeted at the cervical spine drastically decreased pain intensity and pain sensitivity (through the PPT evaluation) in patients with cervicocraniofacial pain of myofascial origin immediately after the application of the technique when compared with placebo treatment. The effect sizes found by this study for pain intensity were 28.75 points (95% CI = 21.65, 35.85) and 1.12 kg/cm^2 (95% CI = 0.96, 1.29) for pain and PTT, respectively, which is encouraging. These results exceeded suggested values for the minimum clinically important differences for pain[181–184] and for PPT outcomes.[185,186] The minimal important difference (MID) for Pain and PPT outcomes have been reported to be from 15 to 32 points[181–184,187] and ≥1.10 kg/cm^2 per second,[185,186] respectively, which suggest a potentially beneficial effect for this specific treatment to improve symptoms in patients with myogenous TMDs.

This early evidence provides support for more specific treatment directed at the cervical spine to treat pain and impairments found in TMD patients. Furthermore, preliminary evidence has found that exercises addressing the cervical impairments through the training of neck flexor muscles as part of cervical spine treatment in people with TMDs reduced pain and improved function (i.e., increasing pain-free mouth opening), which potentially supports the fact that patients with TMDs could benefit from treatment to impaired cervical flexor muscles.[188] Thus these results testing the effectiveness of exercise protocols to improve cervical muscular impairments and consequently decrease pain intensity and improve function are promising and might be translated to the area of TMD because, up to now, this type of training has not been proven in a large clinical trial. Therefore future research should be conducted with larger RCTs in this area to confirm these results as well as using a longer follow-up period to evaluate the long-term effects of these types of interventions.

Manual Therapy plus Exercises in Arthrogenous Temporomandibular Disorders

Seven studies[174,189–195] looked at the combined effect of manual therapy plus exercises for subjects with arthrogenous TMDs. Three studies[174,189,190] compared manual therapy and exercises versus splint therapy. One study[191,192] compared them with self-care and advice regarding prognosis, and two studies used medications as a comparison.[143,193] In addition, one study[194] compared anesthetic blockage of the auriculotemporal nerve versus manual therapy and exercises.

In general, it was found that manual therapy plus exercises was successful in reducing symptoms and increasing the ROM for patients with arthrogenous TMDs, especially in subjects with a closed lock.[195] When studies with homogeneous interventions and available data were pooled, it was found that pain was significantly reduced in subjects receiving manual therapy combined with exercises when compared with splint therapy, self-care, or medications. The SMD for pain intensity at 4 weeks to 3 months was 0.40 (95% CI = 0.13, 0.68) with a moderate effect size, based on Cohen guidelines.[139] When looking at active mouth opening, it was found that manual therapy plus exercises significantly increase active mouth opening when compared with splint therapy, self-care, or medications. The mean difference for active mouth opening at 4 weeks to 3 months was 3.58 mm (95% CI = 1.46, 5.70).

Manual Therapy and Mixed Temporomandibular Disorders

Four studies[196–199] looked at manual therapy to mobilize the atlantoaxial joints,[197,199] at another level of cervical spine,[198] or mobilizations to the TMJ joint[196] for subjects with mixed TMDs. When the data from Mansilla-Ferragud et al. and Otano et al. were pooled, it was found that there was no statistically significant difference in mouth opening between mobilization of the atlantoaxial joint[197,199] when compared with a control group receiving no mobilization. The mean difference in mouth opening between control and manual therapy groups was 17.33 mm (95% CI = −10.39, 45.06), which is considered to be a clinically important difference between groups in favor of the manual therapy treatment.[131]

Manual Therapy plus Exercises for Mixed Temporomandibular Disorders

Two studies[200–202] investigated the effect of manual therapy combined with exercises in subjects with mixed TMDs (i.e., both muscular and joint involvement). Tuncer et al.[200] looked at the specific effect of orofacial and cervical manual therapy involving soft tissue mobilization (i.e., intraoral and extraoral deep friction massage to painful muscles), TMJ mobilization (i.e., caudal and ventrocaudal traction, ventral and mediolateral translation), TMJ stabilization (i.e., gentle isometric tension exercises against resistance), coordination exercises (i.e., guided opening and closing jaw movements), cervical spine mobilization (i.e., traction and translation), and postisometric relaxation and stretching techniques for the masticatory and neck muscles. Von Piekartz et al.[202] compared the effect of orofacial physical therapy involving (translatory) movements of the temporomandibular region and/or masticatory muscle techniques, such as tender trigger point treatment and muscle stretching, active and passive movements facilitating optimal function of cranial nerve tissue, coordination exercises, and home exercises with treatment targeted at the cervical spine in subjects with signs and symptoms of TMDs. When the results of these two studies regarding mouth opening were pooled, it was found that manual therapy targeted to the orofacial region or in combination with cervical treatment was better than home exercises or treatment to the cervical spine alone. The mean difference in mouth opening between control and manual therapy groups was 6.10 mm (95% CI = 1.11, 11.09), favoring the manual therapy groups. This difference is considered to be clinically relevant.[131]

Electrophysical Modalities

Electrophysical modalities, such as shortwave diathermy, US techniques, laser treatments, and TENS, are commonly used in the clinical setting.[203] The purpose of these modalities is to reduce inflammation and increase blood flow by altering capillary permeability.[203] The literature suggests that treatments with electrophysical modalities performed early in the course of TMDs are beneficial in reducing symptoms.[203] A discussion of some of the common physical modalities used for treating the TMJ and associated structures and the evidence from a meta-analysis[125] of their effectiveness follows.

Laser

The use of low-level laser therapy (LLLT) has increased in the treatment of TMD due to its pain-relieving effects as well as its simplicity. "The LLLT can be defined as a non-thermal type of light, which causes internal changes in cells and tissues, leading to different types of metabolic activation."[204] It has been reported that LLLT could cause analgesia as well as anti-inflammatory effects[204] by causing a reduction of prostaglandin E_2 (PGE_2), which is involved in inflammation. The dosage associated with PGE_2 reduction has been reported to be between 0.4 and 19 J and within a range of power density between 5 and 21.2 mW/cm^2.

At least two recent systematic reviews[204,205] have been conducted regarding the effectiveness of laser therapy for TMDs. Although both systematic reviews had different studies, both agree that the evidence of LLLT is not conclusive regarding the usefulness of LLLT for treating TMDs. The systematic review of Petrucci et al.[204] involved six[206–211] RCTs, and the systematic review of Melis et al. included 14 RCTs.[206–219] Petrucci et al.[204] performed a meta-analysis of the six analyzed trials. They evaluated the effect of LLLT on pain intensity as well as on mouth opening and mouth lateral movements. They concluded that LLLT was no more effective than a placebo in reducing pain intensity. The mean difference was 7.77 mm (95% CI = −2.49, 18.02), which was not statistically significant. Although this result cannot be considered statistically significant, the 95% CI of the difference between a placebo and LLLT shows a trend indicating that LLLT could be clinically meaningful at reducing pain in patients with TMD.[220] LLLT was significantly more effective than a placebo in improving vertical mouth opening (4.04 mm [95% CI = 3.06, 5.02]) and right lateral movement (1.64 mm [95% CI = 0.10, 3.17]). Interestingly, LLLT was not significantly different from a placebo in increasing left lateral mouth movement (1.90 [95% CI = −4.08, 7.88]). The similarities between LLLT and placebo effect could indicate that LLLT could have a strong placebo effect.

There was great heterogeneity between studies regarding the site of application of the beam, the number of applications performed (between 3 and 20 sessions), their duration (between 10 and 180 seconds), and the dosage used by each study in terms of wavelength, frequency, and output. According to Melis et al.,[205] output varied from 17 mW and 27 W. Frequency varied between 0 and 1.500 Hz; wavelength between 632.8 and 910 nm, and density dosage between 1 and 105 J/cm^2. In addition, different outcome measures were used. According to Petrucci et al.,[204] only one study[208] used doses inside the dose range recommended as effective by Bjordal et al.[221] Power density could not be calculated for most of the studies. This is a serious methodological flaw because it highlights that LLLT could have been ineffective due to the inadequacy of dosages used by the analyzed studies. Thus, it is uncertain if LLLT is effective when applied using the right dosages. More studies using an acceptable level of intensity are needed.

Biofeedback

EMG biofeedback therapy is a muscular relaxation technique in which a signal constantly provides patients with feedback about their masticatory muscles activity level. Biofeedback is based on the idea that stress-induced hyperactivity may be an important component of muscular TMDs. The feedback information assists patients in the self-control and management of their own levels of muscular tension, which may be a contributing factor for the onset, maintenance, or exacerbation of pain.[222]

The mechanisms underlying the apparent efficacy of EMG biofeedback for TMDs are not well understood. Several theories support its use in TMDs. For example, it has been suggested that the clinical improvement obtained with biofeedback is the consequence of reduced EMG activity in facial and/or masticatory muscles, or that biofeedback could enhance awareness of activity in facial and masticatory muscles, thereby improving patients' ability to detect, label, and voluntarily reduce muscle tension before it reaches uncomfortably high levels. In addition, it has been hypothesized that EMG biofeedback could induce patients to believe in their ability to manage and to cope with the environmental stressors and their own psychophysiological states, which in turn may help decrease symptoms associated with TMDs.[223]

A meta-analysis published in 1999 examined the efficacy of EMG biofeedback for TMDs.[224] Based on a meta-analysis of 13 studies (both controlled and uncontrolled trials), the authors concluded that there was evidence to support the use of EMG biofeedback in the treatment of TMD. The results of a recent meta-analysis of these studies,[125] pooling data from all studies regardless of diagnosis (i.e., controlled and RCT studies) investigating the effectiveness of biofeedback versus control or other treatments, such as splint and physical therapy exercises[138,225–229] on pain intensity, found a beneficial effect favoring biofeedback therapy. The SMD for pain intensity outcome was 1.37 (95% CI = 0.24, 2.50), which is statistically significant. The magnitude of effect size is considered high, based on Cohen guidelines.[139] However, the heterogeneity of studies was high as well (90%). Thus, these results should be interpreted with caution. When eliminating an

outlier[226] with a very high positive effect for biofeedback, a positive effect of biofeedback against other treatment on pain intensity was still found (0.87 [95% CI = 0.24, 2.50]). When analyzing only RCTs without the outlier previously mentioned, a small-to-moderate effect favoring biofeedback still remained. The SMD difference for pain intensity outcome was 0.37 (95% CI = 0.00, 0.74), reducing greatly the heterogeneity to 21%.

Transcutaneous Electrical Nerve Stimulation (TENS)

TENS has been a common modality used for physical therapists. It deserves special attention because it presents no side effects and enables both pain reduction and reestablishing the function of the masticatory muscles by modifying the perception of pain and, according to some, it changes the level of activity of masticatory muscles.[230,231] Studies looking at TENS and its effectiveness on masticatory muscles have shown that it is effective in relieving pain, in decreasing the EMG activity of the masticatory muscles at rest, in reducing the myoelectric activity of the jaw-closing muscles during the opening phase of the jaw, and in increasing the muscular electrical activity recorded during clenching in TMD patients.[230,231]

TENS applies a low-voltage, low-amperage, biphasic current at varying frequencies to provide counterstimulation, with the main purpose of pain relief.[232] TENS therapy is supposed to stimulate large, fast, myelinated, nonnociceptive neurons in the painful area, "closing the central gate" for those stimuli generated by pain-specific fibers. This system, associated to the activation of an endogenous opioid system, is supposed to be responsible for the analgesic effect of the TENS.

TENS is regularly employed in patients with TMDs, in view of its analgesic and muscle-relaxing effect, with positive results. Hence TENS therapy is recommended in patients presenting with signs of myofascial dysfunction, limited mouth opening, and pain or tenderness in the masticatory muscles.[233] It should be pointed out that the efficacy of TENS procedures has been challenged. Several controlled trials have indicated that TENS had no greater benefit than a placebo therapy program.[234,235] Furthermore, the antalgic effect of TENS application is still a debated question because contrasting results have been reported in the literature and the possibility of a placebo effect has been suggested.[231]

According to a recent meta-analysis,[125] eight studies have examined the efficacy of TENS for treating TMDs. Five of them[230,236–239] focused on myogenous TMDs, and the remaining focused on arthrogenous TMD.[231,240,241] Because these studies were very heterogeneous in terms of outcomes, pooling of the data was not possible. In general, the studies included in this meta-analysis provided conflicting evidence regarding the effectiveness of TENS therapy. TENS was not found to be significantly better than muscular awareness relaxation, biofeedback, sham TENS, splint, laser therapy, or a control group for patients with myogenous TMDs.[230,236–239] In addition, when analyzing the results for the studies investigating patients with arthrogenous TMDs, conflicting results were also obtained. Myostad et al.[240] and Monaco et al.[231] found that TENS helped at reducing functional pain and decreasing EMG activity of the masticatory muscles when compared with placebo TENS therapy; however, Linde et al.[241] found no significant differences between TENS and splint therapy.

Electromagnetic Fields and Shortwave Diathermy

Only four studies have looked at the effectiveness of electromagnetic fields or shortwave diathermy for treating TMDs versus placebo, muscle relaxants, or other physical agents.[242–245] Some studies[244,245] have favored the use of pulsed electromagnetic fields, whereas others[242,243] have not. Statistical analysis did indicate a borderline positive effect in its use.[243–245]

Iontophoresis

Two trials have been reported in a meta-analysis by Armijo-Olivo et al.[125] investigating the effectiveness of iontophoresis delivering dexamethasone therapy to manage arthrogenous TMDs when compared with placebo therapy.[246,247] The two studies had opposite results. Schiffman et al.[246] found that iontophoresis was helpful in improving pain in a short term, whereas Reid et al.[247] found that the placebo group presented with greater pain reduction than the subjects receiving iontophoresis. The SMD for the pool estimate reported by this meta-analysis[125] was −0.68 [95% CI = −2.83, 1.48], which is not statistically significant.

Ultrasound (US) Therapy

Therapeutic US refers to mechanical vibrations (i.e., sound waves) that are beyond the range of human hearing, commonly at either 1 or 3 MHz (million cycles per second).[248] These waves travel through tissue and are preferentially absorbed in dense collagen structures with lower water content and high protein content (i.e., tendon, ligament, joint capsule).[249] Therapeutic US has a long history of use in physical therapy practice, and its clinical application has evolved during the last decades from being used as a thermal modality to being employed for its nonthermal effects particularly in tissue repair and wound healing.[249] Clinically US has commonly been used for treating inflammation in the TMJ as well as masticatory muscles.

According to a meta-analysis,[125] three studies have looked at the effectiveness of US therapy for treating TMD. Two focused on myogenous TMD[244,250] and one[242] on mixed TMD (i.e., myogenous and arthrogenous TMD). The results of this meta-analysis showed that when the results from Gray et al.[242] and Taube et al.[250] were pooled, the proportion of improvement at the end of the treatment with US in patients with TMD,

a nonsignificant risk ratio (RR) was found to exist with the use of US compared with a placebo (RR: 1.90 [95% CI = 0.35, 10.26]), although a high tendency to favor US therapy was observed when analyzed at the 95% CI. However, these results should be taken with caution due to the high heterogeneity between the studies (93%).

OTHER TEMPOROMANDIBULAR JOINT TREATMENTS

Orthodontics and Other Dental Treatments

Some authors, including Mew,[24] have postulated that orthodontic treatment can cause TMDs. Some studies refute this.[15,97,98] Even more, the orthodontic treatment used in patients with TMDs to improve symptomatology has been debated in the literature.[15] Because no clear link has been shown between malocclusion and the development of TMDs, orthodontics and other dental treatments that alter the bite or teeth (e.g., occlusal adjustment,[251] dental restorations, and TMJ surgery) are inappropriate as initial management methods for TMDs. This is supported by evidence from an overview published by List and Axelsson.[126] They found that no systematic review found evidence that occlusal adjustments are more or less effective than placebo in the treatment of TMD pain. All systematic reviews were restrictive in recommending the use of occlusal adjustments for treatment for TMD pain, especially because this therapy is nonreversible. Sometimes a patient starts to show signs and symptoms of TMDs during orthodontic treatment. These patients may need to be taught ways to reduce any stress through the joints during the period of orthodontic care. During orthodontic treatment a patient who is banded and fitted with elastics to control mandibular motion may develop muscle spasm and reduced mobility. In these cases treatment of the condition and mobilization must be coordinated with the orthodontist so that the elastics can be removed and joint mobilization provided.

Cognitive Behavioral Therapy

It is important that clinicians understand TMD as a complex disorder and that they keep in mind the biopsychosocial model as a basis for the etiology, assessment, and management of TMDs. In this context, cognitive behavioral therapy has emerged as an important option for treating patients with TMDs because it addresses the mind and body as a whole. Counseling, stress management, biofeedback, relaxation therapy, cognition, psychoeducation, and even primary therapeutic exercises are recognized components of a cognitive behavioral program.[48,252] List and Axelsson[126] concluded that this type of treatment was effective in treating TMD pain. Thus the authors recommended that patients with TMD pain and major psychological disturbances were in need of a combined therapeutic approach. Thus clinical examination with a behavioral assessment needs to be combined to direct the patient to the proper mode of treatment.

Acupuncture

Acupuncture increasingly is being used in the treatment of musculoskeletal conditions in North America.[253] Currently the mechanisms underlying the action of acupuncture are unclear.[254] Acupuncture may relieve pain according to the principles of the gate control theory or by acting as a noxious stimulus. Some evidence indicates that acupuncture may stimulate the production of endorphins, serotonin, and acetylcholine within the central nervous system.[254]

In 1999 a systematic review examined the data of preliminary studies and reported that acupuncture was a potentially effective therapy for TMDs, although more rigorous studies were needed to confirm their conclusions.[255] Based on a systematic review and meta-analysis of acupuncture for TMDs[256] including nine trials,[257–265] acupuncture was effective in reducing pain when analyzing the differences before and after treatment and also when comparing with a control group (no numerical data provided). In addition, acupuncture was more effective at reducing pain when compared with a placebo or sham acupuncture treatment.[256] According to a meta-analysis of four trials[257,262,263,265] that provided numerical data performed within the systematic review, it was found that the SMD between acupuncture and placebo acupuncture was 0.83 (95% CI = 0.41, 1.25) for pain intensity, which is considered a high effect size.[139] These results indicated that acupuncture was more effective than a placebo or sham treatment at reducing pain intensity. Acupuncture demonstrated more effectiveness than other interventions, such as occlusal splint therapy. Results suggest that acupuncture is a reasonable adjunctive treatment for producing an analgesic effect in TMD patients; however, methodological issues, such as being the type of technique that can create placebo effects, are unknown, and placebo acupuncture response may rely on patient psychological and physiological expectations.[266]

Surgery

Surgery on the TMJ itself has become rare; only approximately 5% of patients who undergo treatment for TMDs require surgery.[267] There are no generally recognized surgical protocols for TMD, although some guidelines have been proposed as requirements for TMJ surgery.[15] Surgery should be reserved for cases in which surgical treatment can warrant success. According to a systematic review overview, List and Axelsson[126] found that for patients with DDwithR, one systematic review reported similar treatment effects for arthrocentesis, arthroscopy, and discectomy.[268] In patients with DDwithoutR, another review reported similar effects

for arthrocentesis, arthroscopy, and physical therapy.[269] A third review reported an overall high success rate for arthrocentesis but made no comparison of arthrocentesis with other interventions.[270] In patients with TMD pain, a systematic review reported contradictory results following orthognathic surgery.[271] According to List and Axelsson,[126] all of these published systematic reviews dealing with surgery for TMDs showed low levels of evidence, and thus firm conclusions could not be made. Based on a general rule of thumb, conservative treatments are the choice for treating TMD. Surgical or other more invasive treatments should be reserved only for cases unresponsive to conservative approaches.

When surgery is performed, the procedure most often is an arthroscopic technique and includes lavage to free up any joint restrictions and to flush the joint to allow for better function. An ankylosed joint or a joint with a clinical closed lock that has not responded to conservative treatment fits the category of conditions requiring surgery. After surgery, therapy focuses on improving joint function as quickly as possible. The initial treatment is based on the same criteria used for acute capsulitis.

Guidelines for Temporomandibular Joint Surgery

- The TMJ is the source of pain and/or dysfunction that results in significant impairment
- Appropriate nonsurgical management was unsuccessful
- The pain is localized in the TMJ (when loading and with movement)
- Interferences with proper TMJ function are the mechanical type
- The patient requests the surgical approach
- The patient has no medical or psychological contraindications to surgery

Post-Radiation Therapy for Hypomobility of the Temporomandibular Joint

Patients who have had surgery and radiation therapy for treatment of cancer of the neck and oropharyngeal structures can present with severe restriction of ROM of the mandible. Extensive therapy, including mobilization, in an attempt to improve function has not been successful. Radiation therapy appears to cause severe fibrosis of the masticatory and neck musculature that does not respond to therapy. Surgical intervention can cause postoperative muscle spasm that makes swift mobilization difficult. The authors believe that if these unfortunate individuals are to be helped effectively, therapy must be instituted almost immediately after treatment, which entails the use of resources at the hospital where the treatment is given. If physical therapy is not introduced until after the patient has been discharged from hospital, it often is too late to effect any improvement.

PATIENT EDUCATION

As mentioned previously, it is vital that patients know the intent of the treatment so that they do not harbor any incorrect expectations for the treatment outcome. Patients also must be made aware of the likely biomechanical changes caused by the dysfunction, so that they become fully involved in the rehabilitation process and understand why certain activities must be avoided. A useful educational tool is a simple diagram of the anatomy of the TMJ; it need not be anatomically specific nor drawn with an excruciating degree of detail. The objectives of education are to reassure the patient, to explain the nature, etiology, and prognosis of the problem, to reduce repetitive strain of the masticatory system (e.g., daytime bruxism), to encourage relaxation, and to control the amount of the masticatory activity.[136,270,272,273]

The education process can be split into several parts. The first part should provide an explanation of the basic anatomy, joint position, and normal disc-condyle relationship. The second part should include some description of the patient's probable pathological condition. The third part should be a description of possible aggravating factors and various activities to be avoided. The fourth part should include a description of some things patients can do for themselves at home, including a list of required exercises. The fifth part should provide some indication of the extent of recovery expected, the likelihood of recurrence of problems, and the need to bring other health care professionals into the rehabilitation process.

Increased self-management is closely linked to successful rehabilitation, which includes three separate domains: physical, functional, and social.[270] The patient has to be reassured by explaining the problem, supposed etiology, and good prognosis of this benign disorder. Patients require good information to assist them in making choices, overcoming unhelpful beliefs, and modifying behavior. The relationship between chronic pain and psychosocial distress must also be considered. Normal jaw muscle function has to be explained, stressing how to avoid overloading the masticatory system, which could be the major cause of the complaints. The patients have to pay close attention to the jaw muscle activity, they should be informed about normal jaw function and that parafunctions could be a cause of their complaints. They should be instructed to avoid bad oral habits and excessive mandibular movements and to keep the jaw muscles relaxed and the teeth apart except for swallowing or eating. In acute conditions they have to avoid hard food, cut hard and tough food into small pieces, chew with the back teeth on both sides, and avoid chewing gum and nail biting. Later in the rehabilitation program, training of restrictive activities of daily living as mentioned previously (i.e., avoid

bad oral habits and excessive mandibular movements) is part of the procedure to return to normal or desired levels of activity and participation and to prevent the development of chronic complaints. Patients must learn to keep the muscles relaxed by holding the mandible in the resting position (i.e., teeth apart) rather than in occlusion because occlusion requires "unintentional" muscle contraction.[271] The mandibular resting position can be determined by asking the patients to pronounce the letter "N" several times and to maintain the tongue behind the upper incisor teeth, with the lips in slight contact or as an alternative, to exhale through the mouth. Approaches aiming at changing maladaptive habits and behaviors, such as jaw clenching and grinding of the teeth, are important in treating painful tissues. Behavior-modification strategies, such as habit reversal, are commonly used. Although many habits are abandoned when the patients become aware of them, changing persistent habits requires a structured program. Patients should be aware that habits do not change spontaneously and that they are responsible for the change. For this reason, it is important to stress the need for the patients to practice what they have learned at home and during their common activities, often with the help of visual feedback.

Patient Management Program: Diaphragmatic Breathing

- If you breathe through your mouth, you are breathing abnormally. Consequently, your jaw will be dropped and can never be in a normal resting position unless you change your breathing habits. Your symptoms will never entirely go away, and you will not receive maximum benefit from your treatment.
- When breathing and at rest, hold the tip of your tongue against the back of your top teeth. Keep your lips lightly together; the upper and lower teeth should be slightly separated. This technique will prevent mouth breathing. All breathing should be done through your nose, with your tongue elevated, for the rest of your life. Your teeth should be slightly apart (0.32 to 0.63 cm [0.125 to 0.25 inches]).
- Do not suck in air through your mouth.
- Concentrate your breathing on your stomach. Your stomach should expand and contract, *not* your chest. Put your hand on your stomach and feel it go in and out; this is called *abdominal,* or *diaphragmatic, breathing.* This is the way you should breathe from now on. Simultaneously, keep your tongue against the roof of your mouth.
- Do five breaths every hour (i.e., at 1-hour intervals, consciously inhale and exhale from your stomach five times; hopefully you will also be breathing this way subconsciously in between).
- Never use nasal inhalants or sprays.
- Never put your tongue between the biting surfaces of your teeth.

Patient Management Program: Everyday Activities

Successful treatment and management of temporomandibular joint/muscle dysfunction depends in large part on the way these injured areas are treated. The following instructions can greatly enhance the correction and healing of this area.

- For the next few months, be sure to cut all your food into bite-sized (i.e., small) pieces. Try not to open your mouth any wider than the thickness of your thumb.
- Do not eat hard crusts of bread, tough meat, raw vegetables, or any other food that requires prolonged chewing.
- Do not chew gum during this period of treatment.
- Be sure not to protrude your jaw, as you must do in biting off a piece of meat.
- Do not bite any food with your front teeth.
- When you chew, make sure you chew equally on each side of your mouth. Do not get in the habit of doing all your chewing on one side only.
- If you wear lipstick, do not bring your jaw forward when applying it.
- Avoid protruding your jaw during any other activities (e.g., smoking, conversation).
- Make every effort not to strain your joint ligaments unnecessarily. For example, do not stretch your mouth open when yawning.
- If you find yourself clenching your teeth, try to remember, "lips together, teeth apart."
- Try to sleep on your back or side. Avoid sleeping on your jaw or in the prone position.

In summary, patient education involves explaining the nature of the pain and ways to avoid painful conditions. Information about the biopsychosocial model of TMDs, chronic pain, and self-management needs to be included in the education program.[272] In addition, the patient needs to be advised about posture and ergonomic conditions (e.g., work-related postures or loads) and the adverse effects of certain positions and oral behaviors, such as biting, chewing, and grinding, that create constant microtrauma in the tissues. Patient education has been found to be crucial to the success of treatment.[252]

Temporomandibular Joint Education Process

The following points are covered at the first visit:

- Explanation of anatomy, joint position, and the normal disc-condyle relationship
- Description of the probable pathology
- Description of the aggravating factors and activities to avoid
- Guidelines the patient can follow at home, including exercises
- Likely extent of recovery
- Likelihood of problem recurrence
- Inclusion of other health care professionals in the treatment process (if needed)

SUMMARY

Treatment of TMDs and related dysfunctions follows the same principles as treatment of any other musculoskeletal problem. After a comprehensive history has been taken and an assessment performed, a hierarchy of signs and symptoms is formulated, together with a hierarchy of treatments aimed at helping to alleviate the signs and symptoms and restore normal functioning of the CMS. The objective is to return the patient to maximum possible function. To do this, the clinician must have the patient's cooperation and participation; to give these, the patient must understand the condition, what will be required for recovery, and the goals set by the clinician.

Frequently treatment is not only multifaceted but also requires the participation and skills of practitioners from different specialties, such as physical therapists, dentists, clinical psychologists, speech pathologists, and physicians. Concentrating on one area alone does not provide successful outcomes or ensure a happy patient. TMD is recognized as a multidimensional disorder, the result of biological, psychological, and social alterations. Therefore assessment and management of TMD must address the biological, psychological, and sociological aspects of the individual as a whole.[48]

CHAPTER 5

Shoulder Trauma and Hypomobility

JUDY C. CHEPEHA

INTRODUCTION

Optimal functioning of the shoulder and arm can take place only if the delicate balance of healthy anatomy, proper biomechanics, and normal physiology is maintained. Disruption of any one of these three factors may lead to overload and injury, resulting in pain and dysfunction. A vast amount of information regarding the pathoanatomy and biomechanics of the shoulder has contributed to the clinician's ability to understand and manage patients with shoulder complaints more accurately and effectively.[1–11] Surgical techniques grounded in basic scientific principles related to the restoration of normal anatomy, biomechanics, and the physiology of injured or compromised structures have changed to allow for earlier introduction of rehabilitation. Keeping pace with changes in surgical intervention, rehabilitation programs are now based upon principles derived from pathophysiology, functional anatomy, and restoration of the entire kinetic chain from the lower extremity through the trunk, shoulder girdle, and arm.

Proper rehabilitation of the injured shoulder should be based on knowledge of the normal anatomy and function of the entire shoulder girdle complex and the inherent demands and potential mechanisms that may contribute to or cause injury to this region. Goals of simply increasing range of motion (ROM) and/or improving strength at the glenohumeral joint are no longer acceptable; rather, clinicians must be mindful of how the glenohumeral and scapulothoracic complex functions as part of the entire kinetic chain and understand the subtle relationships among all these interrelated components. Rehabilitation programs prescribed for the treatment of shoulder conditions should be centered on **principles of treatment** as well as specific condition exercise protocols, and these principles should be coupled with the clinician's knowledge of the shoulder, particularly how it functions under both normal and abnormal circumstances. Hopefully, advances in management of the injured shoulder are reflected in improved and earlier return to functional status for patients.

An advantage of managing the injured shoulder according to general treatment principles, rather than specific protocols, is the adaptability of these principles to many different situations. In other words, patients with different shoulder pathologies can benefit from the application of some or all of these treatment principles as they share the same goals of "normalizing" shoulder anatomy, biomechanics, and physiology.

Principles of Shoulder Treatment

- Proper and thorough assessment
- Early protected motion after a period of immobilization
- Proper evaluation and treatment of local and distant deficits
- Scapular control
- Pain management
- Sensorimotor control
- Progressions
- Closed chain axial loading exercise
- Functional exercises

Common Principles of Treatment

1. ***Proper and Thorough Assessment:*** As with any musculoskeletal pathology, treatment of the patient with a shoulder injury must begin with a thorough history and physical assessment. Assessment should include an evaluation of all shoulder girdle tissue as well as the cervical and thoracic spine regions. Depending on the patient and his or her shoulder condition, the lumbar spine and lower extremity may be important to also include in the assessment. Patients should be examined statically and dynamically and while they are performing functional activities.
2. ***Protected Motion After a Period of Immobilization:*** The shoulder complex, particularly the glenohumeral joint, is prone to stiffness after trauma or immobilization.[12,13] Early intervention through gentle ROM exercises and joint mobilization techniques may prevent this restriction of ROM, reduce the associated pain, and allow the shoulder to move into positions that can best address normalization of muscle activity and function. Special consideration must always be

given to surgically repaired tissue as well as the adaptive tightening of the glenohumeral posterior capsule, which presents clinically as a medial rotation deficit (i.e., glenohumeral internal rotation deficit [GIRD]), and finally the anterior shoulder muscles (e.g., pectoralis minor), which also tend to shorten.

3. ***Evaluation and Treatment of Local and Distal Deficits:*** Many shoulder injuries are associated with local and/or distal deficits in flexibility, strength, muscle balance, and proper mechanics that affect the whole kinetic chain. For example, hip and lumbar spine inflexibility, altered scapulohumeral rhythm, and reduced medial rotation motion may be part of the cause of the shoulder injury or may occur as a result of the injury. Regardless of the onset, all deficits of the kinetic chain must be noted on assessment and incorporated into a proper treatment plan.
4. ***Scapular Control:*** Scapular dyskinesis, an alteration in the position or motion of the scapula, is caused by weakness or inhibition of the periscapular muscles, especially the lower trapezius and serratus anterior.[14] The resultant loss of scapular control, coupled with an often overactive upper trapezius, can contribute to shoulder impingement and instability syndromes, acromioclavicular (AC) dysfunction, and rotator cuff weakness.[14–17] Proper shoulder rehabilitation must always include a thorough examination of the scapula and correction of any deficits.
5. ***Pain Management:*** Pain is a powerful inhibitor of muscle activation throughout the body. This is especially true at the shoulder because of the degree of muscle activity required to coordinate joint motion, stability, and function. Clinicians must closely monitor and manage pain, making certain that it is not causing inhibition of the weaker, targeted muscles and encouraging perpetuation of an improper muscle recruitment pattern.
6. ***Sensorimotor Control:*** Sensorimotor control is the neuromuscular control basis of sensory input, often known as proprioception. With the increased knowledge about the effect of changes in proprioception and neuromuscular control of joint stabilization in the shoulder, exercises that address retraining of this important factor have been integrated into treatment approaches.[16,18]
7. ***Progressions:*** Indications for progressing a patient to more challenging exercises are based in part on physiological principles of tissue healing and tissue response to injury. Decisions should also be made through the evaluation of the patient's ability to perform key functions at the shoulder girdle (i.e., scapular stabilization) and the entire kinetic chain; these include adequate hip and trunk extension, normal pelvic control, proper scapular control (especially into retraction and depression), normal scapulohumeral rhythm, and glenohumeral joint ROM.
8. ***Closed Chain Axial Loading Exercises:*** Closed chain rehabilitation exercises link the trunk to the scapula and the scapula to the arm; this allows strengthening of the scapular and arm musculature as a functional unit. These exercises should be performed along with early postoperative ROM techniques because they minimize the shear effect and reduce the open kinetic chain loading applied to the glenohumeral joint.[19–22]
9. ***Functional Exercises:*** Rehabilitation of the injured shoulder should always include exercises that are considered functional. However, clinicians must keep in mind that, for an exercise to be considered functional, it must reflect the individual patient's functional activities and goals for work, daily life, and recreation.

These nine shoulder rehabilitation principles form the foundation of treatment for most shoulder pathologies managed conservatively. Greater detail on specific treatments and exercise guidelines are presented throughout the remainder of this chapter and in Chapters 6 and 7.

SHOULDER ANATOMY

When considering the shoulder, the clinician must include the entire shoulder girdle, consisting of three bones (scapula, clavicle, and humerus) linked to each other and to the body by four joints (glenohumeral, AC, sternoclavicular, and scapulothoracic articulation). The combined effect of these four articulations is a high degree of mobility, which not only allows the arm and hand great functional capacity but also makes the shoulder particularly vulnerable to injury because stability is sacrificed for mobility. The glenohumeral joint has an almost global ROM due to the shallow glenoid socket, which is approximately one third to one fourth the size of the humeral head. The glenoid labrum, attached tightly to the bottom half of the glenoid and loosely to the top half, increases the glenoid depth approximately 2 times, adding to glenohumeral stability.[3,4] Normally when the humeral head is moved through its large ranges of motion, only a small amount of translation or excursion occurs between the humeral head and the glenoid. If the dynamic structures controlling this translation (primarily the rotator cuff) are injured, translation may increase, leading to increased wear on the glenoid labrum, failure of the static restraints, and eccentric overload of the dynamic restraints, resulting in instability, impingement, or both.[2,4,6,7,23–25]

The restraints of the glenohumeral joint typically are classified as either active (dynamic) or passive (static). Table 5-1 presents a list of the two groups. It is worth noting that even though the stabilizing components are divided into two groups, the actual mechanism of stability is not achieved through distinctive, separate processes but rather by one that is highly interconnected.

TABLE 5-1

Restraints about the Glenohumeral Joint

Passive (Static)	Active (Dynamic)	
Capsule Labrum Coracohumeral ligament Superior glenohumeral ligament	Suprapinatus Infraspinatus Subscapularis Teres minor	Humeral stabilizers
Middle glenohumeral ligament Inferior glenohumeral ligament Geometry of humeral articular surface Geometry of glenoid articular surface Coracoacromial ligament Articular cartilage compliance	Pectoralis major Latissimus dorsi Long head of the biceps Triceps Deltoid Teres major	Movers of glenohumeral joint
Joint cohesion	Serratus anterior Latissimus dorsi Trapezius Rhomboids Levator scapulae Pectoralis minor	Scapular stabilizers

Modified from Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 510, Philadelphia, 1996, WB Saunders.

SHOULDER FUNCTION

The shoulder is the most proximal link of the upper extremity kinetic chain. It has evolved to allow humans great mobility so that they can position the most distal segment, the hand, for function. This seemingly simple task is achieved through a highly coordinated pattern of movement that begins in the lower extremities and moves sequentially to the trunk, scapulothoracic joint, glenohumeral joint, and elbow and eventually to the wrist and hand, where the function is performed.

Specific shoulder girdle function relies on the combined motion of the sternoclavicular, AC, glenohumeral, and scapulothoracic joints. This collective motion is achieved through the interaction of the muscles that influence the movement of the scapula, clavicle, and humerus relative to the axial skeleton. Research (in vivo and in vitro) has been done to try to elucidate the complex mechanism by which the shoulder moves and muscles act to facilitate these movements.[26,27] Early radiographic studies of arm elevation identified a 2:1 ratio of glenohumeral to scapulothoracic motion when the humerus is elevated in the coronal plane (Figure 5-1).[28] A similar analysis of elevation in the scapular plane found a ratio of 5:4 after the first 30° of elevation.[29,30] Similar studies carried out by other researchers found slight variations of these earlier observations.[31]

Elevation in a 30° to 40° anterior to the coronal plane customarily is referred to as *scapular plane elevation* or *scaption*. However, the scapula is a highly mobile reference point that not only moves with arm elevation but also inclines forward early in motion, obviously in a different direction from that of the intended elevation. Relative motion between the scapulothoracic joint and the glenohumeral joint has been referred to as the *scapulohumeral* or *glenohumeral rhythm*. The ratios of 2:1 and 5:4 are commonly accepted as representing the ratio of glenohumeral to scapulothoracic motion, but these values are only a limited reflection of the scapulothoracic and scapulohumeral combinations possible to achieve a given arm position. These ratios are based on two-dimensional radiographic projections of angular rotations taken at discrete positions of elevation; however, the arm moves in three dimensions, and for positions other than elevation, much of this motion is under voluntary control. These findings and others are not intended to dismiss completely all of our earlier understanding of scapulohumeral motion but rather to broaden awareness of the dynamic, multiplane model of the shoulder.

Muscle function at the shoulder is considered one of the highly intricate systems in the body. The function of a muscle with respect to any joint depends on the position of the skeletal components, distance of the muscle from the joint's center of rotation, and external and

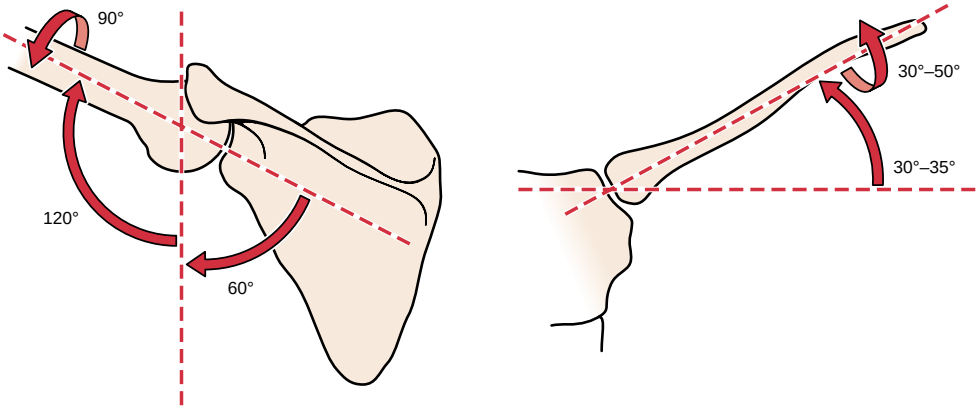

Figure 5-1 Movements of the scapula, humerus, and clavicle during scapulohumeral rhythm. (From Magee DJ: *Orthopedic physical assessment,* ed 6, p 274, St Louis, 2014, Saunders/Elsevier.)

internal forces acting at the time of muscle contraction. Given the three-dimensional, highly mobile nature of the shoulder joint, it is easy to understand why proper functioning of its muscles is essential for a normal, healthy shoulder.

The prime movers of the shoulder are the deltoid, pectoralis major, latissimus dorsi, and teres major muscles. Electromyographic studies[26,32–34] have shown that these muscles function predictably along their line of pull and that they form a drapelike effect over the shoulder, creating the potential for infinite lines of pull that may allow an almost 360° arc of motion.

The rotator cuff contributes to shoulder motion through a variety of means. The muscles of the rotator cuff can function as important movers of the upper extremity if the muscles' line of action is consistent with the intended direction of motion. This group of muscles also serves as a key set of stabilizing muscles for the glenohumeral joint by creating a compressive force that maintains the humeral head on the glenoid surface, and it can function to produce axial rotation of the humerus.

Finally, muscles that attach to the scapula and therefore control scapulothoracic joint motion have been decisively reported as playing a fundamental role in how the shoulder functions or, more appropriately, how *well* the shoulder functions. The work of researchers, such as Kibler[15] and Kibler and Livingstone,[21] has taught clinicians to be mindful of the trapezius, rhomboids, levator scapulae, teres minor, serratus anterior, and latissimus dorsi muscles because their attachments to the scapula allow for control of motion at the scapulothoracic articulation. Dysfunction or inhibition of any of these muscles has been shown to alter the position of the glenoid significantly, which in turn may result in abnormal centering of the humeral head within the glenohumeral joint.[6,15,35] The importance of proper scapulothoracic positioning at rest and during movement cannot be overemphasized, and clinicians must be cognizant of dysfunction at this region of the shoulder girdle.

STERNOCLAVICULAR AND ACROMIOCLAVICULAR JOINT INJURIES

Sternoclavicular (SC) Joint

The sternoclavicular joint is unique because it is the only true articulation between the clavicle of the upper extremity and axial skeleton. It is a diarthrodial type of joint, with the enlarged medial end of the clavicle creating a saddle-type articulation with the clavicular notch of the sternum. The clavicle is the first long bone in the body to ossify. The epiphysis at the medial end of the clavicle, however, is the last long bone to appear and is the last epiphysis to close at approximately 18 to 20 years of age. The epiphysis does not fuse with the shaft of the clavicle until 23 to 25 years of age; therefore the growth plate is the weakest point and more likely to sustain a displaced physeal fracture than a true dislocation.[36] This joint has the distinction of having the least amount of bony stability; therefore it relies heavily on support from the surrounding capsule and ligaments. These ligaments include the intra-articular disc ligament, extraarticular costoclavicular (rhomboid) ligament, interclavicular ligament, and capsular ligament.

The intra-articular disc ligament is a very dense, fibrous tissue that originates from the synchondral junction of the first rib to the sternum and travels through the sternoclavicular joint, dividing it into two distinct joint spaces (Figure 5-2). Anteriorly and posteriorly, the disc blends with the fibers of the capsular ligament. The intra-articular disc ligament functions as a checkrein for medial displacement of the proximal clavicle.

The costoclavicular, or rhomboid, ligament is short and strong and is made up of an anterior fasciculus and a posterior fasciculus. These two different parts give the ligament a slightly twisted appearance. Below, the costoclavicular ligament attaches to the upper surface of the first rib and at the adjacent part of the synchondral junction

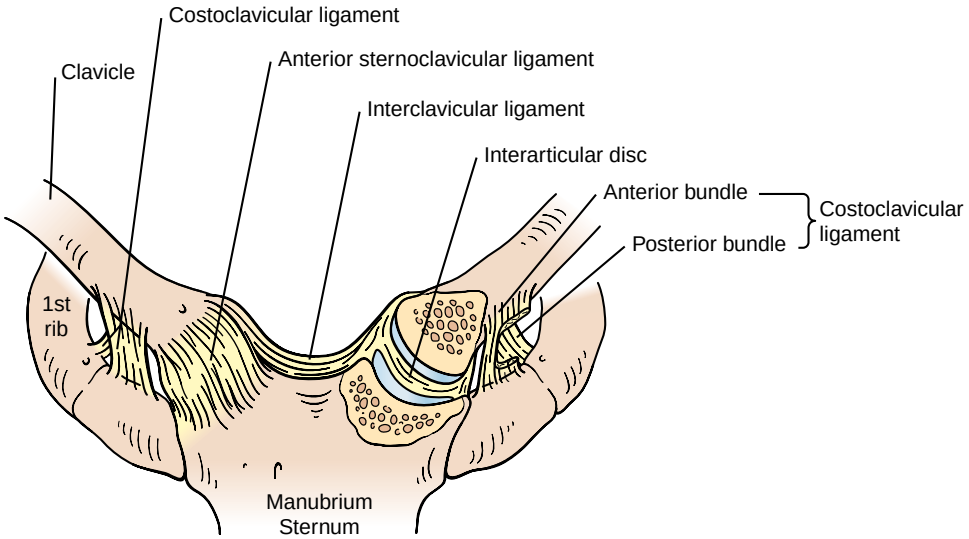

Figure 5-2 Sternoclavicular joint.

with the sternum; above, it attaches to the margins of the impression on the inferior surface of the medial end of the clavicle, sometimes called the *rhomboid fossa*.[37,38] Bearn[39] has shown that the anterior fibers resist excessive upward rotation of the clavicle and the posterior fibers resist excessive downward rotation. Specifically the anterior fibers resist lateral displacement, and the posterior fibers resist medial displacement.

The interclavicular ligament connects the superomedial aspects of each clavicle with the capsular ligaments and the upper aspect of the sternum (see Figure 5-2). Along with the capsular ligaments, the interclavicular ligament helps to hold up the shoulder. To demonstrate this, the clinician can place a finger in the superior sternal notch; the ligament is lax with elevation of the arm but becomes taut when both arms are left to hang at the sides.

The capsular ligament of the sternoclavicular joint, which extends over the anterosuperior and posterior aspects of the joint, represents thickenings of the joint capsule. The posterior capsule is the most important restraint for anterior and posterior translation of the sternoclavicular joint, whereas the anterior capsule acts mostly to prevent anterior translation. These capsular ligaments are considered the most important and strongest ligaments of the sternoclavicular joint and the structures most responsible for preventing upward displacement of the medial clavicle in the presence of a downward force on the distal end of the shoulder.[39]

Function of the Sternoclavicular Joint

The sternoclavicular joint is the most frequently moved, nonaxial joint in the body.[40] It acts similar to a ball and socket joint, allowing for motion in almost all planes, including rotation. In normal shoulder motion, the joint accounts for 30° to 35° of upward elevation, 35° of combined forward and backward movement, and 45° to 50° of rotation about the long axis of the clavicle and sternoclavicular joint.[28,41,42] It is important that clinicians appreciate that almost all motions of the upper extremity impact the sternoclavicular joint and conversely that motion at the sternoclavicular joint influences movement distally, along the upper extremity kinetic chain.

Sternoclavicular Joint Dislocations

Dislocations of the sternoclavicular joint are quite rare, accounting for approximately 3% of all fractures and dislocations affecting the shoulder girdle.[43,44] This is mostly due to the strength and integrity provided by the joint's surrounding capsuloligamentous tissue. Anterior dislocations are 2 to 3 times more common than posterior dislocations, fortunately, because posterior dislocations have a high complication rate with potentially life-threatening consequences (Figure 5-3).[36,38,45] The amount of force required to dislocate the sternoclavicular joint posteriorly is more than 1.5 times the force required for anterior dislocation. In addition, a posterior dislocation may put pressure on the underlying mediastinal structures, including the brachial plexus, vascular structures, trachea, and esophagus (Figure 5-4).[46,47] Complications include brachial plexus lesions, pneumothorax and respiratory distress, vascular injury, dysphagia, and hoarseness.[48,49] Motor vehicle accidents are reported as the most common cause of dislocation of the sternoclavicular joint, followed by direct or indirect trauma during a sporting activity. An example of a direct trauma in a sporting activity might be a hockey player hitting the medial side of the clavicle on the goalpost or on another player's knee. With an indirect injury, the athlete may be lying on his side, and the uppermost shoulder is compressed and rolled backward, resulting in an anterior sternoclavicular dislocation on that side. If the shoulder rolls forward and is compressed, a posterior dislocation is more likely.[45,50]

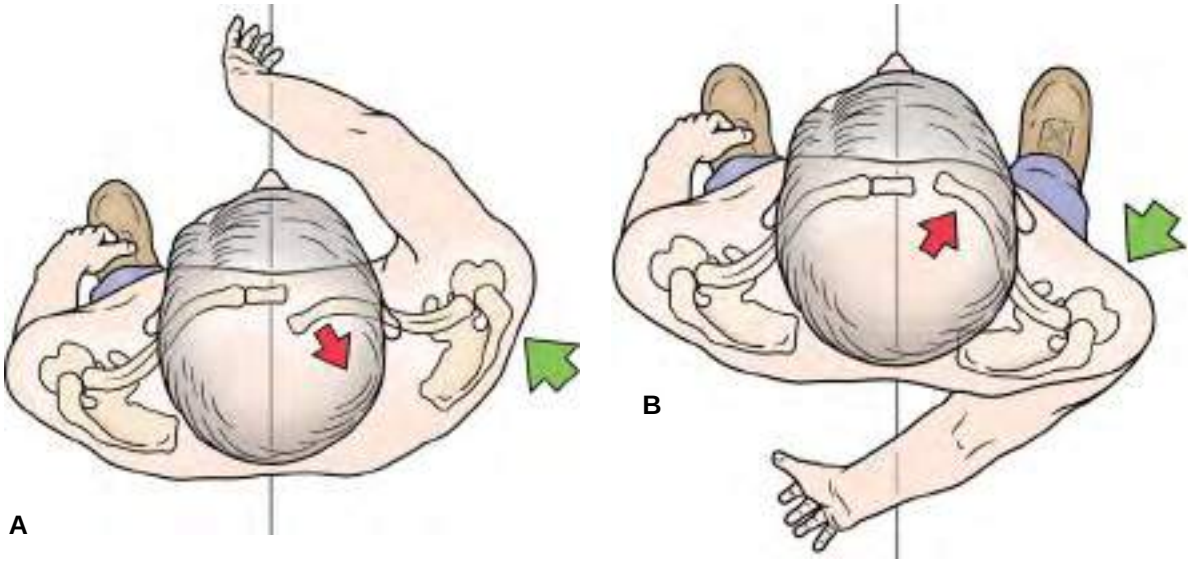

Figure 5-3 Mechanism of injury to the sternoclavicular joint. **A**, Posterior applied force (*green arrow*) directed anteriorly causes proximal end of clavicle to move posteriorly (*red arrow*). **B**, Anterior applied force (*green arrow*) directed posteriorly causes proximal end of clavicle to move anteriorly (*red arrow*). (Redrawn from Emery R: Acromioclavicular and sternoclavicular joints. In Copland SA, editor: *Shoulder surgery,* Philadelphia, 1997, WB Saunders; and Rockwood CA, Green DP, editors: *Fractures,* vol 1, ed 2, Philadelphia, 1984, JB Lippincott.)

Sternoclavicular dislocations are classified according to patient age, severity, and direction of dislocation. Mild sternoclavicular joint injuries are those in which the joint is stable and the ligamentous integrity has been maintained. Moderate injuries have had part of the ligamentous tissue disrupted, and the sternoclavicular joint has partially separated or subluxed. Complete ligamentous disruption, resulting in an unstable sternoclavicular joint, is considered a severe injury. The degree of separation can also be classified as first, second, or third, but this classification is based more on injury to the ligaments supporting the joint rather than injury to the joint itself. A first-degree sternoclavicular dislocation results in minor tearing (first- or second-degree sprain) of the sternoclavicular and costoclavicular ligaments, with no true displacement of the joint. A complete tear (third-degree sprain) in the sternoclavicular ligaments and a second-degree sprain of the costoclavicular ligament constitute a second-degree sternoclavicular dislocation and actually result in subluxation of the joint. A third-degree sternoclavicular dislocation is a true dislocation of the joint, caused by third-degree sprains in the sternoclavicular and costoclavicular ligaments.[51]

Clinical Presentation of Sternoclavicular Joint Dislocations

Sternoclavicular dislocations are characterized by deformity, ecchymosis, crepitus, and local pain or tenderness, especially with arm movements that roll the shoulders forward and/or lying supine. In the acute situation, clinicians should note any tenting of the skin, which could be indicative of an underlying fracture or dislocation of the sternoclavicular joint. A careful neurological and vascular examination should always be performed because of the joint's proximity to these key structures. Observation of an anterior sternoclavicular dislocation will show a prominent medial clavicle that is more anterior compared with the sternum, whereas a posterior dislocation will reveal a medial clavicle that is less visible and often not palpable. With a posterior dislocation or subluxation, some shortness of breath or even venous congestion in the neck may be seen, with decreased circulation sometimes evident in the arm. Reduction of a posterior sternoclavicular dislocation usually is accomplished by extending the shoulders while using some form of roll or sandbag as a fulcrum along the spine. Reduction most often occurs easily, although in some cases supplemental anesthesia may be required. The practitioner also may need to grasp the clavicle with the fingers or, if the anatomy is less defined, with some type of surgical instrument, such as a towel clip.

Treatment of Sternoclavicular Joint Dislocations

Goals of treatment following a sternoclavicular injury include pain control, reduction and/or immobilization as indicated, identification and management of associated injuries, and education regarding protection and prevention of subsequent injury. If the sternoclavicular joint has incurred only a first- or second-degree sprain and the joint is deemed stable, treatment follows a course similar to that for any other injured joint. The patient's shoulder should be immobilized for 3 to 4 days, as pain dictates, and then should make a gradual return to normal use of the shoulder and arm. Local electrical modalities and the use of ice and heat may be helpful for reducing pain and inflammation at the sternoclavicular joint. The clinician should be aware of the impact of a sternoclavicular injury on the entire shoulder complex because the effects of the initial injury may be far-reaching and can lead to compensatory patterns of movement.

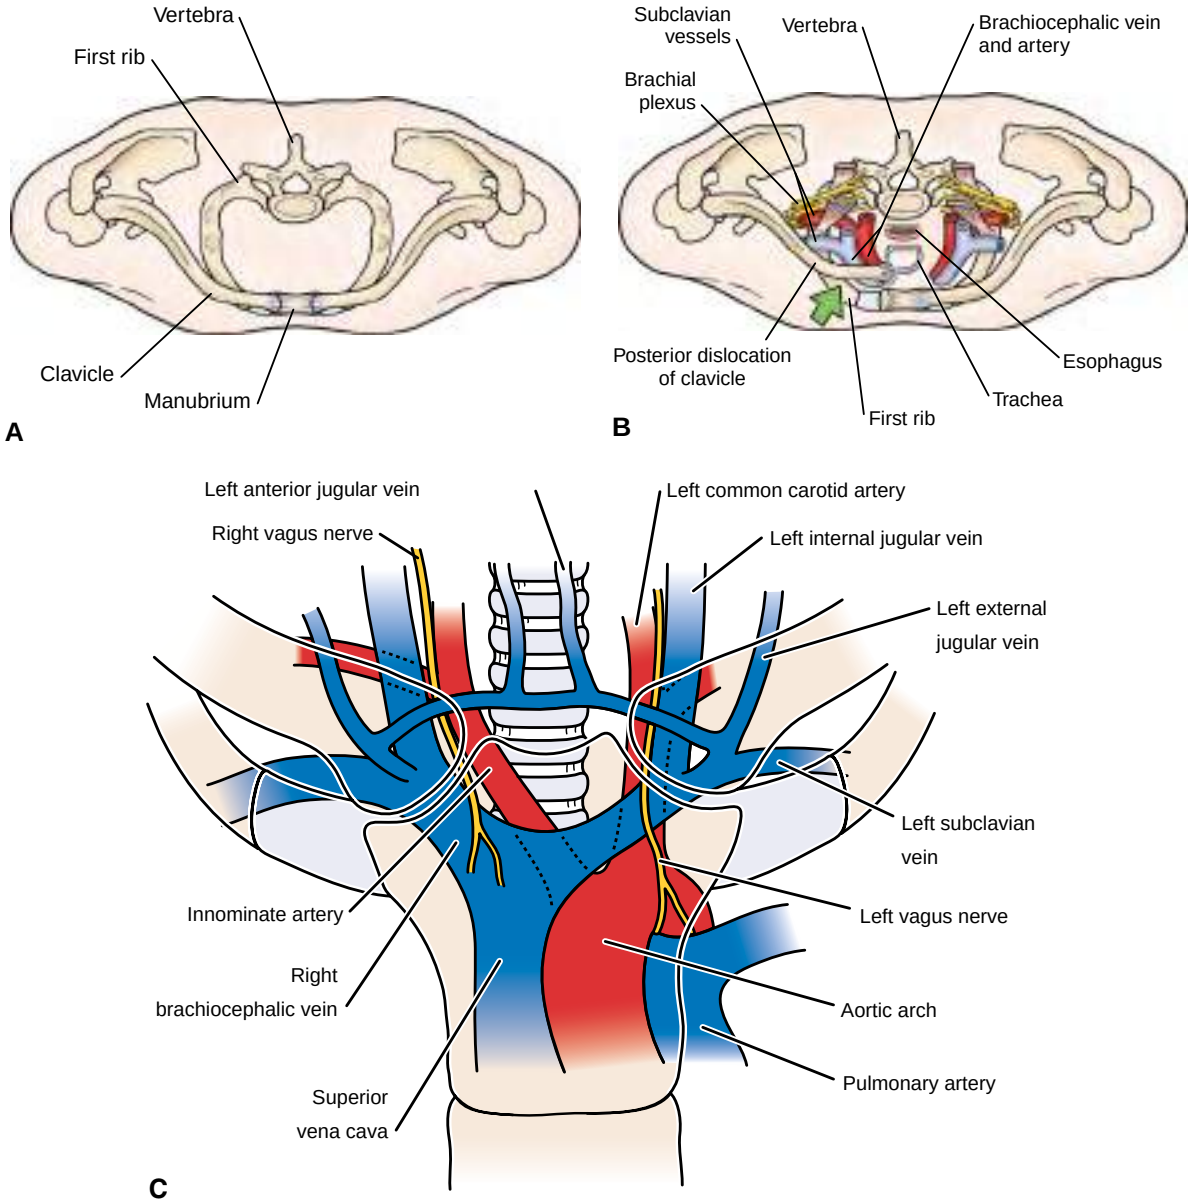

Figure 5-4 Sternoclavicular joint posterior dislocation. **A,** Overhead view of normal anatomical relationships. **B,** Posterior dislocation of the sternoclavicular joint. Note proximity of vessels which could be compressed with dislocation. *Arrow* indicates direction of force. **C**, Anterior view of retrosternal anatomy. Note the proximity of the sternoclavicular joint to the trachea, aortic arch, and brachiocephalic vein. (**C**, From Magee DJ: *Orthopedic physical assessment,* ed 6, p 257, St Louis, 2014, Saunders/Elsevier; redrawn from Higginbotham TO, Kuhn JE: Atraumatic disorders of the sternoclavicular joint, *J Am Acad Orthop Surg* 13:139, 2005.)

In second- or third-degree sprains of the sternoclavicular joint, if the main complaint after reduction is instability, treatment frequently requires sling support for an anterior dislocation or a figure-of-eight bandage for the posterior dislocation. The sling is worn for at least 2 to 3 weeks. Chronic instability may require surgical stabilization of the sternoclavicular joint, which is by no means uniformly successful. Chronic subluxation or damage to the intra-articular disc can produce long-term discomfort with repetitive strong movements of the upper limb.

Complications of anterior sternoclavicular dislocation include cosmetic deformity, recurrent instability, and late osteoarthrosis; complications of posterior dislocation include all of these plus pressure on or rupture of the trachea, pneumothorax, rupture of the esophagus, pressure on the subclavian artery or brachial plexus, voice change, and dysphagia. Although the incidence of one of these complications can be as high as 25%, only about three deaths have been reported in the literature from the more serious complications associated with this injury.[45,51]

Atraumatic anterior subluxation of the sternoclavicular joint during arm elevation is occasionally reported in patients younger than 30 years of age. Many individuals affected by this condition demonstrate signs of generalized ligamentous laxity. Patients report a nontraumatic, spontaneous subluxation of the medial end of the clavicle, occasionally with a pop, that reduces when the arm lowers back down. Most cases are not painful and do not interfere with

functional activities; therefore management is conservative with the focus on patient education regarding the anatomical events involved and reassurance that the condition should not alter lifestyle or limit activity (Figure 5-5).[52,53]

Complications of Sternoclavicular Posterior Dislocation

- Cosmetic deformity
- Recurrent instability
- Late osteoarthritis
- Pressure on or rupture of the trachea
- Pneumothorax
- Rupture of the esophagus
- Pressure on the subclavian artery
- Pressure on the brachial plexus
- Voice change
- Dysphagia

Acromioclavicular (AC) Joint

The AC joint is a diarthrodial joint made up of the lateral aspect of the clavicle and the medial margin of the acromion process of the scapula. In conjunction with the sternoclavicular joint, the AC joint provides the upper extremity with a connection to the axial skeleton. The articular surfaces initially are hyaline cartilage until approximately 17 years of age on the acromial side of the joint and approximately 24 years of age on the clavicular side. After this time, the hyaline cartilage acquires the structure of fibrocartilage. The anatomy of the AC joint varies considerably; the articular surface orientation can range from vertical to overriding at an angle of approximately 50°.[45,54–56] The dramatic variation in anatomy may explain why some individuals seem more susceptible to injury at this joint.

Within the AC joint is an intra-articular disc, which may be partial (meniscoid) or complete. This disc can be damaged through injury to the AC joint leading to further degeneration over time. Unstable discs are often implicated as the cause of clicking and recurrent pain at the AC joint.

The AC joint is surrounded by a thin capsule that is reinforced above, below, anteriorly, and posteriorly by the superior, inferior, anterior, and posterior AC ligaments (Figure 5-6). The fibers of the superior AC ligament blend with the fibers of the deltoid and trapezius muscles, which are attached to the superior aspect of the clavicle and the acromion process. These muscle attachments are important as they strengthen the AC ligaments and add stability to the joint.

The coracoclavicular ligament is a very strong, heavy ligament with fibers running from the outer, inferior surface of the clavicle to the base of the coracoid process of the scapula. The ligament consists of two individual ligaments, the conoid and trapezoid, which sometimes have a bursa between them. As the name suggests, the conoid ligament is cone shaped, with the apex of the cone attaching on the posteromedial aspect of the base of the coracoid process and the base attaching to the conoid tubercle on the posterior undersurface of the clavicle. The trapezoid ligament arises from the coracoid process, anterior and lateral to the attachment of the conoid ligament just posterior to the attachment of the pectoralis minor tendon. The ligament travels superiorly to a rough line on the undersurface of the clavicle. The coracoclavicular ligament plays an important role not only in strengthening the AC joint but also in assisting the glenohumeral joint with scapulohumeral motion. As the clavicle rotates upward, it dictates scapulothoracic rotation by virtue of its attachment to the scapula, that is, the conoid and trapezoid ligaments.[55,57]

Function of the Acromioclavicular Joint

Codman[58] described the motion at the AC joint as "swinging a little, rocking a little, twisting a little, sliding a little and acting like a hinge." Subsequent authors[59,60] observed relatively little motion between the clavicle and the acromion during studies involving percutaneous implanted pins in subjects. They described a synchronous, three-dimensional linkage between clavicular rotation and scapular rotation, such that when the clavicle rotates, the scapula

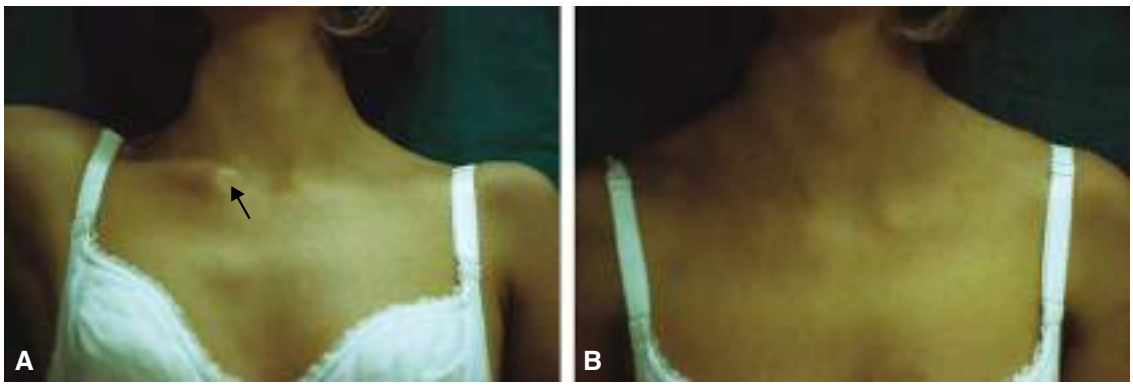

Figure 5-5 Spontaneous subluxation of the sternoclavicular joint. **A,** With the arms in the overhead position, the medial end of the right clavicle spontaneously subluxes out anteriorly (*arrow*) without any trauma. **B,** When the arm is brought back down to the side, the medial end of the clavicle spontaneously reduces. This usually is associated with no significant discomfort. (From Rockwood CA, Matsen FA, Wirth MA, et al, editors: *The shoulder,* ed 4, p 535, Philadelphia, 2009, Saunders.)

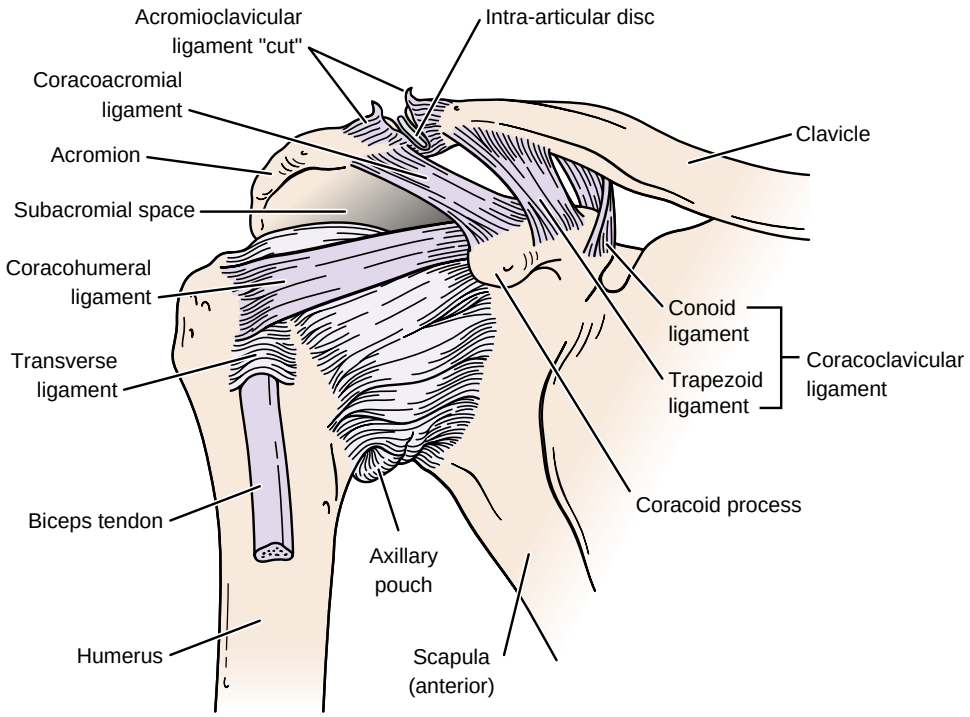

Figure 5-6 Anterior view of the right glenohumeral and acromioclavicular joints. Note the subacromial space or supraspinatus outlet located between the top of the humeral head and the underside of the acromion. The **coracoacromial arch** forming the ceiling of the subacromial space is made up of the undersurfaces of the acromion process, the coracoacromial ligament, and the coracoid process. (From Magee DJ: *Orthopedic physical assessment,* ed 6, p 256, St Louis, 2014, Saunders/Elsevier; modified from Neumann DA: *Kinesiology of the musculoskeletal system: foundations for rehabilitation,* ed 2, St Louis, 2010, Mosby.)

also rotates, concluding that most scapulothoracic motion occurs through the sternoclavicular joint, not the AC joint.

In a classic article published in 1944, Inman[41] suggested that the total ROM of the AC joint was 20° and that clavicular rotation was a fundamental feature of shoulder motion. He noted that motion occurred in the first 30° of abduction and then again after 135° of arm elevation. He also showed that with full elevation, the clavicle rotates upward 40° to 50°. Since these original observations, researchers have disputed the amount of motion that occurs at the AC joint relative to the glenohumeral joint.[54,61,62] Despite the controversy, researchers agree on the important relationship between the two joints and recognize that scapulohumeral rhythm is a delicate balance achieved through a combination of elevation and rotation of the clavicle and proper scapulothoracic and glenohumeral joint motion.

Acromioclavicular Joint Injuries

The AC joint is one of the most frequently injured joints in the body, particularly in sports and activities that require overhead involvement of the shoulder and arm and/or that have a high risk of collision and impact. Injuries to the AC joint result in what is often called a "separated" shoulder, and they account for 9% to 10% or acute injuries to the shoulder girdle in the general population, whereas separations of the AC joint account for 40% of shoulder girdle injuries in athletes.[40,61–64] Common mechanisms of injury include falls on an outstretched hand or elbow (i.e., FOOSH injury), direct blows to the shoulder, or falling onto the point of the shoulder (Figure 5-7).

As with the sternoclavicular joint, AC joint injuries are classified according to ligamentous injury rather than injury to the joint itself. Table 5-2 describes the features and management of the six classifications of AC joint injury (Figures 5-8 and 5-9). Some have suggested that third-degree (type III) disruptions can be further divided according to the magnitude of displacement and the potential accompanying muscle and soft tissue stripping and tearing as well as the direction of displacement of the distal clavicle.[45,59] For instance, displacement of the clavicle of more than 100% is often classified as a fourth-degree (type IV) injury. Type V injuries involve very severe deformity because the distal end of the clavicle is displaced upward a significant degree toward the base of the neck (Figure 5-10). In addition, displacements may occur posteriorly through the trapezius or, in rare cases, inferiorly below the coracoid (type VI). Fourth-degree injuries are associated with considerable disruption of the deltoid and trapezius muscles. A third-degree separation may be treated without surgery, but surgery does have a role in the treatment of fourth-, fifth-, and sixth-degree injuries because of the associated ligamentous disruption and because of cosmetic considerations in leaner individuals (see Figure 5-8).[65–68]

Clinical Presentation of Acromioclavicular Joint Injuries

Patients who have suffered an injury to the AC joint typically present with a history of either a distinctive, traumatic

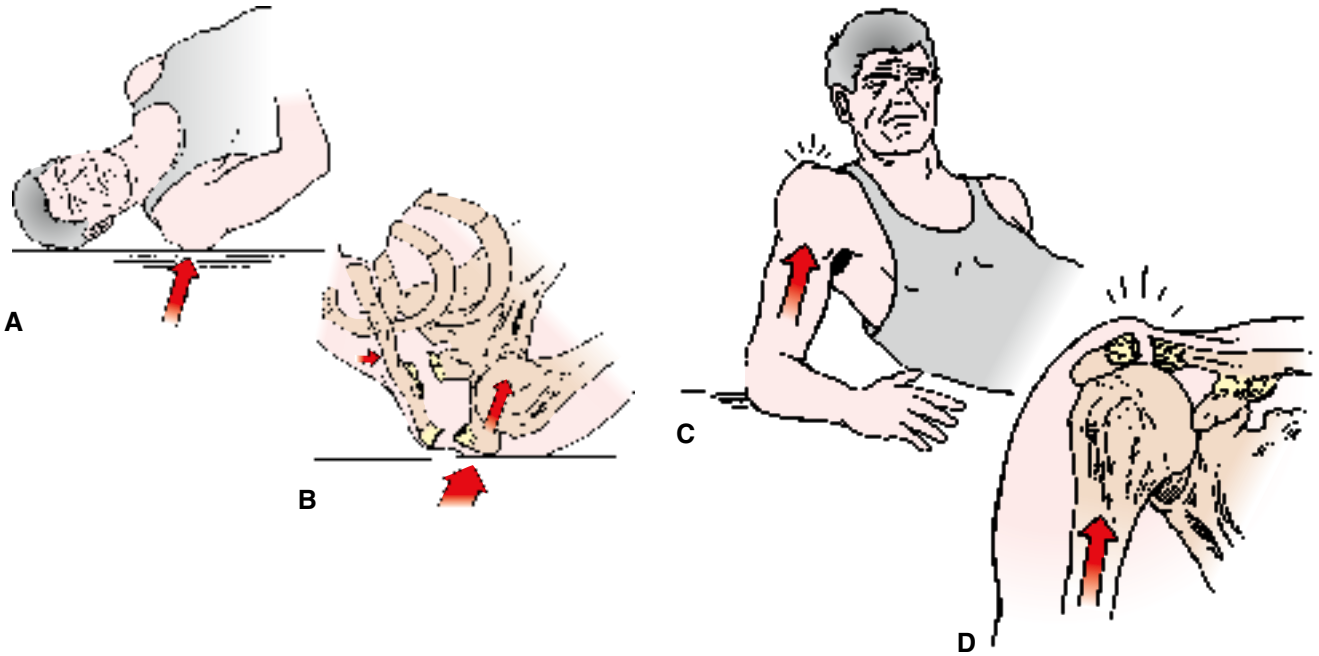

Figure 5-7 Mechanisms of injury to the acromioclavicular joint. **A** and **B,** Direct mechanism of injury. **C** and **D,** Indirect mechanism of injury. mechanism of injury or a more insidious type of onset that began with pain and dysfunction. The diagnosis is made in part by assessing the site of local tenderness, the degree of deformity, and whether instability is present. As with the sternoclavicular joint, injury to the AC joint tends to cause localized pain with minimal referral. Stressing the joint with horizontal adduction elicits pain in the injured AC joint, as does loading the joint by applying leverage at the distal arm. A palpable gap (i.e., a step deformity) may be present with the higher degrees of separation (Figure 5-11). With trauma to the AC joint, the clinician must take care to assess for secondary injury to the surrounding soft tissues (e.g., the rotator cuff) and to the other three articulations of the shoulder complex. Long term, most people function well

TABLE **5-2**

Classification of Acromioclavicular Joint Trauma

Classification	Salient Features	Management
First degree (type I)	• Minimal structural damage • First-degree sprain of the acromioclavicular ligament • Local tenderness on palpation • Full range of motion (may have pain at extreme) • No loss of structural strength • Normal stress x-ray film	• Re-establish full range of motion and strength
Second degree (type II)	• Subluxation of the acromioclavicular joint • Tearing of the acromioclavicular capsule • Second- or third-degree sprain of the acromioclavicular ligament • First- or second-degree sprain of the coracoclavicular ligament • May affect the deltoid and trapezius muscles • No significant increase in the costoclavicular space on stress x-ray film • Slight widening of the acromioclavicular joint on stress x-ray film • Definite structural weakness • Detectable instability on stress • Palpable gap or step deformity possible • Obvious swelling initially with later ecchymosis	• Requires 6 weeks to heal, although ligaments have good structural strength after approximately 3 weeks • Limb support (sling) • Treatments for pain relief (e.g., ice, transcutaneous electrical nerve stimulation [TENS], interferential therapy) • Therapeutic ultrasound therapy for collagen enhancement • Functional exercises (activities at functional speed control)

TABLE 5-2

Classification of Acromioclavicular Joint Trauma—Cont'd

Classification	Salient Features	Management
Third degree (type III)	• Dislocation of the acromioclavicular joint • Complete disruption of the acromioclavicular joint • Third-degree sprain of the acromioclavicular ligament • Third-degree sprain of the coracoclavicular ligament • Tearing of the deltoid and trapezius muscles from the distal end of the clavicle • Obvious step deformity, often without stress • Increased costoclavicular space on stress x-ray film • Widening of the acromioclavicular joint on stress x-ray film	• May be treated surgically or conservatively • If treated conservatively, deformity remains but athlete will function remarkably well with only slight discomfort or instability at high loads • Conservative treatment as above
Fourth degree (type IV)	• Modifications of type III trauma (rare injuries)	• Require surgical repair
Fifth degree (type V)	• Modifications of type III trauma (rare injuries)	• Require surgical repair
Sixth degree (type VI)	• Modifications of type III trauma (rare injuries)	• Require surgical repair

without surgery, although degenerative changes, including clavicular osteolysis, may be seen in some individuals.

Treatment of Acromioclavicular Joint Injuries

Management of an AC joint injury depends on the type of separation. It is generally agreed upon that higher-grade lesions (i.e., type IV to VI) should be treated surgically, whereas lower-grade lesions (i.e., type I and II) are best managed conservatively. How to best treat type III injuries remains controversial; however, current literature suggests the decision should be made on a case-by-case basis with an emphasis on initial nonoperative treatment.[69,70] The ultimate function of the AC joint depends not so much on the amount of separation as on the amount of pain that persists in the joint. Therefore early conservative treatment for first- and second-degree separations focuses

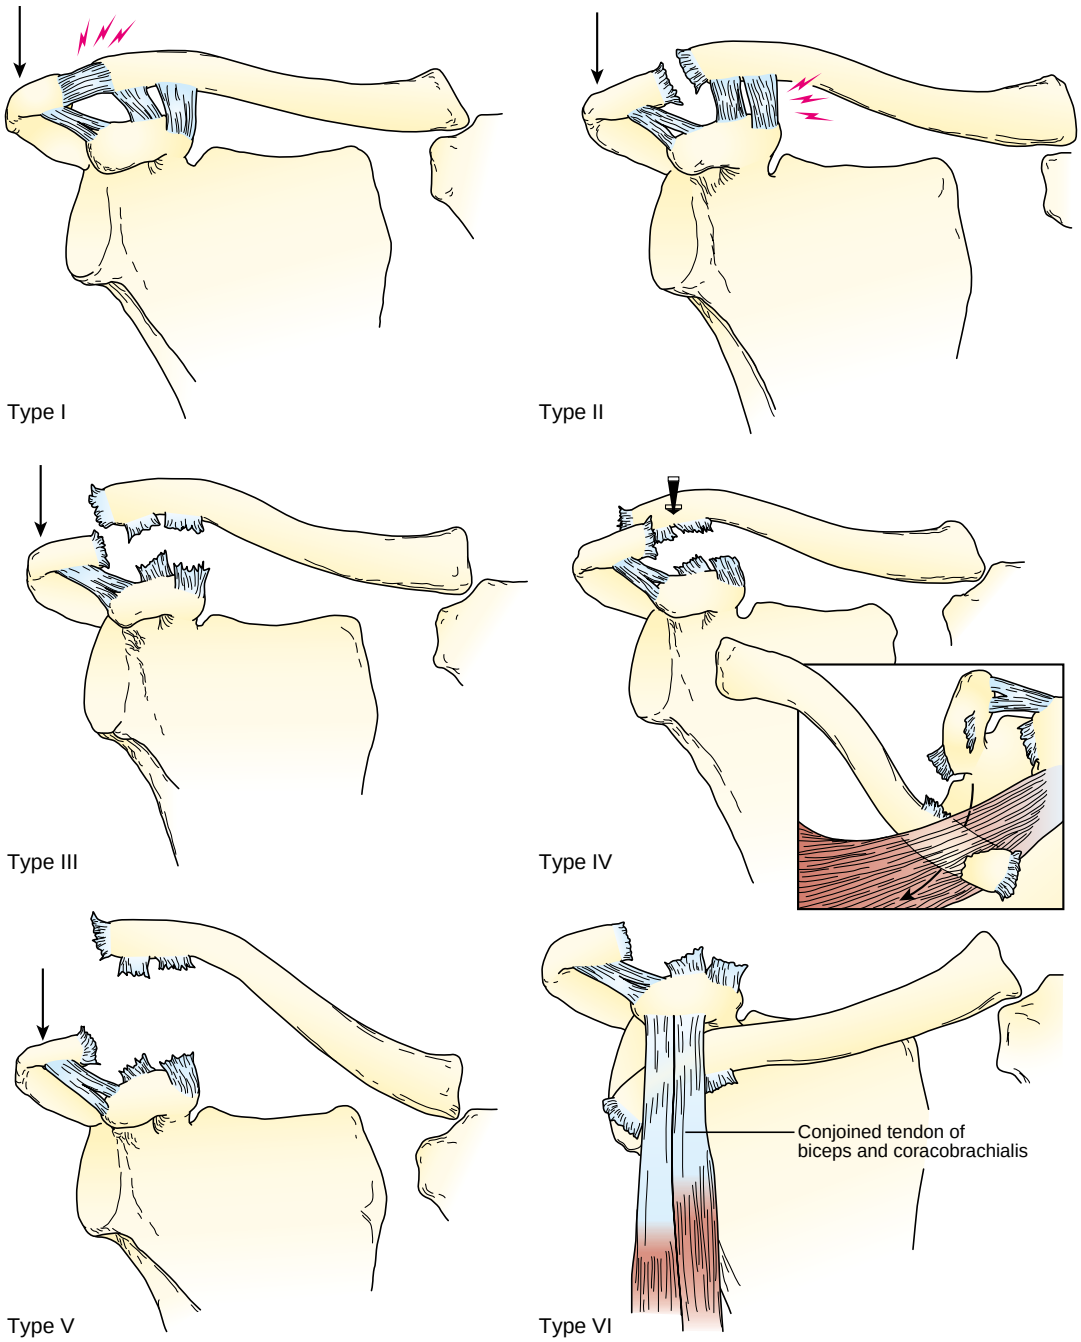

Figure 5-9 Acromiclavicular joint injuries (see Table 5-2). (Rakel RE, Rakel D: *Textbook of family medicine*, ed 9, Philadelphia, 2016, Saunders.)

on pain relief. Initially, the patient's arm may be put in a sling, often accompanied by a swath, to remove the stress of the weight of the limb on the joint and to protect the joint from further damage. This period of immobilization is accompanied by ice and oral analgesic medication, if tolerated. As the pain decreases (within 3 to 7 days), ROM and strengthening exercises, especially for the scapular stabilizers, deltoid, and upper trapezius muscles, are initiated. During this time, heavy lifting and contact sports are avoided to encourage optimal ligament healing. Patients generally return to light-moderate activities 2 to 6 weeks after injury. Return to sport and/or heavy labor is expected following type I and II AC joint separations; however, the timeframe for this is highly dependent upon the individual and his or her specific activity. Associated soft tissue trauma in type II and III injuries typically is more extensive; therefore the time frame is likely to be prolonged for all the suggested treatments.

With third-degree (type III) AC joint injuries, complete reduction is not necessary for satisfactory function; in fact, in terms of strength, endurance, and function, nonsurgical and surgical treatments have been reported to be equally effective.[67–74] Depending on the preference of the surgeon, type III injuries may be treated surgically,

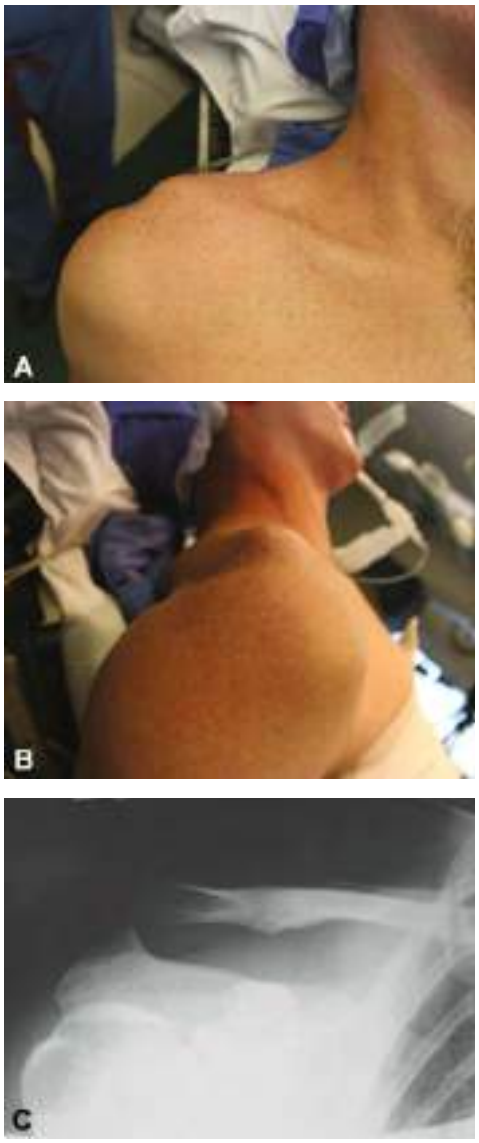

Figure 5-10 Typical findings after a type V AC joint injury, anterior view **(A)** and lateral view **(B)**. There is a twofold to threefold increase in the coracoclavicular distance as well as a stripping of the deltoid and trapezial fascia from the clavicle. This patient was unable to reduce the AC joint with an active shoulder shrug, indicating a true type V injury instead of a type III injury. **C**, Anteroposterior radiographic view demonstrates widening, evidence of a type V injury. (From Miller MD, Thompson SR: *DeLee & Drez's orthopaedic sports medicine: Principles and practices,* ed 3, Philadelphia, 2010, Saunders.)

but the results are seldom better than with conservative treatment, recovery period is longer, and complications of surgery must be considered. For these reasons, most surgeons opt for initial nonoperative treatment, focused on attaining full ROM and scapular stabilization. Surgical consideration is given only to those patients who fail conservative management and present with persistent symptoms and functional limitations.

Types IV, V, and VI require surgical repair to stabilize the joint.

Figure 5-11 Step deformity resulting from acromioclavicular joint trauma (note "step"). (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 265, Philadelphia, 2014, WB Saunders.)

Complications of an AC joint injury include a step deformity produced by the elevated distal end of the clavicle, early skin necrosis if the clavicle is widely displaced in a thin individual, osteoarthrosis, osteolysis, and continuing pain in the long term. For surgical procedures, complications include infection, wound dehiscence, pin migration, and recurrence of the instability, as well as the normal risks of general anesthesia.

FROZEN SHOULDER

The first reported description of frozen shoulder was made by Duplay in the late 1800s.[75] They used the label *scapulohumeral periarthritis* to describe a broad spectrum of pathologies of the shoulder that resulted in pain, stiffness, and dysfunction. This label served as an umbrella term that encompassed disorders such as rotator cuff tendonitis and tears, biceps tendonitis and tears, calcific deposits, AC arthritis, and other painful shoulder syndromes. The term *frozen shoulder* was later coined in 1934 by Codman,[76] who characterized the condition as involving a slow onset, pain near the deltoid insertion, inability to sleep on the affected side, painful and restricted elevation and lateral (external) rotation, and a normal radiological appearance. Even then, Codman described the condition as "difficult to define, difficult to treat and difficult to explain from the point of view of pathology." Subsequent to Codman's observations, Neviaser[77] in 1945 recorded his operative and histological observations from 10 patients with frozen shoulder, noting it was the capsule not the bursa that was thickened and adhered to the humeral head. As a result, he suggested *adhesive capsulitis* as a more descriptive term for shoulders that appeared frozen. More recent investigations have shown that frozen shoulders do not always possess capsular adhesions or, if they do, the adhesions are not always on to the humerus, as first described. Therefore the term *adhesive capsulitis* has been suggested as not appropriate to describe frozen shoulders and should not be used.[78–80]

TABLE 5-3

Types of Secondary Frozen Shoulder

Type	Contributing Causes
Intrinsic	• Calcific tendinosis • Rotator cuff tendinopathy • Biceps tendinopathy • Shoulder surgery
Extrinsic	• Humeral fractures • Clavicular fractures • Cervical radiculopathy • Ipsilateral breast surgery • Chest wall tumor • Cerebrovascular accident
Systemic	• Diabetes • Thyroid abnormalities • Heart disease

Lundberg[81] introduced the terms *primary* and *secondary* to further describe frozen shoulders in 1969. Primary frozen shoulders are those with an idiopathic onset (i.e., no detectable underlying cause), whereas secondary frozen shoulders occur following trauma and/or immobilization. Secondary frozen shoulders have been further classified into intrinsic, extrinsic, and systemic categories by Zuckerman and Rokito[82] and are presented along with contributing causes in Table 5-3.

Despite frozen shoulder being recognized for more than 100 years, there still remains a lack of evidence regarding its etiology, natural history, and best method of management. Clinicians must work closely with their patients with frozen shoulders to tailor treatment plans that best meet the needs of each individual patient, depending on factors such as stage of disease, symptom severity, age, occupation, and expected goals.

Clinical Presentation of Frozen Shoulder

Patients with an idiopathic frozen shoulder tend to progress through three overlapping clinical phases (Table 5-4).[83,84] Phase 1 lasts anywhere from 2 to 9 months and is referred to as the *painful* or *freezing* phase because it is characterized mostly by pain and a progressive loss of glenohumeral joint ROM. Phase 2 is the *stiff* or *frozen* phase and it typically lasts between 4 to 12 months. During this phase considerable stiffness predominates, with a gradual reduction of pain. The final phase (phase 3) is the *resolution* or *thawing* phase, in which there is improvement in ROM and resolution of stiffness. This last phase can range anywhere between 12 and 42 months.[84,85]

Because of the past challenges associated with defining frozen shoulder, authors have begun to adopt definitions of this condition that encompass signs, symptoms, and investigations.[82,86] Table 5-5 presents the symptoms, signs, and investigations that constitute the British Elbow and Shoulder Society's definition of idiopathic frozen shoulder.

TABLE 5-4

Three Phases of Primary (Idiopathic) Frozen Shoulder

Phase	Clinical Presentation
Freezing phase (painful)	Duration: 10 to 36 weeks Pain and stiffness around the shoulder No history of injury Nagging, constant pain that is worse at night Little or no response to NSAIDs
Adhesive/ restrictive phase	Duration: 4 to 12 weeks Pain gradually subsides but stiffness remains Pain apparent only at extremes of movement Gross reduction of glenohumeral movements with near total loss of lateral (external) rotation
Resolution phase	Duration: 12 to 42 weeks Spontaneous improvement in ROM Mean duration from onset of frozen shoulder to greatest resolution exceeds 30 weeks

NSAIDs, Nonsteroidal anti-inflammatory drugs; *ROM,* range of motion.
From Dias R, Cutts S, Massoud S: Frozen shoulder, *Br Med J* 331:1453-1456, 2005.

TABLE 5-5

British Elbow and Shoulder Society (BESS) Survey Definition of Frozen Shoulder

Symptoms	Signs	Investigations
• True (deltoid insertion) shoulder pain • Night pain of insidious onset	• Painful restriction of active and passive motion • Passive elevation less than 100° • Passive lateral (external) rotation less than 30° • Passive medial (internal) rotation less than reaching the level of L5 • All other shoulder conditions excluded	• Plain radiographs normal • Arthroscopy shows vascular granulation tissue in the rotator interval

Modified from Guyver PM, Bruce DJ, Rees JL: Frozen shoulder—a stiff problem that requires a flexible approach, *Maturitas* 78:12, 2014.

The two defining symptoms in patients with frozen shoulders are pain and restricted ROM of the glenohumeral joint (Figure 5-12). The pain is characteristically felt around the deltoid insertion but can also be described as diffuse around the entire shoulder. Patients usually describe the pain as severe, affecting sleep and most activities of daily life. As mentioned earlier, pain is often noted first, followed by a decrease in glenohumeral motion.

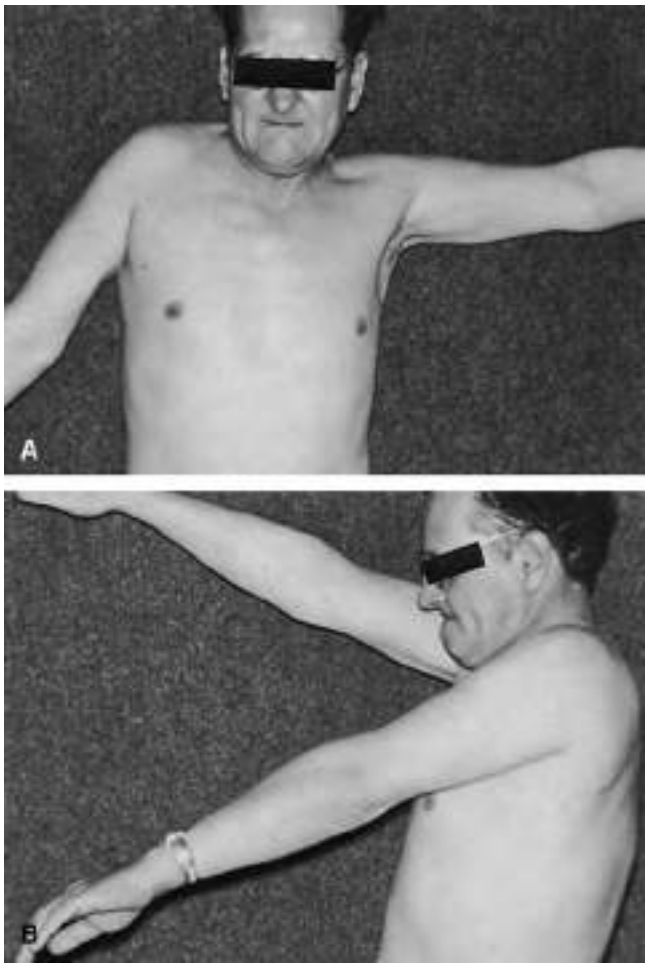

Figure 5-12 **A** and **B,** A 45-year-old man whose right shoulder is in the painful freezing phase of primary frozen shoulder. Note the distress and discouragement in the patient's face. (From Rowe CR, Leffet RD: Frozen shoulder. In Rowe CR, editor: *The shoulder,* p 158, New York, 1988, Churchill Livingstone.)

Patients describe either a slow, progressive loss of movement or occasionally a sudden loss. The reduced ROM follows a *capsular pattern of restriction,* a characteristic pattern of motion loss, secondary to capsular involvement in synovial joints. In the glenohumeral joint, the capsular pattern of restriction is lateral rotation most affected, followed by abduction, and medial rotation. Many clinicians believe that lateral rotation should be reduced more than 50% compared with the unaffected side to consider a diagnosis of frozen shoulder. Plain radiographs are used to rule out bony causes of pain and restricted ROM. To date, there is no evidence to support the use of ultrasound and/or magnetic resonance imaging in diagnosing frozen shoulder.[87]

Clinicians should be mindful of the secondary signs and symptoms that may develop in the patient with a frozen shoulder. Weakness of the glenohumeral and scapular stabilizer muscles is very common as a result of disuse or improper use. This usually occurs in the deep stabilizers of the glenohumeral joint (i.e., the rotator cuff) and in the more superficial movers, such as the three parts of the deltoid muscle. The upper trapezius is often overused in its attempt to compensate for weak and painful shoulder elevation, leading to a reversal of normal scapulohumeral rhythm and further muscle imbalance about the scapula.

Treatment of Frozen Shoulder

Given the uncertainty about the etiology of frozen shoulder syndrome, it is not surprising that the theories of treatment for this condition are equally inconsistent. Systematic reviews regarding the effectiveness of physical therapy[88–91] have concluded limited overall clinical evidence, based upon low-moderate quality evidence, for exercise and manual therapy and low-level laser therapy. The effects of treatment were reported to be greatest during phases 2 and 3 of the condition.

Most patients with a frozen shoulder can be managed successfully with nonoperative treatment, using a multidisciplinary approach of patient education, physical therapy, analgesic medication, and injection therapy.[85,87,88,92] Secondary frozen shoulder requires management of the preceding factor (e.g., shoulder surgery) or contributory factor (e.g., diabetes) as well. Although there is a lack of evidence to support these common treatment interventions, they are noninvasive, inexpensive, and have minimal risk.

Traditional rehabilitation programs focus on exercises and manual therapy techniques that improve glenohumeral ROM and pain-relieving modalities.[87,88,93,94] Joint mobilization techniques, stretching, and passive ROM exercises are done initially because pain usually prevents patients from doing these exercises independently. Some patients may not tolerate any mobility within the first phase of this condition, due to severe pain. In these cases, physical therapy management should focus on patient education and reassurance, pain-relieving strategies and gentle posture, and scapular setting exercises. Patients should also be encouraged to participate in some form of activity that promotes general health and wellness during the time they are dealing with their frozen shoulder. All exercises and techniques should be performed within the limitations of pain to avoid aggravating the affected tissue, especially during the painful, freezing phase.

Clearly no preponderance of evidence points to the best treatment for patients with frozen shoulder syndromes. However, it seems plausible that some, if not all, of the basic principles of shoulder rehabilitation could be applied in dealing with this condition. Patient education about the condition and its expected phases and outcome, postural awareness and treatment (especially of the adjacent cervical and thoracic spine levels), and exercises for the remaining shoulder girdle musculature are all important considerations. In addition, significant care should always be given to reeducate these patients

to control movements of the glenohumeral and scapulothoracic joints because these muscles tend to become "detrained" as a result of the disease and the consequent loss of movement.

SHOULDER FRACTURES

Fractures of the shoulder girdle are relatively uncommon, ranging from minor, nondisplaced, hairline fractures to major, comminuted, displaced fractures with life-threatening consequences.[45] Most fractures in this region require some type of immobilization and/or period of protected motion. This immobilization, although essential for bone healing, often results in secondary stiffness of the glenohumeral joint, generalized muscle weakness, and altered scapulothoracic mechanics. Therefore it is important that the objectives of rehabilitation following a shoulder fracture include normalization of the entire shoulder girdle and trunk, not just the joint adjacent to the local fracture site.

Scapular Fractures

Fractures of the scapula account for only 1% of all fractures, 3% of all shoulder injuries, and 5% of fractures involving the entire shoulder.[95–97] They typically occur as a result of a high-energy situation involving a fall or direct blow and often occur in conjunction with other traumatic injuries. With less severe fractures, the muscles effectively stabilize the fracture, and the patient typically can expect a good functional outcome. However, patients may present with associated injuries to the involved arm, shoulder girdle, and thoracic cage; ipsilateral rib fractures are the most common associated injury, occurring in approximately 27% to 50% of patients.[95] Pulmonary trauma (e.g., pneumothorax, hemothorax, or both) is reported in 16% to 40% of patients, and clavicular fractures and injuries to the brachial plexus and subclavian artery reportedly occur in 26% and 12% of patients, respectively.[95–98]

Scapular fractures are classified according to the location of the fracture, specifically the body, neck, glenoid fossa, acromion, spine, or coracoid. The distribution of the different fracture sites has been reported as 35% to 43% at the scapular body, 26% at the neck, 10% at the glenoid fossa, 8% to 12% at the acromion, 6% to 11% at the spine, and 5% to 7% at the coracoid.[95,98–100]

Clinical Evaluation of Scapular Fractures

Most patients with a scapular fracture have experienced a traumatic, well-defined mechanism of injury; therefore clinical evaluation usually is precluded by a thorough radiographic and neurological examination. Local physical findings, such as swelling, ecchymosis, and crepitus with ROM, are common, as are subjective complaints of pain in the scapular region. In most cases, a detailed assessment of the entire shoulder girdle and the cervical and thoracic spine should be performed (see Volume 1 of this series, *Orthopedic Physical Assessment*).

Treatment of Scapular Fractures

Nonoperative treatment is recommended for most scapular fractures, with the exception of those that occur at specific sites and/or according to certain classifications.[101,102] These include (1) acromion or scapular spine fractures with downward tilting of the lateral fragment and resultant subacromial narrowing (Figure 5-13), (2) coracoid fractures that extend into the glenoid fossa (Figure 5-14), and (3) glenoid rim and intra-articular glenoid fractures associated with persistent or recurrent glenohumeral instability (Figures 5-15 and 5-16). Relative indications for the surgical treatment of scapular fractures include displaced acromion or coracoid process fractures (>10 mm), displaced intra-articular glenoid fractures (>5 mm), and those associated with humeral subluxation.[101,103]

Nonsurgical treatment of scapular fractures consists of approximately 7 to 10 days of sling immobilization, followed by a progressing regimen of pendular and gentle passive ROM exercises as comfort and control allow. Once follow-up radiographic findings indicate sufficient healing, the patient is encouraged to discontinue immobilization and proceed with active-assisted and active ROM exercises. Consideration must always be given to restrengthening the muscles that attach to the scapula and those that arise from the scapula (i.e., the rotator cuff and biceps brachii), which may have been affected by disuse and painful inhibition. In a number of cases, patients with a scapular fracture develop stiffness in the adjacent spine, specifically the lower cervical spine to the midthoracic spine. Clinicians must take care to assess these regions and treat accordingly. Failure to address this important

part of the kinetic chain may lead to further problems in the shoulder region and most certainly will result in a less than optimal outcome. Most minor scapular fractures are sufficiently healed by 6 to 12 weeks and able to withstand the progressive load delivered through ROM and strengthening exercises at this time. Clinicians and patients must keep in mind that maximum functional recovery, which encompasses more than just bone healing, may take as long as 6 to 12 months.[104,105]

"Floating Shoulder"

The term *floating shoulder* was introduced by Herscovici[106] in 1992 to describe an ipsilateral fracture of the clavicular shaft and the scapular neck (Figure 5-17). The combination of these two types of fractures has a significant effect on the stabilizing role of the clavicle. Goss[107] defined *floating shoulder* as "a double disruption of the superior suspensory shoulder complex (SSSC)." He described three struts of this complex: (1) the AC joint–acromial strut, (2) the clavicular–coracoclavicular ligament–coracoid linkage, and (3) the three process–scapular body junction. A potentially unstable anatomical condition exists when the complex is disrupted in at least two places with significant displacement at either or both sites (Figure 5-18). This condition has a high risk of poor bone healing from delayed union or malunion of the clavicle, the scapular neck, or both.

Combined clavicular and ipsilateral scapular neck fractures are usually caused by a high-energy mechanism of injury, most commonly motor vehicle accidents (80% to 100%).[108] Other causes have been cited, such as a direct blow, fall onto the tip of the shoulder, or a FOOSH injury.[106,107] As with most scapular fractures, combined clavicular and ipsilateral scapular neck fractures have a high incidence of associated traumatic lesions, and when severe accompanying injuries are present, the clinical signs and symptoms of this specific fracture type often are overlooked. The definitive diagnosis therefore is made on the basis of radiographic findings.

Very little research to date has addressed the most effective way to treat a floating shoulder. Literature related

Figure 5-17 Radiograph showing right floating shoulder with scapular neck and ipsilateral midclavicular fractures. (From Hashiguchi H, Ito H: Clinical outcome of the treatment of floating shoulder by osteosynthesis for clavicular fracture alone, *J Shoulder Elbow Surg* 12(6):589-591, 2003.)

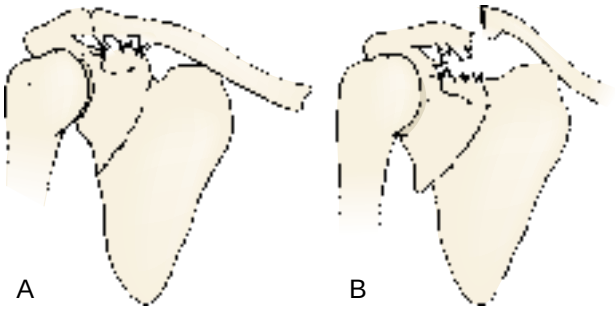

Figure 5-18 Fracture of the scapular neck. **A,** If the coracoclavicular and acromioclavicular ligaments are intact, there is little displacement of the glenoid (stable scapular neck fracture). **B,** Fracture of the scapular neck with disruption of the coracoclavicular and acromioclavicular ligaments creates a floating shoulder (unstable neck fracture). to this fracture type is limited to case reports and retrospective studies of small patient series.[106–108] Treatment options mentioned range from conservative management with or without early mobilization to operative treatment through open reduction and internal fixation of the clavicle only or of the clavicle and the scapular neck fracture sites together. Clearly, further research and clinical study are necessary to elucidate this interesting pathology. Any rehabilitation plan should be derived from a careful analysis of the anatomy involved and a thorough examination of the entire shoulder girdle and adjacent spine.

Clavicular Fractures

The most commonly reported fracture of the shoulder girdle is the clavicular fracture (Figure 5-19).[109,110] The incidence is highest among children and adolescents, in whom the mechanism of injury is either a direct blow from a fall onto the affected shoulder or an impact such as a tackle in football. In a direct blow, the compressive force causes buckling of the clavicle, which leads to a fracture once the compressive force exceeds the tensile strength of the clavicle. The clavicle can also sustain a direct impact that results in a fracture. Eighty-seven percent of clavicular fractures occur from falls onto the shoulder, whereas direct impact to the shoulder accounts for 7%. FOOSH injuries account for 6% of clavicle fractures.[40,110,111] In these instances the shoulder is driven downward, causing the clavicle to forcefully impinge on the underlying first rib, resulting in a fracture (Figure 5-20).

Although a fracture can occur anywhere along the clavicle, the most common site is reported to be between the medial two thirds and lateral one third of the bone (80%) followed by fractures in the distal one third (17%) and those that occur in the proximal one third (2%).[45,109,110,112] Fractures are classified according to their anatomical location: group I are in the midshaft (middle third) of

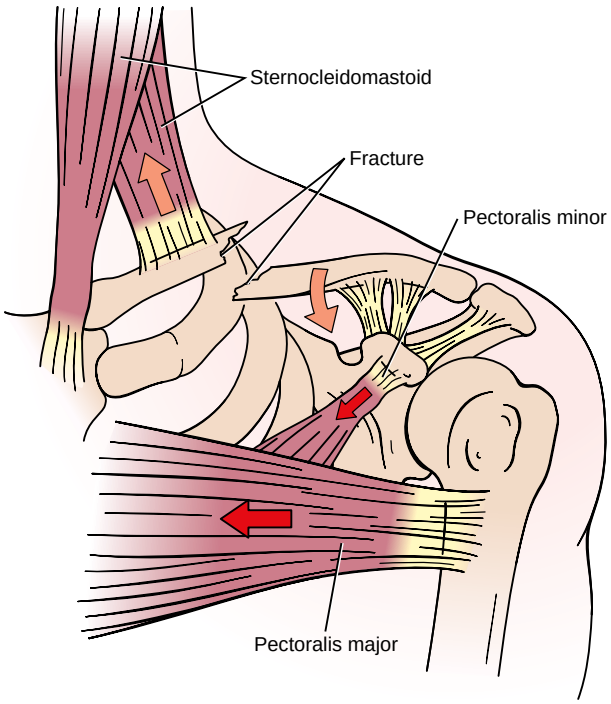

Figure 5-20 Clavicular fracture. With displacement, the proximal fragment is pulled superiorly by the sternocleidomastoid and the distal segment drops forward pulled down by pectoralis minor on coracoid process and pectoralis major on humerus.

TABLE **5-6**

Subclassification of Group II Clavicular Fractures

Type	Description
Type I	Fractures lateral to the coracoclavicular ligaments
Type II	Fractures medial to the coracoclavicular ligaments
Type III	Fractures extending into the acromioclavicular joint
Type IV	Fractures in which the proximal fragment is displaced out of its periosteal tube
Type V	Comminuted fractures in which coracoclavicular ligaments remain attached to an inferior bone fragment but are not attached to the proximal or distal fragment

From Craig EV: Fractures of the clavicle. In Rockwood CA, Matsen FA, editors: *The shoulder*, Philadelphia, 1998, WB Saunders.

the clavicle, group II are in the distal (lateral) third of the clavicle, and group III are in the medial (proximal) third of the clavicle. Craig[112] devised a five-part subclassification system of the group II clavicular fractures (Table 5-6).

Clinical Evaluation of Clavicular Fractures

Because of their superficial location, clavicular fractures are easily recognizable through inspection and direct palpation. Patients are able to recall a specific mechanism of injury, describing localized pain and possibly a cracking or popping sound or sensation. If the patient is seen directly following the injury, they may be holding the ipsilateral arm with the contralateral arm or it may be held in adduction at the side. Swelling, ecchymosis, and gross deformity may be visible with possible tenting of the skin. Tenderness to palpation and crepitus may be palpated over the fracture site. If the patient is able to move his or her arm, a grinding sensation may be felt or described.

The degree of deformity depends on the location of the fracture and the amount of displacement (see Figure 5-19, *A*). Associated injuries, although not common, may occur, including scapular fractures, scapulothoracic dissociation, rib fractures, pneumothorax, and neurovascular compromise (Figures 5-21 and 5-22). The brachial plexus is of particular concern because of its proximity to the clavicle, which makes it susceptible to injury.[111,112]

Treatment of Clavicular Fractures

The goal of treatment, relative to clavicular fractures, is to minimize the risk of nonunion and malunion. **Nonunion** is defined as the absence of clinical radiographic healing after 4 to 6 months, whereas **malunion** is associated with angulation, shortening, and poor cosmetic appearance. Generally it was believed that malunion did not affect functional capacity; however, studies have discovered that malunion may lead to weakness and fatigability.[113–116] Most

Figure 5-21 Fracture of the left clavicle and ribs with associated pneumothorax. Note the displaced midshaft clavicle fracture. (From Kim W, McKee MD: Management of acute clavicle fractures, *Orthop Clin North Am* 39(4): 491-505, 2008.)

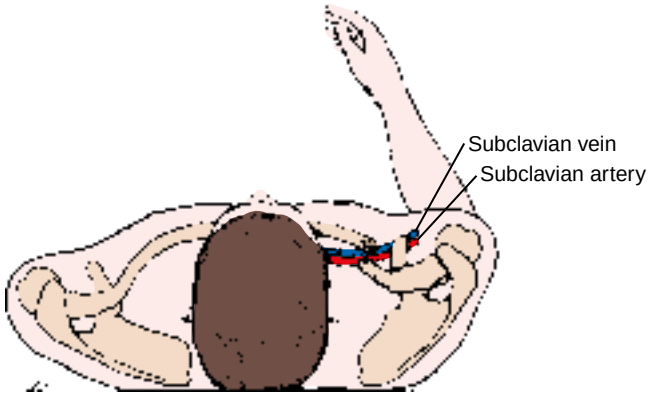

Figure 5-22 Potential injury to the subclavian vessels resulting from a fractured clavicle. (From Rockwood CA, Matsen FA, Wirth MA, et al, editors: *The shoulder,* ed 4, p 400, Philadelphia, 2009, Saunders.)

minimally displaced clavicular fractures do not require surgical intervention and can be treated conservatively with immobilization using either a sling or a figure-of-eight brace for approximately 4 to 6 weeks.[112,114–116] Both immobilizers appear to be effective; however, the sling is reported to provide more comfort with fewer complications, such as skin breakdown because the figure-of-eight brace must be kept in some degree of tension. In addition, the sling allows the patient to more easily perform light ROM exercises.

Clavicular fractures that require surgical consideration include open fractures, concomitant displaced scapular neck fractures that disrupt the superior shoulder suspensory complex, the presence of neurovascular or skin compromise, and a patient with multiple trauma who needs assistance with early mobilization.[116,117] Surgical treatment may be considered in some cases, for certain high-demand patients (such as heavy laborers or athletes), who are exposed to large, repetitive, potentially deforming forces, and individuals who have had a previous nonunion at the same site. However, careful patient selection and preoperative counseling are recommended because of the potential risks (e.g., implant infection, migration of intramedullary wires, neurovascular injuries) and sometimes less than optimal outcomes of the procedure.

Once bone healing is well established (**clinical union** occurs in 2 to 3 weeks), the patient can be guided through active-assisted and then active ROM exercises. Because most clavicular fractures do not involve the adjacent articulations, ROM is quite easily regained. Care must always be taken not to overload the healing fracture site with activities that produce too great a leverage point on this important fulcrum. Restrengthening exercises are prescribed for any muscles that were weakened as a result of painful inhibition and/or the immobilization period. As with any type of shoulder injury, the patient should be checked to ensure that the scapulohumeral rhythm is normal and symmetrical and that the essential stabilizing musculature of the glenohumeral joint is intact. Normal healing times vary slightly depending upon the site of the clavicular fracture but generally range between 6 and 9 weeks in young children and 8 and 12 weeks in adults.[109,111,112] It is important to ensure that both clinical and radiographic healing of the clavicular fracture are obtained before a patient's return to sport or heavy work. Factors to consider include the patient's age, sport or activity, location and severity of the fracture, extent and speed of healing, method of treatment (operative versus nonoperative), and any complications encountered during the recovery period.[114,116] Complications are possible following any fracture of the shoulder girdle, but the most serious consequences occur when neurovascular structures are compromised. Clinicians must be careful to continually assess for changes in sensation related to this and deal with this concern immediately. Less severe clavicular fracture complications include malunion (which results in a bony prominence but rarely a functional deficit), nonunion, and poor cosmesis.

Proximal Humeral Fractures

The proximal humerus is a common site of injury in the young and the elderly. In a skeletally immature athlete, the fracture frequently presents as a fracture at the proximal humeral growth plate or physis (*Little Leaguer's shoulder*); this type of injury most often is associated with young patients involved in throwing sports.[118–121] The injury is caused by a powerful medial rotation and adduction traction force on the proximal humeral epiphysis that occurs during the deceleration and follow-through phases of throwing or pitching. The rotational forces that occur during the arm-cocking and arm-acceleration phases can compound the problem. The result of these forces is a stress fracture, usually a Salter-Harris type I or type II. Radiologic signs, which may take up to 4 to 6 weeks to become evident, include widening of the growth plate, demineralization and rarefaction on the metaphyseal side of the physis, and metaphyseal bone separation.[119–121]

Radiographic Signs of Little Leaguer's Shoulder

- Widening of the epiphyseal plate
- Demineralization and rarefaction of the metaphyseal side of the physis
- Metaphyseal bone separation

The athlete typically complains of acute shoulder pain when attempting to throw hard. If these complaints are ignored, it can result in acute displacement of the weakened physis. Rest is the primary treatment, along with patient education regarding why absolute cessation from activity, at least initially, is essential. The bone may require up to 8 to 12 months to reossify and remodel.

Following a period of rest, rehabilitation should include activities to improve strength, coordination, proprioception, endurance, and ROM. The exact timing for beginning active exercises, as well as when and how much to progress these exercises, varies, depending on the stage of bone healing evident, the patient's tolerance of pain, and the condition of the surrounding soft tissue and adjacent joints. The most prudent decisions related to exercise prescription for these young patients is guided by the radiologic evidence and a thorough assessment and monitoring of the patient's clinical signs and symptoms. Clinicians must proceed cautiously, applying gentle stress to the area to encourage healing but never exceeding what the tissue can sustain.

In the elderly, proximal humeral fractures usually occur in patients with osteoporosis, and women are affected twice as often as men are. Predictions of incidence are estimated to triple during the next three decades as the population ages.[122] Most fractures are caused by minimal trauma, such as a FOOSH injury from a standing height or lower, or a direct blow to the lateral aspect of the shoulder (Figure 5-23).[123,124] Occasionally, they occur in association with a dislocation

Figure 5-23 **A,** Anteroposterior x-ray film of a two-part anterior fracture-dislocation with a displaced greater tuberosity fracture. **B,** After a closed reduction, the greater tuberosity fracture reduced and healed without further displacement. (From Rockwood CA, Green DP, Bucholz RW, Heckman JD: *Fractures in adults,* ed 4, p 1069, Philadelphia, 1996, Lippincott-Raven.)

or with excessive rotation of the arm, especially while in the abducted position.[58] In this situation, the humerus locks against the acromion in a pivotal position, resulting in a fracture.

Most proximal humeral fractures are nondisplaced or minimally displaced; these should be differentiated from the more serious displaced fractures, which are managed quite differently. The most commonly used classification system is the four-part fracture classification developed by Neer in 1970, in which he divided fractures into displaced and nondisplaced (Figure 5-24).[125,126] Displaced fractures, according to this classification, have more than 1 cm of displacement or more than 45° of angulation. Nondisplaced fractures may be called *one-part fractures,* regardless of how many fracture lines are seen. A *two-part fracture* involves displacement of the anatomical neck, surgical neck, lesser tuberosity, or greater tuberosity in relation to the remaining intact proximal humerus. Similarly *three-* and *four-part fractures* involve displacement of two or three fragments in relation to the main humeral fragment.

According to Neer's classification, the most commonly reported fracture of the proximal humerus is a displaced or nondisplaced (one-part or two-part) fracture involving the surgical neck (Figure 5-25). Researchers have investigated the clinical impact of greater tuberosity displacements less than 1 cm and found that the shoulder has very little tolerance for greater tuberosity displacement. Displacements of 5 mm to 1 cm were found to result in substantial dysfunction from either impingement or rotator cuff tearing.[122,126,127]

Clinical Presentation of Proximal Humeral Fractures

Because most proximal humeral fractures present acutely, common symptoms are pain, swelling, and tenderness about the shoulder, particularly in the region of the greater tuberosity. Crepitus may be evident with movement of the shoulder, but in most cases the patient is reluctant to initiate any active movement and holds the arm closely against the chest wall. The definitive diagnosis is made through radiographic evaluation.

A thorough assessment should be performed, including evaluation of the integrity of the bony tissue and careful examination of the neurovascular and musculotendinous structures intimately situated in this region. A fracture-dislocation or a fracture resulting from a high-energy trauma is much more likely to be associated with neurovascular injuries. The axillary nerve can be injured during a shoulder fracture–dislocation; in most patients the injury results in axonotmesis and a full recovery is expected. Of particular concern is the rotator cuff, which attaches to the different tuberosities of the humerus and consequently may have a deforming effect, depending on where the proximal humerus has been injured. For example, with a fracture of the greater tuberosity, the fracture fragment is pulled superiorly and posteriorly due to the muscle action of the supraspinatus, infraspinatus, and teres minor muscles. Conversely, in a fracture of the lesser tuberosity, the fragment is pulled anteriorly and medially by the subscapularis muscle (Figure 5-26).[127,128]

The deltoid and pectoralis major muscles must also be evaluated in patients with a proximal humeral fracture. Because the deltoid muscle attaches to the lateral shaft of the humerus, it can cause displacement of fractures of the proximal humeral shaft. Similarly, the pectoralis major muscle's insertion onto the lower portion of the bicipital groove can displace the proximal shaft of the humerus medially, as is typically seen in surgical neck fractures.

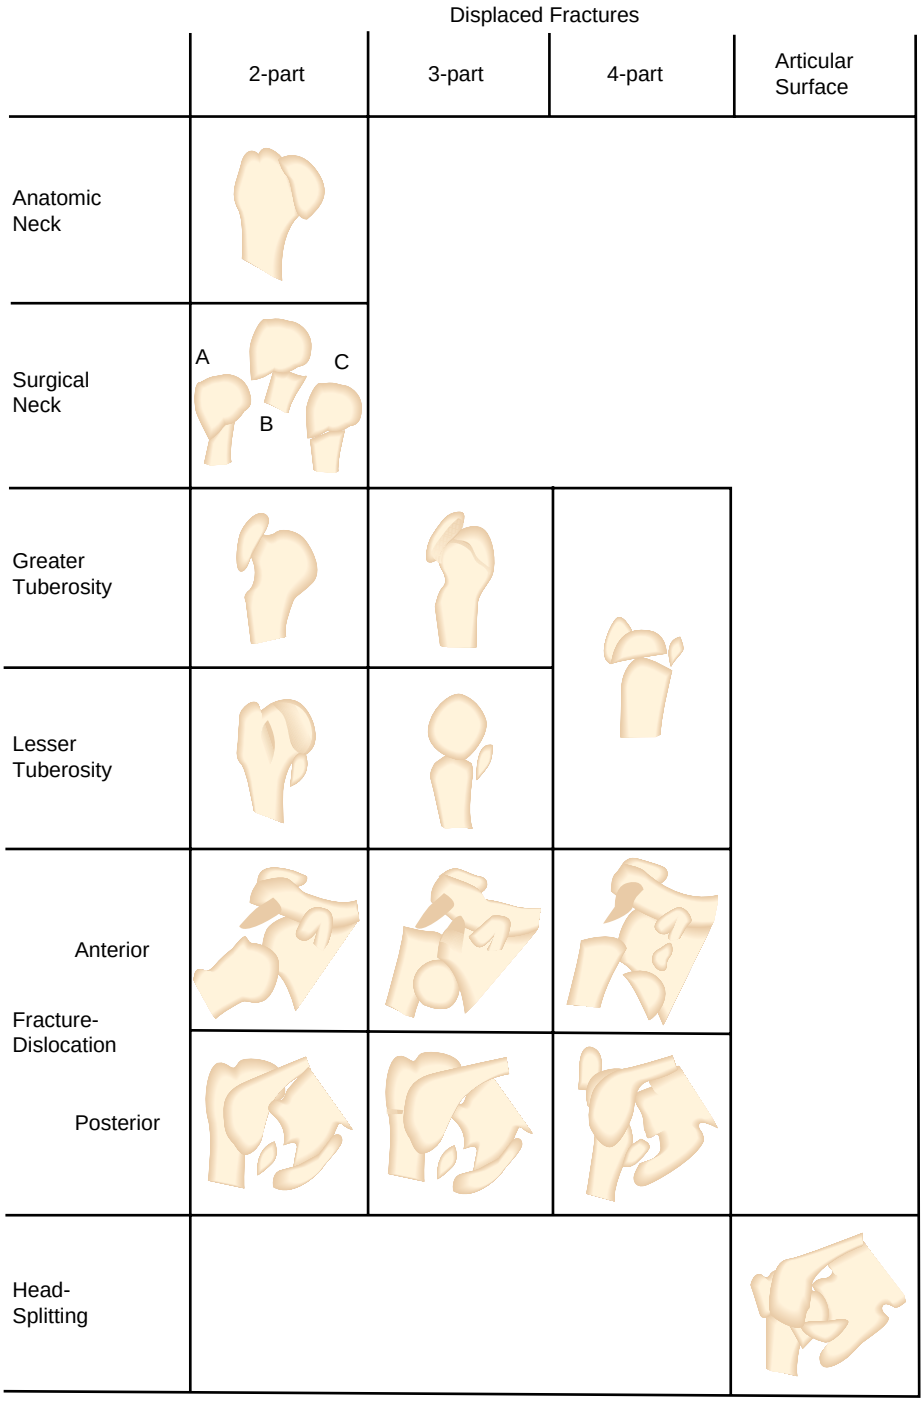

Figure 5-24 Neer four-segment classification of displaced proximal humeral fractures. A fragment is considered displaced when greater than 1 cm of displacement or 45 degrees of angulation is present. A fracture-dislocation is present if the articular segment is no longer in contact with the glenoid. (Redrawn from Neer CS: Displaced proximal humeral fractures. Part I. Classification and evaluation, *J Bone Joint Surg Am* 52:1077-1089, 1970.)

Treatment of Proximal Humeral Fractures

Most proximal humeral fractures are minimally displaced and are successfully treated without surgery.[121,127,129] If the fracture is classified as nondisplaced and is impacted or stable, an initial period of immobilization is indicated, using either a conventional sling or a collar and cuff sling that allows the weight of the arm to apply slight traction to the fracture. Early ROM exercises follow, at approximately 2 weeks after injury. If the fracture is classified as nondisplaced but is considered unstable, the immobilization period is more strictly adhered to with ROM exercises beginning after approximately 4 weeks when clinical union has occurred.

Diminished pain and an easing of the patient's apprehension are reasonable indicators for beginning gentle exercises. Obtaining intermittent radiographs before

Figure 5-25 Displaced fracture of the surgical neck. **A** and **B,** Anteroposterior and lateral x-ray films of a displaced surgical neck fracture. The fracture was treated for 3 weeks as an undisplaced fracture on the basis of an anteroposterior x-ray film only **(A)**. The follow-up lateral x-ray film **(B)** in the scapular plane revealed a significant anterior shaft displacement. **C** and **D**, Anteroposterior and lateral x-ray films after open reduction and internal fixation with two figure-of-eight wires. (From Rockwood CA, Matsen FA, editors: *The shoulder,* p 353, Philadelphia, 1998, WB Saunders.)

beginning rehabilitation is important to establish the fracture is clinically stable and the bone moves as a unit. Rehabilitation programs should follow general shoulder treatment principles of patient education, mobility of the entire shoulder girdle and relevant kinetic chain segments, optimal neuromuscular strength, and return to functional activities. Bertoft et al.[129] reported that the greatest amount of improvement in ROM occurs between 3 and 8 weeks after injury.

Management of the young athlete with an epiphyseal fracture of his or her proximal humeral growth plate is nonoperative with a 3-month period of rest followed by a program of shoulder ROM exercises, scapular and rotator cuff strength, and endurance exercise and functional exercises incorporating the entire kinetic chain. A progressive throwing program and subsequent return to play are considered when the athlete demonstrates resolution of symptoms as well as optimal shoulder ROM and neuromuscular control.

Complications following nonoperative management of a proximal humeral fracture are primarily related to shoulder stiffness and limited motion or to the consequences of displacement of the greater tuberosity. Early initiation of passive and active-assisted ROM exercises compared with delaying exercises until 3 weeks post injury results in less pain and faster recovery in people with stable fractures.[130] Additional complications that may affect outcomes in patients with proximal humeral fractures are those related to associated soft tissue damage (e.g., rotator cuff) and neurovascular injury. Clinicians must be diligent in evaluating for and treating any associated injuries that may have been injured, along with

Figure 5-26 Greater tuberosity malunion resulting from unopposed pull of the supraspinatus and infraspinatus muscles. (From Antuña SA, Sperling JW, Sánchez-Sotelo J, et al: Shoulder arthroplasty for proximal humeral malunions: long-term results, *J Shoulder Elbow Surg* 11(2):122-129, 2002.)

the humerus, in the original trauma or at the very least may have been strained or traumatized as a result of the fracture.

Surgical indications for a fracture of the proximal humerus are not straightforward. Humeral head vascularity, fracture pattern, bone quality, and overall geometry are important considerations in determining appropriate treatment. Osteoporosis influences the degree of comminution, magnitude of cancellous defects secondary to impaction, and likelihood of fixation failure or loss of reduction.[131] Surgery is reserved primarily for fractures that are significantly displaced; it involves mainly closed reduction with or without percutaneous pinning or open reduction and internal fixation.[131,132] An osteoporotic fracture is often more appropriately treated with arthroplasty than with reduction and internal fixation. Treatment of proximal humeral fractures with surgery is considered difficult, not only because of the complex anatomy of the shoulder girdle but also because of the difficulty achieving and maintaining anatomical reduction and stable fixation. Rehabilitation following these types of surgical procedures is rigorous and involved, and practitioners should ensure patients are well informed and educated about the procedure and are suited to handle the important postoperative period. In some cases, because of the co-morbidity status and the patient's age, nonsurgical treatment is the most appropriate choice despite substantial fracture displacement.

ROTATOR CUFF INJURIES

Injuries affecting the rotator cuff comprise the largest proportion of all injuries reported at the shoulder.[133–136] They range from minor tendon or muscle injuries to full-thickness tears and have been reported to cause disability in individuals that has been compared with health issues such as congestive heart failure, diabetes, myocardial infarction, and depression.[137] More information on rotator cuff injuries and their management can be found in Chapter 7.

BICEPS TENDON AND SUPERIOR LABRAL LESIONS

The long head of biceps is a tendinous tissue, susceptible to trauma and injury by the nature of its anatomical site and its role in shoulder mechanics. Some debate exists regarding the etiology of biceps injuries, namely, whether they have a primary cause directly associated with the biceps tendon complex or whether they occur secondary to dysfunction elsewhere in the shoulder girdle. Some authors suggest that greater than 90% of patients with a diagnosis of biceps tendonitis actually have a primary diagnosis of impingement syndrome or scapular instability that is causing secondary involvement of the biceps tendon.[138,139] Studies based on the results of magnetic resonance imaging and arthroscopic procedures have shed new light on the pathophysiology of the long head of the biceps tendon.[138–142]

One of the most significant contributions to understanding biceps injuries has come as a result of studies that have investigated the superior glenoid labrum. Andrews et al.[143] in 1985 described tears in the superior labrum of the glenohumeral joint noting the placement of these tears at the attachment of the biceps tendon (Figure 5-27). In 1990, Snyder et al.[144] first described the superolabral anterior to posterior (SLAP) lesion, a lesion of the superior labrum and adjoining biceps anchor. They categorized SLAP lesions into four types. Type I lesions show degenerative fraying with no detachment of the biceps insertion; type II lesions show detachment of the biceps insertion; type III lesions show a bucket handle tear of the superior aspect of the labrum with an intact biceps tendon insertion to bone; and type IV lesions show an intrasubstance tear of the biceps tendon with a bucket handle tear of the superior aspect of the labrum.

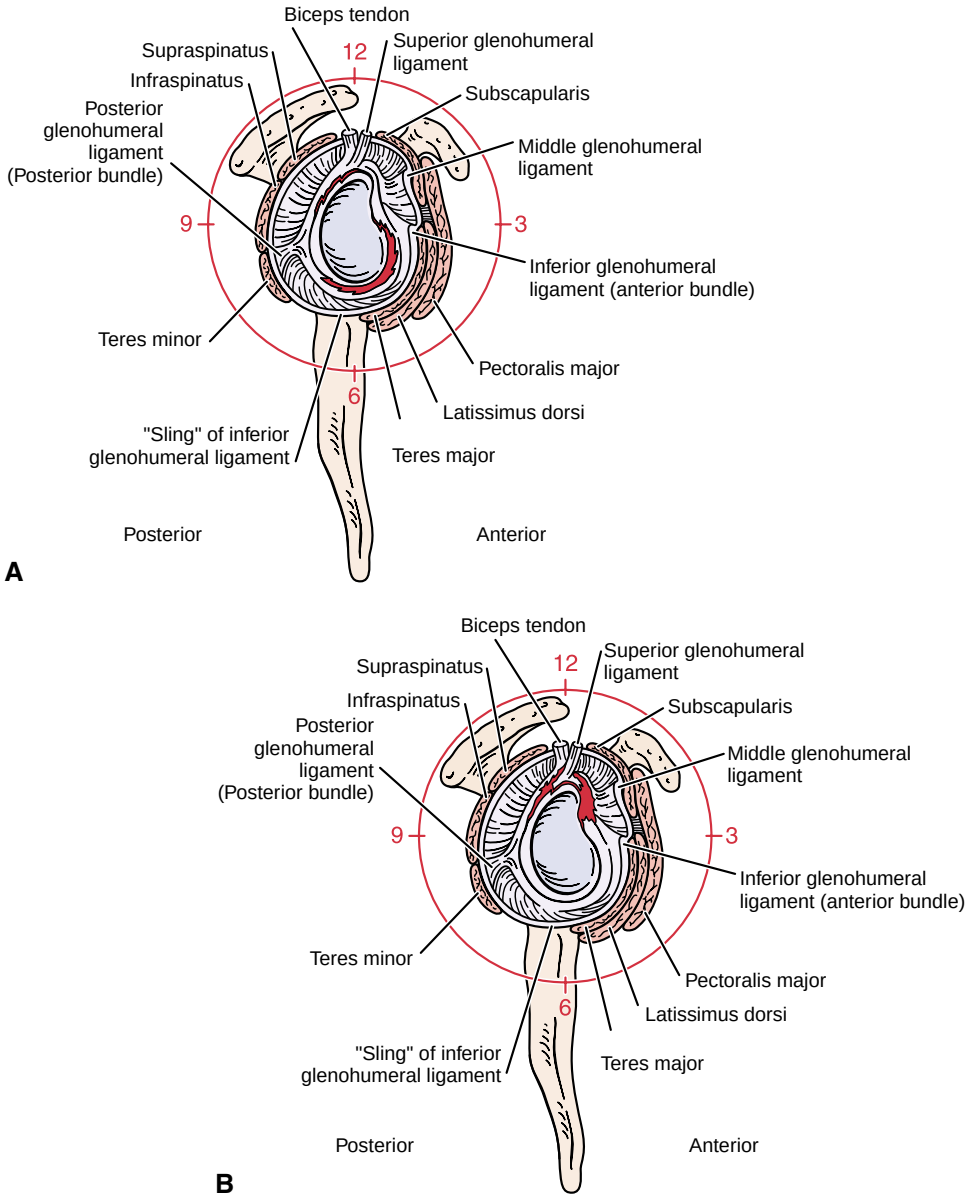

Figure 5-27 Labral lesions of the right shoulder. **A,** Bankart lesion. **B,** SLAP lesion. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 320, Philadelphia, 2014, WB Saunders.)

Morgan[145] further divided type II SLAP lesions into three subtypes, depending on whether the detachment of the labrum involved the anterior aspect of the labrum alone, the posterior aspect, or both.

In their three-part series, *"The Disabled Throwing Shoulder,"* Burkhart et al.[5,14,146] described the type II SLAP lesion (i.e., involving detachment of the biceps tendon) as the most common pathological entity associated with a "dead arm" syndrome, which they defined as any pathological shoulder condition that deems an athlete unable to throw due to pain and subjective unease in the shoulder. In an arthroscopic study done earlier, these same authors observed what they called a dynamic "peel-back phenomenon" in throwers with posterior and combined anteroposterior SLAP lesions.[147] They found that with the arm in the cocked position of abduction and lateral rotation the peel-back occurred as a result of the effect of the biceps tendon as its vector shifted to a more posterior position in late cocking. The change in angle and the twist of the biceps tendon produced a torsional force to the posterosuperior labrum, causing detachment if the superior labrum was not well anchored to the glenoid. These findings suggested a mechanism of injury for SLAP lesions in throwers that was different from the mechanism postulated earlier by Andrews et al.[143] These researchers had described a *deceleration* mechanism of labral injuries in throwers, which occurred as the biceps contracted to slow the rapidly extending elbow in the follow-through phase. They believed that this created a high tensile load in the biceps that acted

to pull the biceps and superior labrum complex from the bone. Burkhart et al.[146] essentially described the opposite, an *acceleration* mechanism of injury; specifically, in late cocking, as the arm began to accelerate forward from an abducted and laterally rotated position, the long head of the biceps and the superior labrum were peeled back rather than pulled from the bone.

Also of interest in studies of type II SLAP lesions are the clinical factors associated with the primary pathology. Burkhart et al.[146] called these factors the "ultimate culprits" in dead arm syndrome: (1) a tight posteroinferior capsule, which causes a GIRD and a shift in the glenohumeral rotation point, (2) the peel-back mechanism produced by the biceps tendon, which leads to a SLAP lesion, (3) hyperexternal (lateral) rotation of the humerus, and (4) scapular protraction. Of the throwers with SLAP lesions whom they examined, 31% were also found to have rotator cuff tears (38% were full-thickness tears, and 62% were partial-thickness tears).

As can be seen, the biceps tendon plays an important role in the overall anatomy and function of the shoulder joint. Most importantly it has a strong relationship to its adjacent tissue, namely the glenoid, glenoid labrum, and rotator cuff. Injury to any one of these structures undoubtedly affects the integrity of the biceps tendon and the well-being of the entire shoulder girdle.

Etiology of Biceps Lesions

Two main etiologic categories have been proposed relative to biceps lesions.[148–151] One includes young patients with anomalies of the bicipital groove in whom repetitive trauma is the most important causal factor; the other includes patients in an older age group, where associated degenerative changes in the tendon tend to be the predominant causal factor. In most cases, the cause of biceps pathology is multifactorial and is related, in some manner, to the anatomical location of the tendon. As mentioned, the potential for impingement of the biceps tendon under the coracoacromial arch is great, especially if dysfunction of the rotator cuff and/or scapular misalignment are present. The blood supply of the biceps has been shown to be diminished in the long tendon region, with a "critical zone" similar to that seen in the supraspinatus tendon.[152] In abduction, a zone of avascularity exists in the intracapsular portion of the biceps tendon, which is felt to be caused by pressure from the head of the humerus, a phenomenon referred to as *wringing-out*. Considering these positions, it is easy to see why patients involved in overhead lifting and throwing are more susceptible to ruptures, elongations, and dislocations of the biceps tendon. The past several years have produced a proliferation of information about the superior labrum and its relationship to the biceps tendon.[138,140,142–146] As noted earlier, Andrews et al.[143] and Snyder et al.[144] originally described lesions of the biceps and superior labrum, known as *SLAP lesions*. Two cited causes of SLAP lesions are (1) a FOOSH, which drives the humeral head up onto the labrum and the biceps tendon, and (2) excessive and forceful contraction of the biceps in throwing athletes (e.g., baseball and football players).

Relevant Anatomy

The long head of the biceps tendon originates from the superior glenoid labrum and the supraglenoid tubercle and travels obliquely within the shoulder joint, turning sharply inferiorly to exit the joint underneath the transverse humeral ligament within the bicipital groove. Interestingly, the biceps tendon does not slide in the groove; rather, the humerus moves on a fixed, passive biceps tendon during shoulder motions. The groove can move along the tendon as much as 4 cm (1.5 inches). The origin of the biceps tendon reportedly varies, not only in the type of insertion (single, bifurcated, or trifurcated) but also in the specific anatomical location where it inserts.[148,153,154] Vangsness et al.[148] dissected 105 cadaveric shoulders to study the biceps tendon origin and its relationship to the labrum and the supratubercular groove. They classified their findings into four insertion types. Type I insertions occurred in 22% of the subjects and showed a labral attachment that was entirely posterior with no contribution to the anterior labrum. In type II insertions the labral contribution was primarily posterior with a small anterior band present. Type III insertions had equal contributions to the anterior and posterior labrum and were found in 37% of the cadavers. Type IV insertions occurred in 8% of the cadavers and consisted mainly of an anterior labral attachment. A different study[138] noted the biceps tendon originating from the supraglenoid tubercle 20% to 30% of the time, from the posterosuperior portion of the glenoid labrum 48% to 70% of the time, and from both the supraglenoid tubercle and the glenoid labrum 25% to 28% of the time. It is clear to see from these studies why the biceps tendon and superior labrum are commonly injured together.

The biceps tendon is surrounded by a synovial sheath, which ends at the distal end of the bicipital groove, making the tendon an intra-articular but extrasynovial structure. As the long head of the biceps tendon moves from its origin on the superior glenoid labrum and supraglenoid tubercle to its muscle insertion, it is stabilized in position by the supraspinatus and subscapularis tendons and the capsuloligamentous tissues. The triangular-shaped area between the supraspinatus and the subscapularis tendons is referred to as the *rotator interval*. It contains the coracohumeral and the superior glenohumeral ligaments and has on its medial side the coracoid process. Histoanatomical studies have found that both the superior glenohumeral ligament and the coracohumeral ligament are important structures in the stabilization

of the biceps tendon in its groove, and lesions associated with any of the components of the rotator interval leave the biceps tendon and the rotator cuff vulnerable to injury.[141,152,155]

Function of the Biceps

The biceps extends from the scapula to the forearm and as a result plays an important role in function of the shoulder and elbow. Basmajian and Latif[150] characterized the action of biceps as flexion of the elbow when the forearm is in the neutral or supinated position. The muscle is also described as having an important role in decelerating the rapidly moving arm during activities such as forceful overhand throwing. The exact function of the biceps at the shoulder is not well understood. Most references regard it as a weak flexor,[140,153,155] but its proposed role as a humeral head depressor remains controversial.[152,154,155] One study, which used simulated muscle forces on a biomechanical cadaver model, showed that the biceps tendon force restrained superior humeral translation. A key factor in this study was that this occurred in the presence of a large rotator cuff tear.[141] A similar study demonstrated that the biceps assisted glenohumeral anterior stability through increased resistance to torsional forces. Other studies have disputed biceps role as a shoulder stabilizer, finding only a small amount of muscle activity during shoulder motion.[140,155–157] Despite the debate, the relationship between the long head of biceps and the function and stability of the glenohumeral joint is an important clinical feature, which must always be considered in the management of patients with a shoulder dysfunction.

Classification of Biceps Lesions

Historically, lesions involving the biceps tendon have been categorized as being either a *tendonitis* or *instability*. Tendonitis can be further divided into *primary tendonitis,* which occurs as a result of pathology of the tendon sheath, or *secondary tendonitis,* which occurs secondary to an underlying injury that causes subsequent biceps irritation and injury. Many believe that the pathology seen in the biceps is directly related to its intimate relationship with the rotator cuff because they both pass under the coracoacromial arch and are therefore susceptible to impingement. "Isolated" ruptures of the long head of the biceps tendon are reportedly uncommon. Neer believed that most ruptures of the long head of the biceps tendon were associated with supraspinatus tears.[158,159] One study documented isolated biceps tendon ruptures in as many as 25% of patients,[145] but this incidence has not been reproduced in subsequent studies.

Slatis and Aalto[160] developed a three-part classification for biceps lesions. A type A lesion is referred to as *impingement tendonitis* because it occurs secondary to an impingement syndrome and rotator cuff disease. The defective cuff exposes the biceps to a rigid coracoacromial arch, resulting in tendonitis. This is the most common cause of biceps tendonitis. Type B lesions describe a *subluxation of the biceps tendon*. All subluxations and dislocations of the biceps tendon are included in this category. Lesions of the coracohumeral ligament allow the biceps tendon gradually to displace medially; the slipping of the tendon into and out of its groove leads to inflammation and fraying. A type C lesion is called *attrition tendonitis.* These are primary lesions of the biceps tendon that occur inside the canal, resulting in inflammation and eventual degeneration of the biceps tendon. Often spurring and fraying are evident with this type of tendonitis.

Biceps lesions have also been classified according to their anatomical location, specifically, at their origin, in the rotator interval, or in association with rotator cuff tears.[138] As noted earlier, the third category has spurred considerable study regarding the intimate relationship between the rotator cuff and the biceps tendon complex.

Clinical Presentation of Biceps Lesions

Patients with biceps tendon injuries typically present with pain in the proximal anterior area of the shoulder directly over the biceps tendon, with occasional radiation of pain down into the muscle belly. Similar to rotator cuff impingement syndromes, the pain can also be described at the deltoid insertion. It is unusual for biceps-related pain to radiate into the neck or distally beyond the elbow joint. Night pain is sometimes reported with biceps lesions. However, this likely can be explained by overall problems associated with trying to sleep with a painful shoulder. Most shoulder conditions are worse at night for a number of reasons. A compressive load may be present (e.g., lying on the affected shoulder) or in some instances traction may be applied to the shoulder (e.g., arm hanging over the bed); either of these results in pain. Positioning to avoid pain is difficult; however, most patients find that, with the use of many pillows, lying on the contralateral side with the affected arm in neutral, resting on the pillows, is among the most comfortable positions. Many patients with a painful shoulder report that their best rest is achieved in a semireclined position, such as in a recliner, with the arm resting on a pillow in the shoulder resting position.

Patients with a biceps injury usually describe an insidious onset of their symptoms; however, the pattern of pain can be linked to repetitive types of activities. Acute trauma may be part of the original injury that predisposed the biceps tendon to subsequent rupture or dislocation. Patients with bicipital tendonitis tend to be young or middle aged, with a pain pattern that is less at rest and more intense with activity. This is especially true with overhead activities in daily living, work, and/or sports. Rotation of the humerus at or above the horizontal level brings the tuberosities, bicipital groove, biceps tendon, and rotator cuff in direct contact with the anterior acromion and the coracoacromial ligament. Biceps instability is most commonly

associated with the throwing athlete, where in certain positions of overhead rotation, the motion is accompanied by a palpable snap and pain. Pain is felt locally at the anterior aspect of the shoulder and is aggravated by elevating the arm to around 90°. If the biceps tendon ruptures, there is associated acute pain and sometimes an audible pop in the shoulder, followed in a few days by a notable change in the contour of the arm, with ecchymosis that often tracks downward to the distal muscle belly.

Numerous special tests have been described that can assist in the diagnosis of biceps conditions; however, their findings should be interpreted in combination with other clinical tests because the sensitivity and specificity of these tests have been reported to be only moderate (see Volume 1 of this series, *Orthopedic Physical Assessment,* Chapter 5). Most biceps lesions present with tenderness on palpation in the bicipital groove, which often disappears as the lesser tuberosity and groove rotate medially under the short head of the biceps and coracoid process. This is different from the tenderness noted with subdeltoid bursitis and impingement syndromes, which has a more diffuse pattern that does not change with arm rotation. According to Burkhead et al.,[153] this "tenderness in motion" sign is among the most specific for differentiating biceps lesions. ROM may be slightly restricted and painful into full abduction and medial and lateral rotation, usually as a result of pain rather than capsular constriction. Resisted isometric testing reveals a painful weakness with forward flexion of the shoulder.

Treatment of Biceps Injuries

As is almost universally true of all injuries, the most effective form of treatment of a biceps injury is prevention. As noted, the biceps is often part of the domino effect that occurs as a result of other primary shoulder pathologies. Therefore prevention of injury and overuse in these regions of the shoulder (e.g., rotator cuff) conceivably could prevent injuries to the biceps tendon. Individuals involved in manual labor with either repetitive overhead work or heavy lifting, as well as individuals participating in sports that demand overhand motions, are particularly at risk for biceps injury and should be educated on how to monitor and prevent injuries in this region. Developing a balanced shoulder musculature that includes a strong, healthy rotator cuff and scapular muscle region can help prevent the vicious cycle of impingement tendonitis, irritation, and muscle weakness that leads to altered kinematics, instability, and further impingement of tissue, such as the long head of the biceps.

Once the biceps tendon has been injured, the first step in proper management is a thorough examination of the anterior shoulder, structures of the shoulder girdle, and, if appropriate, kinetic chain. Failure either to identify associated lesions (e.g., those affecting the glenoid labrum and rotator cuff) or to note contributing factors (e.g., poorly stabilized scapula, hypomobile cervical and/or thoracic spine, or altered muscle recruitment patterning) may lead the clinician to direct the sole treatment to the affected biceps tendon rather than addressing the true cause of the shoulder injury. Depending on the specific nature and severity of the biceps injury, treatment can range from managing an early, acute inflammatory situation locally at the tendon to treating the biceps tendon by retraining the scapular stabilizing muscles and rotator cuff to properly position the glenohumeral joint and therefore reduce impingement on the long head of the biceps anteriorly. Whichever is the case, the message is always the same: the clinician must make sure that treatment encompasses not only the affected tissue but also the causal tissue.

NERVE INJURIES OF THE SHOULDER

Nerve injuries of the shoulder represent a relatively small percentage of overall problems reported.[43,161–165] They are most commonly caused by direct trauma but also may occur as a result of repetitive microtrauma. In some instances, nerve injuries affecting the shoulder occur secondary to the predominant injury (e.g., axillary nerve damage from an anterior glenohumeral dislocation) or they may be the consequence of an underlying shoulder condition (e.g., poor posture and/or scapular instability that leads to thoracic outlet syndrome). Nerve injuries affecting the shoulder are being recognized with increasing frequency in sports, such as football and rugby, that comprise higher risk of injury from direct contact.[162–164,166] Nerve injuries as a result of compression and/or stretching from muscle hypertrophy have been reported in weight lifters, body builders, and/or volleyball players as well as individuals who perform repetitive motions in their occupations, such as computer analysts and assembly line workers.[161,163]

It is important to note that a fair number of neurological-like symptoms that patients experience may originate from sites well beyond the actual shoulder. These could include the spinal cord, cervical disc, cervical or thoracic nerve roots, nerve branches, and peripheral nerves, as well as unsuspected sites (e.g., the pleural or abdominal cavity) that can refer pain to the shoulder. Patients with nerve injuries often describe inconsistent, vague symptoms that may involve some combination of pain, paresthesia, or motor weakness in the limb; however, this is highly variable and depends on the patient's particular injury and the component of the nerve affected.[161,163,165] To make a diagnosis, the clinician must recognize the muscles innervated, sensory distribution, muscle stretch reflex, and compressive sites associated with a particular nerve. Commonly affected nerves in the shoulder region include the dorsal scapular, long thoracic, suprascapular, axillary, and musculocutaneous nerves. Table 5-7 presents the clinical features associated with injury to these nerves. Conservative management of most nerve injuries includes avoidance of precipitating factors to allow

TABLE 5-7

Clinical Findings of Nerve Injuries About the Shoulder

Nerve	Injury Site	Motor Findings	Sensory Findings	Other Findings
Dorsal scapular nerve	Within scalenus medius muscle	Weakness in pressing the elbow backwards against resistance while hand is on hip or in pushing the palm backward against resistance with arm folded behind the back	None	Scapular winging with lateral displacement; shoulder pain
Long thoracic nerve	Supraclavicular region	Weakness in raising arm above the head	None	Scapular winging when patient pushes arm against the wall while elbow is extended
Suprascapular nerve	Suprascapular notch Spinoglenoid notch	Weakness in both abduction and lateral (external) rotation of arm Weakness of only lateral (external) rotation of arm	None	Deep scapular pain
Axillary nerve	Lateral aspect of the humerus and quadrilateral space	Weakness of abduction of shoulder between 15° and 90°	Lateral shoulder	Deltoid atrophy
Musculocutaneous nerve	At the level of the coracobrachialis	Elbow flexor and forearm supination weakness	Lateral forearm	Proximal forearm pain aggravated by elbow extension; reduced biceps reflex

recovery, physical therapy, and anti-inflammatory medications. Most injuries resolve spontaneously within 6 to 24 months.[161–165] For nerve injuries that have failed conservative treatment, surgical techniques involving various combinations of fascial graft or transfer of adjacent muscles may be effective.[167] A more detailed description of nervous tissue and the pathology of nerve injuries about the shoulder can be found in Chapter 25 and in Volume 2 of this series, *Scientific Foundations and Principles of Practice in Musculoskeletal Rehabilitation*, Chapter 8.

CHAPTER 6

Shoulder Instability

RONALD R. MATTISON, MARTIN J. BOULIANE, DAVID J. MAGEE*

INTRODUCTION

The impression gained from a cursory glance at the shoulder belies its complexity. This proximal part of the upper kinetic chain starts at the trunk and includes the scapula, glenohumeral joint, acromioclavicular joint, and sternoclavicular joint.[1] As part of the kinetic chain, the shoulder acts as a funnel, transferring the forces generated by the lower extremity and trunk to the arm.[2–5] The human shoulder has evolved to allow an incredible range of motion (ROM) for reaching and placing the human hand through a large functional arc, largely at the expense of bony stability. Elevation, depression, protraction, retraction, and rotation of the scapula, along with elevation and rotation of the clavicle, enhance or facilitate the motions of forward flexion, extension, abduction, adduction, medial and lateral rotation, and circumduction of the glenohumeral joint, which allow the arm and hand to be placed in many positions. Unfortunately, every anatomical adaptation toward mobility creates the potential for problems, which can be compounded by the large ROMs needed, frequent repetitions, and high stress loads seen in sports and occupations involving the upper limbs.

It is imperative that clinicians consider the whole kinetic chain as well as the shoulder girdle, rather than any one articulation when assessing the shoulder. With less bony support than other articulations, the shoulder girdle must be supplemented by strong ligaments and careful arrangement of all muscle groups to ensure stability.[7,8] With such a large ROM available at the shoulder, glenohumeral stabilization comes from the osseous anatomy, specifically the "pear-shaped" glenoid (Figure 6-1), as well as joint compression. This "concavity" compression is the result of precise sequencing of all the shoulder muscle groups involved along with the labrum, glenohumeral ligaments, and joint capsule.[9–12]

FUNCTIONAL ANATOMY

Although bony containment is lacking in the scapulohumeral articulation, the articular surfaces are positioned to contribute to stability, especially with the arm in elevated positions. For example, the scapula faces 30° anteriorly to the chest wall and is tilted upward 3° to augment functional reaching motions above shoulder height.[3,13,14] The "pear-shaped" glenoid is almost a perfect circle, being much wider in the lower half than in the superior half. It is also tilted upward 5° to help to control inferior instability and to further augment movements above shoulder height (see Figure 6-1).[15]

At the glenohumeral joint, a large humeral head articulates with the shallow glenoid cavity, which is deepened by the glenoid labrum. The surface area of the humeral head is significantly larger than the glenoid.[13,16,17] However, the articular surfaces of the humeral head and glenoid are functionally congruent, having radii within 3 mm. During movement, the area in contact between the two surfaces constantly changes, with the greatest contact in mid-elevation rather than at the extremes of glenohumeral motion, where the potential for instability is greatest.[18] Only approximately 25% to 30% of the large, spherical humeral head is in contact with the glenoid surface at any one time.[13,19] Stability in the glenohumeral joint is achieved through several factors: the bony glenoid, labrum, glenohumeral ligaments, rotator cuff, negative pressure within the joint capsule, and coefficient of friction of the synovial fluid.

During 180° of elevation of the arm, there is 120° of glenohumeral motion, along with 60° of scapulothoracic motion. This large ROM (i.e., scapulohumeral rhythm) is brought about by precise muscle sequencing, and the resultant force couples generate rotary torques on the scapula and humerus, creating complex arm movement patterns. The term *force couple* refers to muscles working together by applying different forces to create a common motion—some act concentrically to initiate and provide movement or control movement and others act isometrically, concentrically, or eccentrically to control or decelerate movement (Figure 6-2).[20] For example, abduction by the deltoid, which is part of a force couple, is counterbalanced by the supraspinatus, infraspinatus, and subscapularis, the other part of the force couple, to allow abduction by compressing the humeral head in the glenoid and preventing its

*The authors, editors, and publisher wish to acknowledge David C. Reid for his contributions on this topic in the previous edition.

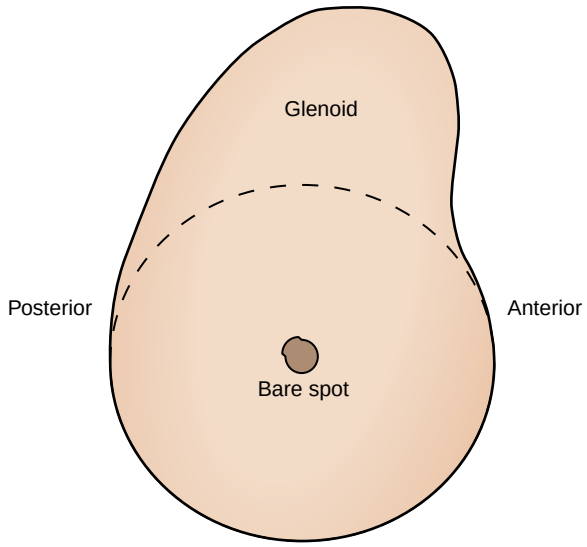

Figure 6-1 "Pear shape" of the right glenoid. (Redrawn from Lo IKY, Parten PM, Burkhart SS: The inverted pear glenoid: an indicator of significant glenoid bone loss, *Arthroscopy* 20(2):171, 2004.)

elevation under the acromion (see Figure 6-2, *A*). Similarly the serratus anterior is counterbalanced by the three parts of trapezius, levator scapulae, and rhomboids to control the scapula (see Figure 6-2, *B*).

Any structural injury, scapular dyskinesia (i.e., abnormal positions or patterns of movement of the scapula), or dysplasia (i.e., abnormal development) of the humerus or the glenoid or its labrum can affect the stability of the glenohumeral joint.[21] Normally, translation of the humeral head on the glenoid is limited to a few millimeters in every direction during movement.[20,22–24] If the dynamic structures controlling this translation (i.e., primarily the rotator cuff) or the passive structures (e.g., the labrum or ligaments) are injured, this translation increases. The increased translation leads to increased stress on the glenoid labrum, failure of the static restraints (i.e., ligaments) (see Table 5-1), and eccentric overload of the dynamic restraints (i.e., rotator cuff and biceps), which work individually and in unison to provide stability in the joints of the shoulder, where mobility is paramount. The result is instability, impingement because of the translation and/or abnormal movement, or both.[25,26]

Any alteration in biomechanics or trauma may lead to a tear in the glenoid labrum. The glenoid labrum increases the glenoid depth approximately twofold, which contributes to glenohumeral stability.[13,16,17,19] However, labral anatomy can be quite variable, even being deficient in certain locations. Such variations often occur in the anterosuperior location and are referred to as a sublabral foramen or **Buford complex**.[27–29] A **Bankart lesion** is a traumatic labral tear that usually occurs with an anterior dislocation. However, the labrum can tear anywhere along its attachment on the glenoid. A Bankart lesion can also be a bony lesion. This typically occurs in the anteroinferior quadrant of the glenoid

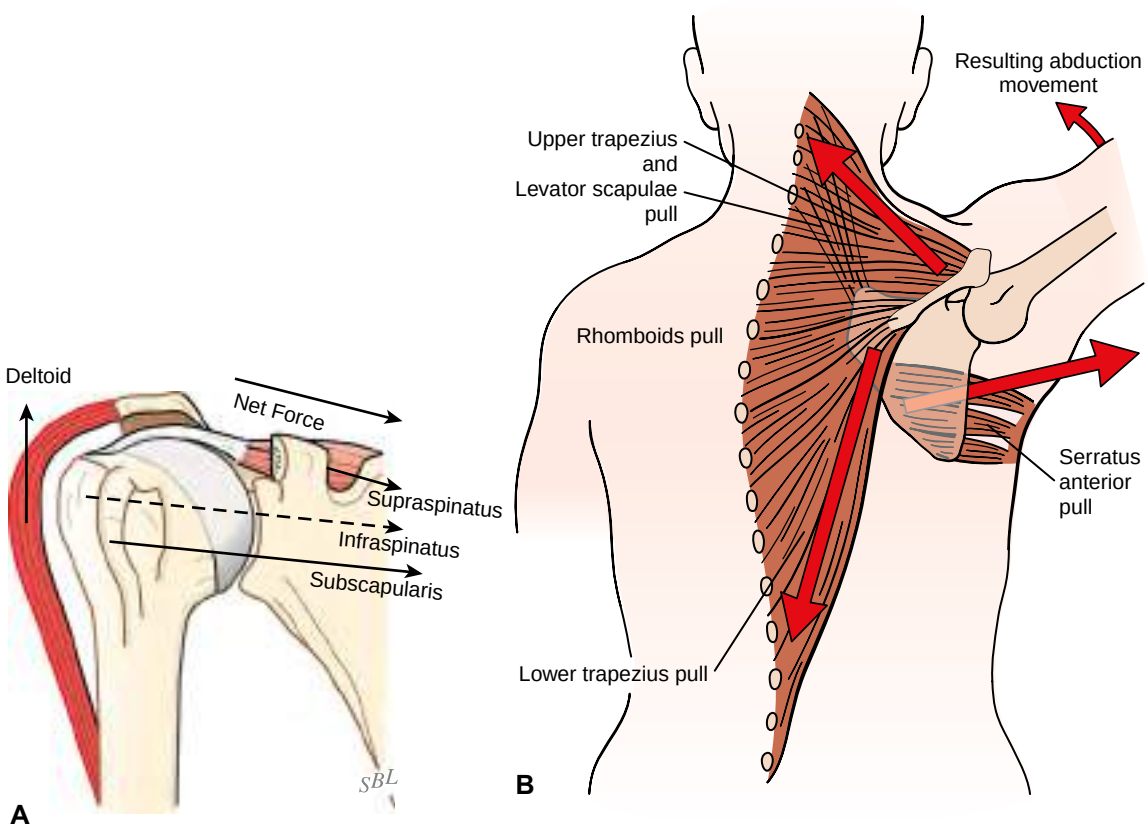

Figure 6-2 Force-couple examples about the shoulder. **A**, Glenohumeral joint. **B**, Scapula. (**A** Modified from Matsen FA, Lippett SB, Sidles JA, Harryman DT, editors: *Practical evaluation and management of the shoulder*, p 98, Philadelphia, 1994, WB Saunders.)

after traumatic anterior glenohumeral dislocation. As the size of the bone fragment increases, so does the risk of recurrent dislocation, especially in young, contact athletes. A **Hill-Sachs lesion** is the corresponding lesion or impaction fracture that usually occurs in the posterolateral aspect of the humeral head as the soft cancellous bone of the humeral head rests on the hard cortical glenoid bone during a traumatic glenohumeral dislocation. A condition that occurs in the superior labrum anterior and posterior (SLAP) to the biceps, **SLAP lesion**, is a lesion around the long head of the biceps where it crosses over the glenohumeral joint. Single or repetitive trauma can cause the labrum to fray, tear, or peel back from the bone, resulting in a SLAP lesion.[2–4]

The surrounding soft tissue envelope (i.e., the capsule) is the primary contributor to stability in the normal glenohumeral joint, with a normal lax inferior capsule allowing movement into full elevation. The capsule is reinforced by the coracohumeral and glenohumeral ligaments, which act as checkreins at the extreme ROM, assisting the compression caused by the dynamic rotator cuff.[21,29] These two components augment normal scapulohumeral rhythm to create functional stability. The concavity formed by the glenoid labrum, along with the muscles that provide compression and the unique tightening mechanism of the inferior glenohumeral ligament, provides a "concavity-compression" mechanism that stabilizes the glenohumeral joint.[13,21]

The glenohumeral ligaments, which are thickenings in the capsule, show a high degree of variability, especially the superior and middle glenohumeral ligaments. Of the three, the inferior glenohumeral ligament is the most important and shows the least variability. It acts like a hammock for the humeral head, preventing some inferior translation, with the anterior and posterior bands tightening on rotation (torsion), which, in turn, limits anterior and posterior translation.[24] This ligament takes on even greater importance with glenohumeral elevation. At 0° abduction, the subscapularis muscle, labrum, and superior glenohumeral ligament are the primary restraints to anterior translation. At 45° abduction, the subscapularis muscle and middle and inferior glenohumeral ligaments, along with the labrum, prevent anterior translation. When the arm is abducted more than 90°, which is the usual position of anterior dislocation, the anterior fibers of the inferior glenohumeral ligament are the primary restraints to anterior movement.[13,16,17,19,30] The long head of the biceps tendon can sometimes act as a secondary dynamic support to reduce stress anteriorly in the abducted and laterally rotated position.[31] Similarly, the posterior band of the inferior glenohumeral ligament prevents posterior translation above 90°.[16]

If the ligaments are hypomobile, they can restrict translation of the humeral head in the glenoid,[32] and restricted translation can adversely affect shoulder motion, especially when the shoulder is under load. If the labrum, capsule, or ligaments are injured or stretched through repetitive microtrauma, such as occurs with repetitive throwing or swimming activities, the resulting hypermobility can lead to functional instability even without major trauma.

The tendons of the rotator cuff have important dynamic roles, but they can perform these roles only when acting from a stable scapular base from which they all originate. The muscles serve in a complementary function to adjust the tension in the capsuloligamentous system.[33] It is possible that stretch receptors within the capsular ligaments are activated by tension to induce selective contraction of the surrounding musculature, protecting these structures at the extremes of motion.[34] As stated previously, contraction of these muscles compresses the humeral head into the glenoid cavity and increases the force needed to translate the humeral head.[16,35,36] Cadaveric studies have shown that simulated maximal contraction of the posterior rotator cuff muscles reduces anterior ligamentous strain and posterior rotator cuff contraction reduces anterior ligamentous strain.[37]

A second and equally important group of muscles that affects glenohumeral stability is the scapular control muscles (see Table 5-1). These muscles control (stabilize) the scapula, which is the dynamic base (i.e., the origin) for the rotator cuff, biceps, and triceps (long head) muscles. Through their action on the scapula, these muscles position the glenoid beneath the humeral head, adjusting for the changing position of the arm. With scapular dyskinesia, failure to maintain the stable glenoid platform (i.e., the scapula) may occur, causing an alteration in scapulohumeral rhythm and mild-to-severe winging of the scapula.

These concepts form the basis for rehabilitation of the unstable shoulder. Four key components must be addressed in rehabilitation: (1) normal scapulohumeral rhythm, (2) normal arthrokinematics at the joint, (3) balancing of the ligamentous structures, and (4) normal function of the rotator cuff muscles, biceps and scapular stabilizers (normal osteokinematics).[1]

PRINCIPLES OF SHOULDER ASSESSMENT

The essential ingredients for assessing the spectrum of shoulder injuries are a detailed history, identification of the precipitating or perpetuating factors (i.e., the mechanism of injury), and a careful physical examination, including special tests for differential diagnosis. Palpation of the specific structures generating the pain or dysfunction concludes the physical examination. This process should lead the examiner to choose the specific investigations (e.g., diagnostic imaging) needed to confirm the diagnosis, and it also provides a framework that is essential to successful treatment.

Key Elements for a Clinical Diagnosis

- Recognition of the salient points in the history
- Identification of precipitating or perplexing factors
- Careful examination including individual muscle testing
- Palpation of pain-generating structures

In the shoulder, dysfunction and pain may arise from a variety of sources, including the scapulohumeral complex, acromioclavicular or sternoclavicular articulations, rotator cuff and other shoulder muscles, associated subacromial (subdeltoid) bursa, biceps tendon, or labrum. Pain may even be referred from the cervical and thoracic spine and ribs. Shoulder pathology shows a common pattern of pain along the anterior glenohumeral joint line and biceps tendons, at the origin of the levator scapulae, and at the teres minor on the posterior joint line. Pain also may be present at the deltoid insertion and upper trapezius, along the medial border of the scapula and, in some cases, over the whole scapula.

When evaluating pain, clinicians should keep in mind the patient's age, occupation, recreational goals, and side dominance. The examiner must make sure that the patient is not confusing pain with weakness, instability, or apprehension. The mode of onset is important and may present as a spectrum of injury mechanisms, from a single traumatic episode to repetitive microtrauma.

Detailed examination of the shoulder can be found elsewhere (see Volume 1 of this series, *Orthopedic Physical Assessment,* Chapter 5). When assessing the shoulder, the examiner must keep in mind several important concepts:

1. *Shoulder pain must always be distinguished from referred pain arising from the cervical spine* (Table 6-1). The embryological derivation of the shoulder girdle from the cervical myotomes results in a close relationship for specific innervation, as well as for referred pain. With any complaint of shoulder girdle discomfort, cervical pathology must be ruled out. Neck pain and dysesthesia (i.e., numbness, tingling, burning) that radiate past the elbow in a dermatomal distribution normally implicate cervical disc disease, although nerve entrapment at the elbow or wrist or a local pathological lesion in the hand must be considered.[1] True shoulder pain rarely extends below the elbow. In any patient over age 50, a coexisting cervical degenerative abnormality must also be considered.[38]
2. *Generally shoulder pathology is characterized by pain on use, weakness, stiffness, and guarded apprehension.* (In many cases, the patient reports that the shoulder "just doesn't feel right.") These findings help distinguish shoulder pathology from cervical pain, which often is present even at rest and generally is aggravated by chronic compensatory postures, such as sitting, reading, or studying at a desk. Neck and shoulder pain cannot be totally isolated. The clinical points that are most suggestive of pain of spinal origin include absence of shoulder tenderness, guarded cervical spine motion, decreased biceps strength and reflex, and a positive cervical compression test (see volume I of this series, *Orthopedic Physical Assessment,* Chapter 3).[1] The most common pattern of cervical disc disease (i.e., spondylosis) refers into the C5-C6 dermatome with pain and/or paresthesia over the shoulder, the lateral arm, and even into the forearm and the thumb side of the hand.
3. *The patient's ability to maintain a static and dynamic stable core is important in shoulder rehabilitation.* A stable core (i.e., the ability to maintain control of the pelvis and spine) is the transfer zone between the lower extremity and the upper extremity, and as such, it plays a significant role in shoulder rehabilitation. If the practitioner tries to correct shoulder and/or cervical posture without addressing the unstable or incorrectly positioned core, treatment will be unsuccessful.
4. Neer[39] thought that mechanical "*impingement" could sometimes occur against the anterior edge of the acromion, coracoacromial ligament, or inferior acromioclavicular joint.* Others think that the anterior pain is due more to a complex interplay of rotator cuff dysfunction and degeneration ("rotator cuff disease") rather than impingement.[40] Structural narrowing of the subacromial space may occur secondary to inferior acromial tilting (i.e., anti-tilt), the so-called hooked acromion (i.e., type III), an unfused acromial ossification center called an **os acromiale**, or subacromial spurring. In addition, acromioclavicular joint hypertrophy and marginal osteophytes may irritate the rotator cuff.[9] Postural changes, particularly slouching with rounded shoulders and a protruding, chin-forward head posture, contribute to impingement. Magnetic resonance imaging (MRI) has demonstrated narrowing of the subacromial space as the shoulder girdle moves from a retracted to a protracted position.[41]
5. *Stability of the shoulder complex depends on an intimate relationship between the muscles controlling the scapula and those controlling the humerus.* The examiner must ensure correct functioning of the periscapular

TABLE **6-1**

Factors Suggesting the Site of Origin of Shoulder Pain

Neck Pathology	Shoulder Pathology
• Pain at rest • Pain with neck motion • Pain with overpressure on the neck • Pain aggravated by postural positions • Pain past the shoulder • Reflex changes • Altered peripheral sensation • Guarded cervical spine motion	• Pain with use • Pain when working overhead • Feeling of instability • Local palpable tenderness • Painful arc of motion • Pain into the deltoid area • Pain mainly on the dominant side • Pain relief with local injections

stabilizers and the rotator cuff (i.e., inner cone muscles). Commonly, the power (i.e., outer cone) muscles (i.e., the pectoralis major, deltoid, and latissimus dorsi) are not the problem, although they may contribute to the problem by being tight or substituting for the inner core muscles. Weakness or injury in any of the inner cone muscles leads to an imbalance of the synergistic inner cone (i.e., stabilizer) and outer cone (i.e., mobilizer) muscles and the prime mover muscles, resulting in abnormal shear forces which, in turn, can lead to instability (i.e., functional subluxation), labral injury, impingement, muscle imbalance, abnormal joint mechanics, and/or rotator cuff tears.[6,7,42] A thorough, detailed assessment of the strength and flexibility of each individual muscle of the shoulder complex is essential to identify weak and tight links in the kinetic chain and to ensure proper return to correct function. (For muscle testing, the reader is referred to the appropriate muscle testing books.[43–45])

6. *The examiner should watch for scapular dyskinesia, especially if the patient is under 35 and has anterior shoulder pain.*[2–4,46–48] If the scapula cannot be controlled by its stabilizer muscles, extra load is transferred to the humeral control muscles and they become overused, which leads to tendon and labral problems. Scapular instability is a common cause of rotator cuff and bicipital tendonitis or tendinosis and secondary impingement. A functional scapular base is essential for correct shoulder movement, especially in sports.[49]
7. *Hypomobility can be a major issue in shoulder instability and impingement.* The clinician must determine the mobility of the glenohumeral joint capsule (especially posteroinferiorly), ribs, scapula, and acromioclavicular and sternoclavicular joints, as well as assessing for tight muscles (e.g., pectoralis major and minor). Addressing tight structures helps to ensure normal shoulder arthrokinematics and function.[2–4] For example, glenohumeral arthrokinematics are markedly altered by a **glenohumeral internal (medial) rotation deficit (GIRD)** or by a tight posterior capsule when medial (internal) rotation is limited and lateral (external) rotation is excessive (also called **glenohumeral external (lateral) rotation gain [GERG]**). One theory proposed by Burkhart and coworkers[2–4,29] states that GIRD of 10° to 20° has a beneficial effect of offsetting the center of rotation of the glenohumeral joint posterosuperiorly. The advantage is that the greater tuberosity can "clear" the posterosuperior glenoid and labrum. Unfortunately, this process can get worse; with medial (internal) rotation deficits greater than 20° of the contralateral shoulder, combined with loss of the total motion arc, there continues to be stress on the superior labrum, and a SLAP lesion eventually results. Thus, a tight posterior capsule results in a pathological "decentering" of the humeral head.
8. *Immobility of the thoracic spine and ribs can significantly influence the movement patterns of the shoulder complex and can affect the dimensions of the subacromial space.* A careful assessment of the cervical and thoracic spine and ribs is an important part of any shoulder assessment.[50]
9. *Any shoulder rehabilitation program must involve assessment of the whole kinetic chain.*[3] The clinician cannot assess the upper quadrant in isolation. Power movements and accelerating motions begin in the lower limb and trunk musculature. In patients with shoulder problems, the clinician should look for inflexibility in the hips (especially on the nondominant side) and in trunk rotation and the anterior shoulder muscles, along with weakness of the hip abductors and the pelvic core.[2]
10. *Exertional left shoulder pain in individuals over age 45 with coronary risk factors should be considered as cardiac pain until proven otherwise.* Coronary risk factors include smoking, obesity, hypertension, and a family history of cardiac disease.
11. *Pain from the lungs and abdominal organs can be referred to the shoulder, and injury to these structures should be considered in conditions involving trauma.*
12. *The initial observation should include the thoracic spine, ribs, and shoulder girdle and requires adequate exposure of the patient.* Viewing the disrobed patient from behind allows the clinician to note any wasting of the shoulder girdle muscles, especially the supraspinatus, infraspinatus, serratus anterior, and posterior deltoid. Such wasting may indicate a nerve injury (e.g., suprascapular, long thoracic, or axillary nerve)[51] or apparent hypertrophy of the upper trapezius as a result of superior migration of the scapula (i.e., type III dyskinesia).[2–4,46–48] The presence and size of stretch marks or scars often reflect poor quality collagen and may be a clue to the possibility of generalized ligamentous laxity or steroid abuse in athletes. Excessive lordotic curvature, a kyphotic thoracic spine, and/or associated poking chin with rounded shoulders should be noted. The clinician must assess for lack of pelvic or core control with these postural problems, which often contributes to shoulder problems. In addition, these anterior and posterior postural imbalances can lead to a tight pectoralis major and minor, resulting in increased stress on the anterior capsule, tightness of the posterior capsule, and overuse of scapular control muscles.[51]
13. *The examiner must always be aware of the possibility of referred pain.* The response to palpation must be put in the context of the patient's presentation and the implications of this presentation (e.g., secondary gain, pain threshold) must be judged correctly.

14. *Clinicians must know their patients.* The patient may have other issues and agendas that affect the clinical presentation.

ROTATOR CUFF DEGENERATION AND DYSFUNCTION (SHOULDER "IMPINGEMENT")

Shoulder impingement or "pinching" is associated with various degrees of inflammation or rotator cuff degeneration. It frequently occurs as a result of microtrauma, macrotrauma, or functional instability. The suspicion of impingement is raised by the presence of a painful arc during attempted active abduction or forward flexion or in patients with a complaint of anterosuperior or posterior shoulder pain with no history of trauma. There has been a tendency to move away from calling pain in the anterior region "impingement" because this implies that this is largely a mechanical phenomenon alone, when, in fact, it may be a more complex interplay of rotator cuff dysfunction and degeneration and less to do with attritional irritation from rotator cuff impingement.[40]

The subacromial space can be identified as a source of impingement by taking the arm passively into full forward elevation with gentle overpressure (i.e., Neer impingement test).[51] This test can be supplemented with the Hawkins-Kennedy impingement test, which involves taking the patient's arm to 90° of abduction and then moving it into horizontal adduction, followed by forced medial rotation.[51] The Hawkins-Kennedy impingement test can be enhanced by having the patient resist a force applied downward to the dorsum of the hand. A positive Hawkins-Kennedy test result implies impingement of the rotator cuff under the acromion. Historically a positive Neer impingement test result is thought to represent impingement of the rotator cuff on the anterosuperior glenoid rim or coracoacromial ligament.[52] Unfortunately, the sensitivity and specificity of these tests are quite poor and localizing the pain to one area is quite difficult.[53] Many sources of pain exist in this anterior region, including the bursa, rotator cuff, long head of biceps, anterosuperior labrum, and even the acromioclavicular joint.

Shoulder pain caused by impingement would seem to be easily distinguishable from that caused by posttraumatic instability. However, over time, clinicians have come to recognize that these conditions comprise a spectrum of both injury and pathology (Figure 6-3). At one end of the spectrum is an unstable painful shoulder along with rotator cuff degeneration and dysfunction, and at the other end is frank dislocation.[54,55] Rotator cuff degeneration is most often the result of a gradual attrition and irritation of the tendons that is associated with pain and dysfunction and that often is the result of repetitive overuse. Frank dislocation frequently goes on to become a recurrent dislocating joint. Similarly the spectrum of natural collagenous laxity ranges from extreme tightness to abnormal looseness; therefore the degree of trauma or overuse required to generate a dislocation or subluxation varies.

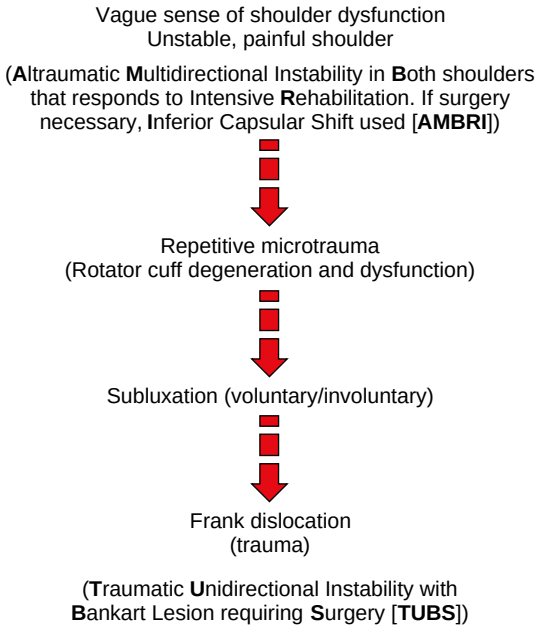

Figure 6-3 Shoulder instability spectrum. (Modified From Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation*, p 520, Philadelphia, 1996, WB Saunders.)

Between these extremes lies the mildly unstable shoulder that predisposes the patient to impingement and pain; this condition is often seen in athletes, such as swimmers, and assembly line workers. The throwing shoulder in which the pitcher alters the mechanics to increase range of lateral rotation to get into the "slot" is another example.[2]

The aging process also fits into this spectrum, and its effects are manifested more in the soft tissue rotator cuff and in the joint surface itself.[52] Furthermore, internal derangements in the form of labral tears, attrition of the rotator cuff muscles, and degeneration of or partial tears in the biceps tendon have begun to be diagnosed with more prevalent use of the arthroscope and the increasing availability of MRI and computed tomography (CT) scanning. As a result, the previously simple, distinct diagnostic categories have become blurred into a spectrum of injuries.

Rotator cuff degeneration and dysfunction is often the result of cyclical repetitive abduction, forward flexion, and medial rotation motion at the glenohumeral joint.[56,57] Such movement is seen in swimmers who commonly swim approximately 10,000 to 14,000 m (6.2 to 8.7 miles) or more per day.[52] Impingement may also occur when the arm is forward flexed, medially rotated, and abducted within the coracohumeral space. This **coracoid impingement syndrome** occurs when the lesser tuberosity of the humerus encroaches on the coracoid process and has been associated with subscapularis tears.[58,59] The condition has been reported in swimmers,

tennis players, weight lifters, and brick layers. With force overload, the humeral and scapular control muscles (see Figure 6-2) become fatigued, resulting in muscle weakness and muscle imbalance in the scapulohumeral force couples, which leads to incorrect movement patterns.[56,57] The resultant abnormal shear stresses can lead to secondary impingement.

Another type of impingement occurs in individuals over age 40, arising from alterations in the soft tissues (e.g., rotator cuff, labrum) and possibly bony changes. This has been called **primary anterior (external) impingement**. Although it has been classically thought of as a pure mechanical process of irritation and attrition of the rotator cuff secondary to physical contact between the anterosuperior rotator cuff and under the surface of the acromion, it is now recognized that this is a largely oversimplified point of view.[40] Although some mechanical irritation certainly occurs, it is unlikely that this is the source of the problem and is more likely the result of an aging, fatigued, and degenerating rotator cuff. This patient seldom has instability.[5,60,61]

In younger patients (ages 15 to 35), muscle dynamics is the primary problem (i.e., weakness of the scapular and humeral stabilizers). This has been called **secondary anterior (external) impingement**, which primarily is due to scapular dyskinesia and posterior rotator cuff fatigue.[5,60,61]

The fourth type of impingement is **posterior internal impingement** (Figure 6-4), which involves contact of the undersurface of the rotator cuff with the posterior superior glenoid labrum.[62–64] Burkhart et al.[3] reported that posterior internal impingement is a normal phenomenon that sometimes can result in pathology of the rotator cuff and labrum.

If significant inflammation is present, impingement tests are less specific because all testing positions tend to be uncomfortable. Very inflamed tissues are uncomfortable even on passive stretching or when put under tension by contraction of the associated muscle. By testing for pain in the nonimpingement position for each specific structure, the clinician can distinguish and isolate the inflammatory response of the tendon from a simple impingement area. For example, a partial rupture of the biceps tendon within the joint may give positive impingement signs and may also be maximally painful with resisted forward flexion. The clinician can further confirm the diagnosis by injecting approximately 3 mL of 0.25% to 1% lidocaine (Xylocaine) directly around the most painful areas (or 5 mL into the subacromial space) and then waiting a suitable interval (usually a few minutes) before repeating the impingement test.[62] Relief of at least 50% of the patient's pain through the painful arc or the impingement positions helps to confirm the source of the pain. However, it is important to keep in mind that although the source of the pain has been found, the source of the real problem may be more elusive. Most nontraumatic shoulder pain is the result of posterior muscle problems involving the muscles stabilizing the scapula resulting in loss of scapular stabilization or control, overuse of the rotator cuff, loss of dynamic thoracic and pelvic control, and muscle imbalance in all four areas. In addition, when a rotator cuff tear is suspected, elimination of most of the pain allows a more specific examination of strength. The classic findings with a rotator cuff tear are pain even at rest (and especially at night), wasting of

Figure 6-4 Posterior internal impingement. **A**, Posterior contact between the glenoid lip and the insertion of the cuff to the tuberosity occurs in the apprehension, or fulcrum, position, especially if the anteroinferior capsule has been stretched, allowing the humerus to extend to an unusually posterior scapular plane. This contact can challenge the integrity of the posterior cuff insertion and the tuberosity. **B** and **C**, Activity positions causing potential posterior impingement. (**A**, From Matsen FA: Stability. In Matsen FA, Lippett SB, Sidles JA, Harryman DT, editors: *Practical evaluation and management of the shoulder*, p 98, Philadelphia, 1994, WB Saunders.)

the supraspinatus and infraspinatus muscles, weakness of scaption (i.e., abduction in the scapular plane), and loss of lateral rotation strength. Small tears or partial-thickness tears may generate impingement signs without significant loss of rotator cuff strength. Diagnostic tests, such as ultrasound, MRI, or CT arthrograms can help to identify the true problem.

Functional Assessment of the Unstable or Dysfunctional Rotator Cuff and "Impinging" Shoulder

As the clinician goes through the assessment of the shoulder, he or she should carefully watch how patients position themselves and their shoulders to do the tasks they are asked to do. Proper alignment and a "streamlined" posture (i.e., major joints in line, ears squeezed by the arms, pelvis in neutral, feet and hands together, head in neutral) both in standing and sitting are key both during assessment and when doing exercises (Figure 6-5). Patients must be able to place the pelvis "in neutral" (anterior superior iliac spine [ASIS] one to two finger widths lower than posterior superior iliac spine [PSIS]) with the lower spine in proper postural alignment. Any alteration resulting in poor posture or altered scapular stabilization can lead to alterations in the position of the glenoid fossa, which can, in turn, lead to several different sequelae. For example, when the patient is lying, supine or prone, the humeral head should align with the cervical spine and not project anteriorly (Figure 6-6). Similarly there should be no "shoulder bump" (i.e., shoulder hiking) (Figure 6-7). If the patient is slouching, the head of the humerus shifts anteriorly against the anterior capsule and labrum, resulting in undue pressure on these anterior structures. Shoulder ROM and rib motion both must be observed with motion on both sides of the body compared during the assessment.

Scapular posture should show the medial border of the scapula parallel to the normally straight thoracic spine and approximately 5 to 8 cm (2 to 3 inches) apart (Figure 6-8). There should be no scapular tilt (i.e., the inferior angle tilted away from the ribs), and the inferior angles of both scapula should be horizontally level and equidistant from the thoracic spine. The upper trapezius and levator scapulae should not be tight on palpation. To observe scapular functional movement, the examiner can have the patient hold the core and do a squat posture (Figure 6-9, *A*), with the shoulders in the power square position (Figure 6-9, *B*), open or closed shutters (Figure 6-9, *C*), and fly shutters. Lateral plank exercises may be performed from the knees or ankles as long as the patient can hold proper alignment (Figure 6-10).

Treatment of the Unstable Shoulder and Impingement

In the early clinical stages, the patient may complain of aching only after activity, and ROM is preserved. The clinician seldom sees the patient at this point, which is unfortunate, because postural correction involving the scapula, spinal postural line, and pelvis (see Figure 6-5, *A*) along with patient education could play a significant role. If the patient detects the early onset of symptoms, preventive measures can be instituted, such as modification of an activity. For example, during their workouts, swimmers could use a different stroke (e.g., the breaststroke), do only kicking drills, use speed fins, use a center snorkel, or alter their stroke pattern (e.g., different hand entry, altered body roll). The use of resistance devices should be kept to a minimum or, if used, monitored closely to ensure incorrect movement patterns do not develop and the arm is not being positioned in compromising positions. For example, the use of hand paddles or swimming with elastic cords, use of water barrels, or pulling foam can increase the stress on a swimmer's shoulder. In addition, using a flutter board held in front of the head while

Pillow used to put shoulder in its resting position (40°-55° abduction, 30° horizontal adduction [scapular plane]). **B**, Sitting support (note shoulder is not elevated). **C**, Standing support with bolster.

doing kicking strokes in prone position may position the arm in a vulnerable impingement posture.

The patient should be instructed in healthy shoulder care (e.g., positioning or supporting the shoulder in resting positions) (Figure 6-11), the application of ice, especially after a workout, and how to take the shoulders slowly through a full ROM in a controlled fashion while ensuring a dynamically stabilized scapula and normal shoulder activation patterns. The patient should avoid compensatory shoulder impingement positions in activities of daily living and dry land training programs. Ideally, muscle strength should be monitored regularly for weakness of the scapular stabilizers, compensatory movement patterns, loss of ROM (which is demonstrated by unequal movement or range when comparing both sides), pain, and compensatory postures. *Correct posture is an important concept that clinicians must keep in mind and continuously monitor when asking patients to do shoulder exercises.* The practitioner

should not allow poor posture with protracted scapulae, which leads to **anti-tilt,** or the position in which the glenoid fossa is no longer superiorly and anteriorly tilted. This anti-tilt position allows the humeral head to "fall" out of the glenoid (Figure 6-12). With instability and impingement, any combination of poor posture or altered scapular stabilization and control can lead to compensation with the glenoid fossa facing inferiorly (anti-tilt). Matsen's "scapular dumping" seen in dislocations[32] is another, more traumatic, example of this glenoid anti-tilt.

As the pathology progresses, the patient experiences discomfort and pain during and after the activity. A positive impingement sign is elicited on examination (i.e., positive Hawkins and Neer tests, restriction in abduction and scaption). Palpation may demonstrate tenderness along the upper corner and medial border of the scapula, over the origin of the levator scapulae, around the insertion of deltoid, and long head of biceps, anterior capsule, and off the lateral edge of the acromion. These patients may also present with tenderness over the infraspinatus and teres minor muscles. Pathological changes may consist of thickening and fibrosis of the tendon, involvement of the subacromial bursa, residual adhesions, and possibly fraying of the labrum.

In the final stages, the patient complains of continuous pain over the supraspinatus and biceps tendons and tenderness over the coracoacromial ligament. A painful arc, especially in the empty can (Jobe's) position, is commonly demonstrated, and ROM can be restricted into medial and lateral rotation motions, which are not equal bilaterally, and impingement signs can be grossly positive. X-ray films may demonstrate infra-acromial and infraclavicular spurs, bony sclerosis near the supraspinatus insertion, and subacromial erosion.

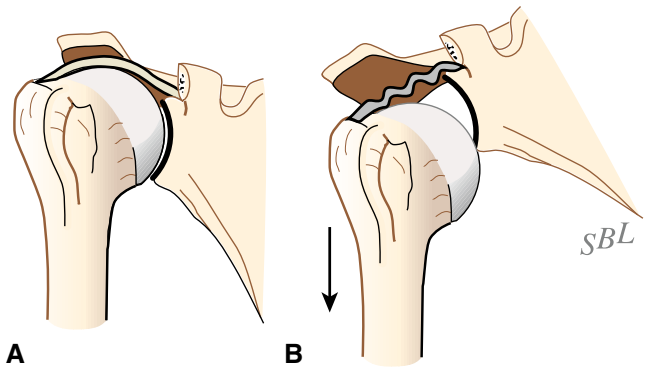

Figure 6-12 Scapular anti-tilt or dumping. With the scapula in a normal position (**A**), the superior capsular mechanism is tight, supporting the head in the glenoid concavity. Drooping of the lateral scapula (**B**) relaxes the superior capsular structures and rotates (anti-tilts) the glenoid concavity so that it does not support the head of the humerus. Conversely, stability is enhanced by elevating the lateral aspect of the scapula. (From Matsen FA, Lippett SB, Sidles JA et al: *Practical evaluation and management of the shoulder*, p 81, Philadelphia, 1994, WB Saunders.)

Surgical Treatment of Rotator Cuff Dysfunction

Surgery is considered a treatment of last resort for impingement-type syndromes. The indications for surgery include unremitting pain and failure to respond to nonoperative, conservative treatment. The timing of surgery depends on the functional disability and pain. There has been a strong trend away from surgical management of this condition, with aggressive physical therapy programs having equal or greater success to surgery.[65–67]

The surgical procedures used historically have been performed arthroscopically and were designed to increase, or decompress, the subacromial space. In the case of anterior impingement, this is achieved by some combination of shaving or excising the undersurface of the anterior edge of the acromion process with release or resection of the distal part of the coracoacromial ligament, thus decompressing the acromioclavicular space. The decision to remove inferior osteophytes or resect the acromioclavicular joint, combining the procedure with diagnostic arthroscopy of the glenohumeral joint and varying degrees of correction of labral lesions, and bicipital tendon pathology usually is a preoperative determination refined by intraoperative findings. It should be noted that several randomized controlled trials all have failed to show the benefit of subacromial decompression in the setting of anterosuperior shoulder pain.[65,66,68–70] Even in the setting of rotator cuff repair, routine use of subacromial decompression appears to not be warranted.[65,66,69,70] Select cases do still exist in which the degree of bony pathology is severe, such as those with huge subacromial spurs encroaching into the subacromial space, and may still warrant a subacromial decompression.[71] Surgical management of coracoid impingement is directed toward subscapularis repair and debridement of the undersurface of the coracoid if it is determined that the space between the coracoid and the humerus is narrowed.[72] Internal impingement is best identified early because surgical management is not often successful in returning the individual back to the same level of activity.[2–4] Once superior labral and rotator cuff damage occurs, the result of surgical repair becomes quite unpredictable. Significant, recalcitrant posterior capsular tightness that has failed to respond to an aggressive stretching program may be addressed by posterior capsular release, which is aimed at reducing GIRD. Associated labral and rotator cuff tearing may warrant debridement and/or repair.[3,73]

As might be expected with the array of surgical decisions to be made, the progress of postoperative rehabilitation varies. The clinician should have accurate and detailed information before starting the planning of the treatment regimen. In the simplest scenarios of surgical debridements and arthroscopic subacromial decompression, gentle ROM can be commenced within the tolerance of discomfort. The initial emphasis is on isometric muscle contractions, with progression to ROM exercises and strengthening. This progression is dictated by

the ability to restore appropriate scapulohumeral rhythm and functional scapular control. Impingement positions must be avoided, and the exercises should focus on medial and lateral rotation in neutral, along with forward flexion motions, before abduction motions are initiated. It is better to go slow early, until most of the discomfort has subsided. The clinician should follow the principles of rehabilitation outlined later in this chapter, including those for nonoperative treatment of impingement.

SHOULDER INSTABILITY, SUBLUXATION, AND DISLOCATIONS

Shoulder instability, due either to significant trauma or to inherent ligamentous laxity and overuse with associated functional instability, is a common problem, especially in those under 35 years of age and in individuals who engage in a lot of overhead activity. The condition may be compounded by pseudo-laxity, which is an apparent increase in anterior laxity that results from a decreased cam effect, along with a tear of the superior labrum (i.e., SLAP lesion), congenital joint laxity (i.e., hypermobility), congenital muscle weakness, congenital anomalies, and/or muscle weakness or atrophy after injury.[2]

The glenohumeral joint is the most frequently dislocated major joint in the body. In one case series, glenohumeral dislocations are more common than all other joint dislocations combined.[63] Anterior dislocations of the shoulder account for 80% to 95% of all initial shoulder girdle dislocations, and recurrence is common.[64,74,75]

Classification of these injuries is necessary to develop a logical treatment plan. As previously mentioned, instabilities can range from subtle subluxation to a frank dislocation in which the articular surfaces are no longer in contact (i.e., true dislocation). Recurrent transient subluxation results in a feeling of instability or loss of control due to positioning of the arm. An example of this is forced hyperextension of the arm in elevation and/or lateral rotation, which may result in the "dead arm" syndrome seen in throwing athletes or in tennis players during a serve. In these cases, altered mechanics or traction, or pressure on the nerves generates the symptoms.[2,76,77]

Instabilities are basically classified as traumatic or atraumatic instabilities; Neer added a third type, acquired instabilities.[78] A traumatic dislocation is caused by a single force that applies excessive overload to the joint. This often damages the bony glenoid and/or the labrum and may even disrupt the capsule. This type of dislocation is seen in patients who present with a condition known as a **TUBS lesion** (i.e., *T*raumatic *U*nidirectional instability with a *B*ankart lesion that responds well to *S*urgery), as described by Matsen et al.[32] An atraumatic dislocation usually occurs in patients with multiple joint laxities who frequently have experienced episodes of subluxation before a relatively minor injury results in a dislocation. These individuals often show functional instability (i.e., lack of muscular control) as a result of congenital hypermobility or congenital muscle weakness. This classification includes patients who present with an **AMBRI lesion** (i.e., *A*traumatic *M*ultidirectional instability that is *B*ilateral and the primary treatment is *R*ehabilitation, not surgery;[32] if surgery is required, an *I*nferior capsular shift is often recommended). Capsular laxity is common in these patients, and Bankart lesions are not seen, although the labrum may be frayed.[48]

However, the clinician must keep in mind that overlapping gradations of instability cover the entire spectrum, from TUBS to AMBRI lesions (see Figure 6-3).[25] Individuals with acquired instability who become symptomatic usually are engaged in overhead occupational or recreational activities, such as plastering ceilings, installing ceiling lighting, swimming, gymnastics, and baseball (i.e., pitching), in which the repetitive microtrauma of ill-conceived stretching or rapid, large range motion gradually contributes to capsular stretching. Although the shoulder becomes hypermobile, other joints may test within the normal range. A traumatic episode may push the joint over the edge and produce the first dislocation, but this major episode is only a small component of the problem.[63]

Many clinicians recognize functional instability as a pathological entity, particularly when the joint is put under high stress loads. Scapular control is lacking in these patients, which is one of the clinician's primary concerns.[3] This instability manifests itself from muscle fatigue or scapular dyskinesia after excessive load or repetitions. The mechanical etiology of **functional instability** is uncontrolled translation (i.e., loss of the arthrokinematic control) of the humeral head within the glenoid cavity.[19,56,79–83] Strong, coordinated muscle activity and proper neuromuscular balance contribute significantly to a reduction in functional instability and the often accompanying impingement, and these elements form the basis of treatment.

The glenohumeral instability, which is commonly due to asynchronous firing and fatigue of the scapular and humeral control muscles, can lead to subluxation, rotator cuff strains, and tendonitis or tendinosis injuries. Therefore movement control becomes the primary focus of the clinician.[3,21,84–87] Movement control focuses on maximizing coordinated and correct contraction of muscles through strength, endurance, proprioception, and coordination. Burkhead and Rockwood[8] reported that 80% of patients with atraumatic subluxations had good or excellent results with conservative treatment when appropriate rehabilitation was used. Other researchers are more conservative regarding the efficacy of the outcomes.[88–90] An accurate diagnosis and an appropriate, conservative treatment program can lead to a successful outcome in most patients and are essential for successful rehabilitation.[88] Functional instabilities occur primarily in one direction. However, they can present with global laxity, commonly referred to as *multidirectional instability*.[91]

Voluntary instability, another classification of instability, is usually due to congenital hypermobility or laxity

combined with the patient using the shoulder muscles to purposely and spontaneously subluxate the joint.[63,92] For example, these patients commonly say, "Look what happens when I do this," as they voluntarily sublux the shoulder. This condition may provide an element of secondary gain for these individuals, and treatment is difficult. *Involuntary instability* is a recurrent dislocation in a person whose shoulder is so unstable that it dislocates spontaneously.[9]

A dislocation may be acute or chronic. An *acute, frank dislocation* is commonly traumatic and is usually reducible with a variety of manipulation techniques described elsewhere.[93,94] Reduction of a traumatic dislocation by manipulation should be attempted only by an experienced clinician. Occasionally the dislocation is irreducible, and open reduction may be required to extricate the structures preventing reduction. This condition is called a *complex dislocation,* in which interpositioning soft tissue blocks reduction.

With a *chronic dislocation*, the humeral head has been out of contact with the glenoid cavity for a protracted period (i.e., days to years). Unreduced posterior dislocations are the most common chronic dislocations because of the incidence of missed diagnosis. If the chronic nature of the dislocation is not recognized, attempts at closed reduction will be unsuccessful or may even result in a fracture.[75] Chronic dislocations invariably require open reduction. In studies of posterior instability, damage occurs to both the anterior and posterior aspects of the capsule.[94,95]

The principles of diagnosis of a dislocated or unstable shoulder were outlined earlier in the chapter. Usually the diagnosis is self-evident from the history, signs, and symptoms. The two most common mechanisms of traumatic injury are the arm being forced into 90° or more abduction and 90° lateral rotation and falling backward with the arm in extension.

The signs and symptoms of any dislocation or instability vary, depending on the severity. Patient complaints range from a vague sense of shoulder dysfunction to marked apprehension and pain, especially if the injury has been traumatic and the dislocation is unreduced. Reduction of the dislocation or subluxation usually provides immediate relief of pain, which is followed by a residual dull ache. Muscle spasm may make reduction difficult without the use of muscle relaxants, especially for the glenohumeral joint. A step deformity and loss of ROM are evident with a dislocation. Several days later, bruising and ecchymosis may be seen. If the patient complains of paresthesia, numbness, or muscle weakness, the clinician must be alert to the possibility of nerve injury, especially to the axillary nerve.

For dislocations, at least two radiographic views of the shoulder from two different angles are desirable to prevent a missed diagnosis, particularly with a posterior dislocation. X-ray films for an anterior dislocation should include a true anteroposterior (AP) view of the shoulder and a true lateral view of the scapula (Table 6-2).[51] An axillary view is difficult to obtain in an acutely injured shoulder but is extremely useful in ruling out a dislocation and thus should be obtained whenever possible. Specialized x-ray views, including Stryker Notch and a West Point Axillary, are required to further elucidate the size of Hill-Sachs lesion and Bankart fractures, respectively, but are not typically obtained in the acute setting.

TABLE 6-2

Radiographic Imaging for Different Shoulder Pathologies

Pathology	Radiographic Imaging
Impingement	Anteroposterior (AP) x-ray film in the plane of the scapula Supraspinatus outlet view Axillary AP x-ray film, 30° caudal view (anterior acromial view)
Instability	AP x-ray film in the plane of the scapula Stryker Notch view West Point axillary view Axillary
Arthritis	AP x-ray film in the plane of the scapula Full humerus AP x-ray film in the plane of the scapula with laterally rotated 30° Axillary
Trauma	AP x-ray film in the plane of the scapula Axillary True scapular lateral view (Y view)

Anterior Dislocations

Anterior dislocations account for approximately 95% of acute traumatic glenohumeral injuries.[95] They occur most frequently in young adults. With an anterior glenohumeral dislocation, the head of the humerus is driven or levered anteroinferiorly. Typically, the glenoid labrum is stripped from the anteroinferior aspect of the glenoid (i.e., Bankart lesion). As previously noted, it frequently involves the anteroinferior glenoid bone (Bankart fracture) (Figure 6-13) and an impaction fracture in the posterolateral aspect of the humeral head (Hill-Sachs lesion) (Figure 6-14). The bony Bankart lesion can be an acute fracture or an erosive process in which the glenoid slowly becomes deficient anteroinferiorly with multiple recurrent disclocations[96] (see Figure 6-13). If no Bankart lesion is found, the anterior or lateral capsule may be disrupted at the humeral insertion site. This is called **humeral avulsion of the glenohumeral ligament**, or **HAGL lesion** (Figure 6-15).[94,96] With significant labrum damage, especially with increasing bone loss, the chances for recurrent dislocation are greater because the potential for healing and spontaneous reattachment of the fibrocartilaginous labrum and/or Bankart fracture fragment back to its anatomical location is poor. The disrupted osseus or soft tissue Bankart lesions do heal back to the glenoid but often in a more medial position along the glenoid neck,

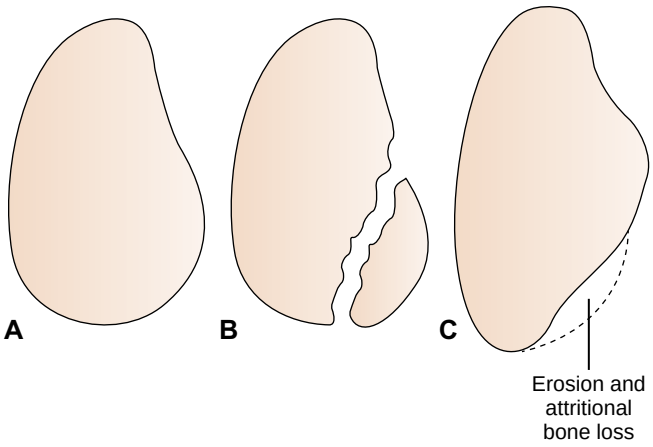

Figure 6-13 Bankart lesion. **A**, Pear-shaped normal glenoid. **B**, Bankart fracture. **C**, Erosive or attritional bone loss. (Redrawn from Burkhart SS, De Beer JF: Traumatic glenohumeral bone defects and their relationship to failure of arthroscopic Bankart repairs: significance of the inverted-pear glenoid and the humeral engaging Hill-Sachs lesion, *Arthroscopy* 16(7):684, 2000.)

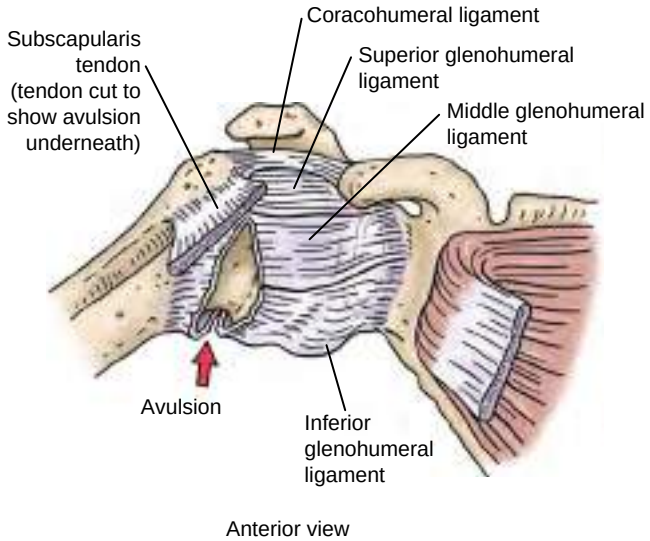

Figure 6-15 Schematic of humeral avulsion (*arrow*) of the glenohumeral ligament (HSGL Lesion) showing avulsion of middle and inferior glenohumeral ligaments from the humerus (subscapularis tendon cut for clarity). (Redrawn from Wolf EM, Cheng JC, Dickson K: Humeral avulsion of the glenohumeral ligaments as a cause of anterior shoulder instability, *Arthroscopy* 11(5):602, 1995.)

resulting in an inadequate anterior buttress to humeral head translation. This is further exacerbated if there is a large Hill-Sachs lesion.

The intact labrum is important for maintaining a suction-like vacuum effect to hold the humeral head in the glenoid cavity and for its buttress effect. Although it is most important as a static stabilizer, it also enhances dynamic support of the joint.[16,17] The glenohumeral joint usually is bathed in less than 1 mL of synovial fluid,[97] which helps hold the articular surfaces together and enhances the normal negative intra-articular pressure.[18,33] However, excessive fluid (usually blood) in the joint can negate this effect.

On examination, an acutely dislocated shoulder demonstrates a deformity (i.e., step deformity), or a space usually is detected under the tip of the acromion, resulting in prominence of the acromion, flattening of the deltoid muscle, pain, and loss of motion. The patient tends to support the arm in 30° of abduction with the other arm while listing or leaning to the affected side. Attempts at movement in any direction are painful, and the humeral head may be palpable in the axilla.

Anterior glenohumeral dislocations have several associated complications (of which recurrence is the most common). These may include injury to the axillary, musculocutaneous, or median nerves or more rarely the brachial plexus.[20] Only approximately 20% of these dislocations show minimal clinical signs, and 5% show significant evidence of neurological involvement; however, Rockwood demonstrated that up to 80% of individuals show electromyographic evidence of nerve injury.[63] This damage initially may be subclinical, with the patient showing no detectable weakness. Consequently *it is essential that the clinician repeatedly check and monitor for paresthesia and changes in the strength of the deltoid muscle.* Other complications include rotator cuff tears

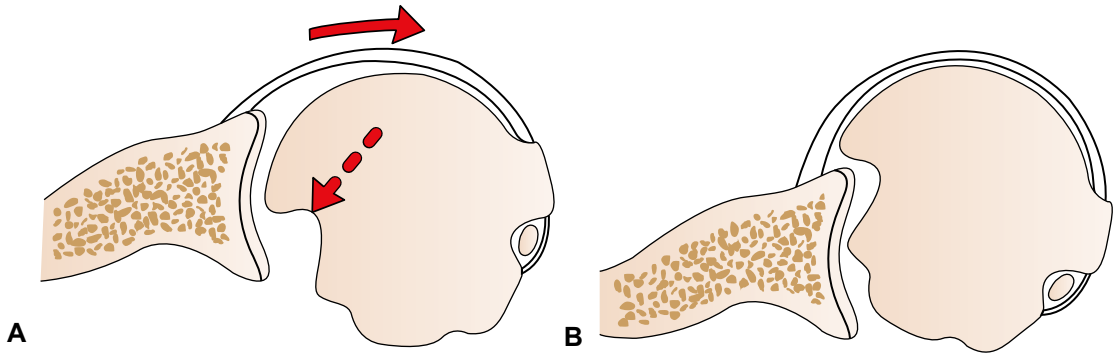

Figure 6-14 **A**, Hill-Sachs lesion (*dashed arrow*). **B**, Hill-Sachs lesion causes engagement of the humeral head in the anterior glenoid with lateral rotation. (Redrawn from Burkhart SS, De Beer JF: Traumatic glenohumeral bone defects and their relationship to failure of arthroscopic Bankart repairs: significance of the inverted-pear glenoid and the humeral engaging Hill-Sachs lesion, *Arthroscopy* 16(7):681, 2000.)

(the likelihood of these tears increases with advancing age, typically greater than 40 years of age), damage to the biceps tendon, and, on occasion, fractures of the greater tuberosity or the neck of the humerus. Vascular injury must also be considered, especially if distal pulses are diminished, and can be potentially limb threatening.[98]

Recurrent dislocations typically occur in active male patients under age 20, with recurrence rates being possibly as high as 90% after a traumatic dislocation.[95] Other factors that increase the risk of occurrence include contact, overhead activities, and significant glenoid and humeral head bone loss. The recurrence rate declines with age, with fewer recurrent dislocations occurring after age 40.[22,24,99,100] Most of these dislocations (75%) occur within 2 years of the initial traumatic event.[99]

Examination of a patient with recurrent instability is confirmed by a positive apprehension and relocation test. Signs of hyperlaxity, including lateral (external) rotation beyond 85° or hyperabduction of greater than 105°, should be watched for because these patients have a higher incidence of failure of a surgical repair.[101,102] Intact rotator cuff function should be confirmed. If there is concern for rotator cuff integrity, ancillary imaging, such as an ultrasound or an MRI, should be performed.

Nonoperative treatment may be successful in some patients with recurrent dislocations because restoration of kinetic chain function, shoulder strength, and proprioception may suffice in rendering the joint stable. Unfortunately, it is ineffective for most individuals with recurrent episodes; therefore, surgical stabilization is appropriate for those with significant functional instability, and excellent success rates usually are achieved.[24] The choice of surgical technique and the timing and extent of surgery depend on the degree and direction of instability, the requirements for ROM, the associated soft tissue and bone damage, and the surgeon's preference and skills.

Posterior Dislocations

Posterior dislocations result from the arm being forced or thrust backward when it is forward flexed and medially (internally) rotated; these injuries account for approximately 2% of all glenohumeral dislocations. Although falling on an outstretched, adducted arm can cause the injury, the typical mechanism is the result of a grand mal seizure. On examination, posterior prominence of the humeral head may not be evident, and rounding of the shoulder or deltoid is maintained; therefore these dislocations are sometimes missed or misdiagnosed, leading to prolonged periods of dislocation, especially in more heavily built individuals. Some flattening of the anterior shoulder may be seen, and the coracoid process may be more prominent than on the uninjured side. The patient will have limited lateral (external) rotation (less than 0°) and limited elevation (less than 90°), which are signs that further investigation is needed. In addition, medial rotation and cross-flexion (horizontal adduction) cause pain and apprehension. Posterior dislocations are recognized by the "empty glenoid" sign on the x-ray film (Figure 6-16). The true glenohumeral AP view of the posteriorly dislocated shoulder shows abnormal overlapping of the humeral head and glenoid shadows, which are normally on this view. Again, an axillary view will clearly show this dislocation but is often difficult to obtain in cases of an acutely posterior shoulder dislocation. If this injury is missed, it results in considerable morbidity because the relatively soft humeral head becomes severely damaged as it rests on the edge of the hard glenoid. Reduction becomes very difficult and it can often only be achieved through operative intervention.

In recurrent posterior dislocations, the patients complain of apprehension with shoulder elevation, especially with the arm adducted. Physical examination confirms excessive posterior translation of the humerus and subluxation, or even frank dislocation, with a posteriorly directed force on the humerus. The complex pathophysiology

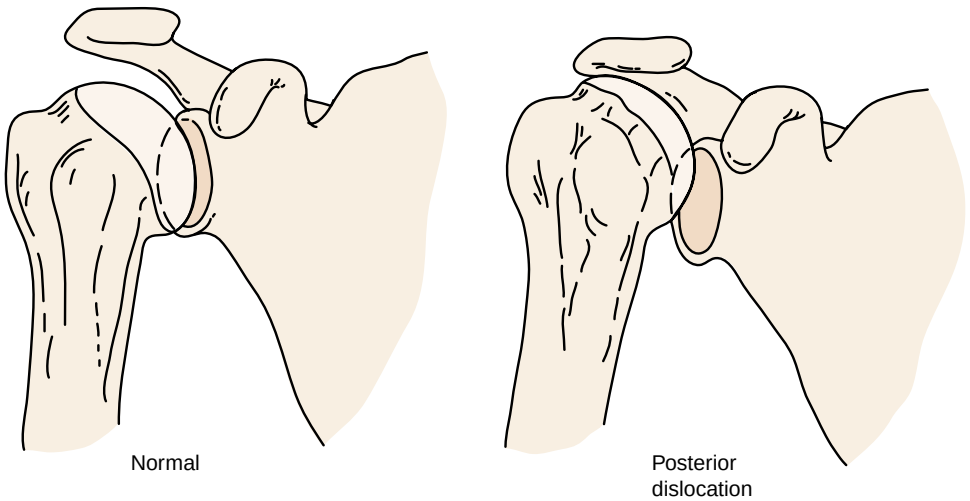

Figure 6-16 "Empty glenoid" sign of posterior dislocation on an anteroposterior x-ray film. Note that the head of the humerus fills the glenoid in the normal x-ray film (*left*). With a posterior dislocation, the glenoid is "empty," especially in its anterior portion (*right*). (From Zachazewski JE, Magee DJ, Quillen WS: *Athletic injuries and rehabilitation*, p 523, Philadelphia, 1996, WB Saunders.)

involved in posterior shoulder dislocations has led to the development of numerous surgical techniques to address this problem.[100] Soft tissue techniques range from a simple arthroscopic posterior labral and capsular plication to a posteroinferior capsular shift.[103] Additional bony techniques include wedge osteotomies with or without a bone block, and humeral rotation osteotomies can be performed in only the most severe and rare cases.[104] With advanced arthroscopic techniques, surgeons have been able to perform arthroscopic stabilization with fairly good functional outcomes.[105] Postoperative care varies widely, but if the practitioner has an appreciation of the techniques used and follows the treatment principles outlined in this chapter, a customized treatment program can be developed to suit each specific situation. However, in all cases of posterior stabilization, the patient is immobilized in neutral to slight lateral rotation to protect the repaired posterior structures.

TREATMENT PRINCIPLES FOR A DISLOCATED SHOULDER

In the management of acute dislocations of the shoulder, an attempt must be made to characterize the injury. A major difficulty in developing a treatment plan from the older literature is the failure of the literature to separate groups adequately according to the underlying degree of injury and the direction of laxity.[106] A glenohumeral dislocation usually is reduced using closed techniques and adequate anesthesia. Post reduction, it is important to recheck the patient's neurovascular status both before and after reduction and to obtain second AP and lateral x-ray films to ensure proper positioning.

With dislocations, subluxations, or instability, a concerted, focused effort at nonoperative treatment with a well-planned, well-coordinated therapy program must be attempted. This principle is more important in cases in which the shoulder is more lax, the collagen hyperelasticity is greater, and/or less trauma is involved in the initial dislocation. If a larger Bankart fracture (i.e., greater than 25% of glenoid area) or other structural deficiencies, such as an acute rotator cuff tear, are found, they usually are dealt with surgically as soon as possible.

For acute anterior dislocations, treatment begins with early controlled immobilization. After closed reduction, the shoulder may be immobilized with a swath and sling or just a sling for up to 6 weeks (in young adults) to prevent extension, abduction, and lateral rotation, which helps to promote capsular healing. Commonly, after 3 weeks, the sling is used primarily to protect the glenohumeral joint from potential injurious outside forces (e.g., a fall, bumping into people) Some researchers have reported that the period or position of immobilization bears little relation to the recurrence of the dislocation,[100] and some authors advocate a shorter period of immobilization (1 to 3 weeks).[36,99] The duration of immobilization depends on the philosophy of the physician or surgeon and the type of reconstruction, if surgical repair is performed.

In the first 2 weeks following reduction, a program of strong isometric deltoid, shoulder abductor, adductor, and biceps work is instituted within the limits of pain tolerance. Scapular control exercises should be initiated right away within a pain-free ROM in standing or prone positions (Figure 6-17). This minimizes muscle wasting, keeping the muscles active following injury and decreases pain as the edema and hemorrhage resolve and the shoulder becomes more comfortable. The sling can be removed for exercises, controlled ROM, and unresisted eccentric exercises (to biceps and triceps) "in the cone" several times a day. When doing biceps exercises, the clinician should use a "block brace" or towel (Figure 6-18) to ensure the

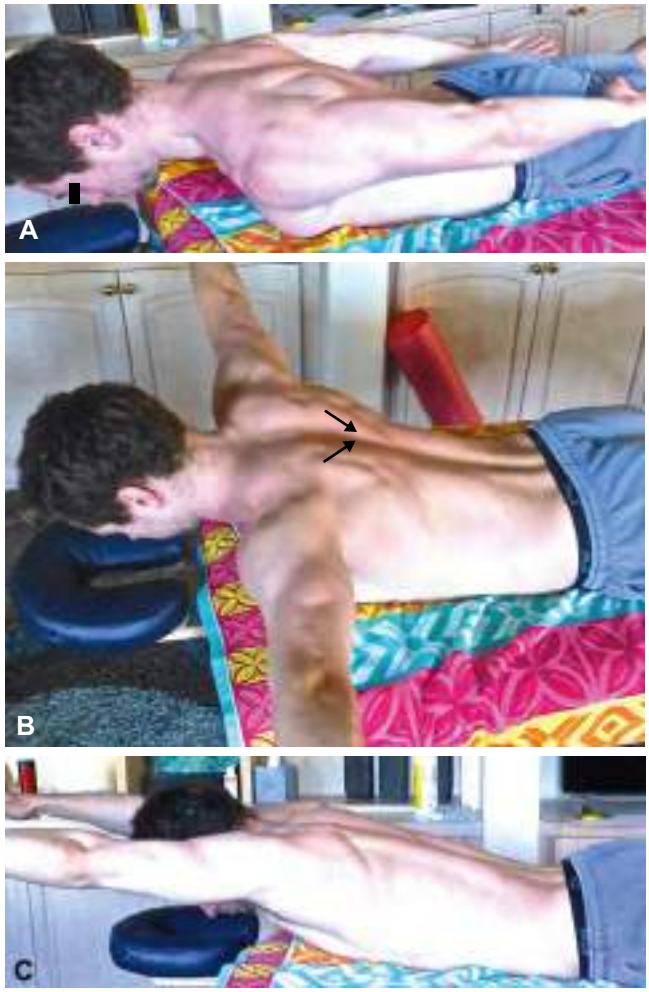

Figure 6-17 "Prone series of 3" scapular exercises used to engage scapula in streamlined position. **A**, Patient lies in prone with hands on gluteals, palms up. Patient then reaches for feet, lifting head and chest off bed, maintaining a straight spine with scapula engaged, core set, and neck in neutral (i.e., not looking up). **B**, Shoulders brought to 90° ("T" position) with thumbs facing forward. Patient then squeezes scapulae together and down (*arrows*) while maintaining a straight spine, core set, and neck in neutral. **C**, Patient brings arms over head and then pulls scapulae down and toward opposite hips while maintaining a straight spine, core set, and neck in neutral.

Figure 6-18 "Block brace" (towel or wedge) to prevent arm adduction in early rehabilitation. Note: The "block" (*arrow*) should be used with caution for glenohumeral rotator cuff exercises especially if the patient does not have good control of scapula. When using a towel at the elbow, the clinician must ensure that the scapula is able to stabilize. If the patient does not have good control of the scapula, stabilization of the shoulder occurs through the elbow with the rotator cuff working through reverse origin insertion to stabilize the scapula.

arm does not adduct or stays in alignment with the body line during elbow movement. Adduction may result in the humeral head being laterally levered against the lateral structures of the glenohumeral joint.

"**In the cone**" implies movement at the shoulder of 30° abduction (i.e., the range in which scapula becomes engaged or the scapular muscles begin to contract to stabilize the scapula and allow it to move in coordination with the moving arm), 30° to 60° forward flexion, and lateral (external) rotation to neutral (the hand does not move outside the plane of the body), with the elbow never extending through the frontal plane (behind) of the body (to prevent the humeral head from translating too far forward) (Figure 6-19). Pendular exercises may also be initiated at this stage (Figure 6-20), starting with momentum pendular exercises (i.e., leaving the arm hanging while rotating the hips) and progressing to controlled pendular exercises (i.e., moving relaxed arm in circles, forward and backward and side to side), and finally to modified pendular exercises (e.g., placing hand on ball and moving ball). Small range, gentle, closed kinetic chain exercises can be initiated, provided the movement is pain free.

The emphasis in the early stages is still on isometric activities, with neutral (i.e., not outside the body plane) shoulder medial and lateral rotator isometric exercises taking precedence using "closed stick" and "power square" drills in the supine position (Figure 6-21). The clinician must ensure that the patient is able to maintain and hold starting postures when doing the exercises. The patient should always start in supine position (to help to stabilize the scapula), performing the exercises in three positions—at the level of the diaphragm, shoulder, and forehead. Exercises should be colinear and coupled so the Hawkins position (which stabilizes the glenoid under the humerus) (Figure 6-22), and the "power square" position (which is the basis of many shoulder movements) may be used as foundations for a number of different exercises.

In addition, concentric exercises through a limited range ("in the cone") are permitted, with the clinician bearing in mind that capsular healing is well under way at 3 weeks. The limits of range are determined by pain and whether the patient can comfortably control the movement. When stability is obtained "within the cone," the patient can carefully begin to increase the ROM outside the cone.

Controlled movements are essential during proper rehabilitation. The controlled active movement applies small amounts of stress to the joint structures to reduce the adverse effects of immobilization on the glenohumeral joint.[36,42,107,108] During this time, active abduction beyond 20° to 30°, forward flexion beyond 90°, or lateral rotation past neutral (outside the cone) should be performed carefully. In older individuals, in whom the danger of stiffness leading to adhesive capsulitis and frozen shoulder is greater than the risks of redislocation, the movement program is initiated at the beginning. Once immobilization has ended and dynamic control achieved, the treatment protocol follows the same principles as for treatment of patients with instability (see later discussion).

SURGICAL TREATMENT OF SHOULDER INSTABILITY

Indications for surgery and open reduction include the inability to reduce by closed reduction, presence of a large flake of avulsed bone on the inferior glenoid margin (which may contribute to future instability), a fracture through a significant portion of the articular surface, vascular impairment, and an associated displaced tuberosity fracture or a fracture of the neck of the humerus. On occasion, very athletic individuals may want a guarantee of stability in the shoulder by having early surgery. Postoperative care depends on the type and degree of associated problems that led to open reduction and repair.

Surgical procedures may be arthroscopic or open and involve either a soft tissue or bony reconstruction. The spectrum of surgical approaches depends largely on the pathology involved. Patients with largely soft tissue lesions, such as simple labral tears, are ideal candidates for a simple arthroscopic Bankart repair. If the inferior capsule is avulsed from the humeral side (i.e., an HAGL lesion), an open or arthroscopic capsular repair is indicated. A capsular plication is indicated for the rare occasion when surgery is indicated for the patient with multidirectional instability. Bony procedures also may be performed,

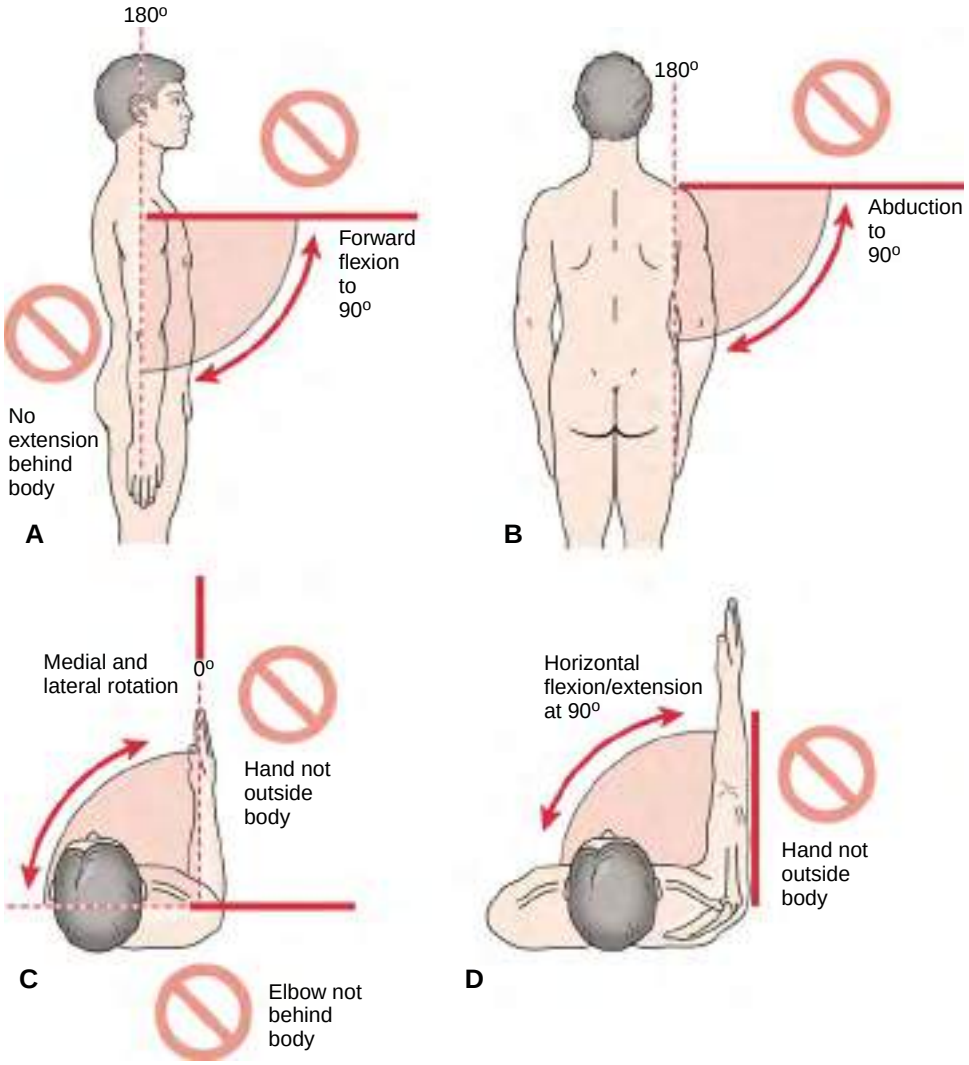

Figure 6-19 Low-risk postsurgical movement allowed "in the cone." **A**, Forward flexion to 90°. **B**, Abduction to 90°. **C**, Lateral rotation—hand not outside the body, elbow not behind body. **D**, Horizontal flexion—hand not outside body. Note: Horizontal flexion/extension is also called horizontal adduction/abduction. (Modified from Magee DJ: *Orthopedic physical assessment*, ed 6, p 273, Philadelphia, 2014, WB Saunders.)

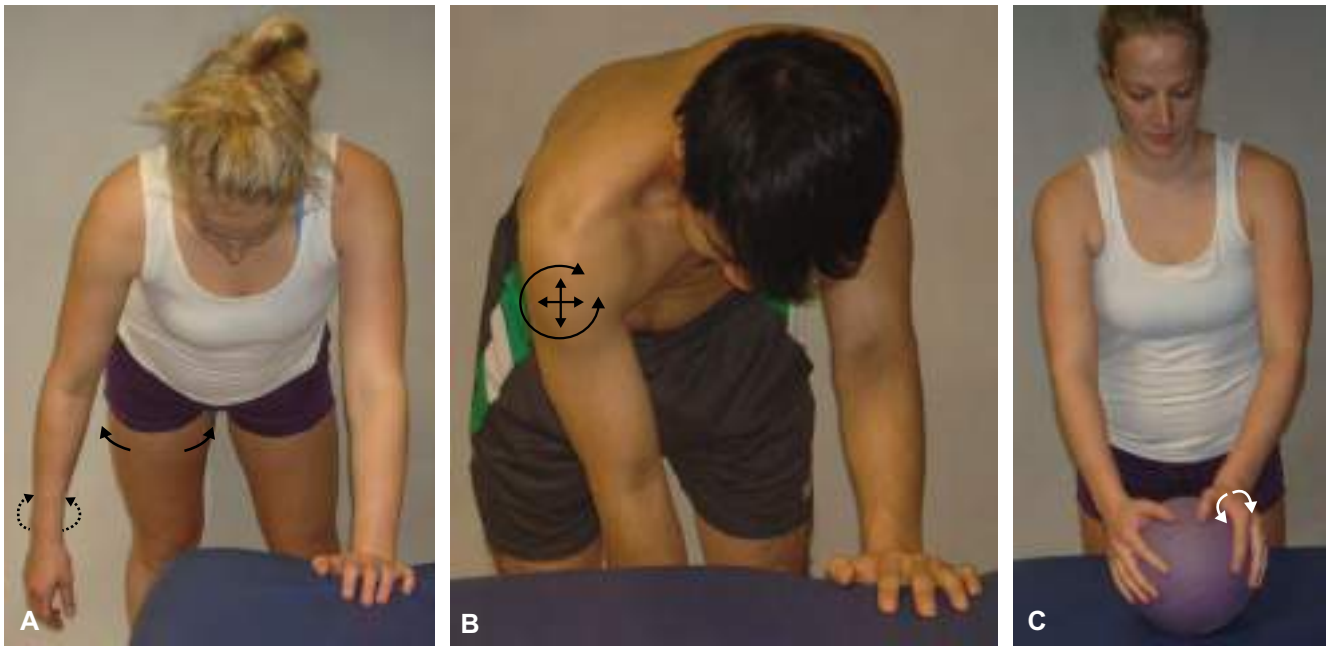

Figure 6-20 Pendular exercises. **A**, Injured arm hangs down free. "Momentum" pendular movement achieved by swinging hips to initiate movement in different directions. **B**, Active controlled pendular movement—muscles control movement in different directions. **C**, Ball pendular movement. Both hands press down on a ball to compress humeral head into glenoid. The unaffected left arm moves the ball in circles, back and forth, or side to side while injured right arm "goes along for a ride."

mainly focusing on restoring anteroinferior glenoid bone loss with local bone graft from a transferred coracoid and the attached conjoined tendon. Historically the Bristow procedure involves transferring the tip of the coracoid, whereas the more recently popularized Latarjet procedure involves transferring a larger fragment of the coracoid, allowing for a more robust bony reconstruction of the anteroinferior glenoid bone stock (Figure 6-23).[29] This procedure has the added stabilizing effect of lowering the inferior half of the subscapularis muscle belly, as well as adding the dynamic sling effect of the conjoined tendon with the shoulder in positions of apprehension (i.e., abduction and lateral rotation). This procedure is usually reserved for severe cases of instability in which there is substantial glenohumeral bone loss and patients who require a robust repair, such as athletes involved

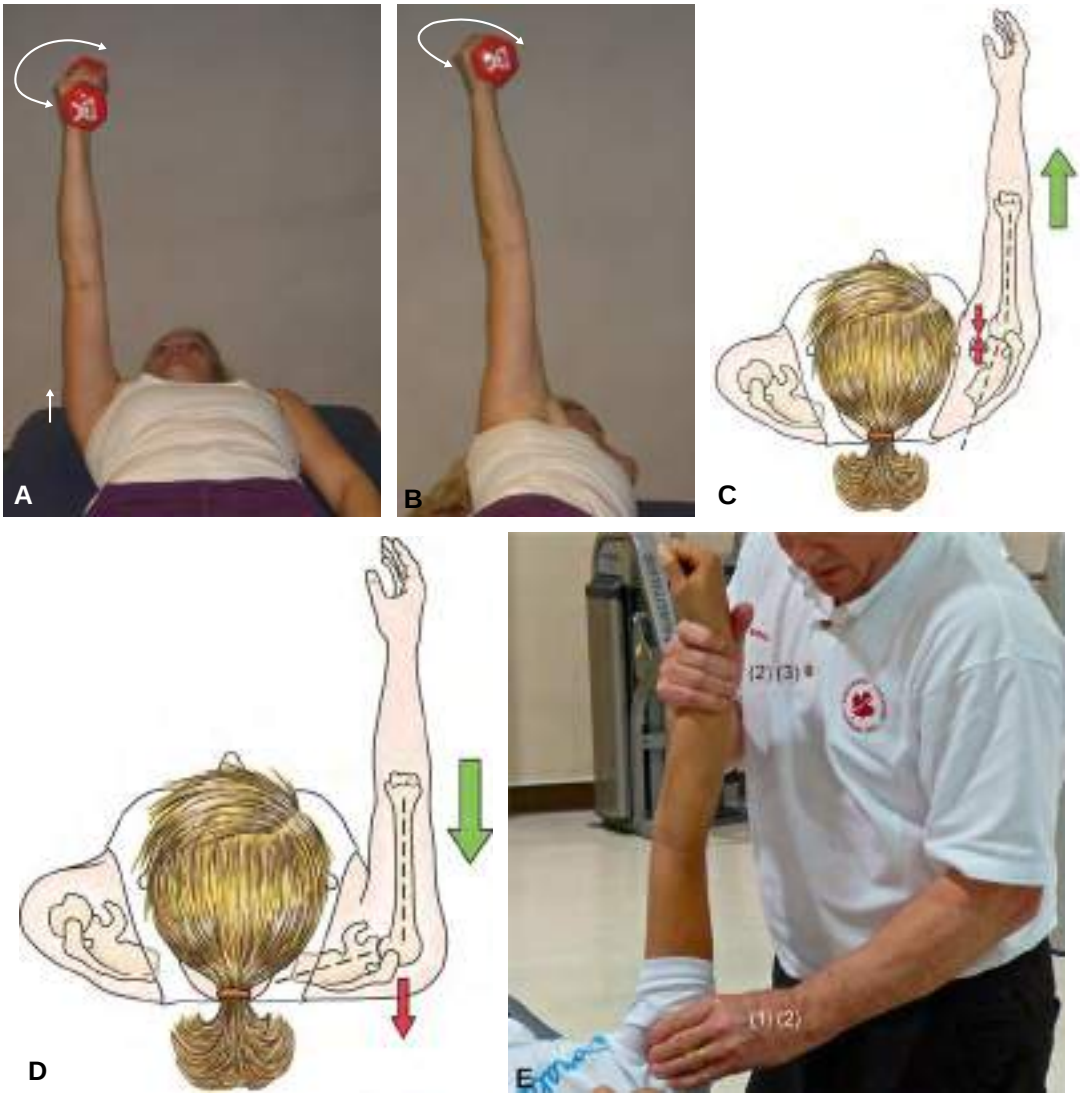

Figure 6-22 Hawkins ("punch out") position ensuring glenoid is sitting under humeral head for added stability. **A,** In forward flexion doing circles, horizontal, or up and down movement. **B,** In abduction. **C**, Line drawing shows how the glenohumeral joint is more stable with the glenoid lying under the head of the humerus in the Hawkins position than in **D**. **E**, To gain arthrokinematic control, the clinician applies resistance in all directions at the glenohumeral joint (*1*). To ensure arthrokinematic control at the glenohumeral joint while doing osteokinematic movement, the examiner applies resistance at the glenohumeral joint (arthrokinematic stabilization) and the wrist (osteokinematic movement) (*2*). To strengthen osteokinematic movement, the clinician applies resistance at the wrist (*3*) while palpating the glenohumeral joint to ensure there is minimal translation and to ensure arthrokinematic control during the perturbations. **(C** and **D,** modified from Matsen FA: Stability. In Matsen FA, Lippett SB, Sidles JA et al: *Practical evaluation and management of the shoulder,* p 64, Philadelphia, 1994, WB Saunders.)

in contact sports. The inferior glenoid can also be augmented by other bone graft options, including iliac crest and other cadaveric sources.[109] Large Hill-Sachs lesions have been addressed using allograft bone implantation to the humeral head defect or suturing the posterior cuff into the Hill-Sachs lesion. The latter procedure is called a *Remplissage*, which is the French word meaning "to fill" (Figure 6-24).[110,111] Other procedures have been described and may now be only of historical interest. Such procedures as the Putti-Platt and Magnuson-Stack involved excessive tightening of the anterior structures of the shoulder, specifically the subscapularis and anterior capsule, thus restricting lateral rotation and thereby preventing pathological translation and engagement of the Hill-Sachs lesion. Unfortunately, there is a report of these procedures directly resulting in early osteoarthritis of the glenohumeral joint.[112] Excessive anterior capsular tightness results in posterior subluxation of the humeral head on the glenoid, and this eccentric loading of the glenohumeral joint can lead to the rapid development of arthritis. In addition, any procedure that involves restriction of lateral rotation is very undesirable to an athlete who requires full shoulder motion.[36,113–128]

Complication rates of instability surgery vary depending on the procedure performed. Arthroscopic procedures carry a higher risk of recurrent dislocation, especially in young athletes involved in contact sports with significant bone loss.[29,129] In the past, these arthroscopic approaches have been associated with worrisome redislocation rates.[130,131] With strict technical criteria,

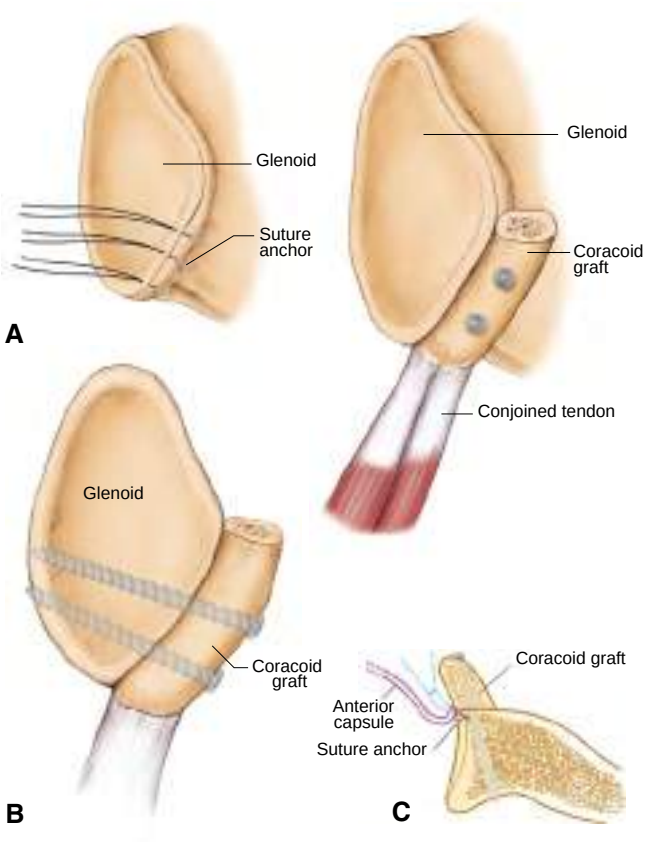

Figure 6-23 Latarjet procedure. **A**, Conjoined tendon of biceps sutured to glenoid. **B**, Screws hold conjoint tendon. Note how graft restores pear shape of glenoid. **C,** Graft is placed so that it acts as an extension of the articular arc of the glenoid. (Redrawn from Burkhart SS, De Beer JF: Traumatic glenohumeral bone defects and their relationship to failure of arthroscopic Bankart repairs: significance of the inverted-pear glenoid and the humeral engaging Hill-Sachs lesion, *Arthroscopy* 16(7):677-694, 2000.)

including restoration of the proper resting length of the anterior-inferior glenohumeral ligament and recreation of the labral "bumper" or "chalk-block" effect, current arthroscopic techniques offer success rates comparable to open techniques. Strict clinical guidelines for suitable patient selection also are important. Open bone grafting procedures, such as the Latarjet procedure, have lower recurrence rates documented in the literature but unfortunately have higher rates of infection, hematoma formation, iatrogenic nerve injury, and degenerative changes related to poor bone graft positioning.[132,133]

With soft tissue surgical techniques, it is important to allow sufficient time for capsular healing with minimal stress to these tissues. With bony techniques, such as the Latarjet procedure, a period of approximately 4 to 6 weeks is required to allow for union of the bone block before stress is applied. After operative treatment, the traditional Putti-Platt procedure has a 1% to 5% incidence of recurrent dislocation; the Magnuson-Stack operation, 1% to 9%; and the Bristow repair, 1% to 6%.[125] These results should be compared with the increasingly successful outcomes of arthroscopically assisted techniques, which, as surgeons have become more experienced, have reached and surpassed the open techniques. Return to a high level of function is the rule with an appropriately selected and executed technique performed with due regard for the pathological lesion, follow-up rehabilitation, and the activity goals of the patient.

Although postoperative therapy is based on tissue healing principles and proper stress to the tissues, each surgeon has certain criteria that he or she wants to be followed in a rehabilitation program. The clinician must be aware of these criteria, including the reasons for them, along with any restrictions or modifications to treatment, to prevent any misunderstanding with the surgeon and patient's desired outcome.

POSTSURGICAL TREATMENT OF THE SHOULDER

The basic rehabilitation plan may be modified, depending on the type of surgical procedure performed, precautions to treatment noted by the surgeon, the individual surgeon's preferences, and whether pain, restriction, or both are factors. For the most part, the treatment of patients who have undergone arthroscopic procedures parallels that for patients who have had open techniques, although the former have less tissue disruption and muscle wasting. The patient's willingness to move and the quality of the patient's movements also are of concern to the clinician. Only broad guidelines are given here for progression. The treatment principles remain constant: to relieve

pain, observe for complications, regain muscle control, strengthen, regain ROM safely, improve endurance, and retrain proprioceptive control. These guidelines form the foundation of an activity-based protocol. Specificity plays a major role with each program being individualized to the patient and his or her activities.

Principles of Specificity Related to Sports and Rehabilitation

Every activity makes specific demands in terms of load (stress), rate, repetitions, duration, and neurophysiological adjustment. When a new or modified task with a different demand in intensity, load, rate, repetitions, duration, or neurophysiological adjustment is instituted, an entirely new pattern of adjustment must be acquired. Therefore training and rehabilitation must be specific to the sport or activity in which the patient hopes to take part or return to. This principle applies to all of the following:

1. Cardiovascular fitness (aerobic and anaerobic activities)
2. Strength training (isometric, isotonic [concentric and eccentric], econcentric, isokinetic)
3. Open-chain and closed-chain activities
4. Motor skills and motor learning
5. Flexibility (static, dynamic)
6. Coordination
7. Proprioceptive or kinesthetic control (stimulation of different mechanoreceptors)
8. Timing, reaction time, and movement time
9. Progressions
10. Biomechanical demands
11. Tissue healing and stress on tissues

To achieve progression in these areas, the clinician proceeds from:

1. General to specific
2. Simple to complex
3. Easy to difficult
4. Lesser to greater volume
5. Lesser to greater intensity
6. Lesser to greater frequency
7. Smaller to greater ROM

Modified from Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 527, Philadelphia, 1996, WB Saunders.

Postsurgical treatment initially concentrates primarily on the scapula. Scapular control exercises focus primarily on the lower and middle trapezius and serratus anterior. These exercises include scapular retraction, depression, protraction, and elevation with the arm at the side. Careful observation should detect compensatory trunk, pelvic, and especially shoulder postures that indicate incorrect firing (i.e., contraction) sequences and lack of proper stabilization. As the patient improves, the glenohumeral joint can be taken out of "the cone" into abduction, scaption (i.e., plane of the scapula), forward flexion, and other elevation movements, provided the patient can maintain control of the scapula and can stabilize the humerus in the glenoid. Lateral rotation should be performed only with extreme care and never beyond neutral in the early stages of rehabilitation (i.e., the hand should never go outside the sagittal plane of the body, and the elbow should never go behind the frontal plane of the body). These are important early rules, regardless of the surgical procedure used. Keeping inside "the cone" reduces the stress on the anterior labrum and the repaired soft tissues to a minimum. During rotation exercises, the clinician should watch for excessive scapular winging or motion because the scapula may be compensating for tight medial or lateral rotators. If present, this can be treated with joint play techniques or muscle energy or proprioceptive neuromuscular facilitation (PNF) techniques, depending on whether the restriction is caused by inert (i.e., collagen) or contractile (i.e., muscle) tissues.

As control of the scapula is being achieved, isometric exercises to the muscles that control the humeral head can be initiated, starting with light contractions (importantly, not maximum voluntary contraction [MVC]) and progressing to stronger isometric contractions for the deltoid and rotator cuff muscles. Initially the clinician should start with exercises that cause the muscles controlling movement at the glenohumeral joint to compress the humeral head into the glenoid for stability (see Figure 6-22). If the patient has good pelvic and scapular control, plank exercises may be performed as long as correct posture can be maintained while doing the exercise (see Figure 6-10).

Postoperative exercises for the shoulder should not cause sharp or severe pain. It is acceptable for the patient to be slightly uncomfortable when doing exercises, but the exercises must be performed with confidence and a sense of control. The discomfort should disappear when the exercise stops. The clinician must ensure that the exercises are performed correctly. Correct movement patterns are more important than load or speed. Once proper scapular control is achieved up to 30° of abduction, the clinician can move to 30° to 90°, and when proper dynamic control has been gained in that range, the patient can be progressed to 180°.[134]

Once control of the scapula is achieved, isometrics to the muscles of the glenohumeral joint are instituted at several positions in the ROM below shoulder level, with no lateral rotation beyond 0°. The positioning and resistance depend on the patient's response to pain and discomfort. The clinician must ensure that compensatory pelvic, trunk, and cervical postures are addressed and that the scapular and humeral control (i.e., stabilization) muscles receive attention.[35] The patient is instructed to perform proper functional isometric position exercises in abduction, medial rotation, lateral rotation (to 0°), extension, and a "full can" (neutral with thumb up) scaption (below horizontal) for the supraspinatus.

Rhythmic stabilization exercises and co-contraction at the joint (e.g., supine or lateral Hawkins positions [see Figure 6-22, *C*]) can be performed to the affected shoulder. The progression of stabilization-co-contraction sequence follows three steps in each selected isometric position. Ensuring the patient has assumed a correct posture and has the appropriate scapular muscles engaged and, if possible, the glenoid under the head of the humerus for greater stability (e.g., supine Hawkins with punch out [see Figure 6-22, *C*], the clinician places one hand around the

glenohumeral joint and one hand distally near the wrist. For the first step, the clinician applies perturbations to the humeral head while asking the patient to hold the head of the humerus stabilized (i.e., not moving or translating) in the glenoid. This is called **establishing arthrokinematic control** at the joint. The hand around the wrist offers no resistance but is there to keep the patient's arm extended. Once arthrokinematic control at the glenohumeral joint is gained, the clinician can progress to the second step, in which the clinician applies perturbations not only to the humeral head but also at the wrist. It is important that the clinician ensures that minimal translation occurs at the glenohumeral joint during the double perturbations and the hand applying the perturbations to the humeral head applies only enough counterforce that translation does not occur. Thus this hand is applying perturbations while palpating to ensure no unwanted translation occurs at the glenohumeral joint. If translation does occur, the wrist perturbations being applied at the wrist are too strong. The hand at the wrist can also apply "eccentric breaks" to the whole arm. This second phase establishes **osteokinematic control of the arm** along with arthrokinematic control at the glenohumeral joint. The final or third stage is resistance at the wrist doing eccentric breaks into functional movements. The position of the clinician's hands is the same (around the humeral head and at the wrist), and perturbations are applied only at the wrist into functional positions. The hand around the glenohumeral joint only palpates to ensure minimal translation is occurring at the glenohumeral joint. The result should be eccentric movement of the arm with minimal translation at the glenohumeral joint, which mimics normal arthrokinematic control at the glenohumeral joint and osteokinematic control of the arm. Once co-contraction and coupling are obtained, functional isometrics can be started. If the patient is having difficulty engaging different muscles (e.g., different parts of the deltoid—anterior deltoid often does not engage or contract following injury to the anterior shoulder), electrical stimulation may be used (Figure 6-25).

If the patient complains of pain in the shoulder, ice can be applied to give some relief. In addition, active exercise to the other joints of the arm, cervical spine, trunk and pelvis, and the rest of the body may be instituted to ensure involvement of the whole kinetic chain.

As the patient improves (as evidenced by decreased pain and discomfort), isotonic exercises, especially flexion and extension, can be initiated (usually by the third or fourth day), again below shoulder level and with no lateral rotation beyond 0°, within the pain-free and controllable range. By the fourth day, medial and lateral rotation to 0° with the arm in the adducted position may be performed very carefully. For the lateral rotators, only very careful isometrics should be performed, to prevent excessive stress to the healing tissues. By the fifth day, the patient may begin assisted abduction. To achieve proper scapular and humeral control, exercises are used when appropriate and when strength and pain allow.[134] Once the pain has diminished and as the patient is weaned from the sling, the clinician can follow the treatment concepts for rehabilitation of shoulder instability described later in the chapter.

Figure 6-25 Electrical stimulation of anterior deltoid.

PITFALLS OF TREATMENT FOR SHOULDER INSTABILITY AND IMPINGEMENT MANAGEMENT

As with any treatment, the clinician must be aware of common pitfalls. If the following mistakes are kept in mind, the rehabilitation program will have every chance of success.

1. *Failure to perform a complete and thorough assessment.* The assessment must involve the shoulder complex, trunk, pelvic core, and lower kinetic extremity to determine which structures are weak and which are tight and to check for incorrect movement patterns.[85,135]
2. *Failure to assess and address scapulohumeral dysfunction.* The clinician must remember that scapular motion is dynamic for the most part and that the scapula constantly moves, even as it functions as a stable base from which most of the glenohumeral muscles originate. Proximal stability (i.e., scapular control) must be achieved early in the rehabilitation process, before distal mobility (i.e., glenohumeral movement) is encouraged.[47,85] Coordinated scapulohumeral movement is affected by muscle length, muscle strength (especially eccentric muscle strength), capsular tightness, the type of muscle contraction (e.g., isometric, concentric, eccentric, econcentric), timing, and pain. Scapular movement itself is affected by gravity, altered posture, tight muscles, whether the activity is an open or closed kinetic chain, the amount of load the arm lifts, and the speed of arm movement. The clinician must keep all these issues in mind when progressing activity.
3. *Failure to understand the mechanics and demands of the activities to which the patient is returning.* The clinician must have a clear picture of these activities, whether they involve sports or are part of the

individual's everyday life, such as work or recreational activites.[85] Driving is obviously not the same as throwing. Although patients may present with similar types of painful movement, the clinician must be able to assess the problem with a clear understanding of the demands of the activities the patient wants to accomplish. The practitioner must understand that an injury in one part of the body may cause an alteration in another part (i.e., alteration in shoulder mechanics, movement patterns, and how they are accomplished). The shoulder is a link in a kinetic chain of movement.[2–4,85] This kinetic chain allows the generation, summation, transfer, and regulation of forces from the foot to the hand during everyday activity.[2–4,47,81,85] Although individual muscles are the early emphasis in rehabilitation, eventually, as the patient progresses, the whole body must be integrated with shoulder movement patterns (i.e., so that the lower extremity and "core" drive the shoulder).

4. *Failure to deal with any hypomobility early in the treatment to ensure that the joint can regain normal arthrokinematic movement.*[85] Particular attention should be paid to tightness of the posterior glenohumeral capsule, restricted glenohumeral medial rotation (GIRD) or imbalance between the medial (internal) and lateral rotation ROM,[3] tightness of the pectoralis minor and pectoralis major muscles, tightness of the inferior glenohumeral ligament (caudal glide of the glenohumeral joint), and hypomobility in the thoracic spine and ribs.[3] Treatment of structures must ensure proper movement patterns. Testing for tight anterior structures may be accomplished by doing the Mattison 20 cm test and the horizontal extension test. For the **Mattison 20 cm test**, the patient lies supine while the examiner places one hand over the humeral head to palpate humeral head anterior movement with the patient's arm in 90° abduction. The clinician, using the other hand, medially rotates the patient's arm over the clinician's arm (Figure 6-26). Normally, the patient's hand should be within 20 cm (horizontally) of the ASIS on the same side without the humeral head projecting anteriorly. For the **horizontal extension test**, the patient again lies supine with the arm abducted to 90°. The examiner is positioned such that the elbow of one hand lies over the humeral head to prevent it translating forward. While holding the humeral head down, the examiner horizontally extends the patient's arm (Figure 6-27). The examiner should normally be able to horizontally extend the arm at least 20° to 30° without the humeral head translating anteriorly.
5. *Failure to make sure that stretches are performed properly.* Although stretching may be necessary to restore normal arthrokinematics in a joint, it should not compromise other structures (e.g., scapular stabilizers)

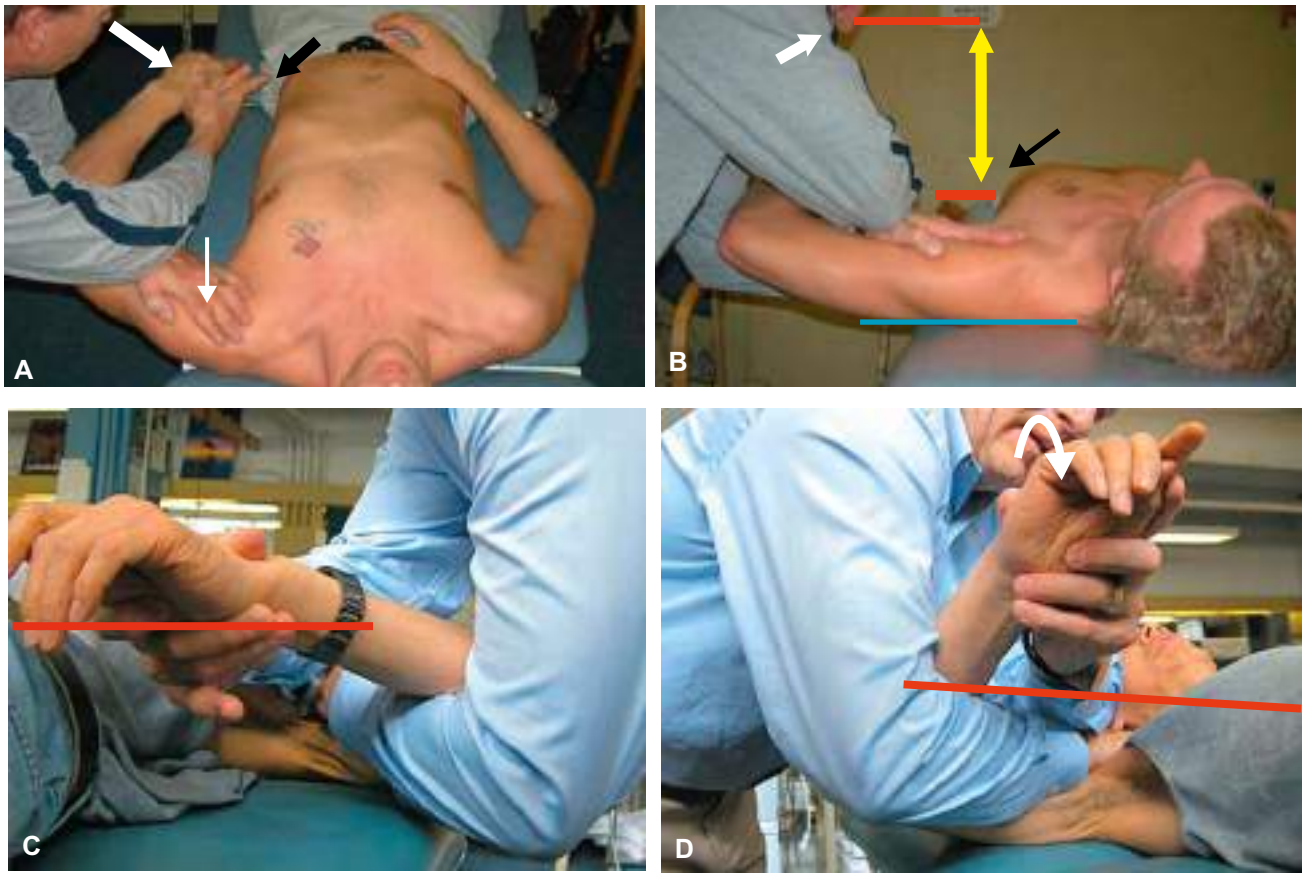

Figure 6-26 Mattison 20 cm test. **A**, Medial rotation of the patient's arm over the clinician's arm. Note how the clinician is holding the humeral head down with his hand. **B**, The distance from the patient's wrist to the ASIS is measured. **C**, Negative test. **D**, Positive test.

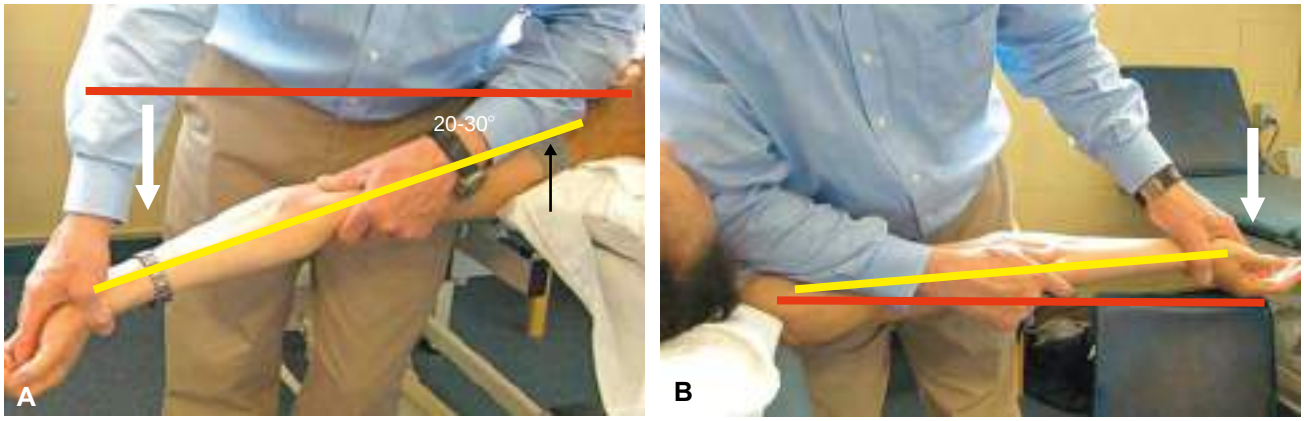

Figure 6-27 Horizontal extension test. Note how the examiner is using his elbow to prevent anterior movement of the humeral head in the glenoid. **A**, Normal. **B**, Restricted movement.

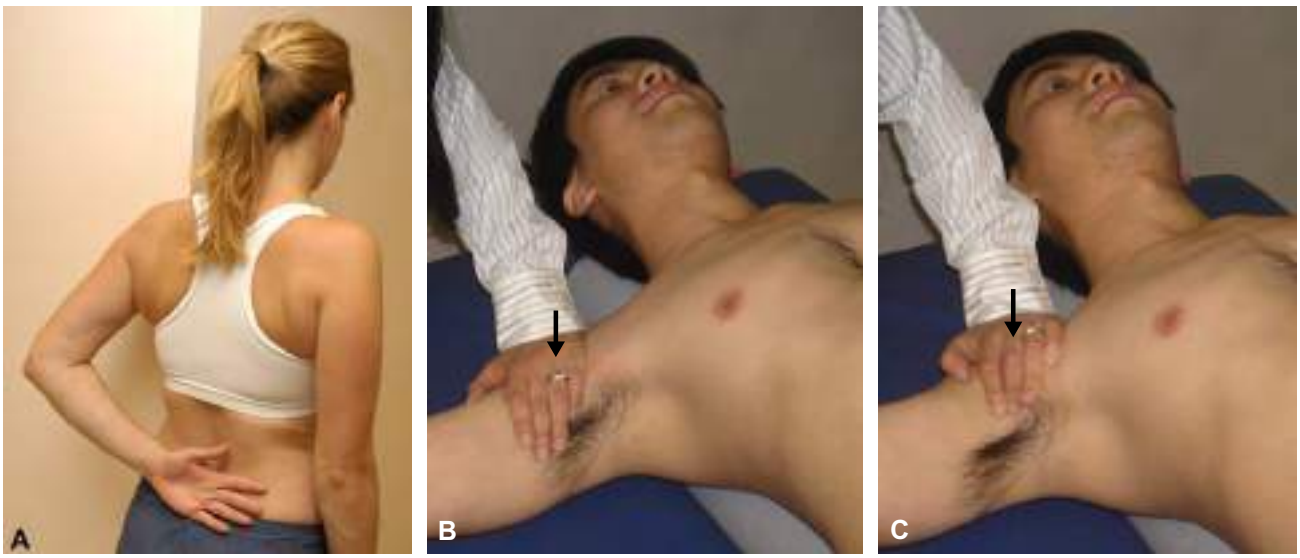

Figure 6-28 Stretching pectoral muscles. **A**, Doorway stretch (shoulder should not hike up) for pectoralis major. **B**, Clinician stretching pectoralis major (push down on head of humerus). **C**, Clinician stretching pectoralis minor (push down on coracoid process).

or reinforce faulty movement patterns. The clinician should teach the patient how to do stretches correctly so that normal tissues are not compromised and surgically repaired structures are not abused.[3,85] Anterior stretching involving a tight pectoralis major may be done by doing a "doorway" stretch (Figure 6-28, *A*). Pectoralis major and minor may be stretched by the clinician ensuring that the humeral head and scapula do not tilt forward and by giving resistance over the coracoid process for pectoralis minor and over the humeral head for pectoralis major (Figures 6-28, *B* and *C*, respectively). Posterior scapular stretching should be performed in three positions—at nipple-diaphragm line, shoulder-acromion line, and chin-mouth (Figure 6-29). Traction stretching (Figure 6-30) can be used to stretch the whole upper kinetic chain, but the clinician must ensure stress is applied to (i.e., is felt by the patient in) the tight structures. The sleeper stretch and modified sleeper stretch (Figure 6-31) are two examples of stretches for a tight posterior glenohumeral joint capsule, provided the clinician is sure the stretching is occurring posteriorly and is not the result of impingement.

6. *Failure to control pain, fatigue, and painful movement.* Exercises must be virtually pain free (pain is less than 4 on a 0 to 10 pain scale [0 being no pain; 10 being the worst pain the patient can imagine]). Otherwise, rehabilitation will be compromised. Ideally, exercises should be performed in a pain-free ROM. The clinician must design exercises that enable the patient to do the activity without pain. It is important to watch for signs of fatigue and to terminate the exercise before excessive fatigue leads to incorrect movement patterns. For example, early activity or overactivity of the upper trapezius is an early sign of fatigue in shoulder exercises.
7. *Failure to correct poor posture.* A normal posture (i.e., no rounded shoulders) is important for reducing anterior pressure on the anterior labrum and anterior structures of the shoulder both statically and dynamically, so the clinician must watch the patient closely to ensure correct

Figure 6-29 Stretching the posterior capsule of the glenohumeral joint. The clinician forward flexes the arm to 90° and then pushes the humeral head backward by pushing down on the elbow. While pushing down, the clinician carefully adducts the arm, increasing the tension on the posterior capsule. The stretch is performed at the nipple-diaphragm line, shoulder acromion line, and chin-mouth line, and the patient should feel the stretch posteriorly.

Figure 6-30 Self-traction stretch. **A**, In elevated forward flexion. **B**, In abduction. Patient should relax muscles around glenohumeral joint as much as possible while doing the stretch.

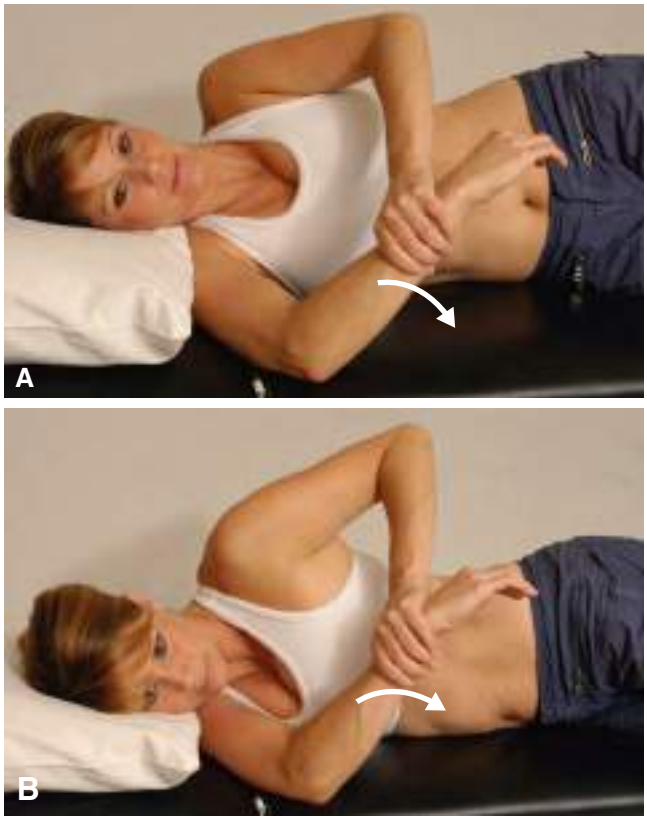

Figure 6-31 **A,** Sleeper stretch. **B,** Modified sleeper stretch.

posture and muscle action during movement. The clinician must make sure the patient can maintain a neutral pelvis position (i.e., patient can hold the neutral pelvis statically and dynamically by ensuring correct alignment of the pelvis and spine), proper trunk alignment, rib mobility, and scapular positioning. The clinician should also teach the patient to maintain the correct shoulder position by discouraging exercises that cause rounding of the shoulders (e.g., scapular dumping).

8. *Failure to control for fatigue and compensating postures.* The number of repetitions a patient is asked to do should be based on the number the patient can do correctly with control. The clinician should be specific in the instructions regarding the number of repetitions or sets the clinician wants the patient to complete. Normally, a specific number of repetitions should not be given; rather, the clinician should watch for and

Indicators of Fatigue or Loss of Control or that Load Being Used is Too Great

- Erratic movement
- Incorrect movement patterns
- Breath holding
- Inability to "hit" target
- Phasic movements
- Instability jog or catching movement
- Trick movements, loss of control of the scapular base
- Facial signs of fatigue

teach the patient to be aware of evidence of fatigue. The patient should recognize fatigue and its compensating postures and stop when they occur. Motor control, muscle memory, the firing (contraction) sequences of muscles (stabilizers, then mobilizers), fatigue patterns, and muscle and cardiovascular endurance all play major roles in the rehabilitation process.

9. *Failure to note habitual exercises performed in compensatory postures.* Many clinicians tend to progress exercise routines too quickly, before achieving isolated muscle control, especially of the scapular control muscles. Scapular control implies that the patient is able to control the scapula through contraction of the scapular force couple (lower and upper trapezius, serratus anterior) (see Figure 6-2, *A*). This is essential because it enables the patient to establish proper scapular rhythm while moving the arm (i.e., the humerus) in a controlled fashion. Many activities start with little or no weight, often with gravity eliminated or only very small amounts of weight (0.5 to 0.8 kg [1 to 2 lb]). Progression in resistance should be small. No advantage is gained from lifting heavy weights.
10. *Failure to select appropriate (low risk) exercises.* When asking the patient to do exercises, the clinician must remember to correct the patient's posture, ensure scapular control or stabilization, ensure functional isometric exercises are performed in uncompromising positions, and retrain co-contraction or arthrokinematic control at the glenohumeral joint. Speed of movement should only come toward the end of treatment and should not be a major focus until the functional phase. Initially the goal should be to use low-risk exercises that use the rotator cuff to compress the head of the humerus into the glenoid, such as two-hand stick drills (narrow and wide handle), medial and lateral rotation, and wiper drills (Figure 6-32). Such exercises may include rhythmic stabilization and co-contraction using the supine or lateral Hawkins position (i.e., placing the glenoid under the humerus) (see Figure 6-22, *A* and *B*).[2–4,85] Hawkins drills can include, in the Hawkins positions, small circles, bilateral open and closed gate, scapular movements on a stable arm, one and two arm punch outs, and table and floor push ups with a plus to flys and arm scissors and, as the patient progresses, core exercises—scapular push ups, wall or floor planks (hold core while allowing scapula to move in and out of winging), lateral plank, and V-plank (Figure 6-33).

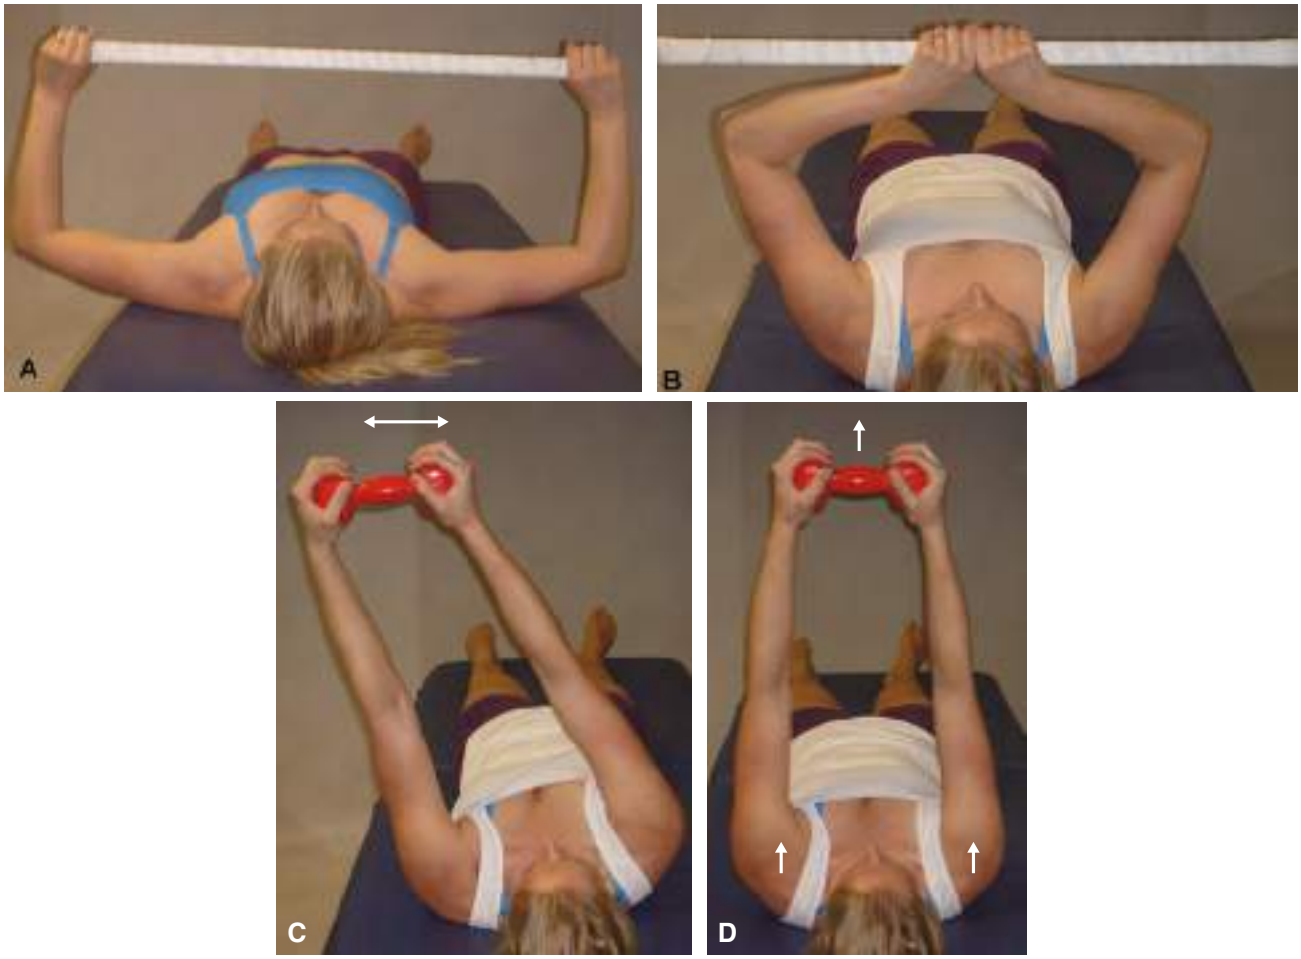

Figure 6-32 Low-risk exercises. **A**, Stick drill–wide hands (power square position). **B**, Stick drill–narrow hands. **C**, Supine wiper drill (can go side to side and up and down to 90°). **D**, "Reach for ceiling" then do circles while maintaining reach. (All exercises can be done in the three zones - i.e., level of diaphragm, shoulder, and forehead.)

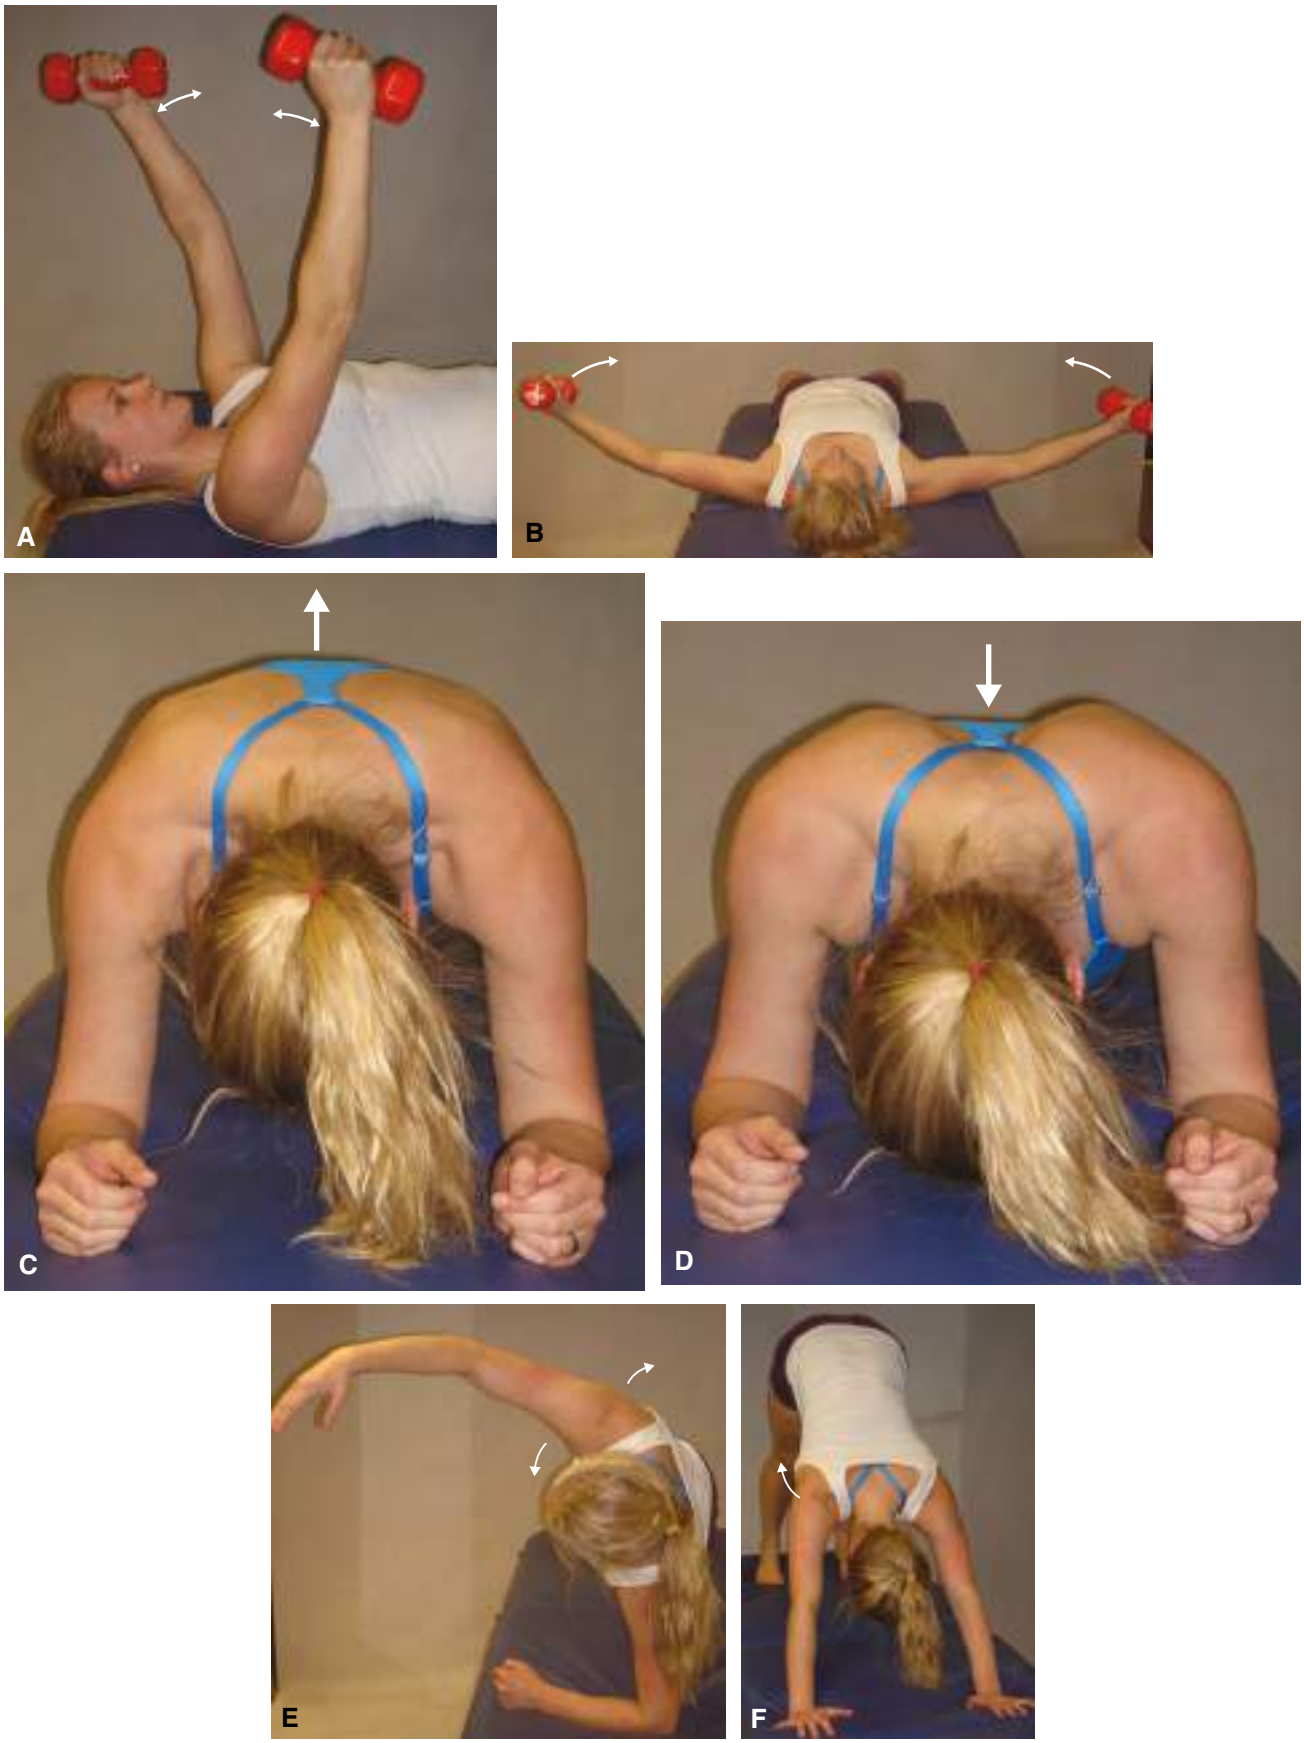

Figure 6-33 Advanced low-risk exercises. **A**, Scissors (punch to ceiling). **B**, Pectoral flies. **C**, Scapular push up (stabilize core, straight spine, scapula should be flat against ribs). **D**, Scapular push up down (relax). Note how scapula wing away from ribs. **E**, Lateral plank with arm motion. Note how left humerus is compressed into glenoid. Motion of right arm and trunk allows arthrokinematic slide at left glenohumeral joint. **F**, "V" plank. Patient can roll back and forth over shoulder again allowing arthrokinematic sliding at the glenohumeral joint.

Low-risk exercises that help to stabilize the humeral head and keep the shoulder away from compromising pinching or impingement postures are preferable. While the patient does the stabilization exercises, the clinician can palpate the humeral head to make sure that it is properly aligned, compressing into the glenoid, and not translating excessively which would indicate loss of arthrokinematic control. The clinician also can make sure that the anterior deltoid contracts and is part of the exercise routine. Shoulder depression against tubing resistance while doing circles or figures of eight (Figure 6-34) is another example of a low-risk exercise. Punch out exercises (Figure 6-35, *A*), dynamic hug (Figure 6-35, *B*), and push ups with a plus (Figure 6-35, *C*) along with PNF exercises (D2 patterns) (Figure 6-36) work the serratus anterior and help to ensure minimal upper trapezius activity. Forward flexion wall exercises with the hands on a ball in a closed kinetic chain (Figure 6-37) also are low-risk exercises. The clinician's repertoire of rotator cuff exercises must include more than simple medial and lateral rotation in neutral.

The empty can position puts the glenohumeral joint in a compromising impingement posture and in the anterior tipped (i.e., scapular anti-tilt) position. The classic empty can strengthening exercise actually is an impingement posture and is not functional for most activities.[136] This exercise does not help to re-establish scapulohumeral rhythm and often is painful early in the rehabilitation process, leading to counter-productive exercises.

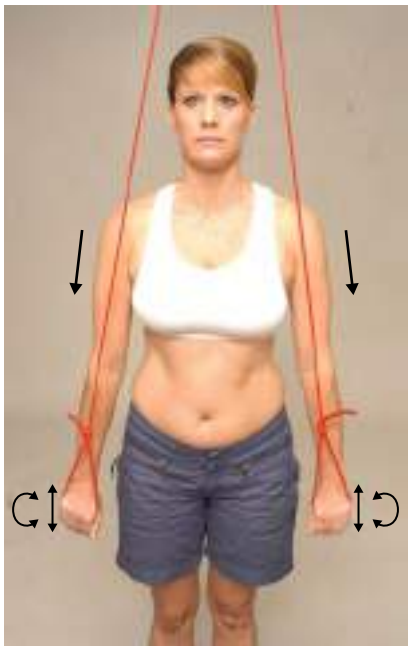

Figure 6-34 Shoulder depression (i.e., dynamic caudal glide) using tubing. Example exercises include having a patient do circles or figures of eight or write his or her name. Clinician should always watch for scapular control.

The clinician should always be aware that traditional weight room exercises used to strengthen the shoulder musculature and surrounding structures can often compound an injury and should be discouraged until the person is in the functional stage of recovery. Traditional gym exercises, such as the bench press and military press, may compound or precipitate shoulder problems. A common mistake of clinicians is to introduce these exercises too early in the rehabilitation program. Early rehabilitation concentrates on training the individual stabilizers of the scapula and humerus. Once this has been achieved, more complex functional motor patterns can be initiated.

11. *Failure to create an exercise program or to make use of functional patterns in later stages of rehabilitation that integrate lower extremity and trunk movements.* These exercises incorporate the whole kinetic chain and are complementary to traditional rotator cuff and scapulohumeral exercises.[2–4,48,82] Examples include the lunge walk with and without trunk rotation (Figure 6-38) and using "lift and chop" patterns.
12. *Failure to rehabilitate the deceleration (eccentric) component of shoulder activity.* Controlled eccentric lengthening of muscles, especially the posterior shoulder muscles, is essential for proper functional return to activity. The patient needs to control both the concentric and, even more important, the eccentric components (i.e., eccentric braking and shock absorption, especially for the posterior muscles). The patient must be able to control movement regardless of its direction. This is especially important when tubing is used. If the patient has to eccentrically control the shortening of the tubing as well as its lengthening (concentric movement), the exercises become more difficult, the patient will be able to do fewer repetitions, and control will improve more quickly.
13. *Failure to address proprioception (static) and kinesthesia (dynamic).* Proprioception is an important and integral part of the rehabilitation process for shoulder instability and any exercise performed by the patient has a proprioceptive or kinesthetic component. The patient must develop an understanding of the sensation of joint movement as well as joint position. Lephart and Kocker[137] recommended a progression of activities to restore proprioception and neuromuscular control, including starting with joint position sense, moving on to dynamic joint stabilization (i.e., kinesthesia), then reactive neuromuscular control, and finally function-specific exercises. For joint position sense, the Hawkins position can be used to position the glenohumeral joint with the patient's eyes open or closed, for rhythmic stabilization and eccentric break exercises (see Figure 6-22, *C*, and text for description). To do these exercises, the clinician positions the patient

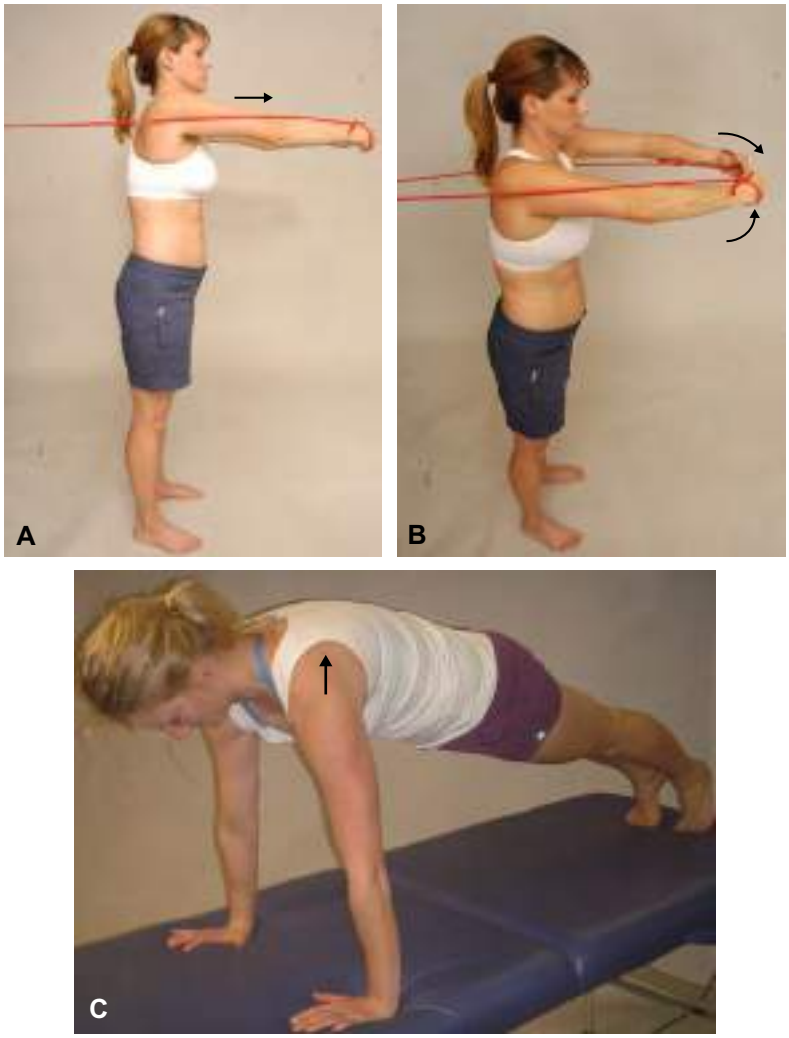

Figure 6-35 Exercises for serratus anterior. **A**, Punch out. **B**, Dynamic hug. **C**, Push up with a plus.

Figure 6-36 Exercise for proprioceptive neuromuscular facilitation (e.g., D2 pattern) using tubing in a lunge position. Note patient aiming for a target, which will help to give an indication of onset of fatigue. If the patient cannot consistently hit the target, he or she is fatigued or the resistance is too great.

and then says, "Don't let me move you," while applying co-contraction forces at the joint, along with eccentric breaking forces on the arm. PNF exercises can be used for dynamic joint stabilization and joint loading with closed kinetic chain exercise (Figure 6-39). To train reactive neuromuscular control, plyometrics, throwing and catching, balance drills, and "falls" (Figure 6-40) all play a role later in the rehabilitation process. For functional motor patterns, PNF (acceleration and deceleration), Body Blade® and Boing® exercises (Figure 6-41), and actual controlled functional activities can be used.

14. *Failure to take the time to work one on one with the patient.* Clinicians must make sure the patient performs the proper movement patterns and controls posture, and they must assist with the timing and sequencing with compensatory motions. This is performed by using individualized, accommodating resistance through all parts of the ROM.
15. *Failure to integrate the patient into the treatment program.* The clinician must convince the patients that their efforts play a crucial role in the rehabilitation process. Treatment for shoulder instability

Figure 6-37 Forward flexion closed kinetic chain exercises. **A**, Without a ball against wall (stable). **B**, With a ball against wall (unstable). Patient can be told to retract, elevate, depress, and protract the scapula while pushing against wall or ball.

Figure 6-38 Lunge walk with "lift and chop" patterned movement. Patient does lunge as arm goes through PNF pattern, stopping at ASIS bilaterally.

The Patient as "Quarterback"

- Follow clinician instructions
- Ensure correct posture before beginning
- Stabilize the "core," then the scapula before beginning
- Start with "power square" position in supine
- Watch for compensating postures and stop when they occur
- Be sure movement pattern is performed correctly
- Stop when fatigued
- Ask clinician questions if you do not understand

will not succeed unless the patients are actively involved—"they are the quarterback!" who must follow the instability treatment guidelines. The patients must feel confident and in control of the rehabilitation exercise program. They also must have a thorough understanding of the exercises they need to do and why they need to do them.

16. *Failure to use caution when using exercise machines.*[48] Generally machines use long lever arms; this makes controlling the motion difficult and increases the risk of a joint shear, especially if the patient has not

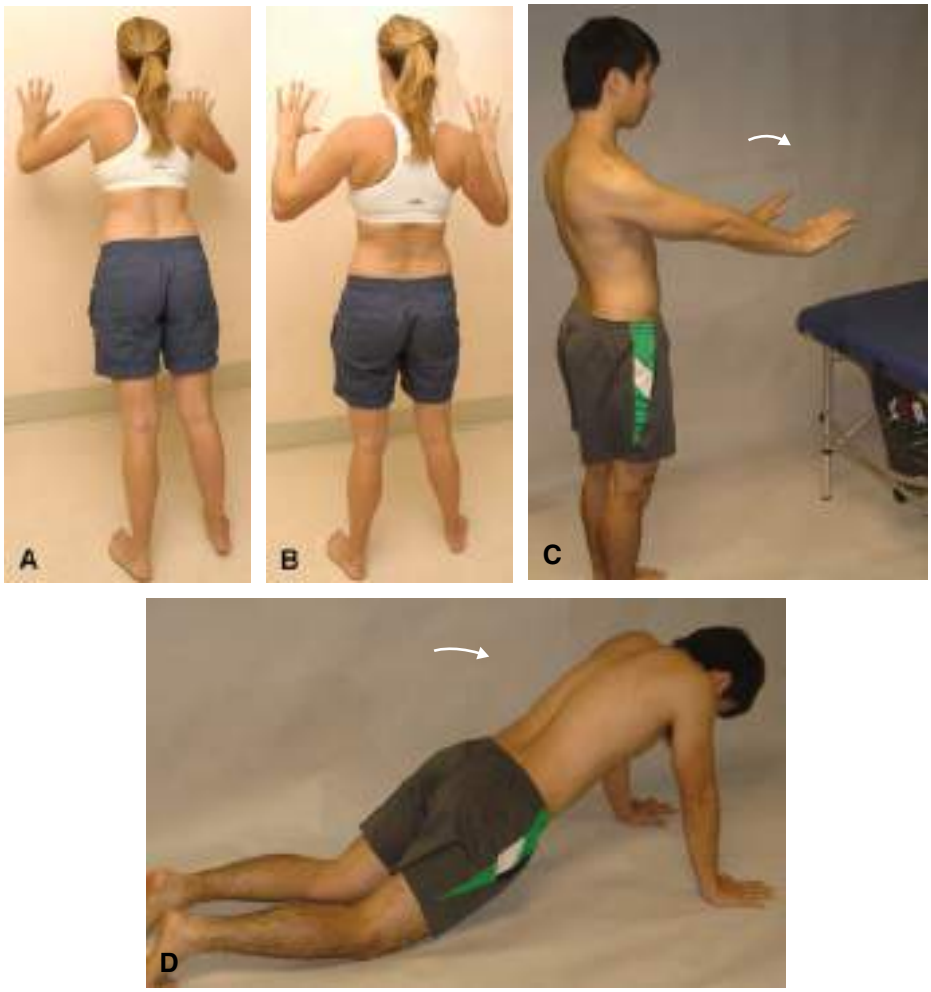

Figure 6-40 Proprioceptive exercises. **A,** Wall push up. **B,** Wall fall: the patient falls forward and catches himself/herself. This can be performed with the eyes closed. **C**, Table fall. **D**, Floor fall.

gained arthrokinematic control. Exercises performed on these machines often are not functional and only work isolated parts of the kinetic chain. In addition, they often emphasize anterior muscle groups rather than posterior muscle groups, which are often more important, especially with anterior instability.

17. *Failure to maintain or restore an appropriate fitness level.* Patients must be encouraged to maintain or do activity during their recovery from injury. Depending on the fitness level of the individual, this may involve low-level activities or higher-level activities within the confines of what the injury will allow them to do. Activities such as walking ("taking the shoulder for a walk"), water activities (walking in water with breast stroke action), and using an upper body exerciser (UBE) (Figure 6-42) to "bicycle the shoulder" are all activities that can help to maintain some aerobic activity and contribute to the feeling of well-being. Improving fitness will also enable the patient to recover from an exercise regime more quickly.

CONSERVATIVE TREATMENT OF INSTABILITY

For proper conservative treatment of impingement or instability syndromes, patients must understand the problem and must recognize that the outcome depends on their compliance with the clinician's instructions about what they should and should not do. The physician will prescribe rest, anti-inflammatory medication, pain-relieving medication, and physical therapy in the early stages. However, in most cases, sound rehabilitation is the key to resolution of these problems.

If the problem is one of atraumatic instability, the rehabilitation process follows a course that ensures that the exercises activate the appropriate muscle or muscle groups in the proper sequence and that functional control is achieved (see Volume 2 of this series, *Scientific Foundations and Principles of Practice in Musculoskeletal Rehabilitation,* Chapter 19).

Although many modalities may be used to treat instability and impingement, the clinician's primary concern is to restore normal shoulder mechanics and function by

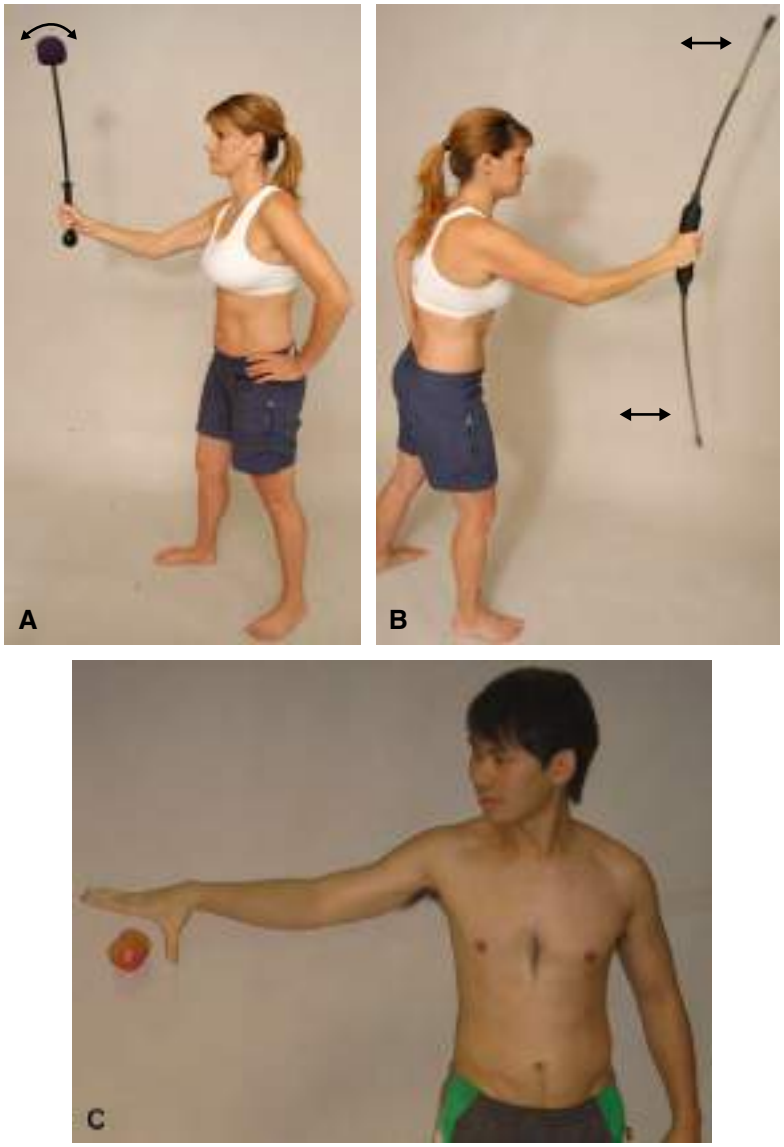

Figure 6-41 Proprioceptive drills using (**A**) Boing, (**B**) Body Blade, and (**C**) Dumbbell drop and catch.

Stabilization Training Sequence

Stages	Steps	Purpose
Stage 1	1.1	Reduce pain
	1.2	Allow freedom of movement (normal arthrokinematic movement)
Stage 2	2.1	Ensure proper muscle function
	2.2	Ensure proper muscle recruitment and motor patterns
	2.3	Correct muscle imbalances
Stage 3	3.1	Correct endurance discrepancies
	3.2	Correct strength discrepancies
Stage 4	4.1	Retrain proprioception and kinesthesia
Stage 5	5.1	Re-educate the muscle stabilizers statically
	5.2	Teach advanced static stabilization exercises
	5.3	Re-educate the muscle stabilizers dynamically
	5.4	Teach advanced dynamic stabilization exercises
	5.5	Teach functional stabilization
Stage 6	6.1	Restore or maintain fitness throughout program

restoring the muscles and improving their coordinated action, contraction sequence, strength, endurance, and proprioceptive or kinesthetic control.[2–4,47,85]

In the early stages of rehabilitation, the emphasis is on scapular control, humeral head stabilization, and restoring the coordinated action of the force couples of the scapulothoracic and glenohumeral joints.[35,85,134,138] This should include integration of the lower limb and trunk as early as possible. Examples of glenohumeral force couples include the subscapularis muscle (a primary stabilizer following anterior dislocation), counterbalanced by the infraspinatus and teres minor muscles, and the deltoid moving the humerus while the supraspinatus, infraspinatus, teres minor, and subscapularis muscles compress the humeral head into the glenoid.[30] By establishing strength and neuromuscular control of these force couples, the patient will regain control of humeral head translation (i.e., arthrokinematic control) during dynamic movement.[79]

Figure 6-42 Upper body exerciser.

Proper rehabilitation of instability of the shoulder involves controlled aggressiveness in terms of pushing the patient and pushing the envelope of progression for the patient as much as possible, while making sure the patient can control the movement and do it correctly. Because corrective movement depends on force generation and coordinated action of the muscles, as well as freedom of joint movement, the clinician must ensure that patients work only in the ROM in which they are able to control the movement and to do the movement correctly (i.e., using correct movement patterns). This is demonstrated by patients working at a speed at which they demonstrate movement control through precise, smooth (nonjerky) movement patterns, although part of the later rehabilitation continuum involves ensuring that patients progress to functional speeds and loads. With instability, the clinician is concerned with dysfunction that is primarily a motor control problem. The stabilization regimen is a multifaceted program that corrects impairment by improving neuromuscular control and coordination of specific muscles and movements of the shoulder. At the same time, the clinician must work to correct the mechanical factors that predispose or contribute to the abnormal movement patterns. This requires active participation and "buy in" by the patient and an accurate diagnosis by the clinician to determine what restrictions are present; that is, what muscles are at fault and which movements are being done incorrectly. This education and exercise program involves maximum psychological concentration on the part of the patient and very specific movement patterns at minimal speed in a range in which the patient has control. Throughout the process, the principles of specificity apply (see the Principles of Specificity Related to Sports and Rehabilitation box on p. 209). Stabilization is best achieved by isometric (co-contraction) exercises for static stabilization and concentric-eccentric exercises for dynamic stabilization.

The following steps are not necessarily sequential, but the clinician must consider each one to obtain optimum treatment outcomes. For example, with anterior instability, the clinician may treat the anterior glenohumeral joint for pain (step 1.1) while at the same time, treating the scapula by ensuring isolated contraction of the lower trapezius (step 2.1).

Step 1.1: Reduce Pain (Aim: Pain Control)

The first step is to relieve pain or at least diminish it because the aim is to establish pain control.[85] Instability training may be fatiguing, but it should not be painful. Generally, pain should be kept below a 4 on a 0 to 10 visual analogue scale or at a level that ensures control throughout the exercise (Figure 6-43). This can be accomplished through the use of pain-relieving modalities (e.g., ice, transcutaneous electronic nerve stimulation [TENS], interferential therapy) or by positioning the shoulder in the resting position (see Figure 6-11, *A*). Other approaches that have a role in pain management include modified traction (e.g., shaking out the arm and "throwing" the arm [Figure 6-44]), glenohumeral compression activities, using a sling, nonsteroidal anti-inflammatory drugs (NSAIDs), and gentle mobilizations.[2–4] Exercises should be low risk (i.e., isometric or slow speed) starting from a stabilized or the resting position and ensuring humeral head compression in the glenoid.

Rest from activity is relative and implies decreased length, intensity, and/or frequency of activity. It seldom means total rest. It is important to "take the shoulder for a walk" for 30 minutes each day, which implies moving the shoulder (e.g., swinging the arms while walking).

Step 1.2: Allow Freedom of Movement (Aim: To Restore Normal Arthrokinematic and Osteokinematic Movement)

The clinician should address any movement restriction in any of the joints, muscles, or inert tissues of the shoulder complex, including the spine and ribs. This often is necessary to restore normal arthrokinematic movement in the glenohumeral joint (i.e., allowing the humeral head to centralize in the glenoid cavity), acromioclavicular joint, sternoclavicular joint, scapulothoracic "joint," and thoracic

Figure 6-43 Pain-monitoring system (visual analogue scale).

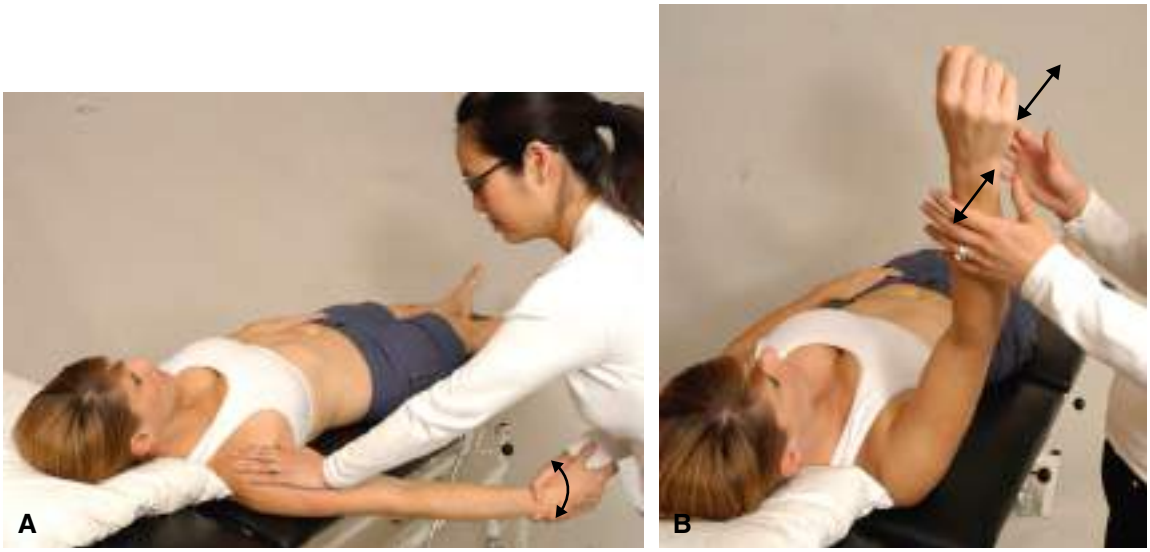

Figure 6-44 **A**, Shaking the arm. **B**, Throwing the arm.

spine and upper ribs.[21,85] The clinician should check for loss of medial (internal) rotation (Mattison 20 cm test) (see Figure 6-26), restriction of the inferior glenohumeral ligament (decreased inferior glide at the glenohumeral joint), a tight posteroinferior capsule (causes the humeral head to migrate anteriorly and superiorly[2]), and any loss of range due to tightness of the pectoralis major and/or pectoralis minor. Restricted rib motion can limit end ranges of shoulder motion. All have the potential of being tight.[2–4]

A tight posterior capsule, which is often seen with instability, can be suspected if, in supine, there is a loss of medial rotation at the glenohumeral joint, tight anterior chest muscles, restricted shoulder extension performed with the elbow at the nipple-diaphragm line, clavicle-shoulder, and/or chin-forehead (three positions), decreased inferior glide, and restriction at arm 90°-90° (arm forward flexed to 90° and elbow bent to 90°), followed by medial rotation.

Tight Structures Seen in Shoulder Instability and Impingement

- Pectoralis major and/or minor
- Subscapularis
- Posteroinferior capsule
- Ribs
- Thoracic spine

The clinician must always keep in mind the possibility of hypermobility at least in some directions, which tends to be common in individuals with an impingement or instability disorder. Altered glenohumeral arthrokinematics must be assessed and treated as necessary. The clinician must assess carefully to determine which movements are restricted and should treat only these movements, so that the joint play mobilization techniques to stretch the capsule are effective.[138–142] As the circle concept of movement implies, if the joint is hypermobile in one direction, it may be hypomobile in the opposite direction. With anterior instability, the posteroinferior capsule tends to be tight and therefore requires mobilization, whereas the anterior capsule is hypermobile and requires protection. The clinician should always check the ribs (Figure 6-45) and upper thoracic spine because these are commonly tight with associated chronic shoulder problems.

Active-assisted exercises using a rigid bar (i.e., a T bar, L bar, wand, or stick) may be used to increase ROM.[8,93,138] Stretching of the posterior structures can be accomplished using a stick (Figure 6-46), with stretches performed in different ROMs of shoulder abduction. In the United States, it is currently popular to use a sleeper, modified sleeper, or rollover sleeper stretch or doorway stretch (see Figures 6-28 and 6-31). If the sleeper stretch is to be used, the clinician must ensure the patient feels the stress or stretch posteriorly. Many patients feel pain anteriorly when doing the sleeper stretch, indicating a compromising position with the tissues being impinged anteriorly. Traction stretch (see Figure 6-30) in several positions of abduction will also gain medial rotation.

Posterior stretching may also be accomplished by forward flexing the arm and then pushing the humerus posteriorly (see Figure 6-29). The technique may also be performed actively by having the patient resist as the clinician pushes the humerus posteriorly. Humeral head depression (Figure 6-47) is an effective technique for ensuring inferior glide of the humeral head if excursion of the humeral head under the acromion is restricted.[143] It also poses less risk of compromising the medial scapular stabilizers. Other posterior stretch techniques include anterior chest eccentric breaks and anterior–posterior traction scoop.

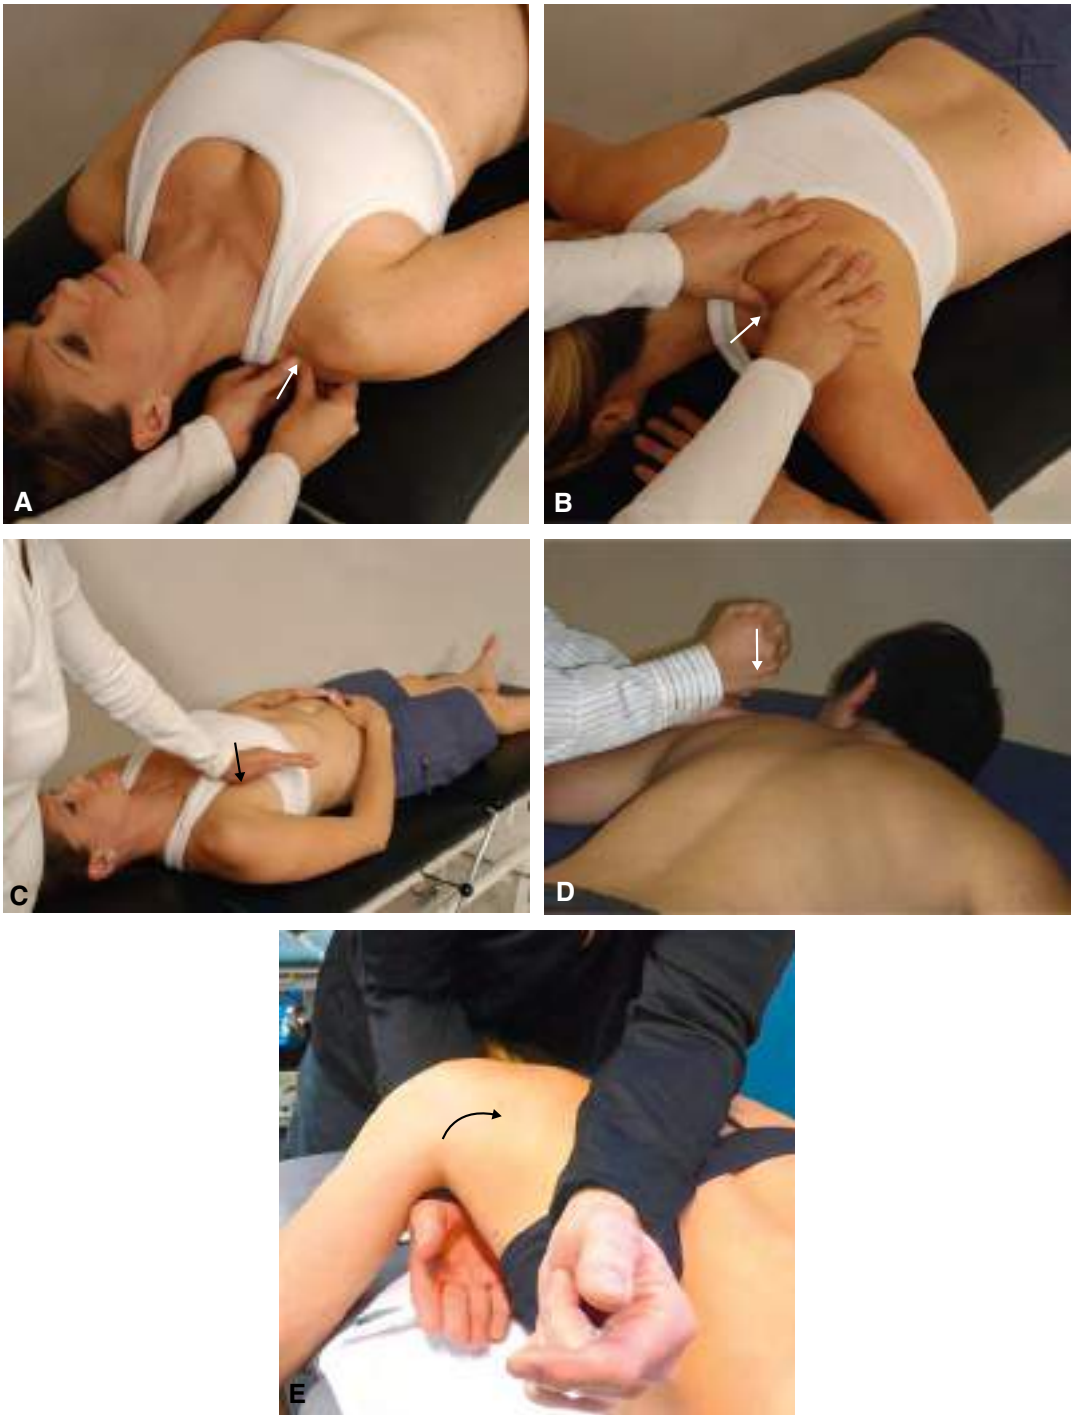

Figure 6-45 Checking the mobility of the ribs. **A,** First rib with patient in the supine position. **B,** First rib with patient in the prone position. **C,** Other ribs. **D,** Gentle "pounding" ribs feeling resistance to movement. **E**, Extension and rotation of thoracic spine and ribs.

Following anterior surgery, the clinician should not stretch or stress the anterior capsule in the early stages of recovery. In most postoperative programs, stretching of vulnerable tissues is contraindicated for the first 6 weeks. In these cases, it is important to follow the surgeon's protocols. In nonsurgical cases, stretching should be performed only in hypomobile directions using precise positions and complete control. Restriction may be the result of inert tissue tightness or muscle tightness, and different techniques are used to address these two problems. If the patient has signs of muscle tightness (most commonly, the pectoralis minor and subscapularis),[86] the clinician may use muscle energy techniques, hold-relax, or active release techniques or passive (anterior chest) stretching (Figure 6-48). Trigger point therapy, another muscle technique, can be used effectively to increase

Figure 6-46 A stick can be used to increase the ROM in the glenohumeral joint by going through different parts of the ROM.

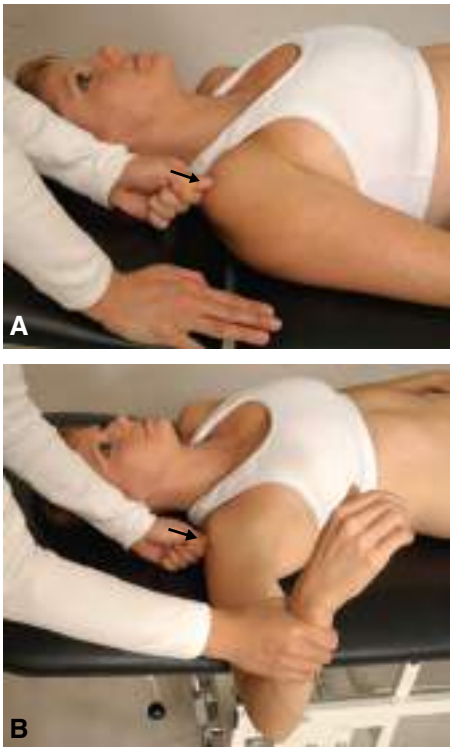

Figure 6-47 Humeral head depression. **A**, Arm by the side. **B**, Arm in 90° abduction.

Figure 6-48 Stretching the anterior structures of the shoulder and trunk on a foam roll ("open book" stretch).

Figure 6-49 Trigger point therapy to "strip" subscapularis. The clinician holds the arm in slight abduction and forward flexion. Using the thumb (or middle and ring fingers) of the other hand, the clinician palpates for the trigger points on the striations of subscapularis. The clinician then applies trigger point pressure with the thumb while with the other hand the clinician resists the patient isometrically holding the arm in various postures. The clinician then eccentrically breaks the postural holds. The clinician does 3 to 5 hold and break positions while applying different trigger point pressure for each of the hold positions

range with isolated muscle tightness (e.g., the subscapularis) (Figure 6-49). Restriction or loss of abduction, inferior humeral glide, or medial or lateral rotation of the shoulder may also need to be addressed.[85]

Clinicians must also consider the effect of crossed syndromes (Figure 6-50) on the mobility and strength of muscles about the shoulder. **Janda's "upper crossed" syndrome** showed that muscles (primarily postural) on one diagonal at a joint could be tight and hypertonic, whereas muscles on the other diagonal were weak and long.[144] Because similar cross syndromes can affect flexibility in the whole kinetic chain, inflexibility in the upper and lower kinetic chains may need to be addressed.[85] The clinician should assess for and treat any tight lower kinetic chain structures, including the Achilles-calf musculature, hamstrings, hip flexors, abductors, and extensors. Tight trunk flexors and abnormal gait patterns must also be considered.[85]

Pendular exercises (e.g., the Codman pendular arm swing exercises) may be used initially (see Figure 6-20), provided the exercises are pain free and the patient can control the movement (start with small pendular exercises progressing to scapular and humeral muscle control

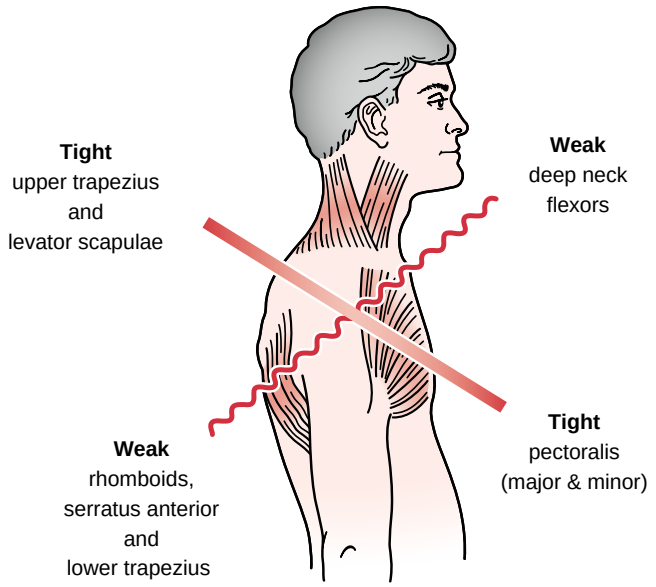

Figure 6-50 Upper crossed syndrome. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 165, Philadelphia, 2014, Saunders/Elsevier.)

with circles). Caution is required with pendular exercises, especially after arthroscopic surgery, because they apply gravity traction to the repaired vulnerable structures. The clinician may also try modified Codman exercises, which eliminate gravity traction by having the patient roll a ball on a low chair or table with the elbow extended (see Figure 6-20, *C*). This prevents inferior translation and caudal traction on the glenohumeral joint. Anterior translation of the humeral head (common in active lateral rotation) must be avoided, especially in patients with anterior instability.[145] The clinician must not allow scapular hitching (i.e., upward movement) or dumping (i.e., downward tilting of the glenoid) with any assisted exercises. The arm may be swung horizontally in a variety of planes. These exercises are useful in the early stages to maintain ROM, but compensated shoulder postures must be avoided because some reports have indicated that in pathological shoulder conditions, the upper trapezius and supraspinatus are less likely to relax.[146] Shoulder depression exercises using tubing (e.g., dynamic caudal glide) help to improve range, enhance scapular control, and promote coordinated scapulohumeral and glenohumeral activity.

Step 2.1: Ensure Proper Muscle Function (Aim: To Ensure All Muscles Contract Individually)

Ensuring Proper Muscle Function

- Start by positioning the muscle in the "muscle test" position
- Use low (10% to 30% MVC) isometric contraction
- STOP as soon as fatigue is evident
- Work muscle in inner range of movement

This stage involves restoring individual muscle function to ensure proper muscle recruitment or proper activation of the muscle. Proper contraction of the scapular force couple, including the lower trapezius with the serratus anterior, requires special attention. If the patient does appropriate exercises and compensatory postures are not allowed, these muscles will contract or "turn on." The upper trapezius and latissimus dorsi can dominate in compensatory postures, causing an incorrect movement pattern. For example, with a Kibler type III dyskinesia of the scapula, the upper trapezius, levator scapulae, and posterior deltoid do not function in concert most of the time, resulting in the postural deformity.[2–4,86] Biofeedback may be used to teach the patient to contract the desired muscle and to "turn off" the unwanted compensatory muscle contraction.

To encourage isolated muscle contractions (i.e., specificity), the patient is positioned in the "muscle test" position for that muscle.[43–45] The clinician positions the patient so as to isolate the muscle and then asks the patient to hold the position against minimal clinician resistance to ensure that the desired isometric contraction is achieved. The patient contracts the muscle only to 10% to 30% of the MVC to ensure an isolated contraction of the muscle while the clinician watches for no compensatory contraction of other muscles. Functional activation may be tested by doing "open shutter" and supine and standing "streamline" exercises, "four corner" drills, and PNF diagonals (Figure 6-51).

During these early stages of treatment, it is important that the clinician watch for the first sign of fatigue and stop the patient when it appears. Signs of fatigue are shaking when doing movement, not being consistently able to hit a target, loss of or change in segmental colinear posture, inability to hold proper functional posture, or contraction

Figure 6-51 Functional activation exercise. PNF D2 diagonal patterns.

of compensatory muscles. Early on, patients commonly find contracting the isolated muscles difficult and in some cases, impossible—these people need electrical stimulation to the muscles to "reboot" them, and they frequently show psychological fatigue, which mirrors physiological fatigue.

If inferior instability is present, the scapula must be able to stabilize both statically and dynamically, the humeral head must be balanced in terms of ROM (e.g., medial and lateral rotation should be close to equal), compression of the humeral head by the rotator cuff must be evident, and the patient must be able to contract the anterior and posterior deltoid muscles simultaneously.

Postural correction is an essential component of this step. The clinician should determine whether the patient can achieve the neutral pelvis position (i.e., stabilize the core) and hold the position during both static and dynamic activities. As the patient begins to assume and hold the neutral pelvis position (i.e., demonstrating a stable core), the posture will begin to correct. If the connection is slow or the patient appears to be having problems, the clinician must look for potential restrictive and weak cross syndromes that are limiting the return to normal posture and stretch (e.g., pectoralis minor, hip flexors) and strengthen these components (e.g., abdominal flexors, scapular control muscles).

Step 2.2: Ensure Proper Muscle Recruitment and Motor Patterns (Aim: To Ensure All Muscles Contract When They Should)

Ensuring Proper Muscle Recruitment and Motor Patterns

- When muscle can be recruited, the aim is then to ensure the muscle contracts when it is supposed to
- Make sure the patterns of movement are correct
- Watch for any compensatory or incorrect movement patterns
- Start with low-load isotonics and progress to eccentric (for muscle shock absorption and braking functions) and concentric (for correct movement) loaded exercises
- Can initiate proprioceptive exercises at this point keeping in mind the different proprioceptive receptors to be stimulated

At this stage, treatment is directed primarily at the stabilizer muscles of the scapula, followed by the stabilizers of the glenohumeral joint, because these muscles maintain the normal relationship between the glenohumeral and scapulothoracic joints. The scapular stabilizers provide a stable base for the arm, preserve deltoid fiber length so that acromiohumeral length is maintained, and help control impingement of the rotator cuff. Proper activation and functioning of the scapular stabilizers is essential (see Table 5-1).[49,85,147] The clinician must ensure that scapular substitution patterns are not occurring and that the stabilizer muscles contract before the mobilizer muscles.[148] For example, when the patient abducts the arm to 30°, the scapula should stabilize and "lock in" in this phase of scapulohumeral rhythm. In the first phase of arm abduction (0° to 30°), no or minimal scapular movement should occur. If the scapula keeps moving during the first 30° of abduction, the scapular stabilizers are not functioning properly and the mobilizers are dominating or the exercise is too advanced (i.e., too hard) for the patient. In the second phase (30° to 90°), the scapula should rotate but show minimal protraction or elevation. In the third phase (90° to 180°), lateral rotation to the humerus is necessary along with some elevation.

In scaption (i.e., the plane of the scapula), scapulohumeral rhythm is slightly different, with more individual variation in the movement. More scapular rotation and protraction often occur. In scaption, less lateral rotation of the humerus occurs and less stress is placed on the tissues of the shoulder. Therefore scaption is a good position for working the patient initially because there tends to be less pain with movement and scaption is a more common functional movement pattern.

If the patient is having difficulty determining how to contract individual muscles, electrical stimulation or biofeedback may be used.[149] Useful scapular control exercises include retraction and depression of the scapula, as well as elevation and protraction. These involve individual exercises for the three parts of the trapezius muscle, serratus anterior, rhomboids, and levator scapulae. Exercises for the scapular control muscles include scapular squeezes or pinch, thumb tubes in the three positions starting in the "power square" (90°-90°) position for the middle and lower trapezius, dynamic hug and punch outs for the serratus anterior, shoulder depression with tubing and press down exercises (Figure 6-52),[85] and V-plank exercises (see Figure 6-33, *F*) for compression of the humeral head into the glenoid.

Figure 6-52 Press down exercise for shoulder depression using bars.

At this step, force-couple training also plays a predominant role. Force-couple training involves recruitment of the muscles, along with synchronized action of the muscles using loaded and unloaded activities. Co-contraction (i.e., arthrokinematic stabilization) with rhythmic stabilizations has a stabilizing and stiffening effect, adds compression for joint position sense, and tends to be done isometrically.[85] Coordinated coactivation results in less torque or sheer loads on the glenohumeral joint on the shoulder and increased joint control. Co-contraction primarily works the small (inner cone) muscles (i.e., the rotator cuff) of the joint. An example is rhythmic stabilization to the humeral head in the Hawkins punch out position (see Figure 6-22, *A*) and scapular movements on a stable arm (e.g., closed kinetic chain scapular "clock" exercises—the patient moves the scapula through the different hours of a clock while stabilizing the hand against the wall). These exercises also help emphasize the rotator cuff, stabilize the glenohumeral joint by compressing the humeral head in the glenoid, and reduce deltoid activation.[48,85]

Closed kinetic chain activities in the shoulder (e.g., rhythmic stabilization) are more stable, involve less translation, provide static stability, and are often used with coactivation.[85] Closed kinetic chain activities provide motion control, sequencing, and improved proprioception and often are more functional.[48] Exercises include weight shifts with the hand on a stable or unstable surface, rotator cuff clock exercises, and wall washes ("wax on, wax off") exercises (Figure 6-53), and "wiper" and "Spiderman" (see Figure 6-21, *D*) exercises.[48]

Once scapular control has been achieved, humeral control exercises can be instituted for the rotator cuff and deltoid. These help to prevent humeral head migration and to restore voluntary arthrokinematic control of the humeral head through rotator cuff coactivation (especially of the supraspinatus and subscapularis) and stabilization, as well as activation of the biceps and triceps (Figure 6-54) and pectoralis major.[134–137,149] These exercises also can be used later in the rehabilitation program, as long as the patient has no impingement signs and good scapular control.

Figure 6-53 Exercises for proprioception, motion-controlled sequencing, and increasing ROM. **A,** "Clock" exercise for the scapula with the arm in abduction. **B,** Wall washes ("wax on, wax off"). **C,** Rhythmic stabilization with a stick in power square position. Note how clinician is palpating for arthrokinematic control of patient's right shoulder. **D,** Rhythmic stabilization with thumb tube in power square position. Clinician is applying perturbations to tube.

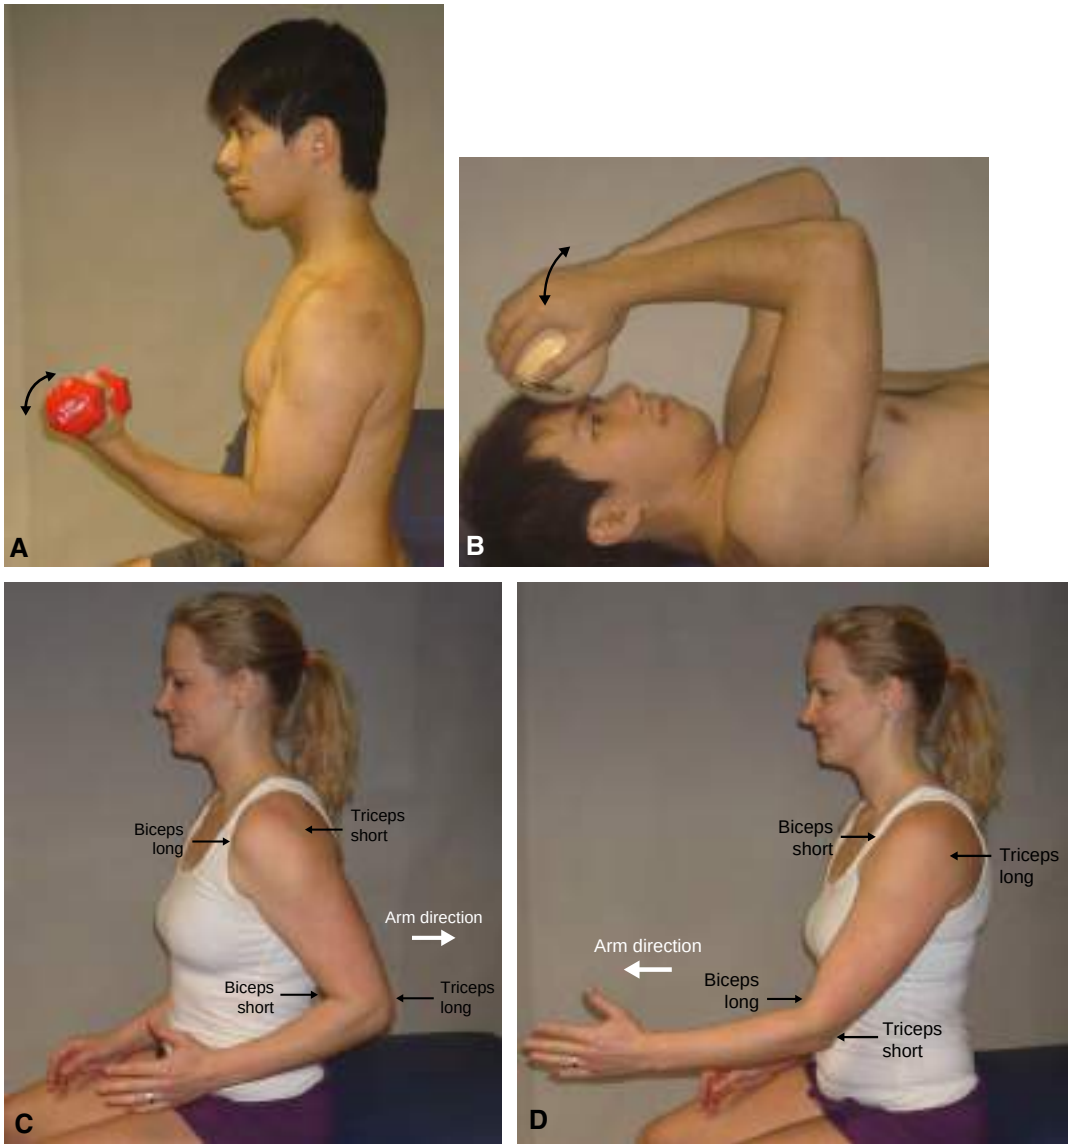

Figure 6-54 Biceps and triceps exercises. **A**, Biceps curls. **B**, Skull crushers (triceps). **C**, Econcentric biceps and triceps in shoulder extension. **D**, Econcentric biceps and triceps into forward flexion. Doing C and D together would result in a functional arm pump.

The patient must concentrate to make sure that the movements are done correctly. If necessary, each movement should be broken down into its component parts so that the patient can do each correctly. At this stage, maximum strength contractions are contraindicated. A contraction of 10% to 30% of MVC at controlled speeds is the aim to ensure correct movement patterns and to keep fatigue of the stabilizers to a minimum. Fatigue is most evidenced by muscle substitution (e.g., contraction of the upper trapezius and posterior deltoid).

Short arc exercises (in this case, in a pain-free range) into scaption, abduction, and forward flexion to 30° initially and then to 90° can be prescribed, especially in the initial treatment phase, once scapular control has been achieved. If scapular control has not been achieved, these exercises should be limited to 30°. Once the patient is able to control motion up to the horizontal plane, movement to full elevation can begin. Exercises above 90° should be performed in lateral rotation to facilitate clearance of the greater tuberosity under the coracoacromial ligament.[52] Tubing exercises, if performed properly, are effective. In most cases, when and how tubing is used should be controlled unless the patient has learned to do the tubing exercises correctly. To be performed correctly, tubing exercises should be performed only at the speed at which the patient has complete functional control of the activity. If functional control is lost, dysfunctional compensatory movement patterns result (usually seen in winging or abnormal movement of the scapula or excessive contraction of the upper trapezius or posterior deltoid).

Once control in most of the ROM has been achieved, diagonal PNF exercises may be used to teach control and stabilization throughout the ROM. The shoulder D2 pattern (flexion, abduction, and lateral rotation) is

especially useful for instability. Full range should not be attempted in patients with signs of impingement or those showing apprehension.[93,134,150,151] Techniques such as slow reversals, contract-relax, rhythmic stabilization, and timing for emphasis are useful for treating instability by increasing awareness of movement, stimulating appropriate weak muscles, and strengthening weak patterns.[93,95,145] Tubing exercises using these patterns have also been found to be effective, provided they are performed with control.

Once the muscles can contract in the correct sequence, the primary shoulder accelerators or movers of the glenohumeral joint (i.e., pectoralis major, anterior deltoid, latissimus dorsi, teres major, biceps, and pectoralis minor) are trained concentrically, whereas the primary decelerators (i.e., infraspinatus, teres minor, supraspinatus, posterior deltoid, and triceps) and scapular stabilizers are trained eccentrically. Concentric and econcentric exercises of the biceps and triceps should begin as the patient progresses toward more functional movement. *Econcentric* or *pseudo-isometric* exercise is so named because commonly during function these two-joint muscles are lengthening over one joint while they shorten over the other joint. For example, when swinging the arms into extension with bent elbows during running, the biceps is lengthening over the shoulder but is shortening at the elbow as the elbow flexes (see Figure 6-54, *C* and *D*). Thus, to ensure correct movement patterns, two-joint muscles need to be trained to function econcentrically.

Step 2.3: Correct Muscle Imbalances (Aim: To Ensure Correct Force-Couple Action)

Correcting Muscle Imbalances

- Ensure joint can move through full ROM by stretching tight structures and allowing lengthened structures to tighten
- Correct any unbalanced cross syndromes
- Ensure near-equal right and left body strength and endurance
- Correct any kinetic chain movement imbalances that involve injured structures
- Proprioceptive (static) and kinesthetic (dynamic) exercises keeping in mind the different proprioceptive receptors to be stimulated and whether they function statically or dynamically

To correct muscle imbalances, any lengthened muscles must be exercised in the inner range to shorten them, and short muscles must be stretched to lengthen them. The clinician must make sure that strength and endurance are equal between the left and right sides for what the patient wants to do and that any strength and/or endurance discrepancies are corrected.[152] For example, with the humeral control muscles, a good relationship should exist between the medial and lateral rotators, between the flexors and extensors, and between the abductors and adductors, which will lead to many exercises being performed bilaterally.[152] Cross syndromes with their strong and tight muscles on one diagonal and weak and long muscles on the other diagonal must also be addressed.[144] People with anterior shoulder instability commonly demonstrate overactivity of the upper trapezius and underactivity of the serratus anterior. A standard push up "with a plus" (this implies scapula is fully protracted) has been reported to be a good exercise to accentuate the serratus anterior while minimizing the upper trapezius, thus reversing this abnormal movement pattern.[152] Isokinetic tests have shown that medial-to-lateral rotation strength ratios should be approximately 3:2, extension-to-flexion strength ratios should be 5:4, and adduction-to-abduction strength ratios should be 2:1.[113,137]

Muscle balance does not necessarily imply maximum strength of the muscles. Rather, it implies that the force couples are able to work in a coordinated fashion and with sufficient strength and endurance to do the correct motor patterns during activity. The "mover" muscles must have the strength and endurance to move an object concentrically one or more times, and the "stabilizer" muscles must have the strength and endurance to stabilize isometrically (statically) and eccentrically (during dynamic movement or as a shock absorber) in the correct movement pattern.[85,153] Eccentric control in throwing activities is more important than concentric control, and if eccentric fatigue occurs, injury is more likely.[154] Tubing may be used provided the resistance and speed of contraction are carefully controlled. The shoulder should not be overloaded, and the patient must understand that the exercises can be done only at the speed at which control and correct movement (i.e., smooth, coordinated movement) are demonstrated. If ROM is a problem, pulleys or T bar routines may be used as active-assisted exercises to help to increase the ROM and control large lever forces.[155,156]

Because synchronization of shoulder movement is important during normal activities, the patient must develop neuromuscular functional control. Therefore any treatment program must ensure good muscle balance between the agonist and antagonist and enable the patient to work at properly controlled speeds. This control eventually must be demonstrated at functional speeds. Too often, the clinician rehabilitates the patient only to have the patient return, complaining of problems when performing the activity. The problem commonly is lack of control at functional speeds.

Step 3.1: Correct Endurance Deficiencies (Aim: To Ensure Sufficient Muscle Endurance to Do Activity and Minimize the Likelihood of Injury)

The clinician must take extreme care in choosing the type of strengthening program to which the patient is exposed, especially if the rotator cuff or biceps muscles are

Correcting Endurance Discrepancies

- Use low load, high repetitions
- Patient must be able to control the pelvis (neutral pelvis), thorax (alignment), and scapula (dynamic stabilization)
- Need to build up endurance to delay fatigue with "built in protection" factor
- Ensure correct movement patterns
- Watch for compensatory postures
- Work at only speeds at which the patient can control the movement (i.e., can do the movement correctly)

involved. Because instability often has an overuse component, unsuitable exercises or too many exercises may aggravate the condition. The quality of the exercises is more important than the quantity. That being said, endurance plays a significant role in instability training because incorrect movement patterns are more likely to be seen with fatigue.

Once scapular control is achieved and the patient can control active exercises, progression to free weights (2.3 kg [5 lb] or less for up to 30 repetitions) and tubing exercises may be initiated, in the range in which the patient is able to control the movement.[157] Pappas et al.[157] found that weights heavier than 2.3 kg (5 lb) tended to precipitate loss of muscle balance in the shoulder. Initially, this movement may occur over 10° to 30° (i.e., a short arc). Once control is demonstrated by smooth, coordinated movement with minimal or no evidence of pain and discomfort, the exercises can be progressed into greater ROMs. The clinician must monitor the exercises to make sure the patient can do them correctly without fatigue, to provide a baseline for improving endurance. For example, if a patient can do four repetitions correctly, this is the starting point for the exercises. The aim is to increase the number of repetitions to a level that meets the patient's eventual functional needs plus a built-in protection (BIP) factor. If a patient needs to do 30 repetitions in a 15-minute period, the aim is to get the patient to be able to do the 30 repetitions in 15 minutes with a 10% to 15% cushion (*the BIP factor*) (i.e., 33 to 35 repetitions), so that there is less chance of injury due to fatigue. It is essential that the patient demonstrate control in terms of scapular stabilization, movement pattern, strength, endurance, and movement direction when progressing into greater ROMs. Exercises such as controlled tubing routines and wall dribbles (Figure 6-55) can enhance endurance.[149]

Figure 6-55 Wall dribbles used for proprioception and endurance.

Correcting Strength Discrepancies

- Start with isometric exercises moving on to concentric, eccentric, and eccentric exercises
- Use concentric exercises to ensure correct movement patterns
- Watch for compensatory postures
- Use eccentric breaks to retrain muscle shock absorption and braking action
- Use eccentric exercises to strengthen and increase endurance of two-joint muscles

Step 3.2: Correct Strength Deficiencies (Aim: To Ensure Sufficient Muscle Strength to Do Activity and Minimize the Likelihood of Injury or Reinjury)

To improve strength, the patient initially should use low repetitions with high-load contractions. Active and resisted exercises may include progressive resisted exercises with minimal weight at the beginning, working up to heavier weights or using various commercial exercise machines, keeping in mind the limitations of these devices (Table 6-3).[149,158]

Once the scapular stabilizers are functioning correctly, the glenohumeral stabilizers may be strengthened. Common exercises for strengthening the glenohumeral stabilizers include those involving the supraspinatus and deltoid ("open can" exercises or prone horizontal abduction at 100° with full lateral rotation),[136] subscapularis (medial rotation, side lying, eccentric breaks), infraspinatus and teres minor (side lying lateral rotation at 0° to 45° abduction, eccentric breaks) (Figure 6-56), biceps (flexion), and triceps (extension).[159,160] Strengthening of the scapular control muscles, along with the supraspinatus, infraspinatus, teres minor, biceps, and all three parts of the deltoid should be stressed.[143,145,146]

Eccentric exercises for the scapular and humeral control muscles help improve their strength and endurance for decelerating the arm and for shock absorption.[30,162] Closed-chain shoulder activities should be encouraged when the patient has attained suitable strength and control. Open-chain activities may begin

TABLE 6-3

Correcting Strength Deficiencies

Muscle	Exercise
Supraspinatus	Side lying, 45° abduction[159] Full can at 90° elevation in scaption[126]
Subscapularis	Side lying, 45° abduction[159] Lift off (Gerber push)[126]
Infraspinatus	Side lying, 0° to 45° lateral rotation[159] Sitting, lateral rotation of the arm from –45° to 0° (multiple angles)[126]
Teres minor	Side lying, 0° to 45° and lateral rotation
Biceps	Yergason's drill (Yergason's test used as an exercise) Speed's drill (Speed's test used as an exercise) Arm pumping
Upper trapezius	Military press[159]
Middle trapezius	T exercise: Scapular retraction with the arm at 90° abduction in the prone position
Lower trapezius	Y exercise: Scapular retraction with the arm abducted to 120° in the prone position, Spiderman exercise
Serratus anterior	Wall walks, dynamic hug, V-plank
Deltoid	Side lying, 45° abduction[159]
Rhomboids	With shoulder abduction at 90°, the patient resists forward flexion of the arm[126] (also exercises the posterior deltoid)

Figure 6-56 Lateral rotation eccentric break. Patient laterally rotates the arm and clinician eccentrically "breaks" the contraction into medial rotation.

early with high repetitions using low weights, as long as the patient can control the movement. High-risk activities (e.g., dead lifts, military presses, hands behind head "lats" for latissimus dorsi and shrugs with weights in the hands) should be avoided if scapular protraction occurs because they can cause harmful sheer forces and lead to lack of control.[150] Similarly, daily activities such as sleeping in a supine position with the hand under the pillow or over the head, fixing the hair, reaching into the back of a car from the front seat, leaning back on the arms while sitting for long periods, and putting on a backpack should be discouraged because of the stress they place on the anterior capsule.

In terms of strength about the shoulder, adduction should be the strongest, followed by extension, flexion, abduction, medial rotation, and lateral rotation. It is especially important to strengthen the medial humeral rotators (i.e., subscapularis, pectoralis major, and latissimus dorsi) and the scapular control muscles, especially the serratus anterior and lower and middle trapezius muscles, all of which show marked weakness when impingement or instability is demonstrated.[35]

Controlled pulleys or tubing may be used in the pain-free ROM for abduction, scaption (thumbs up), and forward flexion with the palm supinated. Supinating the palm causes lateral rotation of the humerus and moves the shoulder out of the impingement position. Such movement in standing may provide gravity assistance to humeral depression.[162] Strengthening exercises should progress from isometric pain-free activity to isotonic pain-free activity.

As the patient progresses through the strengthening regime, special attention must be paid to two-joint muscles because these are the muscles most commonly injured during activity. Functionally, these muscles are moving two joints at the same time and should be exercised this way (i.e., econcentrically).

Step 4.1: Retrain Proprioception and Kinesthesia (Aim: To Ensure Voluntary Control and Awareness of Movement)

Retraining Proprioception and Kinesthesia

- Remember that proprioceptive receptors are stimulated only with specific actions (e.g., muscle spindle–muscle stretch; Golgi tendon organs–muscle contraction; Golgi ligament endings–end range stretch)
- Start with slow, precise movements
- Stop when fatigue evident
- Ensure correct movement patterns
- Watch for incorrect compensatory postures
- Break complex movement patterns down into simple components

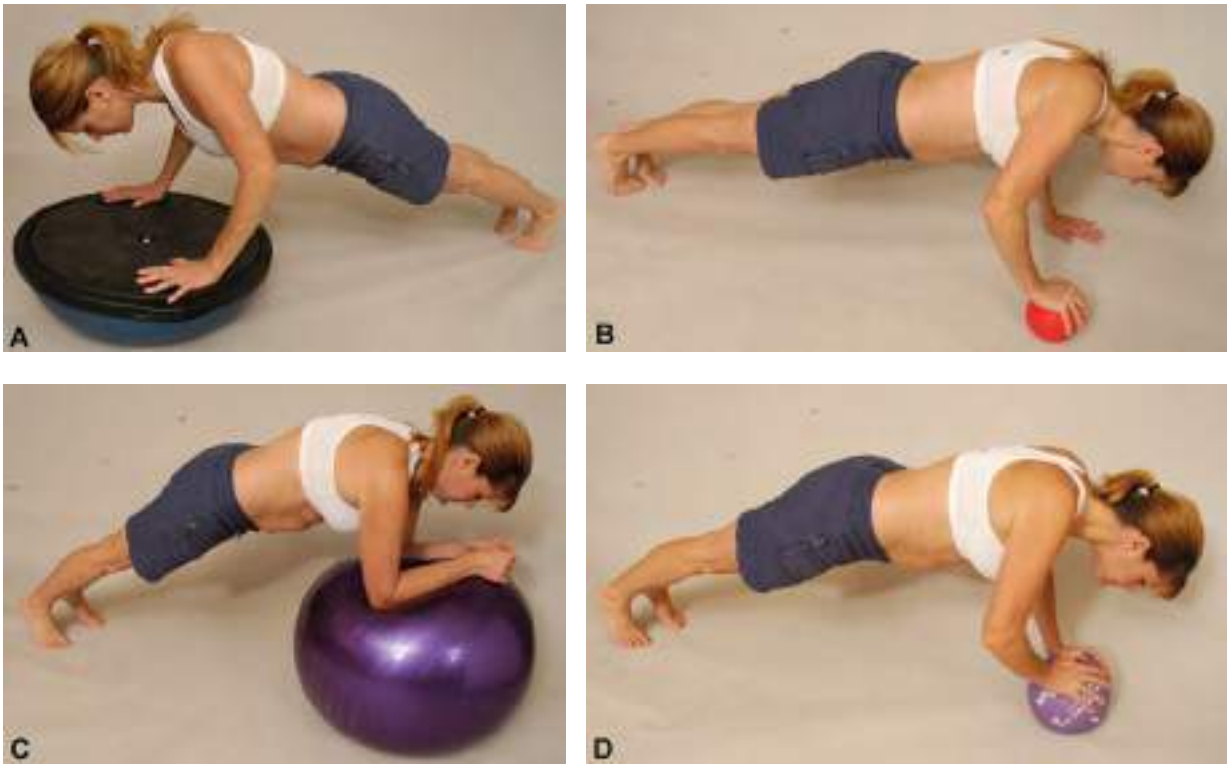

Figure 6-57 Push up on **(A)** a Bosu Ball®, **(B)** small ball using one hand, **(C)** big ball, and **(D)** small ball using two hands for proprioception.

In reality, any exercise can be used for proprioceptive or kinesthetic training because they all have a proprioceptive or kinesthetic effect. However, to specifically target individual proprioceptive receptors, exercises have to be individualized. As soon as the patient has gained scapular control, proprioceptive or kinesthetic training can be instituted to restore proprioceptive deficits.[163] Proprioceptive and kinesthetic training involves gaining voluntary control of different movement patterns, increasing the patient's awareness of correct movement patterns, and establishing automatic control of movements. Proprioceptive and kinesthetic exercises may involve closed kinetic chain weight shift, recovery phase closed kinetic chain exercises, and concentric as well as eccentric motion, movement in different parts of the ROM, and activities at different speeds.

In closed-chain activities, the distal segment is fixed or the patient holds on to an immovable object so that fixation feedback is possible, thus providing better proprioception, co-contraction, and stabilization.[164] Examples include arm wall slides into abduction, flexion diagonal patterns, and "wax on, wax off" routines (i.e., wall washes).[86,87] Dips and many proprioceptive control activities (e.g., balance board, Bosu Ball®, or using different size balls) are considered closed-chain activities (Figure 6-57). Overuse injuries are less likely to occur during closed-chain activities. Closed-chain activities for the shoulder should be primarily eccentric to reduce the effects of gravity and inertia. These activities tend to compress the joint, increasing stability, and may be used in the reverse origin insertion mode. For example, although the latissimus dorsi is viewed as an extensor and medial rotator of the shoulder, it may also be used as a trunk extensor. The clinician should look at each exercise to determine which proprioceptive or kinesthetic receptors he or she wants to stimulate (e.g., different parts of the ROM, different speeds, acceleration or deceleration) and design the exercises to meet that goal.

As the patient progresses and the scapula can be stabilized, closed-chain proprioceptive or kinesthetic activities can be performed. These can include push ups (progressing from rhythmic stabilization) and co-contraction at the joint; wall push ups progressing to wall falls (see Figure 6-40), then table push ups progressing to floor push ups (with or without a ball) (Figure 6-57); weight shifting from the push up position, shifting from a quadruped to a tripod position; ball rolling; target drills; wall washes; balancing on balls; using a Boing® or Body Blade®, dumbbell and ball drops (see Figure 6-41) to cause sudden alterations in joint position; sitting push ups; Profitter® exercises using the hands; use of an UBE (see Figure 6-42) or similar cycling device for the upper limb; hand balancing or using a balance board; hand stair climbing; and hand treadmill walking.* All of these activities are excellent for improving strength, endurance, and proprioception, but the clinician must always watch for faulty compensatory postures, pain, discomfort, and

*Refs. 30, 85, 87, 138, 158, 160, 161, 165, 166.

fatigue resulting in loss of scapular and/or humeral control, leading to compensatory patterns.

Open kinetic chain activities may be used, but they are not as effective, and they do not provide the same stability. However, they are often more functional. They must also be done with good posture. Shoulder dumps and punch outs with weight (e.g., 3 sets of 20) are some open kinetic chain activities that simulate a shoulder function.[85]

Step 5.1: Reeducate the Stability Muscles Statically (Aim: To Ensure Isometric Positioning for Form and Skill Execution)

Stage 5, consisting of five parts, is where true integrated stabilization training begins. The previous parts are individual parts of a stabilization training program that must be addressed before functional integrated stabilization training can begin.

Reeducating the Muscle Stabilizers Statically

- To begin, clinician must ensure the patient has control of the pelvis, thorax, and scapula
- Clinician places the patient in the correct position and asks the patient to hold the contraction isometrically (statically)
- Basic movements can be broken into segments and isometric hold exercises performed in each segment to establish isometric control in different positions
- Initially the contraction is submaximal
- Resistance to holding the correct position is started close to the joint (proximal) and moved distally as the patient demonstrates isometric stabilization of the joint
- Clinician watches for correct force-couple activation
- Co-activation or co-contraction used to ensure arthrokinematic control of the joint–*resistance is given at the joint*
- Closed kinetic chain activities are used to assist joint stabilization (aids compression at the joint and stress distribution)
- Positions close to the close-packed position provide more stability
- Clinician must stop exercise if fatigue or compensatory postures are evident

Once the patient has gained control of the shoulder segments (e.g., the scapulothoracic and glenohumeral joints) through isolated contraction of muscles, ensuring proper muscle function and recruitment in isolation, true integrated stabilization training can be initiated. First, the clinician must ensure that the stabilizer muscles function statically. Part of this training will have been accomplished during training of the individual stabilizer muscles. This stage also involves maintaining a stable scapula, along with correct posture (i.e., stable pelvis, or core), while doing controlled movements of the arm below 30° abduction initially (above 30°, the scapula will rotate) and then progressing to full ROM. To reeducate the stabilization muscles statically, the clinician must be concerned primarily with positioning the arm in different positions. The exercises must be performed isometrically in specific positions with control. The focus of muscle reeducation moves from proximal (i.e., ensuring a stable scapula proximally with correct posture) to distal (while allowing distal movement). Static force-couple action ensures that the muscles work in a coordinated fashion to produce a smooth, coordinated isometric hold both when the upper extremity is loaded (in close pack, or closed kinetic chain) and unloaded (in open pack, or open kinetic chain). Rhythmic stabilization and closed kinetic chain isometric scapular stabilization on a balance board or ball are examples of static stabilization exercises.

Step 5.2: Advanced Static Stabilization Exercises (Aim: Isometric Positioning for Activity-Specific Skills)

Teaching Advanced Static Stabilization Exercises

- Clinician places the patient in the desired position and asks the patient to hold the contraction isometrically (statically) (e.g., start position, follow-through position, mechanism of injury)
- Movements can be broken into segments and isometric hold exercises performed in each segment to establish isometric control in different positions
- Resistance to holding the correct position is given distally to gain static osteokinematic control while maintaining arthrokinematic control at the joint
- Clinician watches for correct force-couple activation
- Move from closed kinetic chain to open kinetic chain activities
- Stronger contractions used to stimulate isometric activation of whole kinetic chain
- Clinician must stop exercise if fatigue or compensatory postures are evident

In advanced static stabilization exercises, the patient works to stabilize the scapula statically in positions above 30°, most commonly in open kinetic chain.[85] The patient may be taken into the position of the mechanism of injury to do rhythmic stabilization exercises or taken into positions related to function, working from submaximal to maximal isometric effort to ensure control of different positions. The clinician can have the patient do isometric hold or eccentric break activities of the medial and lateral rotators in various positions of glenohumeral abduction, scaption, and forward flexion. Rhythmic stabilization with compression with the glenoid under the humeral head in the Hawkins position (see Figure 6-22), "throwing the arm," resisted isometric PNF D1 and D2 patterns, and rhythmic stabilization of the medial and lateral rotators in various postures from low risk to high risk should be attempted. To accomplish this, the patient's arm is taken into the desired position and the patient is asked to hold the position while the clinician

applies perturbations to the arm and affected joint. For example, the clinician can place the patient's shoulder in the position close to the mechanism of injury and then ask the patient to statically stabilize the shoulder while doing rhythmic stabilizations. Wall falls, table falls, and floor falls from the knees are progressions, and balancing on different balance devices are closed kinetic chain examples of this.

Step 5.3: Dynamic Stabilization Exercises (Aim: Dynamic Form and Execution with Voluntary Control)

Re-educating the Muscle Stabilizers Dynamically

- Training correct (specific) movement patterns with voluntary concentric and eccentric control
- Need to ensure proximal stability with distal mobility involving the whole kinetic chain
- Want to establish voluntary control of functional movement patterns
- Clinician watches for correct force-couple activation
- Resistance movement is given distally to gain dynamic osteokinematic control while maintaining dynamic arthrokinematic control
- Clinician watches for correct force-couple activation
- Open kinetic chain activities
- Clinician must stop exercise if fatigue or compensatory postures are evident

Dynamic stabilization exercises involve movement of the joints of the shoulder girdle performed slowly and in control above 30° abduction. This involves controlled eccentric movement of the scapula while the arm moves. When the clinician teaches dynamic stabilization exercises, the focus is on correct movement patterns. The clinician must make sure that the patient has voluntary control and that agonist and antagonist activities are performed involving both concentric and eccentric exercises. Exercises such as bent-over rowing, "lawn mower" pulls using tubing, dumbbell or tubing punch outs, and lunges with dumbbell or tubing reaches are examples of open kinetic chain dynamic stabilization exercises (Figure 6-58).[87,153]

Step 5.4: Advanced Dynamic Stabilization (Aim: Dynamic Form and Execution of Activity-Specific Skills)

Advanced dynamic stabilization involves faster movements and the whole kinetic chain, including multidimensional activities. These exercises should stress functional diagonal patterns that the patient will use when he or she returns to previous activities. They may include exercises against gravity, exercises in water, the use of free weights or tubing, isokinetic exercises, PNF

Teaching Advanced Dynamic Stabilization Exercises

- Training control in activity-specific movement (diagonal) patterns
- Multidirectional stability activities
- Progressive eccentric exercises at functional speeds
- Need to ensure proximal stability with distal mobility involving the whole kinetic chain
- Clinician watches for correct force-couple activation
- Resistance movement is given distally to gain dynamic osteokinematic control while maintaining dynamic arthrokinematic control in diagonal patterns
- Clinician watches for correct force-couple activation
- Open kinetic chain activities
- Clinician must stop exercise if fatigue or compensatory postures are evident

Figure 6-58 Examples of open kinetic chain dynamic stabilization exercises. **A,** Bent-over rowing. **B,** Lunges with dumbbell reaches.

patterns, and medicine ball and plyometric activities. Clock drills and reach-and-stretch (target) drills are examples of these exercises. Oblique or torsional movement, along with plyometrics and eccentric deceleration or braking, plays a major role.

The clinician should keep in mind the rules of specificity and the specific requirements of the patient in the rehabilitation program. Open-chain activity is a concentric movement against gravity with no fixation feedback. Injury to the shoulder from overuse is most likely to occur during open-chain activities and is often the result of loss of functional control of the scapula, the humerus, or both. Consequently, the clinician must make sure the patient has good scapular and humeral control before progressing to open kinetic chain exercises.[164] Open-chain activities include free weight exercises, which often are combined with proprioceptive activities (i.e., eyes open or closed, positioning or mirroring) to teach "free hand" feedback.

Step 5.5: Functional Stabilization (Aim: Functional Form and Skill Execution)

In the final stage of the stabilization program, the clinician teaches the patient functional stabilization, in which functional activities are broken down into their component parts so that the patient can develop particular motor skills that he or she will need in everyday life.[98,167,168] Patients are asked to perform specific, synchronized, multidirectional skilled pattern sequences (Figure 6-59). Eccentric patterns and power development are emphasized to develop the braking action and shock absorption of the muscles to protect the glenohumeral joint and the ability to control movement at functional speeds. All activities should involve most if not all of the whole kinetic chain.

Teaching Functional Stabilization

- Training synchronized skilled movement sequences and activity-specific skills
- Clinician must watch for ***patient carriage*** (e.g., weight shift, weight acceptance, movement symmetry, appropriate limb braking), ***control*** (e.g., smooth, automatic, and unrestricted execution and movement with proper form and skill), and ***confidence***
- Clinician watches for correct force-couple activation
- Clinician must stop exercise if fatigue, apprehension, or compensatory postures occur
- Teach injury or reinjury prevention strategies

Open-chain activities using devices, such as the Body Blade® and Boing® activities, plyometrics, and the use of a medicine ball are helpful in later stages of rehabilitation to teach functional stabilization and control.

Plyometric programs for the upper limb (Figure 6-60) are designed to increase the excitability of the neurological receptors and improve the reaction of the neuromuscular system.[85,126] The patient must be taught to accept greater loads (the clinician must keep in mind that with plyometrics, the rate of stretch rather than the length of stretch

Criteria for Return to Activity[85,167,168]

- Little or no pain
- No or minimal apprehension
- Functional ROM with involvement of the whole kinetic chain
- Near-normal strength (80% to 90%)
- Normal movement patterns
- Normal functional ability
- Able to perform the skills the patient wants to resume
- Appropriate level of fitness
- Appropriate patient expectations

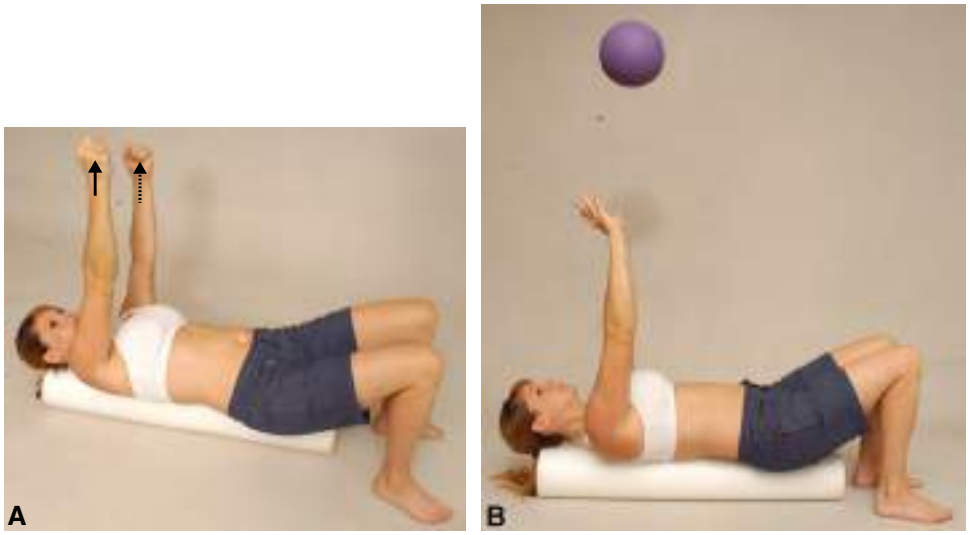

Figure 6-59 Multidirectional instability exercises. **A**, Punch out on roll. **B**, Ball toss on a roll.

is important).[169,170] Activities using a 0.9- to 1.8-kg (2 to 4 lb) ball (e.g., medicine ball or Plyoball), a bounce-back device (Plyoback™) or partner, or tubing (progressing from slow to fast sets) can be effective.

Step 6.1: Fitness Aim: To Restore or Maintain Fitness throughout Program

While the patient's shoulder is being rehabilitated, the clinician must keep in mind that the patient at some point will be returning to activity. A program to maintain or restore cardiovascular fitness should be instituted and should be as specific as possible to the patient's occupation or activity. Little good is achieved if the shoulder is rehabilitated and the patient is cleared medically to participate in activities or return to work, if patients do not have the cardiovascular fitness or activity-specific fitness to compete or to do their job. This process is sometimes referred to as *work hardening*.

To keep the patients involved and to enhance their recovery, it is imperative to have them work to maintain their fitness level if they have been active or to work to improve their fitness level if they have not been active. In both cases, fitness training will help their recovery physiologically and psychologically. Activity may be as simple as asking them to "go for a walk around the block" for someone who has done little activity to someone doing a vigorous workout on a stationary bike or elliptical apparatus. This stage can, in reality, start presurgery or postsurgery using lower limb activities that will not stress the patient's shoulder. Most commonly, patients are started with activity at about 60% of their maximum heart rate working up over time to 75% to 85%, but this will depend on their level of fitness to begin with and the activity they want to return to. There are several ways patients' target heart rate can be calculated, but probably the easiest is (220 − age) × percentage of maximum heart rate. This will give a target heart rate for training. If the activity is going to take place in water (e.g., running in water), then the target heart rate should be 10 to 13 beats less than the target heart rate calculated above because of the increased stress placed on the heart due to water resistance.

Fitness training may be modified based on what the clinician is trying to accomplish and based on the activity the individual wants to return to. For example, initially the desire may simply be to establish a good aerobic base, which will enhance the patient's recovery from exercise. Depending on the activity the individual wants to return to, the clinician may initiate different exercise regimes which may tax the alactic anaerobic system (ATP-PC system), lactic anaerobic system (glycolysis), and/or the aerobic system, each of which have their own special characteristics.

SUMMARY

Rehabilitation of the unstable shoulder can be both a challenging and rewarding experience. Clinicians must always be aware of possible pitfalls and special concerns in the treatment of the unstable shoulder. The process of treating an unstable shoulder takes time, and the patient may require anywhere from 6 months to 2 years to fully rehabilitate and regain the preinjury or preoperative status. The clinician may devise a sterling treatment plan, but ultimately the patient's dedication to and involvement in the rehabilitation program are the main predicators of a successful outcome. Therefore the patient must have enough information to "buy into" the program, understand what to expect as the program progresses, and things to watch for that may indicate he or she is pushing too hard or not hard enough, as well as having realistic expectations as to the outcomes.

CHAPTER 7

Rotator Cuff Pathology

JUDY C. CHEPEHA, MARTIN J. BOULIANE, DAVID M. SHEPS

INTRODUCTION

Shoulder pain is well established as one of the most common musculoskeletal complaints managed by physicians and physical therapists.[1–3] Up to half the population experiences at least one episode of shoulder pain per year,[3] and nearly 50% of patients have some type of rotator cuff disease.[1] Conditions affecting the rotator cuff include tendinopathy of one or more of the muscles of the rotator cuff, partial-thickness tears, and full-thickness tears.[4] Rotator cuff injuries affect individuals across the life span—they are common in young, overhead athletes, as well as in individuals 65 years and older.[5–7] The prevalence of rotator cuff tendinopathy is reported at approximately 30% of all shoulder-related disorders.[8] Studies specific to rotator cuff tears have reported incidence rates between 13% and 32%, with a significant increase in occurrence as an individual ages.[9,10] Kibler et al.[11] suggested that more than 50% of individuals older than 60 years of age have at least a partial-thickness tear of their rotator cuff and that this estimate may be low because a large number of individuals are asymptomatic.[12,13] Rotator cuff disease tends to progress over time, becoming more painful and/or involving more muscles.[14] Because of the current aging population, and that many older individuals are maintaining an active lifestyle, the incidence of symptomatic rotator cuff pathology is expected to grow.

Rotator cuff disease manifests itself clinically in a variety of ways; however, most patients complain of pain worsened with overhead activities, and exhibit strength deficits and functional impairment(s).[9,15,16] These symptoms can cause significant disruption of an individual's physical functioning within activities of daily life (ADL), work, and recreational activities, as well as negatively affect the individual's mental health and social participation.[17] The effect that rotator cuff pathology has on a patient's quality of life and resulting impairment has been compared with that of congestive heart failure, diabetes, myocardial infarction, and depression.[18]

Physical therapy, consisting of cryotherapy, therapeutic exercise, manual therapy, and electrical modalities, is the usual first course of treatment for rotator cuff-related pathology. Surgical intervention is generally considered only after a failed course of appropriate, conservative treatment lasting at least 3 months.

Clinical Note

Rotator cuff surgery should only be considered after at least 3 months of appropriate conservative treatment.

ROTATOR CUFF ANATOMY

Successful treatment of the patient with rotator cuff disease begins with a thorough understanding of the anatomy of the rotator cuff and its adjacent structures. Advances in basic science and surgical technology over the past decade have improved knowledge regarding the osseous and soft-tissue structures of the shoulder and have led to a better understanding of the role these tissues play in normal and abnormal shoulder function.

Rotator Cuff Muscles

- Supraspinatus
- Infraspinatus
- Subscapularis
- Teres minor

The four muscles that constitute the rotator cuff (supraspinatus, infraspinatus, teres minor, and subscapular muscles) arise from the scapula, a bone stabilized by different muscles, and converge with the articular capsule, coracohumeral ligament, and glenohumeral ligaments, to attach on the tuberosities of the humerus (Figure 7-1).[19–21] The supraspinatus muscle arises from the supraspinatus fossa on the upper one third of the posterior scapula. It passes beneath the acromion and the acromioclavicular joint and attaches to the superior aspect of the greater tuberosity. It is innervated by the suprascapular nerve after

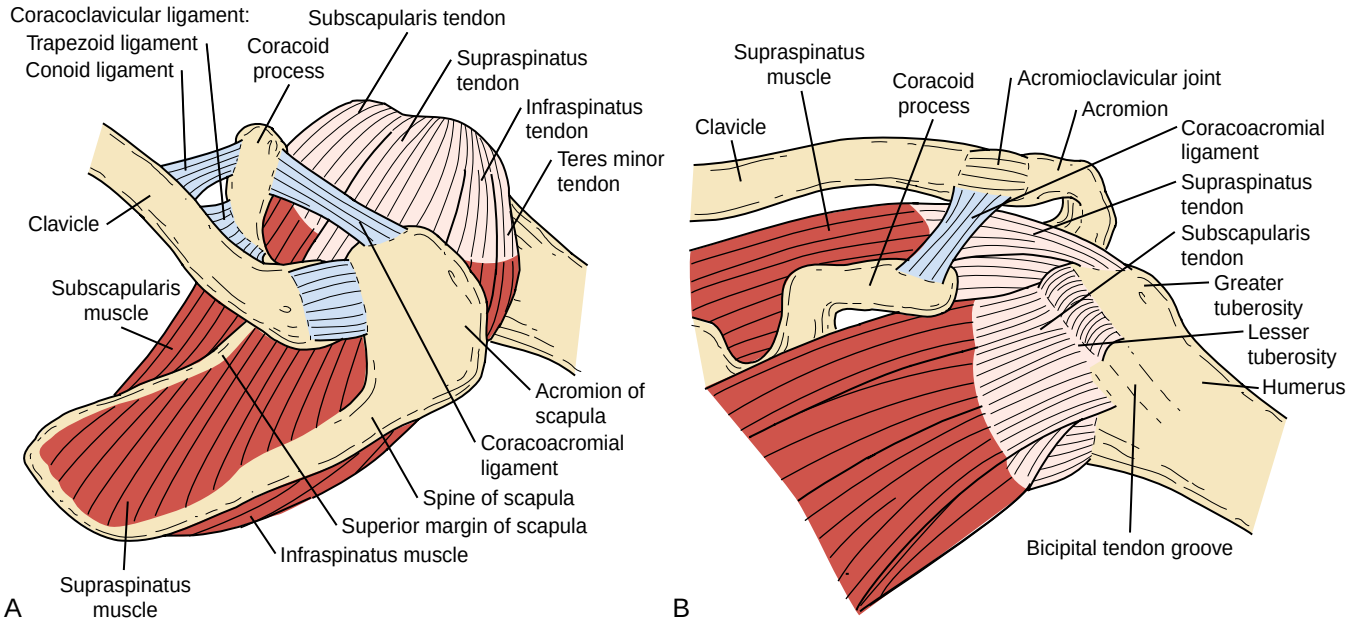

Figure 7-1 **A,** Superior view of the rotator cuff musculature as it courses anteriorly underneath the coracoacromial arch to insert on the greater tuberosity. **B,** Anterior view of the shoulder reveals the subscapularis, which is the only anterior rotator cuff muscle inserting on the lesser tuberosity. It rotates the humerus medially (internally) and provides dynamic anterior stability to the shoulder. (From Firestein GS, Budd RC, Harris ED et al: *Kelley's textbook of rheumatology*, ed 8, Philadelphia, 2008, Saunders/Elsevier.)

it passes through the suprascapular notch. The infraspinatus muscle arises from the infraspinatus fossa on the lower two thirds of the posterior scapula and attaches to the posterolateral aspect of the greater tuberosity. It is innervated by the suprascapular nerve after it passes through the spinoglenoid notch. Despite their distinct attachment sites, the tendons of supraspinatus and infraspinatus join together to form a single tendon, approximately 15 mm proximal to the insertion points on the greater tuberosity.[22] The teres minor muscle, innervated by a branch of the axillary nerve, arises from the lower lateral aspect of the scapula and attaches to the lower aspect of the greater tuberosity. The subscapularis muscle arises from the anterior aspect of the scapula and attaches over much of the lesser tuberosity. It is innervated by the upper and lower subscapular nerves. The tendons of supraspinatus and subscapularis, along with the superior glenohumeral and coracohumeral ligaments, form a sheath that encapsulates and stabilizes the biceps tendon as it enters the bicipital groove. Part of the supraspinatus tendon forms the roof, whereas the subscapularis tendon forms the sheath floor. Tearing or rupture of the anterior supraspinatus or superior subscapularis muscle can cause injury to the biceps "sling" and lead to instability of the long head of biceps.[23–25] The rotator cuff insertions form a horseshoe pattern that tapers away from the anatomic neck inferiorly. The superior insertion is tendinous, becoming more muscular inferiorly.[26] This continuous cuff around the humeral head allows the muscles to provide an infinite variety of moments to rotate the humerus and to oppose unwanted components of the deltoid and pectoralis muscle forces. Research related to the insertional anatomy of the rotator cuff tendons, known as the **rotator cuff footprint**, has helped to improve diagnosis of rotator cuff tears and assist surgeons in surgical repair.[26,27]

The long head of the biceps tendon is an important part of the rotator cuff complex; so much so, it is sometimes referred to as the fifth rotator cuff tendon (Figure 7-2).[28] It attaches to the supraglenoid tubercle of the scapula and travels between the subscapularis and supraspinatus muscles, exiting the shoulder through the bicipital groove under the transverse humeral ligament, finally attaching to its muscle in the proximal arm. Tension in the long head of the biceps tendon assists the rotator cuff in compression of the humeral head into the glenoid and guides the head of the humerus as it is elevated.[24,25,29]

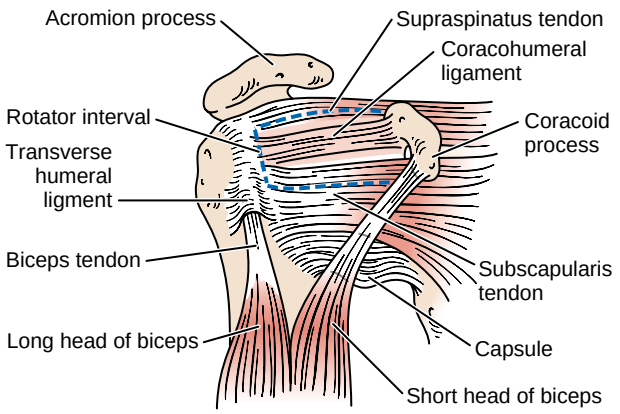

Figure 7-2 Rotator interval (*dashed lines*) showing the relationship between the supraspinatus tendon, long head of biceps, subscapularis tendon, and the coracohumeral ligament. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 255, St Louis, 2014, Saunders/Elsevier.)

The coracoacromial arch refers to the inferiorly concave surface consisting of the anterior undersurface of the acromion, the coracoid process, and the coracoacromial ligament (see Figure 5-6). It provides a strong ceiling for the shoulder joint, along which the rotator cuff tendons must glide during all shoulder movements. The coracoacromial arch has received considerable attention over the years because of its anatomic relationship to the rotator cuff tendons and the role its structures may play in causing rotator cuff injury.[30–33] Investigations[34,35] have highlighted the importance of contact and load transfer between the rotator cuff and the coracoacromial arch in the function of normal shoulders. Because there is normally no gap between the superior rotator cuff and the coracoacromial arch, the slightest amount of superior translation of the humerus compresses the rotator cuff tendons between the humeral head and the arch, resulting in impingement. Bigliani et al.[32] studied 140 shoulders in 71 cadavers with an average age of 74.4 years. They identified three acromial shapes: type I (flat) in 17%, type II (curved) in 43%, and type III (hooked) in 40%. Of the shoulders, 33% had full-thickness tears, 73% of which were seen in association with a type III acromion; 24% with type II; and 3% with type I (Figure 7-3). The clinical significance of this relatively small difference is unknown and controversial because other authors have discovered no significant association between acromial morphology and rotator cuff pathology.[36–38] A fourth type has been added to the classification as convex or upturned, but has no correlation to impingement. However, a significant correlation between age and rotator cuff tears was noted, with older patients more likely to have type II and III acromion.[36,38] These findings suggest that correlations between acromial morphology and rotator cuff tears may be exaggerated because of the confounding variable of age.

The coracoid process acts as the medial attachment site for both the coracohumeral and coracoacromial ligaments. The neighboring supraspinatus and subscapularis tendons must be able to glide past the coracoid process with their full excursion during shoulder motion. Scarring of one or both of these tendons to the coracoid process can inhibit passive and active shoulder motion. Although the coracoid process does not normally contact the anterior subscapularis tendon, forced medial (internal) rotation of the arm, particularly in the presence of a tight posterior capsule, can produce such contact because of the obligate translation, and lead to impingement of the rotator cuff tendons.[34,39]

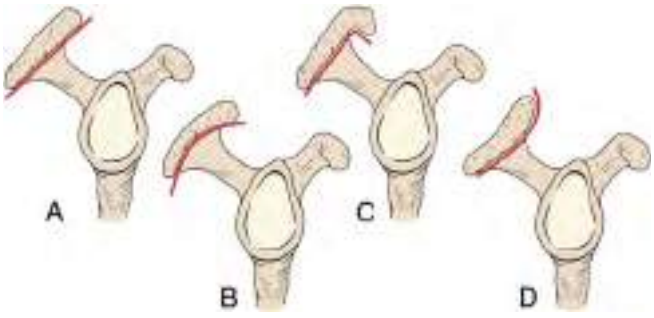

Figure 7-3 Acromion morphology. **A,** Type I (*flat*). **B,** Type II (*curved*). **C,** Type III (*hooked*). **D,** Convex (upturned). (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 257, St Louis, 2014, Saunders/Elsevier.)

The coracoacromial ligament (see Figure 5-6) originates along the distal two thirds of the lateral aspect of the coracoid process as a broad ligament. It passes posteriorly to insert onto the anteromedial and anteroinferior surfaces of the acromion. Spur formation can occur preferentially on the anterolateral band and contribute to impingement syndrome, although it has been suggested that substantial alterations in morphological and biomechanical properties occur in the coracoacromial ligament during aging.[40] Studies are needed to determine whether variations in the coracoacromial ligament morphology cause impingement or are a function of the problem.

There are three bursae relevant to the development of shoulder pain and rotator cuff disease: subacromial, subdeltoid, and subcoracoid (Figure 7-4). The subacromial bursa occupies a space above the rotator cuff and under the acromion. It is a synovium-lined cavity that acts as a gliding surface in two locations: (1) between the rotator cuff tendons and the coracoacromial arch and (2) between the deltoid muscle and the rotator cuff tendon. The subdeltoid bursa is an independent structure located on the deep surface of the deltoid muscle. The subacromial and subdeltoid bursae act together and extend as far medially as the coracoid process. The subcoracoid bursa is located inferior to the coracoid process between the subscapularis tendon and the conjoined tendon of the coracobrachialis muscle and short head of the biceps muscle. Subacromial "disease" encompasses a spectrum of pathologies ranging from bursitis to adhesion formation. Rotator cuff tears are often associated with subacromial bursitis, and this bursitis can lead to the formation of adhesions, which then contribute to rotator cuff impingement. Machida et al.[41] studied 18 patients with shoulder pain and found that subacromial bursa adhesions increased impingement between the acromion process and the rotator cuff insertion.

Anatomical consideration should also be given to the proximal portion of the rotator cuff muscles on the scapula and the relationship between the rotator cuff origins and the scapulothoracic articulation. The scapula, which is stabilized by muscles, provides a stable base for the controlled movements of the humeral head in the glenoid fossa. The muscles that attach to and stabilize the scapula (i.e., trapezius, rhomboids, latissimus dorsi, serratus anterior, levator scapulae, and pectoralis minor) aid in the positioning of the glenoid fossa to accommodate the head of the humerus (Figure 7-5). Scapular dysfunction, from altered muscle balance and/or instability, is one of the contributing factors of rotator cuff injury, especially in the young, active patient population.

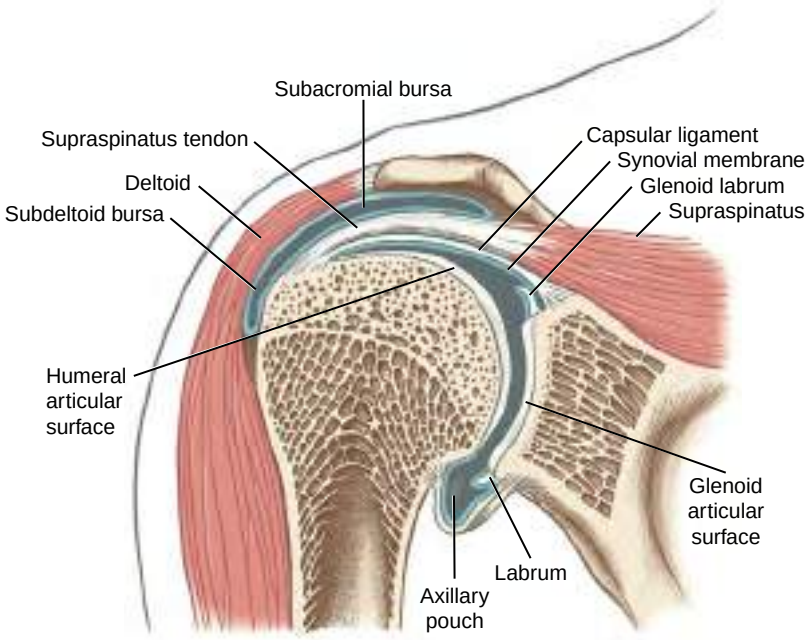

Figure 7-4 Anterior view of a frontal plane cross section of the right glenohumeral joint. Note the subacromial and subdeltoid bursa within the subacromial space. Bursa and synovial lining are depicted in blue. The deltoid and supraspinatus muscles are also shown. (From Neuman DA: *Kinesiology of the musculoskeletal system: foundations for rehabilitation*, ed 2, p 143, St. Louis, 2010, Mosby/Elsevier.)

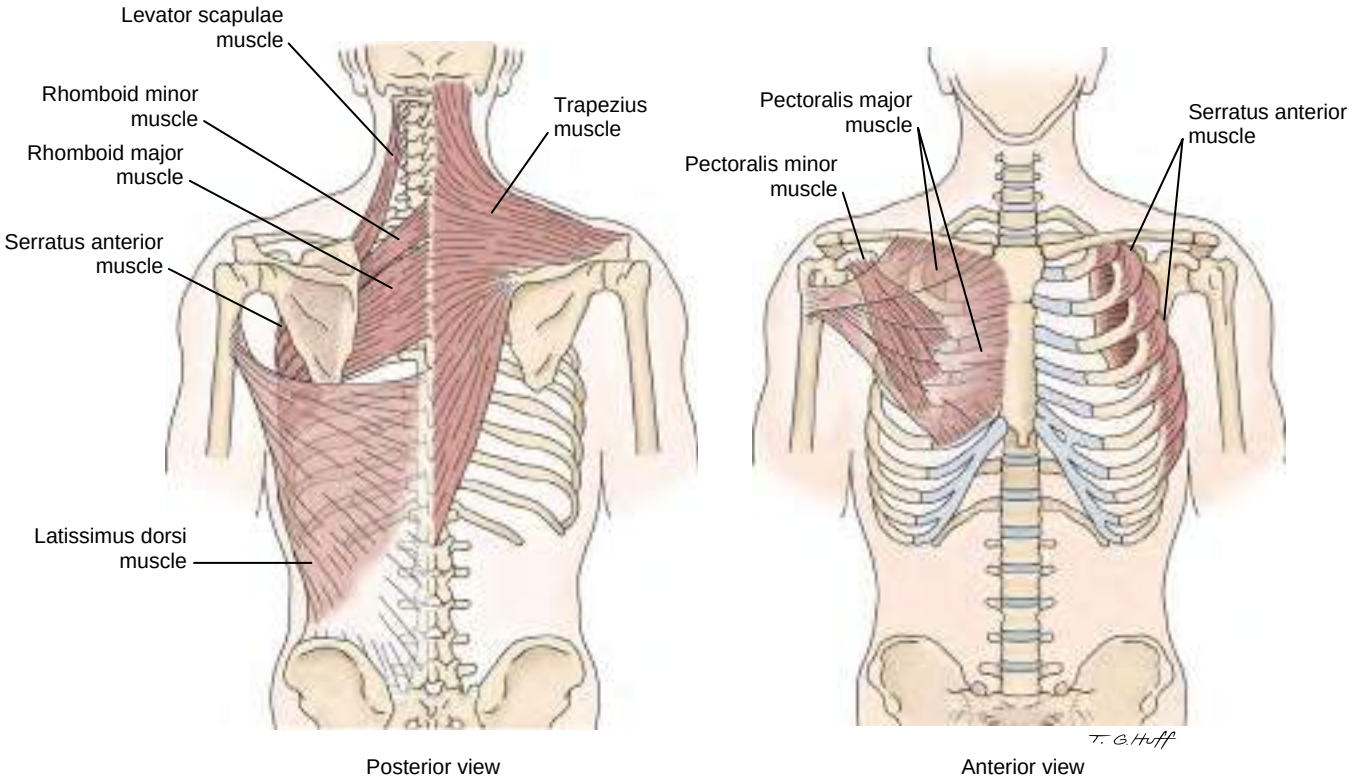

Figure 7-5 The muscles that attach to and stabilize the scapula aid in the positioning of the glenoid fossa to accommodate the head of the humerus. Note that if the elbow is braced, the rotator cuff muscles (supraspinatus, subscapularis, infraspinatus, and teres minor), teres major, deltoid, and pectoralis major can also move the scapula by "reverse origin-insertion."

Muscles Controlling the Movement of the Scapula

- Trapezius (three parts)
- Rhomboids
- Serratus anterior
- Levator scapula
- Pectoralis minor
- Latissimus dorsi (inferior angle)

ROTATOR CUFF FUNCTION

The term *rotator cuff* may be a misnomer because its role relative to shoulder function involves not only joint rotation and muscle force but also joint compression and stability. In the past, the rotator cuff has been referred to as a humeral head depressor; however, evidence now indicates that the inferiorly directed force of the rotator cuff is small compared with the humeral head compressive force it exerts to stabilize the glenohumeral joint (Figure 7-6).[42,43] The four tendons of the rotator cuff perform as a unit, precisely centering the humeral head through compression (called concavity compression) into the glenoid cavity to improve stability, resist translation, and provide rotation about the three major axes of motion.[42–44] Joint stability, through the rotator cuff's concavity-compression mechanism, is provided mostly within the shoulder's midrange positions, where passive capsuloligamentous restraints are lax; however, it has been shown to also be important at the end of shoulder range of motion (ROM), where forces acting on the joint are increased.[45] Rotator cuff compression acts to protect the capsuloligamentous structures in extreme positions by limiting the shoulder's ROM and reducing strain on these structures.[43] The humeral head maintains a relatively constant position in relation to the glenoid during shoulder rotation. The rotator cuff muscles are closer than any other muscles to the axes of rotation and therefore have shorter lever arms to affect rotation.

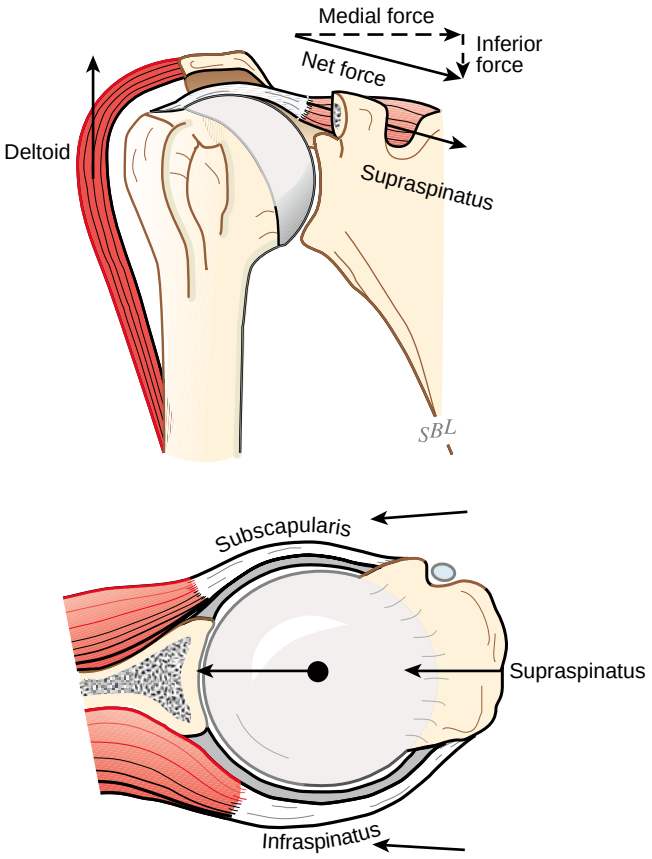

Figure 7-6 Concavity compression of the rotator cuff. (Modified from Matsen FA III, Lippitt SB: *Shoulder surgery: principles and procedures*, p. 85, Philadelphia, 2004, WB Saunders.)

Clinical Note

The rotator cuff muscles work as a unit to center the humeral head in the glenoid cavity through compression, to improve stability at the joint, resist translation at the glenohumeral interface, and provide rotation.

The amount of force that can be generated by a rotator cuff muscle is determined by its size, health or condition, and joint position. The individual rotator cuff muscles' contribution to shoulder strength has been well studied.[44–46] The supraspinatus functions mainly to aid the deltoid muscle in shoulder abduction. The dynamic interplay of supraspinatus and deltoid is well established as essential for proper glenohumeral function.[22,42,44–46] With the arm in adduction at the initiation of elevation, the pull of the deltoid muscle is nearly parallel to the glenoid surface, producing a well-documented upward shear component. The stability of the humeral head provided by supraspinatus compressing and stabilizing the humeral head inferiorly opposes the upward pull of the deltoid, avoiding impingement of the rotator cuff between the humeral head and the undersurface of the acromion. The infraspinatus muscle assists the supraspinatus in its role as a humeral head depressor, especially with the shoulder at 90° of abduction and neutral rotation. Subscapularis functions primarily as a stabilizer during lateral (external) rotation, controlling excessive anteroposterior translation as the shoulder abducts and laterally (externally) rotates. This may explain why subscapularis' contraction has been shown to be so strong in overhead athletes at the initiation of the acceleration phase of throwing. Several powerful muscles contribute to medial (internal) rotation, but tears of the subscapularis may be shown by testing function at the extreme of medial (internal) rotation, indicating the importance of this muscle at this end ROM. Patients who have sustained subscapularis tears feel the loss of joint compression and stabilization normally provided by this portion of the rotator cuff. The infraspinatus and teres minor are the only two muscles that produce lateral (external)

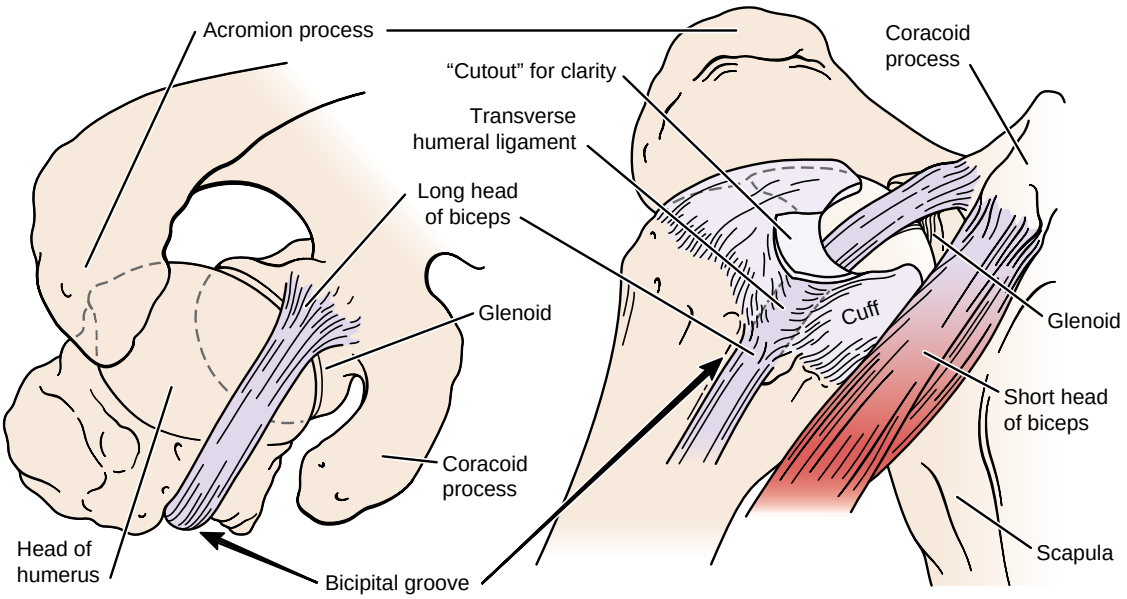

Figure 7-7 The biceps apparatus. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 254, St Louis, 2014, Saunders/Elsevier.)

rotation, and large tears in this region of the rotator cuff have profound effects on a patient's motion and strength.

The long head of biceps is often considered a functional part of the rotator cuff complex due, in part, to its intimate anatomical relationship with the rotator cuff tendons at the glenohumeral joint (Figure 7-7).[23,29] Its superior-anterior location assists the superior-posterior rotator cuff tendons in stabilizing the glenohumeral joint through humeral head compression, especially into forward elevation. The importance of the relationship between the rotator cuff and long head of biceps is evidenced through injury to one or both of these tissues. Greater than 90% of patients with a diagnosis of biceps tendinitis were found to have underlying shoulder impingement and/or instability believed to be the cause of irritation of the biceps tendon.[47] Lesions of the superior labrum, anterior to posterior (i.e., a SLAP lesion), and adjoining biceps anchor have received considerable attention over the past two decades, including work that has demonstrated a high incidence of rotator cuff tears in overhead athletes with superior labral defects (see Figure 5-27).[48–50] Rotator cuff tears were discovered in 31% of throwers with type II SLAP lesions: 38% of these were full thickness, and 62% were partial thickness. Finally, biceps were found to have an increased tendon-tension force in the presence of a large rotator cuff tear, suggesting the increase of its role in restraining superior humeral head translation to compensate for the rotator cuff failure.[25]

It is important to remember that the shoulder joint differs from single axis joints, such as the knee, in that it functions in the absence of a fixed axis. In a specified position, activation of a muscle creates a unique set of rotational moments. For example, the anterior deltoid can produce moments in forward flexion, medial (internal) rotation, and horizontal adduction. If forward elevation is to occur without rotation, the cross-body and medial (internal) rotation moments of the anterior deltoid must be neutralized by other muscles, such as the posterior deltoid and infraspinatus. As another example, use of the latissimus dorsi in a movement of pure medial (internal) rotation requires that its adduction moment be neutralized by the superior rotator cuff and deltoid. Conversely, use of the latissimus dorsi in a movement of pure adduction requires that its medial (internal) rotation moment be neutralized by the posterior rotator cuff and posterior deltoid muscles.[51]

The timing and magnitude of these balancing muscle effects must be precisely coordinated to avoid unwanted directions of humeral motion. Therefore, the simplified view of muscles functioning in isolation or as part of "force couples" must be replaced with the understanding that all shoulder girdle muscles function together in a precisely coordinated way: opposing muscles canceling out undesired elements and leaving only the net torque that is needed to produce the desired action. This degree of coordination requires a fine-tuned strategy of muscle activation or motor engram that must be established before the motion is carried out. The rotator cuff muscles are critical elements of this shoulder balance equation.

Functions of the Rotator Cuff

- Rotation of the humerus relative to the scapula
- Compression of the humeral head into the glenoid fossa, providing a critical stabilizing mechanism known as concavity compression
- Provision of muscle balance and force

ETIOLOGY

Injury to the rotator cuff occurs via several different mechanisms. Often, more than one mechanism of injury and multiple contributing factors occur simultaneously in the same patient. Injuries that are traumatic tend to be acute, with a well-defined mechanism, and occur in individuals younger than 40 years of age. Concurrent clinical findings such as glenohumeral and/or scapulothoracic instability, secondary impingement, and muscle imbalances are common in this population. More frequently, rotator cuff injuries occur atraumatically as a result of multiple, repetitive, overuse mechanisms, in individuals over the age of 40 years of age. Clinical findings in this population often include postural alterations of the shoulder girdle and/or adjacent spine, subacromial impingement, and rotator cuff degeneration.

Although the exact cause of rotator cuff disease is unknown, it is generally accepted that injury occurs because of multiple intrinsic and extrinsic factors.[52–54] Intrinsic factors include traumatic, reactive, or degenerative changes that originate within the tendon from inferior tissue mechanical properties, direct tendon overload, intrinsic degeneration, or other insult. Extrinsic mechanisms are those that damage the tendon through external forces such as compression against surrounding tissue.[55]

The proposed causes of intrinsic degeneration are primarily the vascular supply of the rotator cuff tendon, aging, and tensile overload. Several researchers have suggested that hypovascularity within the area of greatest impingement (i.e., Codman's critical zone) is the main reason why rotator cuff tears occur in this region (Figure 7-8).[56,57]

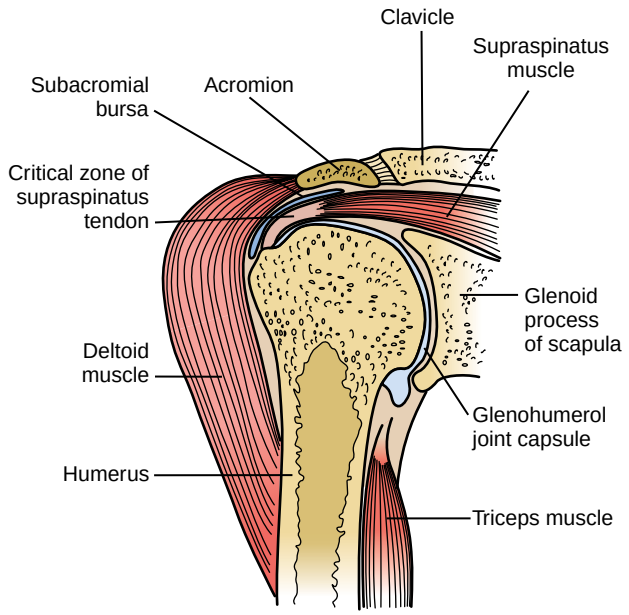

Figure 7-8 The "critical zone." Note the close relationship of the supraspinatus tendon and subacromial bursa to the humeral head and acromion, making an exact clinical diagnosis very difficult. (From Foley BA, Christopher TQ: Injection therapy of bursitis and tendinitis. In Roberts JR, Hedges JR, editors: *Clinical procedures in emergency medicine*, ed 5, Philadelphia, 2010, Saunders/Elsevier.)

Evidence has emerged that both supports and refutes this claim.[58–61] Cadaveric studies confirmed this hypovascular area within the supraspinatus tendon's critical zone, whereas microvasculature studies of the rotator cuff revealed the critical zone as being hypervascular in patients with impingement syndrome.

The effect that age has on rotator cuff tendons is much less controversial. Aging is believed to have a negative effect on the strength and resiliency of the rotator cuff, as evidenced through histological studies that reveal calcification, fibrovascular proliferation, and microtears, suggestive of degenerative changes, in individuals greater than 40 years old.[40,53,60] These same changes are rarely noted in the nonathletic population of those under 40 years. Moreover, it is generally accepted that a correlation exists between a patient's age and the healing abilities of a tendon, where the healing property of tendons of elderly individuals is diminished, as compared with that of younger tendons.[61]

Tension overload is another intrinsic factor found to contribute to rotator cuff injury. Studies have attempted to distinguish specific mechanisms that may contribute to tension overload injuries. One study reported that if the joint and bursal sides of the supraspinatus tendon are subjected to similar loads, the joint side will be more susceptible to failure.[62] Methods to measure intratendinous strain using magnetic resonance imaging have discovered that intratendinous strain fields increased with increasing glenohumeral joint angle, but the strain did not change between the articular and bursal sides.[63] These findings suggest that individuals, such as overhead throwing athletes or those working overhead, may be at risk of articular-sided rotator cuff tears from tendon overload because the joint side of the tendon may be closer to its failure strain during these activities.

Extrinsic factors that contribute to rotator cuff pathology include anatomical findings such as narrowing within the coracoacromial arch or other osseous or soft-tissue changes that result in anterior, external mechanical impingement of the rotator cuff tendons (Figure 7-9). Numerous studies have confirmed that abnormal soft-tissue and bony anatomy surrounding the rotator cuff affect the incidence of pathology; however, the degree to which anatomical variations *cause* rotator cuff injury is less clear.[30,33,34,39] Osteoarthritis of the acromioclavicular joint as well as changes to the coracoacromial ligament have also been implicated as extrinsic factors that could cause anterior impingement and mechanical irritation of the rotator cuff tendons.[38] Internal impingement can occur posteriorly, between the posterior-superior labrum and the posterior rotator cuff tendons (Figure 7-10).[5,50] This is a common problem in overhead throwing athletes because of the tremendous amount of stress placed on the rotator cuff as the athlete accelerates and decelerates the arm during the throwing motion. The rotator cuff muscles must counteract these forces, especially during the

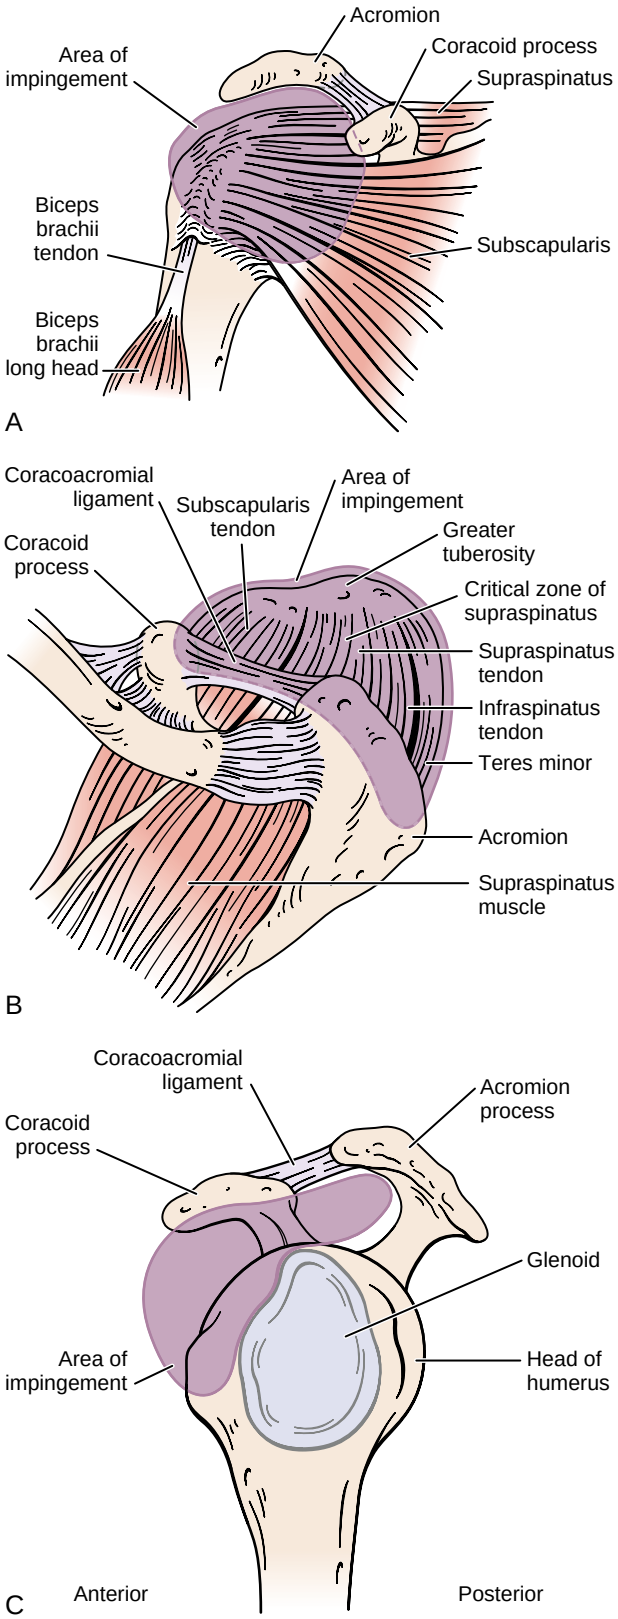

Figure 7-9 Impingement zone. **A,** Anterior view. **B,** Superior view. **C,** Lateral view. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 316, St Louis, 2014, Saunders/Elsevier.)

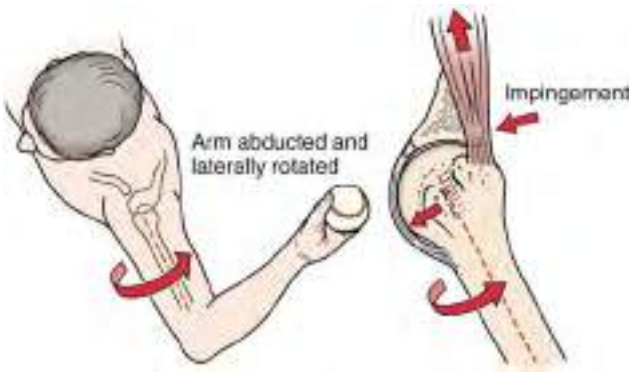

Figure 7-10 Internal impingement of the undersurface of the rotator cuff against the posterior aspect of the labrum in maximum lateral rotation and abduction. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 318, St Louis, 2014, Saunders/Elsevier.)

deceleration phase, to keep the humeral head centered in the glenoid. Thus, repetitive throwing motion can lead to repetitive microtrauma or impingement on the posterior glenoid margin, usually involving the undersurface of the posterior half of the supraspinatus and the superior half of the infraspinatus. With repeated injury, articular-sided partial-thickness tears can develop.[5,6,50]

Finally, glenohumeral instability and altered scapulothoracic motion must also be considered as possible extrinsic factors leading to rotator cuff injury. Whether instability is due to a structural defect, such as a torn labrum or from muscle imbalance and altered kinematics, the resultant increased translation at the glenohumeral joint affects the integrity of the rotator cuff through either direct compression and/or increased demand on the rotator cuff to stabilize the humeral head on an unstable glenoid.

Pain in the shoulder exists as a vicious cycle of instability, impingement, weakness, and inflammation: all signs and symptoms associated with rotator cuff pathology. Clinicians must have a clear understanding of the multiple etiological factors that can contribute to rotator cuff injuries, and identify clinical findings associated with the cause of the injury, in addition to those resulting from the injury process. Failure to recognize and address *both* of these etiological factors will affect patient outcomes and possibly lead to recurrent rotator cuff injury.

ROTATOR CUFF INJURIES

Optimal functioning of the rotator cuff occurs if all of its muscles are healthy, intact, and well conditioned, and if there is a normal amount of capsular laxity present at the glenohumeral joint, a smooth contour of the undersurface of the coracoacromial arch, a thin, lubricating bursa, and concentricity of the glenohumeral joint and rotator cuff and coracoacromial spheres of rotation.[19–21,34] Given its intricate anatomy and complex role, it is easy to understand why injuries are so common in the rotator cuff.

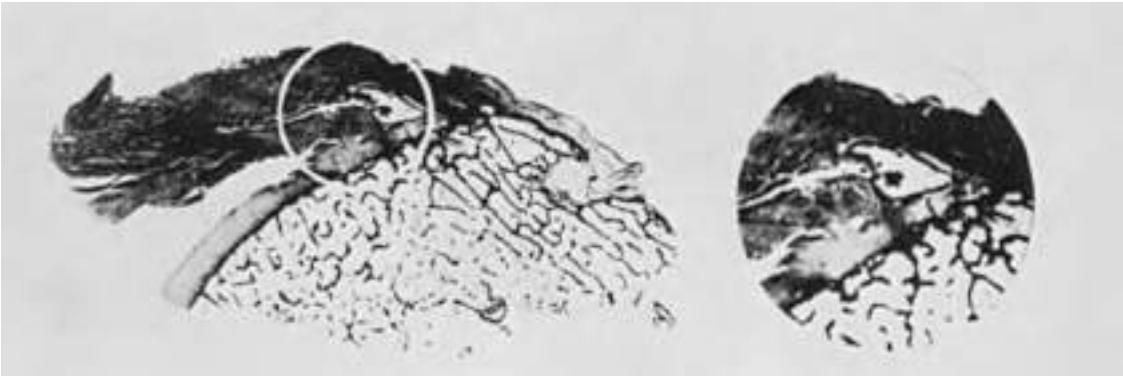

Figure 7-11 Codman's illustration of "a rim rent where all the tendon is torn away from the sulcus except the superficial portion which extends into the periosteum." These photomicrographs provide a convincing argument that cuff tears frequently begin on the deep surface and extend outward until they become full-thickness defects. (From Codman EA: *The shoulder: rupture of the supraspinatus tendon and other lesions in or about the subacromial bursa*, Malabar, 1984, Robert E. Krieger.)

Pathology of the rotator cuff includes a spectrum of injuries, ranging from minor tendinitis to various degrees of partial- and full-thickness tearing. Authors dating back to the 1930s have proposed terms and classification systems to help describe the different types of rotator cuff disease. Codman, considered a pioneer in the realm of rotator cuff injuries, described four different lesions of the supraspinatus tendon, including what he described as a "condition of great clinical importance"—partial tears or "rim rents" (Figure 7-11).[64] The Neer three-stage classification of subacromial impingement lesions has been used extensively to describe injury in this area.[30] Stage I refers to reversible edema and hemorrhage within the rotator cuff and is typically seen in patients under 25 years of age. Stage II occurs with repeated inflammation and results in fibrosis and tendinosis of the rotator cuff, typically in patients 25 to 40 years of age. Stage III occurs with further degeneration of the rotator cuff and adjacent osseous tissue(s) and results in partial or complete tears in individuals older than 40 years of age. Newer classification systems have focused on describing tears of the rotator cuff. Ellman[65] graded partial-thickness tears into three types according to depth. Grade 1 is noted as less than 3 mm deep; grade 2, 3 to 6 mm deep; and grade 3, greater than 6 mm deep. He also included information on the location of the tear, identifying bursal surface, articular surface, or interstitial tears. Fukuda[7] labeled rotator cuff injuries as grade 1, a subacromial bursitis or tendinitis (a "pretear"); grade 2, a partial-thickness tear (involving at least one-quarter thickness of the supraspinatus tendon); and grade 3, a full-thickness tear. Fukuda also classified the location of partial-thickness tears as bursal-side tears, intratendinous tears, and joint-sided tears. Snyder[66] described a classification based on tear location and severity: articular and bursal for partial-thickness tears, named "A" and "B," and "C" for complete tears. Degree of damage is labeled from zero (normal tendon) to four (very severe partial-thickness tear).

Tendinopathy

Tendinopathy of the rotator cuff encompasses a fairly broad category of pathology involving the tendon(s) of one or more rotator cuff muscles. The term *tendinopathy* is preferred to its predecessor, tendinitis, as it includes conditions of the rotator cuff with and without inflammation. Strictly speaking, tendinitis is a misnomer because inflammatory infiltrates within the rotator cuff tendon are not a predominant feature. The difficulty in adequately and consistently defining rotator cuff tendon injuries stems from a lack of routine tissue histological evaluation because patients with tendinopathies are generally treated nonoperatively.[67] This may explain why reviews undertaken to assess the effectiveness of interventions, such as therapeutic exercise in managing rotator cuff tendinopathies, have produced mixed results.[68–72]

Not surprisingly, the clinical presentation of patients with rotator cuff tendinopathy varies, depending on (1) which of the four rotator cuff muscles is involved, (2) where along the muscle and/or tendon the insult has occurred (i.e., muscle belly, musculotendinous junction, or tenoperiosteal attachment), (3) the etiology of the injury (i.e., trauma, overuse, or secondary to a primary injury), and (4) the severity of the pathology (i.e., first, second, or third degree). Treatment of rotator cuff tendinopathy should be based on information pertinent to these four points, as well as a thorough subjective and objective assessment of the entire shoulder girdle.

Determinants for Treatment of Rotator Cuff Tendinopathy

- Which of the four rotator cuff muscles is involved?
- What is the cause of the injury?
- What part of the tendon has been injured?
- How severe is the injury?

The majority of patients with rotator cuff tendinopathy describe shoulder pain as aggravated with overhead activities and relieved with rest. ROM is generally

preserved, with possible decrease at the extremes of motion. Resisted strength testing reproduces pain and, depending on the severity of tendon injury, possible weakness. Patients' chief complaints are usually related to diminished function lasting longer than 3 months.[68] Tendinopathy of the rotator cuff has been shown to demonstrate similar pathological changes to tendon disorders in other areas of the body in which loaded (i.e., against gravity or resistance) exercise has proven beneficial. Littlewood et al.[68,73] evaluated the effectiveness of loaded exercise programs for rotator cuff tendinopathy and concluded that the role of loaded exercise in treating rotator cuff tendinopathy was promising, but it required further high-quality research.

Impingement Syndromes

The term *impingement syndrome* was popularized by Neer in 1972, in an evaluation he performed on 100 dissected scapulae.[74] He described 11 as having a "characteristic ridge of proliferative spurs and excrescences on the undersurface of the anterior process of the acromion," which he attributed to repeated contact or impingement of the rotator cuff and the humeral head, with traction of the coracoacromial ligament (Figure 7-12). Of special interest was his discovery that the anterior lip and undersurface of the anterior third of the acromion were involved in all cases. In this region, the supraspinatus tendon inserts onto the greater tuberosity, lying anterior to the coracoacromial arch with the shoulder in the neutral position. With forward flexion, the structures must pass beneath the arch, providing the opportunity for impingement. This early description of shoulder impingement syndrome is now commonly referred to as *primary impingement* because the primary cause of the resultant impingement is the actual abutting of soft-tissue structures (e.g., the rotator cuff and glenoid labrum) and bony prominences (e.g., the acromion and coracoid process). Static factors believed to cause impingement include abnormalities of the coracoacromial arch that may lead to areas of higher than normal compression of the rotator cuff.

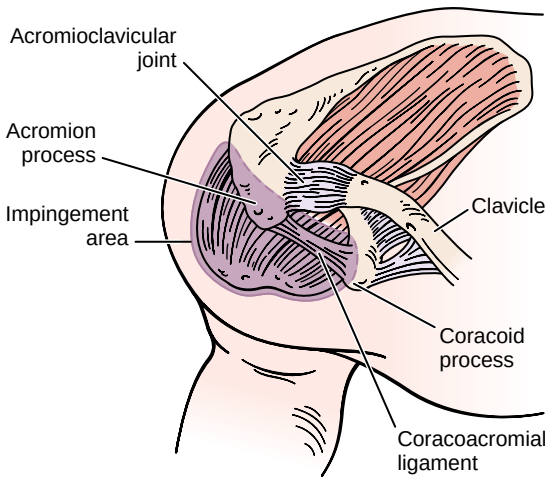

Figure 7-12 The functional arc of elevation of the proximal humerus is forward, as proposed by Neer. The greater tuberosity impinges against the anterior one third of the acromial surface. This critical area comprises the supraspinatus and bicipital tendons and the subacromial bursa. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 317, St Louis, 2014, Saunders/Elsevier.)

The shape of the acromion has been implicated as one cause of mechanical impingement of the supraspinatus tendon. Bigliani et al.[32] studied the relationship between acromion shape and external impingement by comparing the shape of the acromion to full-thickness supraspinatus tears in cadaveric specimens. Their results concluded that there are three distinct acromion shapes: flat (type I), curved (type II), and hooked (type III). Type II and type III acromion shapes had the strongest correlation with full-thickness tears, leading the authors to conclude that rotator cuff disease is influenced by acromion shape (see Figure 7-3).

Importantly, subacromial impingement is not always the sole cause of rotator cuff disease; in fact, it is more accurately described as the phenomenon that occurs because of the more probable causes of aging and physical loading of the shoulder and arm (Figure 7-13). The process of aging causes degeneration in the rotator cuff, particularly at its insertion points, which leads to fiber thickening and the formation of granulation tissue. The damaged rotator cuff then malfunctions, leading to further disorders in the subacromial area. Excessive loading of the rotator cuff may occur either through a static or "structural" (e.g., hooked acromion) mechanism, or dynamically because of the humeral head and rotator cuff moving against an unyielding structure. Current evidence indicates that both static and dynamic factors act upon the rotator cuff, leading to eventual rotator cuff disease.[33,62] With dynamic causes, the coracoacromial arch and other subacromial structures initially may be normal; however, abnormal motion of the humeral head and the rotator cuff relative to the scapula is the cause of the impingement, leading to sometimes permanent structural changes.[39,75,76] This type of anterior, external impingement is known as *secondary impingement* because the impingement is secondary to the underlying instability and pathology. A third type of impingement, termed *posterior internal impingement*, occurs with the shoulder in 90° of abduction and lateral (external) rotation, and involves compression of the undersurface of the posterior rotator cuff tendons against the posterior-superior glenoid rim (see Figure 7-10). This type of impingement commonly affects individuals involved in overhead work or throwing sports.[28,75]

Rotator Cuff Tears

Rotator cuff tears are among the most common conditions affecting the shoulder, accounting for 4.5 million physician visits in the United States per year.[77] They may

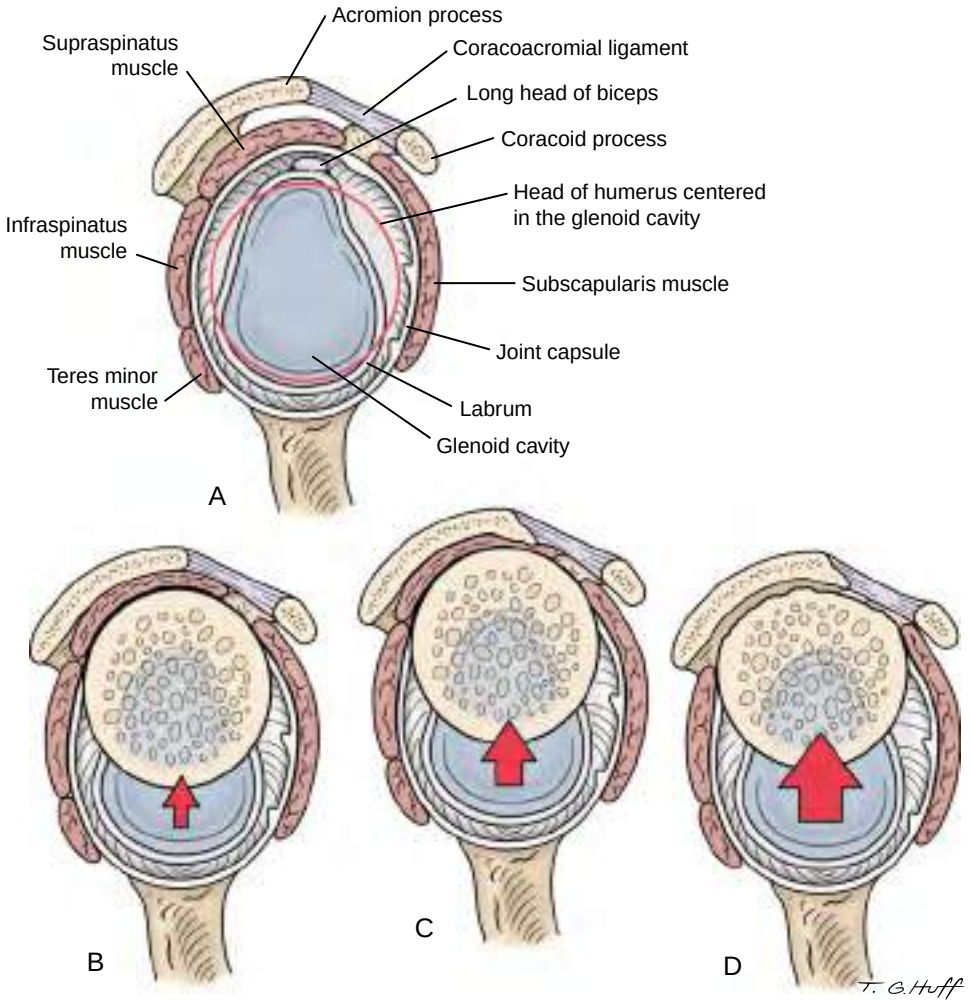

Figure 7-13 Rotator cuff degeneration. **A,** Normal relationships of the cuff and the coracoacromial arch. **B,** Upward displacement of the head, which squeezes the cuff against the acromion and the coracoacromial ligament. **C,** Greater contact and abrasion give rise to a traction spur in the coracoacromial ligament. **D,** Still greater upward displacement, resulting in abrasion of the humeral articular cartilage and cuff tear arthropathy.

be classified as partial or full thickness, acute, chronic, or acute on chronic, and traumatic or atraumatic or degenerative. Tears can range from mild microtearing to total absence of one or more of the rotator cuff tendons. In a young, active patient, rotator cuff tears are almost always the result of a traumatic insult and may occur in combination with other injuries such as an avulsion fracture of the greater tuberosity or injury to the glenoid labrum (Figure 7-14). Degenerative rotator cuff failure, associated with the older individual, typically begins with a partial-thickness defect on the deep undersurface of the supraspinatus as it attaches to the greater tuberosity (Figure 7-15).[78,79] A common misdiagnosis of shoulder pain (e.g., tendinitis, bursitis, and impingement syndrome) may actually represent failure of the deep surface fibers of the rotator cuff. The degree to which the intact fibers may hypertrophy, strengthen, or adapt to stabilize the tear and take up the function of the damaged fibers is unknown. Pettersson[80] used the term *creeping tendon ruptures* to describe a condition in which major rotator cuff defects may occur without symptoms or a recognized injury. He suggested that previous minor, often subclinical, fiber failure could leave the shoulder weaker and the rotator cuff tendons progressively less able to withstand the loads encountered in daily living.

The majority of rotator cuff tears involve the supraspinatus tendon, followed by the infraspinatus and upper subscapularis tendons.[52,54,78] The articular (deep) surface of the supraspinatus tendon has approximately half the strength of the bursal (upper) surface, making it more vulnerable to tearing. The presence of tearing within the anterior supraspinatus or superior subscapularis can also cause injury to the biceps tendon, specifically instability of the long head of the biceps. In addition, long head of biceps dislocations are commonly associated with lesions of the rotator cuff.[29,47,81]

The reported incidence of rotator cuff tears ranges anywhere from 13% to 32%; however, the actual frequency of all tears is unknown because partial-thickness tears are poorly defined and can occur without symptoms.[4,10,82]

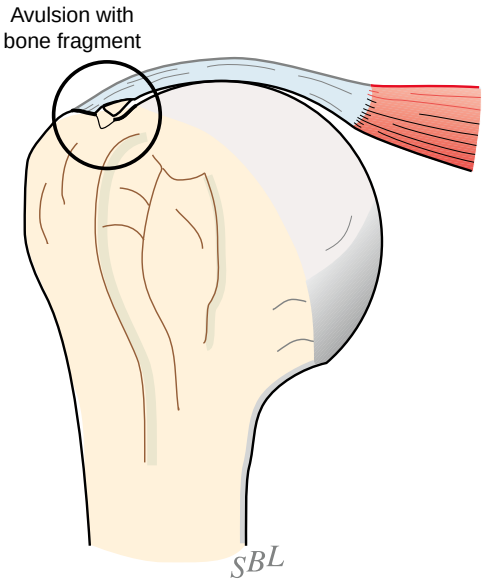

Figure 7-14 Partial-thickness cuff tear with avulsion of a bony fragment from the tuberosity. (From Matsen FA III, Lippitt SB, Sidles JA, et al: *Practical evaluation and management of the shoulder*, Philadelphia, 1994, WB Saunders.)

One group of authors,[82] studying the role age plays in the prevalence of rotator cuff tears, noted that the incidence in cadavers younger than 60 was 6%, compared with cadavers older than 60 years, where it was 30%. Partial-thickness tears appear approximately twice as often as full-thickness defects and can occur on the bursal side, on the articular side, or in the intratendinous region of the rotator cuff. Bursal-sided tears are reported to produce the most severe symptoms due in part to the large number of pain receptors in bursal tissue and the location of the tear within the subacromial space.[7,62,83]

Massive rotator cuff tears are reported as ranging from 10% to 40% of all rotator cuff tears[84] and defined as tears larger than 5 cm in combined areas or a tear involving two or more tendons.[85] The conditions that lead to a massive tear of the rotator cuff are diverse, and its presentation is similarly diverse. A common feature of the shoulder with a massive rotator cuff tear is the subsequent upward migration of the humeral head, which develops over time because of the shear forces created by muscles such as deltoid (Figure 7-16). These tears can cause an uncoupling of forces across the glenohumeral joint and result in unstable shoulder kinematics. Patients typically present with pain, periscapular atrophy, and significant weakness. Rotator cuff tear arthropathy is a pathological condition of the glenohumeral joint in which chronic rotator cuff tearing is associated with structural glenohumeral joint destruction.[86] The joint destruction involves humeral head erosion or collapse, and in some patients, glenoid erosion (Figure 7-17). Rotator cuff tear arthropathy does not include rotator cuff disease in which proximal migration of the humeral head is present without advanced structural changes in the joint surfaces. After a massive rotator cuff tear, the shoulder joint is progressively affected by the profoundly altered biomechanical and biological changes. The corresponding morphological changes were recognized as early as the mid-1800s, when tear-associated joint destruction was compared with localized destructive arthritis. The term *rotator cuff tear arthropathy* was first used by Neer in 1977 to describe shoulder joint destruction secondary to rotator cuff tearing.[87]

Natural History of Rotator Cuff Tears

Natural history refers to the progression of change of the rotator cuff over time in the absence of medical intervention. An understanding of natural history allows for the development of prevention and treatment programs and allows the clinician to inform the patient about what may happen should the disorder go untreated.[88]

As previously noted, rotator cuff tears may be either asymptomatic or symptomatic, and appear to increase in prevalence with increasing age.[89] Approximately 50% of

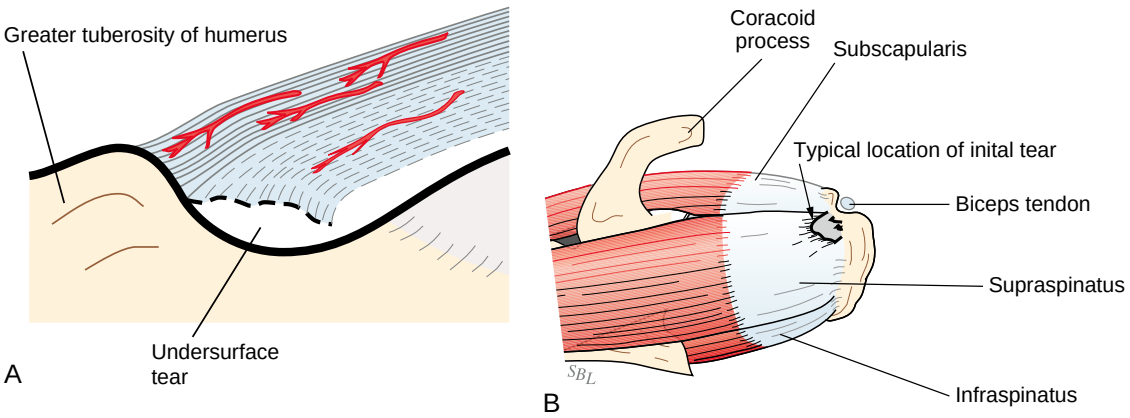

Figure 7-15 In degenerative cuff disease, the tendon fibers fail a few at a time, usually starting at the deep surface of the supraspinatus near its insertion, close to the long head of the biceps. **A,** Anterior view. **B,** Posterior view. (From Matsen FA III, Lippitt SB, Sidles JA, et al: *Practical evaluation and management of the shoulder*, Philadelphia, 1994, WB Saunders.)

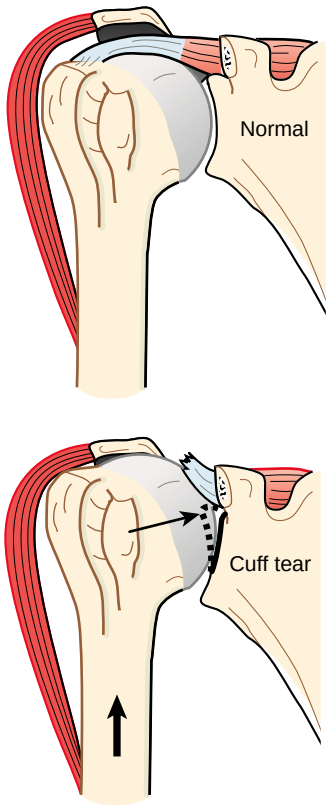

Figure 7-16 In chronic cuff deficiency, erosion of the upper glenoid may leave the shoulder with a permanent tendency toward superior sublux-ation that cannot be reversed by cuff repair surgery. (From Matsen FA III, Lippitt SB, Sidles JA, et al: *Practical evaluation and management of the shoulder*, Philadelphia, 1994, WB Saunders.)

Figure 7-17 Collapse of the humeral head in combination with massive cuff deficiency because of cuff tear arthropathy. (From Walch G, Edwards TB, Boulahia A, et al: Arthroscopic tenotomy of the long head of the biceps in the treatment of rotator cuff tears: clinical and radiographic results of 307 cases, *J Shoulder Elbow Surg* 14(3):238-246, 2005.)

asymptomatic, untraumatized shoulders, belonging to patients between 60 and 90 years of age, were reported as having partial- or full-thickness rotator cuff defects.[12,89–91] Thus, when describing the natural history of rotator cuff tears, the course of the asymptomatic tear and the symptomatic tear both must be examined.

It remains unclear why some asymptomatic rotator cuff tears become symptomatic. To answer this question, two longitudinal studies have assessed a series of patients with asymptomatic tears. The first series of 45 patients were followed for an average of 5.5 years, with 23 returning for repeat ultrasound assessment. Over a mean of 2.8 years, 51% developed symptoms, and there was an association with a significant increase in pain and decrease in the ability to perform activities of daily living in patients who developed symptoms. It also appeared that the onset of symptoms was associated with an increase in tear size.[14]

A second series of 195 patients, followed with ultrasound, demonstrated an association between pain and the progression in tear size and a greater likelihood that larger tears were more likely to develop pain in the short term compared with smaller tears.[92] Of note, both of these studies examined individuals with a symptomatic rotator cuff tear in the contralateral shoulder. The authors acknowledged that there may have been differences between the patient population studied and individuals without involvement of the contralateral shoulder.

No longitudinal studies exist that examine the untreated symptomatic rotator cuff tear. A series of 59 shoulders receiving nonoperative treatment and followed with serial magnetic resonance imaging suggested that full-thickness tears were more likely to progress in size compared with partial-thickness tears, and that this rate of progression was more prevalent after 18 months than it was during the first 18 months. Additionally, the authors also demonstrated greater progression in individuals over 60, atrophy only with full-thickness tears, and a 17% rate of development or progression of fatty infiltration.[93]

Increased use of diagnostic imaging, such as magnetic resonance imaging and arthrography, over the past decade has identified a seemingly "normal" indicator of aging tissue. Furthermore, rotator cuff defects have been found to be compatible with normal, painless, functional activity. Yamanaka and Matsumato[94] used arthrography to study the progression of 40 untreated partial-thickness tears in asymptomatic patients with a mean age of 61 years. Their 1-year results revealed overall improvements in their subjects' shoulder function scores, despite arthrography findings that showed greater than 50% of subjects had either an enlargement of their tear or a progression to a full-thickness tear.

General Treatment of Rotator Cuff Tears

The management of rotator cuff tears is the subject of substantial debate among clinicians and researchers. In a number of studies, the clinical results of rotator cuff repairs in symptomatic patients, who were followed for as long as 10 years, were good to excellent in a high percentage of cases, even though rerupture of the rotator cuff was known to occur in 20% to 65% of cases.[94–97] Interestingly,

a massive, irreparable rotator cuff tear is not incompatible with good overhead function. Observations such as these have made clinical decision making relative to the treatment of symptomatic rotator cuff tears challenging. Historically, treatments have consisted of rehabilitation and surgical repair such as subacromial decompression without repair, tendon transfers, and tendon substitution techniques. The most commonly reported prognostic factors for rotator cuff repair are patient age, chronicity of tear, and size of tear.[28,97–100] Rerupture is clearly a major concern in these patient populations, and it has been correlated with tear size, tear chronicity, and patient satisfaction.

Some current controversies in the management of rotator cuff tears include the role of rehabilitation, the indications for and timing of surgical repair, the method of surgical repair, and the management of irreparable defects. Important factors that must be considered in the decision between surgical and conservative management of a patient with a symptomatic, full-thickness rotator cuff tear are the patient's age and expected activity level and whether muscle or tissue retraction and rotator cuff muscle atrophy and fatty replacement are present.[100–102] Surgery is almost always suggested for patients in the fourth or fifth decade of life who have suffered a traumatic injury that resulted in a full-thickness tear. Patients in the sixth, seventh, or eighth decade of life may or may not be well suited for surgical repair, depending on the chronicity of the tear and the quality of the remaining tendon and muscle tissue, as well as other health issues.[97,98] If the tissue is less than optimal, failure to heal is a significant possibility. Most patients in the older age groups are more interested in eliminating shoulder pain and achieving a functional ROM than in having powerful overhead use of the arm. However, the average age of the general population is increasing, and a sizable proportion of these individuals are remaining active. Therefore, the clinician is likely to be faced with challenging questions about the best way to manage rotator cuff tears and maximize a patient's functional goals and requirements.

CLINICAL PRESENTATION OF ROTATOR CUFF PATHOLOGY

Rotator cuff pathology manifests itself clinically in a variety of ways, depending on the type and severity of pathology, as well as the individual patient characteristics (i.e., concurrent injuries, co-morbidities, and activity level). Common complaints include pain worsened with overhead activities, strength limitations, and functional impairments. Limitations in mobility are related to muscle weakness; therefore, active ROM is usually affected more than passive ROM is. Pain is reported at the end point of motion and is generally greater in abduction and lateral (external) rotation planes of motion. Patients with subacromial impingement or rotator cuff tears, however, may present with limitations in both active and passive ROM because of altered anatomy and/or biomechanics of the shoulder girdle. Patients with subacromial impingement also may possess a characteristic painful arc of movement between 60° and 120° of abduction (Figure 7-18). Patients with rotator cuff tendinopathies and partial-thickness tears tend to have more pain because of the intact sensory components, as compared with patients with full-thickness tears. Functional impairments commonly described by this patient population include difficulty with reaching overhead and behind one's back, lifting (especially with an extended elbow), and lying on the affected shoulder.

Weakness and pain are the primary causes of functional limitations associated with rotator cuff pathology. The degenerative tendon fibers may be weakened and may fail without a specific clinical manifestation.[40,53,54] Patients with partial-thickness tears have substantially more pain on resisted muscle action than those with full-thickness tears have, again because of the often intact nervous tissue, and bursal-sided tears seem to be more symptomatic than deeper tears because of the resultant problems with roughness of the articulation between the upper surface of the rotator cuff and the undersurface of the coracoacromial arch.[62,83,103] Some authors and clinicians believe that a subacromial injection of local anesthetic can be used to differentiate weakness caused by painful inhibition from weakness caused by a tendon defect.[104]

Rotator cuff tears may cause shoulder instability because of a loss of efficient centering of the humeral head in the glenoid. Acute tears of the subscapularis, although less common, may contribute to recurrent anterior instability. Chronic loss of the normal compressive effect of the rotator cuff mechanism and of the stabilizing effect of the superior rotator cuff tendon interposed between the humeral head and the coracoacromial arch may contribute to superior glenohumeral instability (and secondary impingement).[105]

Patients with rotator cuff tears frequently complain of a symptomatic crepitus during passive glenohumeral ROM. This roughness often is caused by bursal hypertrophy, secondary changes in the undersurface of the coracoacromial arch, loss of integrity of the upper aspect of the rotator cuff tendons, or degenerative changes in the tuberosities of the humerus.[28,34,78,103] These factors culminate in a condition known as **subacromial abrasion** (Figure 7-19). Neer et al.[87] used the term *rotator cuff tear arthropathy* to describe a similar phenomenon, which they believed was a cause of this roughness associated with rotator cuff defects.

Patient History

Clinical evaluation of the patient with suspected rotator cuff pathology begins with a detailed medical history, as well as a comprehensive objective examination of the shoulder girdle and adjacent spine and ribs. Shoulder pain can be caused by injury to the osseous and/or soft tissue of the

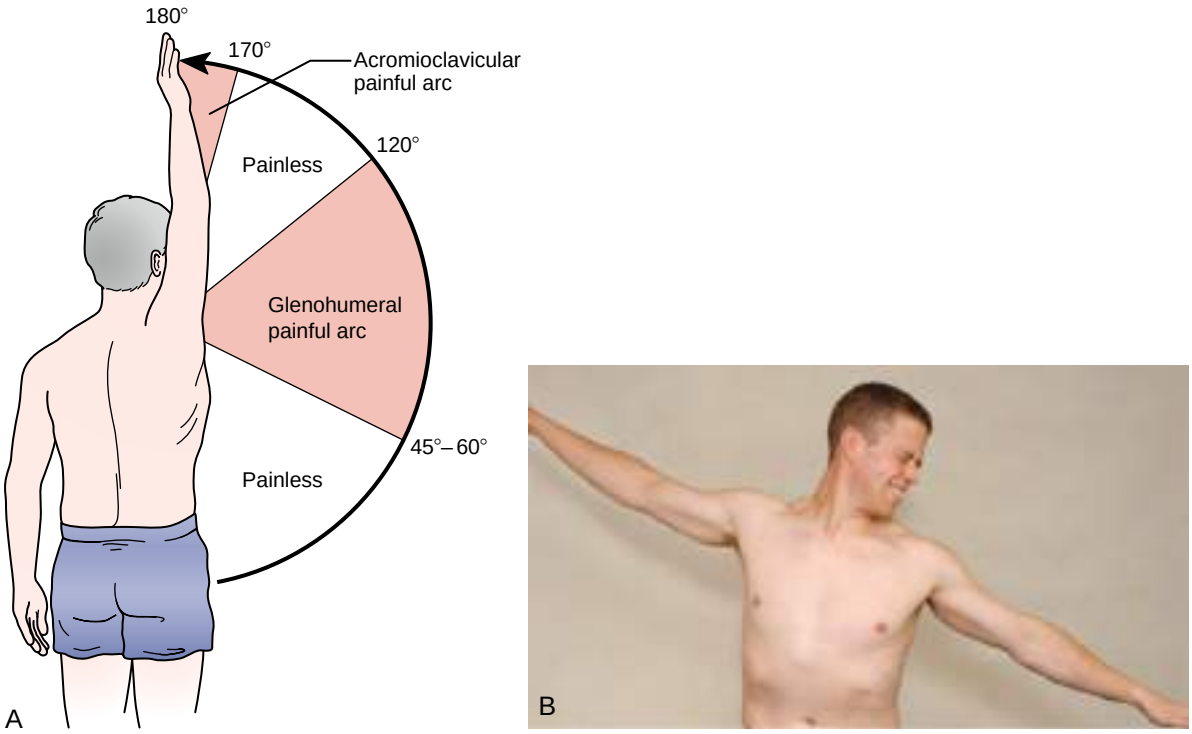

Figure 7-18 Painful arc in the shoulder. **A,** Painful arc of the glenohumeral joint. In the case of acromioclavicular joint problems only, the range of 170° to 180° would elicit pain. **B,** Note the impingement causing pain on the right at approximately 85°. Figure 7-19 Abrasion sign. Symptomatic subacromial crepitance on rotation of the arm elevated to 90° with respect to the thorax, a position in which the capsule and ligaments are normally not under tension. (Modified from Rockwood CA, Matsen FA, editors: *The shoulder*, p 824, Philadelphia, 1998, WB Saunders; Matsen FA III, Lippitt SB, Sidles JA, et al: *Practical evaluation and management of the shoulder*, Philadelphia, 1994, WB Saunders.)

glenohumeral joint, dysfunction about the scapulothoracic region, or it may originate within the cervical or thoracic spine regions. Clinicians must be cognizant of primary and secondary causes of rotator cuff pathology and include all suspected regions within a patient's assessment. The subjective history should follow a systematic approach, similar to all other musculoskeletal assessments, with particular attention given to the following factors.

Patient Profile

Factors such as patient age, occupation, and activity level are key in understanding the etiology and pattern of rotator cuff injuries. Injuries are common in young, active individuals, as well as in patients over 65 years of age who possess normal, degenerative processes at the glenohumeral joint. Younger patients with rotator cuff injuries are often involved in some type of overhead sport or an occupation that places excessive force and repetitive demand on the shoulder, especially during overhead activities. The rotator cuff is particularly susceptible to conditions such as subacromial impingement and partial tears in patients over 50 years of age, where normal degeneration of the shoulder joint occurs. The prevalence of subacromial impingement and rotator cuff tears has been shown to increase significantly in this population, but it is not limited to older adults—partial-thickness tears are also reported in younger athletes.[5] Age does, however, seem to be most consistently related to the incidence of full-thickness tears, with older patients being significantly

more affected.[12,16,79] Activities that are repetitive and occur overhead, place individuals at greater risk of rotator cuff injury. These include daily life, work, and/or recreational activities. Minagwa et al.[10] performed a population study that showed an increased prevalence of full-thickness tears in people who performed heavy labor. The nature of work performed may also influence frequency of partial-thickness tears, but no studies have looked at this as a risk factor.

Mechanism of Injury

Rotator cuff injuries can occur as a result of an acute traumatic mechanism, such as a fall on an outstretched hand ("FOOSH" injury), or they can be atraumatic in nature, often because of repetitive overload or degeneration. Many patients possess a combination of mechanisms ("acute on chronic"), describing one incident that caused the eventual injury on a shoulder that was previously injured to a lesser degree and/or was always "sore." The literature indicates that a memorable incident of trauma is related to degree of tearing. Of patients with a full-thickness tear, 65% were able to describe a defined incident that caused their shoulder injury, whereas only 47% of patients with partial tears, and 37% with tendinitis were able to recall a specific onset.[7] Differences between grades of lesion and mechanism have also been reported: patients with a well-defined injury more often had full tears (65%), versus 53.3% of patients with partial tears, who had no episodic injury.[95]

Aggravating and Easing Factors

Information related to what aggravates and eases a patient's injured shoulder is helpful in establishing the type and degree of rotator cuff pathology involved. In addition, these factors form important, patient-directed functional outcome measures. Typical aggravating factors include movements and positions that place the arm overhead and behind the plane of the body. Both of these positions are made worse if load is added to the arm and the elbow is extended, resulting in greater leverage forces directed on the shoulder joint. Activities performed in abduction are worse than flexion and scaption (i.e., movement in the scapular plane), and most patients with rotator cuff pathology describe impingement-type symptoms when their arm is medially (internally) rotated and elevated to around 90° of elevation, especially in combination with horizontal adduction.

Pain

Pain almost certainly accompanies the patient with rotator cuff pathology. It typically presents in the anterolateral aspect of the shoulder with a common referral pattern to the deltoid insertion point. A deep ache that intensifies to a sharp pain when the arm is placed in aggravating positions is commonly noted in this patient population. Night pain is also a common complaint for both partial-thickness and full-thickness tears, with pretears and partial-thickness tears generally more painful than full-thickness tears are.[7] Pain is a strong motivator for patients seeking care and the most common symptom of a rotator cuff tear.[15] Radicular pain is not indicative of rotator cuff pathology, and if reported, it should direct the clinician to perform a cervical spine examination.

Function and Health-Related Quality of Life

Rotator cuff disease has a high incidence rate, and active individuals are often affected.[106] As noted, common clinical features are pain at rest and at night, motion loss, and weakness.[26,33,51] These symptoms can lead to disruption of activities of daily living, work, and leisure, with overall poor quality-of-life experience.[17] The functional disability of rotator cuff injuries affects not just the physical aspect of a patient's life but also the mental and social aspects.[17,18] Therefore, clinicians should include outcome measures related to upper-extremity functional capacity and quality-of-life measures to understand and monitor the level of effect a rotator cuff injury has on the patient's livelihood.

Physical Examination

The objective physical examination of the patient with suspected rotator cuff pathology should include the entire shoulder girdle, as well as the proximal (cervical and thoracic spine), ribs, and distal segments (elbow, wrist, and hand) of the upper-extremity kinetic chain. Diagnostic imaging (i.e., ultrasound and magnetic resonance imaging) and arthroscopic surgery may or may not be included in the diagnostic procedure. Objective assessment of the shoulder consists of a series of tests that measure how the shoulder and related tissue(s) move, as well as "special tests" designed to discern the type and severity of rotator cuff involvement. Despite this systematic approach, accurate diagnosis of an injured rotator cuff is notoriously difficult. Partial-thickness tearing is especially troublesome to diagnose because its signs and symptoms mimic those of other shoulder conditions such as rotator cuff tendinopathy, impingement syndromes, and atraumatic instability.[107–109] Open surgery is considered the gold standard for rotator cuff disease diagnosis; however, this is clearly impractical for use in every patient with suspected pathology. Magnetic resonance imaging and ultrasound are considered reference standards.[110] However, there is uncertainty regarding the accuracy of these tests in identifying conditions such as partial-thickness tears.[107] Special tests for the rotator cuff, although easy to apply and inexpensive,[110] generally have high sensitivity but low specificity.[109,111,112] Most research into the diagnosis of rotator cuff pathology concludes that no single test (physical or imaging) is accurate on its own,[113] reinforcing the importance of considering all components of the patient's assessment (i.e., subjective, objective, and imaging tests) when determining a patient's diagnosis.[114]

Observation

Observation starts at the beginning of the patient-clinician interaction and continues throughout the entire examination. The patient should be observed at rest and with movement, from the anterior, lateral, and posterior views (Figure 7-20). Ideally, the patient should be observed in positions he or she reports as aggravating, as well as while performing his or her functional activities. Careful inspection of the scapulothoracic region and adjacent spine and ribs is important because these regions may play a role in the cause and effect of the rotator cuff pathology. In the young patient, there may be evidence of scapular dyskinesis or muscle imbalance seen, specifically the lower trapezius (i.e., decreased) and the upper trapezius muscles (i.e., increased) (Figure 7-21). The older patient with rotator cuff disease may have an altered or reversed scapulohumeral rhythm because of significant rotator cuff weakness and/or pain, and this may be in combination with muscle atrophy of one or more of the rotator cuff muscles. The thoracic and lumbar spine regions may be important to inspect depending on the patient's history and/or initial presentation. The young, athletic patient with suspected rotator cuff pathology should be carefully observed for postural abnormalities of the spine and hypomobility of the ribs and lower kinetic chain that may be contributing factors to his or her shoulder injury. Postural abnormalities such as shoulder girdle rounding, chin poking, and thoracic spine kyphosis are common in older patients with shoulder pain.

Mobility

Mobility testing assesses several components involved in movement: a patient's willingness to move, joint range, and muscle power.[115] Active and passive ROM testing of the scapulothoracic and glenohumeral joints, as well as selective testing of tissue known to be tight in this population, should all be included in this portion of the examination. Because the primary tissue at fault (i.e., rotator cuff) is contractile, active ROM should be affected more than passive ROM is; however, this will depend on whether the tissue surrounding the rotator cuff is involved (i.e., coracoacromial arch). Common limitations include: (1) glenohumeral abduction affected more than flexion, (2) greater than 90° elevation positions affected more than those less than 90°, and (3) active ROM affected more than passive ROM. Patients with impingement or acute rotator cuff pathology may demonstrate a painful arc of movement from approximately 60° to 120° of abduction and a compensatory shoulder hike pattern (i.e., reversed scapulohumeral rhythm). Overhead athletes with an injured rotator cuff should be carefully assessed for deficits of medial (internal) rotation ROM at 90° of abduction, particularly of their dominant shoulder (Figure 7-22). Loss of this movement, with a concurrent increase in lateral (external) rotation ROM, is believed to occur as a result of osseous and soft-tissue changes about the shoulder, and it has been linked to shoulder pathology.[50,116,117]

Limitations in movement about the shoulder can occur as a result of different mechanisms. They can be as a direct result of the injured rotator cuff, as seen in the patient with decreased abduction from a supraspinatus tear, or a painful arc of motion in the patient with subacromial impingement. Motion can also be altered because of a compensation pattern adopted by the patient to avoid pain, impingement, or instability at the glenohumeral joint.

Figure 7-20 Views of the shoulder. **A,** Anterior. **B,** Posterior. **C,** Side. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 265, St Louis, 2014, Saunders/Elsevier.)

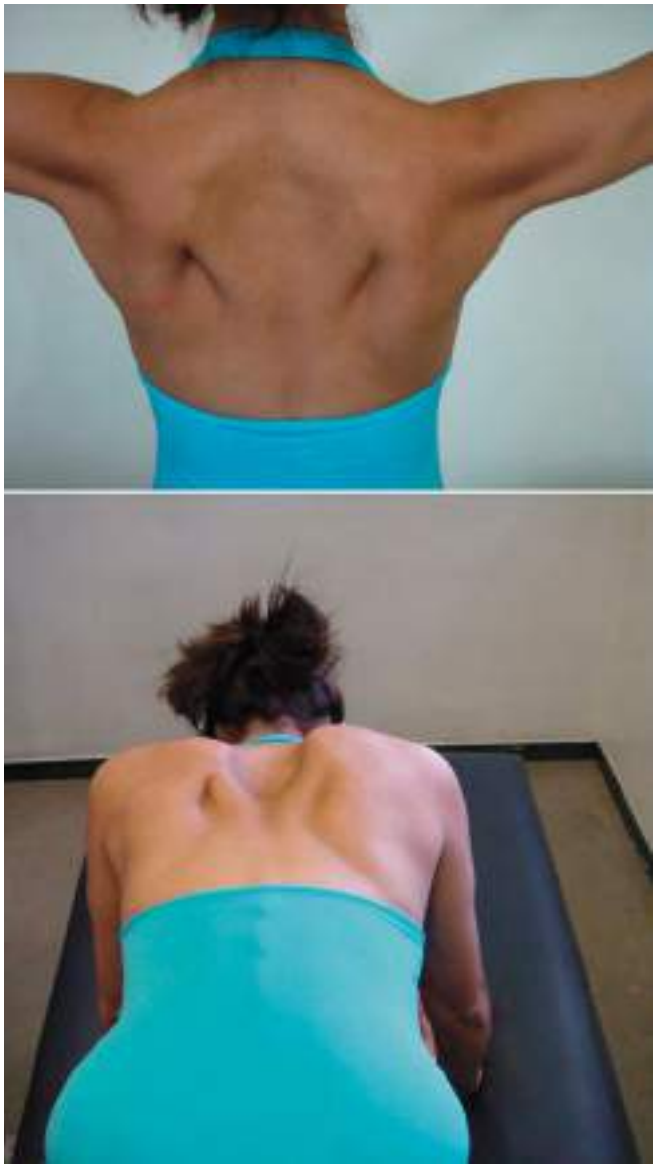

Figure 7-21 Imbalance pattern of the upper and lower trapezius. Note the overdevelopment of the upper trapezius and lower trapezius working to prevent rotary winging. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 269, St Louis, 2014, Saunders/Elsevier.)

Figure 7-22 Glenohumeral medial rotation passive ROM measurement using stabilization of the scapula by holding the coracoid process and the scapula down. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 277, St Louis, 2014, Saunders/Elsevier.)

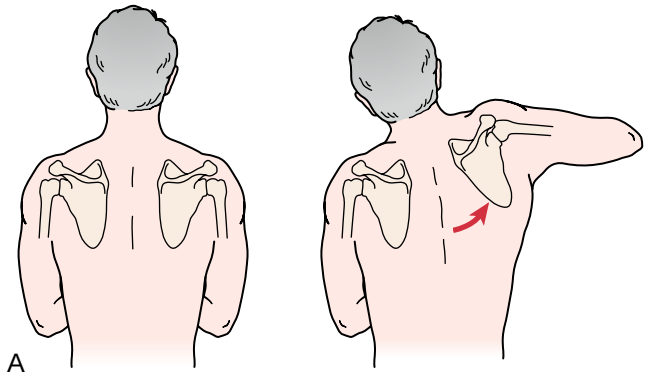

Figure 7-23 Reverse scapulohumeral rhythm (notice shoulder hiking) and excessive scapular movement. Examples include **A,** frozen shoulder or **B,** tear of rotator cuff. (**A,** From Magee DJ: *Orthopedic physical assessment*, ed 6, p 276, St Louis, 2014, Saunders/Elsevier. **B**, From Beetham WP, Polley HF, Slocum CH et al: *Physical examination of the joints*, p. 41, Philadelphia, 1965, WB Saunders.)

An example of this is the patient who uses a reversed scapulohumeral rhythm (i.e., shoulder hike) to elevate his or her arm because of significant rotator cuff weakness or the patient who uses scapular retraction instead of lateral (external) rotation to avoid painful motion or instability at the glenohumeral joint (Figure 7-23). Finally, abnormal ROM may be part of the contributing cause of the rotator cuff pathology. Common clinical features associated with patients with rotator cuff pathology include scapular instability (i.e., in the young patient) and decreased thoracic spine extension (i.e., in the older patient). Distal ROM alterations such as decreased hip and trunk rotation can affect the efficiency of the kinetic chain and have a detrimental effect on the shoulder and rotator cuff in individuals who use their arm in overhead positions.[118] Clinicians must be aware of all of the interrelationships of the kinetic chain during shoulder movement and be careful to differentiate which of the three categories the limitation falls into for successful treatment planning.

Strength

Strength testing should include the muscles of the entire shoulder girdle, not just the rotator cuff. Muscles that attach to and control the stability and movement of the

scapulothoracic articulation are often weakened because of rotator cuff injury or they are part of the cause of the rotator cuff failure in the first place. Furthermore, shoulder rehabilitation programs emphasize the strength of the scapular muscles; therefore, establishing baseline strength measures of these muscles is essential for determining outcome. Rotator cuff strength should be assessed with the glenohumeral joint in neutral, as well as in abduction (at 90°), if pain allows. In young, athletic individuals with rotator cuff pathology, information related to the rotator cuff muscles' endurance, as well as strength, may prove more useful. Most patients with rotator cuff pathology present with weakness of lateral (external) rotation (i.e., primarily infraspinatus) and abduction (i.e., supraspinatus) movements of the glenohumeral joint.[115] McCabe found all grades of rotator cuff tears had strength deficits in most movements, but 10° abduction showed a distinction between partial and full thickness—full-thickness tears had a greater loss of strength.[16] The most common finding relative to the scapulothoracic joint includes weakness of the lower trapezius and serratus anterior muscles with a concurrent increase of overactive upper trapezius muscle.[119,120]

Special Tests

Special tests are designed to confirm or rule out a tentative or preliminary diagnosis. Although strongly suggestive of a particular injury or condition when they yield positive results, they do not necessarily rule out the injury or condition when a negative result is obtained. Ever since Codman's original description of rotator cuff disease, special tests have been developed to identify lesions of the rotator cuff. Tests most commonly included in the shoulder examination of a patient with suspected rotator cuff pathology are those that measure rotator cuff integrity (e.g., empty can test) and detect impingement (e.g., Neer test) (Figure 7-24). Shoulder instability tests should also be included when examining a young, overhead athlete. A comprehensive description of the special tests for the shoulder may be found in *Orthopedic Physical Assessment*.[115] Systematic reviews evaluating many of the special tests used to diagnose rotator cuff disease have found the tests to be adequate at ruling out rotator cuff lesions but less accurate for ruling them in (Table 7-1).[4,109,110,121–123]

Diagnostic Imaging

Although the importance of a thorough history and physical examination for a patient with suspected rotator cuff pathology cannot be understated, the suspicion of an acute rotator cuff tear or the failure of nonoperative treatment supports obtaining objective imaging of the rotator cuff. Imaging helps to confirm or refute a suspected diagnosis, and it assists the clinician with planning further nonoperative and potential operative management. Imaging may also assist the clinician in better assessing the prognosis of a rotator cuff tear.

Figure 7-24 Impingement sign. **A,** A positive Neer impingement sign is present if pain and its resulting facial expression are produced when the examiner forcibly flexes the arm forward, jamming the greater tuberosity against the anteroinferior surface of the acromion. **B,** An alternative method (Hawkins-Kennedy impingement test) demonstrates the impingement sign by forcibly medially rotating the proximal humerus when the arm is forward flexed to 90°. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 318, St Louis, 2014, Saunders/Elsevier.)

Many imaging options exist, including x-rays, arthrography, computed tomography arthrography, ultrasound, and magnetic resonance imaging without or with contrast. However, it is critically important to assess imaging in the context of clinical findings. Imaging is highly sensitive, and management based solely on imaging findings may lead to unnecessary or overtreatment.[124]

Multiple studies exist assessing the accuracy of the various imaging modalities for rotator cuff tears. Regional variations exist in the preference of one modality over the other, with computed tomography arthrography being more prominent in Europe than in North America. Studies assessing the accuracy of imaging compared with surgical findings generally provide the highest level of evidence; however, the assessment of atrophy and fatty infiltration cannot be done surgically, which is why these studies provide a measure that is less defined.

Studies with a higher level of evidence exist for the assessment of ultrasound and magnetic resonance imaging, compared with surgical findings, as well as for the comparison of ultrasound, magnetic resonance imaging and magnetic resonance imaging with contrast, and surgical findings. The literature does demonstrate a trend for imaging to define full-thickness tears better, compared with partial-thickness tears and tendinosis, with the accuracy of ultrasound and magnetic resonance imaging decreasing with tears that are less severe. As with all imaging, the results require interpretation and are thus dependent on the skill and experience of the interpreter.

For the evaluation of the rotator cuff specifically, ultrasound should be considered as the imaging modality of choice for the initial detection of full- and partial-thickness rotator cuff tears in patients with a history and clinical findings that do not suggest any other intra-articular disorder.[125] Magnetic resonance imaging may be reserved for cases with equivocal findings and in patients with involvement of anatomical structures not well defined by ultrasound.[126] Ultrasound has the advantage of being noninvasive, well tolerated, inexpensive with minimal risk, and it can be used for bilateral comparisons. However, it does not reveal pathological conditions in bone or intra-articular lesions, and there is a significant learning curve before obtaining adequate results.[127] In most cases, the use of both modalities is redundant, and their use in combination with the use of magnetic resonance imaging with contrast should be reserved for cases where the desired information can only be provided by the specific modality or combination of modalities.

All of these tests, however, have limitations when compared with the gold standard of arthroscopic surgery. Magnetic resonance imaging has fairly high sensitivity and specificity for full-thickness tears, but for partial-thickness tears, sensitivity is much lower with continued high specificity.[109] Although magnetic resonance imaging is acceptable for ruling in any rotator cuff tears, cost and wait times for testing are additional issues.[108] Ultrasound is also more accurate for full-thickness tears but only fair for evaluating partial-thickness tears (Table 7-2).[109]

TREATMENT OF ROTATOR CUFF PATHOLOGY

Treatment of the patient with rotator cuff pathology is based upon the specific nature of the injury or condition, as well as the individual patient's goals and functional requirements. Care must be taken to understand and address the underlying pathology, as well as the causal factors that led to or are secondarily contributing to the injury. Finally, treatment plans should be based upon information obtained from the patient history and physical examination.

The initial treatment of most rotator cuff injuries, including partial-thickness and some full-thickness tears, is nonoperative. The literature, however, is diverse with respect to best practice recommendations, specifically regarding which patients require surgical intervention and when and what nonoperative interventions are most effective in managing the various rotator cuff pathologies.

Operative versus Nonoperative Management

As mentioned, the majority of rotator cuff injuries benefit from nonoperative management for a period of at least 3 months, before surgical consideration. Exceptions to this include an acute, traumatic tear, especially in a

young, active individual or chronic full-thickness tears in patients younger than 65 years of age.[99,101,128] Early operative intervention may also be considered in cases with mitigating factors such as severe recalcitrant pain, inability to work because of symptoms, or timing of surgery according to the start or end of an athlete's season to minimize time lost for recovery.[28] Comparative outcome studies of operative versus nonoperative interventions in rotator cuff patients have yielded inconclusive results. Seida et al.[69] studied the benefits and harm of conservative and surgical treatments on clinically important outcomes in adults with full- and partial-thickness rotator cuff tears. They identified five studies in their review that compared nonoperative with operative treatments. Four of these studies included physical therapy (treatment components not specified) with or without the addition of steroid injections, oral medications, activity modification, or manual therapy.[102,128–130] One study examined the use of shockwave therapy.[131] All study groups showed statistically significant improvements regardless of the intervention; however, the reviewers noted that the evidence was too limited to draw conclusions regarding comparative effectiveness. Decisions regarding which patients with rotator cuff pathology ultimately require surgery and at what stage remain unclear.

Nonoperative Management

The state of evidence, relative to physical therapy management of patients with rotator cuff disease, is limited and of low-moderate methodological quality.[68,102,128–130,132–134] Very little evidence exists to support its effectiveness in treating patients with rotator cuff injuries. Reports of treatment programs are inconsistent and often lacking in detail regarding specific interventions, exercise dosage parameters, and treatment delivery methods. In fact, "physical therapy" is often labeled as the intervention with no further description provided. Very little work has examined the effect of physical therapy on specific rotator cuff pathologies. Most studies combine tendinopathies, impingement syndromes, partial-thickness tears, and full-thickness tears within their study populations, despite evidence that some rotator cuff injuries (i.e., full-thickness tears) require surgical repair.[69,84,85] Conversely, some studies investigate a specific physical therapy intervention (e.g., laser) but have applied it to a heterogeneous sample of patients with varying types of shoulder pathologies.[69,71] Despite this, physical therapy remains a mainstay of treatment for rotator cuff injuries, and clinicians should continue to deliver treatments grounded in general shoulder rehabilitation principles. Goals of treatment include (1) protecting and encouraging optimal healing of the injured rotator cuff muscle or tendon(s) and surrounding tissue, (2) educating patients (including how to avoid repeated injury), (3) managing pain, (4) restoring normal mobility or tissue length of the shoulder girdle and adjacent kinetic chain segments, (5) restoring normal strength with emphasis on the affected and nonaffected rotator cuff muscles and scapular stabilization muscles, (6) including or encouraging a component of aerobic exercise to the overall treatment, and (7) educating patients on modifying work and recreational activities that may interfere with achievement of the optimum outcome.

Pain is a powerful inhibitor of muscle activation at the shoulder. This is particularly problematic given the number of muscles that act to coordinate shoulder girdle motion, stability, and function. Efforts should be taken to relieve or manage pain in the patient with rotator cuff pathology. This can be accomplished through the use of pain-relieving modalities, patient education, and active exercise. Complete rest from activity is seldom recommended; instead, exercises should be modified by reducing the intensity and/or frequency and altering factors such as arm position (e.g., neutral versus overhead), leverage (e.g., bent elbow versus straight elbow), and degree of motion (e.g., small arc versus large arc exercises). Ideally, exercises should be done within a pain-free ROM, and patients should be instructed on how to manage and monitor pain responses.

Rotator cuff injuries are commonly associated with local and distant deficits in flexibility, strength, and muscle balance that can affect the entire kinetic chain. For example, poor upper-body or trunk posture is often observed in individuals with chronic rotator cuff impingement syndrome. Exercises to correct poor posture should be implemented early in the rehabilitation process, and patients should be instructed that all subsequent exercises begin with establishing "proper posture." Reduced hip and lumbar spine flexibility (i.e., rotation) can lead to increased stress on the shoulder of an overhead athlete. To maintain the maximum force output, the athlete compensates for the loss of hip and trunk flexibility by overextending his or her shoulder into greater degrees of abduction and lateral (external) rotation—a position known to stress the rotator cuff. A breakdown or deficit of any part of the kinetic chain may cause shoulder injury or may occur because of the injury. Regardless, all deficits of the kinetic chain should be noted on assessment and incorporated into the overall treatment plan.

The stabilizing muscles of the scapula should always be included in a strengthening program for the rotator cuff. Scapular winging, abnormal periscapular muscle recruitment, and disruption of the scapulohumeral rhythm are all common in patients with rotator cuff pathology.[116,135] The lower trapezius and serratus anterior muscles are often affected and become "underactive," whereas the upper trapezius compensates and becomes "overactive." The resultant loss of scapular control can contribute to or worsen shoulder impingement, acromioclavicular dysfunction, and rotator cuff disease.[135,136] Proper shoulder rehabilitation should include careful evaluation and treatment of any abnormalities in this region. Patients should

be first taught how to perform an isolated contraction of the weakened scapular muscle(s), followed by a sequence of progressions that encourage the muscle(s) to work in a coordinated, synchronous manner with other scapular muscles, postural trunk muscles, and finally muscles of the glenohumeral joint and arm. Proximal stability (i.e., scapular control) must be achieved early in the rehabilitation process, before distal mobility (i.e., glenohumeral and arm movement) is encouraged.

It is important to remember that activation of the rotator cuff muscles involves a concentric movement, whereas stabilization is both static (i.e., isometric) and dynamic (primarily eccentric). Exercise programs should reflect all three of these types of muscle contractions. As previously mentioned, patients must be taught to stabilize their scapula while performing rotator cuff exercises, to ensure a proper base of support for the working muscles. Initially, rotator cuff exercises should be performed with minimal resistance in low-risk positions (i.e., neutral position with a 90° bent elbow) that encourage proper muscle firing without compensation, pain, and/or impingement (Figure 7-25). When appropriate, progressions toward more complex, functional movement patterns that incorporate the rotator cuff should be initiated. Examples include increasing the amount of glenohumeral elevation, eventually performing rotation in overhead positions; increasing volume and resistance; incorporating muscles and joints from the rest of the upper kinetic chain (e.g., proprioceptive neuromuscular facilitation [PNF] patterns); altering the body's base of support to engage the trunk and lower kinetic chain (e.g., sitting on a physioball, standing on one leg); and proprioception and balance types of exercises (e.g., Body Blade® and closed kinetic chain exercises). The patient's signs and symptoms, as well as his or her ability to perform the exercise(s) properly, are always the best guide for progressing to more challenging levels. The goals of rehabilitation for a patient with a symptomatic, full-thickness rotator cuff tear are a combination of education about activity modification, pain management, and ROM and strengthening exercises that focus on the remaining muscles of the rotator cuff and the supporting musculature.[137,138]

The shoulder complex, particularly the glenohumeral joint, is prone to stiffness after trauma, injury, or immobilization.[139] Early intervention through a combination of gentle stretching and joint mobilization techniques may

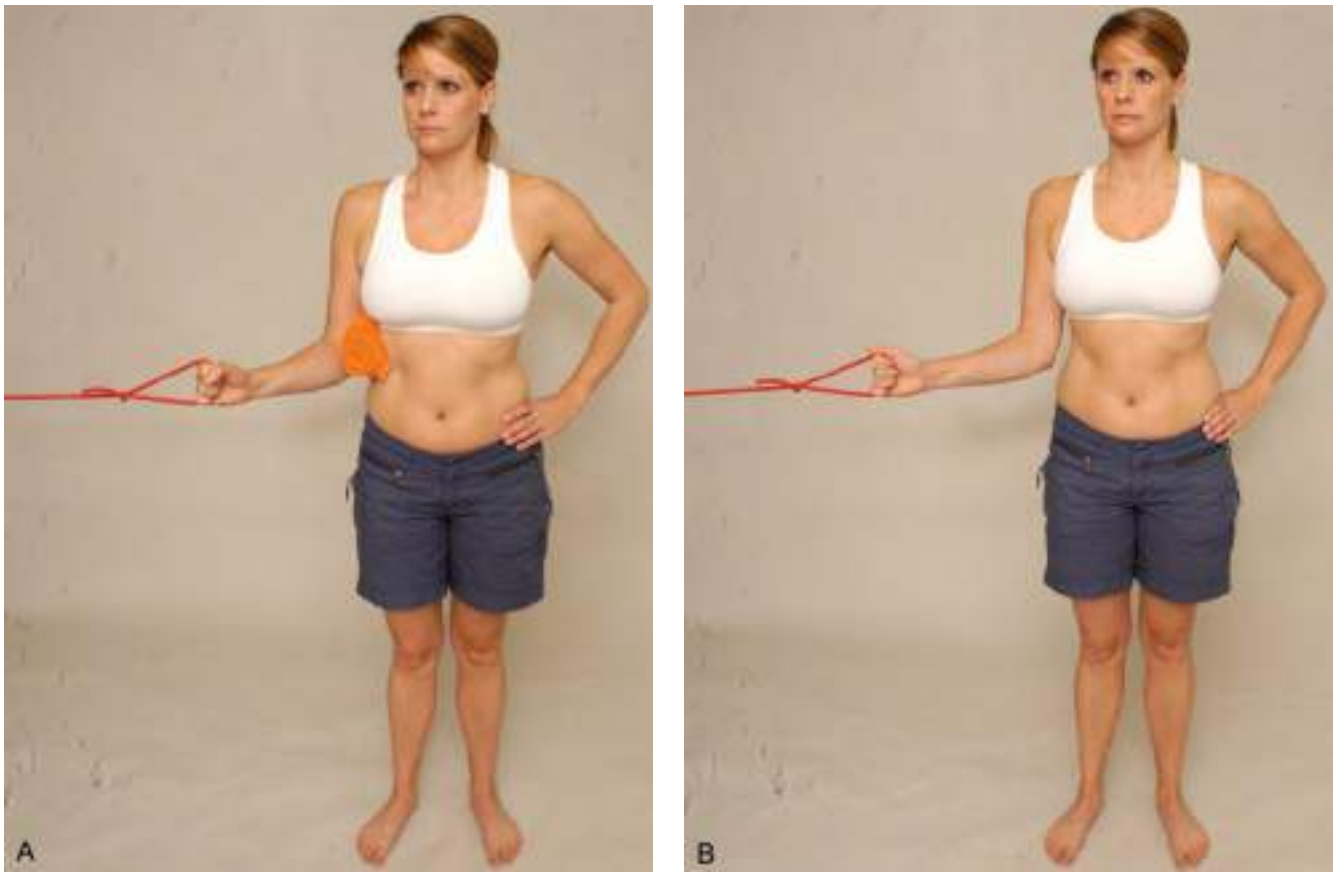

Figure 7-25 Examples of tubing exercises into medial rotation, with the arm at the side, both with (**A**) and without (**B**) a towel at the elbow. Note that the clinician should be cautious in using a towel to hold the elbow against the side. If the patient does not have good control of the scapula, stabilization through the elbow occurs, and using a towel reinforces the incorrect pattern.

prevent this restriction, reduce associated pain, and allow the shoulder to function normally. Special consideration must be given to the adaptive tightening of the glenohumeral posterior capsule, which presents clinically as a medial (internal) rotation ROM deficit, and to the anterior shoulder muscles (e.g., pectoralis minor), which also tend to shorten because of postural and scapular malpositioning.[116,117,140] The sleeper stretch (for posterior capsule tightness) (see Figure 6-31) and the open book stretch (for pectoralis minor tightness) are two examples of appropriate stretches that may be useful with this patient population. Exercises such as the pendular arm swing and the active-assist stick or cane may be used initially to increase ROM. Once a patient is able to actively move his or her shoulder with proper scapulohumeral rhythm (i.e., no upper trapezius shoulder hiking) and minimal pain, he or she should be progressed to active ROM exercises. Eventually, patients with rotator cuff pathology should be performing a variety of ROM exercises—in both open and closed chain positions, with and without load—that mimic functional movement patterns (see Figure 6-37). The goal of nonsurgical treatment of partial-thickness tears specifically is to ensure that the scar collagen that forms in the defect becomes as supple as a normal tendon. If this does not happen, scar contracture tends to concentrate the load of the rotator cuff on the scar, leading to recurrence and further propagation of the injury.[141,142]

Operative Management

Surgical intervention is an option for symptomatic rotator cuff tears that fail a trial of nonoperative management, which has included an active exercise program.[143] When determining whether surgery is appropriate, both patient and rotator cuff–specific factors should be considered. Patient-specific factors include age, medical comorbidities, worker compensation status, and ability or willingness to follow instructions and participate in postoperative physical therapy.

The primary goal of rotator cuff repair surgery is pain control, and although function can be improved, patients need to be appropriately counseled that even though the shoulder will be significantly better after surgery, it will likely still not be normal. Patients may be unable to return to their previous line of work or sport if they are heavy laborers or overhead or throwing athletes. Surgical outcomes tend to be better in patients who are younger than 65, nonsmokers, and are free of other medical comorbidities such as diabetes and osteoporosis.[143–148] Worker compensation patients demonstrate worse outcomes.[149] Managing patient expectations in terms of length of time to recovery is also important because full recovery may take up to 1 year. Physical therapy is recommended to aid in this recovery, and patients who are unwilling or noncompliant in following postoperative instructions should be counseled to avoid surgical management.

Rotator cuff–specific factors to be considered include tear size, chronicity, and status of the rotator cuff musculature. Large, retracted tears that are associated with significant atrophy of the involved muscles have a worse prognosis with surgical intervention.[143,148,150] For acute traumatic tears, early surgical management should be considered, providing the absence of muscle atrophy and retraction.[143,151]

Surgical repair of the torn rotator cuff can be performed through an arthroscopic, mini-open, or an open approach. The repair involves securing the torn edge of the rotator cuff back down to its native insertion on the proximal humerus. The tendon can be reattached using suture anchors or through transosseous tunnels with heavy suture material. Tears can be repaired either through a formal open incision, a smaller mini-open approach, or an all-arthroscopic technique. Over the past decade, the latter technique has significantly increased in popularity. At the time of surgery, concomitant pathology of the long head of biceps, labrum, and acromioclavicular joint can be treated if warranted. At present, evidence is lacking for routine subacromial decompression or removal of bone from the undersurface of the anterolateral acromion.[152] Furthermore, the type of surgical repair that has the best outcome has yet to be elucidated, with all approaches and techniques providing significant improvement in disease-specific and health-related quality-of-life outcome measures.[153–155]

Postoperative Management

A patient who has undergone rotator cuff repair surgery is managed initially with a period of sling and swath immobilization, followed by a progressive regimen of ROM, strength, and functional exercises.[155–157] The length of time patients are immobilized varies, but for most, it is 4 to 6 weeks, depending on the specific surgical procedure and patient adherence.[156] Most postoperative protocols are divided into phases with specific goals and treatment interventions for each phase. Phases generally coincide with tissue-healing timeframes: phase I extends from 0 to 4 to 6 weeks after surgery (depending on the immobilization period); phase II from 4 to 6 weeks to 12 weeks; and phase III from 12 to 24 weeks. Primary goals of phase I are to encourage optimum healing of the repaired rotator cuff and decrease pain and inflammation. Clinicians must be mindful of the equally important secondary goals during this initial phase, which are protecting glenohumeral joint ROM, scapulothoracic stabilization, kinetic chain exercises, and general health and wellness. Patients should be considered ready to progress to phase II of their rehabilitation if pain is significantly reduced at rest, there has been no disruption to normal tissue healing, and the patient has been able to manage the exercises within phase I. The goals of phase II, following rotator cuff repair, include increasing glenohumeral

joint ROM and shoulder girdle strength, while still protecting the healing rotator cuff tissue. During this stage of recovery, patients should begin to resume normal ADL and should be able to engage in increased integration of the whole kinetic chain. Clinicians must remain careful not to disrupt the repair through aggressive stretching or loading of the healing tissue during phase II. By the end of phase II, it is expected that most patients will be able to achieve approximately 120° of active shoulder elevation in either flexion or scaption and about 40° of lateral (external) rotation. Active ROM should be achieved with minimal or no pain and with proper scapulohumeral rhythm.

The primary goals of phase III are directed primarily toward improving strength and endurance of the shoulder girdle. Full, functional ROM of the glenohumeral joint and the entire upper-extremity kinetic chain is also expected by the end of this stage of rehabilitation. The majority of patients achieve these goals and are able to use their affected arm in most to all ADL by 6 months' time. The decision regarding when to return to heavy work and/or overhead sporting activities is generally at the discretion of the surgeon and physical therapist; however, most patients resume these high-demand activities sometime between 6 and 9 months.

CHAPTER 8

Shoulder Arthroplasty

TIMOTHY F. TYLER, THOMAS F. HOBSON, STEPHEN J. NICHOLAS, NEIL S. ROTH

INTRODUCTION

According to the American Academy of Orthopaedic Surgeons, approximately 4 million people in the United States seek medical care each year for shoulder problems. These conditions range from injuries, such as dislocations and fractures, to chronic debilitating diseases, such as arthritis. Shoulder arthroplasty has been available to patients with severe, chronic, debilitating shoulder pathology since the early 1960s (Figure 8-1).[1–3] Like other joint replacement surgeries, it is designed to remove diseased portions of bone and joint and replace them with a prosthesis, thereby reducing the friction caused by disease and improving range of motion (ROM), eliminating the associated pain.

PREVALENCE OF SHOULDER ARTHROPLASTY

The prevalence of total shoulder arthroplasty in the United States is less than that of total hip or knee arthroplasty but more than total elbow replacements. Shoulder arthroplasty has become the treatment of choice for many patients with a glenohumeral articular disease. The frequency of shoulder arthroplasties has increased substantially, from approximately 10,000 in 1990 to 20,000 in 2000.[4] From 1990 to 1993, fewer than 5000 total shoulder arthroplasties were performed each year in this country; in comparison, combined hip and knee replacement operations exceeded 500,000 per year. According to an orthopedic news source, the prevalence of total shoulder arthroplasty in 1998 was 15,266, of which 8556 were hemiarthroplasties and 6710 were total shoulder athroplasties.[5] As the average age of the population increases and the outcome of shoulder arthroplasty continues to improve, the prevalence of this procedure will continue to rise.

ANATOMY AND JOINT DESIGN

Because of its anatomy and design, the glenohumeral joint does not lend itself to mechanical overload and cartilaginous breakdown. This non–weight-bearing joint is a ball and socket joint. The top of the humerus widens and forms the humeral head, which fits into a shallow socket of the scapula (glenoid fossa). During motion the humeral head moves upon the glenoid fossa, providing a wide ROM. Because of the fit of these two bones, very little surface area of the bones is actually in contact at any given moment, which may contribute to site-specific cartilage breakdown. The stability of the glenohumeral joint relies primarily on the joint capsule and the rotator cuff musculature. The tendons of the rotator cuff help create dynamic stability to the glenohumeral joint by connecting the humerus to the scapula. The primary force producer of the glenohumeral joint is the large deltoid muscle, which creates a force couple with the rotator cuff to allow normal kinematics to occur.

A layer of articular cartilage covers the head of the humerus and the surface of the glenoid fossa; in a healthy joint, this cartilaginous layer protects the bones against friction during movement. In addition, the glenoid labrum surrounds the periphery of the glenoid fossa and provides a slightly deeper socket for the humeral head to rest in. The joint capsule is lined with a synovial membrane, which provides synovial fluid to help reduce friction. In a normal glenohumeral joint, these parts work together to provide stability during a wide ROM. When any of these joint surfaces become diseased, the normally smooth surface becomes rough, causing friction and pain (Figure 8-2). Arthritis leads to the breakdown of cartilage, allowing the bones to rub against each other. When this happens, scar tissue and bone spurs may also develop, leading to further pain and stiffness.

INDICATIONS FOR SHOULDER ARTHROPLASTY

Many different conditions can affect the glenohumeral joint and lead to a discussion about total shoulder replacement. (A hemiarthroplasty replaces the humeral head only, whereas a total shoulder arthroplasty involves replacing the glenoid fossa as well.) Some of these

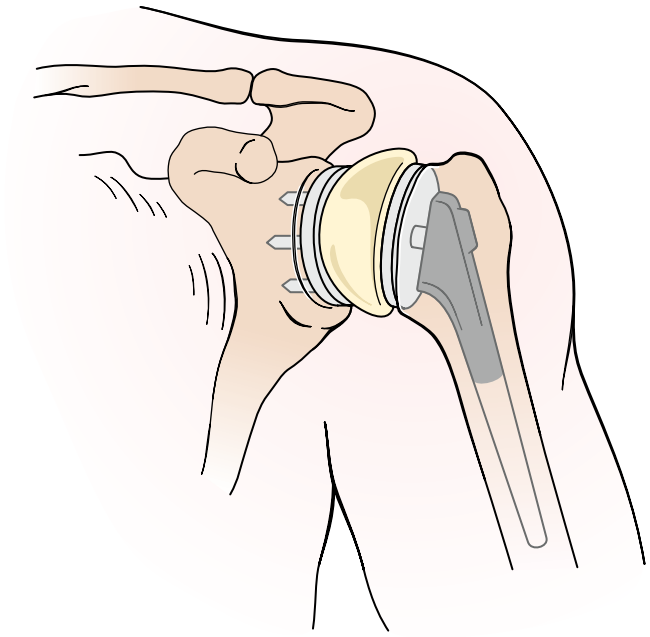

Figure 8-1 Components of a total shoulder arthroplasty.

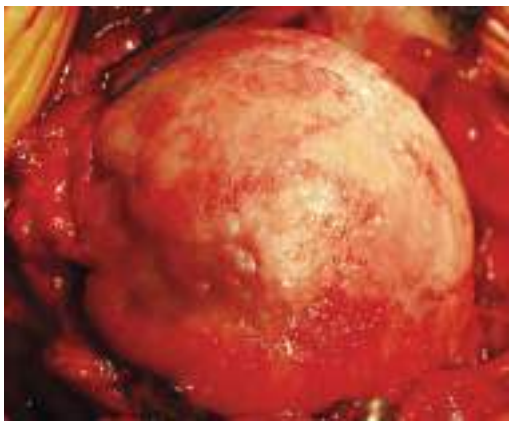

Figure 8-2 Humeral head with severe degenerative disease.

conditions include rheumatoid arthritis, osteoarthritis, rotator cuff arthropathy, avascular necrosis, fractures of the shoulder region, and a failed shoulder prosthesis (from a previous joint replacement).[6–9] Some proximal humeral fractures (e.g., displaced anatomical neck fractures, four-part fractures, fracture-dislocations, and head-splitting fractures) are also indications for shoulder replacement (Figure 8-3).[10–13]

Deterioration of the glenohumeral joint after capsulorrhaphy for recurrent instability is more common in athletes; this condition arises more commonly after surgical procedures such as Bristow, Magnuson-Stack, and Putti-Platt and less commonly after the Bankart and capsular shift procedures.

Pain relief is the primary indication for total shoulder arthroplasty. Most surgeons are cautious about recommending shoulder replacement for improved ROM and function. However, the most common reason for

Figure 8-3 Proximal humeral fracture requiring shoulder arthroplasty.

Figure 8-4 Inferior glenohumeral dislocation.

total shoulder arthroplasty is arthritis. Because arthritis causes the cartilage to break down, it can cause a number of associated problems, such as scar formation and osteophytes. Posttraumatic arthritis is a form of osteoarthritis that develops after an injury, such as a fracture or dislocation of the shoulder (Figure 8-4). Arthritis also can develop after a rotator cuff tear. Rheumatoid arthritis is a systemic inflammatory condition of the joint lining that can affect people of any age and that usually affects multiple joints on both sides of the body.

EVALUATION OF THE ARTHRITIC SHOULDER

History

Total shoulder arthroplasty has become the treatment of choice for most glenohumeral arthritides. A systematic, reproducible approach to each patient ensures comprehensive information gathering and therefore the proper diagnosis and choice of surgical procedure. Initially the patient's age, hand dominance, occupation, athletic activities, medical history, and family history are recorded.

Hand dominance is important to treatment recommendations because the dominant arm of an active individual provides a different therapeutic challenge than the nondominant shoulder of a sedentary individual. Most arthritic shoulders and rotator cuff tears affect the dominant shoulder.[14] Although a patient's age is not necessarily diagnostic, full-thickness rotator cuff tears are found almost exclusively in patients more than 50 years of age. A complete general medical history should be obtained, with special attention given to any systemic or rheumatological disorders. In addition, a family history of generalized ligamentous laxity is important in the treatment of an arthritic patient with multidirectional shoulder instability. A previous incident of trauma can be the precursor of an arthritic shoulder; this can be an important piece of information in presurgical planning.

The patient's chief shoulder complaint usually consists of some element of pain, weakness, or loss of motion. Documenting the pattern of these symptoms is important, most notably the duration, severity, provocation, and location. Shoulder arthritis can arise from a traumatic event, but it often is atraumatic in origin, arising from repetitive loading. Severe night pain and pain at rest are common complaints in patients with mechanical shoulder pathology and usually are due to glenohumeral arthritis; however, infection and tumor must be ruled out.

Weakness of the affected shoulder is a frequent complaint, but splinting from pain commonly contributes to this lack of strength. Patients with concomitant large rotator cuff tears often report weakness or fatigue with overhead use, but they also can have surprisingly good motion and function once the arthritic shoulder has been replaced. Patients also may complain of "crackling" in their shoulders with motion; this can be due to a variety of disorders, including full-thickness tears (which produce crepitus when the greater tuberosity comes into contact with the undersurface of the acromion), glenohumeral osteoarthritis, and acromioclavicular (AC) arthritis. However, when the "crackling" is accompanied by severe pain on movement, glenohumeral osteoarthritis needs to be ruled out.

Physical Examination

Physical examination of the arthritic shoulder should proceed in an organized, reproducible manner. The examination consists of five basic parts: inspection, palpation, ROM, strength testing, and provocative tests. The shoulder often is the site of referred pain, commonly from the cervical spine. Therefore the cervical spine must be thoroughly examined for any coexisting or referred pathology. Often a patient with shoulder arthritis has some degree of cervical spine arthritis and some degree of referred pain to the shoulder. The cervical spine is brought through an ROM, including flexion, extension, and lateral rotation. Pain and crepitation with motion should be noted. Spurling's test, which is effective in distinguishing cervical spine radiculopathy from intrinsic shoulder arthritis, is performed with gentle cervical extension and rotation toward the affected shoulder with axial compression; a positive test result is indicated by posterior shoulder pain and radiculopathy. The deep tendon reflexes should be assessed bilaterally, and a thorough dermatomal sensory and motor evaluation should be performed.

Inspection (Observation)

The patient should be examined with both shoulders exposed, which allows access anteriorly and posteriorly. A thorough inspection of the shoulder should note any muscular atrophy, hypertrophy, asymmetry, or deformity, as well as bony prominences. An arthritic shoulder sometimes presents as an extremely large mass on inspection. The examination may reveal a prominent scapular spine resulting from spinati atrophy; this often indicates a long-standing rotator cuff tear but may also be present with suprascapular nerve entrapment. The shoulder is evaluated for any deformity of the biceps muscle because the long head of the biceps tendon often is ruptured in patients with rotator cuff disease and severe glenohumeral arthritis. Bony prominences and the contour of the shoulder also are noted because a patient with glenohumeral arthritis loses normal contour and shows squaring and anterior fullness.

Palpation

Palpation around the shoulder joint should be done systematically so that each muscle, joint, and bony prominence is evaluated. The sternoclavicular joint; the clavicle; the AC joint; the anterior, lateral, and posterior acromion; the anterior and posterior joint lines; and the biceps tendon each should be tested for discrete tenderness. Localized tenderness over the AC joint often is overlooked as a source of symptoms and may be implicated in rotator cuff pathology or degenerative joint disease. Pain often is elicited by palpation of the greater tuberosity with rotator cuff pathology, but it also may be due to glenohumeral arthritis, and the finding should be correlated with rotational radiographs of the humerus (Figure 8-5). Tenderness in the bicipital groove may be present with involvement of the biceps tendon and can be implicated in both rotator cuff pathology and glenohumeral instability. Anterior and posterior joint line tenderness may be present with glenohumeral instability, whereas posterior joint line tenderness commonly is noted in patients with glenohumeral arthritis.

Range of Motion

The general motion of the shoulder complex is observed for glenohumeral rhythm, scapulothoracic motion, and overall synchrony of motion. The American Shoulder and Elbow Surgeons professional organization currently recommends that four functionally necessary arcs of motion be measured both actively and passively: total elevation, lateral rotation at neutral abduction, lateral rotation

Figure 8-5 Radiograph confirming the diagnosis of severe glenohumeral arthritis.

at 90° abduction, and medial rotation.[15,16] Patients with limited motion in a single or multiple planes must be examined carefully to differentiate the possible etiologies, such as a rotator cuff tear, adhesive capsulitis, and glenohumeral arthritis.

In this patient population, total elevation, including both glenohumeral and scapulothoracic motion, may be more reproducibly measured than attempting to isolate glenohumeral motion and is more functionally relevant. However, both measurements are important for determining which joint is contributing to a functional loss. Passive elevation is more accurately measured in the supine position, whereas active elevation is measured erect. Lateral rotation is tested with the arm at the side, the patient supine (to eliminate trunk rotation), and with the arm at 90° abduction.

Functional rotation ranges of motion are also documented. Functional medial rotation is measured according to the highest vertebral level an upright patient can reach with the thumb. Apley's scratch test evaluates the available functional lateral rotation ROM.

Strength Testing

The strength and integrity of joints, muscles, and tendons are important aspects of surgical planning. Manual strength testing may be difficult to assess quantitatively because of coexistent pain. Crepitation with motion from the glenohumeral joint, subacromial space, or scapulothoracic joint should be noted. Manual muscle testing of the supraspinatus is performed with the arm in 90° forward elevation and 20° medial rotation with the elbows extended (i.e., the empty can test). Manual muscle testing in lateral rotation is performed with the elbow flexed and the arm at the side to prevent deltoid contribution; weakness in this position is a common finding with a tear involving the infraspinatus tendon. Weakness in lateral rotation at neutral may indicate a long-standing rotator cuff tear,[17] and with concomitant weakness in shoulder abduction it shows a statistically significant correlation with the size of the tear.[18]

Manual muscle testing of the shoulder in lateral rotation above 45° abduction is performed primarily to assess the teres minor. Patients with large or massive tears involving the infraspinatus often are unable to maintain the arm in lateral rotation at neutral and when the arm is abducted. The lateral rotation lag sign is designed to test the integrity of the supraspinatus and infraspinatus tendons; it is performed by passively flexing the elbow to 90° and the shoulder to 20° elevation and near maximum lateral rotation. The patient then is asked to maintain this position while the clinician releases the wrist; a positive result is a lag or angular drop.[19] The drop sign is designed to assess infraspinatus function; for this test, the patient is seated with his or her back to the clinician, who holds the affected arm at 90° elevation and maximum lateral rotation with the elbow at 90° flexion. The patient is asked to maintain this position while the physician supports the elbow and releases the wrist; the result is positive if a lag occurs.

Patients with subscapularis tears have an increased passive lateral rotation ROM and weakness of medial rotation. The competence of the subscapularis muscle can be assessed using the lift-off test, which has been shown to be both sensitive and specific for a tear in the subscapularis tendon. Originally the lift-off test was determined to be positive (i.e., poor subscapularis function) when a patient could not lift the hand posteriorly off the lumbar region; however, the test was modified to achieve even greater sensitivity for subscapularis tears.[20] In the modified lift-off test, the examiner places the arm in maximum medial rotation by passively lifting the patient's arm posteriorly off the lumbar region; the test result is positive (poor subscapularis function) if the patient is unable to maintain that position and the arm falls or "springs back" onto the back.

The internal (medial) rotation lag sign is used to assess subscapularis competency. It is similar to the modified lift-off test except that the examiner releases the wrist at maximum internal (medial) rotation, maintains support of the elbow, and then measures the lag between the maximum internal (medial) rotation position and the lag position (Figure 8-6).

The abdominal compression test (Figure 8-7) also is used to assess subscapularis weakness or deficiency, especially when passive medial rotation is difficult to perform during the lift-off test or internal rotation lag sign. A positive abdominal compression test is indicated by an inability to keep the palm of the hand compressed against the abdomen while bringing the elbow anterior to the scapular plane. A side-to-side difference between the affected and unaffected shoulders during the abdominal compression test may indicate subtle subscapularis weakness or a tear and warrants further investigation. Medial rotation strength and integrity must be taken into consideration during surgery for proper intraoperative muscle balancing.[21]

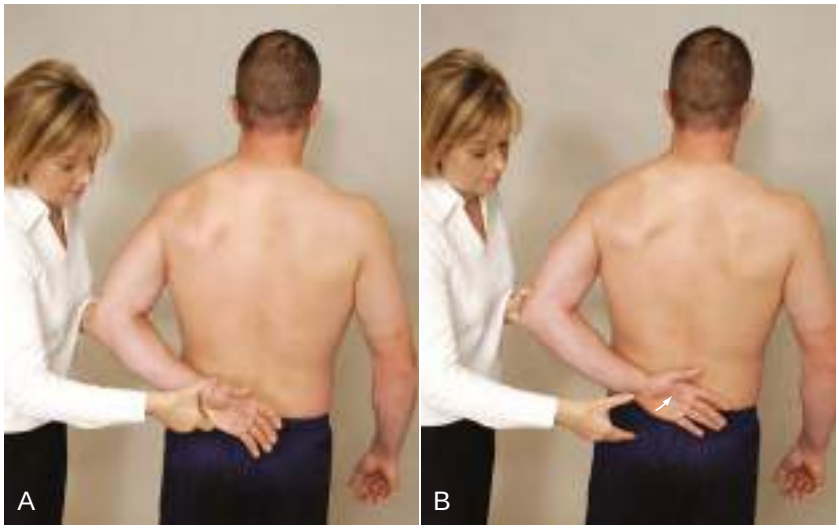

Figure 8-6 Internal (medial) rotation lag sign (also called the subscapularis spring back or lag test). **A**, Start position. **B**, Patient is unable to hold the start position and hand springs back toward the lower back. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 339, St Louis, 2014, Elsevier/Saunders.)

To ensure maximum shoulder function after arthroplasty, a thorough assessment of shoulder motion and strength must include evaluation of the scapular muscle stabilizers. Some of the key muscles tested before shoulder arthroplasty that may affect the final outcome include the serratus anterior, trapezius, and rhomboids. Weakness in the serratus anterior muscle can cause scapular winging and disruption of the synchronous glenohumeral motion. Scapular winging, which can be detected by having the patient flex to 90° or do a wall push up, is commonly the result of a palsy of the long thoracic nerve. Trapezius muscle function is tested with a shoulder shrug, and weakness or atrophy of this muscle may be due to a palsy of the spinal accessory nerve. The motor strength of the rhomboid muscles is tested with the patient prone, shoulder abducted 90°, and arms extended.

When assessing function in shoulder arthritis and arthroplasty patients, the clinician should be aware of the possible existence of contractures as well as generalized ligamentous laxity. In addition, identification of a pattern of instability or contracture is a key component in planning for a shoulder arthroplasty.[16,22] The presence of glenohumeral instability affects the surgical procedure. For example, if excessive posterior laxity and anterior contracture are factors, a posterior capsulorrhaphy and anterior capsular releases can be performed. Conversely, if the patient has anterior laxity, precise soft tissue balancing and prosthetic positioning are needed to prevent functional deficits.

DIAGNOSTIC MODALITIES

Imaging studies, such as radiographs, computed tomography (CT), arthrography, and magnetic resonance imaging (MRI), are used to confirm and further define the pathological process. Early in the development of glenohumeral arthrosis, subtle radiographic findings may suggest the diagnosis when the symptoms are mild. Later in the progression of joint destruction, imaging studies are crucial to the planning of prosthetic arthroplasty. Subsequent to arthroplasty, imaging studies can identify coexisting or potential problems that might correlate with the clinical outcome.

Plain Radiographs

Plain radiographs or x-rays are part of a comprehensive history and physical examination for a patient with shoulder arthritis. All patients should have anteroposterior

(AP) views in the scapular plane in neutral, medial, and lateral rotation, a lateral view in the scapular plane, and an axillary view. Although these radiographs usually are normal in early rotator cuff disease or glenohumeral instability, they are essential to the diagnosis of glenohumeral arthritis, tumors, fractures, or dislocations. Cervical spine films should be ordered for patients with concomitant neck and shoulder pain.

With more advanced glenohumeral arthritis and rotator cuff disease, AP radiographs may demonstrate degenerative changes of the greater tuberosity, AC joint, or anterior acromion, as well as the glenohumeral joint. Radiographic criteria for evidence of a rotator cuff tear, such as the acromiohumeral interval, can also be assessed on the AP view; a decrease of more than 7 mm is considered abnormal and suggestive of chronic cuff pathology.[23] Rotational AP views are valuable for detecting calcium deposits in the rotator cuff. The lateral rotation AP view shows the greater tuberosity in profile, which may reveal sclerosis, cysts, or excrescences. These tests are included for a complete evaluation of the surgical candidate and to allow the surgeon to visualize any other pathology or conditions that may be encountered before the start of the surgical procedure.

Axillary radiographs are useful for demonstrating glenoid degenerative changes or fractures associated with instability, as well as posterior dislocations that may be overlooked on routine AP views. Special views to visualize the AC joint often are obtained using an underpenetrated, or soft tissue, technique in the AP and cephalic tilt AP views. These views often demonstrate osteolysis of the distal clavicle, arthritic changes, and inferior osteophyte formation, as well as fractures. Although patients have shoulder arthroplasty primarily for pain relief, the arthritic changes on radiographs and degree of degeneration can be key factors in the decision on whether to have surgery. Changes visualized on the radiographs can also assist the clinical evaluation in determining the source of pain if no degenerative changes appear on the radiographs.

Key Factors That Determine the Need for Arthroplasty

- Pain
- Arthritic changes on radiographs (decreased joint space, decreased acromiohumeral interval, degenerative changes to greater tuberosity, acromion, osteophytes, subchondral sclerosis, bone deformation)[24,25]
- Degree of degeneration

Arthrography

Long considered the gold standard for imaging full-thickness rotator cuff tears, the arthrogram is an invasive procedure with significant risks, such as infection, allergic reaction, radiation exposure, and pain. Double contrast arthrography is inexpensive and easily performed; however, it has a limited ability to diagnose partial cuff tears accurately and provide information about their size and location. Despite this, arthrography remains an excellent modality for diagnosing full-thickness rotator cuff tears that may accompany glenohumeral arthrosis (Figure 8-8).

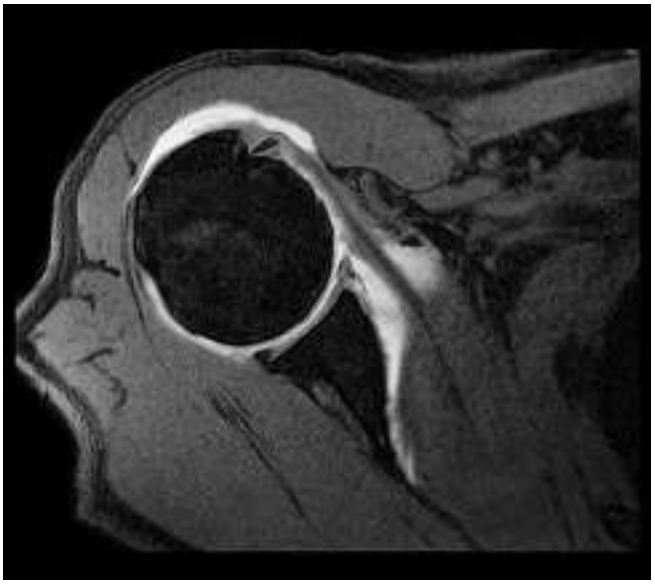

Figure 8-8 Infiltration of dye into the subscapularis fossa indicates a possible rotator cuff tear.

Computed Tomography

When an arthritic patient is suspected of having glenohumeral instability, CT images can be obtained to delineate bony and soft tissue intra-articular pathology. CT images also can be useful in a standardized technique to determine the humeral torsion angle and landmarks that can be used during surgery.[26,27] Three-dimensional CT scans (Figure 8-9) can further delineate complex proximal humeral fractures and assist planning for a hemiarthroplasty.[28,29] Hernigou et al.[26] found that retroversion with CT is more accurate than palpating the epicondylar axis or using the forearm as a goniometer during surgery. CT is useful for measuring the amount of rotation of the humerus with a malunited fracture or severe arthritic deformity.

Magnetic Resonance Imaging

MRI is an excellent, noninvasive, radiation-sparing modality that is useful in the diagnosis of rotator cuff pathology and glenohumeral instability but is not always necessary for patients with shoulder arthritis. Soini et al.[30] demonstrated that in severely destroyed rheumatoid shoulders scheduled for arthroplasty, MRI soft tissue findings were not consistent with tissue changes at the time of surgery. The integrity of tendons could not readily be elucidated with MRI because of an inflammatory process and scarred

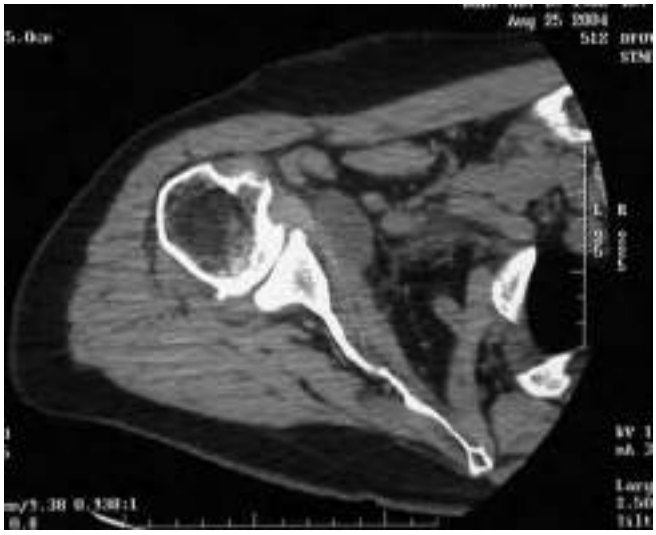

Figure 8-9 CT scan showing signs of glenohumeral arthritis, which is important in preoperative planning.

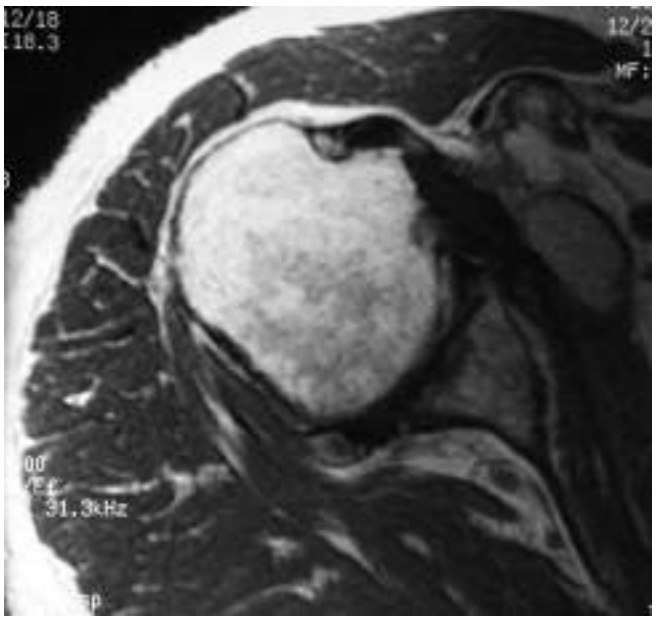

Figure 8-10 MRI scan showing increased signal in the glenoid and humeral head in addition to joint space narrowing; these findings indicate severe degenerative disease.

tissues. Often, during surgery, the changes were difficult to categorize. MRI scans of severely destroyed rheumatoid shoulders before arthroplasty were shown to be of only minor importance. However, this may not be true for patients with osteoarthritis of the glenohumeral joint (Figures 8-10 and 8-11).

Other Modalities

When systemic disorders are suspected, routine blood tests to evaluate for rheumatological disorders, infection, and tumors should be considered. A complete blood count with differential, sedimentation rate, C-reactive protein

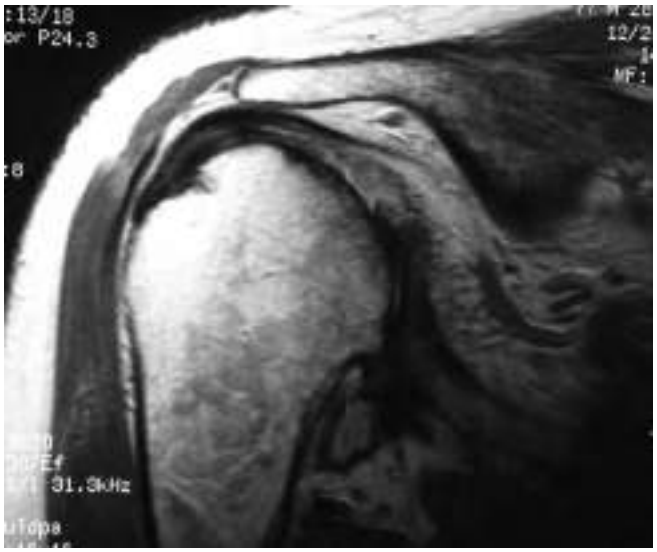

Figure 8-11 MRI demonstrating humeral head migration superiorly with rotator cuff arthropathy.

level, chemistry profile, latex fixation test, serum protein electrophoresis, and an acid phosphatase level should be obtained as part of preoperative testing (Table 8-1). This panel allows the surgeon to rule out any other significant factors and pathology and provides a baseline for comparison after surgery, if necessary.

YOUNG SHOULDER ARTHROPLASTY PATIENTS

Shoulder arthroplasty is becoming more common in young patients. Although trauma to the glenohumeral joint is associated with a dislocation episode, little is known about the incidence of shoulder arthroplasty in patients with shoulder instability. The long time span between dislocation and the development of arthritis makes determining any cause and effect relationship difficult.

Severe damage to the humeral head cartilage can occur after a dislocation. Taylor and Arciero[31] reported on 63 young patients under 24 years of age with first-time, traumatic anterior shoulder dislocations who were evaluated arthroscopically within 10 days of dislocation. Fifty-seven patients had Hill-Sachs lesions. However, osteochondral lesions of the humeral head were identified in 34 patients, and chondral lesions were noted in an additional 24, providing evidence that humeral head damage occurs. Hovelius et al.[32] followed 245 patients 10 years after primary anterior dislocations of the shoulder. The patients' ages at the time of dislocation ranged from 12 to 40 years. Radiographs taken on 185 shoulders at the time of primary dislocation demonstrated a Hill-Sachs lesion in 99 shoulders. This finding was associated with a significantly worse prognosis with regard to recurrent instability but had no effect on the development of arthritis. Radiographs made for 208 shoulders at the 10-year follow-up examination were evaluated for

TABLE 8-1

Preoperative Laboratory Tests with Normal Ranges

CBC with Differential and PLT		Complete Metabolic Panel	
WBC	3.8-10.83/μL	Glucose	65-139 mg/dL
RBC	3.80-5.106/μL	Sodium	135-146 mmol/L
Hemoglobin	11.7-15.5 g/dL	Potassium	3.5-5.3 mmol/L
Hematocrit	35%-45%	Chloride	98-110 mmol/L
MCV	80-100 fL	Carbon dioxide	21-33 mmol/L
MCH	27-33 pg	Urea nitrogen	7-25 mg/dL
MCHC	32-36 g/dL	Creatinine	0.5-1.2 mg/dL
RDW	11%-15%	BUN/creatinine ratio	6-25
PLT	140-4003/μL	Calcium	8.5-10.4 mg/dL
MPV	7.5-11.5 fL	Protein, total	6.0-8.3 g/dL
Total neutrophils, %	38%-80%	Albumin	3.5-4.9 g/dL

posttraumatic dislocation arthritis. Twenty-three shoulders (11%) had mild arthritis, and 18 (9%) had moderate or severe arthritis. No further instability was reported in some of the shoulders that had arthritis.

The most defining study to date was published by Marx et al.,[33] who used a case-control study to examine whether shoulder dislocation was associated with the development of arthrosis. Patients with osteoarthrosis who had undergone hemiarthroplasty or total shoulder arthroplasty were asked whether they had ever sustained a shoulder dislocation. Ninety-one patients who had undergone shoulder arthroplasty and 282 control subjects responded. The authors concluded that the risk of developing severe arthrosis of the shoulder is 10 to 20 times greater for individuals who have had a dislocation of the shoulder. It is evident that some degree of chondral injury and hemarthrosis may be associated with a shoulder dislocation and is not beneficial to the glenohumeral joint. Whether the hemarthrosis predisposes this patient population to arthritis and an eventual shoulder arthroplasty remains unclear.

One thing that is clear is the effect of overconstraining the glenohumeral joint during surgery for shoulder instability. Sperling et al.[34] reported on the intermediate to long-term results of shoulder arthroplasty performed to treat osteoarthritis after instability surgery in 33 patients with glenohumeral arthritis. The mean age at the time of the shoulder arthroplasty was 46 years. Twenty-one patients who had a total shoulder arthroplasty and 10 who had a hemiarthroplasty were followed for a minimum of 2 years. Shoulder arthroplasty was associated with significant pain relief and significant improvement in lateral rotation and active abduction. Interestingly no significant difference was seen between the hemiarthroplasty group and the total shoulder arthroplasty group with regard to postoperative lateral rotation, active abduction, or pain. This study suggests that shoulder arthroplasty for the treatment of osteoarthritis of the glenohumeral joint after instability surgery in a group of young patients provides pain relief and improved motion. However, it may be associated with a higher incidence of revision surgery. Three patients in the hemiarthroplasty group and eight patients in the total shoulder arthroplasty group underwent revision surgery. In contrast, this was not the case in a series of 22 shoulder arthroplasties followed up over an average of 6 years. Burroughs et al.[35] reported no evidence of accelerated deterioration of shoulder function, and only two patients underwent revision surgery.

Given this conflict in the literature, little information is available to guide clinical decision making with regard to shoulder arthroplasty after instability surgery. The management of these patients requires a thorough preoperative evaluation and a careful review of diagnostic modalities. The severity of glenoid wear should be assessed using CT scans to determine the need for glenoid bone grafting. In addition, the surgeon should obtain the previous operative reports to determine the type of stabilization performed; this allows the surgeon to recognize frequently distorted anatomy and facilitates safe, effective soft tissue releases. The decision to proceed with a shoulder arthroplasty in a patient who has had a previous stabilization procedure should be made

with caution. The surgeon should be prepared to address associated soft tissue contracture and potential bone deficiency.

Shoulder arthroplasty in the young patient for osteoarthritis of the glenohumeral joint after instability surgery provides satisfactory pain relief and improvement in motion but may be associated with a high rate of revision surgery and unsatisfactory results as a result of implant failure, instability, and painful glenoid arthritis.[35]

PREOPERATIVE REHABILITATION

Accepting differences in expectations, patient goals, physician goals, and physical therapist goals is essential. The physical therapist ideally should meet with the patient and the patient's caregiver before the surgery. At this time the rehabilitation team can set reasonable goals for both early and eventual outcomes (Table 8-2). At this point, when the patients are not under the influence of pain medications, feeling ill, or experiencing pain, they can better

TABLE 8-2

Rehabilitation Guidelines after Shoulder Arthroplasty

Immediate Postoperative Phase (Days 0 to 7)	
Goals	Patient understands surgery, precautions, and pain-relief methods Protect the surgery Improve ROM at shoulder and maintain ROM of proximal and distal joints Improve scapular stability
PROM	Pendulums, CPM (facility dependent) PROM flexion and lateral rotation (if allowed) by therapist
AAROM	Pulleys for sagittal plane flexion and scaption Cane exercises for flexion and lateral rotation
AROM	AROM of hand, wrist, elbow, scapula, and cervical spine Gripping
Patient education	Sling use (full time for community activities, as needed at home) or as instructed by physician Arm can be used for light, waist-level activity Patient understands that activity should not increase pain level drastically Patient should ice shoulder to reduce pain Patient should sleep sitting up (in chair)
Precautions	Do not force lateral rotation No medial rotation isometrics, isokinetics (no medial rotation muscle activation) Exercises should not cause severe pain Watch for and minimize muscle guarding
Early Postoperative Phase (Weeks 1 to 6)	
Goals	Continue to restore motion, scapular stability Begin light rotator cuff activation Continue pain modulation
PROM	Pendulums for warm-up and pain modulation
AAROM	Pulleys for sagittal plane flexion, medial rotation, and scaption Cane exercises for flexion, horizontal adduction and abduction, and punches
AROM	Continue cervical, scapular, elbow, wrist, and hand motion Continue gripping Begin submaximum isometrics for external rotators (i.e., pushing against towel or ball on wall) Begin submaximum isometrics for deltoid if no pain is present Begin upper body exercises at 4 weeks (shoulder flexion below 80°) Begin serratus strengthening if done below 90° shoulder flexion (punches, dynamic hugs, scaption)
Patient education	No heavy pushing, pulling, or lifting for 6 weeks No weight bearing for 6 months
Precautions	Patient feels fine, but healing is not complete. *Protect the joint.*
Intermediate Postoperative Phase (Weeks 6 to 12)	
Goals	Ensure stable prosthesis and joint stability ROM goals, active and passive Minimal pain Begin improving strength and endurance Improve function

(Continued)

TABLE 8-2

Rehabilitation Guidelines after Shoulder Arthroplasty—cont'd

Intermediate Postoperative Phase (Weeks 6 to 12) *cont'd*	
PROM	Mobilizations as needed Posterior capsule stretching/sleeper stretch
AAROM	As needed (cane, pulleys) Posterior capsule stretching/sleeper stretch
AROM	Muscle activation exercises: • Dusting • Active lateral rotation/medial rotation within pain-free motion Open chain stability exercises: • Flexbar 0°, then 45°, and finally 90°, as tolerated • Body Blade at 0° • Rhythmic stabilizations (at 8 to 10 weeks, higher level patients) Closed chain stability exercises: • Ball stabilization • Perturbation training with therapist • PWB through shoulder Strengthening exercises: • Medial rotation/lateral rotation pain free (e.g., with Thera-Band) • Side-lying lateral rotation with weight • Lateral rotation at 45° with elbow supported (8-9 weeks) • Prone extension • Prone horizontal abduction • Biceps and triceps curls • Anterior deltoid strengthening • Strengthening of all scapular muscles (e.g., punches, lower and middle traps, rows, extensions with Thera-Band)
Patient education	No heavy lifting No sports
Precautions	Do not initiate base strengthening until pain is minimal
Return to Activity Phase (Weeks 12 to 24)	
Goals	Full ROM in all planes Strength 80% or greater of uninvolved side Improved endurance and neuromuscular control Patient confident in shoulder Full return to activity
PROM/ AAROM	PROM as needed
AROM	Strength testing: • Isokinetic Continue activation, stability, and strength exercises; progress as tolerated: • Lateral rotation 90/90 • Overhead wall taps • Light ball toss; chest pass, overhead • Plyometrics up to 90/90 position Functional exercises: • Thera-Band golf/tennis • Golf chipping and putting • Breast stroke
Patient education	Patient very familiar with HEP to maximize strength and ROM gains
Precautions	Avoid increasing inflammation Do not strengthen in abduction Do not strengthen with high weights; use low weights and medium repetitions Use caution with overhead activity until all pain has resolved If pain requires use of treatments, reduce exercise or intensity of ADLs

AAROM, active-assisted range of motion; *ADLs,* activities of daily living; *AROM,* active range of motion; *CPM,* continuous passive motion; *HEP,* home exercise program; *PROM,* Passive range of motion; *PWB,* partial weight bearing; *ROM,* range of motion.

comprehend the rehabilitation program, precautions, and expectations. This allows the patient and physical therapist to establish a relationship that will foster better cooperation during the sometimes painful and frustrating rehabilitation process. After the educational process, the preoperative assessment should include the available ROM, strength, and the presence of visible atrophy, sensation, pain, and functional evaluation.

The educational process is essential for informing the patient of the risks and complications of surgery and anesthesia.[36] These risks for shoulder replacement surgery include injury to nerves and blood vessels, stiffness or instability of the shoulder joint, loosening of the prosthetic parts (requiring additional surgery), tearing of a rotator cuff tendon, and fracture of the humerus. In addition, total shoulder replacement carries with it the normal risks of any elective surgery, such as complications from anesthesia, excessive bleeding, infection, blood clots, and ultimately death.[37–39] The surgical procedure and the components of shoulder arthroplasty also are explained.

The educational process is essential for informing the patient of the restriction on the use of the shoulder and the impact on activities of daily living for at least the next 6 weeks. Because the subscapularis muscle is cut to expose the shoulder joint, no active medial rotation motion is permitted. For the patient, this means no violent squeezing, hugging, or slamming of car doors. However, the patient should be encouraged to use the upper extremity for light functional activities such as eating, brushing the teeth, or putting on a hat; the patient should avoid lifting anything heavier than 0.91 kg (2 lb). The patient also should be instructed to avoid immobilization.

The importance of a postoperative rehabilitation program is reviewed, and the importance of the first 6 weeks of rehabilitation also is emphasized. The immediate and early program is geared toward regaining the motion achieved at the time of surgery. The patient needs to appreciate that this time frame is the most important period of the rehabilitation process, a period in which significant changes and gains in ROM and maintaining optimum neuromuscular function can be accomplished. The home environment is discussed to determine whether the patient is one of approximately 50% of patients who require home nursing assistance, home physical therapy, or, infrequently, discharge to an extended care facility after hospitalization. In addition, special considerations need to be identified for patients who require assistive devices for ambulation, the visually impaired, or those who use wheelchairs.

Patient and family education is essential for achieving consistently good outcomes after shoulder arthroplasty. It is essential that family members be made aware of restrictions on activity and the importance of frequent home exercise. The patient and caregivers must understand that being active, but using only the arms at the side, does not replace stretching overhead to prevent contracture or stiffness. The recommendation for long-term active ROM exercise is 5 times a day for the first 6 weeks, 2 times a day for the next 6 weeks or until goals are achieved, then once a day for a lifetime. Patients who are involved and enthusiastic about their management tend to recover and regain shoulder function rapidly.[40]

Clinical Note

The patient must take an active role because the patient is the most valuable member of the multidisciplinary team.

Risks and Complications of Arthroplasty[37–39]

- Injuries to nerves and blood vessels
- Glenohumeral joint stiffness
- Glenohumeral or scapular instability
- Loosening of prosthesis
- Additional surgery
- Rotator cuff tear
- Humeral fracture
- Ectopic ossification
- Excessive bleeding
- Infection
- Blood clots
- Death

Although age is not a limiting factor, the patient must be able to cooperate in a postoperative rehabilitation program, which is crucial to the success of the surgery.[40] Patients are expected to obtain medical clearance from their primary care physician with regard to any systemic medical conditions, along with preoperative testing (e.g., laboratory tests, electrocardiography [ECG]). Patients should discontinue nonsteroidal anti-inflammatory medications or aspirin-containing medications 7 to 10 days before the scheduled surgery to minimize postoperative bleeding and complications with coagulation. For total shoulder arthroplasty, 1 unit of autologous blood may be donated in anticipation of the surgery, which can result in a blood loss of 1 to 2 units, especially in complicated cases.

The clinical examination includes shoulder ROM and strength measurements. Limited abduction and lateral rotation movements and decreased rotator cuff muscle strength are common.[40–42] Preoperative motions that should be measured include forward elevation, lateral rotation in a supine position, and medial rotation with the hand reaching up the back. Deficits of active versus passive motion also provide information about the function of the rotator cuff, and these data are supplemented with manual muscle testing of abduction and lateral rotation strength against resistance.

A demonstration of therapeutic exercises by a physical therapist can be part of the preparation for the surgical

procedure. Preoperative demonstration of therapeutic exercises in the rehabilitation program is associated with better patient understanding and a more rapid progression after surgery.[40] Unfortunately, most insurance companies do not provide for preoperative therapy or a preoperative home health assessment, despite their intuitive benefits.

HEMIARTHROPLASTY VERSUS TOTAL SHOULDER ARTHROPLASTY

Arthroplasty is the most definitive method for managing the pain associated with severe glenohumeral arthritis. Since 1893 when the first shoulder replacement was performed, shoulder arthroplasty has continued to improve with advances in component materials, instrumentation, and surgical techniques.[1] Good candidates for shoulder arthroplasty are older patients who will place minimal demands on the shoulder and have no rotator cuff damage. A total shoulder arthroplasty involves the replacement of both sides of the glenohumeral joint (the humerus and glenoid).[22] A hemiarthroplasty replaces the humeral head only and is the treatment of choice when replacement of the glenoid is not advised.[43] The decision is made based on the nature and degree of the patient's arthritis. Individuals who should not have shoulder arthroplasty at all are contact athletes and heavy laborers. They are not good candidates for shoulder replacement because of the long-term demands they place on the shoulder. In addition, total shoulder arthroplasty is not always appropriate for patients with large, inoperable rotator cuff tears. Because the rotator cuff muscles hold the humeral head tightly to the glenoid, these massive tears would allow excessive movement of the humeral component, leading to abnormal loading and loosening of the glenoid component.[44] Hemiarthroplasty is recommended for patients with isolated humeral head arthritis and normal glenoid cartilage. Patients with poor glenoid bone quality need to consider a hemiarthroplasty. Patients with an active infection in the shoulder joint should not have shoulder arthroplasty.[45]

Patients Unsuitable for Shoulder Arthroplasty

- Athletes in contact sports
- Heavy laborers
- Patients with large, inoperable rotator cuff tears
- Patients with an active infection

Another subset of patients in whom primary hemiarthroplasty is indicated are patients with proximal humeral fractures. Hemiarthroplasty has become the gold standard for the treatment of such fractures when the humeral head is deemed to be nonviable or not amenable to reconstruction with internal fixation techniques.[46] The current indications for primary hemiarthroplasty include a displaced and translated four-part fracture, with or without associated dislocation of the humeral head, and a head-splitting fracture with involvement of more than 40% of the articular surface.[46] Outcomes with this procedure have been mixed. The shoulder usually is free of pain, but the overall functional result at 1 year varies in terms of ROM, function, and power. A better functional outcome can be anticipated for a younger individual than for elderly patients.[47] However, total shoulder arthroplasty should be considered in these cases; Carroll et al.[48] reported on long-term follow-up of 16 patients after conversion of painful hemiarthroplasty to total shoulder arthroplasty. The authors concluded that revision of a failed hemiarthroplasty to a total shoulder arthroplasty is a salvage procedure, and the results are inferior to those of primary total shoulder arthroplasty. Recently, in patients with rotator cuff arthropathy, a "reverse" shoulder prosthesis was attempted. The premise is that a "reverse" shoulder prosthesis resists glenohumeral subluxation and potential component loosening by preventing superior displacement of the humeral head (Figure 8-12).[49–53] Modern implant designs emphasize a medial center of rotation to recruit more deltoid muscle fibers which aid with active elevation.[54] In a 10-year follow-up study performed by Guery et al.,[55] survival rates for the prosthesis were 91% and 84% among 80 patients with mostly massive rotator cuff tears. However, the authors also found that the protheses were prone to functional deterioration over time; a statistic they attributed to aseptic glenoid loosening.

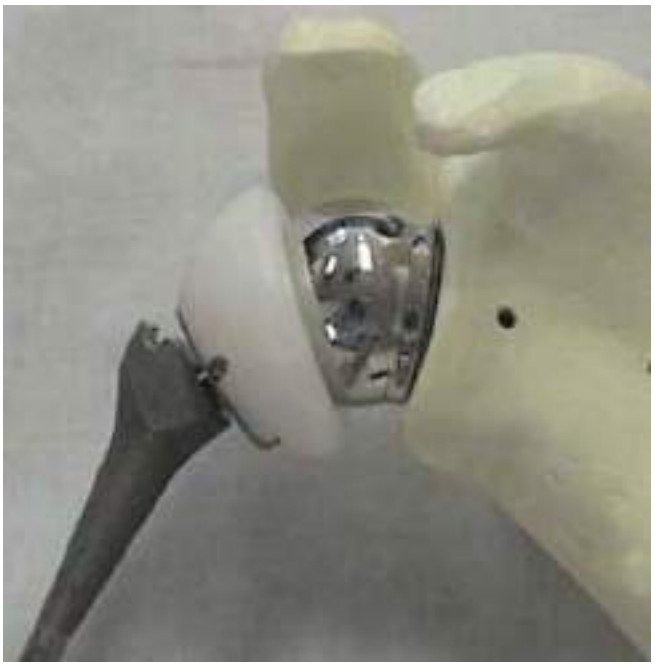

Figure 8-12 Example of a reverse total shoulder replacement prosthesis. (From Harman M, Frankle M, Vasey M et al: Initial glenoid component fixation in "reverse" total shoulder arthroplasty: a biomechanical evaluation, *J Shoulder Elbow Surg* 14[1 suppl S]:162S-167S, 2005.)

FACTORS ASSOCIATED WITH SUCCESSFUL OUTCOMES

The outcome of a shoulder arthroplasty can never be predicted with certainty; however, a number of preoperative, intrasurgical, and rehabilitative factors are associated with a successful outcome.[16] Factors observed at the time of surgery, such as the quality of the cartilage, bone, and rotator cuff, are a recognized influence on the result of arthroplasty, but preoperative information also is associated with greater improvement in patient-assessed function after shoulder arthroplasty (Table 8-3). Preoperative decision making by patients and their surgeons can influence the final outcome. It was found that higher surgeon and hospital case volumes led to improved perioperative metrics with all shoulder arthroplasty procedures, including reverse total shoulder arthroplasty.[56] The success of shoulder arthroplasty also depends on postoperative rehabilitation.[15,36,40,57,58]

The first preoperative predictor of outcome is the presence of systemic disease. Numerous research studies have demonstrated that patients with Parkinson's disease, systemic lupus erythematosus (SLE), and rheumatoid arthritis have poorer outcomes after shoulder arthroplasty.[59–61] In the case of SLE and rheumatoid arthritis, the soft tissues needed for muscle balancing may be severely compromised. The tissue also may have become friable and thin because of excessive use of steroids.[62] In addition, patients with preexisting diabetes are at a higher risk for perioperative morbidity and mortality following shoulder arthroplasty.[63] The progressive multisystem involvement seen in many diabetic patients may be the cause of the higher perioperative mortality encountered in patients with this condition.

Hettrich et al.[64] examined preoperative factors associated with improvements in shoulder function after hemiarthroplasty in 71 shoulders. These researchers were able to demonstrate that shoulders with rheumatoid arthritis, capsulorrhaphy arthropathy, and rotator cuff tear arthropathy had the least functional improvement, whereas those with osteonecrosis or primary and secondary degenerative joint disease had the greatest improvement. The patient's age and gender did not significantly affect the outcome. Shoulders that had not had previous surgery had greater functional improvement than those that had had previous surgery. These results were supported by Kay and Amstutz,[65] who found better results in patients with osteonecrosis compared with those who had a fracture. Trail and Nuttall[66] found that an intact rotator cuff was associated with a better outcome in patients with rheumatoid arthritis. Levy and Copeland[67] found poorer outcomes in patients with cuff tear arthropathy and posttraumatic arthropathy than in those with other diagnoses. As these studies show, patient selection plays an important role in determining the final outcome. In a recent study, Bot et al.[68] noted that patients with preoperative psychological illness were found to be at an increased risk for perioperative morbidity and posthospitalization care following shoulder arthroplasty.

Preoperative ROM can also have an effect on the postoperative outcome. Iannotti and Norris[69] found that patients with less than 10° of passive lateral rotation before surgery had substantially less improvement in lateral rotation after hemiarthroplasty. Thirteen of 128 shoulders had a repairable full-thickness tear of the supraspinatus tendon, but these tears did not affect the overall outcome, decrease in pain, or patient satisfaction. The authors' experience has been that patients scheduled for shoulder arthroplasty who lack passive medial rotation and have a tight posterior capsule have a very difficult time regaining the motion postoperatively and report poorer outcomes. Surgeons and patients thinking of shoulder arthroplasty need to consider identifying these preoperative factors.

Shoulder arthroplasty is considered among the most technically demanding of the current joint replacement procedures because of the glenohumeral joint's lack of intrinsic stability.[21] The tension of the rotator cuff and glenohumeral capsule must be balanced for mobility and stability. The surgeon is faced with many decisions regarding the choice of implant, implant fixation, soft tissue management, and options for glenoid resurfacing.[70,71] In general, if the precise cause of the arthritic condition has been identified, the choices become more straightforward. For advanced osteoarthritis of the shoulder joint in an older patient with asymmetrical posterior erosion of the glenoid, total shoulder arthroplasty renders the best relief of pain and improvement in motion. Similarly, for

TABLE 8-3

Factors Associated with Successful Outcomes

Stage	Factors
Preoperative	Cartilage quality Bone quality Rotator cuff quality Glenohumeral instability Systemic disease Posterior glenoid wear Heterotropic ossification
Intrasurgical	Soft tissue balancing Prosthetic component positioning Intraoperative fracture Nerve injury Infection Inadequate range of motion
Postoperative	Infection Contracture Lack of range of motion Inadequate strength recovery Prosthetic component loosening

advanced rheumatoid arthritis in a patient with an intact rotator cuff, total shoulder arthroplasty results in the best pain relief. If the rotator cuff is deficient and irreparable, an anatomically sized humeral head replacement is appropriate.

Many types of implants are available. Biomechanical and anatomical studies suggest that a better technical result can be achieved with the most recent implant design, which is able to recreate accurately the proximal anatomy of the humerus.[72,73] Nevertheless, complications are inevitable in shoulder replacement surgery (incidence of approximately 14%). Numerous intraoperative complications have been identified. In order of decreasing frequency, they include instability, rotator cuff tear, ectopic ossification, glenoid component loosening, intraoperative fracture, nerve injury, infection, and humeral component loosening.[16,36,74,75] Successful treatment of these surgical difficulties requires careful identification and surgical planning, and the surgeon must always keep in mind that the etiology often is multifactorial.

OPERATIVE TECHNIQUE FOR TOTAL SHOULDER REPLACEMENT

Patient Positioning

Appropriate patient positioning is essential in total shoulder surgery. The patient is placed in a modified beach chair position with a headrest that allows access to the superior part of the table (Figure 8-13). The head of the table should be raised to approximately 25° to 30° to reduce venous pressure, and an arm board should be used on the side of the table that will be raised and lowered as necessary throughout the procedure. A mild sedative and an interscalene block are administered.[76]

Figure 8-13 Patient is placed in a modified beach chair position for shoulder arthroplasty.

Incision and Exposure

The first step is to demarcate all bony landmarks, including the clavicle, and the coracoid process. The incision will be made from the lateral aspect of the coracoid process at the level of the clavicle and extend in line with the deltoid toward the midaspect of the humeral shaft and along the deltopectoral groove. The subcutaneous flaps are dissected from the deltoid fascia to expose the deltoid and pectoralis major muscles. The skin is retracted with self-retaining retractors, and the deltopectoral interval is developed. The pectoralis major is retracted medially, and the deltoid is retracted laterally. The cephalic vein, which delineates the deltopectoral groove, is retracted either medially or laterally (preferably laterally) because this minimizes bleeding from the deltoid muscle or cephalic vein (Figure 8-14). The upper 1 to 2 cm (0.5 to 1 inch) of the pectoralis major tendon is released. The interval between the deltoid, the coracobrachialis, and the short head of the biceps is developed, and a retractor is placed deep to it. The superior portion of the subacromial space is exposed, and the anterior aspect of the coracoacromial ligament is resected. The subscapularis major tendon is identified, as are both the superior and inferior margins of the muscle. The tendon is divided just medial to the bicipital grove and is removed from the lesser tuberosity. Care is taken to avoid the axillary nerve. The subscapularis muscle is retracted medially, exposing the articular surface of the humeral head. As a unit, the capsule and subscapularis tendon are taken laterally off the lateral aspect of the humerus (Figure 8-15). Care must be taken to avoid the axillary nerve during this approach. Lateral rotation of the humerus at this point is helpful for protecting the axillary nerve.[77]

Figure 8-14 Pectoralis major is retracted medially, and the deltoid is retracted laterally. The cephalic vein, which delineates the deltopectoral groove, is retracted to minimize bleeding.

Figure 8-15 Capsule and subscapularis tendon are reflected, and the humeral head is exposed.

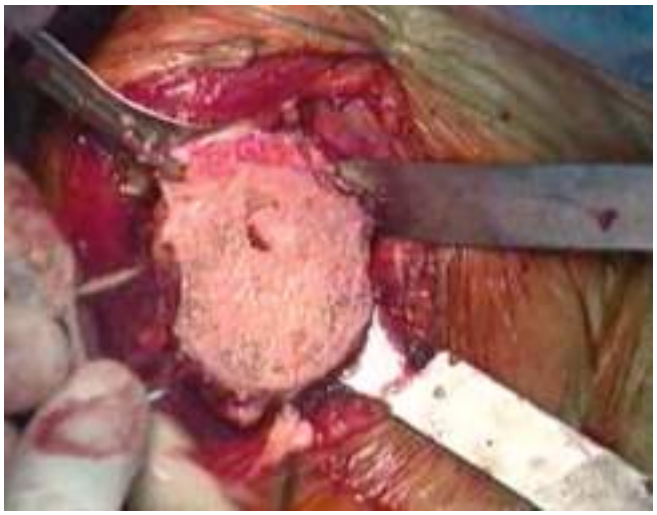

Figure 8-17 Humeral head is removed.

Preparation of the Humerus

Once the subscapularis and capsule have been retracted sufficiently, the arm is placed into extension and lateral rotation to facilitate dislocation of the humeral head. Once the humeral head has been dislocated, arthritic osteophytes are removed so that the anatomical neck of the humerus junction of the articular cartilage and the cortical bone can be identified. An intramedullary reamer (drill) is placed just posterior to the bicipital groove, and a starter hole is made. Sequential reaming then is performed, using a tapered reamer in the intramedullary canal.

The humeral head is then resected with a cutting block technique (Figure 8-16). The cut is made with proper retroversion, which is 20° to 40° retroversion. The resected head is removed (Figure 8-17) and used to size the prosthesis appropriately.[10]

Figure 8-16 Humeral head is resected using a cutting block and oscillating saw.

A provisional humeral stem is used and correlated to the last size of the largest reamer used initially. Retroversion is additionally checked at this point. It is critical that the humeral head be centered relative to the rotator cuff.[43] Many of the current prostheses allow offset head placement; this allows the margin of the humeral head to rest immediately adjacent to the rotator cuff insertion superiorly on the greater tuberosity and slightly overhang the calcar spur medially. ROM could be limited postoperatively if the humeral component is placed too low. If the humeral component is placed too high, the rotator cuff muscles will be under too much tension, and loosening of the glenoid component may occur.[78]

Preparation of the Glenoid

Preparation of the glenoid is essential to a successful outcome in total shoulder arthroplasty. It is essential that the surgeon have a good understanding of the patient's glenoid anatomy before implantation of the component; this involves using either an axillary radiograph of the glenoid or a CT or MRI scan to assess for anterior and posterior wear. It is important to identify the center of the glenoid cavity. Osteophytes that may be obstructing the center of the glenoid need to be removed. If an inadequate or deformed glenoid prevents proper placement of the glenoid component, the surgeon should consider performing a hemiarthroplasty rather than a total shoulder arthroplasty. Any cartilage remaining on the glenoid should be removed, and the glenoid must be sized appropriately.

A centering hole should be made in the glenoid (Figure 8-18). Whether a keeled or pegged glenoid component is used depends on the surgeon's preference.[79] Regardless of the type of component chosen, the appropriate placement for drilling and reaming into the glenoid must be followed. Reaming to the appropriate depth is critical, as is taking care not to remove a

Figure 8-18 Centering and pegged glenoid holes are drilled into the glenoid.

Figure 8-19 Glenoid prosthesis is inserted.

substantial amount of subcortical bone, because this could affect glenoid stability and long-term preservation of the arthroplasty.[80] Reaming is performed by hand and a drill is not used so as to preserve as much subcortical bone as possible. The glenoid then is sized. The optimum glenoid component should not overhang any perimeter of the glenoid.[81]

The humeral head prosthesis is then selected. The prosthesis should be sized according to the removed humeral head. Standard offset heads may be used. The humeral head and its stem as well as the glenoid are then tried together. The joint is reduced and put through a ROM.

Implantation of the Prosthesis

The glenoid component is implanted first. Cement is introduced into the keel or peg holes with a pressurized syringe. The cement is placed, pressurized, and held. The glenoid prosthesis then is inserted and impacted with pressure, which is maintained until the cement has hardened (Figure 8-19). Excess cement is removed.

The humeral component then is prepared for implantation. The surgeon's preference determines whether a press fit or cement is used. Often cement is placed circumferentially around the collar proximally instead of being packed completely into the intramedullary canal.[82]

Various trials should allow for a humeral head that permits 50% of the head to be subluxed posteriorly and inferiorly and to fall back into place once the pressure is released. A prosthetic component that is too large will overstuff the glenohumeral joint and will not allow proper soft tissue balancing.[83]

Before inserting and cementing the final humeral component, the surgeon makes several suture holes through the anterior neck of the proximal humerus. Heavy braided #2 sutures should be passed before cement fixation of the humeral shaft. The suture holes are used to reattach the subscapularis tendon; they often are best placed medially against the neck of the humerus, which effectively lengthens the tendon and thus prevents it from being overtightened.[84] If a cement restrictor plug is used, the proper canal diameter must be determined so that the appropriate-sized cement restrictor can be placed. Before cementing, the intramedullary canal should be thoroughly cleaned and dried. The cement is injected into the humeral canal and finger packed to pressurize it thoroughly. Once the final sizing has been done, the prosthesis is placed and held in position until the cement has dried fully. Bireduction is performed with a modular head. Once the proper sizing has been performed, the humeral taper stem should be thoroughly cleaned and dried. After the proper humeral head has been selected, the humeral head is applied and impacted appropriately (Figure 8-20). The joint then is brought through ROM, and stability is assessed.

Figure 8-20 Humeral head is replaced.

Closure

The wound is irrigated copiously. Then, beginning inferiorly, the subscapularis is reattached using the sutures that were passed before cementing of the humeral shaft. A Hemovac drain is placed deep to prevent hemarthrosis. Care is taken to avoid all neurovascular structures upon closure. The deltoid and subcutaneous layers are closed, with the subarticular stitches close to the skin (Figure 8-21). Steri-Strips and a sterile dressing are applied. A postoperative radiograph is then taken (Figure 8-22). The patient is kept in a sling and swath until interscalene anesthesia has worn off, and perioperative antibiotics are continued for 24 to 48 hours. Major complications that can arise before discharge include neurovascular injuries and dislocation.

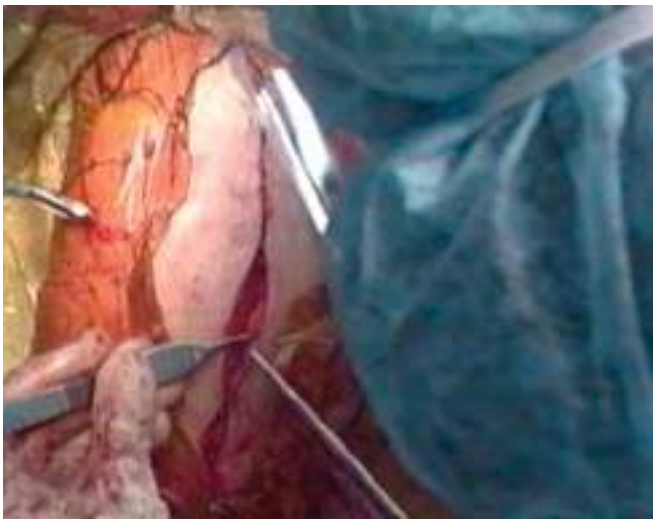

Figure 8-21 Deltoid and subcutaneous layers are closed, with the subarticular stitches close to the skin. Steri-Strips and a sterile dressing are applied.

Figure 8-22 Postoperative radiograph is taken.

READMISSION

Readmission rates for shoulder arthroplasty have not been closely evaluated in very many studies. Fehringer et al.[85] assessed the Veterans Association population for postoperative complications and found that 14-day readmission rates and 30-day mortality rates in total shoulder arthroplasty incidence compared favorably with knee and hip arthroploasty. Mahoney et al.[86] found that the readmission rate for all arthroplasties was 5.9%. For hemiarthroplasty, total shoulder arthroplasty, and reverse total shoulder arthroplasty, 90-day readmission rates were 8.8%, 4.5%, and 6.6%, respectively. Thirty-day readmission rates were significantly more common for hemiarthroplasty and reverse total shoulder arthroplasty.[86]

POSTOPERATIVE REHABILITATION

A successful outcome for total shoulder arthroplasty depends on a well-designed and well-executed physical therapy program. For maximum benefit, the program usually is initiated immediately after surgery and follows a logical pattern of joint mobilization and stretching, followed by muscle strengthening. This design attempts to balance the need to obtain and maintain motion with the need to allow adequate soft tissue healing. Overly protective rehabilitation can result in stiffness, whereas overly aggressive therapy could compromise healing of the subscapularis and rotator cuff musculature and therefore shoulder stability and function.[87]

Immediate Postoperative Phase (Days 0 to 7)

The rehabilitation process should start as soon after surgery as the surgeon allows. Many surgeons begin at least some passive mobility on the same day as surgery, while the patient is still under the influence of a regional nerve block. At the authors' hospital, continuous passive motion is not used for the shoulder; however, some surgeons may prescribe this modality. The patient is seen in the hospital for 2 to 4 days after surgery. Immediate postoperative care involves monitoring pain management and evaluating vital signs and the neurovascular status of the operated arm, as well as caring for the surgical wound site. Pain control is essential during hospitalization. The authors use a regional block to provide effective pain relief for approximately 12 hours. Patients can use an indwelling patient-controlled analgesia (PCA) pump at home for the first 24 hours, but most surgeons want to avoid the extra risk for infection.[88]

After the surgery, the surgeon delineates the extent of soft tissue damage and repair for the physical therapist because these factors determine when exercises can begin. For example, a Z-plasty lengthening, which sometimes is performed on the subscapularis if a long-standing medial rotation contracture is present, may limit the amount of

lateral rotation allowed. Also, a massive rotator cuff repair may delay active lateral rotation for up to 8 weeks. Finally, the authors find it extremely useful for the surgeon to inform the physical therapist of the motion achieved at the end of the case.[15,87]

Early mobilization is essential to prevent the formation of adhesions and capsular contracture, especially if a complete capsular release was performed at the time of surgery. Early mobilization exercises (e.g., pendulum exercises) are recommended to relieve pain and prevent adhesion formation. Pendulum exercises produce minimal muscle activity and are considered a safe exercise during this period. The authors have even found that having the patient rest the hand on a physioball and perform pendular exercises makes the patient feel more relaxed and in control (Figure 8-23). Active-assisted shoulder flexion also is initiated at this time in the hospital bed (Figure 8-24). In fact, the electronic bed can be raised or lowered to use the influence of gravity to the patient's benefit. During this period, elbow and wrist ROM and gripping exercises are encouraged.

Milestones the authors look to achieve for discharge and progression to the next rehabilitation phase are (1) review with the patient the surgical procedure, precautions, and expectations during rehabilitation, (2) provide some pain relief, (3) ensure the patient's independence in performing exercises, and (4) accomplish initial ROM goals. With mobilization of the soft tissues, capsular releases, and proper component placement, the hospital therapy goals of 140° of forward elevation and 40° of lateral rotation before discharge can be achieved in many patients.

Immediate Postoperative Phase Milestones

- Review surgical procedure with patient
- Review precautions and expectations during rehabilitation
- Provide pain relief
- Help patient attain independence in performing exercises
- Achieve initial ROM goals (140° forward flexion, 40° lateral rotation)

Early Postoperative Phase (Weeks 1 to 6)

The early postoperative phase focuses on returning motion, restoring scapular stability, and initiating rotator cuff muscle activation. Active-assisted ROM (AAROM) should be initiated, using a pulley for sagittal plane flexion and scapular plane elevation. In addition, a cane, golf club, or umbrella can be used to help the patient regain flexion, abduction, adduction, and lateral rotation at 0°, 45°, and 90° abduction. An early series of exercises the authors prefer is using the cane supine three different ways for a total of 90 repetitions of horizontal adduction, serratus supine, and flexion (Figures 8-25 and 8-26). Unfortunately, the authors have not found a preferred method of AAROM for medial rotation with a cane, nor have they found the towel stretch to be useful for regaining medial rotation ROM. The authors' preferred method is to have the patient use pulleys in the standing position (Figure 8-27) or to perform the sleeper stretch (Figure 8-28) after 6 to 8 weeks of healing.

Joint mobilization and passive ROM can be important adjuncts if ROM difficulties occur. As mentioned, passive motion exercises, such as pendulum exercises, are good for pain relief and preventing the formation of adhesions.

Figure 8-23 Example of the pendulum exercise in the supported position.

Figure 8-24 Active-assisted shoulder flexion can be done anywhere with the use of the uninvolved upper extremity.

Figure 8-25 Active-assistive shoulder flexion can be accomplished with the use of a cane or stick.

Figure 8-26 Horizontal abduction and adduction can be accomplished with the use of a cane or stick.

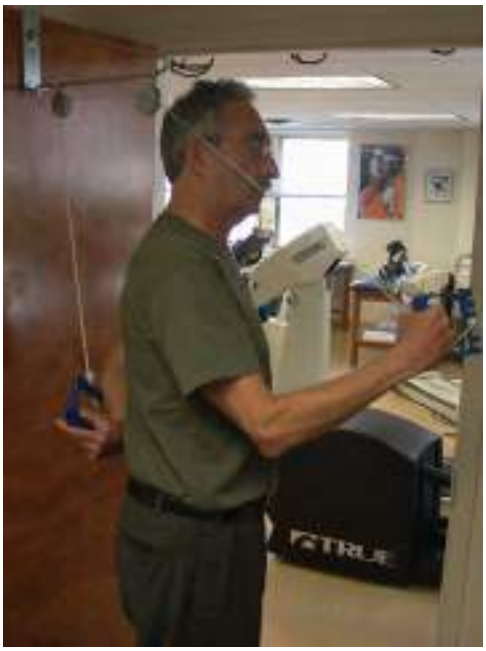

Figure 8-27 Use of pulleys to regain functional medial (internal) rotation ROM.

Figure 8-28 Sleeper stretch.

At this time, the mobility of the sternoclavicular joint, AC joint, and scapulothoracic joint is addressed, and these joints are mobilized if indicated. Once the milestone of mobility of these proximal joints has been reached, manual scapular stabilization is initiated. In the side-lying position, manual resistance can be applied to the scapula to resist elevation, depression, protraction, and retraction. The authors have found that pain can be a limiting factor when starting scapular stabilization and rotator cuff isometrics. However, submaximum pain-free isometrics for lateral rotation can be started as early as 7 days after surgery provided there is no rotator cuff involvement (Figure 8-29).

Isometric deltoid activity may also be initiated during this phase, provided pain is not a limiting factor. An arm upper body ergometer (UBE) using light resistance can be beneficial at this time (4 weeks) to facilitate ROM and initiate active muscular control of the shoulder. The axis of rotation of the UBE should remain below the level of the shoulder joint so that forward flexion is not forced above 80°. The authors also stress the retro component of performing the UBE. By performing retro UBE (going backward), the authors hypothesize, the patient mobilizes the scapula and encourages proper posture.

Early strengthening of the serratus anterior muscle also is encouraged, provided the arm is maintained slightly below 90° of shoulder flexion and movement is pain free. Subsequent atrophy of the serratus anterior muscle, as a result of disuse, may allow the scapula to rest in a downwardly rotated position, causing inferior border

Figure 8-29 Early lateral (external) rotation strengthening.

Figure 8-30 Serratus anterior strengthening in the supine position.

prominence. Decker et al.[89] used electromyography (EMG) to determine which exercises consistently elicited the highest percentage of the maximum voluntary contraction (MVC) of the serratus anterior. They found that the serratus anterior punch out, scaption, dynamic hug, knee push up plus, and push up plus exercises consistently elicited greater than 20% MVC. Most important, they determined that the push up plus and the dynamic hug exercises maintained the greatest percentage of the MVC and maintained the scapula in an upwardly rotated position. Although the early postoperative phase is too early in the rehabilitation process to perform these late exercises, Decker et al.[89] highlighted the serratus anterior punch out as a valuable exercise. Performed in a controlled, supervised setting, this is an excellent choice to initiate early serratus anterior neuromuscular reeducation (Figure 8-30). Progression to the more challenging serratus anterior strengthening exercises can be considered during the intermediate phase of rehabilitation, keeping in mind that the patient is instructed to avoid heavy pushing, pulling, and lifting for the first 6 weeks, and no upper extremity weight-bearing activities are allowed for 3 months.

A delicate balance exists between pushing patients too hard and progressing them as planned. Too often the patient may feel better rather than worse during this early protective phase; therefore the clinician must always respect the laws of tissue healing.

Milestones the authors look to achieve for progression to the next rehabilitation period are (1) toleration of submaximum isometrics of the rotator cuff muscles at 0° abduction; (2) attaining symmetrical mobility of the sternoclavicular, AC, and scapulothoracic joints; and (3) protraction, retraction, elevation, and depression of the scapula against submaximum manual resistance. Adequate passive ROM in flexion, abduction, adduction, and medial rotation at 45° abduction (50% to 75% of the uninvolved side) also should be attained before the patient is progressed.

Early Postoperative Phase Milestones

- Ability to tolerate submaximum rotator cuff isometrics at 0°
- Symmetrical mobility of sternoclavicular, acromioclavicular, and scapulothoracic joints
- Ability to protract, retract, elevate, and depress scapula against submaximum manual resistance
- Adequate passive ROM (50% to 75% of uninvolved side) at 45° abduction

Intermediate Postoperative Phase (Weeks 6 to 12)

During the intermediate postoperative phase of rehabilitation, the patient attempts to regain all available ROM, including passive medial rotation. Initiation of passive lateral rotation ROM at 0°, 45°, and 90° abduction and stretching beyond neutral rotation position are emphasized. Advancement to terminal ranges in all planes of motion is advocated unless otherwise specified by the referring surgeon. Medial rotation submaximum resistive exercise progressions also are initiated during this phase. A traditional rotator cuff isotonic exercise program is started, which includes side-lying lateral rotation, prone extensions, and prone horizontal abduction (which may need to be limited between neutral to the scapular plane position initially, with progression to the coronal plane

Figure 8-31 Rhythmic stabilization in open kinetic chain.

Figure 8-32 Rhythmic stabilization in closed kinetic chain.

as ROM improves). Biceps and triceps curls in the standing position with glenohumeral joint rotation in a neutral resting position are begun. In addition, oscillation exercises with Flexbar or a Body Blade can begin. Rhythmic stabilization in open kinetic chain (Figure 8-31) and closed kinetic chain (Figure 8-32) environments can begin, with caution in shoulder arthroplasty patients who will be placing higher demands on the shoulder.

Intermediate Postoperative Phase Milestones

- Regaining of full ROM
- Rotator cuff isotonic exercise program
- Oscillation exercises
- Open and closed kinetic chain exercises

Return to Activity Phase (Weeks 12 to 24)

The return to activity phase is the stage of rehabilitation in which clinicians begin "to lose" their patients. Often patients lose focus, exhaust insurance coverage, or neglect the importance of fine-tuning the shoulder's function before fully returning to their lifestyle. This phase is designed to prepare patients to return without hesitation to full participation in all activities.

Milestones to complete this phase successfully include (1) acceptable (functional) pain-free ROM and (2) isokinetic or handheld dynamometry strength testing demonstrating less than a 20% deficit in shoulder flexion, abduction, and medial rotation. A deficit greater than 20% may still exist, depending on rotator cuff integrity at the time of surgery. Although not always considered as such, inadequate ROM is a complication that can occur after total shoulder arthroplasty. Acceptable ROM after shoulder arthroplasty has been defined as forward elevation to 140° to 160°, lateral rotation with the arm at the side to 40° to 60°, full extension, and 70° of medial rotation with the arm at 90° in the coronal plane. Inadequate ROM may be due to insufficient soft tissue release or joint overstuffing.

Return to Activity Phase Milestones

- Functional, pain-free ROM
- No more than 20% strength deficit
- Patient has confidence in shoulder

In this phase, the patient continues to work in functional positions, including plyometrics and strengthening at 90° abduction, and gradually returns to full activity, provided the individual is pain free, has nearly full ROM in all planes, confidence in the shoulder, and 85% to 90% of the strength of the opposite side for the motions of internal and lateral rotation. The patient acquires confidence by being able to perform pain-free functional movement in the person's usual activities. In the authors' experience, recreational athletes require 1 to 2 months more to allow the shoulder to accommodate to the sports-specific motion. The authors currently use the American Shoulder and Elbow Surgeons Shoulder Evaluation Form to standardize the documentation of pain, motion, strength, stability, and function. However, enough data have not been gathered to

determine a criterion score for return to sports after shoulder arthroplasty. In a review article by Healy et al.,[90] 35 members of the American Shoulder and Elbow Surgeons Society were surveyed about their recommendations for athletics and sports participation for their patients who had shoulder replacement surgery. The surgeons were asked to rate 42 athletic activities as recommended or allowed, allowed with experience, no opinion, and not recommended. The 35 responses were analyzed to obtain a consensus recommendation for each activity. If a valid percentage was not achieved for either a positive or negative recommendation, no conclusion was provided for those activities. These recommendations are presented in Table 8-4.

These rehabilitation guidelines are a continuum of rehabilitation phases based on the effect of surgery on the tissue and surrounding structures. Scientific rationale is applied whenever possible, but as surgical procedures evolve, so must rehabilitation procedures. However, these guidelines are by no means set in stone, nor is every exercise distinct to that phase (see Table 8-2). The goals and exercises must be modified based on the performer, pathology, and performance demands. No exercise prescription should be viewed as protocol, but as a guideline upon which to base rehabilitation.

Key Points in Rehabilitation

- Goals and exercises must be modified based on the individual, pathology, performance demand, and functional outcome the individual hopes to achieve
- No exercise prescription should be viewed as a protocol but instead as a guideline based on individual patient needs and desires for a good functional outcome

OUTCOMES OF SHOULDER ARTHROPLASTY

Diagnosis of the correct indication for shoulder arthroplasty, the preoperative planning, and the postoperative rehabilitation program are essential for a good functional outcome and the keys to physical activity after shoulder arthroplasty. Although the optimum method for measuring the outcome in patients with shoulder arthroplasty has yet to be defined, the ideal assessment should include measures of general health, a shoulder-specific assessment, and an assessment specific to the disease state for which the shoulder arthroplasty was indicated.[91] Each of these levels of sensitivity offers a different perspective on the outcome of shoulder arthroplasty until the ideal universal outcome tool is developed.

Overall, shoulder arthroplasty has been shown to provide predictable pain relief and functional improvement in patients with glenohumeral degenerative arthritis and an intact rotator cuff.[92–94] Norris and Iannotti[95] reported on 133 total shoulder replacements and 43 hemiarthroplasties at an average follow-up of 46 months. They found no differences in postoperative pain, function, American Shoulder and Elbow Surgeons scores, or ROM. Also, no differences were seen between total shoulder arthroplasty and hemiarthroplasty in patients with repairable rotator cuff tears. Total shoulder arthroplasty and hemiarthroplasty for the treatment of primary osteoarthritis result in good or excellent pain relief, improved function, and patient satisfaction in 95% of cases. Boyd et al.[96] compared 64 patients who had hemiarthroplasty with 146 patients who had total shoulder arthroplasty in a retrospective review with a mean follow-up of 44 months. They found similar outcomes in terms of patients' functional improvement. No difference in

TABLE 8-4

Activity after Total Shoulder Arthroplasty: 1999 American Shoulder and Elbow Surgeons Survey

Recommended or Allowed	Allowed with Experience	Not Recommended	No Conclusion
• Cross-country skiing	• Golf	• Football	• High-impact aerobics
• NordicTrack	• Ice skating	• Gymnastics	• Baseball, softball
• Speed walking and jogging	• Shooting	• Hockey	• Fencing
• Swimming	• Downhill skiing	• Rock climbing	• Handball
• Doubles tennis			• Horseback riding
• Low-impact aerobics			• Lacrosse
• Bicycling (road and stationary)			• Racquetball, squash
• Bowling			• Skating (roller, inline)
• Canoeing			• Rowing
• Croquet			• Soccer
• Shuffleboard			• Tennis, singles
• Horseshoes			• Volleyball
• Dancing (ballroom, square, and jazz)			• Weight training

overall patient outcomes was observed between hemiarthroplasty and total shoulder arthroplasty.

Secondary to improvements in design and implant survivorship, total shoulder arthroplasty patients strive to return to higher levels of function and sports activity. In a case series conducted in 2010, 100 consecutive patients with unilateral total shoulder arthroplasty were followed for at least 1 year. Of the 55 patients who played sports before shoulder disease, 89% were still playing at a mean follow-up of 2.8 years, whereas more than two thirds (69.4%) reached the same level of intensity as before the shoulder pathology.[97] McCarty et al.[98] exhibited similar findings among 75 patients followed for a minimum of 2 years. Of the 48 patients who stated one of the reasons they opted for surgery was to return to sport, 71% demonstrated an improvement in their ability to play their sport and 50% increased their respective frequency of participation postoperatively (Figure 8-33). Jensen and Rockwood[99] retrospectively evaluated 24 golfers with shoulder replacements and found 23 players (96%) were able to resume playing golf. Three of these patients had bilateral shoulder arthroplasty. Among the 26 shoulder replacements in 24 patients, 6 were hemiarthroplasties and 20 were total shoulder arthroplasties. Of the 18 patients who were able to report a preoperative handicap, an average improvement of five strokes was reported after the operation.

SUMMARY

The success of shoulder arthroplasty depends on proper patient selection through a comprehensive history and physical examination, appropriate use of diagnostic modalities, good surgical skill, and effective rehabilitation. A thorough understanding of the pitfalls and complications that can affect patients undergoing shoulder arthroplasty is essential to a successful outcome. Technical advances in shoulder arthroplasty have allowed surgeons the use of this procedure with confidence and have helped optimize results.

CHAPTER 9

Elbow

KEVIN E. WILK, CHRISTOPHER A. ARRIGO, MARC R. SAFRAN, STEVEN A. AVILES

INTRODUCTION

Elbow injuries affect patients of all ages and activity levels. Whether caused by acute trauma or chronic overuse, elbow pathology can result in significant pain and disability. Because the elbow positions the hand for use, normal elbow motion, strength, and stability are essential not only for activities of daily living (ADLs) but also for higher level professional and athletic skills. Appropriate diagnosis and treatment require a detailed understanding of the normal anatomy of the elbow and the pathophysiology of injuries that affect the joint and its surrounding tissues. Symptoms can arise from abnormalities in bone, cartilage, muscles, tendons, ligaments, and/or neurovascular structures. The clinician should consider the functional expectations of the individual patient when determining the most appropriate course of treatment. Many patients can be managed successfully with medications, physical therapy, and other nonsurgical approaches. However, depending on the specific pathology and the response to conservative care, some patients require surgical treatment.

FUNCTIONAL ANATOMY AND BIOMECHANICS

The anatomical structures of the elbow must provide stability through a complex range of motions. Normal elbow function, whether for ADLs or high-level activities, requires motion through both flexion/extension and pronation/supination. The dynamic stability seen in the normal elbow depends on varying contributions from the osseous, ligamentous, and other soft tissue structures about the elbow.

Bony Anatomy

The ulnohumeral joint acts primarily as a hinge joint and provides most of the anteroposterior stability to the elbow.[1] In addition, it is a major contributor to varus-valgus stability, particularly near full extension and with higher degrees of flexion. The normal carrying angle across the elbow joint is 11° to 16° of valgus (Figure 9-1).[2] Pronation and supination are provided by the articulation of the proximal radius with the capitellum of the distal humerus and proximal ulna (Figure 9-2). The radial head acts as a secondary restraint to valgus stress when the medial ligaments of the elbow have been injured.[3,4]

Range of Motion

Normal range of motion (ROM) at the elbow is full extension to 140° of flexion with 75° of pronation and 85° of supination.[5] The basic functional goals and tasks of ADLs generally can be accomplished with a ROM of 30° to 130° of elbow extension to flexion and approximately 50° of pronation/supination.[6] However, for many high-level and athletic goals, the functionally acceptable ROM may be different. For instance, a gymnast or power lifter will not tolerate any less than full extension because of the weight that must be borne by the upper extremity. Baseball pitchers, on the other hand, can throw effectively with a flexion contracture exceeding 20° and only 100° of elbow flexion.

Ulnar/Medial Ligament Complex

The medial ligament, or ulnar collateral ligament (UCL), is the ligamentous complex on the medial aspect of the elbow between the distal humerus and the proximal ulna (Figure 9-3). Its anterior portion, the anterior oblique ligament (AOL), is the elbow's primary restraint against valgus stress, especially the forces associated with throwing.[3,4,7,8] The AOL consists of an anterior band, which is taut between 0° and 60° of flexion, and a posterior band, which is taut from 60° to 120° of elbow flexion.[8,9] The anterior band is primarily responsible for stability against valgus stresses at 30°, 60°, and 90° of flexion, making it the most important component in resisting the valgus forces associated with overhead sports activities. The posterior band of the AOL begins as a secondary restraint to valgus stability at 30° and 90° and is a primary restraint to valgus force at 120° of flexion.[7] The posterior oblique ligament forms the floor of the cubital tunnel and plays a bigger role as a restraint against valgus stress at higher degrees of flexion. The role of the transverse ligament (Cooper's ligament) in elbow stability remains unclear,

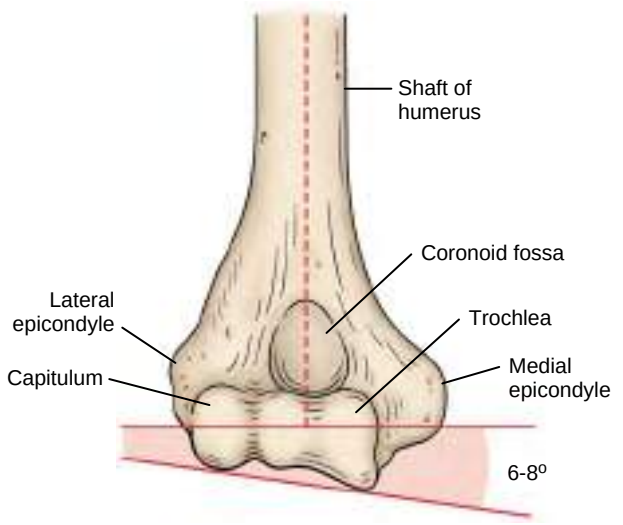

Figure 9-1 Anatomy of the distal humerus showing how the bony anatomy contributes to the overall valgus alignment of the elbow. There is approximately 6° to 8° of valgus tilt of the distal humeral articulation with respect to the long axis of the humerus.

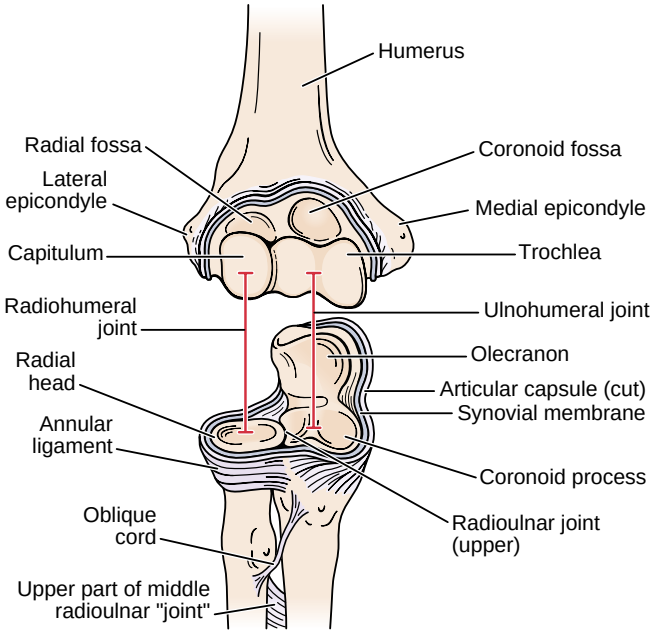

Figure 9-2 Anterior view of the right elbow, disarticulated to expose the ulnohumeral and radiohumeral joints. The margin of the proximal radioulnar joint is shown within the elbow's capsule. (From Magee DJ: *Orthopedic physical assessment,* ed 6, p 389, St. Louis, 2014, Saunders/Elsevier.)

because this ligament originates from and inserts into the olecranon.

Lateral Ligament Complex

The lateral ligament complex consists primarily of the lateral ulnar collateral ligament (LUCL), the lateral radial collateral ligament (RCL), and the annular ligament (AL) (Figure 9-4). The LUCL, first described by Morrey and An,[9] originates from the lateral epicondyle. It passes over the AL and then begins to blend with the AL distally, where it inserts onto the supinator crest of the ulna. O'Driscoll et al.[10,11] have suggested that the LUCL is the essential structure that prevents posterolateral rotatory instability. However, other studies have indicated that many components of the lateral ligament complex contribute to the prevention of posterolateral instability. Isolated sectioning of the LUCL distal to the AL results only in minor laxity. In contrast, significant rotatory instability is observed with more proximal transection of the LUCL and RCL.[12] Most likely all the components of the lateral ligament complex act together to prevent rotatory instability, but the LUCL clearly is the major contributor.

Capsule

The anterior capsule originates from the distal humerus proximal to the radial and coronoid fossae. It then

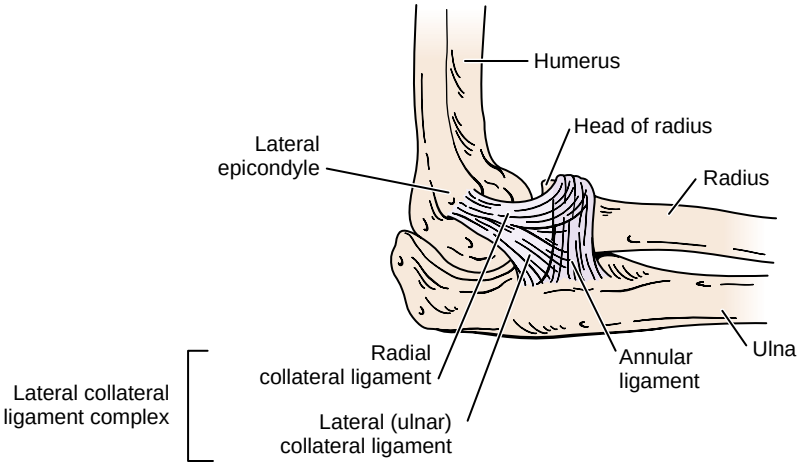

Figure 9-4 The lateral (radial) collateral ligament complex of the elbow. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 390, St. Louis, 2014, Elsevier/Saunders.)

inserts distally onto the rim of the coronoid and the AL. Posteriorly, the capsule incorporates the area proximal to the olecranon process. It attaches distally along the articular margin of the sigmoid notch and the proximal aspect of the olecranon fossa.[13] In terms of elbow stability, most of the literature has focused on the osseous articulation and ligaments. However, the anterior capsule apparently does make a significant contribution as well. The anterior capsule has been shown in a cadaveric study to contribute 38% of the resistance to valgus force and 32% of the resistance to varus force in full extension.[14] The posterior capsule's contribution to stability has not been well documented.

Muscles

The muscles about the elbow also provide stability. Because of the conformity of the elbow joint, the muscles about the elbow provide dynamic stability by compressing the joint surfaces through muscular contraction.[13,15–17] The muscles also may passively assist in stability by means of a "bulk effect."[13,18]

PATHOPHYSIOLOGY AND PATHOMECHANICS

The elbow can be subjected to numerous external forces in activities that place high loads on it, especially during sports. The elbow of the athletes doing overhead activities is subjected to major valgus forces and as a result is at risk for specific elbow injuries. Sports such as baseball, football, tennis, volleyball, golf, and water polo are most commonly associated with both acute and chronic elbow pathologies. Overhead throwing athletes are predisposed to overuse syndromes secondary to the repetitive, high-velocity stresses placed on the elbow during these high-velocity activities. The highest stress at the elbow occurs during the late cocking and acceleration phases of the throwing cycle.[19] Studies have indicated that the valgus stress at the elbow during the acceleration phase of throwing can be as high as 64 N-m, which exceeds the ultimate tensile strength of the UCL.[20] These supraphysiological stresses create the potential for injuries that can typically be determined based on the pathophysiology of the forces applied to the elbow complex. These include traction or tensile forces on the medial-sided structures, compression of the lateral side of the elbow, and medially directed shear posteriorly (Figure 9-5).[21,22] Overhead athletes commonly exhibit both chronic and acute injuries to the UCL with or without medial epicondylitis, as well as ulnar nerve symptoms. Laterally, compression leads to radiocapitellar degeneration and loose bodies, and posterior shear forces may lead to olecranon osteophyte formation, loose bodies, and olecranon stress fractures.

Golf and tennis players have a high incidence of medial and lateral epicondylitis. Gymnasts can develop radiocapitellar overload, including osteochondritis dissecans, and posterior impingement secondary to weight bearing on an extended elbow.[23] Weight lifters and shot-putters may develop posterior elbow compressive injuries, including chondral damage and loose bodies, in addition to being susceptible to developing triceps injuries.[24]

Acute injuries, such as fractures and dislocations, can occur as a result of a fall on an outstretched hand (**FOOSH injury**) or direct trauma. These occur in sports as well as in everyday activities.

FRACTURES AND DISLOCATIONS

Dislocations

The elbow is the second most commonly dislocated major joint in the body and the most frequently dislocated joint in children.[25] Elbow dislocation is most often produced with high-energy mechanisms of injury. It usually results from a FOOSH, which imparts a combination of axial compression, supination, and valgus stress to the elbow dislocating the bony elements of the joint.[26]

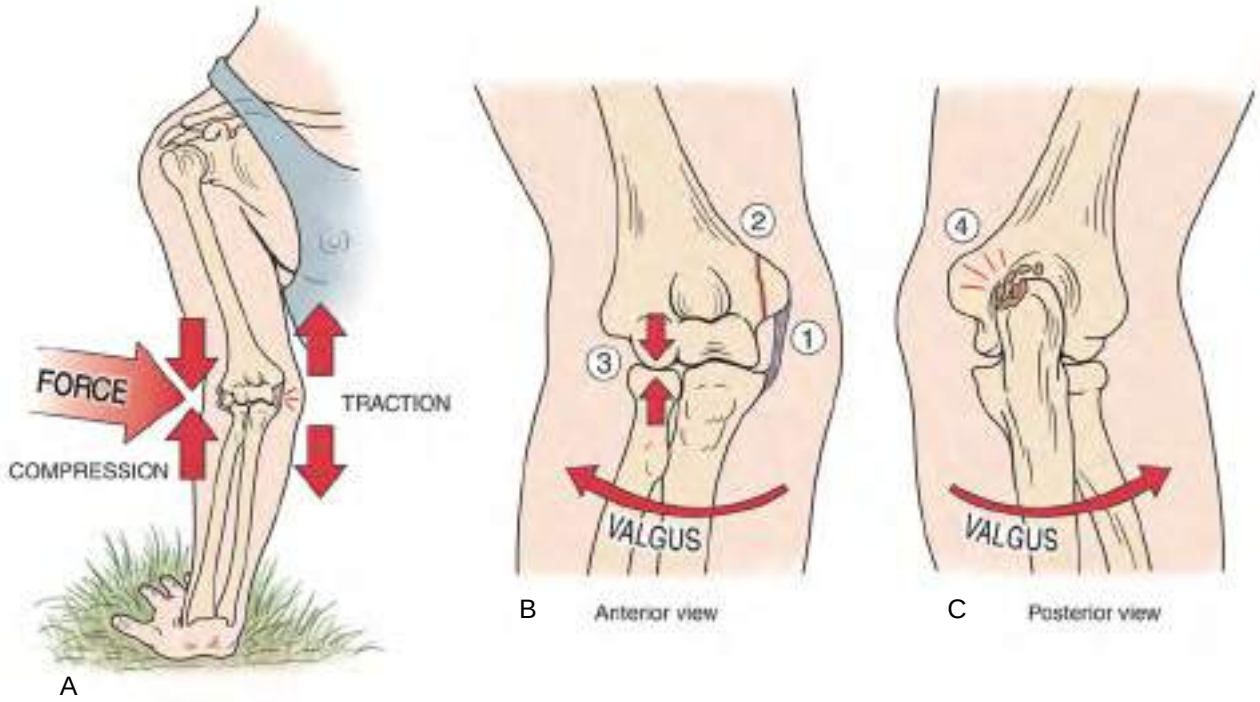

Figure 9-5 Valgus overload to the elbow. **A**, Mechanism of injury. **B**, Anterior view. **C**, Posterior view. Injury may lead to (1) stretching of medial collateral ligament, (2) stress on epicondylar growth plate (pitcher's or little leaguer's elbow), (3) compression at radiohumeral joint, or (4) compression of the olecranon in the fossa, which may lead to osteophyte and loose body formation. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 391, St. Louis, 2014, Saunders/Elsevier.)

No single classification system is used consistently for elbow dislocations. They generally are described according to the direction and degree of displacement, whether associated fractures are present, and the acuity or chronicity of the injury.

Elbow Dislocations

- The elbow is the second most frequently dislocated major joint
- Elbow dislocations are the most common dislocation in pediatric patients

O'Driscoll et al.[27] described the most common mechanism of acute elbow instability as posterolateral rotatory instability (PLRI). This instability involves a complex pattern of injury that involves rotational displacement of the ulna on the trochlea and subluxation or dislocation of the radius posteriorly from the capitellum, while the radius and ulna maintain their normal relationship to each other. The full spectrum of injury seen with an elbow dislocation can be understood as a disruption of the circle of soft tissue and bone that begins on the lateral side of the elbow and progresses medially (circle of Horii).[26] Stage 1 involves partial or complete disruption of the LUCL, resulting in posterolateral rotatory subluxation. In stage 2, additional disruption occurs anteriorly and posteriorly, resulting in an incomplete posterolateral dislocation, or "perched" dislocation. More severe injury results in stage 3A, in which all soft tissues except the UCL have been disrupted and the elbow is stable only in pronation. In stage 3B the UCL has been disrupted, and in stage 3C the entire distal humerus has been stripped of soft tissues, resulting in stability only with flexion greater than 90°. Josefsson et al.[25,28] in his series, however, reported that all simple elbow dislocations (i.e., those not associated with fracture) involved injury to the UCL.

In children, elbow dislocations are associated with fractures in up to 50% of cases, especially fractures of the radial head, neck, and medial or lateral epicondyle.[29] Elbow dislocations in children may involve avulsion of the medial epicondyle apophysis instead of direct injury to the ligaments because the physis is weaker than the ligaments. The avulsed fragment may be nondisplaced or displaced a few millimeters; or worse, it may be even more displaced and become incarcerated in the joint. Avulsions of the medial epicondyle may occur in up to 30% of children with dislocations.[30–32]

Injury to the musculotendinous origins of the wrist flexors and/or extensors is not uncommon in elbow dislocations. Other concomitant injuries include radial head and neck fractures, which may occur in 5% to 10% of elbow dislocations, and olecranon fractures.[33] It is important that the examiner identify coronoid fractures, because the prognosis for recurrent elbow instability is directly affected by the amount of the coronoid involved (see discussion later in this chapter).

The initial treatment for elbow dislocations is closed reduction after a careful neurovascular examination of the extremity has been performed and appropriate radiographs have been obtained to check for concomitant fractures. Immediately after reduction, the elbow should be examined to determine how smoothly the joint glides during movement and its stable ROM. These findings should be documented, because they will determine the amount of restriction of motion during the early treatment period. Postreduction radiographs should be obtained to confirm concentric reduction and to rule out fractures. If no fracture is present, the elbow should be splinted in a position of stability (but no more than 90° of flexion) until the initial swelling has subsided. The patient can then be placed in a hinged elbow brace and allowed to begin gentle motion, with extension limited according to the stability of the postreduction examination. Follow-up radiographs are essential to confirm maintenance of reduction. Motion is then gradually progressed, followed by strengthening.[34] (Rehabilitation is detailed at the end of this chapter.)

Postreduction Elbow Assessment

- The postreduction stable ROM and gliding smoothness determine the amount of motion allowed in early treatment

Follow-up is important. Long-term follow-up studies have reported that persistent valgus laxity after elbow dislocation is associated with poorer overall clinical and radiographic results compared with elbows without increased valgus laxity after elbow dislocation.[35] Furthermore, chronic problems related to PLRI may occur; therefore care must be taken to evaluate the patient for this problem.

It is helpful to distinguish simple from complex elbow dislocations. Simple dislocations are not associated with fractures, whereas complex dislocations result in an associated elbow fracture. Simple dislocations rarely require surgical treatment, and recurrent instability is extremely rare (fewer than 2%).[36] Josefsson et al.[28] compared the operative and nonoperative treatment of simple dislocations. In a prospective trial, they found that elbows treated nonoperatively actually had a slightly improved ROM and better subjective results than those treated operatively.

Early ROM is essential to achieve a good outcome. Posttraumatic stiffness is the most common complication. Mehlhoff et al.[37] and Protzman[31] reported that a shorter immobilization time significantly correlated with better outcomes. Regardless, most patients commonly have at least 10° of flexion contracture. For this reason, some surgeons advocate early surgical repair or reconstruction of the injured ligament or ligaments after unstable elbow dislocations to allow for aggressive early ROM.[38]

The same principle of early motion applies in the treatment of complex dislocations. However, with complex dislocations, fractures often need to be stabilized operatively so that the patient can begin early motion. The appropriate operative treatment depends on exactly which bony and soft tissue injuries are present.

Posterolateral Rotatory Instability

Although case reports on PLRI have long been in existence, the condition was brought to the forefront in the early 1990s by O'Driscoll et al. and Osbourne and Cotterill.[27,39] This elbow injury pattern is a rotatory instability caused by injury to the lateral UCL. The mechanism of injury is a combination of axial compression, valgus stress, and supination (or lateral rotation) that exerts a rotational force on the elbow, resulting in a spectrum of soft tissue injuries.[26,27] The initial injury is to the ulnar portion of the lateral collateral ligament complex (LCLC). Further injury results in progressive damage to both the anterior and posterior capsule and eventually may involve the UCL complex if the injury is severe enough.[10,26,27]

Understanding the pathomechanics of PLRI is the key to comprehending this condition. PLRI of the elbow results from a rotatory subluxation of the radius and ulna (which move together as a unit) relative to the distal humerus. Because the AL remains intact in this injury, the radioulnar joint maintains its normal relationship, and the proximal radius and ulna therefore move together in a "coupled" motion. Most give credit to Osbourne and Cotterill[39] as the first investigators to fully appreciate the importance of the lateral ligament complex of the elbow in recurrent instability and to describe the findings of PLRI. Although much of the initial literature by O'Driscoll and the laboratory at the Mayo Clinic reported the results of biomechanical studies demonstrating that the primary stabilizer in PLRI is the LUCL, much of the recent literature suggests that the injury may not be to the LUCL alone.[10,26,27,40] According to some reports, the RCL and anteroposterior capsule serve as secondary stabilizing restraints and are also involved in PLRI of the elbow. However, clinically, it is known that elbow dislocations and injury to the LCLC occur as the primary injury and PLRI is most commonly seen after an elbow dislocation. Subsequent research by other investigators has suggested that isolated injury to the LUCL alone may not be enough to produce PLRI.[12,13,41] Some suggest that the complex works in a Y configuration and that a proximal injury, near the epicondyle, as seen clinically, can and does produce PLRI.[42]

The diagnosis of PLRI is much more elusive than other ligament injuries, including injuries of the UCL. It requires a careful history and physical examination to discern its presence. The clinician must be diligent with the assessment and maintain a high degree of suspicion in patients with vague reports of elbow discomfort. Patients with PLRI frequently report that they have painful

sensations of clicking, snapping, clunking, locking, dislocating, or giving way. The position of the hand during maneuvers that elicit these symptoms is critical, because the symptoms of PLRI often are produced when the patient extends the elbow with the forearm supinated.[27] Examples include using the hands to get out of a chair with the forearms maximally supinated or doing a push-up in full supination.[43]

The standard preliminary physical examination of the elbow is generally unremarkable with regard to strength, ROM, and tenderness. The diagnosis requires a provocative test of stability described by O'Driscoll, called the **lateral pivot-shift test of the elbow**.[27] This pivot-shift test is performed with the patient supine and the examiner standing above the patient's head (Figure 9-6). The affected extremity is brought above the patient's head into

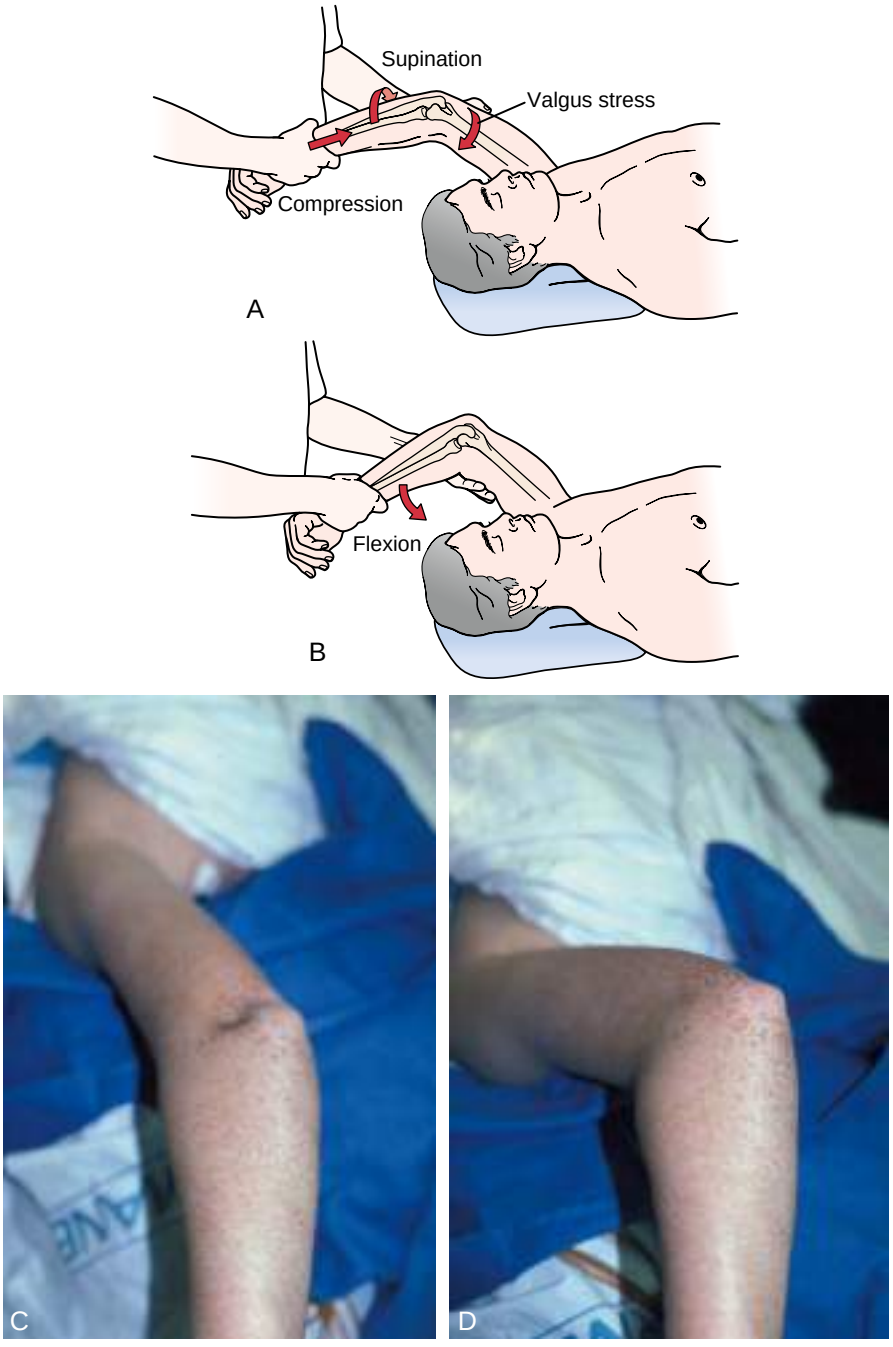

Figure 9-6 Posterolateral rotatory instability. **A,** The patient lies supine with the arm overhead. A mild supination force is applied to the forearm at the wrist. The patient's elbow is then flexed with a valgus stress, and compression is applied to the elbow. **B,** If the examiner continues flexing the elbow at about 40° to 70°, subluxation and a clunk on reduction when the elbow is extended may occur, although usually only in an unconscious patient. **C,** The radial out of anatomical position; this leads to a fullness with dimpling proximal to the radial head. **D,** The same patient as in **C;** as the elbow is brought into flexion, the radial head reduces, eliminating the fullness and dimpling. (**A** and **B** from Magee DJ: *Orthopedic physical assessment,* ed 6, p 405, St Louis, 2014, Saunders/Elsevier.)

forward elevation, and the shoulder is placed in full lateral rotation to stabilize the humerus for the test. The patient's forearm is held in maximal supination, with the examiner using one hand to grasp the wrist distally. A valgus force is applied with the examiner's other hand as the elbow is slowly flexed from a starting position of full extension. The combination of supination and valgus force results in an axial joint compression, which produces a posterolateral rotatory subluxation of the combined radius and ulna relative to the humerus. In an unanesthetized patient, this maneuver reproduces the sensation of instability and often elicits apprehension or guarding. The subluxation usually is maximized in extension and usually is maintained as the elbow reaches 40° of flexion, and further flexion results in a sudden clunk when joint reduction occurs. Dimpling of the skin along the posterolateral elbow proximal to the radial head can be seen with a PLRI in 20° of flexion before the reduction. The clunk of reduction in PLRI generally is felt only by the examiner if the patient is under general anesthesia or occasionally after the patient has had an intra-articular injection of anesthetic. If a patient displays apprehension or guarding during the pivot-shift maneuver, confirmation of the posterolateral instability by examination of the patient under anesthesia is usually recommended. Lateral stress radiographic studies or fluoroscopy during the pivot-shift maneuver demonstrate posterolateral radial head dislocation with widening of the ulnohumeral joint as a result of the subluxation of the ulna out of the trochlear groove and may be helpful for confirmation and documentation of PLRI pathomechanics.

Plain radiographs usually are unremarkable unless a bony avulsion off the lateral epicondyle has occurred (Figure 9-7, *A*). Stress radiographs often show the posterolateral subluxation if the patient is relaxed and allows the application of the forces necessary (Figure 9-7, *B*). Positive lateral stress radiographs will show that the ulna is rotated off the distal humerus with slight gapping of the ulnohumeral joint and that the radial head is rotated with the ulna so that the radial head rests posterior to the capitellum. The normal radioulnar relationship differentiates PLRI from radial head subluxation or dislocation in which the radial head is displaced but the ulnohumeral joint is entirely normal. Although arthrography has not been shown to aid in diagnosis, advances in magnetic resonance imaging (MRI) have allowed good visualization of the LCLC and can be helpful in confirming the diagnosis in some cases.[44] Yet, because PLRI is a dynamic problem and the ligament may be stretched but intact, the sensitivity and specificity of MRI for this condition is less than might be preferred.

Nonoperative treatment protocols have not been reported to be successful in the management of PLRI.[45] Therefore, operative intervention is often necessary because no proven conservative management exists for chronic PLRI.[1] When PLRI markedly interferes with the patient's daily functions, activity modification and a hinged brace with a forearm pronation and elbow extension block may be considered. However, few patients are content with this option for the long term.

Chronic repetitive injury is rarely the cause of PLRI because few activities require repetitive varus stress, although cubitus varus caused by childhood trauma may present as delayed PLRI.[46] Surgical treatment of PLRI involves repair by means of reattachment of the avulsed LCLC or reconstruction of the LUCL with a free tendon graft to the lateral epicondyle, similar to reconstruction of the medial UCL (Figure 9-8, *A*).

Repair usually is reserved for acute avulsions from the distal humerus, the most common site of LUCL injury in

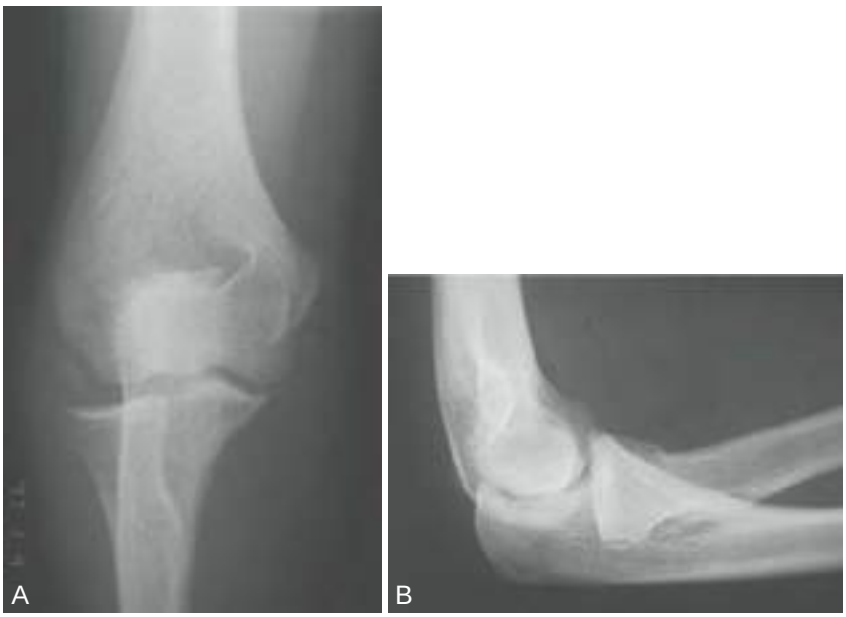

Figure 9-7 Radiographs of patients with posterolateral rotatory instability (PLRI). **A,** Bony avulsion off the lateral epicondyle, leading to PLRI. **B,** Stress radiograph showing the radial head posteriorly subluxated and the ulnohumeral joint slightly widened.

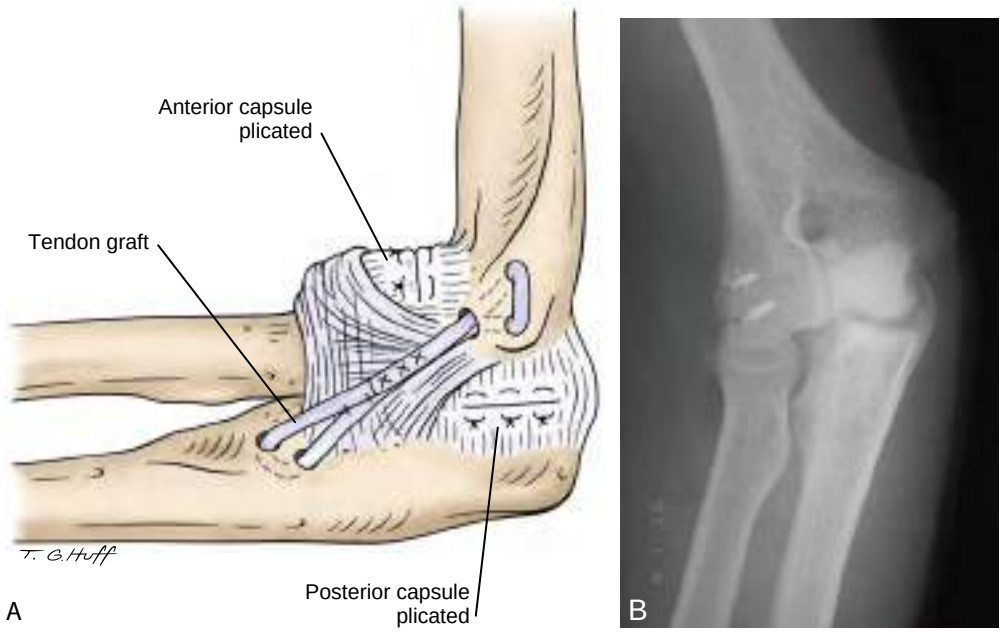

Figure 9-8 PLRI surgical repair and reconstruction. **A,** Schematic representation of PLRI reconstruction using a free graft. The graft is woven through bony tunnels. The bony avulsion of the origin of the lateral collateral ligament (LCL) has been reattached with suture anchors. **B,** Radiograph of the patient in Figure 9-7, *A*.

PLRI bone (Figure 9-8, *B*).[47–49] Because the AL is intact in these patients, radioulnar dislocation does not occur, and surgery to this ligament is not indicated. Ligament reconstruction usually is required in adults, particularly in chronic cases of PLRI. This is done through the same incision as the repair. Ligamentous reconstruction is used to replicate LUCL anatomy using a free tendon graft through bony tunnels in the distal humerus and ulna. Modifications of the technique originally described by O'Driscoll include making the distal connecting tunnels perpendicular to the isometric point of the lateral epicondyle and using the interference screw technique.[46]

Overall, surgical results have been fairly good. Osborne and Cotterill[39] reported excellent results in eight patients with transosseous repair, and Nestor et al.[48] reported excellent results in three patients. Sanchez-Sotelo et al.[49] reported a 90% success rate in restoring stability in the absence of arthritis or radial head fracture at an average follow-up of 6 years, with 60% of patients exhibiting excellent results and 40% continuing to have pain or some loss of motion. The overall patient satisfaction rate was 86%.[49] Lee and Teo[50] had 80% good to excellent results and 100% stability at follow-up, and all 10 patients were satisfied with the surgical reconstruction. Olsen and Søjbjerg[51] used a triceps graft and had 94% satisfactory results and 78% stability at nearly 4 years' follow-up.

Fractures

As with dislocations, the most common complication after elbow fractures is posttraumatic stiffness. The key to minimizing stiffness is early motion. For this reason the goal with elbow fracture surgery is rigid fixation. Rigid fixation allows early motion to be started as part of the rehabilitation process. Some fractures may be considered stable and do not require surgery; however, early motion still is essential to obtain a good result. One of the most important factors is anatomical restoration of articular surface congruity to reduce the risk of posttraumatic degenerative arthritis.

Clinical Point

- In the elbow, the key to minimizing stiffness is early controlled motion

Despite the best treatment, some elbow injuries still have poor outcomes. This is at least partly related to the severity of the trauma to the articular cartilage at the time of the initial injury. The term **terrible triad** of the elbow, coined by Hotchkiss, refers to a high-energy injury that results in elbow dislocation, radial head fracture, and coronoid fracture.[52] Triad injuries require treatment of each component to improve the likelihood of success, because failure to address all three parts of the triad leads to an extremely poor outcome. However, even with aggressive operative treatment to provide anatomical reduction and stable internal fixation, the results may still be poor. These patients are prone to early recurrent instability, chronic instability, and posttraumatic arthritis.[53]

Coronoid Fractures

Coronoid fractures are most commonly seen with high-energy injuries. The coronoid forms a significant

portion of the articular surface of the proximal ulna and acts as an anterior buttress. It also serves as an important attachment site for muscles and ligaments about the elbow. The coronoid is essential for elbow stability and is the most important part of the ulnohumeral articulation.[54] Coronoid fractures occur in 2% to 15% of acute elbow dislocations.[33,36,55] Coronoid fracture nonunion may result in chronic recurrent elbow dislocation.

Regan and Morrey[56] classified coronoid fractures according to the size of the fragment: type I fractures are tip avulsions; type II fractures involve less than 50% of the height of the coronoid; and type III fractures involve more than 50% of the height of the coronoid and frequently are accompanied by instability of the elbow (Figure 9-9). Type I fractures generally are stable and can be treated as simple dislocations with early motion. Many type II fractures are unstable and require open reduction and internal fixation (ORIF). Type III fractures involve the insertion of the anterior portion of the UCL and are inherently unstable. With these more severe injuries, ORIF or a hinged external fixator may be required to maintain reduction of these coronoid fractures.

Radial Head Fractures

Radial head fractures are very common injuries and are often seen in association with other elbow injuries. These injuries usually occur as a result of a FOOSH, which transmits force to the elbow. They can also occur in conjunction with elbow dislocations. The radial head plays an important role as a secondary elbow stabilizer for valgus stress, and it also facilitates pronation and supination of the forearm. Mason[57] divided these injuries into nondisplaced fractures involving less than 25% of the radial head (type I); two-part displaced fractures or fractures that are marginally displaced, including angulation, impaction, and depression fractures (type II); and comminuted fractures and fractures that involve the entire radial head (type III).[57] A type IV fracture is usually described as a comminuted fracture in conjunction with elbow dislocation.

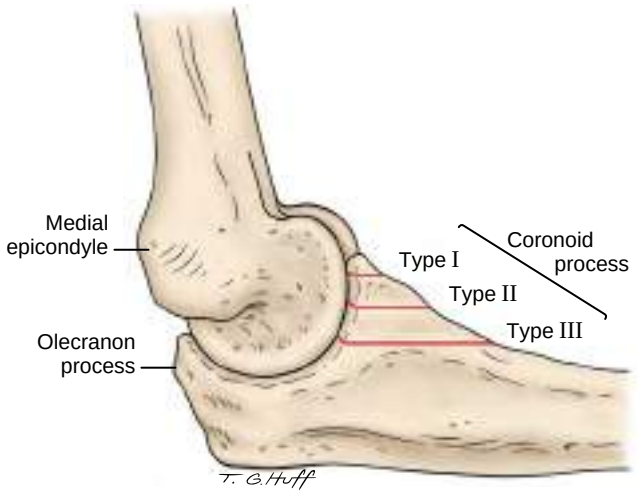

Figure 9-9 Regan-Morrey classification of coronoid fractures. A type I fracture involves the tip of the coronoid. A type II fracture involves less than 50% of the coronoid tip; this usually correlates to a line drawn parallel to the shaft of the ulna from the tip of the olecranon. A type III fracture involves more than 50% of the coronoid.

Nondisplaced fractures (type I) generally can be treated nonoperatively (Figure 9-10, *A*). Once again, early motion is key to a good outcome with these "stable" fractures. Occasionally, clinicians aspirate the hematoma within the joint and even add anesthetic to reduce pain, allowing for earlier ROM of the elbow. However, even with early ROM, some loss of elbow motion (averaging 10°) can be expected.[58]

Some type II fractures can also be treated nonoperatively. In the absence of other injuries, a minimally displaced two-part fracture with no block to ROM is considered a stable fracture and can be treated without surgery.[59] However, displaced type II fractures usually require operative treatment for best results (Figure 9-10, *B*).[60] Excision of a small fragment is acceptable, but larger fragments should be internally fixed.[61] All radial head fractures require careful evaluation of the elbow and the distal radioulnar joint (DRUJ) for any associated injuries. If pain or instability is present at the DRUJ, excision of a significant portion of the radial head is contraindicated. Such an injury, known as an **Essex-Lopresti injury**, can result in proximal migration of the radius after excision of the radial head.[62] In the absence of associated injuries, type III fractures can be treated with excision of the radial head. If a DRUJ injury has occurred, the surgeon must either attempt to reduce and fix the fracture fragments to retain the radial head or replace it with a prosthetic radial head (Figure 9-10, *C*).[53] With interosseous ligament injury and/or DRUJ injury, radial head replacement is mandatory if the radial head cannot be fixed. Temporary radial head replacement, such as with a Silastic implant that is removed later, has fallen out of favor because late displacement after removal of the prosthesis, even after a year, has been reported.[63–65]

Surgery for radial head fractures should be carried out within the first 48 hours or after 3 to 4 weeks, because surgery performed between 2 days and 3 weeks is associated with a higher risk of myositis ossificans.

In skeletally immature patients, most radial head and neck fractures can be treated nonoperatively. In the young throwing athlete, valgus forces at the elbow can result in a physeal fracture at the radial neck. Radiographs generally show an abnormal fat pad sign, which signifies an effusion. With significantly displaced fractures, operative treatment can be considered; however, in younger children, most proximal radial fractures can be successfully treated nonoperatively.

Olecranon Fractures

Because of its subcutaneous location in the posterior elbow, the olecranon is at risk of fracture as a result of

Figure 9-10 Radial head fractures. **A,** Nondisplaced radial head fracture that was treated nonoperatively. **B,** Radial head fracture treated with internal fixation using two screws. **C,** Radiograph of a patient who had a comminuted radial head fracture; treatment required prosthetic replacement of the radial head.

falls, direct blows, or dislocations. By definition, the olecranon is the proximal articulating part of the ulna, and this part of the ulna is critical in serving as the final link in the transmission of force from the triceps mechanism to enable elbow extension. Olecranon fractures usually are intra-articular. Displaced fractures may result in ulnohumeral instability and incongruity of the articular surface. Loss of more than 50% of the olecranon articular surface is associated with a 50% loss of stability.[14,66] In addition, the superior pull of the triceps on the proximal olecranon tends to displace the fracture and prevent healing (Figure 9-11, *A*). For these reasons only nondisplaced fractures can be treated nonoperatively, and even these fractures require follow-up radiographic evaluation to ensure that displacement has not occurred after the initial injury. For most olecranon fractures, ORIF is the recommended treatment.[53] Tension band techniques generally are used for transverse fractures (Figure 9-11, *B*). Other options include screw fixation and other tension band variations. Comminuted and more proximal fractures may require plate fixation (Figure 9-11, *C*). Excision of the proximal fragment and triceps reattachment is an option in an elderly patient with poor bone quality, but this technique should be avoided in younger, active patients because it can lead to elbow instability.

Distal Humeral Fractures

Significant energy is required to cause a distal humeral fracture in young patients. These injuries may be intra-articular or extra-articular. Much of the distal humerus is covered with articular cartilage. The trochlea articulates with the proximal ulna, and the capitellum, with

Figure 9-11 Olecranon fracture. **A,** Displaced olecranon fracture. This intra-articular fracture is displaced because of the pull of the triceps. **B,** Radiograph of a patient treated with tension band wiring for a simple olecranon fracture. **C,** Radiograph of a patient with a comminuted olecranon fracture treated with plates and screws.

the radius. As a result, many distal humeral fractures are intra-articular. The goal of treatment, as with other elbow fractures, is congruent reduction of the articular surfaces and stable fixation of the fracture to allow early motion. Displaced and intra-articular distal humeral fractures generally require ORIF for optimal results.[67] Some extra-articular, nondisplaced, and avulsion fractures can be treated nonoperatively, but these are less common. Very comminuted fractures in older patients who place less demands on the elbow may be treated with noncustom total elbow replacements.[68] Most distal humeral fractures in healthy, active adults are treated with operative fixation and early motion rehabilitation (Figure 9-12). These fractures generally have a high incidence of elbow stiffness, fixation failure, malunion, nonunion, infection, and ulnar nerve injury.

Supracondylar humeral fractures are the second most common fracture in pediatric patients.[69] These injuries usually are the result of a fall onto an outstretched hand or a direct blow to the back of the elbow. They can be treated with closed reduction and casting if the fracture can be maintained in the appropriate position without compromising the neurovasculature structures of the elbow. Otherwise, temporary pin fixation, percutaneously or open, may be indicated. These are important injuries, because complications may occur, such as compartment syndrome, brachial artery laceration or thrombosis, loss of motion, cubitus varus, and nerve injury.

Figure 9-12 Radiograph of a patient who had open reduction and internal fixation for a comminuted distal humeral fracture.

ELBOW ARTHRITIS

The treatment of elbow arthritis is similar to the treatment of arthritis of other joints. Elbow arthritis generally can be categorized as inflammatory arthritis, posttraumatic arthritis, or osteoarthritis. Primary degenerative arthritis of the elbow is relatively uncommon compared with other joints such as the hip, knee, ankle, and shoulder. Rheumatoid arthritis commonly affects the elbow, and posttraumatic sequelae are a more common cause of arthritis of the elbow. The presenting symptom is usually pain, but it can be accompanied by stiffness or loss of motion, weakness, and/or instability. Treatment is dictated by the severity of the symptoms, the etiology, and the patient's age. The initial treatment is generally conservative. However, when pathology and symptoms are severe, operative intervention is indicated. Significant advances have been made in recent years in the surgical treatment of arthritis of the elbow, most notably in arthroscopic techniques.[70–73]

Rheumatoid arthritis is the most common form of inflammatory arthritis. Although other joints are more commonly affected, rheumatoid arthritis of the elbow is often marked by severe pain and disability. Bone loss and articular destruction cause instability at the ulnohumeral articulation. Surgical treatment, often total elbow arthroplasty (TEA), is frequently necessary and can be quite successful at relieving pain and restoring function.[70,74]

Posttraumatic elbow arthritis can result from any insult to the articular cartilage or bony anatomy but most often is seen after intra-articular distal humeral fractures. Stiffness is often present and may occur secondary to associated heterotopic ossification. Osteoarthritis is found almost exclusively in men who have a history of heavy labor or athletic use of the arm, such as weight lifters and throwing athletes. Limitation of ROM, especially a flexion contracture, is common.[70]

Nonoperative treatment for elbow arthritis consists of medications, injections, and physical therapy. Operative treatment should be considered for patients with debilitating and persistent symptoms. Arthroscopic techniques include synovectomy, debridement of impinging osteophytes, loose body removal, and contracture release. Although technically a bit more demanding, arthroscopic excision of the radial head may also be performed. Many think that arthroscopic synovectomy is more complete and effective than an open technique. However, the procedure is technically demanding, and the neurovascular structures are at risk because of their proximity during surgical intervention.[71,72] Open synovectomy, with or without excision of the radial head, is an established procedure for rheumatoid arthritis of the elbow. Open osteotomy or debridement of impinging osteophytes can also be done to reduce pain and improve ROM.[70]

Arthrodesis is poorly tolerated because elbow ROM is essential for use of the hand.[70] It is indicated only for salvage situations when TEA is contraindicated.

Total Elbow Replacement

Total elbow replacement may be performed because of arthritic changes or as a primary treatment for difficult distal humeral fractures in older patients. TEA is an excellent surgical intervention that produces reliable results in a certain subgroup of patients with advanced degenerative changes.[73] Patients with rheumatoid arthritis generally have excellent and reliable pain relief and, because of their relatively low functional demands, tend not to have problems with early loosening or failure of the prosthesis (Figure 9-13).[74] For other elderly patients with low to moderate functional expectations, TEA offers reliable pain relief with medium-term results similar to those for hip and knee arthroplasty.[75] Many now advocate the use

Figure 9-13 Rheumatoid arthritis. **A,** Radiograph of a patient with severe rheumatoid arthritis of the elbow. **B,** Postoperative radiograph after a total elbow arthroplasty for the rheumatoid arthritis.

of TEA as an acute surgical treatment for elderly patients with comminuted osteoporotic elbow fractures, contending that the results are similar to or better than those obtained with ORIF.[68,76–78]

Unfortunately, in younger, more active patients, early failure, including loosening of the prosthesis, limits the use of TEA. The treatment of young patients with high functional expectations and severe elbow arthritis is both difficult and controversial. The results with TEA are inferior to those seen in older, more sedentary patients.[75] However, alternatives such as interposition arthroplasty and resection arthroplasty give less reliable and less sustainable results. In young, active patients who want surgery for painful arthritic changes but who do not want fusion (i.e., arthrodesis) of the elbow, arthroscopy and distraction interposition arthroplasty are currently the only viable alternatives. With either procedure, particularly distraction arthroplasty, limited postoperative goals and expectations should be stressed.[79] With interposition arthroplasty, the arthritic surfaces are conservatively removed and replaced by fascia lata soft tissue. Studies report about 70% satisfactory results (i.e., for pain and function) at 5-year follow-up[79] and 40% at follow-up of more than 20 years.[80] In addition, the role of arthroscopy in the treatment of advanced elbow arthritis needs to be more clearly defined.

OVERUSE INJURIES OF THE ELBOW

Anterior Elbow

Climber's Elbow

The term *climber's elbow* refers to a strain of the brachialis tendon.[81] It usually is seen in association with repetitive pull-ups, hyperextension, or repeated forceful supination or from violent extension against a forceful contraction.[24] Rock climbers are susceptible to this injury as a result of repetitive weight bearing through the upper extremities.[82] Patients typically have pain with extension or resisted flexion and supination. The rule for successful management of this injury is slow and steady improvement with nonoperative treatment. Resolution of the symptoms is obtained with rest and anti-inflammatory treatment. Early rehabilitation should focus on regaining ROM before eccentric strengthening is initiated.

Distal Biceps Tendonitis and Tendon Rupture

Tendonitis at the distal biceps insertion is an uncommon overuse syndrome. It is seen in association with activities similar to those that produce climber's elbow. It also results in pain with resisted flexion and supination, which can be elicited during the physical examination. Rest and conservative care generally result in gradual resolution of symptoms. Surgical treatment is generally not indicated.

Distal biceps tendon rupture is uncommon but is seen more often than biceps tendinopathy, in which the torn end of the biceps, through an acute event without prodromal (i.e., early) symptoms, usually reveals chronic tendinopathy. Distal biceps tendon rupture represents only 3% of all biceps ruptures, with an incidence that has been estimated at 1.2 per 100,000 people per year.[83,84] It typically affects the dominant arm of middle-aged men. Smoking may be a risk factor for this injury.[83] The mechanism is a sudden, forceful overload with the elbow in midflexion. Although degenerative changes in the tendon predispose it to rupture, most patients have no history of prior pain or prodromal symptoms. These individuals present with localized pain and tenderness at the bicipital

tuberosity, proximal displacement of the biceps tendon with a bulge in the distal arm, inability to palpate the taut tendon within the antecubital fossa, and marked weakness of forearm supination and elbow flexion (often associated with increased pain) (Figure 9-14). The pain and tenderness identified after the acute rupture quickly subside, but a dull ache may persist for weeks. Ecchymosis is usually present in the antecubital fossa, and sometimes above and below the elbow, starting 2 to days 3 after the injury.

The two proposed mechanisms of attritional rupture are due to a relatively poor vascular supply and/or a mechanical impingement against the bicipital tuberosity. Both of these mechanisms appear to play a role in the pathophysiology.[85] Partial ruptures have been documented, although they are less common than complete ruptures.[86–88] Partial tears can be managed conservatively and frequently have good outcomes, particularly if less than 50% of the tendon is damaged.

Muscle-tendon junction injuries are highly uncommon. Their presentation is similar to a complete or partial distal biceps avulsion, although the tendon can typically still be felt in the cubital fossa. MRI may confuse the picture, suggesting that the tendon is torn. These injuries do well with relative rest initially, followed by rehabilitation.[89]

MRI is the imaging modality of choice for the diagnosis of partial tears,[90] but it is rarely needed for the diagnosis of complete tears of the distal biceps tendon. Complete tears should be managed with surgical repair; inferior results have been documented with nonoperative treatment of these injuries.[91,92] Patients who do not undergo surgical repair have significant limitations in terms of strength and ability to perform certain activities. Nonanatomical tendon reinsertion also gives inferior results compared with anatomical reinsertion. Rantanen and Orava[93] found that for both acute and chronic injuries, nonanatomical reinsertion gave good to excellent results in 60% of patients compared with 90% who had anatomical reinsertion.[93]

Figure 9-14 Patient with a distal biceps rupture; note the proximal migration and muscle bulge in the arm that are associated with this injury.

Only 14% of the patients treated nonoperatively had a good to excellent result, and the main complaint was loss of strength, or muscular endurance, with elbow flexion (30% loss of strength) and/or supination (40% loss of strength).[91,93] Recently, it was reported that following conservative treatment of distal biceps tendon rupture resulted in a 60% decrease in supination strength with the forearm in a neutral position. This strength loss was not different between dominant and nondominant arms.[94]

Distal Biceps Tendon Repair

Initially, the biceps tendon was repaired with a one-incision technique. However, the exposure required to repair the biceps tendon avulsion to the radial tuberosity with bone tunnels put the radial nerve at risk, and several cases of radial nerve injuries have been reported.[95] For this reason, a two-incision technique was devised so that bone tunnels could be made with the arm in full pronation. This forearm rotation pushed the nerve out of the way, reducing the risk of nerve injury. With the advent of new devices, such as suture anchors, the EndoButton, and interference screws, exposure of the proximal radius can be limited, reducing the risk to the nerve with a one-incision technique.[96,97] However, concerns still exist with the use of the one-incision technique with bone anchors; for example, the anchors may back out, and the tendon may heal onto the bone.

Overall, the results of distal biceps tendon repair using either one or two incisions have not been shown to be different, and the technique used generally is based on the surgeon's preference.

The method of anatomical reinsertion is controversial. The two-incision bone tunnel technique produces reliable results but has a relatively higher risk of radioulnar synostosis (fusion).[98,99] However, modification of the Boyd-Anderson technique so that contact with the ulna is avoided has reduced this uncommon complication.[95] Traditionally, the one-incision technique has been associated with more neurological complications, because it required more extensive dissection, particularly movement of the posterior interosseous nerve. More recently, however, many authors have recommended a one-incision technique that does not require bone tunnels and thus can be performed with less dissection, theoretically reducing the risk of nerve injury. Both suture anchors and EndoButton techniques have been described, with good early results with the one-incision technique.[100–105] Overall, anatomical repair restores strength and function in more than 90% of patients, regardless of the technique used.[93]

The general recommendation is to perform distal biceps reattachment acutely. Chronic biceps tendon ruptures require a more extensive approach.[96,106] A distal biceps rupture is considered chronic if it is not treated within 4 weeks, although excellent results have been obtained after anatomical reinsertion 3 years after injury.[107] The key to success in delayed surgery is the status of the lacertus fibrosus

(i.e., the bicipital aponeurosis). If it is intact, the tendon will retract only to the level just proximal to the antecubital fossa. The amount of muscle shortening is not very significant, and delayed repair is easily attainable. However, if the lacertus fibrosus is torn, the tendon may "slingshot" into the arm; significant muscle shortening may occur, along with scarring within the arm; and delayed primary reattachment may be difficult. In such cases, allograft reconstruction may be attempted to bridge the gap between the shortened muscle and the bicipital tuberosity. However, this is a salvage procedure, and although the condition is often improved, the patient is unlikely to regain full strength. Reports have identified a range of 13% to 50% deficit in flexion and supination strength in these cases.[106] The rerupture rate of distally repaired biceps tendon has been found to be low at 1.5% and usually occurs within the first 3 weeks.[108]

Pronator Syndrome

Pronator syndrome is proximal entrapment neuropathy of the median nerve. Pronator syndrome must be distinguished clinically from carpal tunnel syndrome (CTS; distal median nerve entrapment), which is, by far, the most common entrapment neuropathy of the median nerve. An understanding of pronator syndrome is important, because this condition frequently is misdiagnosed, and many patients undergo unsuccessful operations before the correct diagnosis is made.[109]

Four anatomical sites of compression of the median nerve can be found in the elbow region.[110] When a supracondylar process is present at the distal medial humerus (1% of the population), compression can occur under the ligament of Struthers, which originates at the supracondylar process and attaches to the medial epicondyle. At the elbow, the median nerve passes under the bicipital aponeurosis, the second possible location of compression. It then passes between the humeral (superficial) and ulnar (deep) heads of the pronator teres muscle, where compression also commonly occurs. Finally, the nerve passes under the fibrous arch of the flexor digitorum superficialis muscle.

Sites of Compression of the Median Nerve at the Elbow

- Under the ligament of Struthers
- Bicipital aponeurosis
- Pronator teres muscle
- Flexor digitorum superficialis muscle

Although conflicting reports have emerged, the most common site of compression in pronator syndrome is between the two heads of the pronator teres, resulting in its nomenclature.[111] Entrapment at the bicipital aponeurosis and at the arch of the flexor digitorum superficialis is also common.[110,111] Compression caused by the ligament of Struthers is rare.

Clinically, pronator syndrome is seen in patients who engage in repetitive pronation and supination activities, including pitching, rowing, weight training, archery, and racquet sports.[110,112] It occurs most commonly in women in their 40s. Patients most often report activity-related pain in the anterior aspect of the elbow and forearm. A patient may have a history of a direct blow to the forearm, or repetitive trauma may be the cause; however, in most patients the cause is unknown. In contrast to CTS, patients do not usually experience nocturnal symptoms. The pain with pronator syndrome may be described as a dull pain or an ache in the proximal anterior forearm just distal to the antecubital fossa, and it may radiate distally to the wrist. Pronator syndrome symptoms rarely radiate proximally. Paresthesias are common in the median nerve distribution, and unlike with CTS, numbness may be present over the thenar eminence in the distribution of the palmar cutaneous branch of the median nerve.[112–116]

Tenderness over the pronator muscle mass is typically found on examination.[117] Weakness, if present, is usually subtle. A complete examination should include evaluation for Tinel's sign, Phalen's sign, and the carpal tunnel compression test to assess for CTS. Provocative tests that have been described for localizing pathology to a specific anatomical structure should also be performed: resisted forearm pronation and elbow extension for the pronator teres, active supination against resistance with the elbow flexed for the bicipital aponeurosis, and resisted flexion of the long finger for the arch of the flexor digitorum superficialis.[116–118]

When evaluating a patient with possible pronator syndrome, the clinician must consider all potential sites of nerve compression from the cervical spine to the wrist. Also, median nerve compression at more than one location (the so-called **double crush phenomenon**) is not uncommon.[109] Electrodiagnostic studies are rarely helpful in the diagnosis of pronator syndrome. However, they can help confirm an alternative or concurrent diagnosis, such as CTS. Nerve conduction studies are most often normal in pronator syndrome.[116]

Initial treatment should be nonoperative, consisting of activity modification, rest, immobilization, antiinflammatory medications, physical therapy, and in some cases, local cortisone injections. Conservative management usually is successful, but if it fails or if significant abnormalities are noted on nerve conduction studies, the median nerve should be decompressed surgically.[115] Because assessing for sites of significant compression is difficult even intraoperatively, consideration should be given to releasing all the potential sites of compression. The outcomes of surgical treatment generally are good, with reports of a greater than 90% satisfactory outcomes rate.[117]

Annular Ligament Disruption

AL disruption is a rare cause of popping or snapping pain in the anterior elbow. It is associated with injury to

the radial head, either subluxation or dislocation, and it often is seen in throwing athletes, who report popping symptoms with pronation and supination. A complete disruption in a symptomatic patient is treated with surgical repair.[24] One report has described arthroscopic and histological findings of loose, degenerative AL tissue in two brothers who were overhead throwing athletes and who had snapping elbow pain.[119]

Heterotopic Ossification

Pathological bone formation in nonosseous tissues, usually referred to as **heterotopic ossification** (HO), is most often seen as a result of elbow trauma,[120] although it also can be seen in association with burns, head trauma, and genetic disorders.[121–123] Although sometimes asymptomatic, HO can often progress to disabling pain and stiffness. Despite aggressive therapy, nonoperative treatment generally does not reverse the progression of decreased motion. Fortunately, recent results of surgical excision of HO have shown consistently good outcomes with minimal recurrence and complications.[124]

In susceptible individuals, the process likely begins soon after injury. Symptoms of swelling, erythema, and pain may be present in just a few weeks, and elbow stiffness starts 1 to 4 months after the initial injury. Limitation of active and passive ROM often progresses despite aggressive therapy.[125] The ectopic bone formation usually stabilizes after 3 to 9 months. Morrey et al.[6] have demonstrated that most ADLs can be performed with a 100° arc of elbow motion from 30° to 130° of elbow flexion (i.e., normal elbow functional ROM). However, each patient's ROM goals should be assessed based on the individual's professional and recreational activities.

In most cases, the diagnosis, location, and maturity of the HO can be assessed with plain radiographs. Computed tomography (CT) scans can also be helpful in certain cases, especially for preoperative planning. Classification systems for HO are based on location and functional limitation. The most common location about the elbow is posterolateral, but HO can involve almost any part of the elbow.[120]

Initial treatment should involve aggressive therapy to maintain as much motion as possible and minimize progression to ankylosis. Most surgeons recommend both active and passive ROM exercises, although this is somewhat controversial.[124] When elbow stiffness becomes severe enough to limit recreational or daily activities, surgical excision should be considered. Associated nerve compression, most commonly of the ulnar nerve, can develop secondary to ectopic bone and generally should be treated with surgery to prevent the development of a permanent nerve lesion. Furthermore, it recently was found that with long-standing loss of elbow motion, ulnar nerve dysfunction may occur once the patient regains elbow motion. For this reason, ulnar nerve transposition should be considered in conjunction with procedures to gain ROM, even if no ulnar nerve symptoms are present preoperatively, if large gains in elbow motion are expected.[126]

Because of concerns about recurrence, it has long been suggested that HO excision not be undertaken before 1 year after injury. However, multiple reports have demonstrated good results and low recurrence rates with HO excision as early as 3 to 6 months after injury.[127–130] Consideration should be given to prophylaxis after HO excision (e.g., indomethacin or radiation) to prevent recurrence.

Medial Elbow

Medial Epicondylar Physeal Injury

In the adolescent elbow, the medial epicondylar apophysis is the weakest portion of the medial stabilizing structures. As a result, injury to the medial epicondylar apophysis is common in the skeletally immature elbow. This may be manifested by inflammation of the apophyseal growth plate or progress to avulsion fractures of the medial epicondyle. Medial epicondylar avulsion fractures are much more common than UCL injuries in the immature elbow and are the most common fractures in the immature throwing athlete. This fracture is seen in association with elbow dislocation, and the displaced fragment of the medial epicondyle occasionally can become trapped in the joint, preventing reduction. In throwing athletes, this injury generally occurs during an especially hard pitch or throw when valgus stress is coupled with flexor/pronator muscle contraction. However, a less stressful throw or a FOOSH may also result in a medial epicondylar avulsion fracture. These patients have acute onset of medial elbow pain and, occasionally, associated ulnar nerve paresthesias.[131,132] Although some may have prodromal symptoms of medial epicondylar apophysitis, this is not frequently the case. Patients with medial apophysitis complain of pain on throwing and a decrease in throwing distance, accuracy, and velocity. On examination, these children have tenderness over the medial epicondyle and pain with resisted elbow flexion and pronation. Frequently, they have a flexion contracture of approximately 15°, attributable to muscular and capsular tightness.

Radiographs are necessary to confirm the diagnosis, and as is always the case with children, comparison views are important (Figure 9-15). Assessment of apophyseal thickness is important for apophysitis or nondisplaced fractures. This measurement varies by individual and skeletal maturity, which is why the comparison view of the nonaffected elbow is important. With apophysitis, the growth plate can be widened and occasionally fragmented.

The treatment of the inflamed apophysis is rest from throwing for 4 to 6 weeks, application of ice (care must be taken to protect the ulnar nerve from thermal injury), and nonsteroidal medication to reduce the pain and acute inflammation. After the symptoms subside, a rehabilitation program is instituted consisting of stretching to eliminate

Figure 9-15 Medial epicondylar physeal injury. **A,** Anteroposterior radiograph of the elbow of a 13-year-old boy who plays baseball in several leagues year round. The medial physis appears slightly widened. **B,** The contralateral elbow; clearly the injured elbow has significant widening compared with the normal elbow.

the flexion contracture and strengthening of the muscles that cross the elbow joint, followed by transitioning to functional activities.

Clinical Point - Yellow Flag!

- Whenever ice is applied around the elbow as a treatment, care must be taken to ensure nerves, especially the ulnar nerve, are protected from hypothermic injury

Most avulsion injuries can be treated nonoperatively. Certainly in nondisplaced and minimally displaced fractures (the amount of displacement is controversial), when the elbow is stable to valgus stress testing, the condition should be treated conservatively with a short course of immobilization, activity restriction for 2 to 3 weeks, and a gradual return to ROM exercises, strengthening, and functional activities. Absolute indications for surgery include incarceration of a fragment of the medial epicondyle in the joint and complete ulnar nerve dysfunction. Incomplete ulnar nerve deficits generally resolve with conservative treatment.[132]

The treatment of displaced fractures is more controversial. Surgery may be necessary to reduce and fix some displaced fractures. However, historically surgeons have found that even widely displaced fractures have good results with nonoperative treatment. Josefsson and Danielsson[133] reported good to excellent results at long-term follow-up in 56 patients treated nonoperatively with widely displaced medial epicondyle fractures. Although more than half of the patients had a persistent fibrous nonunion, their outcome was as good as that in patients whose fractures healed. Other authors advocate operative treatment for displaced fractures.[1,134,135] They argue that, especially in high-level throwing athletes, no significant displacement should be tolerated (Figure 9-16). However, the benefit of operative over nonoperative treatment for displaced fractures has not been clearly demonstrated. The senior surgical author of this chapter usually treats avulsions that are more than 5 mm (0.2 inch) displaced in the dominant arm of throwing athletes, and those that are 1 cm (0.5 inch) or more displaced in all other individuals surgically.

Medial Epicondylitis

Medial epicondylitis, or **golfer's elbow**, is a term for tendinosis at the common medial flexor/pronator origin. Specifically, the origins of the flexor carpi radialis and the pronator teres are most affected. Medial epicondylitis is much less common than lateral epicondylitis. Young to middle-aged athletes involved in golf, tennis, and overhead throwing are most commonly affected. In fact, medial epicondylitis is more common in professional tennis players than lateral epicondylitis. The repetitive valgus stress of these activities subjects these muscles to injury and chronic inflammation.[19,24]

The peak incidence of medial epicondylitis occurs in the fourth and fifth decades of life.[136] Occasionally, affected patients note medial elbow swelling and medial elbow pain that is worse with gripping, batting, hitting a serve in tennis, and/or throwing. Patients present with medial elbow pain and often symptoms of ulnar nerve irritation. Examination reveals tenderness over the medial epicondyle and slightly distal and lateral in the tendon of the pronator teres, as well as pain with resisted pronation

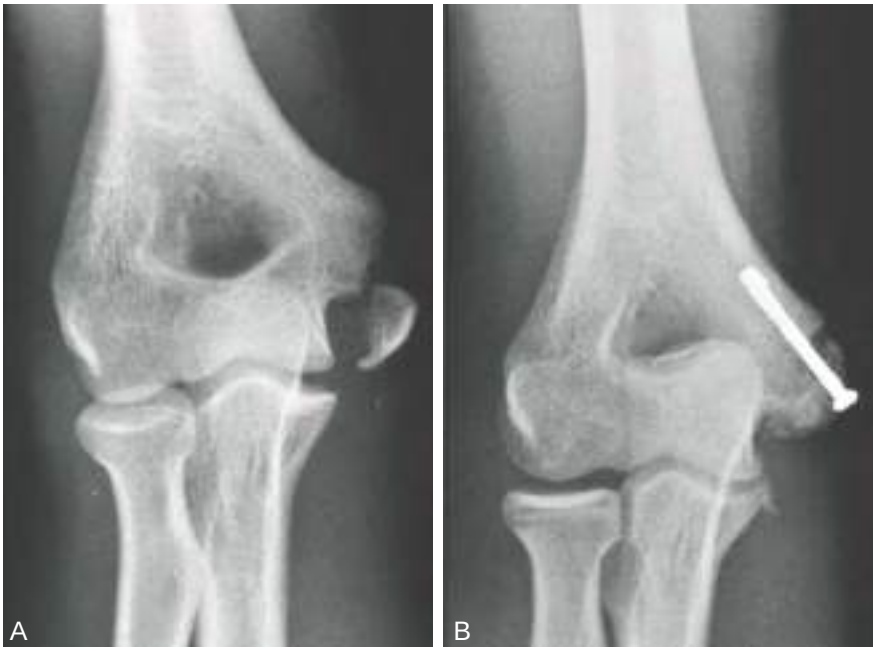

Figure 9-16 Medial epicondylar avulsion fracture. **A,** Radiograph of a 15-year-old baseball player with a medial epicondylar avulsion fracture. **B,** Postoperative radiograph showing a screw in the medial epicondyle to reduce and fix the fracture.

and/or wrist flexion (Figure 9-17). Careful assessment for UCL instability and ulnar nerve symptoms is required, because medial epicondylitis may occur in conjunction with these problems. Radiographs usually are normal. MRI is not usually necessary for the diagnosis of medial epicondylitis, but the changes seen are consistent with a tendinosis, or they may be more extensive and include muscular and/or bony edema.

Treatment is generally nonoperative, including rest and anti-inflammatory medications with a gradual return to stretching and eccentric strengthening of the involved muscles. In more than 80% of patients, symptoms resolve with conservative treatment and the patient is able to return to the sport or activity.[19] Cortisone injections may be of benefit as an adjunct to rehabilitation.[137] Rehabilitation includes application of ice, anti-inflammatory medications, and stretching and strengthening of the flexor/pronator muscle group. A counterforce brace may be beneficial in patients who are rehabilitating but still involved in activities that may aggravate the symptoms.

If the condition does not respond to an appropriate trial of nonoperative treatment, surgery may be required. Surgical intervention involves excision of the abnormal degenerative tissue at the common flexor/pronator origin and reapproximation of the remaining healthy tissue. Unfortunately, the surgery for medial epicondylitis

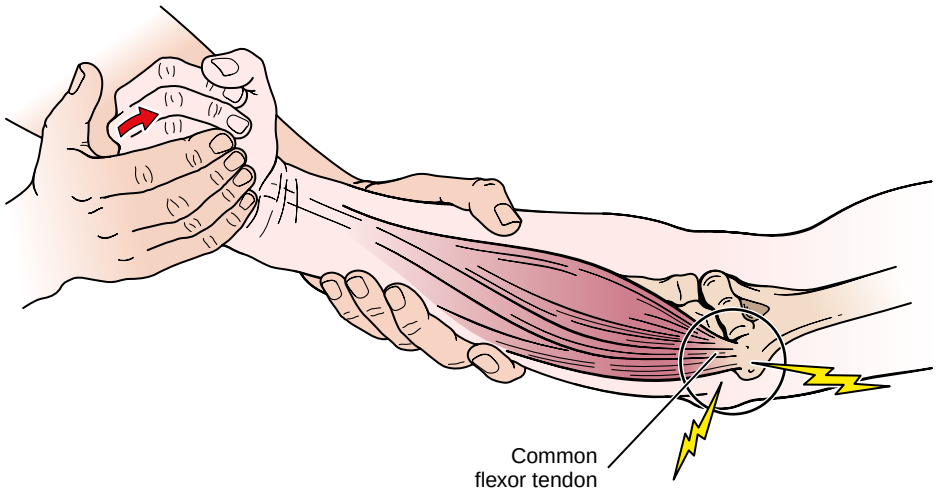

Figure 9-17 Schematic representation of the examination of a patient with medial epicondylitis. Pain in the medial elbow is reproduced by having the patient resist wrist flexion with the elbow extended. (Redrawn from Esch JC, Baker CL: *Arthroscopic surgery (surgical arthroscopy): the shoulder and elbow*, Philadelphia, 1993, JB Lippincott.)

is not as successful as that for lateral epicondylitis. Part of the reason for decreased success is failure to recognize concomitant disease. Ulnar neuropathy is present 40% to 60% of the time. The success of medial epicondylitis debridement is significantly reduced when concomitant ulnar neuropathy is a factor.[138,139] Vangsness and Jobe[140] reported 34 of 35 patients had good to excellent results after surgical debridement and reapproximation of the flexor/pronator musculature for refractory medial epicondylitis. However, Gabel and Morrey[138] showed that 96% of patients treated for medial epicondylitis without ulnar nerve symptoms had good to excellent results, compared with only 40% good to excellent results in patients with concomitant moderate to severe ulnar neuropathy requiring ulnar nerve decompression or transposition at the time of medial epicondylitis surgery. Furthermore, one needs to be suspicious of UCL instability in throwing athletes, and the appropriate workup needs to be performed in these patients.[22]

Flexor/Pronator Muscle Group Disruption

Complete disruption of the flexor/pronator muscle origin is rare. It generally occurs during the acceleration and follow-through stages of throwing in an overhead athlete or in conjunction with dislocation of the elbow. This disruption usually occurs as a result of forceful extension of the elbow and pronation of the forearm or forceful valgus stress. Patients generally present after an acute onset of medial-sided elbow pain during a throw or pitch.[19,141,142] Clinically, disruption of the flexor/pronator muscle origin must be distinguished from a UCL injury, because the two structures frequently are injured concomitantly.[142] Patients with an isolated flexor/pronator rupture have tenderness over the anterior half of the medial epicondyle, which can be distinguished from the more posterior tenderness seen with UCL injury.[143] A muscular bulge may be present in the medial forearm from muscular contraction, as well as pain and/or weakness of wrist flexion and/or pronation. MRI is usually helpful for confirming the diagnosis (Figure 9-18). Although some authors recommend a trial of nonoperative treatment, most advocate surgical repair for complete ruptures because of the significant contribution of the flexor/pronator muscles to dynamic elbow stability and their important contributions to wrist strength. Repair is technically difficult, and results are inconsistent. Athletes frequently cannot return to compete at the same level.[24]

Snapping Triceps

Snapping symptoms at the medial elbow can be caused by dislocation of the medial head of the triceps tendon over the medial epicondyle during elbow flexion, which often produces ulnar nerve symptoms and can be seen in association with ulnar nerve subluxation.[144,145] Underlying anatomical abnormalities are generally present.[146] Snapping of the lateral triceps tendon over the lateral epicondyle has also been described, although it is rare.[147] For persistent symptoms, operative treatment may be necessary. This most commonly involves anterior transposition of the ulnar nerve and correction of the underlying anatomical abnormality that resulted in dislocation of the tendon.

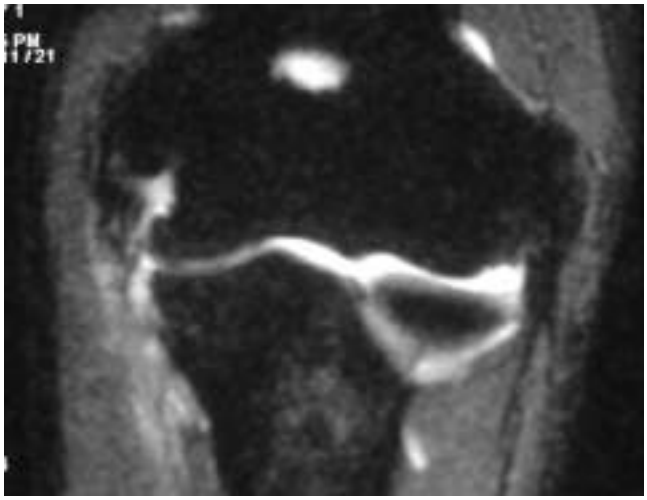

Figure 9-18 MRI scan of a patient with an acute flexor/pronator muscle strain with edema of the muscles and some edema about the tendon.

Ulnar Collateral Ligament Injury

Overhead throwing athletes subject their elbows to severe and repetitive valgus stress. The UCL, particularly the anterior band of the AOL of the UCL complex, which is the primary soft tissue restraint to valgus stress, is commonly injured. Chronic UCL insufficiency results from microscopic tears and attenuation.[148] Patients report pain and soreness in the medial elbow with throwing, usually in the late cocking or early acceleration phases or with ball release. Specifically, the athletes note that they are unable to throw more than 60% to 75% of maximal effort. Acute rupture can also occur with or without chronic changes. Most acute UCL ruptures (i.e., 87%) occur midsubstance.[141] Ulnar and humeral avulsions are much less common. Athletes often report an episode of sudden onset of pain and "giving way" during throwing. The most common situation is an acute exacerbation of a chronically injured ligament. Associated ulnar neuropathy is quite common, and patients may report pain or numbness in the ulnar nerve distribution. Associated pathology, such as loose bodies, osteophytes, and a flexion contracture, can also produce symptoms.

Patients generally have point tenderness at the insertion of the UCL approximately 2 cm (1 inch) distal to the medial epicondyle. The UCL is the most important static stabilizer to valgus stress between 30° to 120° of elbow flexion.[7] Therefore the appropriate position in which to assess for UCL insufficiency is midrange of elbow flexion. The valgus stress test has been described with the elbow at 30° flexion (Figure 9-19, *A*). The **milking maneuver** (Figure 9-19, *B*)[149] and its modification (Figure 9-19, *C*)[21] assess for valgus laxity at a higher degree of flexion. In

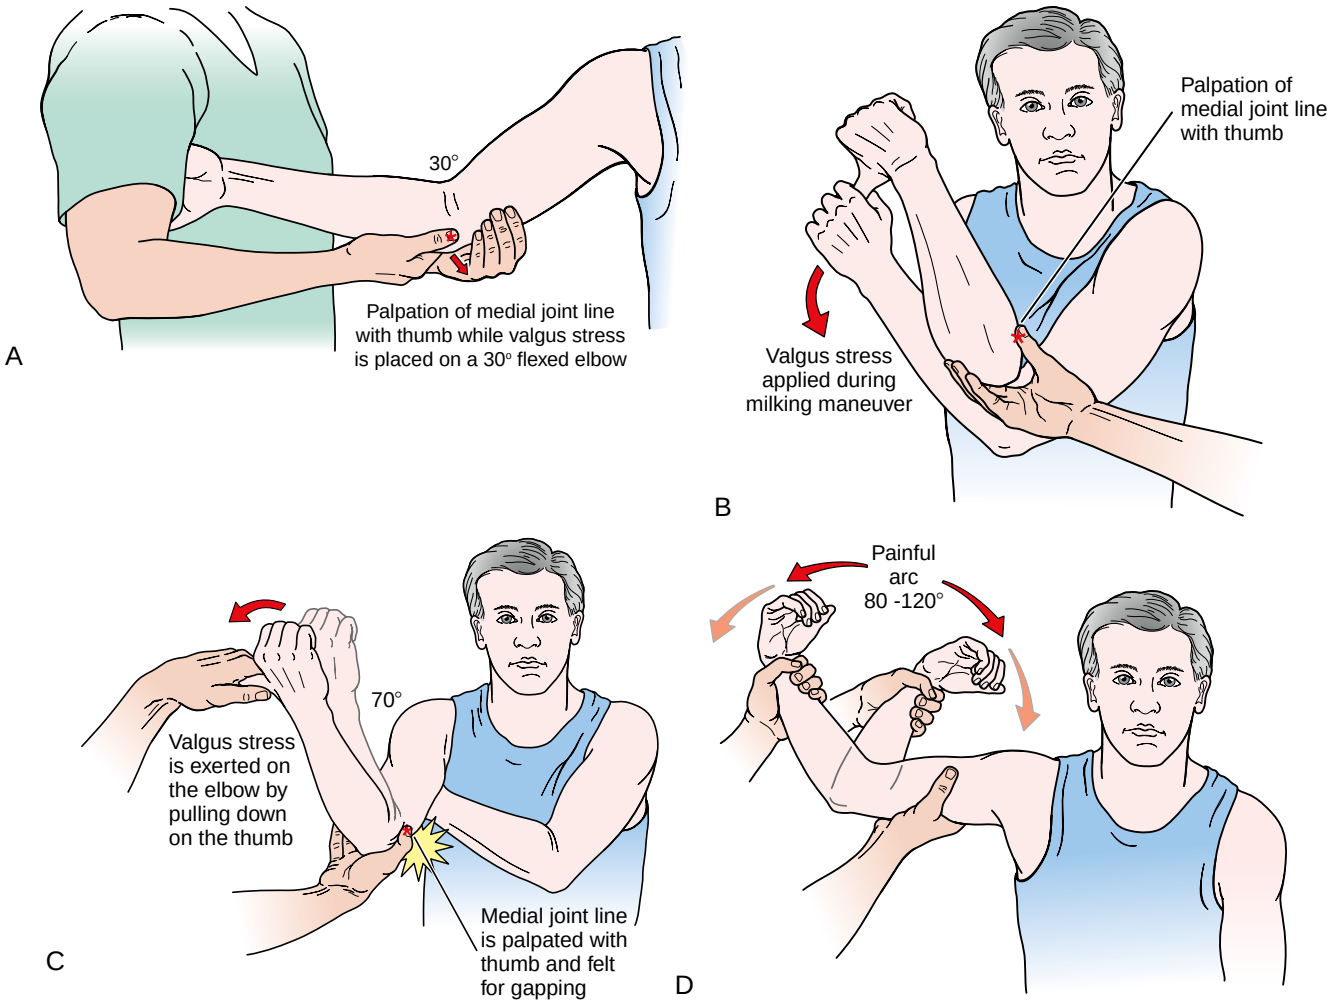

Figure 9-19 Examination of the ulnar collateral ligament (UCL). **A,** Schematic representation of the classic examination of the elbow for UCL injury. The elbow is at 30° flexion, and the hand is positioned between the examiner's elbow and body. The examiner exerts a valgus force on the elbow with one hand while palpating for medial joint opening with the other hand. **B,** The milking maneuver. The patient grabs the thumb on the arm with the affected elbow by passing the other hand beneath the affected elbow. This locks the shoulder, thereby reducing the effect of shoulder rotation and motion, which may confuse the examination. The examiner palpates the medial joint as the patient pulls on the thumb, exerting a valgus force on the elbow. Note that the elbow is in a high degree of flexion, greater than the angle at which a person throws; it also is flexed to the point that bony anatomy contributes to valgus stability of the elbow. **C,** Modified milking maneuver, in which the patient's elbow is flexed approximately 70° and the shoulder is adducted and slightly forward elevated. The examiner pulls on the patient's thumb, exerting the valgus stress with the shoulder locked in lateral rotation, and palpates the medial joint with the other hand. **D,** Schematic representation of the moving valgus stress test. The shoulder is brought into abduction and lateral rotation. The elbow is flexed and extended. The patient should reproducibly note pain in a particular degree of elbow flexion (80° to 120°). (**A** and **B** Redrawn from Selby RM, Safran MR, O'Brien SJ: Elbow injuries. In Johnson DH, Pedowitz RA, editors: *Practical orthopaedic sports medicine and arthroscopy,* Philadelphia, 2007, Kluwer/Lippincott Williams & Wilkins; **C** and **D** Redrawn from Safran MR: Injury to the ulnar collateral ligament: diagnosis and treatment, *Sports Med Arthrosc Rev* 11:19-20, 2003.)

this test the patient's arm is stabilized proximally and the thumb is pulled laterally, imparting a valgus stress to the elbow in 70° to 90° flexion, while the examiner palpates the medial joint line for opening. O'Driscoll et al.[150] described an alternative way to assess for valgus instability, which they called the **moving valgus stress test** (Figure 9-19, *D*). In this test the elbow is brought from full flexion into extension with constant valgus force reproducing the patient's medial pain, although the pain from the UCL usually is reproducibly present between 80° and 120° of elbow flexion. The differential diagnosis includes medial epicondylitis and flexor/pronator origin rupture.

Stress radiographs can be helpful for demonstrating UCL insufficiency.[22] These radiographs can be done with manual stress,[151] with a Telos device,[152,153] or by gravity.[154] With the elbow flexed approximately 20° to 45°, an anteroposterior radiograph is taken while a valgus stress is applied. With UCL insufficiency, gapping at the medial joint line exceeds that of the contralateral normal side (Figure 9-20). Recently, it was reported that gravity valgus stress radiography found similar findings with use of a Telos device while testing 57 patients with medial elbow pain.[154] In a retrospective review of 273 baseball players who had undergone UCL reconstruction, bilateral static

Figure 9-20 Stress x-ray films of a UCL injury. **A,** Nonstress x-ray film of a collegiate javelin thrower with chronic UCL insufficiency. Note the widened medial joint space, compared with the nonstress x-ray film.

elbow stress radiographs were taken and reviewed to determine how much valgus laxity could be expected with UCL injuries. The thrower with a UCL injury had a medial opening of 0.4 mm more than the uninjured side. Those with complete tears opened 0.6 mm on average compared with those with partial tears who opened 0.1 mm.[155] Plain radiographs may also show secondary changes of chronic UCL insufficiency, such as osteophyte formation at the medial joint, loose bodies, sclerosis, radiocapitellar degeneration, or osteophytes of the olecranon. MRI can be helpful for detecting a torn UCL and for defining associated pathology. However, a MR arthrogram is even more sensitive (97%) at detecting UCL injury.[156,157] Arthroscopy is limited as a diagnostic tool because most of the anterior oblique portion of the UCL is not visualized arthroscopically. However, dynamic testing demonstrating gapping of the ulnohumeral joint when valgus stress is applied in 70° of elbow flexion and forearm pronation is consistent with UCL injury.[158,159] Diagnostic ultrasonography also has been used to detect UCL injury by demonstrating changes both within the ligament and with medial joint opening with valgus stress, although it continues to be used only sparingly at this time.[160,161]

The initial treatment of UCL injury is generally nonoperative[22] and consists of rest from the overhead sports, anti-inflammatory medications, and physical therapy. One report indicates that about half of these patients were treated successfully without surgery and were able to return to the same level of athletic activity.[162] The patient with a UCL sprain can also be treated with a PRP injection followed by appropriate rehabilitation. The PRP injection is usually performed under ultrasound guidance. Following the injection the rehabilitation program is slow for the first 2 weeks, then isotonic strengthening exercises are performed. At approximately 8 weeks, an aggressive rehabilitation program is initiated with an interval throwing beginning at 12-14 weeks post PRP injection. Podesta et al.[163] have reported a 88% success rate in baseball players treated with PRP injection. Surgery was indicated if symptoms recur after an appropriate trial of nonoperative treatment. Surgical treatment of an UCL injury also should be considered with acute ruptures in high-level throwing athletes, with significant chronic instability, and after debridement of UCL calcification. A concern after surgery is always the level of performance that the athlete will return to. Recently, it has been reported that in Major League Baseball pitchers, the mean percentage change in velocity of pitches thrown by players who underwent UCL reconstruction was not significantly different compared with that of players in a control group. Mean innings pitched were statistically different only for the year of injury and first postinjury year. There were also no statistically significant differences between the two groups with regard to performance measurements, including earned run average, batting average against, walks per 9 innings, and walks plus hits per inning pitched.[164]

Surgery for Ulnar Collateral Ligament Deficiency

When conservative treatment of UCL injuries fails, surgical options must be considered.[22] Elbow arthroscopy is used to treat complex elbow pathology. Although complications with elbow arthroscopy are rare, they can be described as both minor and major. In a series of 417

patients receiving elbow arthroscopy, 37 (8.9%) minor complications developed, compared with 20 major complications (4.8%). These complications included superficial and deep infections, HO, and nerve complications.[165] Surgical treatment of the UCL depends on several variables. Currently, the mainstay of surgical treatment is UCL reconstruction. Primary repair of acute ruptures of the UCL had been advocated for years; however, this has changed because of the overall consistently better results obtained with ligamentous reconstruction.[21,22] Although most tears are midsubstance (87%), some are avulsion injuries, and all are considered amenable to suture repair, particularly in younger throwers with less intrasubstance ligamentous change.[141,166] This was the treatment of choice until 1992, when Conway et al.[141] reviewed their results with repair and reconstruction. They recommended reconstruction, citing the finding that overhead athletes performed significantly worse with repair than with reconstruction. They noted that repair should be considered only if the tear was a proximal avulsion, if the procedure was performed soon after injury, if the rest of the ligament was undamaged, and if no ulnar nerve symptoms were present. Repair of most injuries usually involves repair of tissue that frequently is chronically injured and therefore not ideal tissue, unless in a young athlete. Reconstruction, therefore, has become the treatment of choice for UCL deficiency.

A newer type of surgical repair for the UCL has been performed at the lead chapter author's (Dr. Kevin Wilk's) sports medicine center in Birmingham, AL and will be described later in this chapter.

UCL reconstruction with a free tendon graft is the procedure generally performed for acute rupture in overhead sports athletes and for chronic UCL instability and elbow pain with UCL instability. The procedure has evolved considerably over the years.[22] Azar et al.[156] reported that 81% of patients were able to return to the same level of sports after UCL reconstruction, compared with 63% with primary repair.

Several graft options are available. A palmaris longus autograft is most often used, but other sources of autograft and even allograft can be used for anatomical reconstruction. Sources of grafts include the ipsilateral or contralateral palmaris longus, a fourth toe extensor, a hamstring tendon, a strip of Achilles tendon, the plantaris tendon, and an allograft (e.g., hamstring and posterior or anterior tibialis tendon), although palmaris longus and hamstring grafts currently are used most often.[22] A variety of fixation techniques can be used, including bone tunnels, the docking procedure, and placement of interference screws (Figure 9-21).[167,168]

Although originally recommended with UCL reconstruction,[169] routine ulnar nerve transposition is not performed routinely in conjunction with UCL reconstruction, except by a few surgeons, because of the high rate of complications (21%).[141,156] If significant ulnar nerve symptoms are present, ulnar nerve transposition is performed at the same time as the reconstruction.

As the reconstruction procedure has evolved, the rate of operative success has reliably and reproducibly improved. Over the past several years, successful outcomes have been reported to be between 79% and 97%, with success defined as the patient returning to play at the same level or better than before the injury.[22,156,167,170–172] Long-term follow-up of UCL reconstruction in baseball players indicates that most patients were satisfied, with few reports of persistent elbow pain or limitations of function. During their baseball career, most of these athletes were able to return to the same or higher level of competition in less than 1 year, with acceptable career longevity and retirement typically for reasons other than the elbow.[173] However, recent research suggests that the return to the same or higher level may not be as good as originally thought in professional baseball players.[174] To achieve this level of success all sources of pathology need to be addressed. Medial epicondylitis may also be present. In addition, concomitant valgus extension overload can result in olecranon osteophytes or loose bodies that need to be removed. Osbahr et al.[175] reported that the results of UCL reconstruction were not as good if there was posteromedial chondromalacia of the elbow. If clinically present, associated ulnar neuritis, as noted previously, is addressed through nerve transposition.

Repair of the UCL has been performed in the past with mixed results. Dr. Jeffrey Dugas (Birmingham, AL) has developed the following surgical technique to repair the UCL and use an augmentation tape to provide additional strength.[176] Direct or side-to-side repair of the UCL has a history dating back to the original series published by Conway et al.[141] In that series, only 2 of 9 major league pitchers returned to competition after UCL repair. Subsequent to that, Azar et al.[156] reported on similarly poor outcomes with direct repair of the ligament. In 2008, Savoie et al.[166] reported on a series of overhead athletes using direct repair of the UCL to bone using modern anchor and suture technology, with 95% success at minimum one-year follow up. In 2013, a novel technique of direct repair of the ligament with augmentation using an ultra-strong collagen coated tape was first performed at the main author's institution. Biomechanically, this construct has been shown to allow for less gap formation than standard UCL reconstruction at time-zero in cadaveric specimens, with no difference in ultimate failure load.[176] The clinical outcomes of these procedures have been very encouraging, with shorter recovery time back to competition (approximately 6 months) than standard UCL reconstruction techniques (approximately 12 months). The author indicates they are currently using this technique for many end-avulsions and partial-thickness tears of the UCL, particularly in high school and collegiate throwers. Further experience with this technique may allow for expansion of the indications, however at this point we feel

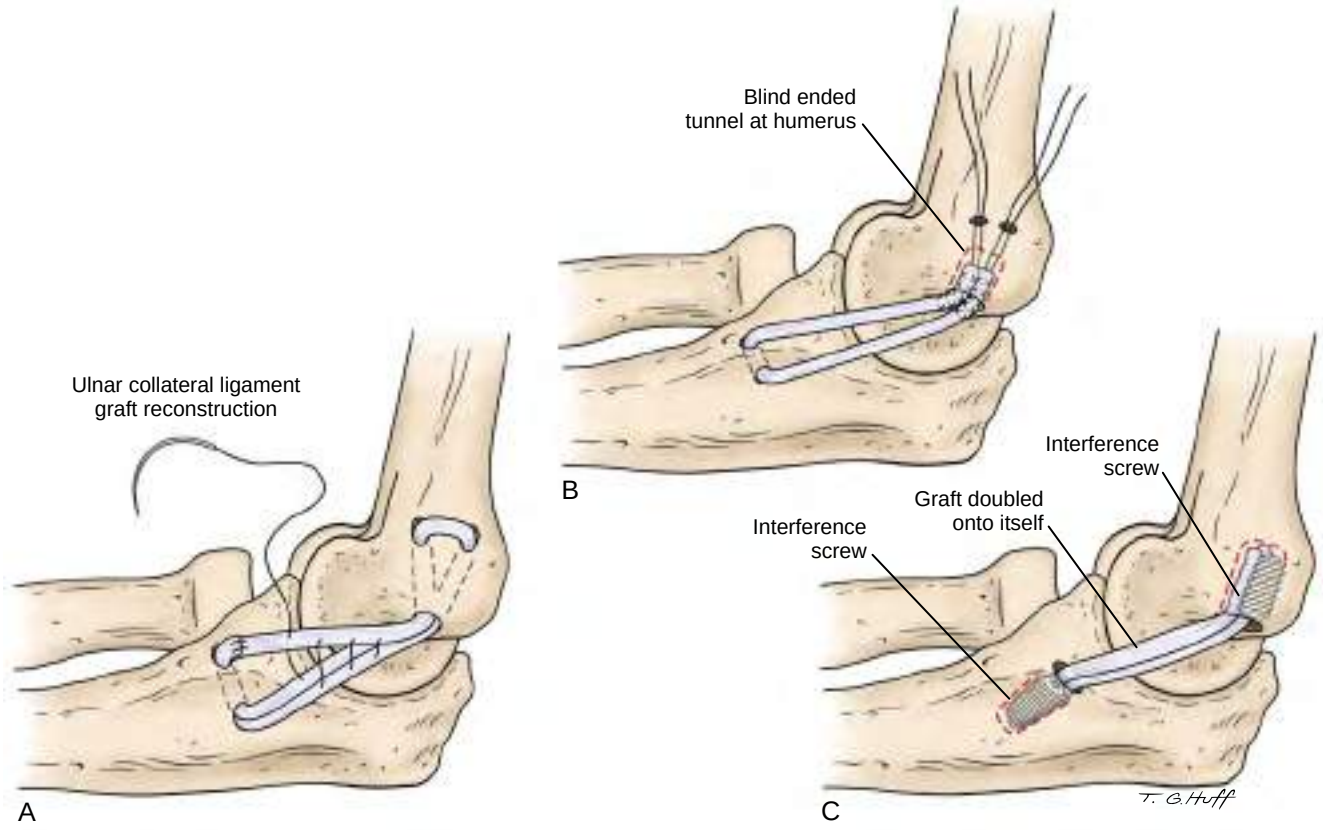

Figure 9-21 Reconstruction of the UCL. **A,** Classic three-ply UCL reconstruction. Two holes are drilled to make a tunnel in the ulna, and three holes are drilled to make two tunnels on the humeral side. This figure-of-eight appearance of the free tendon graft allows the tendon to have three strands at the medial elbow. **B,** Schematic representation of the docking technique of UCL reconstruction. The ulnar tunnel is made in the same way as for the classic technique, but a single, blind-end tunnel is used on the humeral side. This technique results in only two strands of tendon across the medial elbow, but it has two advantages: the graft is easier to tighten/tension, and the risk of medial epicondylar fracture is reduced. **C,** Interference screw technique of UCL reconstruction. Two strands are brought across the medial elbow, and both ends are fixed with interference screws in blind-end tunnels. This technique reduces the risk of tunnel fracture and, for the ulnar side, helps reduce injury to the ulnar nerve. (Redrawn from Safran MR: Injury to the ulnar collateral ligament: diagnosis and treatment, *Sports Med Arthrosc Rev* 11:21-22, 2003.)

that any tissue deficiency (e.g., bone within the ligament, poor quality tissue from chronic overuse) still warrants standard UCL reconstruction using tendon autograft.

Ulnar Nerve Injuries

After CTS, ulnar nerve compression at the elbow is the most common compressive neuropathy of the upper extremity.[177] It is frequently seen in the general population but is even more common in overhead athletes. This medial elbow pathology seen in throwing athletes is associated with ulnar nerve symptoms approximately 50% of the time.[19] The ulnar nerve is susceptible to injury because of (1) the tight path it follows, which changes its dimensions with elbow flexion and extension; (2) its subcutaneous location; and (3) the considerable excursion required of it to accommodate the full motion of not only the elbow but also the shoulder (Figure 9-22, *A*). Proximally, the ulnar nerve can be compressed by the intermuscular septum or by a hypertrophied medial head of the triceps. At the cubital tunnel, nerve irritation and injury can result from osteophytes, loose bodies, a thickened retinaculum, or an inflamed UCL, especially with elbow flexion (Figure 9-22, *B*). The most common site of ulnar nerve compression is distal, between the two heads of the flexor carpi ulnaris (Figure 9-22, *C*).[1]

Both physiological and pathological factors contribute to irritation and compression of the ulnar nerve. Compression, either alone or in combination with other causes, can result in ulnar nerve irritation. With the elbow in full flexion, the confines of the cubital tunnel become restrictive and the retinaculum becomes taut, compressing the nerve. Flexion of the elbow and wrist extension increase the normal pressure on the ulnar nerve threefold. In overhead throwing, the pressure on the nerve has been demonstrated to be up to six times greater than normal.[178] The confines of the cubital tunnel may be reduced by scarring of the UCL to the floor of the cubital tunnel or by osteophytes of the medial ulna at the olecranon or distal humerus (see Figure 9-22, *C*). The cumulative effect of repeated and prolonged pressure elevations is nerve ischemia and fibrosis. This pathology can be exacerbated when it occurs in association with ulnar nerve subluxation or dislocation.

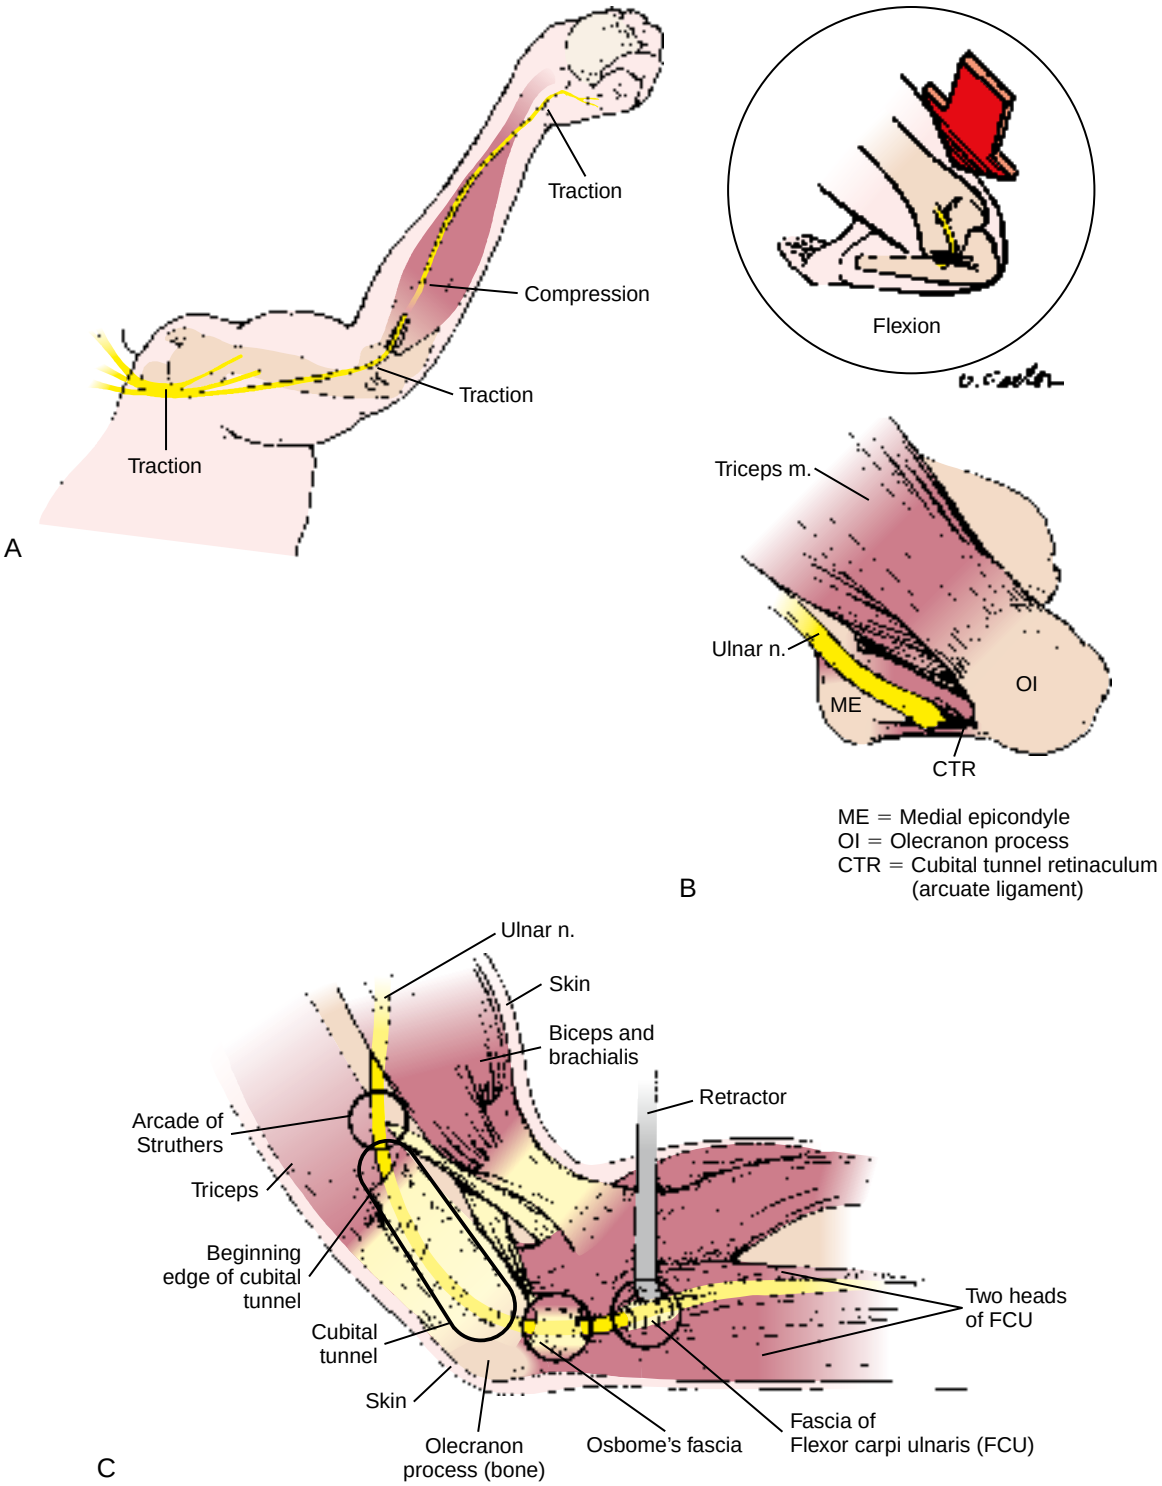

Figure 9-22 Ulnar nerve injury. **A,** Multiple sites of stress to the ulnar nerve in the throwing athlete. **B,** Elbow flexion leads to compression of the ulnar nerve within the cubital tunnel. Anything that occupies space in the tunnel (e.g., osteophytes, thickened retinaculum or ligament) can increase compression on the nerve. *ME,* Medial epicondyle; *OI,* olecranon process; *CTR,* cubital tunnel retinaculum (arcuate ligament). **C,** Multiple sites of compression where the ulnar nerve may become entrapped about the elbow. The fascia forming the roof of the cubital tunnel is sometimes called the cubital tunnel retinaculum. (**A** and **C** from Miller MD, Howard RF, Plancher KD: *Surgical atlas of sports medicine*, Philadelphia, 2003, Saunders; **B** modified from O'Driscoll SW, Horii E, Carmichael SW, Morrey BF: The cubital tunnel and ulnar neuropathy, *J Bone Joint Surg Br* 75:615, 1991. Copyright Mayo Foundation.)

The first symptoms of ulnar nerve involvement are medial elbow pain and clumsiness or heaviness of the hand. Subsequently, paresthesias and more significant weakness can ensue; however, these usually are not present in the athlete with ulnar neuritis. Patients may note numbness at night along the ulnar side of the hand (i.e., the little and ring fingers) if they sleep with their elbow bent. Throwers usually note loss of control. The results of nerve conduction tests can be normal, especially in the earlier stages.[1,19,179] Symptoms may be reproduced by a Tinel's sign and/or by having the patient maximally flex the elbow and extend the wrist and hold that position for 1 minute. Subluxation of the ulnar nerve is also common in the general population and frequently occurs without symptoms (Figure 9-23). Overhead athletes with subluxating ulnar nerves can have symptoms and may require surgery to prevent the nerve from becoming irritated as it traverses the medial epicondyle during repetitive flexion to extension movements of the elbow. Radiographs usually are normal, but MRI scans may reveal the ulnar neuritis (Figure 9-24).

The initial treatment is nonoperative and in the general population often is successful. Throwing athletes, however, tend to have recurrence of symptoms upon resumption of throwing, particularly those with subluxation of the ulnar nerve.

Ulnar Nerve Transposition Surgery

When conservative measures fail or are deemed inappropriate, ulnar nerve neuropathy may be addressed surgically. The primary goal of surgery is decompression of the ulnar nerve at all sites of potential tightness. However, addressing all possible sites of decompression may result in instability of the ulnar nerve and painful subluxation of the nerve out of its groove. For this reason, the second goal is to prevent instability by transposition of the nerve to a position that would prevent instability if necessary, particularly in athletes.

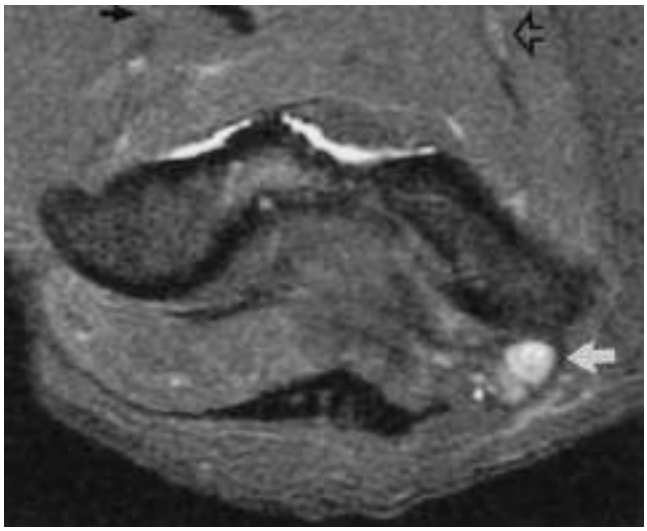

Figure 9-24 MRI scan of an inflamed ulnar nerve, showing the white nerve on T2 image.

Surgical treatment most often involves either anterior subcutaneous or submuscular transposition of the nerve. The disadvantage of subcutaneous transposition is that the nerve remains vulnerable to direct injury in contact sports. Submuscular transposition requires a longer rehabilitation because of detachment and reapproximation of the flexor/pronator origin, but the nerve is protected from direct trauma. With submuscular transpositions, the wrist must be immobilized as well. The postoperative rehabilitation must be considered carefully, because early motion is encouraged to prevent scarring about the nerve, but the flexor/pronator muscle attachment must be protected until it heals.

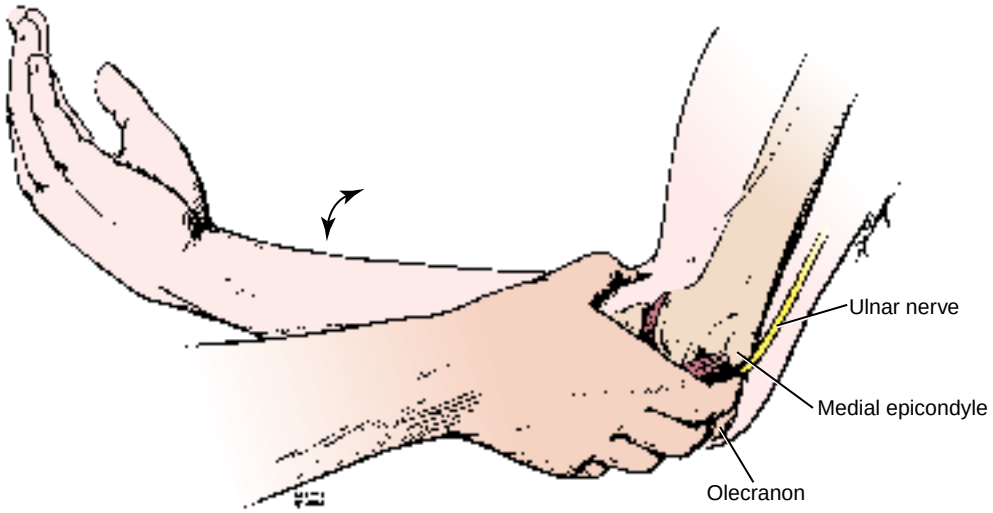

Figure 9-23 Examination for a subluxing ulnar nerve. The ulnar nerve is palpated as the elbow is flexed and extended. The nerve tends to slip out of the ulnar groove in higher degrees of elbow flexion (the more unstable the nerve, the less flexion is needed to sublux the nerve). (Modified from Morrey BF: *The elbow and its disorders,* ed 2, Philadelphia, 1993, Saunders.)

Simple decompression and medial epicondylectomy are thought to produce poor results in the throwing athlete because of the risk of UCL injury and subluxation of the nerve.[19] However, simple decompression may be a reasonable alternative in nonthrowing athletes. Two recent prospective studies reported similar results for simple decompression and anterior submuscular decompression.[180,181] The preference of the senior surgical author of this chapter is to perform submuscular transposition in athletes at risk for direct trauma to the area of the nerve (e.g., football and rugby players) and subcutaneous transposition in all others.

Posterior Elbow

Olecranon Apophysitis/Stress Fracture

In the adolescent athlete, the olecranon physeal plate is susceptible to injury, especially with overhead throwing.[24] The repetitive pull of the triceps tendon can lead to olecranon apophysitis and physeal widening.[182,183] These injuries tend to occur in adolescents and may also be the result of valgus extension overload (discussed later in this chapter). These patients report pain on resisted elbow extension and tenderness over the olecranon. Widening of the olecranon apophysis is visible on radiographs, and the findings should be confirmed by comparison with radiographs of the contralateral elbow (Figure 9-25, *A*). Recently a new classification system for olecranon stress fractures has been developed. This classification system has devised five different types, including physeal, classic, transitional, sclerotic, and distal stress fractures. The physeal type was further separated into stages 1 to 4 based on severity. The mean age for each type identified was as follows: physeal, 14.1 years; classic, 18.6 years; transitional, 16.9 years; sclerotic, 18.0 years; and distal, 19.6 years. Among baseball-related elbow disorders, the incidence of olecranon stress fractures was 5.4%.[184] An MRI can help confirm the diagnosis when radiographs are not conclusive (Figure 9-25, *B*).

When the apophysis is widened but not separated or avulsed, the initial treatment is rest from the offending activity, gentle ROM and flexibility exercises, and progression to strengthening. Ice and nonsteroidal anti-inflammatory drugs (NSAIDs) are useful if acute inflammation is present. If the child is in severe pain, a short course of immobilization in a splint or cast may be beneficial.[185] If separation of the secondary growth center has occurred or if the adolescent has pain despite conservative management because of lack of fusion of the physis, internal fixation is recommended (Figure 9-26, *A*). Surgical intervention to promote fusion of the apophysis may require internal fixation with a screw, in addition to bone grafting, because of the high incidence of fibrous union when bone grafting is not used (Figure 9-26, *B*).[183,186,187] Left untreated, apophysitis of the olecranon may result in an incompletely fused olecranon apophysis, which may fracture as a result of direct trauma when the patient is older.[183,187–189]

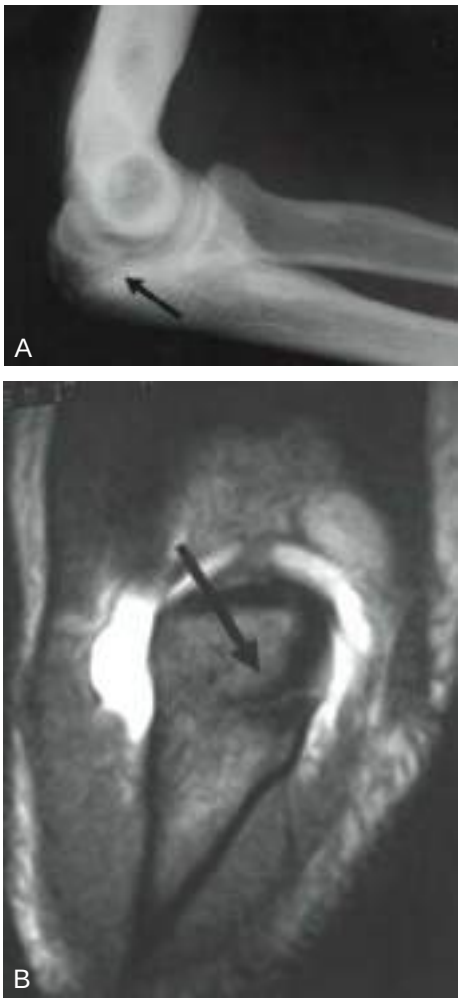

Figure 9-25 **A,** Olecranon stress fracture on a lateral x-ray film. **B,** MRI scan of a patient with an olecranon stress fracture.

In mature athletes, posterior elbow pain may represent an occult (or stress) fracture of the olecranon. This type of fracture, which is most common in baseball players, javelin throwers, shot-putters, and gymnasts, can be associated with valgus extension overload syndrome (discussed later in this chapter). If radiographs are inconclusive, a bone scan or MRI may be necessary for diagnosis. Most of these injuries heal with rest from the offending activity. Surgery is rarely necessary.[186,190–193]

Triceps Tendonitis and Tendon Rupture

Tendonitis of the triceps insertion at the olecranon is most often seen in weight lifters. It also occurs with other sports in which large forces are required in elbow extension, such as shot put, javelin, and football. In addition, the problem has affected participants in motocross racing and BMX cycling, because the riders absorb the force of landing with the arms.[1] Patients have pain at the triceps insertion that is worsened by resisted active elbow extension and throwing. On examination these

Figure 9-26 **A,** X-ray film of an unfused olecranon apophysis, which was treated with intramedullary screw fixation **(B).**

individuals have tenderness at the tip of the olecranon and slightly proximal to the triceps insertion point. The pain may be accentuated by resisted elbow extension and full elbow flexion combined with shoulder flexion. This problem may be acute or chronic. Treatment is conservative. Corticosteroid injections into the tendon are contraindicated because of the risk of tendon rupture.[194]

Triceps tendon rupture is rare, the least common of all tendon ruptures in the body, although it has been reported in weight lifters and football players.[195,196] In many cases, it is associated with corticosteroid injections or oral anabolic steroids.[197] It commonly involves avulsion with a bony fragment as a result of a decelerating counterforce during active extension of the elbow or a direct blow. Patients with this injury usually are unable to extend the elbow against gravity and have a palpable defect in the tendon proximal to the olecranon (Figure 9-27).

Figure 9-27 Photograph from the operating room with a patient in the prone position. This patient has a triceps tendon rupture, as evidenced by the palpable defect just proximal to the olecranon. Ecchymosis also is present, because the injury occurred only a few days before the patient underwent surgical repair.

In the intact tendon, squeezing the triceps will result in extension of the elbow, whereas with triceps rupture, this does not occur. This injury rarely occurs at the musculotendinous junction. A small fleck of bone off the olecranon is classically seen on radiographs (Figure 9-28). MRI is rarely necessary to make the diagnosis but can confirm it. Treatment for complete ruptures is acute surgical repair, which gives consistently good results compared with the universally poor results seen with nonoperative treatment.[195,198,199]

Valgus Extension Overload Syndrome (VEOS)

Overhead throwing athletes are at risk for specific elbow pathology that occurs secondary to the repetitive valgus stresses involved in throwing, which causes the olecranon to be repeatedly and forcefully driven into the olecranon fossa. A valgus stress typically causes shearing posteriorly, resulting in impingement of the posteromedial olecranon against the lateral aspect of the medial wall of the olecranon fossa (see Figure 9-5, *B*). Ahmad et al.[200] demonstrated that UCL injury results in contact alterations in

Figure 9-28 X-ray film of a patient with a triceps tendon avulsion. Note the small fleck of bone just proximal to the olecranon; this is a common finding in this rare injury.

the posterior compartment that lead to osteophyte formation. This suggests that osteophyte formation may result from subtle UCL injury or increased valgus laxity as a result of increased shear forces to the posteromedial elbow. Compounding this posterior impingement is the bony hypertrophic narrowing of the olecranon fossa and hypertrophy of the proximal ulna that occurs in overhead athletes who have been involved in the activity since childhood. Moreover, the repeated high-extension velocities produced during overhead athletic activities may result in impaction of the olecranon tip within the fossa, producing localized inflammation, chondromalacia, and further osteophyte formation. With persistent impaction and shear forces, the osteophytes may break off and become loose bodies within the joint.[201,202] These loose bodies can get caught in the joint surfaces and damage the articular cartilage.

Individuals with valgus extension overload syndrome (VEOS) have posterior elbow pain, pain with forced extension of the elbow, and occasionally, locking caused by loose bodies. On examination the patient may have a flexion contracture, swelling of the joint, and pain on forced extension of the elbow that is exacerbated by applying a valgus force to the extended elbow.[22,202] It is important that the examiner evaluate the integrity and tenderness of the UCL, because studies have reported that 42% of patients who undergo surgery for VEOS require a second operation, and 25% of these patients required reconstruction of the UCL as a result of valgus instability.[202,203]

Initial conservative treatment should focus on strengthening of the flexor/pronator muscle group while reducing inflammation. This is achieved through relative rest, application of ice, and use of NSAIDs. However, surgery is often required if loose bodies are present. Furthermore, our experience has been that patients with posteromedial osteophytes on the olecranon tend not to respond to therapy and require surgery to remove the osteophytes.[21,22,202] Nonetheless, surgery usually is indicated if 6 to 12 weeks of conservative management does not lead to improvement.

Surgery for Valgus Extension Overload Syndrome (VEOS)

VEOS surgery involves the removal of loose bodies, which can be done arthroscopically. The osteophytes on the proximal medial olecranon also are debrided, but the surgeon must take care not to remove any normal olecranon because this may create a risk of UCL injury by eliminating the proximal olecranon's function as a secondary stabilizer to valgus stress. Most authors recommend arthroscopic over open techniques for the removal of osteophytes and loose bodies (Figure 9-29)[202–206] because arthroscopic procedures have proven to be safe and effective. Because VEOS often is associated with UCL injury, the surgeon must carefully assess for evidence of valgus instability when a patient presents with VEOS.

It is unclear whether debridement uncovered a UCL injury or laxity or whether removal of the osteophytes

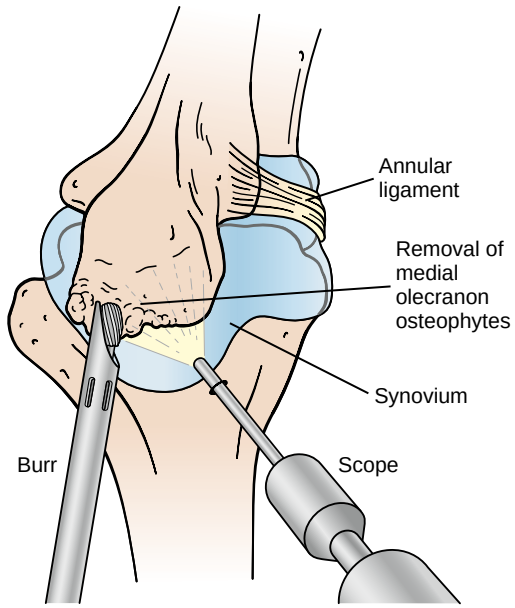

Figure 9-29 Schematic representation of arthroscopic excision of the posterior olecranon osteophytes seen in valgus extension overload syndrome (VEOS). (Redrawn from Selby RM, Safran MR, O'Brien SJ: Elbow injuries. In Johnson DH, Pedowitz RA, editors: *Practical orthopaedic sports medicine and arthroscopy*, Philadelphia, 2007, Kluwer/Lippincott Williams & Wilkins.)

increased stress on the UCL, leading to injury.[200,207–209] Removal of just the loose bodies and the osteophytes is recommended when the UCL is intact; however, removal of more than just the osteophytes, as was recommended in the 1980s and 1990s, is no longer recommended. Removal of too much olecranon may put the UCL at risk by increasing the stress on the ligament with throwing, possibly leading to UCL injury.[199,206–209] However, some believe that concurrent but untreated chronic UCL injury probably is responsible for the relatively high reoperation rate when only the posterior osteophytes and loose bodies are addressed.[1]

Olecranon Bursitis

The olecranon bursa, normally a subcutaneous potential space over the olecranon, can become inflamed or infected. This is a common problem both in the general population and in some athletes. Direct or repetitive trauma over the olecranon is the most common cause of olecranon bursitis.[24] This is seen frequently in football and rugby players, especially those who play on artificial turf.[210] Patients have swelling, fluctuance, and pain over the olecranon. If the bursa is infected, fever and surrounding erythema may be prominent. Nonseptic bursitis generally can be treated conservatively with protection (i.e., not resting on the elbow, use of a clean elbow pad), a compressive dressing, and occasionally NSAIDs. If the bursitis is severe, therapeutic aspiration with or without injection of a corticosteroid can be performed, although reaccumulation of fluid is common and the risk of introducing an

infection arises. If septic bursitis is a concern, the bursa should be aspirated and the fluid sent for Gram staining and standard bacteriological cultures. Appropriate antibiotics should also be given. For severe or recurrent cases of inflammatory or septic olecranon bursitis, debridement and complete excision of the bursa should be performed. Although this traditionally has been done with open procedures, arthroscopic techniques have also been described.

Lateral Elbow

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) is a disorder seen in the elbow of the skeletally immature (often young athletes) that involves separation of a localized area of articular cartilage and subchondral bone. OCD most often is localized to the capitellum, although it also is commonly seen in the knee and ankle. The exact etiology and natural history remain unclear.

OCD needs to be distinguished from Panner's disease. Panner's disease is a focal osteonecrosis of the entire capitellum that is not specifically associated with a history of trauma. It generally affects boys 7 to 12 years of age, and the peak incidence is age 9 years. It is a self-limited disease that can almost always be treated nonoperatively and rarely results in significant morbidity.[211–213]

In contrast, OCD is generally seen in a slightly older age group and is associated with a history of repetitive trauma and overuse. It usually presents in athletes between 10 and 21 years of age, with a peak range between 13 and 16 years. It most commonly affects the capitellum of the dominant arm of patients who participate in sports such as baseball, gymnastics, weight lifting, racquet sports, and cheerleading.[211–213] Kida et al.[214] assessed 2433 baseball players in junior high and high school using diagnostic ultrasound with further examination with radiographs. OCD of the humeral capitellum was found in 3.4% of elbows. Players with a lesion began playing baseball at an earlier age, had a longer duration of competitive play, and had more present and past elbow pain compared with players without a lesion.[214]

The exact etiology of OCD is unknown. The association with a history of overuse in throwing athletes and gymnasts supports the theory of repetitive microtrauma as an etiological factor.[211,212,215] Biomechanical studies have indicated that the radiocapitellar joint acts as a secondary stabilizer of the elbow and receives a large proportion of forces transmitted across the elbow with axial compression.[216] Microtrauma in these patients can lead to fatigue fracture of the subchondral bone. During the reparative process, repetitive stress could inhibit healing and lead to fragmentation of the involved segment of subchondral bone and articular cartilage.

Ischemia also appears to play a role in the pathophysiology of OCD.[217,218] The distal humerus, specifically the capitellum, has been reported to have a tenuous vascular supply.[217] In fact, the histopathology of OCD is consistent with osteonecrosis of the subchondral bone.[219] Therefore repetitive microtrauma in a genetically predisposed individual results in vascular insufficiency and necrosis of the bone at the subchondral plate. The resorption of the bone under the articular cartilage puts the chondral surface at risk of collapse as a result of stresses and loss of underlying support, which leads to loose bodies.

Patients with OCD most often have pain of insidious onset that is activity related.[132] They have tenderness laterally over the elbow and often have limitation of full extension. Flexion contractures of 5° to 23° have been reported. Mechanical symptoms and swelling are common.[132] The **active compression test** may result in pain when the extended elbow is pronated and supinated. Radiographs may show the classic findings of radiolucency and rarefaction of the capitellum with flattening or irregularity of the articular surface (Figure 9-30, *A*). Loose bodies may also be present in the elbow joint. Further imaging should involve MRI, which can help define both the size and stability of the lesion (Figure 9-30, *B* and *C*). MR arthrography can be helpful as well,[211] and ultrasound has been reported to be useful in the evaluation of the elbow for OCD.

Both MRI and arthroscopic classification schemes have been used in an attempt to differentiate lesions that are stable, those that are unstable but attached, and those that are detached or loose.[106,220] Stable lesions with intact cartilage are managed conservatively. The initial treatment is rest with avoidance of sports or other aggravating activities for 3 to 6 weeks. When symptoms resolve, stretching and gradual strengthening should be initiated to restore maximal functional ability of the elbow. Some clinicians have recommended unloading-type braces to protect the radiocapitellar joint and help reduce stresses during healing. Return to unrestricted activities usually is not allowed before 3 to 6 months. Healing evident on a radiograph usually lags behind the clinical resolution of symptoms.[1,132]

Indications for surgical intervention include evidence of loose bodies; unstable lesions where the overlying articular cartilage is not intact, either partially or completely; and failure of prolonged conservative treatment.[132,211,213] If loose bodies are present, the recommended treatment is removal of the fragment or fragments, usually arthroscopically. Arthroscopy is the most direct and reliable way to assess the integrity of the articular cartilage and the stability of lesions. The most appropriate treatment for unstable but attached lesions remains controversial. Most surgeons advocate excision of the unstable fragment, debridement, and possible microfracture of the exposed bony bed.[211] Others, such as the lead surgical author of this chapter, recommend fixation of the fragment whenever possible.[215,221,222]

Bauer et al.[223] reported an average 23-year follow-up on 31 patients who underwent open fragment excision, loose body removal, and debridement. The results showed significant resultant morbidity, with 40% of the patients

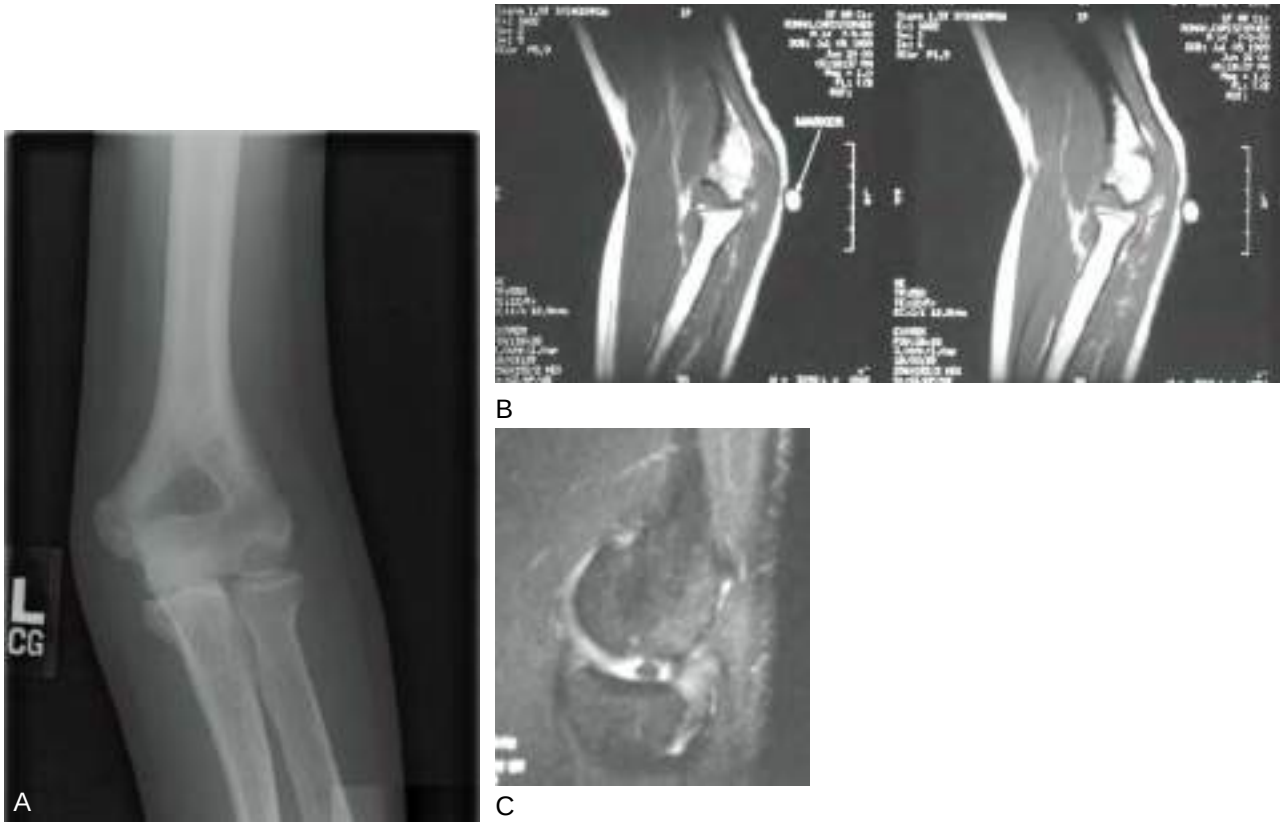

Figure 9-30 Osteochondritis dissecans (OCD). **A,** X-ray film of a 14-year-old male baseball player with OCD of the capitellum. **B,** MRI scan of the same boy. The lesion was partly detached and ultimately was repaired surgically. **C,** MRI scan of the elbow of a 16-year-old gymnast with OCD and an apparent loose body.

reporting pain and 60% showing radiographic evidence of degenerative joint disease. Subsequent studies have reported improved but variable short-term outcomes with arthroscopic techniques.[220,224] Takeda et al.[225] recently reported a 57-month follow-up on 11 baseball players who underwent open bone grafting and wire fixation of OCD lesions that had failed conservative treatment. Of the 11 players, 9 had excellent results and returned to their previous level of activity. Removal of lesions that are repairable, therefore, may result in premature arthritis of the elbow and poor function in the long term. Repair of the fragments, when possible, appears to produce a better long-term outcome.

Overall, it appears that regardless of treatment, larger lesions carry a significantly worse prognosis with a higher incidence of persistent pain and the development of degenerative changes.[226] For lesions that do not involve a bony fragment to fix, some recommend debridement and microfracture of the bony bed. Others have tried osteochondral autograft plugs, particularly when the lateral column is involved in the lesion. Early experience with the osteochondral plugs is encouraging.[227,228]

Radiocapitellar Degeneration

As previously discussed, radiocapitellar degeneration most often occurs with UCL insufficiency.[22] Incompetence of the medial stabilizing structures (UCL) results in increased force at the radiocapitellar joint, which leads to softening and degeneration of the articular cartilage. Osteochondral loose bodies are common and often cause mechanical symptoms and pain.[24] Eventually, degenerative arthritis of the radiocapitellar joint may develop. Tenderness at the lateral elbow that is worsened by pronation and supination of the elbow is a common finding on examination. Arthroscopic surgery is effective for removing loose bodies but cannot reverse the changes in the articular cartilage. In athletes the symptoms usually recur when the individual returns to the same level of throwing, especially if the UCL instability has not been corrected. For constant pain caused by radiocapitellar arthritis, radial head excision, using either open or arthroscopic techniques, often is successful. Some clinicians also advocate isolated radiocapitellar arthroplasty.

Lateral Epicondylitis

Lateral epicondylitis, or **tennis elbow**, is by far the most common overuse injury of the elbow. It is approximately seven times more common than medial epicondylitis.[136,229] It is commonly seen in tennis players and other athletes, although 95% of individuals with tennis elbow do not play tennis (Figure 9-31). Lateral epicondylitis, or more appropriately, epicondylosis, is very common in the general

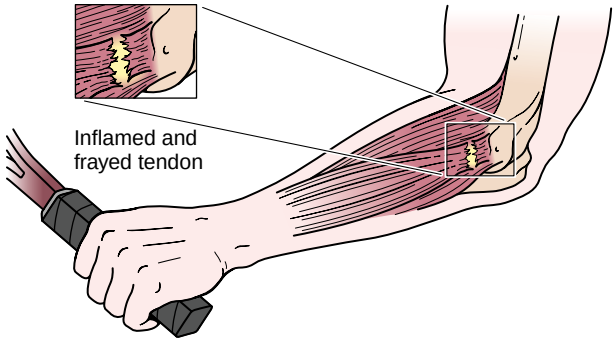

Figure 9-31 Lateral epicondylitis, a tendinosis of the wrist extensor muscles at the lateral epicondyle as a result of overuse of the wrist extensors, such as may occur in tennis players.

Figure 9-32 MRI scan of a patient with epicondylosis of the wrist extensors at the lateral epicondyle.

population, particularly in individuals who do repetitive work, such as typing on the computer.

Nirschl and Pettrone[230] first described this condition as a degenerative more than inflammatory process involving primarily the extensor carpi radialis brevis. The extensor digitorum communis can also be involved to a lesser degree. These researchers' histological observations led them to label the condition *angiofibroblastic hyperplasia*.[230] Given the absence of inflammatory findings, the term *tendinosis* is used instead of *tendonitis*.

Lateral epicondylitis is most common in patients 35 to 50 years of age and is associated with higher levels and frequency of activity.[24] Poor conditioning and poor technique likely exacerbate the problem in many tennis players, and certainly many racquet factors have been attributed to tennis elbow, including heavy racquets, metal racquets, stiffer racquets, incorrect grip size, and string tension. As many as half of club tennis players older than age 30 have had tennis elbow.[230,231] Patients initially report activity-related lateral elbow pain, often a dull, aching, lateral pain, and may show weakness of grip strength. Symptoms can progress to pain at rest in the more severe stages and difficulty holding a cup, lifting a milk carton, shaking hands or opening a door, or engaging in any activity that requires holding the wrist in its functional position (slightly extended) while loading the wrist.[24] On examination patients have tenderness approximately 1 to 2 cm (0.5 to 1 inch) distal to the lateral epicondyle and pain with passive wrist flexion, with resisted active wrist extension, and during grasping or lifting. Radiographs often are normal but may show a spur at the lateral epicondyle or calcification of the common extensor tendon.[1,229,231] MRI is rarely necessary but can reveal changes consistent with a tendinosis of the extensor muscles at the elbow (Figure 9-32).

Initial treatment is typically nonoperative. Of patients, 95% improve with conservative treatment.[231] Rest (i.e., avoidance of the stress or overuse) must be combined with a program that reestablishes the patient's strength, flexibility, and endurance. Counterforce bracing is thought to reduce the load at the lateral epicondyle by preventing the forearm muscles from fully expanding or changing the direction of musculotendinous pull.[229] Corticosteroid injections can be helpful and are a common form of treatment by orthopedic surgeons. A survey of 400 members of the American Academy of Orthopaedic Surgeons found that 93% of its membership had administered cortisone injections for tennis elbow.[232] Corticosteroid injections have been reported to be particularly effective in reducing symptoms, allowing the patient to perform rehabilitation exercises, but repeated injections (i.e., more than three in a 1-year period) are not recommended.[233] A recent randomized study showed a short-term benefit to iontophoresis of dexamethasone in patients with severe lateral epicondylitis.[234] Other research suggests that topical nitric oxide, metalloprotease inhibitors, and botulinum toxin may be beneficial.[235–237] Shock wave therapy has not been shown to be beneficial.[238] Blood injections and platelet-rich plasma (PRP) injections recently have been reported to be beneficial in small case series.[239,240] Additionally, a recent larger sample randomized controlled trial of 230 patients found meaningful improvements with leukocyte-enriched PRP injection at 24 weeks compared with a control group.[241] Recreational tennis players should be encouraged to seek professional instruction, because improper technique often contributes to the problem.[24]

Surgery for Lateral Epicondylitis

If 6 months of nonoperative treatment for lateral epicondylitis fails to result in satisfactory improvement, surgery is indicated.[1,24] Lateral epicondylitis can be treated percutaneously, by an open technique, or arthroscopically. A detailed review is beyond the scope of this chapter but can be found in the literature.[242] Only one paper in the literature compares the three main procedures for tennis elbow: percutaneous release, the open procedure described by Nirschl and Ashman,[231] and arthroscopic release. None of the three was found to be superior.[243] A systematic review also did not reveal any difference between the

different procedures, but this may be due to the limited number of quality studies in the literature.[242] The principal goals generally are to remove abnormal, degenerative tissue at the origin of the extensor carpi radialis brevis and to encourage healing with minimal disruption of normal stabilizing structures (Figure 9-33). Outcomes after surgical treatment are excellent. According to Nirschl and Ashman,[231] 85% of patients experience complete pain relief and full return of strength. Similar outcomes have been noted with arthroscopic release. In addition, concomitant intra-articular problems may be identified and treated arthroscopically that might not be seen with an open approach.[242,244] Arthroscopy for lateral epicondylitis provides significant improvements in pain and functional recovery up to 3 months after surgery. However, it takes more than 6 months for pain scales to decrease to normal levels.[245]

Extensor/Supinator Muscular Disruption

Lateral muscle disruption is rare. It has been reported in patients who have had repeated corticosteroid injections for lateral epicondylitis.[233] Patients report an acute onset of pain associated with a snap that results in weakness of wrist extension and forearm supination. For complete or near-complete injuries, surgical repair is recommended.[1]

Radial Nerve Entrapment

For some time, it has been accepted that certain cases of persistent tennis elbow represent radial or posterior interosseous nerve compression, the so-called **radial tunnel syndrome**.[246] The radial tunnel is defined by the bony and soft tissue structures that surround the radial nerve and its posterior interosseous branch as they travel through the proximal forearm. Nerve compression in this area most commonly occurs at the **arcade of Frohse**, the tendinous proximal edge of the supinator muscle. Other potential sites of compression include the proximal edge of the extensor carpi radialis brevis, branches of the radial artery, and fibrous bands.[247,248]

When persistent forearm pain and tenderness are associated with muscle weakness in the distribution of the posterior interosseous nerve, nerve entrapment in the radial tunnel is the likely etiology. The tenderness associated with radial nerve entrapment is more distal and medial than that seen in lateral epicondylitis. That is, it is located more over the muscular area of the proximal forearm.[24] Nonoperative management is typically successful in treating this problem.[1] Cases that do not respond to conservative treatment may require surgical decompression.[24] However, many cases of persistent or recurrent tennis elbow are not associated with objective neurological deficits. These cases most likely do not represent a true entrapment neuropathy, and practitioners should be cautious about recommending surgical decompression.[248,249]

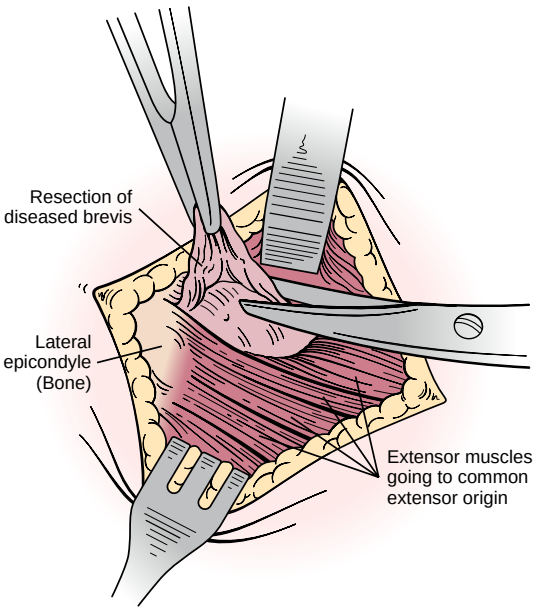

Figure 9-33 Schematic representation of open surgery for tennis elbow with excision of the degenerative tissue. (Redrawn from Safran MR: Elbow tendinopathy: surgical repair of the epicondylitides. In Craig E, editor: *Clinical orthopaedics,* p 279, Philadelphia, 1999, Lippincott Williams & Wilkins.)

CONSERVATIVE THERAPY AND MODALITIES

Ice and Nonsteroidal Anti-inflammatory Medications

Nonoperative treatment of elbow injuries usually involves multiple approaches. Ice is often recommended, especially in the acute period, because it has minimal risks and may provide symptomatic relief of swelling and pain. NSAIDs also are used as a first-line medical treatment for painful and inflammatory conditions about the elbow. They are most often administered topically or orally, although intramuscular injection is also available. For lateral elbow pain, topical NSAIDs have shown a significant effect, compared with placebo, for short-term pain relief and patient satisfaction.[250] Oral NSAIDs are also often used, although the benefit is not as well documented and the adverse effects are more significant. Long-term oral use of NSAIDs can be associated with adverse effects on the gastrointestinal and renal systems. Fortunately, these complications are uncommon with short-term use in medically healthy patients when taken with food.

Therapeutic Ultrasound

Therapeutic ultrasound has been used as a treatment for chronic musculotendinous problems. Phonophoresis involves the addition of a gel containing a corticosteroid to the ultrasound treatment. In one study, therapeutic ultrasound was reported to achieve short-term improvement in pain and pressure tolerance in patients with tendonitis, but adding phonophoresis did not provide any additional benefit.[251]

High-Voltage Electrical Stimulation

Electrical stimulation frequently has been used as a treatment for various musculoskeletal conditions. Specifically, it often is used to treat nerve and tendon injuries of the upper extremity, and some evidence in animal models indicates that it may help stimulate nerve repair. However, no human clinical studies have demonstrated a significant effect in the treatment of nerve or tendon injuries.[252]

Transverse Friction Massage

Transverse friction massage has been suggested as a physical therapy modality for tendonitis pain. However, the controlled studies that have been reported have not shown a significant effect. One study looked at lateral epicondylitis and showed no difference in terms of pain relief, grip strength, or functional status compared with other physical therapy modalities.[253] **Scar massage** is a gentle transverse friction massage.

Cortisone Injections

Local corticosteroid injections are commonly used to treat a variety of chronic musculoskeletal problems. They have been used extensively to treat lateral epicondylitis. Smidt et al.[233] did an extensive review of the literature on the use of corticosteroid injections for this condition. They found a statistically significant short-term effect for pain, grip strength, and global improvement; however, no medium- or long-term effect could be demonstrated.[233] The most commonly cited complication of corticosteroid injection was tendon rupture.[254] Although some have attempted to use cortisone injections as a treatment, most use cortisone, such as oral NSAIDs, as an adjunct, to make it more tolerable for patients to do their rehabilitation.

GENERAL REHABILITATION GUIDELINES

Rehabilitation after elbow injury or elbow surgery follows a sequential and progressive multiphased approach. The ultimate goal of elbow rehabilitation is to return patients to their previous functional level as quickly and safely as possible. The following sections provide an overview of the rehabilitation process after elbow injury and surgery. Rehabilitation protocols for specific pathologies are then presented.

Four Phases of Elbow Rehabilitation

- Phase I: immediate motion phase
- Phase II: intermediate phase (full ROM, minimal pain, good muscle strength)
- Phase III: advanced strengthening phase
- Phase IV: return to activity phase

Phase I: Immediate Motion Phase

The first phase of elbow rehabilitation is the immediate motion phase. The goals of this phase are to minimize the effects of immobilization, reestablish pain-free ROM, reduce pain and inflammation, and retard muscular atrophy. Early ROM activities are performed to nourish the articular cartilage and assist in the synthesis, alignment, and organization of collagen tissue.[255–263] ROM activities are performed for all planes of elbow and wrist motions to prevent the formation of scar tissue and adhesions. Active-assisted and passive ROM exercises are performed for the ulnohumeral joint to restore flexion/extension, as well as supination/pronation for the radiohumeral and radioulnar joints. The reestablishment of either full elbow extension or preinjury motion is the primary goal of early ROM activities to minimize the occurrence of elbow flexion contractures.[263–265] Preoperative elbow motion must be carefully assessed and recorded. Patients should be asked whether they have had full elbow extension in the past 2 to 3 years. Postoperative ROM often is related to preoperative motion, especially with UCL reconstruction. Elbow flexion contractures can be a deleterious side effect of surgery for the overhead athlete. The elbow is predisposed to flexion contractures because of the intimate congruency of the joint articulations, the tightness of the joint capsule, and the tendency of the anterior capsule to develop adhesions after injury.[262] The brachialis muscle also attaches to the capsule and crosses the elbow joint before becoming a tendinous structure. Injury to the elbow may cause excessive scar tissue formation of the brachialis muscle and to the adjacent tissues, which may require functional splinting of the elbow.[262]

Phase I: Goals of Immediate Motion Phase

- Minimize the effects of immobilization
- Reestablish pain-free ROM
- Reduce pain and inflammation
- Reduce muscle atrophy

In addition to ROM exercises, joint mobilizations may be performed as tolerated to minimize the occurrence of joint contractures. Posterior glides with oscillations are performed at end ROM to help regain full elbow extension. Initially grade I and grade II mobilizations are used, with progression to aggressive mobilization techniques (grade III/III+ and grade IV/IV+) at end ROM during later stages of rehabilitation, when symptoms have subsided. Joint mobilization must include the radiocapitellar and radioulnar joints.

If the patient continues to have difficulty achieving full extension using ROM and mobilization techniques, a low load–long duration (L3D) stretch (also called *collagen creep* or *plastic flow stretch*) may be performed to produce a deformation or creep of the collagen tissue, resulting in tissue elongation.[265–268] We have found this technique to be extremely

beneficial for regaining full elbow extension. The patient lies supine with a towel or foam roll placed under the distal brachium to act as a cushion and fulcrum. Light-resistance exercise tubing is applied to the wrist and secured to the table or to a dumbbell on the ground (Figure 9-34). The patient is instructed to relax as much as possible for 12 to 15 minutes. The patient performs this type of exercise at home periodically during the day, totaling 60 minutes of stretching per day. The resistance applied should be low enough in magnitude to enable the patient to perform the stretch for the entire duration without pain or muscle spasm. The technique should impart a low load but a long duration stretch.

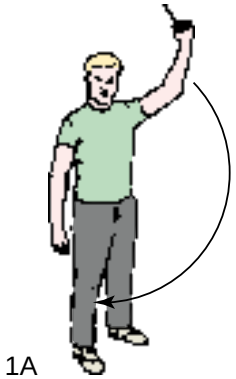
The aggressiveness of stretching and mobilization techniques is dictated by the healing constraints of the involved tissues, the specific pathology or surgical technique, and the amount of motion and end feel. If the patient has decreased motion and a pathologically hard end feel without pain, aggressive stretching and mobilization techniques may be used. Conversely, a patient who has pain before resistance or an empty end feel must be progressed slowly with gentle stretching.

Another goal of phase I is to reduce the patient's pain and inflammation. Grade I and grade II mobilization techniques are used to neuromodulate pain by stimulating type I and type II articular receptors.[269,270] Cryotherapy and high-voltage stimulation may be performed as required to further assist in reducing pain and inflammation. Once the acute inflammatory response has subsided, moist heat, warm whirlpool, and therapeutic ultrasound may be used at the onset of treatment to prepare the tissue for stretching and improve the extensibility of the capsule and musculotendinous structures. In addition, joint mobilization glides are increased to grade III/III+ and grade IV/IV+ mobilizations.

The early phase of rehabilitation also focuses on voluntary activation of muscle and the retardation of muscular atrophy. Nonpainful, submaximal isometrics are performed initially for the elbow flexors and extensors, as well as for the wrist flexor, extensor, pronator, and supinator muscle groups. Shoulder isometrics may also be performed during this phase, but care must be taken to avoid medial (internal) and lateral (external) shoulder rotation exercises if these are painful. Alternating rhythmic stabilization drills for shoulder flexion/extension/horizontal abduction/adduction, shoulder medial/lateral rotation, and elbow flexion/extension/supination/pronation are performed to begin reestablishing proprioception and neuromuscular control of the upper extremity.

Figure 9-34 Low load–long duration (L3D technique) stretching to improve elbow extension. A low-intensity stretch is applied for 10 to 12 minutes. Note that the elbow is pronated and the shoulder is internally rotated to lock the humerus and prevent compensation.

Phase II: Intermediate Phase (Full ROM, Minimal Pain, Good Muscle Strength)

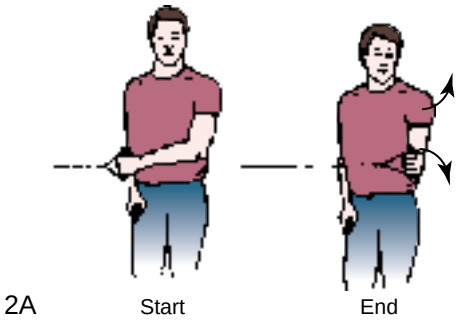


Phase II, the intermediate phase, is initiated when the patient exhibits full ROM, minimal pain and tenderness, and a good (4/5) manual muscle test of the elbow flexor and extensor musculature. The emphasis in this phase includes enhancing elbow and upper extremity mobility, improving muscular strength and endurance, and reestablishing neuromuscular control of the elbow complex.

Stretching exercises are continued to maintain full elbow and wrist ROM. Mobilization techniques may be progressed to more aggressive grade III techniques as needed to apply a stretch to the capsular tissue at end range. Flexibility is progressed during this phase to focus on wrist flexion, extension, and forearm pronation and supination. Elbow extension and forearm pronation flexibility is specifically emphasized in throwing athletes so that they can perform efficiently. Shoulder flexibility is also maintained in athletes, with emphasis on medial and lateral rotation at 90° of abduction, flexion, and horizontal adduction. In particular, shoulder lateral rotation at 90° of abduction is emphasized because even a slight loss of lateral rotation may result in increased strain on the medial elbow structures during the overhead throwing motion. Medial rotation motion should also be diligently performed.

Wilk et al.[271] has reported that bilateral differences in shoulder total rotation and flexion had a significant effect on the risk for elbow injuries in pitchers. Pitchers with deficits of greater than 5° in total rotation in their throwing shoulders had a 2.6 times greater risk for injury. Pitchers with a deficit of greater than 5° in flexion of the throwing shoulder had 2.8 times greater risk for injury.

Strengthening exercises are progressed during this phase to include isotonic contractions, beginning concentrically and progressing to include eccentric contractions. Emphasis is placed on elbow flexion and extension, wrist flexion and extension, and forearm pronation and supination. The glenohumeral and scapulothoracic muscles are placed on a progressive resistance program during the later stages of phase II, emphasizing strengthening the shoulder lateral rotators and scapular muscles. A complete upper extremity strengthening program, such as the thrower's 10 program (Figure 9-35), may be performed.

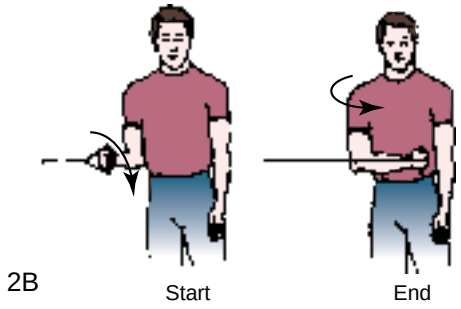


1A. Diagonal D2 Extension Pattern: Involved hand grips tubing handle overhead and out to the side. Pull tubing down and across the body to the opposite side of leg. During the motion, lead with the thumb.

1B. Diagonal D2 Flexion Pattern: Gripping tubing handle in hand of involved arm, begin with arm out from side 45° and palm facing backward. While turning palm forward, proceed to flex elbow and bring arm up and over involved shoulder. Reverse to take arm to starting position while turning the palm down. Note: D2 flexion pattern is the reverse of the D2 extension pattern.

2A. Lateral (External) Rotation at 0° Abduction: Stand with involved elbow fixed at side, elbow at 90° and involved arm across front of body. Grip tubing handle while the other end of tubing is fixed. Rotate arm out, keeping elbow at side leading with the thumb. Return to start position moving slowly and in a controlled fashion.

2B. Medial (Internal) Rotation at 0° Abduction: Standing with elbow at side fixed at 90° and shoulder rotated out. Grip tubing handle with thumb out while other end of tubing is fixed. Pull arm across body keeping elbow at side leading with thumb. Return to start position moving slowly and in a controlled fashion.



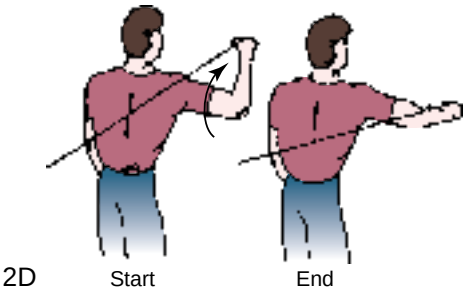


Figure 9-35 The thrower's exercise program. This program is designed to exercise the major muscles necessary for throwing. The goal is to establish an organized, concise exercise program. All exercises included are specific to the thrower and are designed to improve the strength, power, and endurance of the shoulder complex musculature along with elbow "2 joint" muscles. (Modified from Wilk KE, Reinold MR, Andrews JR: *The athlete's shoulder*, ed 2, New York, 2009, Churchill Livingstone/Elsevier.)

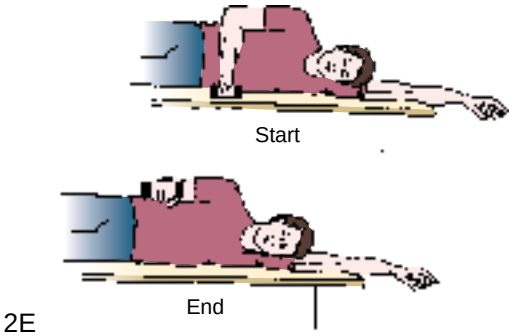
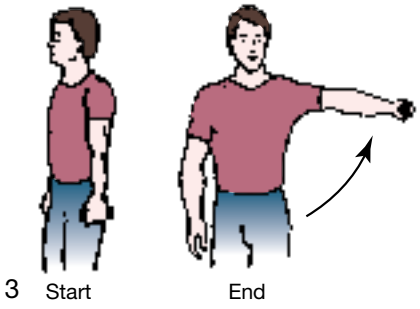
(Continued)



2C. Lateral (External) Rotation at 90° Abduction: Stand with shoulder abducted to 90°. Grip tubing handle while the other end is fixed straight ahead, slightly lower than the shoulder. Keeping shoulder abducted, rotate shoulder back keeping elbow at 90°. Return hand to start position. Start at slow speed. As control achieved, do rotations faster.

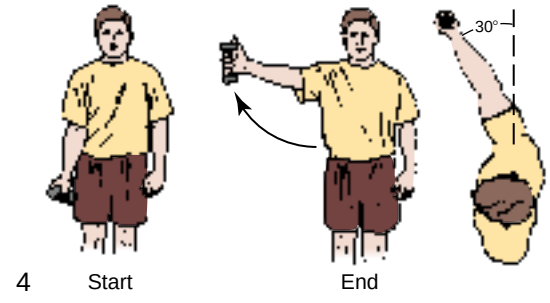


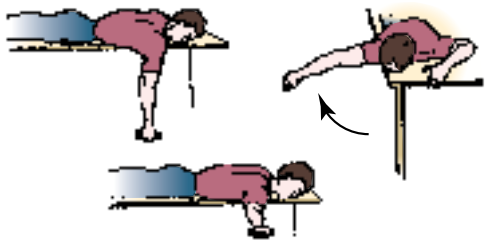
2D. Medial (Internal) Rotation at 90° Abduction: Stand with shoulder abducted to 90°, laterally rotated 90° and elbow bentto 90°. Keeping shoulder abducted, rotate shoulder forward, keeping elbow bent at 90°.Return hand to start position.Start at slow speed. As control achieved, do rotations faster.

2E. Sidelying Lateral (External) Rotation: Lie onuninvolved side, with involved arm at side of body and elbow bent to 90°. Keeping the elbow of involved arm fixed to side, raise arm and lower slowly.

3. Shoulder Abduction to 90°: Stand with arm at side, elbow straight, and palm against side. Raise arm to the side, palm down, until arm reaches 90° (shoulder level). Be sure to engage scapula before beginning.

4. Scaption, Lateral (External) Rotation: Stand with elbow straight and thumb up. Raise arm to shoulder level at 30° angle in front of body (scaption). Do not go above shoulder height. Be sure to engage scapula before beginning.





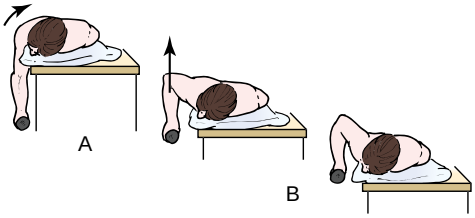


Figure 9-35 Cont'd

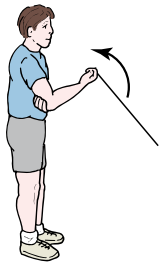
5. Prone Horizontal Abduction (Neutral): Lie on table, face down, with involved arm hanging straight to the floor, and palm facing down. Engage scapula and raise arm out to the side, parallel to the floor. Hold 2 seconds and lower slowly.

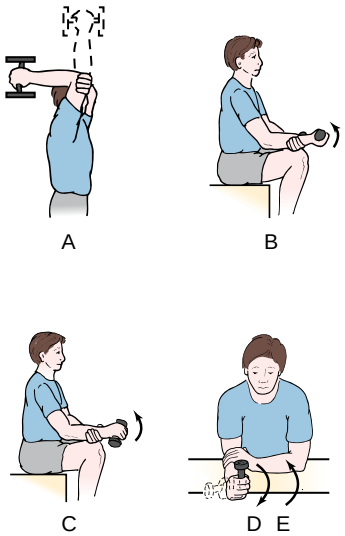
5

6. Prone Rowing: Lying on your stomach with your involved arm hanging over the side of the table, dumbbell in hand and elbow straight. Slowly retract the scapula (A) then raise the arm, bending elbow (B), and bring dumbbell as high as possible. Hold at the top for 2 seconds, then slowly lower arm and then release scapula.



6

7. Press-ups: Seated on a chair or table, place both hands firmly on the sides of the chair (or arms of the chair) or table, palm down and fingers pointed outward. Hands should be placed equal with shoulders. Slowly push downward through the hands to elevate your body. Hold the elevated position for 2 seconds and lower body slowly.



7

8. Biceps Strengthening with Tubing: Stand with one end of the tubing securely in the involved hand and the opposite end under the foot of the involved side while controlling tension. Assist with the opposite hand so that the arm is flexed through the full range of motion. Return to the starting position with a slow 5 count.

8

9. Dumbbell Exercises for the Triceps and Wrist Extensors/Flexors: ***A. Triceps curls:*** Raise the involved arm holding weight overhead. Provide support at the elbow with the uninvolved hand. Straighten the arm overhead. Hold for 2 seconds and lower slowly. ***B. Wrist flexion:*** Support the forearm on leg or on a table with the hand off the edge, the palm facing upward. Hold a weight or hammer in the involved hand and lower it as far as possible, then curl it up as high as possible. Hold for a 2 count. ***C. Wrist extension:*** Support the forearm on leg or on a table with the hand off the edge, the palm facing downward. Hold a weight or hammer in the involved hand and lower it as far as possible, then curl it up as high as possible. Hold for a 2 count. ***D. Forearm pronation:*** Support the forearm on a table with the wrist in neutral position. Hold a weight or hammer in a normal hammering position and roll the wrist to bring the hammer into pronation as far as possible. Hold for a 2 count. Raise to the starting position. ***E. Forearm supination:*** Support the forearm on a table with the wrist in neutral position. Hold a weight or hammer in a normal hammering position and roll the wrist to bring the hammer into full supination. Hold for a 2 count. Raise back to the starting position.

9

Figure 9-35 Cont'd

10. Serratus Anterior Strengthening (Push Up with "+"): Start with a push up away from the wall (wall push up). Gradually progress to the tabletop (table push up) and eventually to the floor (floor push up) as tolerable. Push up in any of the 3 positions as far as possible without hunching the shoulders.

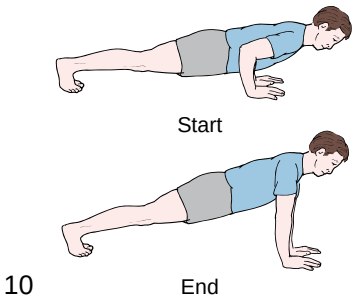


Figure 9-35 Cont'd

Neuromuscular control exercises are initiated in this phase to enhance the muscles' ability to control the elbow joint during athletic activities. These exercises include proprioceptive neuromuscular facilitation exercises with rhythmic stabilizations (Figure 9-36) and slow reversal manual resistance elbow/wrist flexion drills (Figure 9-37).

Phase II: Goals of Intermediate Phase (Full ROM, Minimal Pain, Good Muscle Strength)

- Enhance elbow and upper extremity mobility
- Improve muscle strength and endurance
- Re-establish neuromuscular control

Figure 9-36 Proprioceptive neuromuscular facilitation (PNF) exercises to the elbow to enhance elbow stability.

Figure 9-37 PNF exercise drills that include slow reversal of manual resistance.

Phase III: Advanced Strengthening Phase

The third phase of elbow rehabilitation involves a progression of activities to prepare the patient or athlete for high-level stress situations or participation in sports. The goals of this phase are to gradually increase strength, power, endurance, and neuromuscular control to prepare for a gradual return to sports. Specific criteria that must be met before this phase is entered include full, nonpainful ROM; absence of pain or tenderness; and strength that is 70% of the contralateral extremity.

Phase III: Goals of Advanced Strengthening Phase

- Increase strength to functional levels
- Increase power to functional levels
- Increase endurance to functional levels
- Increase neuromuscular control

Criteria for Progression to Phase III

- Full, pain-free ROM
- No pain
- No tenderness
- Strength at least 70% of contralateral limb

Advanced strengthening activities during this phase include aggressive strengthening exercises that emphasize high speed, eccentric contractions, and plyometric activities. Elbow flexion exercises are progressed to emphasize eccentric control. The biceps muscle is an important stabilizer during the follow-through phase of overhead throwing; it eccentrically controls the deceleration of the elbow, preventing pathological abutment of the olecranon within the fossa.[272,273] Elbow flexion can be performed with elastic tubing to emphasize slow and fast concentric and eccentric contractions. Manual resistance may be applied for concentric and eccentric contractions of the elbow flexors. Aggressive strengthening exercises done with weight machines are also incorporated during this phase. These most commonly begin with bench press, seated rowing, and front latissimus dorsi pull-downs. The triceps is exercised primarily with a concentric contraction because of the acceleration (i.e., muscle shortening) activity of the triceps during the acceleration phase of throwing.

Neuromuscular control exercises are progressed to include side-lying lateral (external) rotation with manual resistance. Concentric and eccentric lateral rotation is performed against the clinician's resistance with the addition of rhythmic stabilizations. This manual resistance exercise may be progressed to standing lateral rotation with exercise tubing at 0° and finally at 90° (Figure 9-38).

Plyometric drills can be an extremely beneficial form of functional exercise for training the elbow in overhead athletes.[263,274] Plyometric exercises are performed using a weighted medicine ball during the later stages of phase III to train the shoulder and elbow to develop and withstand high levels of stress. Plyometric exercises initially are performed with two hands performing a chest pass, side-to-side throw, and overhead soccer throw. These may be progressed to include one-handed activities such as 90/90 throws (Figure 9-39), external and internal rotation throws at 0° abduction (Figure 9-40), and wall dribbles. Specific plyometric drills for the forearm musculature include wrist flexion flips (Figure 9-41) and extension grips (Figure 9-42). Wrist flexion flips and extension grips are important components of an elbow rehabilitation program because they emphasize the forearm and hand musculature.

Figure 9-38 Standing lateral rotation with exercise tubing at 0° abduction.

Figure 9-39 Plyometric drills: one-handed baseball throw at 90° abduction.

Figure 9-40 Plyometric drills: one-handed medial rotation side throws at 0° abduction.

Phase IV: Return to Activity Phase

The final phase of elbow rehabilitation is the return to activity phase. It allows the patient to progressively return to full activity or, for the overhead athlete, the ability to return to competition using an interval athletic program be it throwing, tennis, golf, swimming, volleyball, and so on.[275]

Figure 9-41 Plyometric drills: wrist flexion ball flips.

Figure 9-42 Plyometric drills: wrist extension with ball grips.

Phase IV: Goal of Return to Activity Phase

- Program geared to individual functional needs
- Return to full activity

Criteria for Progression to Phase IV

- Full ROM
- No pain or tenderness
- Satisfactory isokinetic test
- Satisfactory clinical examination

Before being allowed to begin the return to activity phase of rehabilitation, patients must exhibit full ROM and have no pain or tenderness. They also must have a satisfactory isokinetic test and a satisfactory clinical examination.

Isokinetic testing is commonly used to determine the readiness of the athlete to begin an interval sports program.[275] Athletes routinely are tested at 180° and 300°/sec (degrees per second). The bilateral comparison at 180°/sec indicates the dominant arm's elbow flexion to be 10% to 20% stronger and the dominant extensors 5% to 15% stronger than the nondominant arm.

Upon achieving the previously mentioned criteria for returning to sports, a formal interval sports program as described by Reinold et al. can begin.[275] For the overhead thrower, a long toss interval throwing program begins at 13.7 m (45 feet) and gradually progresses to 36.6 or 54.9 m (120 or 180 feet) (player and position dependent) (Table 9-1).[276] Throwing should be performed without pain or a significant increase in symptoms. We believe it is important for the overhead patient or athlete to perform stretching and an abbreviated strengthening program before and after performing the interval sports program. Typically, overhead throwers warm up, stretch, and perform one set of their exercise program before throwing, followed by two additional sets of exercises following throwing.[275] This not only provides an adequate warm-up but also ensures maintenance of necessary ROM and flexibility of the shoulder joint. The next day, the thrower exercises the scapular muscles and external rotators and performs a core stabilization program.

After completing a long toss program, pitchers progress to phase II of the throwing program, throwing off of a mound.[275] In phase II the number of throws, intensity, and type of pitch are progressed to gradually increase stress on the elbow and shoulder joints.[275] Generally, the pitcher begins at 50% intensity and gradually progresses to 75%, 90%, and 100% over 4 to 6 weeks. Breaking balls are initiated once the pitcher can throw 40 to 50 pitches with at least 80% intensity with no symptoms.

TABLE 9-1

Postoperative Rehabilitation Following Elbow Arthroscopy

Initial phase (week 1)	*Goals:* achieve full wrist and elbow ROM; reduce swelling and pain; retard muscle atrophy. **1.** Day of surgery • Begin gently moving elbow in bulky dressing **2.** Postoperative days 1-2 • Remove bulky dressing, and replace with elastic bandages • Immediate postoperative hand, wrist, and elbow exercises: ○ Putty/grip strengthening ○ Wrist flexor stretching ○ Wrist extensor stretching ○ Wrist curls ○ Reverse wrist curls ○ Neutral wrist curls ○ Forearm pronation/supination ○ AA/AROM elbow extension/flexion **3.** Postoperative days 3-7 • Begin PROM elbow extension/flexion (motion to tolerance) • Begin progressive resistance (PRE) exercises with 0.5-kg (1-pound) weight: ○ Wrist curls ○ Reverse wrist curls ○ Neutral wrist curls ○ Forearm pronation/supination ○ Broomstick rollup
Intermediate phase (weeks 2-4)	*Goals:* improve muscular strength and endurance; normalize joint arthrokinematics. **1.** Week 2: ROM exercises (overpressure into extension) • Add biceps curls and triceps extension • Continue to progress PRE weight and repetitions as tolerable **2.** Week 3 • Initiate eccentric exercises for biceps and triceps • Initiate exercises for rotator cuff: ○ Lateral (external) rotators ○ Medial (internal) rotators ○ Deltoid ○ Supraspinatus ○ Scapulothoracic strengthening
Advanced phase (weeks 4-8)	*Goal:* prepare patient for return to functional activities. Criteria for progression to advanced phase: • Full, pain-free ROM • No pain or tenderness • Isokinetic test that fulfills criteria for throwing • Satisfactory clinical examination **1.** Weeks 4-6 • Continue maintenance program, emphasizing muscular strength, endurance, and flexibility • Initiate interval throwing program phase

ROM, Range of motion; *AA/AROM,* active assisted and active range of motion; *PROM,* passive range of motion; *PRE,* progressive resistance exercises.

SPECIFIC REHABILITATION GUIDELINES

Tendinopathy

The treatment of tendinopathy is based on a careful examination to determine the exact pathology present. Often practitioners diagnose patients as having "tendonitis" only to discover later that the tendon actually had undergone a degenerative process, or *tendinosis.*[230,231] The treatments for tendonitis and tendinosis are dramatically different.

The treatment for tendonitis typically is targeted at reducing inflammation and pain. This is accomplished through reduction in activities, anti-inflammatory medications, cryotherapy, iontophoresis, light exercise, and stretching.

The treatment for tendinosis focuses on increasing circulation to promote collagen synthesis. This includes

application of heat, class IV deep tissue LASER, ultrasound, stretching, eccentric exercises, transverse friction massage, and soft tissue mobilization.

Medial Epicondylitis

The treatment of medial epicondylitis should focus first on reducing pain and inflammation and then on increasing strength. Heat therapy followed by stretching and light strengthening is the hallmark of treatment for this condition. The session is finished with cryotherapy and electrical stimulation to decrease inflammation and pain. A gradual increase in stretching and strengthening should be attempted, with care taken not to exacerbate the patient's symptoms. If exacerbation occurs, a step back should be taken in the program, and the patient should be readvanced more slowly.

In some cases, medial epicondylitis is treated with surgical debridement. Rehabilitation after surgery may be aggressive, because the flexor/pronator mass has not been stripped from the medial epicondyle. The patient is placed in a protective posterior splint for 10 to 14 days to allow the soft tissues to heal. Once the splint is removed, ROM of the elbow is allowed immediately in all directions, including elbow flexion and extension and forearm supination and pronation. Full motion should be obtained by 4 weeks. Light isometric exercise (i.e., 10%-40% of the maximum voluntary contraction [MVC]) can be performed immediately after surgery. Once full motion has been obtained, strengthening may begin. Strengthening begins with isometric exercises and progresses to concentric and then eccentric exercises. Plyometric exercises are the final step.

As with all surgical procedures at the elbow, scar massage is incorporated at 2 to 3 weeks and nerve glides (i.e., neurodynamic techniques such as "flossing") commence when adequate motion is established. In addition, transverse friction massage can be performed over the debrided and released tendon.

In some cases, the surgeon may choose to detach the flexor/pronator mass in the process of debridement. In these patients, active wrist extension and flexion should be prevented for 4 weeks. Although full passive motion is allowed, it should be done gently and only in the presence of the clinician for the first 4 weeks.

Lateral Epicondylitis

A principal aspect of conservative treatment for lateral epicondylitis is therapy. Despite the misnomer, lateral epicondylitis is not a disease of inflammation but rather a disease of degeneration. Usually little or no swelling is present; therefore heat therapy should begin each treatment session. Stretching of the extensor mass with wrist flexion is an important component of treatment. This may be done in conjunction with soft tissue mobilization. If the stretching and mobilization are well tolerated, isotonic eccentric strengthening exercises for the lateral extensor muscle mass may be attempted. The patient also should perform shoulder and scapular flexibility and strengthening exercises during the rehabilitation program.

Conservative measures should be attempted for at least 6 months before surgical intervention is considered. Rehabilitation after surgical debridement primarily depends on whether the surgeon chooses to detach and reattach the extensor mass during surgery. If the extensor mass is detached during the procedure, active wrist extension and flexion should be prevented for 4 weeks. Although full passive motion is allowed, it should be done gently and only in the presence of the therapist for the first 4 weeks.

Caution with Elbow Surgery/Rehabilitation

- If the flexor or extensor muscle mass is detached during surgery, active wrist movement is prevented for 4 weeks to allow sufficient time for healing

The posterior splint is removed at 10 to 14 days. Elbow flexion and extension and forearm supination and pronation are allowed immediately after removal of the splint. Care should be taken to perform supination and pronation gently. Cold therapy and electrical stimulation are instituted to reduce swelling and pain after sessions. Scar massage may begin at 2 to 3 weeks, and nerve glides may commence when adequate motion has been obtained. Full active motion at the elbow and wrist may begin at 4 weeks. If full motion already has been restored as a result of the passive motion instituted earlier, strengthening exercises may begin. Isometric exercises are succeeded by concentric exercises, which are followed by eccentric exercises. If the flexor mass was not detached, full motion of the elbow and wrist is allowed once the splint has been removed.

Ulnar Neuropathy

Therapy aimed at treating ulnar neuropathy depends on the pathology present. The nerve may be stretched secondary to instability at the elbow joint or compressed secondary to hypertrophy of surrounding soft tissue structures, or the condition may be a result of compression secondary to fibrous bands anywhere along the path of the ulnar nerve. This compression usually is observed in extremes of flexion or extension. The initial goal should be to bring the pain under control. This may involve the use of a nighttime splint with the elbow in 45° flexion to prevent recurrent compression and further damage. A full-time splint is not advised because elbow stiffness may develop. If stability is a concern, strengthening exercises also should be performed, focusing on the elbow flexors and extensors. In other patients, particularly those

with a large muscle mass, this may be contraindicated because the musculature may be a contributing factor to the problem.

All patients with ulnar neuropathy have nerve irritation that may result in scar formation. For this reason, nerve glides may be helpful in breaking scar tissue enveloping the nerve and possibly causing compression. The glides should be done gently at first using distal stretching techniques, graduating to more aggressive proximal stretching. This helps prevent a traction neuropraxia.

In the athlete, ulnar neuropathy often is a sequela of some other pathology and will not improve unless the underlying pathological condition is addressed. Numerous theories have been advanced on the cause of ulnar neuropathy of the elbow in throwing athletes. Ulnar nerve changes can result from tensile forces, compressive forces, or nerve instability. As noted previously, any one or a combination of these mechanisms may be responsible for ulnar nerve symptoms.

Ulnar neuropathy has three stages. The first stage is marked by the acute onset of radicular symptoms. The second stage is manifested by a recurrence of symptoms as the patient attempts to return to competition. The third stage is associated with persistent motor weakness and sensory changes. If the patient first seeks treatment in the third stage of injury, conservative management may not be effective.

Nonoperative treatment of ulnar neuropathy focuses on reducing ulnar nerve irritation, enhancing dynamic medial joint stability, and gradually returning the patient to previous levels and types of activities. NSAIDs often are prescribed, and rehabilitation includes an iontophoresis disposable patch and cryotherapy. With a diagnosis of ulnar neuropathy, throwing patients are instructed to discontinue throwing activities for at least 4 weeks, depending on the severity and chronicity of symptoms. The patient progresses through the immediate motion and intermediate phases over 4 to 6 weeks, with emphasis on eccentric and dynamic stabilization drills. Plyometric exercises are used to facilitate further dynamic stabilization of the medial elbow. The patient is allowed to begin an interval throwing program when full, pain-free ROM and muscle performance are present without neurological symptoms, and the individual may gradually return to activity if progression through the interval throwing program does not reveal neurological symptoms.

Ulnar Collateral Ligament Injury

Isolated UCL injuries usually are the result of chronic degeneration in repetitive movement overhead athletes. Pain and inflammation usually are present, as is loss of muscle strength throughout the extremity. Because instability may be present, a brace to protect against varus and valgus stresses may be helpful. The athlete must be instructed not to perform the throwing motion or to throw a ball until adequate healing time has elapsed (to control and limit valgus stress on the UCL). The first goal of treatment is to establish a painless ROM. The clinician begins with passive and active-assisted motion. Motion should be restored in a painless fashion to allow the ligament proper time to heal. Elbow flexion and extension ROM does not create deleterious stress on the UCL and is actually beneficial for ligament healing. Motion begins in a pain-free arc, and ROM is increased as tolerance allows. The patient progresses to active ROM after full motion has been established with the previous measures. Elbow flexion and extension and forearm supination and pronation are addressed, as are all wrist movements.

Gradual strengthening should begin with isometric exercises of the elbow and wrist. A shoulder program should be implemented to normalize ROM and flexibility and to improve shoulder strength.

Light isotonic exercises at the elbow and wrist are started around weeks 3 to 4, after full motion has been established. The goal is to increase wrist flexor and pronator strength to assist in elbow stability. This is continued until weeks 6 to 7. At this point, plyometric exercises are initiated slowly. Once full motion, full strength, and dynamic stability have returned and the patient is symptom free, the patient may begin an interval throwing program. Upon satisfactory completion of the interval throwing program (i.e., pain-free throwing at full velocity), the patient may return to high-level activity. To assist in pain-free throwing and sports, the overhead athlete should undergo a biomechanical evaluation to determine whether improper throwing mechanics are a factor or whether any biomechanical faults need to be corrected to help control the forces applied to the elbow joint.

Osteochondritis Dissecans (OCD)

In OCD, conservative measures typically are reserved for nondisplaced lesions. In the painful elbow associated with this lesion, a brief period of immobilization (i.e., up to 3 weeks) can be beneficial. Used in association with cryotherapy and NSAIDs, immobilization can help limit the inflammatory process. At the end of the immobilization period, ROM exercises can begin. When motion returns, strengthening may begin with isometric exercises. Care must be taken to avoid compressive forces on the radiocapitellar joint. Progression to isotonic exercises may begin with the same limitations. Sequential MRI and bone scans are obtained to assess the progression of healing. If healing does not progress, conservative measures should be abandoned in favor of surgical intervention. If the bone scans show evidence that the elbow is attempting to heal or is making progress, exercises that create stress in the radiocapitellar joint must be avoided to prevent detachment or collapse of the fragment.

Medial Epicondylar Apophyseal Injury (Little Leaguer's Elbow)

Medial epicondylar apophyseal injury is the result of abnormal stress to the epicondylar growth plate (apophysis) caused by excessive traction stresses. A rehabilitation protocol similar to that for a UCL strain is used for medial epicondylar apophyseal injuries. Reducing pain and restoring motion are the initial priorities. When pain dissipates and motion returns, gradual strengthening may commence. One goal is to begin heavy lifting and plyometrics by 14 weeks. In milder cases, such as nondisplaced injuries, a more aggressive rehabilitation protocol may be used. An interval throwing program is the last step of the rehabilitation process.

Ulnar Nerve Transposition

The goal of rehabilitation for ulnar nerve transposition is to return motion, function, and strength while minimizing pain and preventing failure of the surgery and complications, including adhesions to the nerve. A splint is applied immediately postoperatively with elbow flexion at 45°. This is left in place until approximately the tenth postoperative day to allow the soft tissues to heal and to enable some scar tissue to form and further secure the ulnar nerve in its new location. As with most rehabilitation around the elbow, the initial goal is to restore motion while minimizing pain.

Several techniques can be used for ulnar nerve decompression. Decompression in situ decompresses the ulnar nerve only at a specific site of compression, and no transposition takes place. In general, the ulnar nerve is quite stable and is not at risk for subluxation. For this reason, immediate active motion and passive motion are allowed. Motion should be fully restored by 4 weeks after surgery. Once motion has been restored, nerve glides are commenced to prevent scar adherence to the nerve. Isometric strengthening exercises may begin as well.

If a medial epicondylectomy or submuscular transposition is performed, active motion of the wrist should be avoided for 4 weeks to prevent flexor muscle mass avulsion. Although full passive motion of the wrist is allowed, it should be done gently and only in the presence of a clinician for the first 4 weeks. Full active and passive motion at the elbow may begin when the splint is removed, but care should be taken to be gentle with forearm supination and pronation. Scar massage may begin at 2 to 3 weeks, and nerve glides may commence when adequate motion has been obtained. Full active motion at the elbow and wrist may begin at 4 weeks. If full motion has already been restored, strengthening exercises may begin at 6 weeks. Isometrics may graduate to isotonic exercises. Plyometric exercises follow next. If the goal is to return a throwing athlete to his or her sport, an interval throwing program may commence by week 8. Return to competition may begin around week 12.

With a subcutaneous transposition, the flexor/pronator mass is not disrupted. The ulnar nerve is kept in place with a fascial sling. The splint is removed in 14 days, and this initial 2 weeks should be sufficient time for the soft tissues to heal. Once the splint has been removed, unlimited motion at the elbow and wrist may begin. Motion should be restored by 4 weeks. Once motion has been restored, strengthening can begin, in the same fashion as described previously. Nerve glides may begin when adequate motion has been restored. As described, scar massage may begin at 2 to 3 weeks.

Cryotherapy and electrical stimulation are encouraged in the initial stages to help minimize inflammation while motion exercises are performed; however, the nerve must be protected from thermal injury (particularly important with subcutaneous transpositions). Table 9-2 outlines a postsurgical treatment protocol.

Arthroscopic Excision of Osteophytes

Osteophytes most often appear on the olecranon in the posterior elbow, but they also may appear anteriorly on the coronoid. Throwing athletes may develop posteromedial olecranon osteophytes associated with VEOS.

Direct posterior osteophytes on the olecranon may limit extension of the elbow. Depending on the duration and magnitude of osteophyte formation, the resultant loss of motion may cause contracture of the anterior capsule. Therefore, even with surgical excision of the osteophytes, return of full extension may be a challenge, especially if no concomitant anterior capsule release is performed. Rehabilitation focuses on return of motion, particularly extension. The general rehabilitation guidelines for the elbow should be followed. However, less emphasis is placed on strengthening and more emphasis is placed on ROM exercises. Instability should not be expected with this procedure; therefore the clinician can be more aggressive with motion exercises, provided they do not result in increased inflammation. Control of inflammation and pain is crucial to this process, because pain markedly limits the amount of stretching a patient can tolerate. NSAIDs, cryotherapy, and high-voltage electrical stimulation all play roles in pain control. Once motion has been restored, strengthening may commence on a more aggressive basis. It is important to note that restoration of full extension may not be possible; therefore communication between the surgeon and clinicians is important to clarify the realistic goals of the surgical intervention.

Anterior coronoid osteophyte formation has a similar pathology. Full flexion is limited because of a bony blockage of motion anteriorly. This also results in soft tissue contractures. Therefore, even after the bone is removed, the motion in flexion is difficult to restore. Rehabilitation is similar to that described earlier, although more aggressive flexion exercises are instituted.

TABLE 9-2

Postoperative Rehabilitation after Ulnar Nerve Transposition

Phase I: immediate postoperative phase (weeks 0-2)	*Goals:* allow soft tissue healing of relocated nerve; reduce pain and inflammation; retard muscular atrophy. **1.** Week 1 • Posterior splint at 90° elbow flexion with wrist free for motion (sling for comfort) • Compression dressing • Exercises such as gripping exercises, wrist ROM, shoulder isometrics **2.** Week 2 • Remove posterior splint for exercise and bathing • Progress elbow ROM (PROM 150° to 120°) • Initiate elbow and wrist isometrics • Continue shoulder isometrics
Phase II: intermediate phase (weeks 3-7)	*Goals:* restore full, pain-free ROM; improve strength, power, and endurance of upper extremity musculature; gradually increase functional demands. **1.** Week 3 • Discontinue posterior splint • Progress elbow ROM, emphasizing full extension • Initiate flexibility exercises for wrist extension/flexion, forearm supination/pronation, and elbow extension/flexion • Initiate strengthening exercises for wrist extension/flexion, forearm supination/pronation, elbow extensors/flexors, and a shoulder program • Initiate nerve glide (flossing) techniques combining movements at the shoulder, elbow, wrist and fingers simultaneously **2.** Week 6 • Continue all exercises previously listed • Initiate light sports activities
Phase III: advanced strengthening phase (weeks 8-12)	*Goals:* increase strength, power, and endurance; gradually initiate sports activities. **1.** Week 8 • Initiate eccentric exercise program • Initiate plyometric exercise drills • Continue shoulder and elbow strengthening and flexibility exercises • Initiate interval throwing program
Phase IV: return to activity phase (weeks 12-16)	*Goal:* gradually return to sporting/functional activities. **1.** Week 12 • Return to competitive throwing • Initiate thrower's 10 exercise program (see Figure 9-35)

ROM, Range of motion; *PROM,* passive range of motion.

Throwing athletes can develop posteromedial osteophytes of the olecranon. This condition is different from the posterior osteophytes mentioned previously. One fourth of throwing athletes require instability surgery after excision of posteromedial osteophytes of the olecranon.[202] It is unclear whether a subtle preexisting instability caused these osteophytes and their removal unmasked the true nature of the injury or whether removal of the osteophytes was the primary pathology leading to instability. Regardless, this surgery is associated with instability, a factor that needs to be addressed in the rehabilitation process. Care must be taken to avoid valgus stress on the elbow. Medial and lateral rotation exercises of the shoulder should be avoided until 6 weeks after the operation. Thrower's isotonic exercises may begin at week 6, and an interval throwing program may begin by week 10.

Ulnar Collateral Ligament Reconstruction

Surgical reconstruction of the UCL attempts to restore the stabilizing functions of the anterior bundle of the UCL.[276] The palmaris longus or gracilis graft source is taken and passed in a figure-of-eight pattern through drill holes in the sublime tubercle of the ulna and the medial epicondyle.[276] An ulnar nerve transposition may be performed at the same time.[275]

The rehabilitation program the authors currently use after UCL reconstruction is outlined in Table 9-3. The patient is placed in a posterior splint with the elbow immobilized at 90° flexion for the first 7 days after surgery. This allows adequate healing of the UCL graft and soft tissue slings involved in the nerve transposition. The patient is allowed to perform wrist ROM and gripping and submaximal isometrics for the wrist and elbow. The

TABLE **9-3**

Postoperative Rehabilitation after Ulnar Collateral Ligament Reconstruction Using an Autogenous Palmaris Longus Graft

Phase I: immediate postoperative phase (weeks 0-3)	*Goals:* protect healing tissue; reduce pain and inflammation; retard muscle atrophy; protect graft site to allow healing. **1.** Postoperative week 1 • Brace: posterior splint at 90° elbow flexion • ROM: wrist AROM extension/flexion immediately postoperative • Elbow ROM: day 1 • Elbow postoperative compression dressing: 5-7 days • Wrist (graft site) compression dressing: 7-10 days as needed • Exercises: o Gripping exercises o Wrist ROM o Shoulder isometrics (no lateral [external] rotation of the shoulder) o Biceps isometrics • Cryotherapy: to elbow joint and to graft site at the wrist **2.** Postoperative week 2 • Brace: elbow ROM 25° to 100° (gradually increase ROM by 5° extension/10° flexion per week) • Exercises: o Continue all exercises previously listed o Perform elbow ROM in brace (30° to 105°) o Initiate elbow extension isometrics o Continue wrist ROM exercises o Initiate light scar mobilization over distal incision (graft) • Cryotherapy: continue ice to elbow and graft site **3.** Postoperative week 3 • Brace: elbow ROM 15° to 115° • Exercises: o Continue all exercises previously listed o Perform elbow ROM in brace o Initiate active ROM for wrist and elbow (no resistance) o Initiate light wrist flexion and stretching o Initiate active ROM for the shoulder: – "Full can" exercises – Lateral raises – Lateral rotation/medial rotation exercises with tubing – Elbow flexion/extension • Initiate light scapular strengthening exercises. • May incorporate bicycle workouts for lower extremity strength and endurance
Phase II: intermediate phase (weeks 4-7)	*Goals:* gradually advance to full ROM; promote healing of repaired tissue; regain and improve muscle strength; restore full function of graft site. **1.** Week 4 • Brace: elbow ROM 0° to 125° • Exercises: o Begin light resistance exercises for the arm (0.5 kg [1 pound]): – Wrist curls, wrist extensions, forearm pronation and supination – Elbow extension/flexion • Progress shoulder program; emphasize rotator cuff and scapular strengthening. • Initiate shoulder strengthening with light dumbbells. **2.** Week 5 • ROM: elbow ROM 0° to 135° • Discontinue brace. • Continue all exercises: o Progress all shoulder and upper extremity exercises (progress weight 0.5 kg [1 pound]) **3.** Week 6 • AROM: 0° to 145° without brace (i.e., full ROM) • Exercises: o Initiate thrower's 10 program o Progress elbow strengthening exercises o Initiate shoulder lateral rotation strengthening o Progress shoulder program

(Continued)

TABLE 9-3

Postoperative Rehabilitation after Ulnar Collateral Ligament Reconstruction Using an Autogenous Palmaris Longus Graft–Cont'd

	4. Week 7 • Exercises: o Progress thrower's 10 program (progress weights) o Initiate proprioceptive neuromuscular facilitation (PNF) diagonal patterns (light)
Phase III: advanced strengthening phase (weeks 8-14)	*Goals:* increase strength, power, and endurance; maintain full elbow ROM; gradually initiate sports/functional activities (specificity). **1.** Week 8 • Exercises: o Initiate eccentric elbow flexion/extension o Continue shoulder program (thrower's 10 program) o Initiate manual resistance PNF diagonal patterns o Initiate plyometric exercise program (two-handed plyometrics close to the body only): – Chest pass – Side throw close to the body o Continue calf and hamstring stretching **2.** Week 10 • Exercises: o Continue all exercises listed previously o Advance plyometrics to two-handed drills away from the body: – Side-to-side throws – Soccer throws – Side throws **3.** Weeks 12-14 • Continue all exercises • Initiate strengthening exercises on isotonic machines (if desired): o Bench press (seated) o Latissimus dorsi pull-down • Initiate golf, swimming • Initiate interval hitting program
Phase IV: return to activity phase (weeks 14-32)	*Goals:* continue to increase strength, power, and endurance of upper extremity musculature. Gradually return to sports/functional activities. **1.** Week 14 • Exercises: o Continue strengthening program o Emphasize elbow and wrist strengthening and flexibility exercises o Maintain full elbow ROM o Initiate one-handed plyometric throwing (stationary throws) o Initiate one-handed wall dribble o Initiate one-handed baseball throws into wall **2.** Week 16 • Exercises: o Initiate interval throwing program (phase I) (long toss program) o Continue thrower's 10 program and plyometrics o Continue stretching before and after throwing **3.** Week 22-24 • Exercises: o Progress to phase II throwing (once phase I has been successfully completed) **4.** Week 30-32 • Exercises: o Gradually progress to competitive throwing/sports o Functional activities

ROM, Range of motion; *AROM,* active range of motion.

patient is progressed from the posterior splint to an elbow ROM brace, which is adjusted to allow elbow ROM of 30° to 100° flexion. Motion is increased by 5° of elbow extension and 10° of elbow flexion thereafter to restore full ROM (0° to 145°) by the end of weeks 5 to 6. The brace is discontinued by weeks 5 to 6.

Isometric exercises are progressed to include light resistance isotonic exercises at week 4 and the full thrower's 10 program by week 6. Progressive resistance exercises are incorporated at weeks 8 to 9. Emphasis again is placed on developing dynamic stabilization of the medial elbow. Because of the anatomical orientation of the flexor carpi ulnaris and flexor digitorum superficialis muscles overlying the UCL, isotonic and stabilization activities for these muscles may assist the UCL in stabilizing valgus stress at the medial elbow.[277] For this reason, concentric strengthening of these muscles is performed.

Aggressive exercises involving eccentric and plyometric contractions are included in the advanced phase, usually weeks 9 to 14. Two-handed plyometric drills are performed by week 10, one-handed drills by weeks 12 to 14. An interval throwing program is allowed by week 16. In most cases, throwing from a mound is progressed within 4 to 6 weeks after initiation of an interval throwing program, and return to competitive throwing is permitted at approximately 9 months after surgery. The actual rate of progression of the throwing program should be individualized to each athlete and adjusted based on symptoms, mechanics, and desired goals.

Lateral Collateral Ligament Complex Reconstruction

Lateral-side instability of the elbow usually is the result of a sudden traumatic injury rather than a chronic repetitive injury. It results in varus instability and a PLRI that can be promoted with forearm supination. For this reason, special attention to elbow rotation is emphasized during the rehabilitation.

Initially, the postoperative elbow is placed in a splint with 90° of flexion and mild pronation. The splint is removed at the end of the first week (we immobilize for 2-4 weeks, depending on the type of activity to which the patient will return), and a brace is used that incorporates an extension block of 30° and a flexion block of 100°. Extension is increased by 5° per week, and flexion is increased by 10° per week. Supination encourages the radial head to sublux laterally, potentially stretching the graft. Therefore supination is restricted for 3 weeks. Active supination is allowed when the elbow passes 90° of flexion. Once supination is obtained at greater than 90° of elbow flexion, supination may be attempted in extension. Full motion about the elbow should be obtained by 6 weeks. Shoulder forward elevation and abduction may be treated aggressively for motion restriction, but medial and lateral rotation are limited to active motion only. Passive and active-assisted motion of the shoulder for rotation requires torque through the elbow and should be avoided until week 9.

Isometric strengthening exercises of the elbow and wrist are initiated once the splint has been removed. Lateral and medial rotation strength exercises for the shoulder are avoided until 9 weeks after surgery, because these motions put the graft at risk. Light isotonic exercises may begin about the elbow and wrist at week 6. At week 9, an aggressive strengthening regimen may commence, including eccentric contraction exercises and plyometrics.

Nerve glides (e.g., flossing) and scar massage are important to prevent pain from adherent scar after surgery. Scar massage should begin at 2 weeks, and nerve glides should commence once the appropriate motion has returned.

Total Elbow Arthroplasty

The complexity of TEA depends on the disease requiring the prosthesis, the type of prosthesis to be implanted, and the presence of soft tissue constraints. Despite these variables, the rehabilitation regimens for most total elbow arthroplasties remain relatively similar. The most popular prosthesis is a linked, semiconstrained prosthesis with joint stability that is quite solid. On the first postoperative day, the elbow is elevated to minimize soft tissue swelling. Motion in all directions may begin on postoperative day 1. Elbow flexion and extension and forearm pronation and supination may begin and can be progressed as tolerated. Lifting is limited to less than 0.5 kg (1 pound) for the first 3 months. To preserve the viability of the prosthesis, the patient is limited to lifting less than 4.5 kg (10 pounds) at one time and no more than 0.9 kg (2 pounds) repetitively in the affected arm.

Soft tissue mobilization, cryotherapy, and electrical stimulation help minimize inflammation. Scar massage and nerve glides help reduce the likelihood of problems associated with scar formation.

Arthroscopic Arthrolysis

Loss of motion is a difficult problem associated with injuries of the elbow. It can be a result of soft tissue contracture or HO associated with the injury. Often, the motion cannot be regained through conservative measures alone, and surgical intervention is necessary. The surgeon should inform the therapist of what motion has been obtained in the operating room so that realistic goals can be set.

Motion and pain control are at the forefront of rehabilitation for this procedure. HO represents a difficult rehabilitation problem. It has been reported that passive stretching outside the painless arc of motion may cause the generation of ectopic bone in patients with burns or brain injuries.[278] Whether this literature, in a rather unique population, is relevant to other patients with HO is unclear; however, caution is advised, and aggressive passive

motion exercises should not be performed. The goal is to obtain full motion by 4 weeks. The most beneficial means of achieving this goal has been the L3D technique described earlier. As with all the motion exercises, the stretching should not cause pain.

With arthrolysis for soft tissue contractures, the clinician may be more aggressive with motion exercises. Although the risk of generating HO may be in question, other problems may arise with aggressive rehabilitation. Aggressive motion can create an inflammatory cascade and generate pain that could inhibit progress, which would be self-defeating. The goal of establishing full motion at 4 weeks does not change with soft tissue contractures.

As with the other protocols, pain should be treated with cryotherapy, high-voltage electrical stimulation, and gentle soft tissue mobilization. Heat and therapeutic ultrasound may be used once the initial swelling from surgery has dissipated. These are used before motion exercises to "warm up" the joint.

Strengthening exercises should begin after motion has been established. There are no contraindications to an aggressive approach to strengthening once motion has been restored. Isometric exercises are begun and progressed to plyometrics in the usual fashion. Regardless of the origin of the contracture, stretching should be continued for 4 to 6 months after activities are resumed to prevent return of the contracture.

Fractures

The complexity of the fracture and the degree of stability after internal fixation can vary considerably in the elbow. Communication between the surgeon and all members of the rehabilitation team is essential to determine the aggressiveness of the rehabilitation process. Several different fractures about the elbow merit attention. The goal of rehabilitation after a fracture is to facilitate osseous healing, restore full motion and strength, and gradually return the individual to functional activities. With an elbow fracture (whether treated surgically or nonoperatively), the goal is to minimize immobilization to prevent loss of motion. Loss of motion is more common in adults than in children after an elbow fracture.

Radial Head and Neck Fractures

When fractures of the radial head and neck are nondisplaced, the injury may be treated conservatively and motion should be initiated immediately. Unlimited passive and active motion is the priority. This is achieved through the use of stretching techniques, as well as techniques for reducing swelling and pain, which have been mentioned earlier. The goal is to reestablish motion by 4 weeks. Strengthening about the elbow and wrist may begin once full motion has been established. Valgus stress should be avoided until the fracture has healed.

With displaced or angulated fractures, internal fixation may be necessary. In some cases, the fracture is beyond repair and requires replacement with a metal implant. With stable fixation or an implant, the elbow is placed in a posterior splint at 45° to 90° of elbow flexion for 10 days. Once the splint has been removed, motion exercises are initiated without limitation. Full elbow flexion and extension and forearm supination and pronation should be obtained by 4 to 6 weeks. Often patients present with mechanical blocks to motion. This may result in soft tissue contractures. With these patients, the goals for motion may be more limited. Valgus stress is avoided in patients with internal fixation until the fracture has healed. This is not necessary when a radial head prosthesis is used. Once full motion has been achieved, strengthening of the elbow and wrist may commence. If swelling and pain persist, cryotherapy and electrical stimulation may be used to limit these symptoms.

Olecranon Fractures

For most olecranon fractures, the treatment of choice is open reduction and internal fixation. Several fixation techniques yield a stable fracture, and rehabilitation should not have to be altered because of the type of fixation. Traditionally, a posterior splint is used for 7 to 10 days to allow the soft tissues to heal. The length of immobilization depends on the patient's variables (e.g., age, osseous status, health, desired goals, healing response). Once the splint has been removed, unlimited passive motion may begin. Active forearm pronation and supination and elbow flexion are allowed, but active extension is avoided for 6 weeks. Full motion in all directions should be achieved by 6 weeks. Gentle active extension may be initiated, and strengthening of the elbow and wrist in all directions may begin at 8 weeks.

As with all fracture fixations at the elbow, cryotherapy and electrical stimulation should be used to reduce pain and swelling. Scar massage should be initiated at 2 weeks, and nerve glides should be used when possible.

Distal Humeral Fractures

Distal humeral fractures usually require open reduction and internal fixation. If the surgeon has difficulty with stability, a hinged external fixator that allows elbow flexion and extension may be used, although this is not common. After fixation, a splint is used for 10 to 14 days. Once the splint has been removed, gentle passive motion at the elbow and wrist may begin. Pain and swelling are limiting factors in restoring motion to the elbow; therefore cryotherapy and electrical stimulation are crucial to this process. The clinician must take care with cryotherapy to avoid nerve injury, because ulnar nerve transposition is a routine part of distal humeral fixation.

Active motion at the elbow and wrist may begin at 6 weeks. Once full motion has been established and bony healing is apparent, strengthening may begin. Strengthening should be limited to pain-free exercises. It begins with isotonic exercises and gradually progresses to plyometrics.

Coronoid Fractures and Elbow Dislocation

After reduction of a dislocated elbow, the patient is temporarily immobilized to allow healing of the injured capsule. The length of immobilization varies, depending on the required use of the elbow for ADL or work activities, the type of sport or activity the patient takes part in, whether it is the dominant or nondominant elbow, the patient's age, and whether concomitant lesions are present. Coronoid fractures (see Figure 9-9) often put the patient at risk for future elbow instability. For this reason, the rehabilitation protocols for elbow dislocation and coronoid fractures are similar. The priority is to restore motion quickly while guarding against instability. The patient is placed in a posterior splint for 10 to 14 days in a position that allows no visible subluxation on radiographs. In the initial evaluation, the stable ROM is determined. The elbow will sublux with further extension; therefore parameters are set so that the initial restrictions do not permit extension beyond this point. When the splint is removed, a dynamic elbow brace that prevents valgus and varus forces is used. This splint should also have a variable locking mechanism that blocks various degrees of extension. The clinician may work on elbow flexion and forearm pronation without limitation. Passive extension may be increased by 10° every week until full extension is obtained. The patient should be closely watched for any evidence of subluxation. Often, with elbow dislocations, either the UCL or the LUCL may rupture. If the LUCL ruptures, supination should be limited for at least 3 weeks after removal of the splint. The goal is to restore motion by 8 weeks.

Motion of the wrist should be instituted immediately. Upon removal of the splint, control of pain and swelling must be established immediately to aid in the restoration of motion. As mentioned earlier, cryotherapy and electrical stimulation are beneficial. Gentle soft tissue mobilization also may help.

Strengthening may begin at 8 weeks. If the expected motion has not been achieved, strengthening should be delayed until the desired motion is obtained. Strengthening is performed in the usual fashion.

If the patient's clinical picture requires operative intervention, rehabilitation should be dictated by the procedure performed. LCL reconstruction, UCL reconstruction, and radial head fixation are common surgical procedures. If a coronoid fracture is present and fixed, it should not change the protocol; the other fixations present should guide the treatment.

SUMMARY

The elbow is a complex joint, and our understanding of it continues to evolve. The elbow is important for positioning the hand in space and for the specialized functions demanded of athletes and the everyday requirements of the general population. Many injuries and pathological conditions can affect the elbow and its associated bony and soft tissue. The rehabilitation of these injuries, as well as conservative and surgical treatments, has been reviewed, although the depth of these discussions has had to conform to the limitations on the length of the chapter. Clearly, the anatomy and biomechanics of the elbow guide our understanding of the pathophysiology of elbow injury and pain and help direct the treatment of elbow conditions. However, the elbow's response to trauma, even iatrogenic trauma, can be tricky, because stiffness or loss of motion is a common problem after such challenges.

CHAPTER 10

Hand, Wrist, and Digit Injuries

JENNIFER B. GREEN, CHARLES DEVEIKAS, HELEN E. RANGER, JOANNE G. DRAGHETTI, LINDSAY C. GROAT, EVAN D. SCHUMER, BRUCE M.LESLIE

"Most of the fundamental ideas of science are essentially simple, and may, as a rule, be expressed in a language comprehensible to everyone."

Albert Einstein

INTRODUCTION

The hand is one of the preeminent tools of human beings. The hand allows an individual to touch and take hold, but the anatomy allows much more than gross grasp and coarse sensation. The structure of the hand allows a musician to play with different shades of meaning; it allows an artist to apply subtle shades of texture; it allows a parent to convey meaning by touching a child. The hand can convey all these emotions. The inability to accomplish gross grasp and coarse sensation or the subtleties in these higher functions can affect the ultimate outcome of the patient.

The anatomy of the wrist and hand is not too difficult to understand. However, its compact nature and precision create a complexity in which subtle changes in the way tissues move in relation to one another can have a dramatic effect on function. Seemingly simple injuries that ultimately prevent tendon gliding can severely affect the ability to flex or extend the digits. Wounds that heal by secondary intention may be acceptable in some areas but in others may greatly diminish the ability to feel and move.

Insight into hand function arises from an understanding of the way in which anatomy, biomechanics, physiology, and wound healing work together to allow the hand to perform a myriad of tasks. This knowledge then needs to be tempered by the patient's expectations, needs, and socialization. An operation to restore hand function in one patient may be totally unacceptable to another patient. Each intervention needs to be customized to the individual patient.

Hand rehabilitation plays a critical role in restoring upper extremity function. The therapist is a crucial member of a team whose ultimate goal is to improve hand function. Not only does the therapist assist in promoting the restoration of the soft tissues to maximize function, in many cases the therapist is in the best position to recognize the patient's goals and needs. A good hand therapist is not only knowledgeable of upper extremity anatomy but also recognizes the social and psychological implications of the original injury and subsequent treatment.

This chapter presents a fundamental approach to the diagnosis and classification of wrist and hand injuries. It also includes treatment and rehabilitation guidelines for bone and soft tissue injuries of the hand.

FRACTURE INJURIES OF THE HAND

Phalangeal Fractures

General Considerations

Phalangeal and metacarpal fractures are among the most common skeletal injuries. In one large series of 11,000 fractures, these two injuries accounted for 10% of the total.[1] Modes of injury are predictable based on population age groups. Children and young adults are usually injured in sports-related activities. Young and middle-aged men are prone to work-related injury. Elderly patients are vulnerable to hand trauma from falls or accidents.[2] Unfortunately, these fractures frequently are treated as a trivial malady by both patients and health care providers. This can lead to a profound loss of digital and hand function, either from neglect or, worse still, from poorly executed treatment.

The force required to fracture one of the phalangeal bones also damages the soft tissue structures of the digit. This can lead to significant scarring and fibrosis in the postinjury period. Function can best be restored with early intervention by the treating physician and by allowing the patient to begin rehabilitation of the digit as soon as

stability permits. Studies have reported that immobilization for longer than 3 weeks leads to loss of total active range of motion (AROM).[3] Before the 20th century, treatment of phalangeal fractures was limited to nonoperative methods. Today, most of these fractures can be successfully treated in this fashion because most fractures are functionally stable either before or after closed reduction.

Indications for surgical intervention for phalangeal fractures include angulation more than 25° to prevent compromised digit flexion and extension[4]; malrotation; bone loss; open fracture; intra-articular fracture with displacement; associated soft tissue injury (skin, vessel, tendon, nerve); and multiple trauma to the upper extremity. The treating physician must also take into consideration the patient's age, occupation, ability to cooperate with the postoperative regimen, and the surgeon's experience and skill.

Indications for Surgery for Phalangeal Fractures

- Angulation greater than 25° and/or malrotation
- Bone loss
- Open fracture
- Intra-articular fracture with displacement
- Associated soft tissue injury
- Multiple trauma to the upper extremity

Anatomy

The proximal and middle phalanges are similar in their osseous anatomy. The distal phalanx is different in shape and in the specialized attachment of the nail bed to the dorsal periosteal surface. The soft tissue envelope can greatly affect the stability of the fracture, treatment of the injury, and the ultimate outcome. In the digits are found the osteocutaneous ligaments of Cleland and Grayson. These can serve to stabilize the bone and prevent fracture displacement. The ligaments can prevent closed reduction of a fracture if they are interposed between the displaced fragments. The proximal interphalangeal (PIP) joint and distal interphalangeal (DIP) joint are highly constrained hinged joints that do not tolerate even a small amount of fracture displacement. The metacarpophalangeal (MCP) joint has a less constrained configuration that allows for more lateral motion, some rotation, and slightly more forgiveness in terms of fracture displacement.

Injury Classification

Shaft fractures can be classified by their location, that is, in the neck, the midshaft, or the base of the bone. They can be further classified according to the fracture geometry; for example, the fracture may be spiral, transverse, short or long oblique, or comminuted. This characteristic can predict fracture stability and can help determine the best type of surgical treatment if fracture stabilization is required. The fracture can be further classified as open or closed, which is less than intuitive during the examination of a crushed distal phalanx and a nail bed injury that, for all intents and purposes, is an open injury.

Diagnosis and Medical Treatment

Fractures of the Distal Phalanx

Tuft Fractures. Tuft fractures are the most common fractures of the fingers[5] and are frequently the result of a crushing injury. A crush injury may result in comminuted fractures that fail to unite. Nonunion, however, does not usually lead to instability because the bone fragments are held tightly to the pulp tissue of the fingertip. An associated laceration of the nail matrix may be seen. Splinting for 1 to 2 weeks for comfort, with a rapid return to function, is the usual treatment course for this injury (Figure 10-1).

Repair of the nail bed is warranted if the injury causes wide displacement of that tissue. Replacement of the nail plate, if it still exists, creates a template for the nail bed to heal, provides protection for the sensitive tissues of the fingertip, and also serves as a splint for the underlying distal phalanx. Despite adequate treatment, the end result of this injury may be some loss of motion, decreased sensation, and chronic mild pain. These unfortunate sequelae are exacerbated by prolonged immobilization. In the case of the index finger, the phenomenon of *bypassing* (i.e., using a different finger) may be observed and should be addressed early in the course of treatment.

Shaft Fractures. Shaft fractures are either longitudinal or, more commonly, transverse in orientation. If displacement or angulation is present, they often are easily repaired. Displacement signifies an injury of the nail bed or germinal matrix, as well, which, if left untreated, can lead to nail plate deformity. If the dorsal cortex of the bone can be realigned and the overlying nail plate is also intact, the matrix will be sandwiched into the correct orientation for healing, and no further treatment likely is necessary. Displaced fractures are easily treated with a longitudinally oriented Kirschner wire (K-wire) or headless screw (Figure 10-2).

Figure 10-1 Snow blower injury, which resulted in multiple tuft fractures and fractures of the middle phalanx with overlying soft tissue trauma.

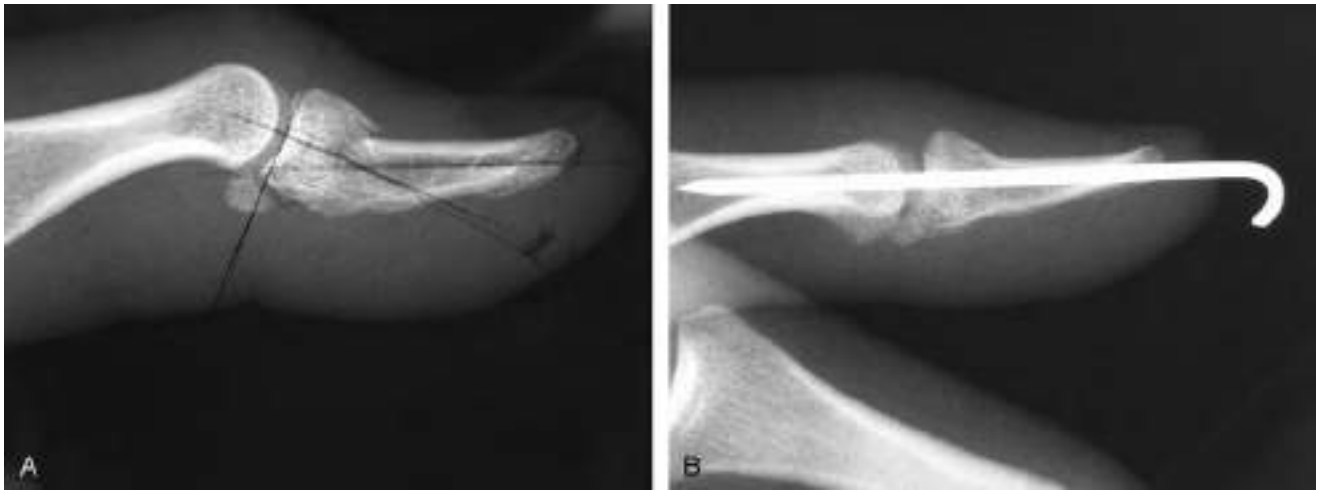

Figure 10-2 **A,** Angulated shaft fracture of the distal phalanx; the fracture has created a deformity of the digit that will affect the growth of the nail. **B,** Correction of the shaft fracture with a pin, which holds the bone aligned for 3 weeks. The pin subsequently was removed in the outpatient setting.

Intra-articular Fractures. Intra-articular fractures in adults usually involve either the volar or dorsal lip at the end of the bone. In children, an epiphyseal separation also may occur. Dorsal rim fractures usually are associated with a terminal tendon avulsion injury (sometimes called a *bony mallet injury*). If the dorsal fragment of bone is small enough, no volar translation of the distal phalanx occurs at the joint surface, and the injury can be treated in the same way as a soft tissue mallet injury, only with splinting. However, the larger the fragment, the greater is the potential that the flexor digitorum profundus (FDP) tendon, which is still attached to the volar fragment, will translate the distal fragment palmarly. This can be a subtle finding on the lateral x-ray film, and the possibility must always be considered with a fracture fragment of more than 30% of the joint surface. In such cases operative intervention to restore joint alignment is indicated (Figure 10-3).

Volar Lip Fractures. Volar lip fractures are also tendon avulsion injuries. In these fractures, the FDP tendon remains attached to the small fracture fragment. This type of injury is also known as a *rugger Jersey finger* or *sweater finger* because it commonly occurs when gripping to tackle an opponent in football or rugby. Unlike its counterpart on the extensor surface, these flexor tendon injuries frequently require surgery because the flexor tendon retracts toward the palm after injury, pulling the fracture fragment along with it. In these cases, if the fragment is more than a few millimeters in size, it is usually caught and held in place under one of the distal annular pulleys. The fragment usually can easily be found there and reattached surgically with a screw, suture anchor, or suture over a button.

Fractures of the Proximal and Middle Phalanges

Shaft Fractures. A direct blow frequently causes transverse fractures to the shaft, whereas twisting injuries cause spiral or oblique fractures. Whether or not displacement of the fracture occurs is determined by the location of the fracture and the influence of the intrinsic and extrinsic forces at that specific site.

Fractures of the proximal phalanx, when displaced, fall into apex volar angulation. This occurs because the insertion of interosseous muscles on the proximal fragment

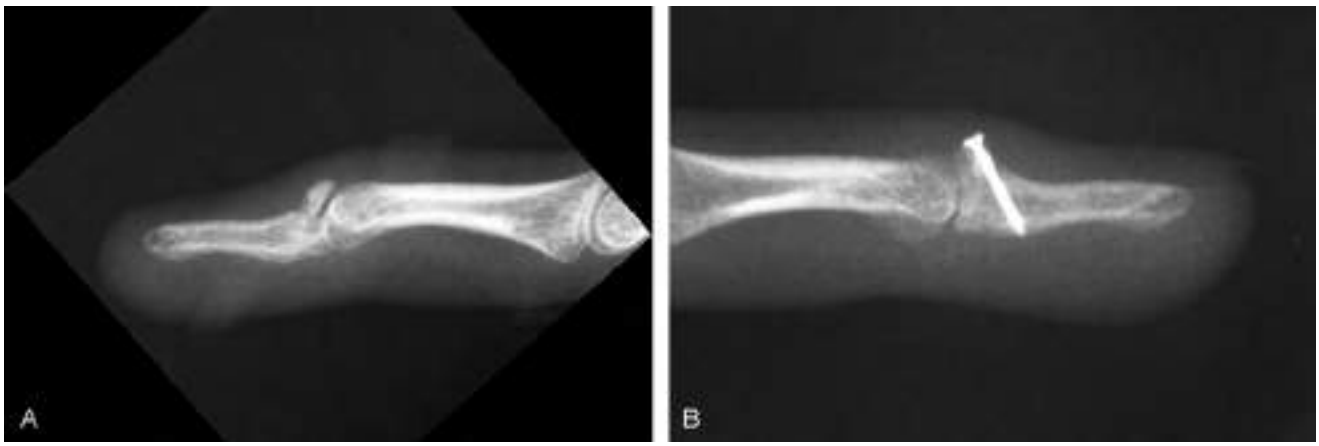

Figure 10-3 **A,** Bony mallet injury in which a large fracture fragment has caused volar displacement. **B,** Operative fixation is required to restore joint congruency. In the preoperative x-ray film, note that despite the splint, the joint is not congruent because of the volar translation of the distal fragment.

flexes the MCP joint while the pull of the lateral bands and central slip extends the distal fracture fragment.

Fractures of the middle phalanx are affected more by the pull of the central slip insertion and the flexor digitorum superficialis (FDS) tendon and therefore tend to angulate apex dorsally when they are displaced.

Rotational malalignment is poorly tolerated and is best assessed with active flexion of the digit, which may require digital block anesthesia for comfort. Tenodesis is preferable to passive motion for assessment of this type of deformity. Patients sometimes use the adjacent digits to "capture" the fractured finger, thus limiting their deformity. Care must be taken to observe for this during the examination to evaluate the true extent of digital scissoring from malrotation (Figure 10-4).

The majority of proximal and middle phalanx fractures are stable or will be stable after closed reduction, which often is the first course of treatment considered for these injuries. Significant stripping of the soft tissue from the bone makes reduction easier, but the fracture will be more unstable in the long run, often requiring implant augmentation. If closed reduction is not possible, the reason may be a bony spike caught on the soft tissue envelope. Most surgeons prefer to gain anatomical alignment of these fractures,[6,7] because any degree of malrotation and angulation over 25° can negatively affect hand function.[8,9] Closed treatment can be accomplished with digital block anesthesia in the office or operating room. Immediate postreduction x-ray films should be obtained, before immobilization, to confirm the reduction and stability. If satisfactory alignment is achieved, the usual treatment protocol is intrinsic plus splinting for 2 to 3 weeks, with weekly confirmatory x-ray films, followed by range of motion (ROM) with the affected finger buddy-taped. Dynamic or static progressive splinting and formal therapy are initiated at week 5 if motion fails to return toward normal.

K-wire fixation is used if there is loss of reduction, comminution, or inability to hold the initial reduction. The wires can be placed down the intramedullary shaft or across the fracture to affix adjacent cortices. In this way, transverse, oblique, and spiral fractures are all amenable to this treatment. Frequently K-wire fixation can be accomplished without a skin incision if the fracture is reducible by closed means. Intraoperative fluoroscopy is essential for proper pin placement and confirmation of the reduction in multiple planes. Midlateral placement of the pin or pins prevents interference with the flexor and extensor tendons and the neurovascular structures. Two pins are required for stability unless an intramedullary pin is used. The pins usually are removed at 3 weeks, when fracture tenderness subsides, to allow resumption of motion and stretching of the scar tissue (Figure 10-5).

Open reduction may be required even in simple fracture patterns if intervening soft tissue or a hematoma prevents reduction. In addition, comminution or an open fracture with bone loss may require open reduction for bone grafting or the application of stabilizing plates. K-wire fixation may be an acceptable alternative in some open cases. Long oblique and spiral fractures, however, are highly amenable to interfragmentary screw fixation. These fracture patterns may allow anatomical reduction and early return to motion with little interference from overlying gliding structures. Transverse and short oblique fractures cannot be treated with interfragmentary screws and must be held with a plate. Plates also can bridge gaps in the bone or secure a bone graft to the reduced fracture fragments and allow early motion. The downside to plate fixation in the phalanges is that scar adherence may cause the plate to interfere with tendon gliding. Also, some patients complain of persistent pain at the plate site, requiring removal of the hardware once the fracture is healed (Figure 10-6). External fixation currently is used less often, but indications for its use still exist (Figure 10-7).

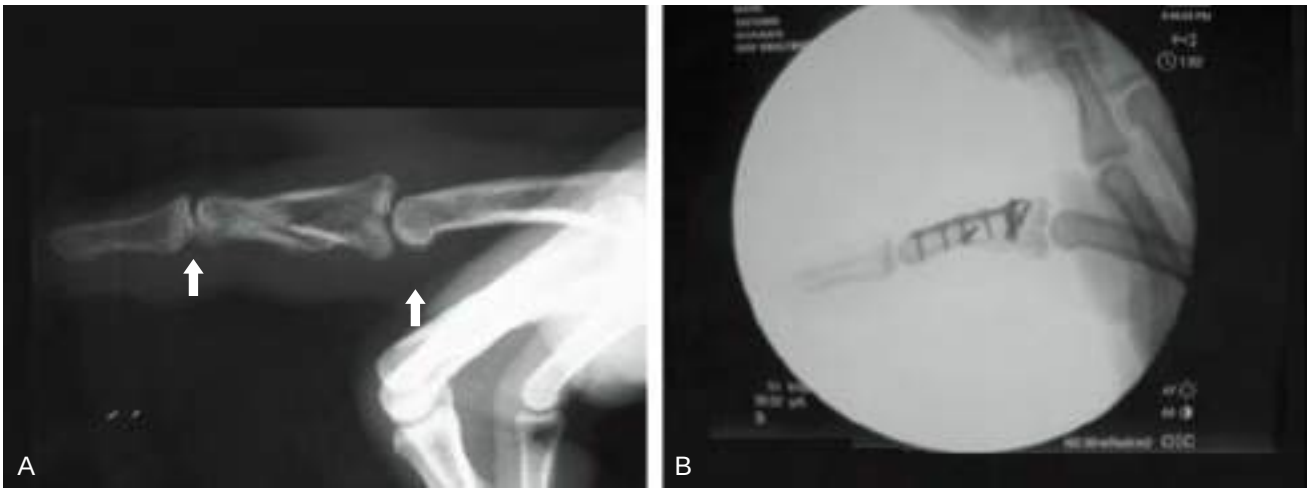

Figure 10-4 **A,** In the preoperative x-ray film, the distal aspect of the proximal phalanx is a perfect lateral, as evidenced by the complete overlap of the two condyles. This should also be true of the distal aspect of the middle phalanx; however, the fracture has caused a rotational deformity. **B,** A lateral fluoroscopic view obtained in the operating room shows the correction of the rotational deformity.

Figure 10-5 **A,** Low-energy transverse fracture of the proximal phalanx results in volar apex angulation. **B,** This simple fracture pattern requires only closed reduction and pinning to obtain anatomical alignment of the bone and to correct the secondary deformity at the MCP and PIP joints seen in the preoperative x-ray film.

Figure 10-6 **A,** Markedly unstable, comminuted, intra-articular fracture of the proximal phalanx. **B,** Plate fixation was required to obtain alignment and stability. Active range of motion was started on postoperative day 5.

Indications for External Fixation of a Fracture

- Fractures with marked comminution and soft tissue injury or that have been contaminated
- Fractures with significant soft tissue injury in which further dissection may compromise digit viability
- Fractures with a segmental defect in which length needs to be preserved until formal open reduction and internal fixation (ORIF) is done
- Temporary stability in a patient with multiple injuries

Articular and Periarticular Fractures

Unicondylar Fractures. Unicondylar fractures of the phalanges occur from a shearing force and tend to be unstable, falling into a shortened and malrotated position. This injury, although subtle, causes pain, deformity, and loss of motion. The collateral ligament remains attached to the fragment, causing it to rotate, creating an angular deformity and intra-articular incongruity. Often the fracture malalignment is best appreciated on a true lateral or oblique x-ray film because, on an anteroposterior (AP) x-ray film, it may appear only mildly gapped (Figure 10-8).

Unicondylar fractures are treated surgically because open reduction and fragment stabilization are required. Often the size of the fragments prevents the use of anything but a K-wire for fixation (Figure 10-9), but occasionally a larger fragment can be fixed with a screw.

Bicondylar Fractures. A bicondylar fracture occurs when a compressive load to the digit splits the head of the phalanx into two pieces and further separates it from the shaft. Each condylar piece is held by the collateral

Figure 10-7 Roller crush injury with extensive soft tissue and bony damage. The patient was a poor candidate for internal fixation; he presented with open wounds, infection, and unstable fixation. External fixation was the ideal treatment in this case because it allowed the soft tissues to heal and the infection to resolve, and it permitted eventual bone grafting and stabilization, which facilitated bony union.

ligament, which tends to separate and rotate them apart. These injuries usually require open reduction and internal fixation (ORIF); K-wires often are used, but they do not allow early motion. Newly devised plates allow early motion but can be difficult to use.

Pilon fractures occur with an axial load to the digit. Fracture of the dorsal and volar lip of the middle phalanx occurs, with loss of congruency and stability of the PIP joint. Dynamic external fixation uses ligamentotaxis (i.e., the use of the ligament to reduce the fracture) to restore overall joint alignment. The dynamic nature of the fixator allows early motion to promote joint congruency and cartilage health (Figure 10-10).

Rehabilitation Principles and Considerations for Hand Fractures

Fracture healing is the regeneration of mineralized tissue, which results in the restoration of bony mechanical strength. The primary concern during rehabilitation and before motion is initiated is the stability of the fracture. The ultimate goals of rehabilitation are (1) to produce pain-free, functional motion and strength and (2) to restore and optimize soft tissue balance and glide without disrupting the healing tissues.

The progression of rehabilitation is based on the stages of soft tissue and bony healing. Two well-documented progressions of fracture healing, described as primary and secondary healing, have been classified based on both the approximation and motion between the bone fragments.

Progression of Fracture Healing

- Primary healing
- Secondary healing

Primary Healing. Primary healing occurs when the fracture fragments are aligned and compressed so that no motion is allowed between the fragments. Motionless fixation of the fracture fragments is achieved through open reduction and internal fixation. The fixation hardware acts as a support matrix to provide immediate strength at the fracture site. Calcification and remodeling of the tissues, which are required for true fracture strength, generally take 6 weeks. Primary healing allows for early therapeutic intervention to initiate motion and soft tissue glide, to control edema, to address wounds, and to restore normal

Figure 10-8 The displacement seen with a unicondylar fracture of the phalanx is not as easily appreciated in the AP view as in the oblique view. The articular incongruity and instability of the fracture require operative treatment.

Figure 10-9 Fixation of a unicondylar fracture with K-wires.

neurological input to prevent guarding or avoidance of use. Primary healing does not allow for early strengthening because true fracture strength is not achieved until week 6 or later.[10,11]

Secondary Healing. Secondary healing takes place when the fracture fragments are approximated but not compressed, leaving a slight gap and/or potential for motion. Bone healing occurs through progressive stages in which callus formation is a precursor to bone.[10,11] Fractures primarily managed by closed reduction heal in these stages. Closed reduction is achieved through casting and semirigid fixation, such as K-wires, external fixators, and intramedullary pins.

Secondary healing progresses in three stages. The first stage, which lasts approximately 2 weeks, is the inflammatory stage. During this stage, high cellular activity occurs, which is required for ultimate healing. The healing tissues are at their weakest and are vulnerable to mechanical disruption. The fracture site requires protection and

Figure 10-10 **A,** Pilon fracture with loss of volar and dorsal bony stability of the middle phalanx at the PIP joint. **B** and **C,** It is critical to obtain PIP joint alignment and to begin motion early. This can be accomplished with dynamic fixators through ligamentotaxis.

immobilization by means of splinting or casting during the inflammatory stage.[10,11]

The second stage, the repair stage, occurs during weeks 2 through 4. During this stage, soft callus forms and stabilizes the fracture site. Splint protection continues, and controlled motion, tendon gliding, and edema management are initiated.[10,11]

During the third stage, which can last from weeks 4 to 6 up to 2 years, remodeling of the fracture progresses. During this stage, restoration of bone strength occurs. At this point, the tissues have regained enough strength to tolerate passive range of motion (PROM), stretching, splinting for motion, strengthening, and return to preinjury function. In general, as with primary healing, fractures progressing through the stages of secondary healing should not be subjected to strengthening exercises until weeks 6 to 8, when healing is confirmed (Figure 10-11).

Factors that can impede healing should be considered before increased demand is placed on a fracture through stretching, strengthening, or high demand activity. These include infection, prolonged steroid use, diabetes, anemia, osteopenia, and use of alcohol, nicotine, or caffeine.[12–16] Fracture healing is a dynamic process in which healing stages are progressive but overlap. Special care must be taken with patients with multiple trauma, in whom multiple fixation methods are used and who may have fractures that are progressing through both primary and secondary healing. Multiple trauma also causes significant soft tissue damage. Attention should be given to soft tissue healing, which takes place in a well-documented, staged healing process.[11,17–21] In devising a therapeutic approach and initiating therapy, clinicians involved in the rehabilitation of patients with these types of fractures should pay close attention to differences in the healing time frames for the various tissues involved.

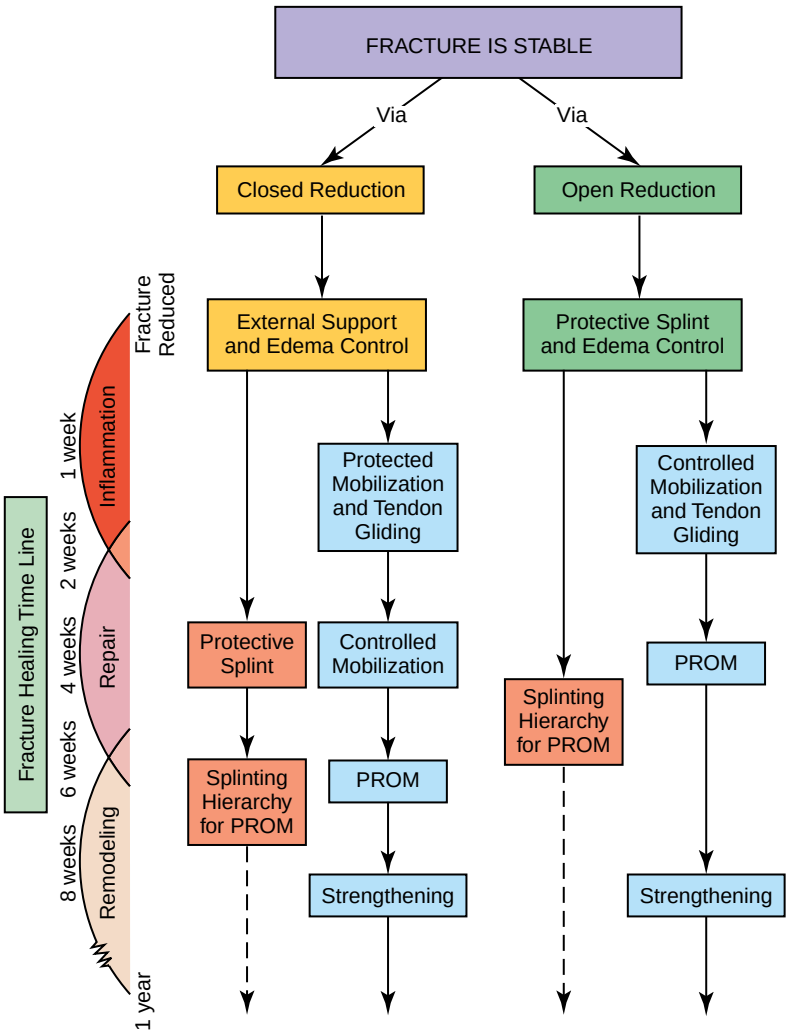

Figure 10-11 Algorithm for therapeutic management of a fracture. *PROM,* passive range of motion. (From LaStayo PC, Winters KM, Hardy M: Fracture healing: bone healing, fracture management and current concepts related to the hand, *J Hand Ther* 16:90, Copyright © Paul LaStayo, PhD, PT, CHT, 2003.)

Factors That Delay Healing

- Infection
- Prolonged steroid use
- Diabetes
- Anemia
- Osteopenia
- Use of alcohol, nicotine, or caffeine

The combined impact of soft tissue injury and the effects of immobilization creates challenges for both the treating physician and the therapist. Immobilization can cause a reduction in spacing and lubrication among collagen fibers, leading to reduced soft tissue gliding, shortening, and contracture development.[22] Muscle atrophy, with decreased extensibility and motion loss, is another documented effect of immobilization.[23]

Effects of Prolonged Immobilization

- Reduced soft tissue glide
- Soft tissue contracture
- Muscle atrophy
- Motion loss

The importance of direct communication between the surgeon and the therapist cannot be overstated. The most important information that determines the rehabilitation strategy is the stability of the fracture. Additional information that is significant for determining a therapeutic approach includes the type and location of the fracture and the fixation method or methods used to stabilize it.

Fractures of the Distal Phalanx. Rehabilitation guidelines for fractures of the distal phalanx can be found in Table 10-1. Therapeutic considerations are presented, taking into account the stage of healing and whether the fracture has been fixated (Figure 10-12).

Mallet Finger. Treatment of a bony mallet injury consists of continuous splint immobilization of the DIP joint in extension for 6 to 8 weeks (Figure 10-13). Care should be taken to avoid skin blanching on the dorsum of the finger with forced hyperextension. The remaining joints of the finger are left free. Immobilization promotes healing and scarring of the terminal tendon. Skin checks should be performed during the immobilization period to prevent complications from skin breakdown. Care should be taken to keep the DIP joint in full extension during skin checks.

Gentle active motion is initiated around week 8. Splinting is continued when the patient is not exercising. Blocking exercises (i.e., limited movement at one joint) should be avoided until week 10 to protect the oblique retinacular ligament (ORL) from stretching (the ORL assists in DIP extension with the PIP in extension) (Figures 10-14 and 10-15). Stretching and strengthening to increase motion are initiated at week 12. If a lag of more than 10° persists at week 8, continuous static splinting can be continued through week 16.[24]

Fractures of the Proximal and Middle Phalanges

Shaft Fractures. Table 10-2 presents details and considerations the clinician should keep in mind when

TABLE **10-1**

Rehabilitation Guidelines for Tuft and Distal Phalanx Fractures[24–27]

Healing Stages	Fractures Without Fixation	Fractures with Fixation
Stage I: Inflammatory stage (weeks 0 to 2)	Wound care and dressing changes: If the nail bed has been repaired, sterile dressing changes may be required every 24 hours using a gauze-covered petroleum or nonstick dressing (e.g., Xeroform or Adaptic) over the injury site Static and resting splint with DIP immobilization AROM of PIP and MCP joints	Fixation for 3 weeks Static resting splint to protect the fixation
Stage II: Fibroplasia and repair stage (weeks 2 to 4)	AROM of DIP joint Edema management is required Light functional tasks may be performed Splint is discontinued Protective padding with silicone is used Desensitization: Because of the high number of nerve endings in this region of the finger, patients often complain of cold sensitivity and hypesthesia for a prolonged period after this type of injury Blocking exercises for DIP joint	AROM of uninvolved joints Week 3: Progress as stage II of tuft fracture without fixation
Stage III: Remodeling and maturation stage (weeks 4 to 6+)	Functional progression Strengthening Splinting to increase motion	Functional progression Strengthening Splinting to increase motion

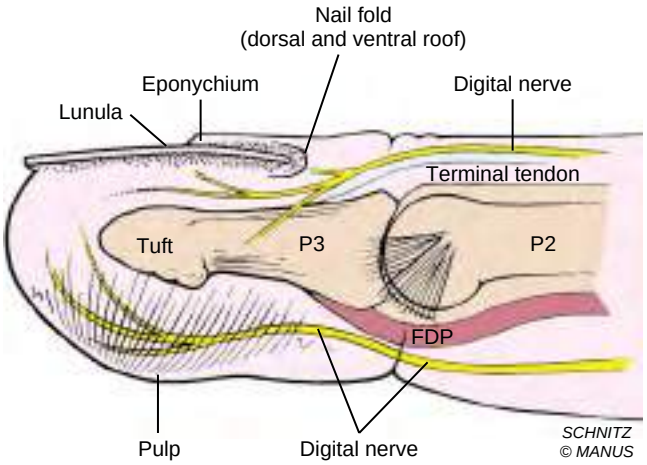

Figure 10-12 Schematic of the distal phalanx. The distal phalanx often is referred to as *P3*, the middle phalanx as *P2*, and the proximal phalanx *(not shown)* as *P1*. *FDP*, flexor digitorum profundus. (From Cannon NM: Rehabilitation approaches for distal and middle phalanx fractures of the hand, *J Hand Ther* 16:105-116, 2003.)

working with patients who have sustained proximal and middle phalanx fractures (Figures 10-16 to 10-18).

Articular and Periarticular Fractures. Initiation of motion after ORIF or percutaneous pinning of unicondylar and bicondylar fractures depends on the stability of the fragments after surgery.

With an early AROM program, a forearm-based dorsal block splint is fabricated for protection and worn for up to 6 weeks. Positioning within the splint may vary, depending on the injured structures and the surgical repair procedure. An AROM program begins on postoperative days 3 to 5, with the affected finger buddy-taped to the adjacent finger or fingers to prevent lateral or rotary stresses to the joint. Motion parameters differ, depending on the stability of the fracture and bony fixation. Limitations in both terminal flexion and extension may be necessary to protect the healing structures. Advancement in 10° increments per week should be done if the initial motion has been restricted. PROM, stretching, splinting for motion,

Figure 10-13 Custom splint for mallet finger. Similar prefabricated splints are available in a variety of designs and in the choice of thermoplastic materials used. A variation of the design shown is a simple clamshell splint in which thin perforated splinting material is brought up and around the tip of the finger, providing both dorsal and volar support to the DIP in extension. Although the middle phalanx is enclosed in the splint, the PIP joint is left free to move. If splinting materials are not available, a similar splint can be formed using aluminum strips covered with foam. In each case, strapping or tape around the middle phalanx portion of the splint is required for stability. Maintaining skin integrity is a prime concern with any type of splint. (From Tocco S, Boccolari P, Landi A et al: Effectiveness of cast immobilization in comparison to the gold standard self-removal orthotic intervention for closed mallet fingers: A randomized clinical trial, *J Hand Ther* 26:191-201, 2013.)

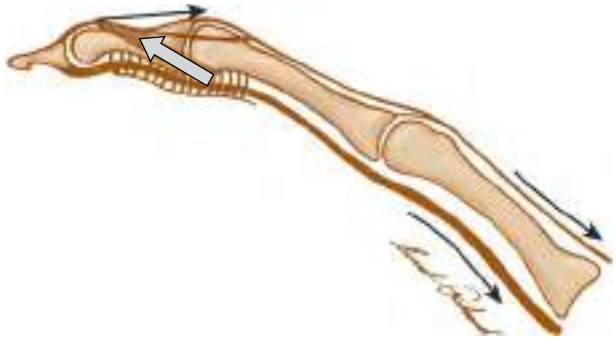

Figure 10-14 The ORL *(arrow)* arises from the volar lateral ridge of the distal tip of the middle phalanx and courses distally and dorsally to attach to the terminal tendon. (Redrawn from Tubiana R: *The hand*, Philadelphia, 1981, WB Saunders.)

Figure 10-15 Blocking of the metacarpophalangeal (MCP) joint in extension. **Note:** If the proximal interphalangeal (PIP) joint is blocked in extension and the distal interphalangeal (DIP) joint is flexed, a stretch is placed on the oblique retinacular ligament (ORL) which should be avoided until week 10. (From Skirven TM, Osterman AL, Fedorczyk JM: *Rehabilitation of the hand and upper extremity*, ed 6, Philadelphia, Mosby, 2011.)

TABLE **10-2**

Rehabilitation Guidelines for Fractures of the Proximal and Middle Phalanges[27–30]

Healing Stages	Fractures with Rigid Fixation	Fractures with Semirigid Fixation
Stage I: Inflammatory stage (weeks 0 to 2)	AROM is initiated on postoperative day 5 (pain level should be kept under 5 on a 1-10 pain scale) Edema management Soft tissue mobilization Splinting is done in the intrinsic plus position and includes the adjacent finger or fingers for added stability (hand or forearm based, depending on the fracture's site and stability and the patient profile) (see Figure 10-16) In the intrinsic plus position (MCP joint: 70° flexion; IP joints, straight): • Intrinsic muscles are placed at rest, reducing forces to the proximal phalanx • The extensor hood glides distally, providing compressive stability to a fracture of the proximal phalanx • The IP joints are held in extension, reducing force imbalances, which can lead to flexion contracture • The periarticular structures, including the MCP collaterals, the IP collaterals, and the PIP volar plate, are held in the optimum position for preventing flexion contracture	Fixation usually is removed at 3-4 weeks; midshaft fractures of the proximal or middle phalanx may take 1-2 weeks longer to heal Casting or splinting may be used for 3-6 weeks, depending on the stability of the fracture in the intrinsic plus position Forces should not disrupt, loosen, or dislodge wires or pins. The surgeon should be contacted if any change in the hardware occurs
Stage II: Fibroplasia and repair stage (weeks 2 to 4)	Tendon gliding exercises Blocking for differential flexor tendon gliding and extensor tendon excursion (see Figure 10-17) Light functional tasks begin at week 4 Protective splinting continues until week 6 Protective splinting or buddy taping for sports or high-level activity may be indicated until week 8, depending on the stability of the fracture	After 3-6 weeks of immobilization in a cast or splint: • AROM is initiated (with fractures of the middle phalanx, the pull of the FDS can put stress on the fracture fragments; therefore *gentle* AROM is indicated) • Protective splint in the intrinsic plus position is fabricated for wear between exercises and is used until week 6-8 • Light functional tasks are begun at week 4
Stage III: Remodeling and maturation stage (weeks 4 to 6+)	Functional progression Stretching Strengthening begins after fracture healing is confirmed at 6-8 weeks Splinting to increase motion (see Figure 10-18) Dynamic and/or static progressive splinting can be initiated at week 6 when healing is confirmed. Studies have shown the positive effects of prolonged stretching of a stiff joint and presented considerations for choosing dynamic versus static progressive splinting[31–34]	Functional progression Stretching Strengthening begins after fracture healing is confirmed at 6-8 weeks Splinting to increase motion

AROM, Active range of motion; *MCP*, metacarpophalangeal; *IP*, interphalangeal; *PIP*, proximal interphalangeal; *FDS*, flexor digitorum superficialis.

and strengthening occur at 8 weeks or when healing is confirmed.[30]

With hinged external fixation of a pilon fracture, motion is initiated within 3 to 5 days. If the external fixator does not lock into extension, a static resting extension finger splint is fabricated, and the patient wears it at all times when not exercising. The resting splint is removed for AROM exercises in the clinic and 3 to 5 times daily as a home program (Figure 10-19). External fixators generally are removed at week 6. Gentle strengthening and splinting for motion begin at week 8 or when healing is confirmed.

Traction splinting may also be used in the treatment of unicondylar, bicondylar, and pilon fractures. In some cases, ORIF to restore articular congruency is used in combination with traction splinting. The traction splint is fabricated using an outrigger. Outriggers can be custom fabricated or prefabricated. The finger is attached to the outrigger, which is designed to provide consistent traction to the PIP joint

Figure 10-16 Hand-based ulnar gutter static resting splint in the intrinsic plus position: MCP joints in 70° flexion; PIP and DIP joints, extended.

Figure 10-17 An MCP extension block splint promotes isolated IP extension.

Figure 10-18 Rehabilitation for proximal phalangeal fractures. Dynamic splinting **(A)**, serial casting **(B)**, and static progressive splinting **(C)** can be used to regain PIP extension and IP flexion. (**A,** From Canale ST, Beaty JH: *Campbell's operative orthopaedics,* ed 12, Philadelphia, 2013, Mosby. **B,** From Tang JB, Amadio PC, Guimberteau JC et al: *Tendon surgery of the hand,* Philadelphia, 2012, Saunders. **C,** From Freeland AE, Hardy MA, Singletary S: Rehabilitation for proximal phalangeal fractures, *J Hand Ther* 16:129-142, 2003.)

through an arc of motion. The traction reduces the fracture fragments through ligamentotaxis and restores optimal joint space for tissue healing and gliding (Figure 10-20). The optimal traction and motion parameters vary, depending on the fracture. Imaging and a tension gauge are used to measure appropriate traction on the tissues within a safe range. The splint usually is removed at week 6. After removal of the splint, a program of edema management, AROM and PROM exercises, differential tendon gliding, and stretching is initiated. Gentle strengthening and splinting for motion begins at week 8 or when healing is confirmed.[30] Management of fractures with external fixators or traction splinting requires direct, consistent communication with the physician. The risk of infection is a complication with external fixation or traction splinting.

Complications of fractures of the proximal and middle phalanges include soft tissue adherence of the flexor and extensor tendons. Moreover, the imbalance in strength between the flexor and extensor tendon forces creates an initial extensor lag (inability to fully extend actively). This lag can lead to a chronic flexion contracture of the PIP joint (Figure 10-21).[30]

Metacarpal Fractures

General Considerations

The metacarpals support the phalanges, ensuring the proper length for optimal function and balance between the extrinsic and intrinsic tendons of the hand. They also provide for the origin of the intrinsic muscles and the mobility

Figure 10-19 A pilon fracture of the ring finger is stabilized with finger-based dynamic external fixation, which allows for active PIP flexion and extension at day 3. The ring finger is buddy-taped to the long finger to provide increased stability to the PIP joint.

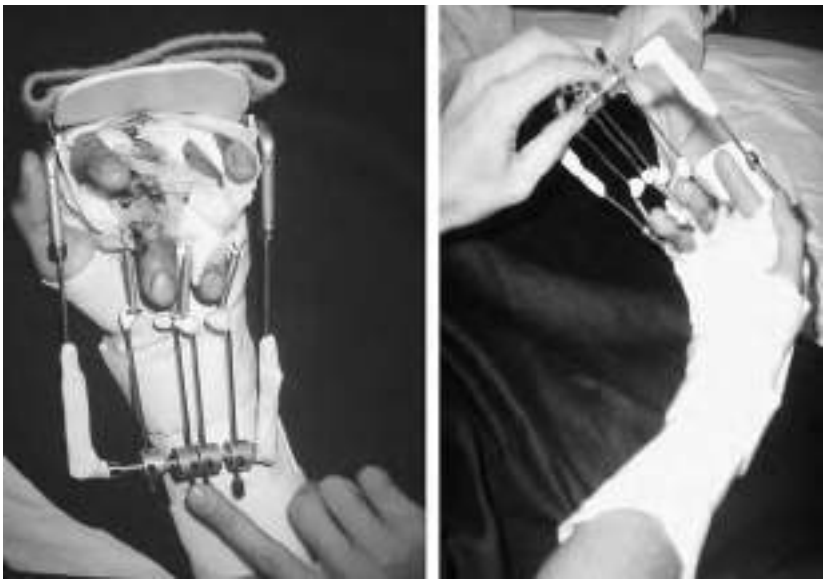

Figure 10-20 Custom-fabricated traction splint for traumatic PIP intra-articular fractures of the middle and ring fingers. This type of splint allows flexion and extension of the PIP joints. The fingers are attached to a custom-made outrigger by means of springs, which are hooked to surgically placed K-wires that exit through the skin from the middle phalanx, providing consistent traction through the available range of motion. The patient rests at night against the dorsal protective hood with the PIP and DIP strapped into extension. (External finger dressings have been taken down for clarity.)

obtained at the carpometacarpal and metacarpophalangeal joints. A change in the normal length and alignment of the metacarpals as a result of injury must be recognized and treated to prevent a loss in hand function. Fractures of the metacarpals account for up to one third of hand fractures, and fifth metacarpal fractures account for more than 50% of metacarpal fractures.[35] The goal of treatment is to regain stability with enough osseous length for correct tendon balance and to prevent the complications of soft tissue injury, tendon adhesion, and malalignment.

Anatomy

The anatomy of the metacarpals, specifically their articulations and muscle attachments, directly affects the injury pattern and the management of these fractures. The index and middle finger metacarpals articulate with the trapezoid and capitate bones, respectively. These carpometacarpal (CMC) joints have very little motion. The ulnar two metacarpals articulate with the hamate bone, which, with its relatively flat articular surface, allows for substantial motion both in flexion and extension and to a lesser degree in rotation. Because these metacarpals align with a joint allowing considerable motion in the plane of flexion and extension, more fracture malalignment can be accepted on this side of the hand. Deformity is much more obvious and difficult to compensate for in the two radial metacarpals, where little to no motion occurs at the CMC joints.

The deforming forces that displace metacarpal fractures are related to the crossing extrinsic tendons and the attachments of the intrinsic musculature. The intrinsic hand muscles, including the palmar and dorsal interossei, originate on the metacarpal shafts. The lumbrical muscles,

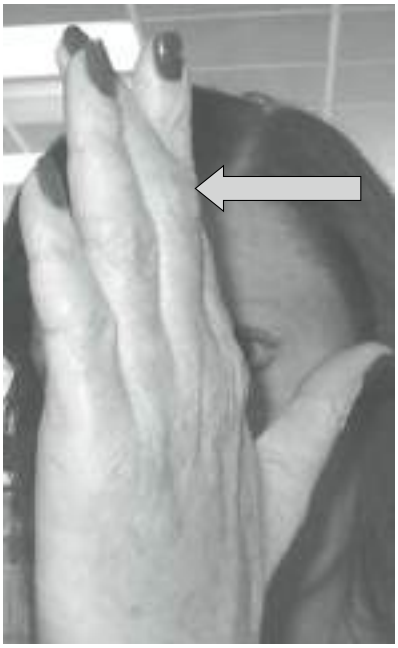

Figure 10-21 Flexion contracture of the long finger PIP joint.

originating from the tendons of the flexor digitorum profundi and the interossei, are the primary flexors of the MCP joint. The metacarpal bones act as a fulcrum for digital motion by stabilizing the phalanges against the pull of the flexor and extensor tendons. When these bones are fractured, the resulting disruption causes an imbalance in these forces, leading to specific patterns of deformity.

Diagnosis

Fractures of the metacarpal shaft generally are caused by a fall or direct blow to the hand. Neck fractures, particularly those of the fourth and fifth metacarpals, are the result of an axial load, such as when a fist strikes a hard surface. Areas of edema, ecchymosis, and tenderness should alert the examiner to the potential for an underlying fracture and should be thoroughly examined. Clinical suspicion should be increased if the patient has a gross deformity over the dorsum of the hand, loss of normal knuckle height or contour, and an alteration in the rotational alignment of the digits.

Rotational malalignment is best appreciated in digital flexion, and the injured finger or fingers should be examined under AROM, with use of a digital block if pain is limiting the evaluation (Figure 10-22). PROM is not reliable because the examiner may inadvertently alter the digital rotation while flexing the digit. Tenodesis active motion is better than PROM for an uncooperative patient who cannot actively range the digits. The clinician also must ensure the patient does not use an adjacent finger to "capture" and hold the affected digit "in alignment." The results of the examination should be compared with the findings for the contralateral hand. Plain x-ray films, including AP, lateral, and oblique views, are necessary to evaluate most metacarpal fractures, and special views occasionally are required (e.g., Brewerton, 20° pronation).

Figure 10-22 Malrotation of the little finger, caused by a metacarpal fracture, is best appreciated during active finger flexion. (From Skirven TM, Osterman AL, Fedorczyk JM: *Rehabilitation of the hand and upper extremity,* ed 6, Philadelphia, 2011, Mosby.)

Injury Classification and Medical Treatment

General Principles. Metacarpal fractures usually are discussed in terms of the location of the fracture, the pattern of the fracture, and the resulting deformity. Fractures can occur at the level of the metacarpal base, shaft, neck, or head. The pattern that results usually is secondary to the mechanism of injury; the fracture may be transverse, oblique, spiral, or comminuted (Figure 10-23). A direct blow usually produces a transverse fracture, whereas torsion of the digit causes a spiral or oblique fracture. Comminuted fractures result from higher energy injuries. Fracture deformity is described relative to changes in angulation, rotation, or length. Malrotation is problematic because, if not corrected, it may interfere with flexion of the adjacent fingers (referred to as *scissoring*). Malrotation of as little as 5° may cause 1.5 cm (0.6 inch) of digital overlap with flexion of the fingers.[36,37] An uncorrected angular deformity of the metacarpal shaft (usually a flexion deformity) not only results in a cosmetic concern; if severe enough, it may cause hyperextension at the MCP joint with resultant flexion at the PIP joint (e.g., clawing) (Figure 10-24). Metacarpal fractures with significant shortening may cause an imbalance of the intrinsic and extrinsic tendons with subsequent loss of full motion.

Management Approach. The management of a patient with a metacarpal fracture depends on a variety of factors. The location of the fracture, degree of displacement, angulation, and rotation all influence the acceptability of fracture alignment and also predict the likelihood that the injury will proceed to further displacement. The patient's age, occupation, general health, and concomitant injuries also must be considered.

Transverse fractures with minimal displacement usually have little potential for further displacement and are relatively stable. Treatment usually is nonoperative, consisting of immobilization in a plaster splint or cast for 3 to 4 weeks.[38] Displaced and unstable transverse fractures can be treated

Figure 10-23 Types of metacarpal fractures. **A,** Transverse. **B,** Spiral. **C,** Oblique. **D,** Comminuted.

Figure 10-24 Oblique x-ray film showing the secondary claw deformity that occurs at the MCP joint as a result of a flexion deformity of the metacarpal shaft at the site of the fracture.

with closed reduction and splinting or closed reduction and percutaneous pin fixation, depending on the perceived fracture stability at the time of evaluation and reduction.

Oblique and spiral fractures with a minimal amount of shortening and no malrotation can be treated nonoperatively with casting or splinting. If any malrotation or significant shortening is present, open reduction and fixation with interfragmentary lag screws is indicated. Short fracture lines may need the additional stability of a dorsal plate for resistance to torsional and bending stresses. Fractures of the index and small finger metacarpals have less inherent stability because they lack the suspensory effect of the intermetacarpal ligaments; therefore these fractures may benefit from the added stability of plate fixation.

Specific Metacarpal Fractures

Metacarpal Head Fractures. Fractures of the metacarpal head are a rare injury. They often are the result of an axial load or direct trauma, and they generally are

intra-articular. These fractures can be classified in terms of their descriptive characteristics: epiphyseal, ligamentous avulsion, osteochondral, comminuted, and compression fractures. Treatment of metacarpal head fractures is individually based on the type of fracture and the degree of displacement. Nondisplaced fractures are stable and can be treated with a short course of immobilization. Noncomminuted fractures with more than 1 mm of articular displacement or with joint surface involvement greater than 25% likely will require operative fixation in the form of ORIF using K-wires, interfragmentary screws, or headless screws.[39] Fractures that involve ligamentous avulsion and displaced osteochondral fragments can also be treated with open reduction and internal fixation (Figure 10-25). Comminuted intra-articular metacarpal fractures usually are the result of a higher energy injury. This makes them difficult to manage because of the surrounding soft tissue injury, the degree of bone loss, and the presence of small bony fragments. Treatment options include immobilization, ligamentotaxis through placement of an external fixator, or primary or secondary joint arthroplasty if the degree of bone loss and fragmentation prevents adequate reduction and stabilization.

Metacarpal Neck Fractures. Fractures of the metacarpal neck are common and usually occur in the ring and small fingers. The mechanism of injury commonly involves a flexed MCP joint striking a solid object, causing a neck fracture with apex dorsal angulation. This pattern of angulation occurs because the traumatic impact causes volar comminution at the level of the neck and also because the intrinsic muscles maintain the metacarpal head in a flexed position, leading to apex dorsal angulation. The CMC joints in the ring and small fingers allow more mobility than the CMC joints in the index and middle fingers, and they therefore compensate for a larger degree of angular deformity. The amount of angulation that can be tolerated without functional impairment varies throughout the orthopedic literature, ranging from 20° to 60° in the small metacarpal and 10° to 40° in the ring metacarpal.[40–42] Malrotation of a metacarpal neck fracture cannot be tolerated because it will affect the flexion ability of the other fingers and impair the ability to grip.

Treatment of metacarpal neck fractures depends on the stability of the fracture and whether a reduction will hold the fracture within the acceptable range of alignment. Closed reduction may be attempted, with subsequent immobilization. If the fracture remains reduced and stable and has no associated malrotation, immobilization may be the definitive treatment. If the reduction cannot be maintained because of fracture instability or comminution or if an unacceptable degree of angulation or rotation is present, closed reduction and fixation with K-wires or open reduction with plate and screw constructs may be necessary (Figure 10-26).

Metacarpal Shaft Fractures. Fractures of the metacarpal shaft are common injuries, and the management of these fractures must take into account several factors, including the fracture pattern, the degree of displacement, and the overall stability of the fracture.

Transverse fractures usually are caused by a direct blow or an axial load. Because of the deforming force of the intrinsic muscles, these fractures tend to fall into apex dorsal angulation. As with metacarpal neck fractures, a certain degree of angulation can be tolerated without compromising hand function. More deformity is tolerated in the small and ring finger metacarpals because of the larger degree of motion at their CMC joints. Angulation of the index and middle metacarpal shafts is not as well tolerated because of the limited motion at these CMC joints. The acceptable degree of angulation is the subject of debate in orthopedic literature. The acceptable degree of angulation for the ring and small finger metacarpals ranges from less

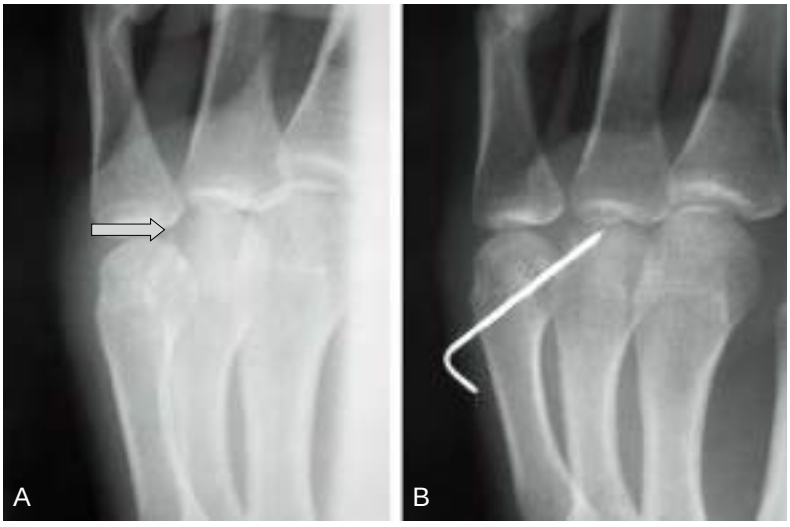

Figure 10-25 Osteochondral avulsion fracture **(A)** involving the ulnar collateral ligament and part of the articular surface in a thin section of bone fixed with a K-wire **(B).**

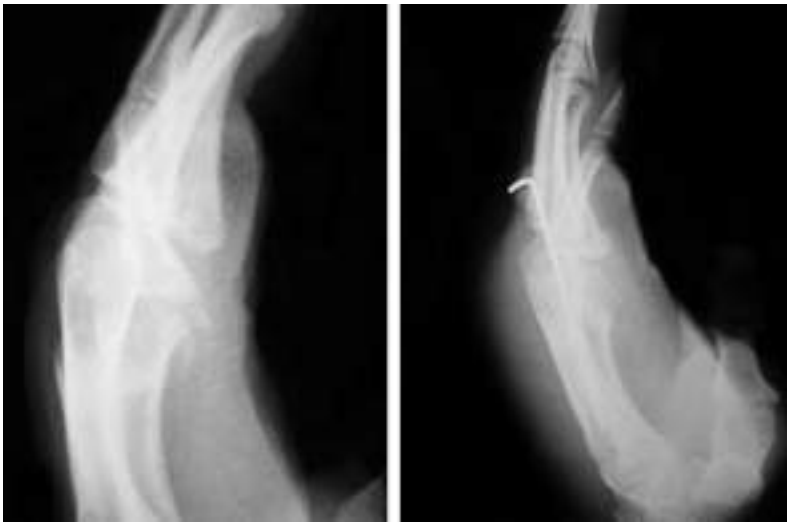

Figure 10-26 Preoperative and postoperative lateral x-ray films of a transverse displaced fracture of the fifth metacarpal. Note that in the preoperative view *(left)*, the metacarpal head does not align with the other metacarpals nor along the shaft of the fifth metacarpal, as it does in the postoperative view *(right)* after reduction and pinning.

than 20° to 40°, whereas the acceptable angulation for the index and middle metacarpals ranges from 0° to 10°.[38,43,44] Excess angulation causes prominence of the metacarpal head in the palm, which can make gripping uncomfortable; it also results in hyperextension of the MCP joint, causing limited MCP joint flexion and loss of grip.

Oblique and spiral fractures typically are caused by a torsional load. If these fractures are unstable, they tend to cause a rotational deformity. The presence of any degree of malrotation, regardless of the specific metacarpal involved, warrants reduction and stabilization; otherwise, the fingers will overlap, causing problems with digital flexion.

Comminuted fractures usually are caused by a high-energy force and often are associated with significant soft tissue injury. The clinician must include the integrity of the skin and soft tissue envelope as part of the treatment algorithm when determining management options. Comminuted fractures tend to cause shortening of the metacarpal because of the multiple small bone fragments and the overall unstable fracture pattern. Shortening of the metacarpals results in an imbalance of forces and compromised function of the flexor and extensor mechanisms. For every 2 mm of shortening, a 7° extensor lag of the MCP joint results.[45] The degree of acceptable shortening for metacarpal fractures is somewhat controversial, ranging from 3 to 6 mm in the orthopedic literature.[46–48]

Management of metacarpal shaft fractures is based on the degree of displacement, including angulation, malrotation, and shortening, and the stability of the fracture. In essence, the clinician needs to determine whether the fracture is acceptably aligned and whether it is likely to remain that way if treated by closed techniques.

For minimally displaced, stable fractures, nonoperative management with cast or splint immobilization is adequate treatment. However, surgical intervention is warranted if the fracture is unstable, if the resulting deformity compromises function, and in some cases when the concomitant injury necessitates correction. The surgical options for shaft fractures include transosseous percutaneous or open K-wire fixation, cerclage wires, intramedullary wire fixation, interfragmentary screws, plate fixation, and external fixation (Figure 10-27).

Transverse fractures with minimal displacement usually have little potential to further displace and are relatively stable. Treatment usually is nonoperative, consisting of immobilization in a plaster splint or cast for 3 to 4 weeks.[38] If the degree of angulation is unacceptable or the reduction cannot be maintained by nonoperative methods, operative fixation is warranted.

Oblique and spiral fractures with a minimal amount of shortening and without malrotation can be treated nonoperatively with casting or splinting. If malrotation, significant shortening, or instability is present, open reduction and fixation are necessary.

Metacarpal shaft fractures with significant displacement, angulation, rotation, or shortening that are still unstable after reduction attempts require either closed reduction with percutaneous pin placement or open reduction and internal fixation. Fractures may be closed, reduced, and pinned directly through the fracture site, or pins may be placed transversely through the metacarpal bone, with at least one proximal and one distal to the fracture site. Flexible intramedullary nail fixation is also an option, in which special rods or K-wires are placed through a small incision near the base of the metacarpal. The closed reduction and fixation technique is beneficial because it is less invasive than open management; however, controlling the rotation of the distal fragment is difficult with this method. Open reduction allows direct control of the

Figure 10-27 Previously seen as Figure 10-23, *C* and *D*, these oblique and comminuted fractures were treated with different operative techniques. The long oblique fractures *(left)* are amenable to interfragmentary screw fixation, which allows early range of motion with little interference from hardware. The more unstable comminuted fracture *(right)* requires the plate for rigidity. This allows early range of motion, but the hardware sometimes interferes with gliding structures.

bone and the potential for perfect anatomical restoration, albeit at the cost of increased trauma to the soft tissue envelope in the surgical approach. Also, rigid fixation may be obtained with interfragmentary compression screws or a plate and screw construct, allowing for earlier return to motion. With an open fracture or an injury with significant bone loss or contamination of the soft tissue envelope surrounding the metacarpal shaft, the best course of action is to rigidly stabilize the skeleton with the least trauma to the surrounding soft tissues. Often this can be accomplished most readily with external fixation.

Metacarpal Base Fractures. Fractures of the base of the metacarpal are often intra-articular and frequently are associated with subluxation or frank dislocation of the CMC joint. This fracture pattern is far less common in the index and middle finger metacarpals because of the tight bony geometry and firm ligamentous support at these CMC joints. On the ulnar side of the hand, an axially directed force causes a fracture of the metacarpal base, along with a proximal and dorsal subluxation of the fourth and fifth metacarpals relative to their articulation with the hamate. This fracture-dislocation can be difficult to visualize on plain AP or lateral x-ray films, and suspicion for this injury should alert the clinician to the need for 30° rotated x-ray views or possibly a computed tomography (CT) scan. This fracture is inherently unstable, and if it goes unrecognized or ignored, it may result in articular surface incongruity and possibly weakened grip strength and arthrosis.[49] These fractures may be treated with closed reduction and percutaneous pinning, but if reduction is difficult or inadequate, ORIF is indicated (Figure 10-28).

Thumb Metacarpal Fractures. The thumb accounts for 40% of hand function, and total disability of the thumb results in a loss of 22% of bodily function.[50] Fractures of the thumb metacarpal are common, accounting for 25% of all metacarpal fractures.[51] Thumb metacarpal fractures have the same type of classification and management options as the other types of metacarpal fractures, and the treatment of head, neck, and shaft fractures usually is similar to that for the digits. More angulation and rotation are tolerated in thumb metacarpal shaft fractures because of the large degree of compensatory motion at the thumb CMC joint.

Fractures of the thumb metacarpal base deserve unique consideration because of the frequency of intra-articular extension and the association of these fractures with CMC joint subluxation or frank dislocation. In order of increasing fracture fragmentation and instability, these fractures are **Bennett's fracture**, **Rolando's fracture**, and intra-articular comminuted fractures. The mechanism of injury is the same; all are the result of an axial load applied through a partially flexed metacarpal shaft. Bennett's fracture is a two-part fracture involving an avulsion of the thumb metacarpal from the volar ulnar aspect of the metacarpal base. The ligament attached to this fragment, the volar oblique ligament, keeps the small avulsed fracture fragment aligned to the joint while the remainder of the metacarpal shaft is subluxed. The deforming forces that create the subluxation include the thumb extensors, the abductor pollicis longus (APL), and the adductor pollicis longus. The pull of these muscles results in a dorsal, radial, and proximal subluxation of the thumb metacarpal shaft. Rolando's fracture is similar to Bennett's fracture, except that the metacarpal is broken into three pieces instead of two. An intra-articular comminuted fracture has additional fracture components and therefore is more difficult to treat. Because of strong deforming forces and bony

Figure 10-28 AP and lateral x-ray views of a fracture-dislocation of the fifth CMC joint. On the AP view, note the inability to see the joint space between the base of the metacarpal and the hamate, as well as the loss of the normal height cascade of the metacarpals. The lateral view shows the dorsal displacement of the base of the fifth metacarpal compared with the rest of the hand.

instability, these injuries tend to displace and therefore require operative fixation. The disrupted articular congruity may hasten the onset of post traumatic arthritis, which can lead to pain and functional compromise.

Thumb metacarpal fractures often are difficult to manage because of the degree of displacement and the involvement of the articular surface. The degree of articular incongruity that is acceptable without predisposing a patient to symptomatic post traumatic arthritis is the subject of controversy. Some authors believe that the articular surface must be restored as anatomically as possible (within 1 mm),[52,53] whereas others believe that good outcomes result with articular surface incongruity up to 2 mm.[54] When closed reduction can produce restoration of the articular surface, K-wires may be used to secure the reduction. If the articular surface remains significantly displaced after attempted reduction, open reduction and fixation are indicated to maintain length, using lag screws, plates, K-wires, or possibly an external fixator.

Rehabilitation of Metacarpal Fractures

Therapeutic intervention for metacarpal fractures differs, depending on the location and stability of the fracture. The progression of rehabilitation is determined by bony healing (see Figure 10-11). The major complication of these fractures is adherence of soft tissues as a result of injury, immobilization, and persistent edema. Soft tissues can adhere to extrinsic tendons, intrinsic muscles, and periarticular structures. Reduction of soft tissue glide can result in a lag and contractures at the MCP joint and secondarily at the PIP joint. The primary goals of rehabilitation are to restore and optimize soft tissue balance and glide, allowing pain-free motion and strength, while protecting the healing tissues (Tables 10-3 and 10-4).

Splinting Guidelines. Splinting is an essential element of the optimal management of metacarpal fractures. Guidelines for appropriate splinting vary, depending on the particular metacarpal fractured.

TABLE **10-3**

Rehabilitation Guidelines for Fractures of the Second Through Fifth Metacarpals[27,30,55–57]

Healing Stages	Fractures with Rigid Fixation*	Fractures with Semirigid Fixation†
Stage I: Inflammatory stage (weeks 0 to 2)	AROM tendon gliding exercises are initiated on postoperative day 5 (pain level should be kept under 5 on a 1-10 pain scale) Edema management Soft tissue mobilization Scar management with silicone Splinting	Casting or splinting for 3-6 weeks, depending on fracture stability, in the forearm-based intrinsic plus position

(Continued)

TABLE **10-3**

Rehabilitation Guidelines for Fractures of the Second Through Fifth Metacarpals—Cont'd

Healing Stages	Fractures with Rigid Fixation*	Fractures with Semirigid Fixation†
Stage II: Fibroplasia and repair stage (weeks 2 to 4)	Gentle blocking for flexor and extensor pull-through, including isolated EDC exercises and soft tissue mobilization of the scar	After 3-6 weeks of immobilization in a cast or splint: • AROM and tendon gliding are started • Gentle blocking and isolated EDC pull-through exercises are started • Protective hand-based splint in the intrinsic plus position (IP joints may or may not be included) is fabricated for use between exercises and is worn until week 6-8 • Hand-based ulnar gutter or radial gutter splint that leaves the MCP joints free is indicated for stable shaft and base fractures
Stage III: Remodeling and maturation stage (weeks 4 to 6+)	Week 4: Splint is reduced to a hand-based protective splint for use between exercises; it is worn until week 6 Protective splint for sports or high-level activity may be worn until week 8: • Protective, hand-based ulnar gutter or radial gutter splint with MCP joints included at 70° to 90° flexion, IP joints free • Hand-based ulnar gutter or radial gutter splint with MCP joints free is indicated for stable shaft and base fractures Light functional tasks are initiated Functional progression: high-level activities may be limited until week 8 Stretching begins for all tissues, including the intrinsics Strengthening begins after fracture healing is confirmed at weeks 6-8 Splinting to increase motion begins at weeks 6-8	Protective splint for sports or high-level activity may be worn until week 8 Light functional tasks begin at week 4 Functional progression: high-level activities may be limited until week 8 Stretching, including intrinsic stretching Splinting to increase motion begins at week 6, when healing is confirmed Strengthening begins after fracture healing is confirmed at weeks 6-8

Guidelines for Splinting Fractures of the Second through Fifth Metacarpals[26,30,56,58]

- The splint design is based on the location and stability of the fracture and the patient profile, including the individual's compliance with fracture healing precautions and activity level (Figures 10-29 and 10-30)
- The adjacent digit is included for added stabilization and to prevent rotational forces
- A circumferential splint is used (e.g., ulnar or radial gutter splint)
- For fractures of the metacarpal head, the forearm-based intrinsic plus position is used (i.e., wrist, 0° to 20° extension; MCP joints, 70° to 90° flexion; interphalangeal [IP] joints, 0° extension)*
- For fractures of the metacarpal neck, shaft, or base, a forearm-based splint is used with the wrist in 0° to 20° extension, the MCP joints flexed 70° to 90°, and the IP joints left free[30,56]
- For a stable shaft fracture, a three-point stabilization splint is used. This is a hand-based circumferential splint with counterforces that stabilize the fracture site. The involved finger is buddy-taped to the adjacent finger to prevent rotational forces to the fracture site[58]

*The intrinsic plus position (MCP joint flexed 70°, IP joints in 0° extension) allows the intrinsic muscles to relax, reducing forces on the proximal phalanx. The extensor hood glides distally, providing compressive stability to the metacarpal head fracture. The IP joints are held in extension, reducing force imbalances, which can lead to flexion contractures. The periarticular structures, including the MCP joint collaterals, the IP collaterals, and the PIP volar plate, are held in the optimum position to prevent a flexion contracture.[26]

Guidelines for Splinting Fractures of the First Metacarpal[26,30,55,56]

- The splint design is based on the location and stability of the fracture and the patient profile, including the individual's compliance with fracture healing precautions and activity level
- The design should prevent first web contracture
- The splint is circumferential, passing around the thumb, and is forearm based, as in a long-opponens splint
- For fractures of the head, shaft, or base, a long-opponens splint that includes the IP joint is used. IP motion is allowed after fracture stability has been confirmed by imaging

LIGAMENT INJURIES OF THE HAND

Ligament Injuries of the Digits

General Considerations

Stretching and tearing of the soft tissue constraints of the PIP joint are the most common ligamentous injuries in the hand. Sports, industrial mishaps, falls, and motor vehicle accidents account for most of these injuries.

Complete digital dislocations are quite painful, and the deformity is obvious enough that patients usually seek acute treatment; however, follow-up care for these injuries is surprisingly limited. Often patients are seen months later with chronic joint contractures, loss of tendon excursion, and swelling. By this time, they may require extensive therapy or even surgery. In the more acute stage, therapeutic intervention for these injuries is far simpler and more effective. Prompt treatment and immediate follow-up care are particularly important in a patient with an injury to the ulnar collateral ligament to the thumb (see later discussion). In the acute stage, the thumb may be quite swollen and ecchymotic, but no obvious deformity may be present, and in these injuries the acute symptoms improve over several days to a week. Unfortunately, if the ligament remains incompetent and untreated, a chronic painful condition develops perhaps months to years later, as does the potential for arthritis at the MCP joint.[59]

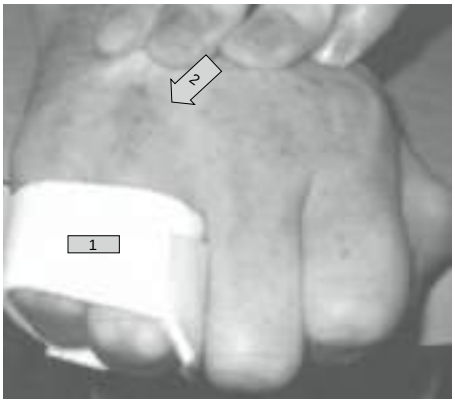

Figure 10-29 *1,* A flexion strap can be made to hold the IPs in flexion. The patient is asked to extend the MCP joints, which encourages isolated pull-through of the extensor digitorum communis (EDC). *2,* Applying pressure on the dorsum of the hand, pushing distally, while the exercise is performed encourages further separation from the scar tissue.

Anatomy

The PIP joint is a constrained hinge joint with tight articular congruency. The proximal phalanx is cam shaped and composed of a bicondylar head with a central groove. The double concave middle phalanx is divided in the midline by a bony tongue that guides the joint through its eccentric arc of motion (Figure 10-31).

The main lateral stabilizer of the joint is the proper collateral ligament, which is 2 to 3 mm thick. This ligament originates at the head of the proximal phalanx and inserts into the base of the middle phalanx. The proper collateral ligament is connected to the volar plate by the shroudlike fibers of the accessory collateral ligament. The collateral ligaments and the volar plate combine to act as a three-sided box that stabilizes the PIP joint through its arc, resisting hyperextension and lateral forces (Figure 10-32). In extension, the volar plate is tight and the collateral ligaments are relatively lax. As the joint flexes, the collateral ligaments are tightened over the bulge of the condyles; as a result, the base of the middle phalanx is firmly seated against the proximal phalanx.

Figure 10-30 Postoperative management of open reduction and internal fixation of a fourth metacarpal neck fracture **(A)** and pinning of a fifth metacarpal head fracture on day 5 after cast removal **(B)**. A custom-made, protective, forearm-based splint is fabricated to put the long, ring, and little fingers in the intrinsic plus positions; this allows active flexion and extension within the splint and prevents adherence of soft tissue structures. The design of this splint provides circumferential, maximum protection for healing fractures. The patient straps the fingers into the hood or roof of the splint for sleeping. A similar, hand-based version can be fabricated if less protection is needed.

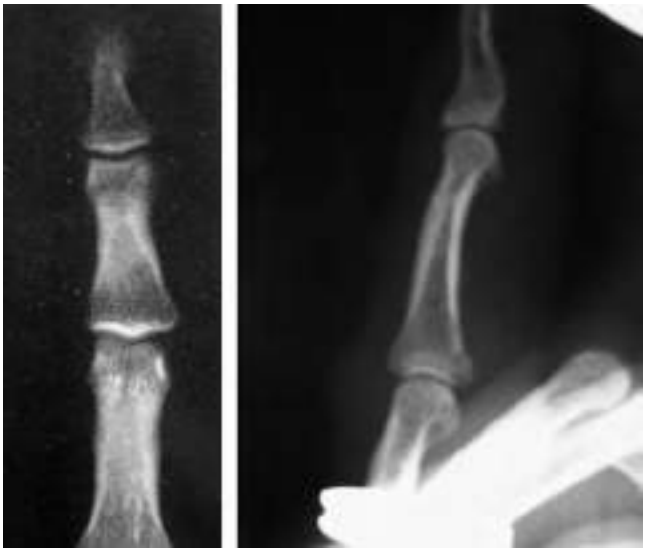

Figure 10-31 AP and lateral x-ray films of the PIP joint. The cam shape of the proximal phalanx is apparent on the lateral view. The tight, bony geometry of the joint can be appreciated on both views.

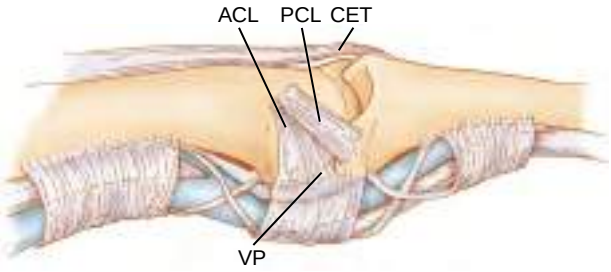

Figure 10-32 Lateral view of the PIP joint. The proper collateral ligament (*PCL*), accessory collateral ligament (*ACL*), volar plate (*VP*), and dorsal capsule with the central extensor tendon (*CET*) provide support to the PIP joint. Note that the ACL inserts into the volar plate, and the PCL travels distally and volarly to insert onto the bone of the middle phalanx. (From Skirven TM, Osterman AL, Fedorczyk JM: *Rehabilitation of the hand and upper extremity*, ed 6, Philadelphia, Mosby, 2011.)

The MCP joint has less bony constraint than the PIP joint because it does not have an intercondylar groove. The PIP joint is considered a "sloppy hinge" joint with only a small amount of motion outside of the sagittal plane (flexion/extension). Far more motion exists in the MCP joint for coronal plane (radioulnar deviation) and transaxial motion (pronation/supination). Despite the lack of bony constraint, the MCP joint is dislocated less frequently than the PIP joint. Its location at the base of the fingers and its surrounding supporting structures serve to protect the joint. The overall ligamentous arrangement of the MCP joint is similar to that of the PIP joint with certain subtle differences. Radial and ulnar proper and accessory collateral ligaments prevent lateral joint movement. These ligaments connect to a volar plate ligament that forms the stabilizing element to hyperextension on the volar portion of the joint.

The main differences in the ligamentous support structures of the MCP and PIP joints are (1) the volar plate of the MCP joint is highly mobile and does not become contracted, unlike the volar plate of the PIP joint, which easily becomes contracted over time, and (2) the distal insertion of the volar plate at the PIP joint is the weakest attachment, whereas in the MCP joint the weakest area of attachment is the proximal portion. Both of these points are clinically relevant. The first is that the position in which patients are splinted to prevent contractures is flexion of the MCP and extension of the PIP joints (Figure 10-33). The second is that dorsal dislocations of the PIP joint rarely interpose the volar plate into the joint, whereas this is more of a concern in the MCP joint.

Figure 10-33 The *intrinsic plus position* of splinting. Positioning the IP joints in extension and flexing the MCP joints to 70° or more prevents the development of contractures.

Injury Classification

Displacement of the MCP or PIP joint can occur in any of three directions, which are referenced by the position of the distal bone: volar, lateral, or dorsal. The direction of displacement aids the classification of the injury.

Diagnosis

Radiographic analysis of the injured digit is instrumental in the diagnostic evaluation of a joint dislocation or subluxation. Standard AP and lateral views of the digit are always warranted. Because the lateral view often is the most helpful, it is important to avoid overlap of the other digits in obtaining this view. Loss of concentric reduction of the joint can be subtle and can be seen only on a perfect lateral view of the joint; therefore the clinician must not settle for inferior x-ray films, particularly in type III injuries (Table 10-5), in which treatment might be affected by joint reduction.

It is important that the examiner first determine whether the digit is currently reduced. If the joint is anatomically located, the examiner should determine whether

TABLE **10-5**

Nonoperative Rehabilitation Guidelines for Dorsal Dislocation of the PIP Joint[27–29,70,71]

	TYPES OF DORSAL DISLOCATION			
	Type I	**Type II**	**Type III (Stable)**	**Type III (Unstable)**
Pathology	Disruption of the volar plate from the middle phalanx Minor disruption of collateral ligaments Joint is stable	Avulsion of the volar plate Major disruption of collateral ligaments Bayoneting of middle phalanx dorsally on top of proximal phalanx Unstable joint	Fragment is less than 30%-40% of the articular surface Collateral ligament remains attached to larger shaft of middle phalanx but is not attached to small fracture fragment After reduction joint is stable	Fragment is more than 30%-40% of the articular surface Collateral ligament remains attached to smaller shaft of the volar fracture fragment No ligament support to the dorsally displaced midphalanx With concentric reduction, PIP joint is stable in flexion
Healing Stages				
Stage I: Inflammatory stage (weeks 0 to 2)	Static IP extension splinting	Static IP extension splinting Alternative: Dorsal block splint at 30° flexion, progressed 10° weekly to week 3-4 Adjacent digit is included and buddy-taped Full motion within the splint is allowed	Hand-based dorsal block splint at 10° to 45° PIP flexion (usually 30°) for 4 weeks, progressed 10° of extension weekly Adjacent digit is included and buddy-taped to prevent lateral stress to the joint Buddy taping ROM within the splint	Hand-based dorsal block splint with PIP joint in flexion to weeks 4-6 When x-ray films confirm a stable PIP flexion position, 5° to 10° is added to the flexion angle to protect the reduction Adjacent digit is included and buddy-taped to prevent lateral stress to the joint Buddy taping ROM within the splint
Stage II: Fibroplasia and repair stage (weeks 2 to 6)	Buddy taping for 2-6 weeks to protect against hyperextension AROM Blocking exercises Edema management with Coban or a compression sleeve Soft tissue mobilization	Buddy taping for 2-12 weeks to protect against hyperextension and lateral stress AROM Blocking exercises to maintain ORL length and tendon gliding exercises Edema management with Coban or a compression sleeve Soft tissue mobilization Static IP extension splint is worn at night	Dorsal block splinting continues Edema management techniques should not place lateral stress on the PIP joint If Coban wrap is used, use 5 cm (2 inches) and make a sleeve that can be removed easily	Dorsal block splinting continues Edema management techniques should not place lateral stress on the PIP joint If Coban wrap is used, use 5 cm (2 inches) and make a sleeve that can be removed easily
Stage III: Remodeling and maturation stage (weeks 6 to 8+)	Strengthening as tolerated at weeks 6-8	Splinting for motion as tolerated at weeks 6-8 Strengthening as tolerated at weeks 8-12 Night static splint continues	Buddy taping for up to 12 weeks for protection Blocking exercises to maintain ORL length Tendon gliding exercises Edema management with Coban or a compression sleeve Soft tissue mobilization Static IP extension splint is worn at night Strengthening is begun at week 12+ as tolerated	Buddy taping for up to 12 weeks for protection Blocking exercises to maintain ORL length Tendon gliding exercises Edema management with Coban or a compression sleeve Soft tissue mobilization Static IP extension splint is worn at night Strengthening is begun at week 12+ as tolerated

PIP, Proximal interphalangeal; *IP,* interphalangeal; *ROM,* range of motion; *AROM,* active range of motion; *ORL,* oblique retinacular ligament.

AROM in flexion and extension causes joint instability and, if so, at what point in the arc of motion. If the joint is stable throughout AROM, passive stability is tested. Each collateral ligament is gently stressed, and the examiner looks for pain and instability.

Medical Treatment

Volar dislocation of the PIP joint is an extremely rare injury. The mechanism usually involves rotation and axial loading of a partly flexed digit. This results in the rupture of at least one of the collateral ligaments and part of the volar plate. The middle phalanx then displaces volarly, causing the distal aspect of the proximal phalanx to move dorsally through the extensor mechanism. This most often occurs with the proximal phalanx rupturing through the interval between the central slip and one of the lateral bands. Less often, the proximal phalanx moves directly dorsally, disrupting the attachment of the central slip on the base of the middle phalanx (Figure 10-34). The latter mechanism produces loss in continuity of the extensor mechanism, which results in a closed boutonniere deformity. After reduction of the joint, the clinician must be sure to evaluate the extensor function at the PIP joint and treat any loss accordingly with extension splinting, as a closed boutonniere injury would be treated. Closed reduction of a volar dislocation can be difficult, especially when the proximal phalanx protrudes through the interval between the central slip and the lateral band. Flexion of the MCP and interphalangeal (IP) joints with the wrist held in extension to relax the extensor apparatus may allow manipulation and closed reduction; otherwise, an open reduction may be required. Once the joint has been reduced, assuming that the extensor mechanism is intact, the ligaments should fall back into anatomical alignment without the need for surgical intervention. Management therefore is aimed at regaining motion and limiting scar formation while protecting the joint from additional injury.

Lateral dislocation of the PIP joint constitutes a rupture of one of the collateral ligaments and at least a partial tearing of the volar plate. The diagnosis is confirmed with stress testing of the joint that indicates more than 20° of deformity.[60] With reduction of the joint, the collateral ligaments and volar plate return to their anatomical locations. By virtue of its bony congruency, the joint should allow for AROM without instability that enables the patient to begin a protected therapy program. The most common complication of this injury is not late instability but rather arthrofibrosis with loss of joint motion. Therefore it is imperative to begin regaining motion, reducing swelling, and manipulating the scar process early to achieve the best possible outcome for the patient.

Dorsal dislocation is the most common of the three types of PIP injuries and occurs when a longitudinal force coupled with some extension is applied to the digit. Basketballs and footballs are frequently the culprits in this injury mechanism. The distal aspect of the volar plate is disrupted, and the interval between the accessory and proper collateral ligaments is torn, allowing the middle phalanx to ride dorsally up on the proximal phalanx. The injury is further classified into three categories that depict increasing energy and further damage and instability of the joint.

In a type I injury (see Table 10-5), hyperextension results in the avulsion of the volar plate from the middle phalanx and a minor longitudinal split in the collateral ligaments. In severe cases, the middle phalanx may be locked in 70° of hyperextension.

A type II injury involves an avulsion of the volar plate plus a major bilateral collateral ligament tear that allows complete bayoneting (overriding) of the middle phalanx on top of the proximal phalanx (Figure 10-35).

When the longitudinal force is great enough to produce shearing of the volar rim of the middle phalanx, a fracture-dislocation occurs. This is a type III injury, which differs from the previous two patterns. As the middle phalanx begins to ride dorsally over the proximal phalanx, the volar rim is fractured off. This type III injury is subclassified simply into two types, stable (type IIIA) and unstable (type IIIB) (Figure 10-36). In a stable dorsal fracture-dislocation of the PIP joint, the fracture fragment is small (i.e., less than 30% to 40% of the articular contour of the joint). In this case the collateral ligaments are not attached to the small fracture fragment but remain

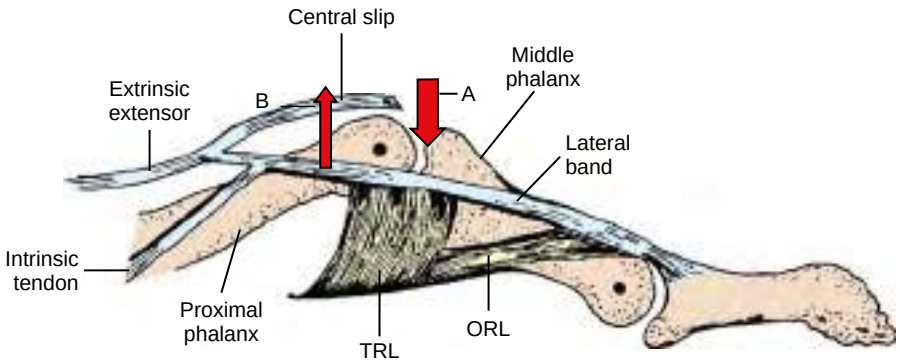

Figure 10-34 Anterior proximal interphalangeal joint dislocation. **A,** Anterior translation of middle phalanx. **B,** Proximal phalanx gets caught between the central slip and the lateral band, which usually is not disrupted from the middle phalanx as depicted here. *TRL,* Transverse retinacular ligament; *ORL,* oblique retinacular ligament. (From Coons MS, Green SM: Boutonniere deformity, *Hand Clin* 11:389, 1995.)

Figure 10-35 Lateral x-ray film of a type II dorsal dislocation of the PIP joint, showing complete overlapping of the bones. This often is an open injury.

attached to the larger shaft fracture. An unstable dorsal fracture-dislocation involves a disruption of more than 40% of the joint. In this instance the collateral ligaments remain with the volar fracture segment. The dorsally displaced shaft no longer has any soft tissue constraint or bony buttress to contain the joint (Figure 10-37).

Type I and type II dorsal PIP dislocations are stable injuries (type II requires reduction). The patient may be splinted for comfort for up to 2 weeks and must take care to avoid excessive flexion of the IP joints, which could promote the formation of a flexion contracture. ROM with the affected finger buddy-taped is then begun, and therapy is initiated to control edema, reduce scar formation, and gain motion.

Type III dorsal dislocations with fracture of the volar rim of the middle phalanx are higher energy injuries. In the stable subtype (type IIIA), the joint is congruent on a lateral x-ray film. The patient is treated with 1 to 2 weeks of immobilization. If a small amount of joint incongruence is present, the joint can be flexed slightly to obtain alignment in a dorsal block splint. ROM with the finger buddy-taped for protection is begun after the period of immobilization.

Multiple treatment options are available for type III dorsal dislocations with a large, unstable fracture fragment (type IIIB). These include a dorsal block splint, ORIF, a dynamic external fixator, volar plate arthroplasty, fusion, silicone arthroplasty, and hemihamate reconstruction of the PIP joint, using bone obtained from the patient's joint between the hamate and the metacarpal.[2]

A dorsal block splint is used if the dislocated joint can be concentrically reduced by some degree of flexion. Beyond this, the joint remains stable in any amount of further flexion. The clinician confirms the position of the stable concentric reduction and creates a splint adding 5° to 10° of further flexion for safety. Extension to this point is allowed with full active flexion. Each week, the splint is adjusted to increase the extension 10°, and x-ray films are taken to confirm that the reduction is maintained (Figure 10-38).

Open reduction and internal fixation is a technically demanding procedure because the bone fragment to be fixed is quite small and frequently more comminuted than it appears on x-ray films. However, if the fragment can be fixed with a screw, rehabilitation can be started much sooner, and the best results are obtained (Figure 10-39).

Dynamic external fixation uses forces to counteract those that displace the intra-articular fracture.[61] The attachment of rubber bands or other dynamic traction forces to pins implanted temporarily into the bone reduces the joint while allowing it to move through an arc of motion to prevent contracture and to facilitate healing of the cartilage (Figure 10-40).[62] Therapy is provided throughout the immediate postoperative period to prevent tendon adherence and joint contracture. The device usually is removed 4 to 6 weeks later, when the joint is stable enough to move without fear of late dislocation.

Volar plate arthroplasty is a technique for inserting the torn distal end of the volar plate into the fractured base of the middle phalanx to reestablish ligamentous attachment to the base of the middle phalanx. The volar plate serves to prevent hyperextension of the joint and to provide a smooth contour for the joint for motion; also, over time,

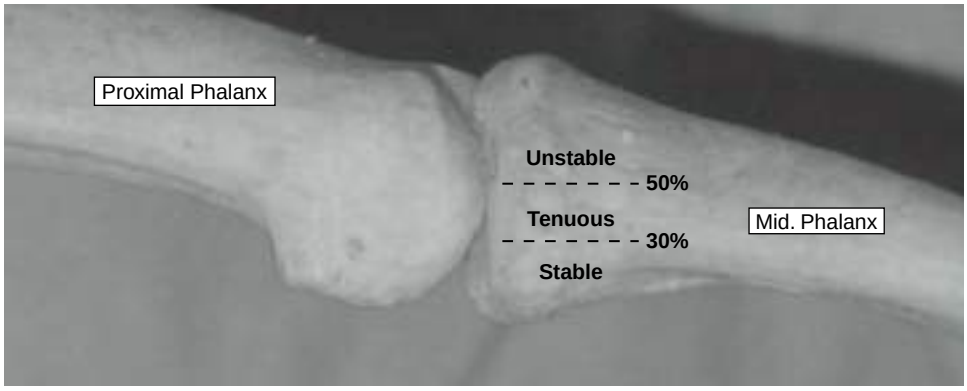

Figure 10-36 The level of the fracture determines the stability of the joint. A large fracture fragment causes a loss of volar support at the PIP joint. With a large volar fragment of bone, the insertions of the collateral ligaments are still attached to the fragment. This leaves the shaft of the middle phalanx without the support of the collateral ligaments or the volar bone at the PIP joint.

Figure 10-37 Clinical example of a type IIIB fracture-dislocation of the PIP joint. In this case, because the fracture fragment is large, the joint no longer remains congruently aligned. This can be appreciated by the V shape formed by the intact middle phalanx and the proximal phalangeal head.

Figure 10-38 A dorsal block splint can be used to allow motion within the stable range for types IIIA and IIIB dorsal fracture-dislocations at the PIP joint.

it has been shown to metaplase (convert) into a more normal-appearing bony joint surface.[63] In the immediate postoperative period, the joint must be protected from extension, which can tear the repair apart. To regain motion, AROM of extension can be attempted at 4 weeks and PROM of extension at 6 weeks (Figure 10-41).

Silicone arthroplasty is a viable primary option for an older patient with an already arthritic PIP joint who has sustained an unstable fracture-dislocation of the PIP joint.[64] In this case, rehabilitation, return to function, and pain issues are greatly simplified by a primary arthroplasty of the joint (Figure 10-42). The caveat with this procedure is the index finger; in this digit, forces from lateral pinch with the thumb are too great for a

Figure 10-39 In this rare case of a volar fracture-dislocation, the insertion of the central slip has avulsed, which allows the middle phalanx to sublux on the proximal phalanx. Screw fixation allows concentric joint reduction and immediate return to motion.

silicone arthroplasty, which will fail. In this unique situation a primary fusion of the PIP joint might be the better course, if the patient's MCP function is adequate. Therapy proceeds as for a primary arthroplasty performed from the volar approach (the extensor mechanism is spared, but the collateral ligaments have been resected or, in this case, torn).[64]

Collateral Ligament Injuries of the Thumb

General Considerations

Injury to the ligaments of the thumb occur most commonly at the MCP joint in ball-handling sports and, even more frequently, from falls during skiing; this injury therefore generally is called *skier's thumb*. In the 18th and 19th centuries, tearing of the ulnar collateral ligament was an attritional injury attributed to the work of Scottish game wardens and was known as *gamekeeper's thumb*. This often is how a hyperextension, abduction, and radial deviation event that occurs with ball contact or a fall with a ski pole in the hand allows the thumb to strike directly into the ground with the weight of the body forcing the thumb radially. Radial collateral ligament injuries occur less frequently, usually in ball-handling sports, and are easily overlooked. Either type of injury, if severe, causes significant bruising and swelling. The patient also may have considerable pain that lasts several days. The pain usually resolves, as does the swelling, with local anti-inflammatory treatment. The rapid resolution of swelling and pain has led many patients to believe that this is a trivial injury that does not require treatment. Unfortunately, this belief can lead to poor outcomes, including chronic laxity, pain, and the onset of MCP joint arthrosis (Figure 10-43).[59]

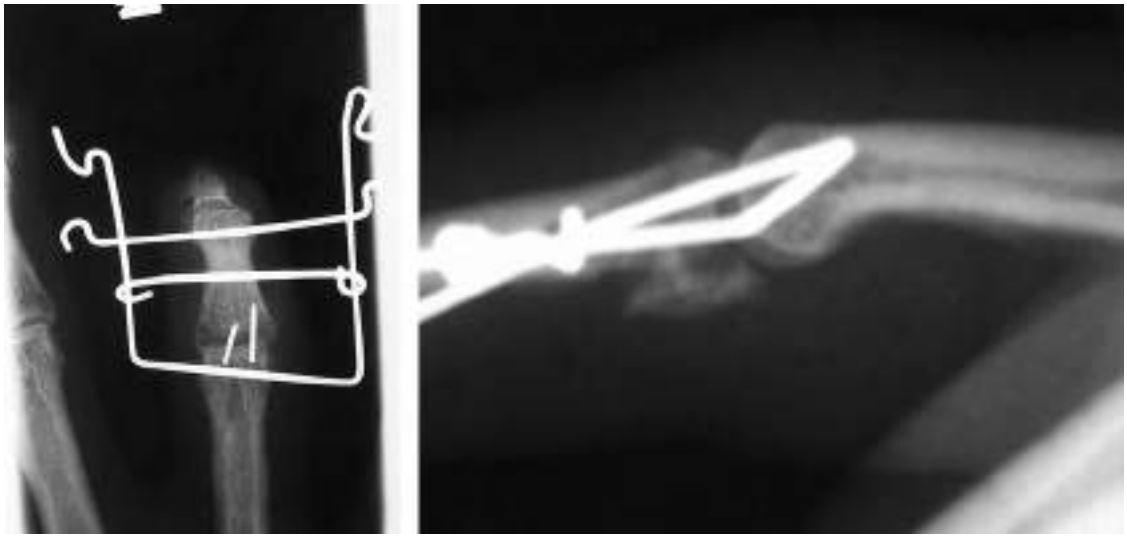

Figure 10-40 Ligamentotaxis can be used to regain joint congruency and allow for motion. This prevents joint subluxation and allows fractures of the middle phalanx to remodel using the intact proximal phalanx as a template during the healing process.

Figure 10-41 Representation of a volar plate arthroplasty. In this operation the volar plate is detached distally and reinserted into the fracture site to reestablish the smooth contour of the joint. The fibrocartilage of the volar plate metaplases into bone, reestablishing a bony joint with a concentric rim for the phalangeal head.

Figure 10-42 Replacement arthroplasty. Newer materials recently have become available that may outlast silicone, particularly for higher demand patients. (Courtesy B.M. Leslie, MD.)

Anatomy

The MCP joint of the thumb is primarily designed to allow flexion and extension. However, some degree of abduction and adduction, as well as rotation, can occur. The shape of the joint is condyloid, with the proximal phalanx behaving like an inverted golf tee sitting on a golf ball (i.e., the metacarpal head). Some people have far more round metacarpal heads than others; therefore the amount of flexion and extension at the joint varies considerably from patient to patient. Radial and ulnar deviation (abduction/adduction) and rotation are limited by both static and dynamic constraints. The primary stabilizers to ulnar and radial motion are the proper collateral ligaments, which originate at the lateral condyles of the metacarpal head dorsal to the axis of rotation. These ligaments pass obliquely and distally to insert on the proximal phalanx volar (anterior) to the axis of rotation. Along the volar aspect of the proper collateral ligament is a shroud-like attachment, the accessory collateral ligament, which connects the proper collateral ligament to the volar plate of the joint. This arrangement creates a three-sided box configuration between the two collateral ligaments and the intervening volar plate, similar to that seen at the PIP joint in the digits (see Figure 10-32). Dynamic support of the joint is created by the adductor pollicis muscle, which inserts into the ulnar sesamoid at the base of the MCP joint, and the flexor pollicis brevis and abductor pollicis brevis (APB) muscles, which insert onto the radial sesamoid bone at the base of the MCP joint. These muscles are intrinsic to the thumb, and they flex the MCP joint and extend the IP joint by way of attachments to the extensor mechanism. They also create dynamic stability to radial and ulnar stress, respectively.

Injury Classification

Collateral ligament injuries of the thumb can be classified in the same way as ligamentous injuries to other parts of the body, such as the ankle and knee. Grade I

Figure 10-43 AP and lateral x-ray films showing chronic laxity of the ulnar collateral ligament of the thumb at the MCP joint. Note the radial deviation of the thumb at rest, as well as the volar subluxation of the joint. These factors, in addition to some rotational malalignment, have created the incongruence that has caused joint destruction.

injuries consist of stretching of the collagen fibers within the ligaments without macroscopic fiber tearing. Grade II injuries involve further deformity of the collagen fibers, with tearing of some portion of the ligament, but overall continuity remains. Grade III injuries are the most severe and show disruption of the collagen fibers, which results in discontinuity of the ligament.

In addition to the tearing of the collateral ligament, the dorsal capsule and the volar plate on the same side as the ligament injury usually are also partly disrupted. Furthermore, the ligament may avulse a portion of the proximal phalanx at its insertion. The fracture fragment usually does not represent a large segment of the articular surface, but on rare occasions it may be as large as 10% of the joint. The clinician cannot assume that the ligament is attached to the small fragment of bone. The presence of a nondisplaced small fracture fragment does not exclude the possibility of a displaced ligament; studies have reported that the two can be present simultaneously.[65]

When the injury involves the ulnar collateral ligament (UCL) at the MCP of the thumb, a unique situation can arise with grade III injuries. As was first described in 1962, the adductor aponeurosis can be interposed between the distal end of the avulsed ligament and the proximal phalanx, holding it in a displaced position.[66] This is known as a *Stener lesion,* and it has important implications in both diagnosis and treatment (Figure 10-44).

Diagnosis

Diagnosis begins with the history and careful attention to the mechanism of injury. The amount of swelling and ecchymosis can alert the examiner to the degree of damage to the soft tissues. If the injury is more chronic and the swelling has receded, the resting posture of the thumb (i.e., both its angle and its rotational alignment) provides clues to the amount of ligamentous disruption.

With a grade III UCL injury, the thumb rests in radial deviation. Also, because of the loss of the ulnar ligament and dorsal capsular support, the thumb tends to rotate around the intact radial collateral ligament in a supinated position. In a complete tear of the radial collateral ligament, the opposite is found.

Tenderness to palpation is noted over the torn ligament, and swelling and induration are present at the site of the ligament injury. With a Stener lesion, a palpable hard mass is felt that is asymmetrical to the patient's other thumb; this is the displaced distal end of the UCL (Figure 10-45). If x-ray films have confirmed that no fracture is present, gentle stress testing should be performed to assess ligament competence. It is imperative to differentiate a grade III injury from either a grade I or grade II tear. A grade III injury shows 30° more instability to radial stress testing than is seen on the patient's opposite side. In addition, usually no firm end point is noted in the stress test.[67,68] Testing should be done with the joint in full extension and in 30° flexion. Clinicians should practice on normal thumbs to get an idea of what a normal end feel is like. Patients often contract the muscles to guard against the pain of stress testing. The clinician must be alert for this, and if the patient is too uncomfortable to reliably relax for the examination, a local anesthetic injected around the torn ligament usually suffices to allow stress testing. Stress x-ray films have little use in the diagnostic process. Alternative imaging studies, including ultrasound and magnetic resonance imaging (MRI), can be performed to delineate the position of the ligament.

Medical Treatment

Differentiation of partial and complete ligament tears is critical. With grade I and II injuries, the ligament remains in its anatomically correct position. In this situation, protection of the ligament with a thumb spica cast for

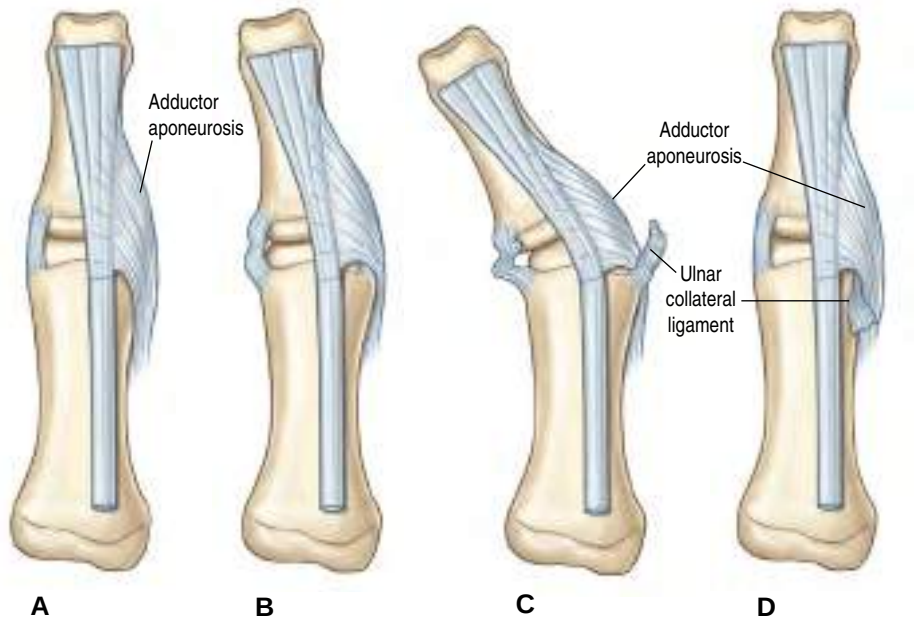

Figure 10-44 Stener lesion: Diagram of the displacement of the ulnar collateral ligament of the thumb metacarpophalangeal joint. **A,** Normal relationship, with the ulnar ligament covered by the adductor aponeurosis. **B,** With slight radial angulation, the proximal margin of the aponeurosis slides distally, leaving part of the ligament uncovered. **C,** With major radial angulation, the ulnar ligament ruptures at its distal insertion. With this degree of angulation, the aponeurosis has displaced distal to the rupture, allowing the ligament to escape from beneath it. **D,** As the joint is realigned, the proximal edge of the adductor aponeurosis sweeps the free end of the ligament proximally and farther from its insertion. This is the Stener lesion. Unless surgically restored, the ulnar ligament will not heal properly and will be unstable to lateral stress. (From Chang J, Neligan PC: *Plastic surgery*, vol 6, *Hand and upper limb*, ed 3, London, 2013, Saunders.)

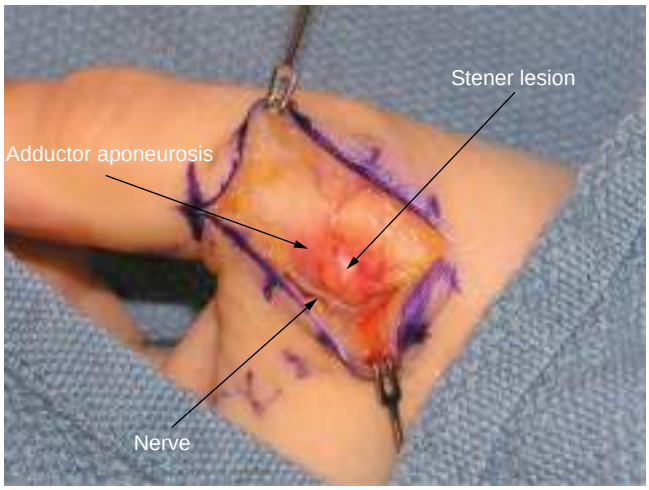

Figure 10-45 Surgical view of a Stener lesion. The ulnar collateral ligament has been torn from its distal insertion on the proximal phalanx. It now is reflected back on itself, resting superficial and proximal to the adductor aponeurosis (it normally is located deep to this structure). Note the nerve encountered during this surgical approach; injury to or irritation of this nerve can result in postoperative symptoms.

4 to 6 weeks, followed by a return to motion rehabilitation program, generally leads to excellent results. In the case of complete ligament disruption, the question arises whether the ligament is anatomically positioned and will heal under conservative management. Clearly, if a Stener lesion can be felt, the answer is no, and some clinicians believe that it is best to surgically fix all grade III injuries so that a displaced ligament is never missed.

In a ligament tear, the torn tissue generally avulses from the bone and can be directly repaired with sutures through drill holes or with the use of small bone anchors. The volar plate and dorsal capsule are repaired at the same time.[69] Four to six weeks of casting is completed before therapy commences.

If a small fracture fragment is associated with the avulsion, the surgeon may choose to discard the fragment and repair the ligament into the cancellous bony bed. However, if the fracture fragment represents a substantial portion of the joint surface, direct repair of the bone with small screw fixation is preferable. It is critical that the tiny sensory nerve branches be protected in the dissection because these can be a source of debilitating pain postoperatively. Even under the gentlest of circumstances, therapists frequently must spend time desensitizing these nerves from the traction endured during the procedure.

Rehabilitation of Proximal Interphalangeal Joint Injuries and Ulnar Collateral Ligament Injuries of the Thumb

Proximal Interphalangeal Joint Injuries

Both the tight articular congruency of the PIP joint and the soft tissue constraints that surround it contribute to the joint's stability. The soft tissue stabilizers include the joint capsule, the proper and accessory collateral ligaments, the volar plate, and the flexor and extensor tendons.

The rehabilitation treatment strategy takes into consideration the direction and type of fracture–dislocation,

which soft tissue structures are implicated, and whether the joint is stable or unstable. Patients often can assist the clinician by describing the mechanism of injury and PIP joint positioning immediately after injury. The direction of the dislocation is based on where the middle phalanx sits in relation to the proximal phalanx.

Rehabilitation strategies are geared toward maintaining joint stability while mobilizing the soft tissues. Restoring and optimizing soft tissue gliding and mechanics are prime considerations. The goal of treatment is to regain and preserve soft tissue and joint mobility while preventing the development of adhesions, joint flexion contractures, deformities, and loss of function. Progression of the treatment program depends on the healing stages of both the soft tissue and bony structures; edema management, soft tissue mobilization, joint mobilization, and splinting are key elements of the program. Strengthening is initiated only when the tissues have fully healed, no instability is present, and the program does not provoke pain. Residual enlargement and stiffness of the PIP joint is common. The clinician should explain to the patient that management of these injuries can take 6 months to 1 year.

Dorsal Dislocation. Rehabilitation guidelines for dorsal dislocations are based on the stability of the joint, the classification type, and nonoperative and postoperative treatment. Soft tissues injured in dorsal dislocations include the collateral ligaments and the volar plate (Table 10-6).

Lateral Dislocation. Rehabilitation for lateral dislocations is based on the degree of injury to the collateral ligaments and volar plate. The Bowers classification system divides soft issue injuries into three grades.[71]

Determinants of Treatment Progression

- Tissue healing (bone and soft tissue)
- Amount of edema
- Degree of stability
- Soft tissue mobility
- Joint mobility
- Pain

Grade I injuries, which involve a sprain to the collateral ligaments without instability, require immobilization up to 1 week in a finger-based extension splint to reduce inflammation. After immobilization, the affected finger is buddy-taped to the adjacent digit for 2 to 4 weeks, depending on the degree of pain and the patient's activity level. Buddy taping provides stability and prevents lateral stresses to the finger. AROM and blocking exercises are also initiated at 2 to 4 weeks.

In grade II injuries, the volar plate remains attached but may be injured, and the collateral ligaments are completely disrupted. Treatment varies, depending on the amount of disruption to the volar plate. Treatment consists of immobilization for 1 to 2 weeks with the finger splinted in 10° to 20° of PIP flexion for pain tolerance. Buddy taping for 8 to 12 weeks follows, and AROM and blocking exercises are initiated at 2 to 4 weeks. If greater disruption of the volar plate is present and the joint is unstable, an extension block splint is fabricated at 0° to 45° flexion. The degree of flexion depends on the stability of the joint, which is determined by imaging. The extension block splint is advanced into extension by 10° per week, and joint reduction should be confirmed by x-ray films.

TABLE **10-6**

Postoperative Rehabilitation Guidelines for Dislocation of the PIP Joint[27–29,70–72]

	Open Reduction and Internal Fixation	External Fixation/Traction Splinting (Weeks 0-6)	Volar Plate Arthroplasty
Special considerations	Hand therapy may or may not be initiated until weeks 4-6, depending on the stability of the reduction	A risk for infection exists with the use of external fixators; a variety of devices can be used for external fixation: • Commercially available finger-based hinge devices • Surgeon-fabricated finger-based fixators using K-wires and elastics • Traction splinting fabricated by a hand therapist (Designs vary. Forearm based. Finger is attached to an outrigger providing consistent traction through a safe arc of motion.) Positioning in the splint varies, depending on the injury classification or the direction of dislocation and implicated structures[73]	The torn distal end of the volar plate is inserted into the fractured base of the middle phalanx to reestablish ligamentous attachment to the base of the middle phalanx

(Continued)

TABLE **10-6**

Postoperative Rehabilitation Guidelines for Dislocation of the PIP Joint—Cont'd

	Open Reduction and Internal Fixation	External Fixation/Traction Splinting (Weeks 0-6)	Volar Plate Arthroplasty
Healing Stages			
Stage I: Inflammatory stage (weeks 0 to 2)	Immobilization is achieved in a forearm-based dorsal protective cast or splint that includes the full hand Gentle AROM with buddy taping may be initiated only if the reduction is stable Positioning in the splint may vary, depending on the implicated structures and surgical procedure	*External fixation:* • Immobilization for 3 days • At days 3-5, AROM is initiated within a safe range determined by the physician • Static protective splinting at night if the device does not lock • Resting PIP position is determined by the physician *Traction splinting:* • Initiation of motion varies from day 1 to week 3, depending on the stability of the fracture and the implicated structures • AROM of the PIP joint within a safe arc of motion is begun, and DIP blocking exercises are initiated • Dorsal block splint is worn, resting the finger in MCP flexion, the PIP joint in the safe amount of extension as determined by the physician, and the DIP joint in extension, until AROM is initiated and also at night until week 6 • Patient is taught to monitor for signs of infection and to modify activities	Immobilization in a cast for 2-4 weeks
Stage II: Fibroplasia and repair stage (weeks 2 to 6)	Gentle AROM with the finger buddy-taped to the adjacent finger Edema management techniques should not put lateral stress on the PIP joint If Coban wrap is used, use 5 cm (2 inches) and make a sleeve that can be removed easily Gentle tendon gliding exercises	*External fixation:* • AROM within the device continues • Blocking initiated with emphasis on DIP flexion *Traction splinting:* • AROM of the PIP joint within a safe arc of motion and DIP blocking exercises are begun or continued	Hand-based dorsal block splint with the PIP joint in 30° flexion is fabricated at weeks 2-4, and extension is increased 10° per week *Or* the digit may remain immobilized, depending on the stability of the repair The finger is buddy-taped to the adjacent digit Edema management techniques should not put lateral stress on the PIP joint If Coban wrap is used, use 5 cm (2 inches) and make a sleeve that can be easily removed Blocking, full tendon gliding, and stretching are initiated at weeks 4-6
Stage III: Remodeling and maturation stage (weeks 6 to 8+)	PROM Stretching Blocking and tendon gliding Splinting for motion Functional progression Gentle strengthening at week 8, respecting tissue tolerance and pain	Device is removed Edema management Full tendon gliding and blocking exercises are initiated The finger is buddy-taped to the adjacent digit to protect soft tissue healing Strengthening begins at weeks 8-12, respecting tissue tolerance and pain Splinting for motion Functional progression	Buddy taping continues Splinting for motion is done, respecting tissue tolerance Strengthening begins at weeks 8-12, respecting tissue tolerance and pain Functional progression

AROM, active range of motion; *PIP*, proximal interphalangeal; *DIP*, distal interphalangeal; *MCP*, metacarpophalangeal; *PROM*, passive range of motion

Active flexion and extension into the block is completed after an initial week of immobilization. After removal of the extension block splint, the finger is buddy-taped for 8 to 12 weeks to protect the joint.

Grade III injuries are associated with complete disruption of both the collateral ligaments and volar plate; these injuries may require surgical intervention for stabilization. Postoperative rehabilitation is similar to that for grade II injuries (see Table 10-6).

Volar (Anterior) Dislocation. Volar dislocation injuries are rare. The soft tissue structures injured in volar dislocations are the collateral ligaments, the volar plate, and the extensor mechanism, including the central slip and lateral bands. Bony involvement can include middle phalanx dorsal lip fractures at the insertion of the central slip.[29,74]

Initial rehabilitation for nonoperative volar dislocations consists of immobilization in a finger-based extension splint with the DIP free for 6 to 8 weeks to protect soft tissue healing (Figure 10-46). AROM of the DIP maintains soft tissue gliding and appropriate positioning of the lateral bands dorsal to the joint axis. The PIP joint is then mobilized at 6 to 8 weeks. Buddy taping is used for 6 to 12 weeks to protect the joint.[29] A PIP extension splint can be worn at night to prevent periarticular soft tissue shortening and can be used for up to 3 to 6 months. An extension block splint with the MCP joints in flexion can help the patient perform blocking exercises to promote pull-through and glide of the extensor mechanism. If the collateral ligaments and volar plate have been completely disrupted, surgical intervention is necessary.

Ulnar Collateral Ligament Injuries of the Thumb

The rehabilitation strategy for the thumb is based on the degree of injury to the ulnar collateral ligament and/or the volar plate, which renders the joint stable or unstable. The degree of ligamentous injury has been classified into three grades. Rehabilitation strategies are geared toward maintaining thumb MCP joint stability while mobilizing the soft tissues to prevent the development of adhesions, flexion contractures, and loss of function. Progression of the therapy program depends on the stages of healing. Emphasis is placed on avoiding lateral and radial stresses to the MCP joint in the initial stages of healing. Terminal thumb abduction should be initially avoided. Force transmission to the MCP joint through pinching and pulling activities, in which the thumb tip is engaged, should also be modified and/or avoided to reduce demands on the healing tissues.

Consideration should be given to protecting the IP joint from hyperextension, which can place stress on the MCP joint. Edema management, soft tissue mobilization, joint mobilization, and splinting are key elements of the program. Care should be taken with cast or splint designs to protect the ligament while preventing a thumb adduction contracture. Strengthening of the thumb is initiated only when the soft tissues have fully healed, no instability is present, and the program does not provoke pain and/or an inflammatory response. Residual problems include stiffness at both the MCP and IP joints (Table 10-7).

Figure 10-46 Static PIP and DIP extension splint.

TENDON INJURIES OF THE HAND

Flexor Tendon Injury

General Considerations

Tendon injuries are common, although the exact incidence is unknown. Patients with a tendon injury face months of profound physical, emotional, and socioeconomic hurdles. These hurdles arise under the best of circumstances, such as when the injury is recognized early and treated appropriately. Unfortunately, many pitfalls can lead to a poor result after a tendon injury, with profound repercussions that can affect the patient's ability to return to gainful employment and to use the hand for activities of daily living.

Tendon injuries often are the result of a sharp instrument coming into contact with the digit, hand, or wrist. This can occur accidentally at work or in the home or sometimes deliberately, as in an altercation or self-inflicted wound. In the case of an accidental injury, the nondominant hand frequently is hurt because the individual is wielding the knife in the dominant hand when the accident occurs. The opposite is true for a person who uses the hand to protect himself or herself from an assailant; these individuals reflexively use the dominant limb to ward off the knife assault.

Spontaneous tendon ruptures can occur without any preceding trauma. The most common cause of this type of tendon injury is rheumatoid arthritis, although other conditions, such as chronic tenosynovitis, partial flexor tendon lacerations, and attrition of the flexor tendons over bony prominences or hardware from previous surgery, may result in the same type of atraumatic tendon rupture (Figure 10-47). Timely recognition, diagnosis, and direct repair are important to increase the chances of restoring function.

TABLE **10-7**

Rehabilitation of Ulnar Collateral Ligament Injuries of the Thumb[27,56,65–67]

	Grade I	Grade II	Grade III
Description	Ligamentous stretching without tearing	Ligamentous tearing without complete disruption	Ligamentous disruption. Surgical repair or reconstruction
Healing Stages			
Stage I: Inflammatory stage (weeks 0 to 2)	Splinting at all times for weeks 0-4. Splint design may vary, depending on the surgeon's preference: • Hand-based short opponens splint with MCP joint in slight flexion, with or without a dorsal hood extending to the thumb tip that allows IP flexion while restricting hyperextension • Thumb spica cast or splint	Weeks 0-4: Thumb spica cast or splint at all times; IP joint may be included or free	Weeks 0-6: Casting
Stage II: Fibroplasia and repair stage (weeks 2 to 6)	Splint immobilization continues until weeks 4-6 Functional use is progressed, with modifications to avoid heavy pinching, pulling, and grasping	Weeks 4-6: Thumb spica cast is reduced to a hand-based short opponens splint that leaves the IP joint free; a dorsal hood prevents hyperextension of the IP joint. The splint must be worn between exercises. Splinting time frames vary, depending on stability and pain at the MCP joint; the splint can be worn up to week 12 for protection Week 6: • AROM • Soft tissue mobilization • Edema management	Weeks 0-6: Casting
Stage III: Remodeling and maturation stage (weeks 6 to 8+)	Week 8: Strengthening to tissue tolerance, focusing on the abductor pollicis brevis, flexor pollicis brevis, and adductor pollicis brevis	Splinting continues Blocking exercises for tendon gliding Light functional tasks Joint mobilization, respecting tissue tolerance Strengthening begins at week 12, respecting tissue tolerance and pain Full pinching and pulling activities at weeks 12-16, as tolerated	Progression to hand-based thumb splint with IP joint free; worn between exercises Splint worn up to weeks 8-12 Straight plane flexion and extension AROM Radial stress (terminal abduction) to the MCP joint must be avoided. Soft tissue and scar mobilization Edema management Blocking for tendon excursion Weeks 8+: Unrestricted AROM, PROM, gentle stretching Strengthening and return to full pinching and pulling activities at weeks 12-16

MCP, Metacarpophalangeal; *IP,* interphalangeal; *AROM,* active range of motion; *PROM,* passive range of motion.

Avulsion injuries to the flexor tendons usually are caused by a closed traumatic injury to the finger. These tend to occur during athletic events, and unfortunately, the diagnosis often is missed initially, which can lead to permanent disability. Avulsion injuries of the flexor digitorum superficialis tendons are rare compared with disruption of the flexor digitorum profundus tendons.

The ability of a tendon to heal and the degree to which adhesions develop in the area of the healing tendon depend on factors that relate to the injury and the surgical repair. The goal of tendon repair is based on establishing a strong enough repair to enable the patient to begin early protected motion while achieving the repair without inducing excessive scarring. Crush injuries and aggressive handling

Figure 10-47 Rupture of a tendon from attrition over prominent hardware. The extensor digitorum communis (EDC) tendon to the index finger ruptured over the K-wire when the wire backed out of the bone. Side-to-side tendon repair produced an excellent result.

of the tendon sheath and tendon during surgery increase the chances of scar formation. Tendon ischemia, tendon immobilization, and gapping at the repair site also contribute to the formation of excursion-restricting adhesions.

After tendon repair, healing progresses through several stages. The first stage involves an inflammatory response. During this stage, the strength of the tendon repair relies primarily on the strength of the sutures in place, with the fibrin clot (between the tendon ends) offering a small contribution. The second stage is the fibroblast-producing stage. The strength of the tendon increases rapidly during this stage as granulation tissue forms at the site of the repair. The final stage is the remodeling stage, in which collagen synthesis continues and the repaired tendon becomes progressively stronger. This restorative progression is important because it is the physiological basis for the protected therapy program, which prevents the formation of adhesions while caring for the still mending tendon.[75,76]

Anatomy

The tendons for the flexor muscle groups insert distally on the metacarpals and phalanges to provide wrist and finger flexion. The forearm flexor muscles that power these tendons originate on the medial aspect of the elbow and are divided into three anatomical layers. The superficial layer of muscles consists of the pronator teres, flexor carpi radialis (FCR), flexor carpi ulnaris (FCU), and palmaris longus (PL). The intermediate muscle group is the flexor digitorum superficialis (FDS). The deep muscle group consists of the flexor digitorum profundus (FDP) and the flexor pollicis longus (FPL). The FDS tendons arise from individual muscle bundles and act independently to provide flexion of the PIP joints. This is in contrast to the FDP tendons, which arise from a common muscle, simultaneously flexing the DIP joints of the four digits. Each digit therefore has two flexors that originate in the forearm, and the thumb has one. Every one of these nine tendons travels through the forearm and enters the wrist through the carpal tunnel beneath the transverse carpal ligament. The tendons continue in the palmar aspect of the hand, with the FDS tendons traveling anterior to the FDP tendons. They remain in this configuration until they enter their individual digits, through the digital sheath at the A1 pulley (Figure 10-48). At this point, the FDS tendon divides into two slips, traveling dorsally and on either side of the FDP tendon. The split FDS fibers rejoin, now dorsal to the FDP tendon, and insert along the proximal half of the middle phalanx, functioning to flex the PIP joint. The FDP tendons pass through the FDS bifurcation (*Camper's chiasm*) and insert on the distal phalanx, providing flexion of the DIP joint (Figure 10-49).

In the digits, the flexor tendons are enclosed in synovial sheaths. These sheaths provide a smooth synovial lining for tendon nutrition and to reduce the work of gliding. An intricate pulley system exists to create an efficient flexor mechanism by maintaining the tendons in close contact with the phalanges and preventing bowstringing of the tendons with the flexion motion. The A1, A3, and A5 annular pulleys arise from the volar plates of the MCP joints, the PIP joints, and the DIP joints, respectively. The A2 and A4 pulleys are functionally the most important pulleys, arising from the periosteum of the proximal half of the proximal phalanx (A2) and the midportion of the middle phalanx (A4). Also present are the thinner, less substantial cruciate pulleys: C1 (between A2 and A3), C2 (between A3 and A4), and C3 (between A4 and A5). These pulleys allow the annular pulleys to approximate each other during flexion (see Figure 10-49).

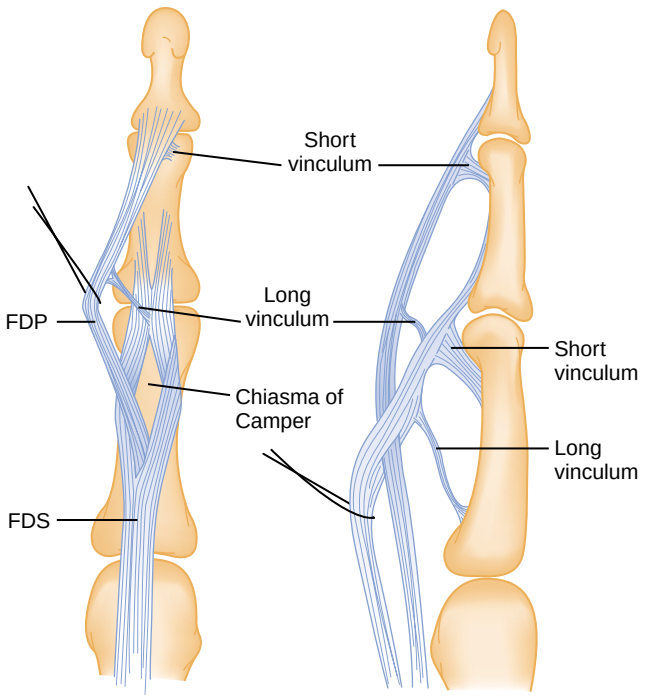

Figure 10-48 Anatomy of the flexor tendon. *FDS,* flexor digitorum superficialis; *FDP,* flexor digitorum profundus. (Redrawn from Schneider LH: *Flexor tendon injuries,* Boston, 1985, Little, Brown.)

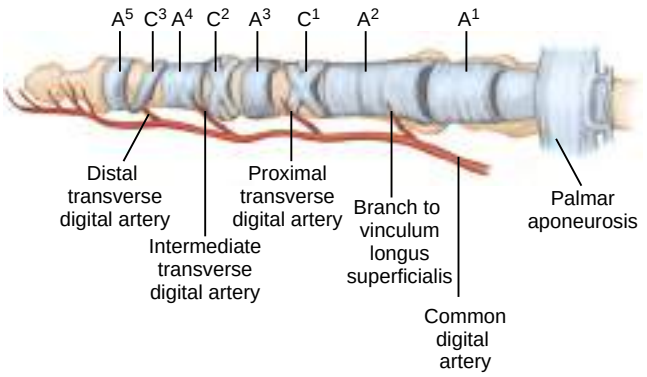

Figure 10-49 Pulley system of the finger, which includes five annular pulleys (A1-A5) and three cruciform pulleys (C1-C3). (From Skirven TM, Osterman AL, Fedorczyk J et al, editors: *Rehabilitation of the hand and upper extremity*, ed 6, Philadelphia, 2011, Mosby.)

Injury or disruption of these tendons anywhere along their course causes functional impairment of the distally involved joints.

Injury Classification

Flexor tendon injuries have been divided into zones over the volar aspect of the hand and wrist, based on differing anatomical characteristics. Zone I, the most distal zone, includes the area distal to the insertion of the FDS on the proximal phalanx. Zone II encompasses the area from the proximal border of zone I to the level of the distal palmar crease, which is the beginning of the flexor tendon sheath. This zone has been known historically as *no man's land* because of the complexity of the flexor tendons and fibro-osseous sheath anatomy in this region, which has led to poorer outcomes after tendon repairs. Zone III represents the area between the start of the fibro-osseous tendon sheath and the distal edge of the transverse carpal ligament. This also happens to be the area of the lumbrical muscle origin. The carpal tunnel region is zone IV, and proximal to the transverse carpal ligament is zone V. The thumb has its own zone distribution: zone T-I is distal to the DIP joint, zone T-II is between the MCP and IP joints, and zone T-III is proximal to the MCP volar flexion crease (Figure 10-50).

Diagnosis

A complete examination of the involved extremity must be performed to evaluate the extent of injury. In the inspection of the upper extremity, the examiner should note the posture of the hand. The presence of an abnormal cascade because of a digit resting in extension and an inability to perform specific flexion motor tests should alert the examiner to possible tendon injury. Specifically, when examining for a potential FDS injury, the examiner must hold the other digits in extension at the tips to prevent flexion of the injured digit through its possibly intact FDP tendon. Likewise, when examining for a FDP injury, the examiner must allow the patient to flex all the fingertips freely because the muscle for DIP flexion is not independent. Sensory evaluation can identify injuries to the digital

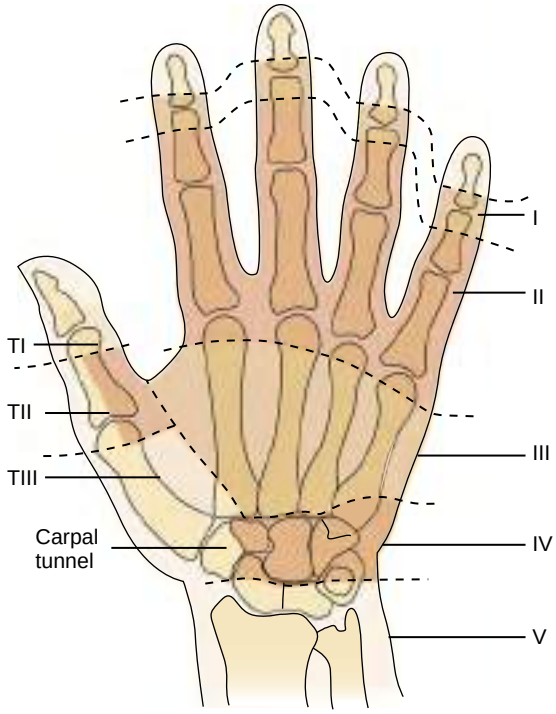

Figure 10-50 Flexor tendon zones: Fingers I, II, III, IV, V; Thumb TI, TII, TIII.

nerves, which may accompany trauma to a flexor tendon. It is important that the clinician recognize concomitant nerve injuries because nerve and vascular injuries affect the approach to operative management.

Medical Treatment

Before surgery is performed on an injured flexor tendon, relevant factors such as timing, prognosis, and concomitant injuries must be considered because they may affect the approach to surgical management. In the past a flexor tendon injury was considered a surgical emergency. This is no longer true, given current evidence that delayed primary flexor tendon repair leads to results that are equal to or better than those obtained with immediate repair.[77] With increasing delay, however, repair of the tendons at the appropriate length becomes more difficult because the tendon ends begin to deteriorate, and the flexor tendon/muscle system shortens.[77] The preferable course, therefore, is to perform the repair within a reasonable period. In most cases the time elapsed before myostatic contraction makes primary repairs technically difficult or impossible to achieve is thought to be 3 weeks.

Any concomitant injuries must be taken into consideration at the time of surgery. A contaminated wound or an injury with significant skin loss usually is a contraindication to repair of an injured flexor tendon. Associated fractures and neurovascular injuries are not a contraindication, and treating these injuries may actually be useful in maintaining stability and adequate perfusion of the tendon as it goes through the reparative process.

The main goals in performing a flexor tendon repair are (1) to retrieve both the proximal and distal ends of the

tendons, (2) to reattach the segments to one another in such a way as to maintain maximum strength of the repair and allow easy tendon gliding within the tendon sheath, and (3) prevent the formation of adhesions as much as possible.

Principles of Flexor Tendon Repair[78,79]

- Repair strength is proportional to the number of strands that cross the repair site
- Repairs usually rupture at the suture knots
- The preferable course is to have as few suture knots as possible and to keep the knots away from the repair site
- Gapping at the repair site should be avoided because it is a major contributor to adhesion formation and negatively affects the strength and stiffness of the tendon repair
- Tension across all suture strands should be equal
- Equal tension prevents asymmetrical loading across the repair site, which can weaken the repair
- Use of a peripheral circumferential suture in addition to the core sutures across the repair increases the strength of the repair

Zone Considerations in Flexor Tendon Injuries

Zone I. With zone I injuries, only the FDP is cut, and locating the proximal end of the FDP tendon is relatively simple. A primary end-to-end suture repair can be performed if adequate length of the distal portion of the tendon is left. If the distal portion is short or nonexistent, the proximal tendon end may be attached directly to the bone of the distal phalanx either by a suture anchor within the bone or by sutures pulled through the bone and tied over a button on the dorsal aspect of the distal phalanx.

Avulsion of the FDP usually results from forced extension of a flexed digit, which causes the profundus tendon to pull away at its insertion on the distal phalanx. This injury has a high incidence among young, male athletes, and the ring finger is involved in more than 75% of cases.[80] This injury should be suspected if a patient has tenderness and swelling over the volar aspect of the finger and is unable to flex the DIP joint.

Three types of avulsion injuries can occur at the level of the profundus tendon.[81] In type I injuries the proximal portion of the tendon retracts into the palm. This end should be retrieved and reattached to the distal segment before muscle contracture occurs, resulting in shortening of the flexor system and making primary repair impossible. Surgical repair should take place within 7 to 10 days.

With type II injuries the proximal segment of tendon retracts to the level of the PIP joint and is held in place by an intact vinculum (small blood vessel to the tendon). Because this muscle-tendon unit has less of a tendency to shorten, surgical repair of this tendon injury is not as emergent as a type I injury. However, the clinician must keep in mind that if the vinculum breaks, the type II injury becomes a type I injury and requires repair within 7 to 10 days.

Type III injuries involve an avulsion of the large bony fragment to which the FDP attaches. The bone fragment tends to prevent proximal retraction of the tendon, and treatment for this injury usually involves internal fixation of the avulsed bone, which repositions the flexor tendon at its appropriate length, correcting the extension deformity.

Zone II. Zone II injuries were previously referred to as *no man's land* because of the difficulty involved in repairing the flexor tendons at this level. In this zone both the FDP and FDS tendons usually are injured, and the ends are retracted in both the distal and proximal directions. Surgical repair to achieve flexor function involves retrieving both ends of both tendons while maintaining the pulley system, realigning the FDP and FDS tendons anatomically, and repairing the tendons with the strength to maintain the repair without generating increased formation of adhesions.

Zone III. Zone III injuries occur in the region just distal to the carpal tunnel. Both the FDP and FDS tendons travel in this region, and either one or both tendons may be injured. Primary repair of the tendon ends has a good prognosis in this region.

Zone IV. In zone IV the carpal tunnel, the FDP and FDS tendons travel together, along with the median nerve. Laceration at this level may result in injury to one or multiple tendons and to the median nerve. A thorough neurovascular examination must be performed to determine the extent of tendon and nerve damage, and primary repair should be performed before muscle contractures occur.

Zone V. In zone V (i.e., the wrist and forearm), the tendons originate from their musculotendinous junctions and travel together toward their insertion sites. They are less constrained in this region, and tendon repair tends to have a favorable prognosis. However, these injuries may be complicated by multiple tendon lacerations or accompanying neurovascular injury.

The Thumb. Flexor tendon repair of the thumb follows the same principles as tendon injury in the digits, even though the thumb has only one flexor tendon and three pulleys. The lacerated proximal portion of the FPL may be located within the thumb, or it may have retracted into the thenar eminence or the carpal tunnel, making retrieval more complicated. The proximal section should be located, retrieved, and then sutured to the distal section of tendon.

Complications

Surgical repair of flexor tendons often is successful at restoring tendon function; however, the procedure is not without associated complications. The most significant complication is rupture of the flexor tendon at the repair site. If this is recognized, treatment involves reexploration of the area and repair at the earliest possible time. Flexion contractures at the DIP or PIP joints are frequent complications of repair of flexor tendon injuries. If noted early, alteration of therapy strategies may help reverse these contractures. The development of tendon adhesions is another frustrating complication of flexor tendon repairs. The formation of adhesions prevents functional excursion of the tendon within the sheath, resulting in decreased motion of the involved digit. A tenolysis procedure may

be performed to remove adhesions once a plateau has been reached in therapy.

Extensor Tendon Injury

General Considerations

The extensor mechanism of the hand is a unique system that relies on an intricate link between the **radial nerve–innervated extrinsic extensor system**, which originates in the forearm, and the **ulnar nerve–innervated intrinsic system**, which originates in the hand.

Injury to the extensor tendon mechanism occurs more frequently than flexor tendon injury because of the more superficial anatomical location of these tendons. This injury should be recognized and taken seriously because a very delicate balance is achieved within the extensor mechanism. Injury that compromises length, alignment, or stability disrupts this equilibrium, and repair must be meticulous to reestablish the balance of function.

Anatomy

The extrinsic extensor muscles located in the forearm and inserting into the phalanges include the extensor pollicis longus (EPL), extensor pollicis brevis (EPB), extensor indicis proprius (EIP), and extensor digiti minimi (EDM). The tendons arising from these muscle bellies have an independent origin and action. The extensor digitorum communis (EDC) is the common origin of four independent tendons. These become the primary extensor component of the four digits. The intrinsic muscle contribution to the extensor system consists of four dorsal interossei, three palmar interossei, and four lumbrical muscles. These intrinsic muscles function to flex the MCP joints of the four digits and extend the PIP and DIP joints.

The extensor tendons leave the forearm and enter the hand through six dorsal compartments at the level of the wrist and are secured by the extensor retinaculum. This retinaculum functions to prevent bowstringing of the tendons, causing close approximation of the tendon to the bone and allowing efficient extension. As the tendons enter the hand and travel dorsal to the metacarpals, the EDC tendons, despite originating as independent tendons, become interconnected by the juncturae tendinum. This interconnection results in some codependence and shared extensor activity by these four digits. As the tendons continue to travel distally toward the fingers, they become centrally located over their respective metacarpal heads. They extend the proximal phalanx by way of a sling mechanism and are stabilized in this central position by the sagittal bands, which run on both sides of the tendon and insert on the volar plate of the MCP joint. As the tendons travel distally along the proximal phalanx (never inserting into that bone), they divide into three slips. The central slip crosses the PIP joint and inserts on the proximal portion of the middle phalanx. The lateral slips travel along both sides of the PIP and the middle phalanx (Figure 10-51).

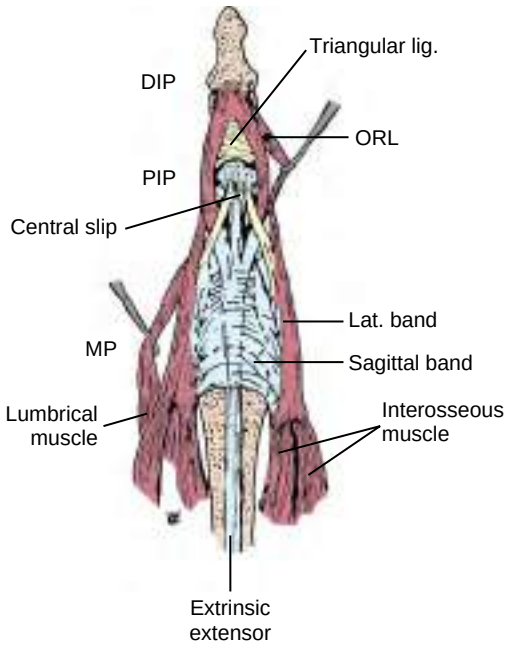

Figure 10-51 Dorsal view of the extensor mechanism. *DIP*, distal interphalangeal joint; *PIP*, proximal interphalangeal joint; *MP*, metacarpophalangeal joint; *ORL*, oblique retinacular ligament. (From Coons MS, Green SM: Boutonniere deformity, *Hand Clin* 11:387-402, 1995.)

In the region of the proximal phalanx, the intrinsic muscle tendons begin their contribution to the extensor mechanism. The lumbrical and the palmar and dorsal interossei tendons converge to form the lateral bands, which travel on either side of the proximal phalanx. A portion of the lateral bands joins with the extensor tendon at the PIP joint to insert as a central slip. The remainder contributes fibers that travel on both sides of the middle phalanx and insert into the dorsum of the distal phalanx as the terminal tendon. Because the intrinsic tendons are located volar to the axis of rotation of the MCP joints and dorsal to the axis of rotation of the PIP and DIP joints, the intrinsic muscles function to flex the MCP joint and extend the PIP and DIP joints. In summary, the central slip insertion on the middle phalanx is a convergence of the extrinsic extensor tendon, lumbrical tendon, and interossei tendon. Portions of these tendons travel distally to form the lateral bands, which then converge to form the terminal tendon, inserting on the proximal aspect of the distal phalanx.

The anatomy of the extensor mechanism of the thumb is somewhat different than that of the fingers. The extrinsic tendons enter the hand via the extensor retinaculum in the wrist. The EPB inserts at the base of the proximal phalanx, and the EPL inserts at the base of the distal phalanx. The EPL is stabilized in its central position over the thumb MCP joint by sagittal bands. The intrinsic extensor component to the thumb comes from the ulnar nerve–innervated adductor pollicis, which functions to adduct the thumb, flex the thumb MCP joint, and extend the thumb IP joint.

Injury Classification and Medical Treatment

Zone Considerations in Extensor Tendon Injuries. The extensor tendon mechanism can be divided into eight zones based on the differing physical characteristics of the tendons and their insertions. The even-numbered zones occur over bones, and the odd-numbered zones are positioned over joints. Zone I represents the most distal aspect of the extensor mechanism, where the lateral bands on either side of the digit converge to form the terminal tendon, inserting on the distal phalanx. The terminal tendon functions to extend the DIP joint in concert with PIP joint extension. Moving proximally, zone II covers the middle phalanx, the area where the two lateral bands join together, and are held in place by the triangular ligament just before forming the terminal tendon. Zone III is at the PIP joint, the area where the central slip inserts; it functions to extend the PIP joint. Zone IV covers the region of the proximal phalanx, where the extrinsic extensor system converges with the intrinsic system. Zone V covers the region over the MCP joint, where the extensor tendons lie centrally over the joint, stabilized by the sagittal bands. Zone VI exists over the metacarpal bones, where the extensor communis tendons are interconnected by the juncturae tendinum. In zone VII, at the level of the wrist joint, the tendons lie within the tenosynovium, covered by the extensor retinaculum. Zone VIII is the most proximal zone, containing the extensor tendons at their musculotendinous junctions. Zone IX consists of the proximal one half of the forearm above the musculotendinous junction (Figure 10-52).

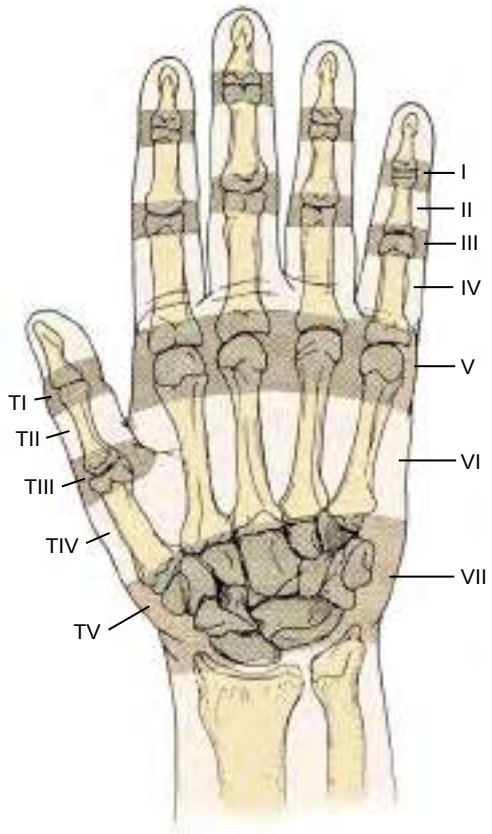

Figure 10-52 Extensor tendon zones. (From Trumble TE et al, editors: *Core knowledge in orthopaedics: hand, elbow, and shoulder*, Philadelphia, 2006, Mosby.)

Zone I (Mallet Finger Deformities). Zone I injuries create a *mallet finger deformity* (Figure 10-53). These injuries result in disruption of the extensor tendon at the level of the DIP joint, caused by a closed avulsion injury, an open skin and tendon injury, or a fracture of the proximal portion of the distal phalanx, where the terminal tendon of the extensor system inserts. Closed injuries occur more often, usually when sudden flexion of the extended digit ruptures the tendon from its bony insertion – or the bony insertion site, with the tendon attached, may avulse from the distal phalanx. Open injuries may be lacerations or crush injuries that disrupt the extensor tendon.

Upon physical examination, the distal phalanx is found to be in some degree of flexion, and the patient is unable to actively extend the distal portion of the injured finger. Hyperextension of the PIP joint may be present, secondary to the unopposed tension of the central slip combined with volar plate laxity, resulting in a *swan neck deformity.*

Mallet finger deformities have been classified according to the cause of the deformity because this assists in the determination of the treatment plan. The goal of management is to restore tendon continuity with maximum return to function.

Figure 10-53 Mallet injury. Note the extensor lag at the DIP joint and the mild hyperextension at the PIP joint (swan neck deformity).

A *type I mallet finger injury* is the result of closed or blunt trauma, with or without a small avulsion fracture. This is the most common type of injury, and splinting of the DIP in extension is the optimum treatment option. Hyperextension should be avoided because this may cause ischemia of the thin dorsal skin. The patient wears a splint continuously for a minimum of 6 weeks, followed by 2 weeks of nighttime splinting.[82] This usually results in excellent recovery. On rare occasions, if a patient is unable

to wear a splint, a K-wire may be placed across the DIP joint to maintain the joint in extension.

A *type II mallet deformity* results from a laceration at the level of or just proximal to the DIP joint, causing disruption of the extensor tendon. Given the numerous attachments of the extensor tendon to the digit, very little retraction of the proximal end occurs, and in this situation the tendon should be primarily repaired. The extensor tendon at this level is broad and thin, and repair should consist of a running suture that reapproximates the skin and tendon simultaneously. After repair, a splint should be worn to maintain the DIP in an extended position for 6 weeks.

A *type III mallet deformity* is caused by a deep abrasion to the distal aspect of the finger, resulting in loss of skin, subcutaneous tissue, and tendon substance. Given the nature of this injury, reconstructive surgery is needed for soft tissue coverage, and tendon reconstruction with a free tendon graft should be the treatment of choice. The loss of tendon substance, resulting in loss of extensor tendon length, impairs the surgeon's ability to restore function of the extensor mechanism using primary repair.

Type IV mallet deformities are further subdivided into three groups. Type IV-A deformities result from a transepiphyseal fracture in children. Because the extensor tendon is attached to the epiphysis, a mallet finger deformity results secondary to the fracture. Closed reduction of the fracture corrects this deformity. Continuous splinting of the DIP in extension for 3 to 4 weeks usually produces union of the fracture and resolution of the deformity. Type IV-B deformities are caused by a hyperflexion injury with a fracture that compromises 20% to 50% of the dorsal articular surface. A hyperextension injury that causes a fracture with a bone fragment larger than 50% of the dorsal articular surface results in a type IV-C mallet finger deformity. Because of the largely compromised articular surface in these injuries, they often are associated with volar subluxation of the distal phalanx relative to the proximal phalanx. In both type IV-B and IV-C injuries, the mallet deformity results because the extensor tendon remains attached to the fractured segment of bone.

For fractures that have subluxed anteriorly, operative management is recommended to achieve an accurate reduction of the fracture and to restore articular congruity (see Figure 10-3). Surgery restores the extensor tendon length and resolves the mallet deformity. For fractures that are not subluxed, splinting of the DIP in extension for 6 weeks results in fracture union and remodeling of the articular surface, with subsequent resolution of the mallet deformity.

Mallet thumb, or injury to the extensor mechanism of the thumb in zone I, at the level of the IP joint is a rare injury, which may be caused by a closed rupture of the EPL insertion or a laceration of the tendon at this level. A closed injury should be treated with IP extension splinting for 6 to 8 weeks. An open laceration is best treated by primary repair, with sutures incorporating both skin and tendon.

Zone II. Zone II injuries of the fingers and thumb occur at the level of the middle phalanx and usually result from a laceration or crush injury that leads to disruption of the extensor tendon. Partial lacerations, in which less than 50% of the tendon is disrupted, are common in this region because of the broad, curved shape of the tendon as it lies against the phalanx. If a partial laceration occurs, treatment involves wound care and splinting for 7 to 10 days. If the laceration causes more extensive tendon damage, the distal and proximal tendon ends should be primarily repaired, followed by extension splinting.

Zone III. Zone III injuries occur at the level of the PIP joint, with disruption to the central slip. If allowed to progress, these injuries cause the classic boutonniere deformity (i.e., hyperflexion of the PIP joint and subsequent hyperextension at the DIP joint). Loss of extension at the PIP joint may not result immediately because the lateral bands retain the ability to extend this joint. However, over time, the head of the proximal phalanx buttonholes through the defect created by the ruptured central slip, and the lateral bands migrate anteriorly below the axis of rotation of the PIP joint, converting them from PIP extensors to PIP flexors. This causes loss of extension at the PIP joint, and a flexion deformity results. At the same time, the more anterior position of the lateral bands at the level of the PIP joint causes increased tension along these bands, which is transmitted to the terminal tendon and leads to hyperextension of the DIP joint. This injury may result from either a laceration of the central slip or closed trauma with acute forceful flexion of the PIP joint, causing avulsion of the central slip. Correction of this deformity requires reestablishment of the tendon balance and the tendon length relationship between the central slip and the lateral bands. If a closed rupture has occurred, the PIP can be splinted, gradually progressing to full extension. This allows reapproximation and healing of the ends of the central slip. A K-wire across the extended PIP joint can achieve the same goal. If the central slip is injured by an acute laceration, primary repair of this tendon should be performed.

Zone III injuries of the thumb at the level of the MCP joint may involve one or both of the thumb extensor tendons. If only the EPB is injured, thumb extension at the MCP joint likely will be retained because the EPL remains functional. If the EPL is disrupted, an extension lag across both the MCP and IP joints results. Primary repair is usually indicated for laceration injuries within this zone.

Zone IV. Zone IV injuries occur at the level of the proximal phalanx. In this region, the lateral bands contribute significantly to the extensor function and offer protection against complete lacerations of the central tendon. Therefore injury in this zone usually results in partial lacerations; however, this diagnosis can be made

only under direct visualization of the tendon. If the tendon is partly lacerated, splinting the PIP for 3 to 4 weeks is adequate treatment.[83] If laceration of a lateral band is diagnosed, primary repair may be performed, followed by early protected motion. For complete lacerations of the extensor tendon, primary repair should be undertaken, followed by 4 to 6 weeks of PIP extension splinting. Preserving appropriate tendon length during this repair is crucial, so that the balance between the central tendon and the lateral bands is maintained.

Zone V. Many types of injuries involving the extensor mechanism can occur in zone V, at the level of the MCP joint. Open wounds often occur at this level and are of special concern given the proximity of the MCP joint to the surface of the skin. If a patient uses a fist to strike someone in the mouth, a fight bite may result, which is a contaminated open wound most likely communicating with the MCP joint. Immediate debridement, irrigation, and antibiotic therapy must be started. Partial tendon injuries usually are associated with this type of wound, but if a complete tendon injury does occur, then either a primary or secondary repair may be performed, depending on the status of the wound. If a clean laceration occurs at the level of the MCP joint, primary repair of the tendon may be performed.

The sagittal bands, which are found on both sides of the extensor tendon at the level of the MCP joint, are vulnerable to injury in zone V. The sagittal bands centralize the extensor tendon over the MCP joint. Injuries to these bands may be caused by a laceration, or the bands may be ruptured by a forceful blow of the clenched fist against a hard surface. Prompt recognition of this injury allows for treatment by extension splinting. If this is not successful, repair of the sagittal bands may be undertaken at a later date to prevent subluxation and to improve extensor function at the MCP joint.

Zone V injuries of the thumb occur at the level of the CMC joint and commonly involve lacerations of the EPB and APL tendons. Injuries in this region must be carefully evaluated for possible compromise of the radial artery and the radial nerve sensory branches. The proximal segment of the APL may retract in this region, therefore retrieval of this tendon and primary repair should be performed.

Zone VI. Injuries in zone VI occur at the level of the metacarpals, where the tendons for the EDC, extensor indicis proprius, and extensor digiti minimi are located. Tendon lacerations, either partial or complete, are difficult to diagnose at this level because full active extension may not be completely lost; extensor action may be transmitted through the juncturae tendinae, or redundant tendon function may be present (in the case of the index and small fingers). To test for independent tendon function on the physical examination, the examiner should hold all digits except the one being examined in flexion at the MCP joints to prevent any possible contribution of the juncturae tendinum from confounding the examination.[84] Ideally, the diagnosis for this injury should be made under direct visualization. Tendons in this region are thicker and more oval and can support a stronger core suture for use in primary repair. After repair, postoperative management includes splinting for 4 to 6 weeks. If an EDC tendon is involved, all fingers should be splinted; if an extensor indicis propius tendon was injured, only the specific index finger needs splinting.

Zone VII. Zone VII injuries occur at the level of the wrist and usually involve injury to the extensor retinaculum. The wrist and finger extensor tendons coexist in this region, and the chance of multiple tendon injuries is high. Injury may result from lacerations, tendon ruptures after fracture, or tendon dislocation after injury to the retinaculum. The distal and proximal ends of the injured tendons retract in this area, making primary repair of these injuries more complicated. If multiple tendons are lacerated, the appropriate proximal and distal regions must be retrieved and anatomically matched and then primarily repaired. Damage to the retinaculum also complicates injury in this zone. This structure is necessary to prevent bowstringing of the extensor tendons, as they function to extend the wrist and the fingers. Part of the retinaculum may be resected to allow adequate exposure and retrieval of the tendons, but the retinaculum should not be fully excised, and its function should be preserved. However, tendon healing at this level is often associated with the formation of adhesions to the overlying retinaculum.[85] Measures attempted to prevent adhesion formation include early dynamic splinting.

Zone VIII. Tendon injuries in the distal forearm, zone VIII, usually occur at the musculotendinous junction and may be caused by a laceration or rupture. Primary repair of these injuries is difficult because, although the distal tendon segment retains suture well, the proximal muscle region does not. Options for restoring adequate extensor function in this type of injury are side-to-side suture repairs or tendon transfers.

Zone IX. Zone IX injuries occur in the proximal forearm and usually are caused by a penetrating wound. Injury at this level is complicated by the multiple structures present and vulnerable. Muscle transection or nerve injury may result in functional impairment. A careful, thorough physical examination must be performed, and often surgical exploration is undertaken for diagnosis. If the muscle is found to be damaged, it is repaired primarily or, if the muscle defect is too extensive, tendon grafting may be performed.

Rehabilitation Principles and Considerations for Tendon Injuries

Flexor Tendon Injuries of the Hand

Numerous articles and studies have been written about the rehabilitation of flexor tendon injuries. Despite the wealth of information available to clinicians, determining which approach to choose can be confusing and difficult.

Effects of Early, Controlled Force on a Repaired Flexor Tendon

- More rapid recovery of tensile strength
- Fewer adhesions
- Improved tendon excursion
- Less gapping at the repair site

Several studies provide evidence that incremental stress and tendon excursion increase the rate at which the repair site achieves normal tensile strength and reduce the amount of scar adhesion. A variety of postoperative flexor tendon protocols have been designed to provide the optimal amount of tension loading at the precise time in the patient's treatment.[10,87,88] Early mobilization, either passive or active, starting within the first week of the repair, has been reported to produce excellent results compared with postoperative immobilization.[88] Early passive mobilization (EPM) consists of passive flexion with active extension within the confines of a protective splint. Early active mobilization (EAM) consists of active flexion and extension of the involved finger within certain parameters of a protective splint.[87–90] Recent literature has also emphasized the importance of the positions of the adjacent fingers on the tendon gliding and excursion of the repaired flexor tendon on the operative digit.[91]

Despite the benefits of these early mobilization programs, questions remain as to how much motion should be allowed and when to begin. If early active motion is too aggressive, it may cause gap formation or even rupture the repaired tendon. However, traditional early passive motion protocols may not provide enough tendon gliding within the tendon sheath to prevent scar adhesions.[92]

Selection of a Treatment Protocol. The postoperative treatment protocol and guidelines chosen to guide rehabilitation decisions and interventions are critically important. Surgical repairs and treatment protocols can vary greatly. Communication between the surgeon and therapist is vital to ensure the most successful outcome for the patient. It is important that the therapist know the type of flexor tendon repair and suture technique performed before initiating a rehabilitation protocol. The combination of advanced suture techniques and immediate passive mobilization has reduced adhesions and repair site gaps and increased tendon excursion. Recent methods of core suture techniques offer greater tensile strength to the tendon at the time of the repair and improve strength up to 6 weeks postoperatively.[93] Stronger suture techniques designed for active motion have also been developed, but it is critical that the therapist know what type of repair was performed before initiating early EAM protocols.

Several factors can affect the strength of a flexor tendon repair, such as the suture caliber, the number of strands crossing a repair, and the type of suture loops used. A suture caliber of 3-0 is recommended over 4-0, and a four-strand repair is thought to be better than a two-strand repair. Also, some surgeons believe that locking suture loops that hold the tendon on either side are best for enhancing the strength of the repair.[94,95] It has become accepted that four- or six-strand flexor tendon repair methods, combined with a strong epitendinous suture, should be sufficiently strong to withstand light active forces through healing.[96]

Factors Affecting the Strength of a Tendon Repair

- Suture caliber (e.g., 3-0)
- Number of suture strands that cross the repair (four to six)
- Type of suture loops

Another important consideration for therapists treating patients with flexor tendon repairs is how much friction is present and how well the tendon glides. In an injured finger, joint stiffness caused by diffuse swelling or soft tissue restrictions becomes a major factor, and significant tendon force is needed to overcome it. Other sources that cause resistance to motion within the tendon sheath include damage to the pulley system, tendon sheath, or gliding surfaces of the tendon, all of which can cause adhesions to form later during the healing process.[94]

Sources of Resistance to Tendon Motion

- Swelling
- Scarring (adhesions)
- Joint stiffness (hypomobility)
- Damage to the pulley system
- Damage to the tendon sheath
- Damage to the tendon gliding surfaces

The effects of drag and other viscous effects on a joint significantly affect the outcome of a tendon repair. Gentle passive motion of the involved finger joints should be performed at slow speeds to eliminate the potential for viscoelastic forces. Passive motion serves to release and reduce fluid around a joint, which reduces the resistance to motion.[96] Passive joint motion also enhances the motion of the tendons with respect to one another. Passive flexion of the DIP joint produces excursion of the FDP in relation to the FDS of 1 to 2 mm for every 10° of motion, and passive flexion of the PIP joint produces 1.5 mm of tendon excursion between the two tendons for every 10° of joint flexion.[97]

An extremely swollen finger will have a significant increase in friction, which can affect tendon gliding. Any degree of joint excursion will require significantly more force, posing the danger of gapping at the tendon repair site. Discrepancy in the literature exists about the acceptable amount of gapping at the repair site. Gaps also cause increased friction, and gaps of 3 mm or more can block tendon motion, causing the tendon to rupture or adhesions to form.[94,97]

Most protocols developed for both EPM and EAM recommend that treatment begin 24 to 48 hours after surgery to prevent adhesion formation and joint contracture. Recently some experts have said that starting passive motion the day after surgery may hurt the final result because the gliding resistance of the tendon is high during this time because of swelling. Starting early motion the day after surgery can be associated with an increased risk of inducing fresh bleeding, which can lead to adhesions; therefore some recommend waiting 3 to 5 days before initiating treatment to prevent joint stiffness and scar formation. The consensus for all tendon rehabilitation is that treatment should begin early, no later than 3 to 5 days after surgery, to prevent joint stiffness and adhesions.[94,98] One of the benefits of early mobilization is an increase in tensile strength, which is achieved by stimulating maturation of the tendon wound and remodeling the scar tissue. This process prevents "softening" of the tendon, which can occur after day 5 if the tendon has been immobile, causing the tendon to be weaker during this time frame.[86,99] Clinicians must evaluate each patient and determine with the patient's surgeon the most appropriate time to begin treatment.

A third consideration in treating flexor tendon injuries involves the position of the wrist and its relationship to the finger flexors. Internal flexor tendon loading is greatly influenced by wrist position. Tendon loading occurs during wrist flexion because passive finger extension causes the tendon to move distally. Internal tendon loading also occurs during wrist extension with passive finger flexion as the tendon is pulled proximally. The tenodesis effect of wrist extension with finger flexion and wrist flexion with finger extension enhances tendon excursion. This concept has been incorporated into both EPM and EAM tendon rehabilitation protocols.[100,101] A study by Savage[102] reported that a position of wrist extension and MCP joint flexion produces the least tension in a repaired flexor tendon during active finger flexion.

It also is important that the clinician know the zone or location of the injury and repair because this affects the patient's treatment. The flexor tendons are divided into five zones, which were described previously. Treatment protocols vary, depending on the zone of the injury and repair. The literature primarily focuses on zone II flexor tendon injuries. This zone has the highest probability of developing adhesions because the FDP travels through the FDS at Camper's chiasm, and the two tendons are located within one flexor tendon sheath.

Other important considerations are associated injuries, patient compliance, and the timing of surgery. The presence of associated injuries, such as digital nerve or artery lacerations, significant soft tissue loss, and dislocations or fractures, also influences the course of treatment for a flexor tendon injury. Clinicians may need to alter rehabilitation protocols to accommodate these injuries. The patient's ability to understand a rehabilitation program and to follow it faithfully is critical to a successful recovery. Rehabilitation protocols are valuable guidelines, but each patient must be evaluated independently to determine the most suitable treatment regimen and the ways it might need to be altered to best serve the individual.

Early Passive Mobilization. Immobilization protocols have largely been abandoned in favor of early mobilization programs, which have resulted in much better motion and greater function. Occasionally, a young child or patient who is unable to participate appropriately with an early mobilization program is a candidate for an immobilization program, which usually consists of 4 weeks of immobilization in a plaster cast or protective splint before initiation of passive and AROM exercises. Patients can begin gentle resistance at 8 weeks and progress with a strengthening program at 10 weeks, with no restrictions by 12 weeks. Unfortunately, some patients treated with immobilization programs may not achieve full motion and have some residual limitations, depending on the location and nature of the injury.

One of the original controlled motion protocols developed by Kleinert for flexor tendon repairs consisted of a dorsal block splint with the wrist positioned at 40° flexion and the MCP joints in 40° to 60° flexion. The injured finger was held in flexion by a rubber band attached from the fingernail to a bandage or strap at the wrist level. Patients were instructed to actively extend against the rubber band up to the dorsal hood of the splint and then relax the finger, allowing the rubber band to passively flex the digit. Active flexion of the finger was not permitted for 4 weeks. After 4 weeks in the dorsal protective splint, patients were instructed to begin active flexion and extension exercises.[103] Modifications of the Kleinert traction approach include a palmar bar with pulley to increase DIP joint flexion. Although results using the rubber bands, or Kleinert method (Figure 10-54), were much better than

Figure 10-54 Kleinert splinting protocol. (From Canale ST, Beaty JH: *Campbell's operative orthopaedics*, ed 12, Philadelphia, 2013, Mosby.)

the immobilization programs, some patients developed flexion contractures at the PIP joint from being held in flexion by the rubber band traction.

In the 1970s, Duran and Houser presented a controlled passive motion method that has been modified over the years. It has become the basis for EPM protocols used today by many clinicians and surgeons. Duran used a dorsal block splint similar to that described previously, but, instead of a rubber band positioning the finger in flexion, the fingers were held in the splint with the PIP and DIP joints held in neutral (0°) with a Velcro strap, up against the hood of the dorsal block splint. The patient was instructed to remove the Velcro strap and perform three passive exercises within the confines of the splint. The first exercise was isolated passive DIP flexion, which allowed the FDP to independently glide from the FDS. The second exercise was passive flexion and extension of the PIP joint with the MCP in flexion in the splint, which allowed the FDS and FDP to move away from the damaged tendon sheath. The third exercise was full composite passive flexion of the MCP, PIP, and DIP joints, alternated with passive extension of the IP joints while the MCP joint was blocked in flexion (Figure 10-55).[104]

Modified Duran protocols incorporate active finger extension to meet the confines of the dorsal block splint, after passive flexion and extension of the finger. Active flexion of the finger is contraindicated for 3½ to 4 weeks after surgery. Proponents of the modified Duran method believe that it is less likely to cause flexion contractures at the IP joints than the Kleinert method and that the involved finger is protected better with a Velcro strap when the patient is not exercising. In recent years clinicians have combined some components of early active motion with the modified Duran protocol.[96,105,106] Modified Duran flexor tendon protocols are used to treat zone I and zone II flexor tendon injuries and may vary slightly among clinicians, surgeons, and clinics; this is the reason good communication with the surgeon and a thorough knowledge of the patient's injury and repair are important. (The modified Duran program with place and hold guidelines are presented in Table 10-8.)

Early Active Mobilization. Early mobilization programs originally focused on EPM. It is now widely accepted that tensile strength at the repair site increases when tendons are mobilized early. Despite improved results with EPM, some patients with zone I and zone II flexor tendon repairs still fail to achieve normal range of motion. This has led to the desire for rehabilitation algorithms that would allow for safe, early active mobilization. Suture techniques have been designed to minimize repair site gapping, which can lead to adhesions and tendon rupture but allow some early active motion. Repair site strength is directly related to the number of suture strands crossing the tendon laceration; however, as the number of sutures increases, so does repair site volume and the work for tendon gliding. The suture technique used by surgeons may vary, and debate continues as to whether four-, six-, or eight-strand repairs are best.[93–95] Strickland[97] has determined that a four-strand core suture plus a strong peripheral suture can withstand the stress of gentle early active motion.

(From Strickland WJ: Biologic rationale, clinical application, and results of early motion following flexor tendon repair, *J Hand Ther* 2:78, 1989.)

TABLE **10-8**

Flexor Tendon Repairs in Zones I and II: Modified Duran Program with Place and Hold

Time Frame	Program Considerations

0 to 5 days	• Inspect the wound. Apply a nonrestrictive sterile dressing (e.g., Xeroform or Adaptic); if bleeding occurs, combine with light gauze. Instruct the patient in all precautions:
	  ○ Avoid all active finger or wrist flexion.
	  ○ Avoid functional use of the injured hand and avoid lifting with the involved extremity.
	  ○ Avoid fully extending the fingers and wrist.
	• *Splint:* Fabricate a dorsal block protective splint (position may vary slightly, depending on surgeon's preference): 20° to 30° wrist flexion, 50° to 70° MCP finger flexion, 0° IP finger extension. (If a digital nerve repair was performed, the PIP joint should be in slight flexion to protect the nerve repair.)
	• *Exercise program:* The protocol may vary depending on the type of repair, the surgeon's preference, and the patient's age and compliance. The following is a modified Duran protocol with a place and hold component (four strand repair):
	  ○ Instruct the patient in *gentle passive flexion* of each digit at the MCP joint, the PIP joint, and the DIP joint, and in *active extension* within the confines of the splint. The splint should be worn at all times and during exercises; only the top strap is removed to complete the exercises. The exercises should be performed 10 times for each digit once an hour if the patient is very restricted in passive flexion; otherwise, the exercises should be performed 5-6 times a day for 3½ weeks after surgery.
	  ○ Apply compressive wrap (e.g., Coban) to reduce swelling: instruct the patient in edema management, ice packs, and elevation. The patient should be assisted by another person in applying the Coban.
	• *Early AROM/place and hold:* In addition to the previous program, the following can be initiated within 5 days after surgery *only* with reliable patients who have full passive flexion and decreased edema. The therapist needs to know whether the procedure was at least a four-strand repair of the flexor tendon before initiating place and hold:
	  ○ Place and hold should be done after passive flexion of the digits within the confines of the splint. Passively place the patient's finger in a partly flexed position and have the patient hold this position with minimum tension for 3 seconds. During weeks 2 and 3, place and hold can progress with the finger held in more flexion, again using minimum tension to hold.
	• Sutures generally are removed within 10-15 days; the patient can begin gentle massage to the scar once the wound has closed.

3½ to 4½ weeks	• Initiate gentle active flexion and extension of the digits within the confines of the splint after passive flexion of the digits. • Continue with edema and scar management as needed. Fabricate an Otoform or elastomer mold for nighttime wear if the wound has closed. • Straighten the wrist position of the splint to neutral and increase MCP flexion, if needed, to 60° to 70°. • At 4-4½ weeks, begin active flexion and extension out of the splint with the wrist in neutral after passive flexion of the digits. The splint is removed only for exercises. Tendon gliding exercises with a hook fist and full composite fist are initiated. • Apply foam padding to the dorsal part of the splint as needed to assist with PIP extension of the digits if a flexion contracture is forming. • Begin active wrist flexion and extension exercises; start with tenodesis wrist motion. • Continue to reinforce the frequency of the home exercise regimen: every 1-2 hours, 10 repetitions of each exercise. • Begin light, nonresistive activity to encourage finger flexion and extension while in therapy. • Begin gentle blocking exercises, emphasizing no resistance, and avoid blocking to the DIP joint of the little finger. Gentle, supervised, passive IP extension can be performed with the tendon on slack (with the wrist and MCP joint flexed). • Ultrasound may be initiated at weeks 4-6.

(Continued)

TABLE **10-8**

Flexor Tendon Repairs in Zones I and II: Modified Duran Program with Place and Hold—cont'd

Time Frame	Program Considerations
6 to 8 weeks	• Depending on the patient's judgment and activity level, the dorsal block protective splint may be discharged. The patient may need the splint for protection only in certain situations; otherwise, it should be kept off. • The patient can begin to use the injured hand for light ADLs (e.g., buttoning a shirt, washing the face). *Emphasize:* ○ No heavy gripping or squeezing ○ No lifting ○ No using the hand for pushing or pulling (e.g., opening doors) • Begin light resistive exercises and activities (e.g., squeeze soft putty, sponge, or light grippers). Some patients may benefit from a resting splint at night to gradually increase finger and wrist extension. • Aggressive scar management is continued. • Gradually increase resistance for strengthening program (moderate resistance). • Dynamic or static progressive PIP extension splinting or casting may be necessary. • Evaluate grip strength at weeks 8-10 after surgery, depending on the level of scar tissue present.
10 to 12 weeks	• Continue with strengthening program and progress as tolerated or as needed. • The patient can return to all normal activities, including heavy work or sports, as tolerated. Most patients should be on a home program by week 12; however, treatment may vary for patients with complex injuries or complications.

Trends over the past decade have been moving toward EAM programs that allow active flexion and extension of the involved fingers within the first 3 to 5 days. In 2004, Gail N. Groth presented the **Pyramid of Progressive Force Application**.[101] Progressive force application to the healing flexor tendon juncture is theorized as a series of eight specific rehabilitation exercise levels. These exercises are conceptualized in a pyramid format with the base of the pyramid signifying the lowest level of force across the juncture as well as exercises that are performed with the highest frequency (Figure 10-56). Loads rise as the pyramid builds, although the frequency of prescription decreases. Patients begin force application at the lowest level progressing upward only as determined necessary, reaching maximum loads (i.e., the pinnacle of the pyramid) on an infrequent basis. The uniqueness of this approach lies in the prescription of specific levels of load according to tendon performance rather than uniqueness in the exercises themselves.[101]

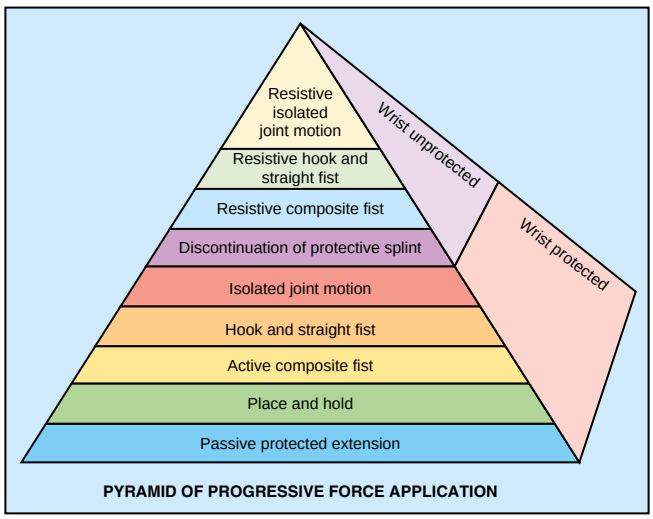

Figure 10-56 Pyramid of progressive force application. (Modified from Groth G: Pyramid of progressive force exercises to the injured flexor tendon, *J Hand Ther* 17:31-42, 2004.)

A concept known as **place and hold** is included in this category of EAM, in which the involved finger is passively flexed to a certain position and the patient is asked to hold it there through active contraction of that muscle. Evans and Thompson[96] studied the forces applied to a tendon with minimal active muscle-tendon tension (MAMTT) and developed guidelines for joint angles and force application with an adequate safety margin. Their study showed that, as the angle of joint flexion increases, the amount of force required also increases. They devised a protocol for treating flexor tendon repairs, recommending a position of place and hold with the wrist in 20° extension, the MCP joint in 83° flexion, the PIP joint in 75° flexion, and the DIP joints in 40° flexion, using a Haldex pinch gauge and string held perpendicular to the digit to measure external force during the active hold position. According to this protocol, the patient should apply only 15 to 20 g of force to hold the position.

This method of treatment has been modified by various clinicians and treatment centers, and EAM protocols have emerged with varying degrees of motion involving the digits and wrist. Incorporating tenodesis, wrist and finger motion has become standard treatment along with decreasing the degree of wrist flexion in the dorsal

block splint. The Indiana Hand Center[107,108] has devised an EAM protocol using a tenodesis wrist hinge splint that allows wrist flexion but blocks wrist extension at 30°; the MCP joints are blocked with a dorsal hood at 60° flexion. The patient wears this splint for exercise only and wears a dorsal protective block splint when not exercising. The patient is instructed to passively flex the involved finger into full composite flexion and then to bring the wrist up to extension. The patient is instructed to actively hold the flexed position of the finger with a minimal amount of tension for a few seconds. The patient then relaxes the muscle contraction and allows the wrist to drop into flexion and the fingers to extend to the dorsal hood of the splint (Figure 10-57).[107,108] This method should be used only by an experienced clinician who can evaluate a patient to determine whether the individual is an appropriate candidate for this type of synergistic protocol. EAM programs should be used with patients who are very compliant and can fully understand the program and its precautions.

Zones I and II. Gratton[106] described an uncomplicated method of splinting and an EAM program, which took place in Great Britain, for the treatment of zone I and zone II flexor tendon repairs. This protocol was devised with the goal of producing a treatment program that could be used for difficult cases and for patients who were less compliant or unable to attend therapy on a regular basis. Immediately after surgical repair, patients were placed in a dorsal block plaster splint with the wrist in 20° flexion, the MCP joints in 80° to 90° flexion, and the IP joints in neutral (0° in extension). No other splints were fabricated. The patients were admitted to the hospital for up to 3 days, and they wore a sling to prevent edema. Patients began motion 24 to 48 hours after surgery. The program consisted of passive flexion, active flexion, and two repetitions of active extension in the plaster splint every 4 hours. If joint stiffness was present, the patient increased the exercises to every 2 hours. The plaster splint was removed at 5 weeks after surgery, and the patients were allowed AROM; they worked toward active loading of the tendon at 8 weeks after surgery and returned to heavy work at 12 weeks. With this approach, 49% of the patients achieved an excellent outcome, 36% achieved a good outcome, and 7% had tendon ruptures.[106]

Figure 10-57 Indiana protocol with a hinge splint allows for active wrist extension combined with passive finger flexion. (From Cannon N: Post flexor tendon repair motion protocol, *Indiana Hand Center Newsletter* 1:13, 1993.)

Protocols vary from clinic to clinic because each clinic develops an individualized approach, which often depends on the surgeons' and therapists' preferences and expertise. A survey of 191 therapists revealed that 33% used some type of active finger flexion exercise within the first operative week. Only 5.5% of the therapists used the tenodesis hinge splint, but most of the therapists reported using a Kleinert type or Duran type of protocol, and 89.6% used some type of dorsal protective splint. More than half of those surveyed reported that their patients had experienced a tendon rupture, but this was less likely to occur in patients whose therapists saw them more frequently.[109]

Hold for Flexor Tendon Repairs in Zones I and II. Evans[110] has devised a postoperative program for treating FDP injuries in zone I that have undergone tendon to tendon or tendon to bone repair, using a technique consisting of limited DIP extension and active flexion. In addition to the dorsal block splint, the patient wears an individual static dorsal splint that positions the DIP joint in 40° to 45° flexion. This prevents the loss of DIP joint flexion that commonly occurs with zone I lacerations. The splint is taped in place to hold the DIP securely flexed, but the PIP joint is not included.

Evans' protocol includes the use of passive flexion/active extension exercises and an active exercise component known as *immediate active short arc motion* (SAM). After gentle passive exercises, the therapist removes the patient's splint and positions the patient with the wrist in 20° extension, the MCP joints in 75° to 80° flexion, the PIP joints in 70° to 75° flexion, and the DIP joints in 40° flexion (SAM position). The patient is instructed to gently hold this position to create minimum active tension in the flexor system. The force of flexion is measured with a Haldex pinch gauge, as described earlier with the MAMTT program. The therapist also performs wrist tenodesis exercises with the patient by passively holding the digits into a composite fist and simultaneously extending the wrist to 30° to 40°. The wrist then is passively flexed to 60° while the digits are allowed to extend through tenodesis action. The patient follows this exercise regimen for 3 to 4 weeks before full AROM and traditional tendon gliding exercises are begun. This protocol was developed with a defined safety margin for the active short arc motion.[110] Many clinicians and clinics have incorporated these concepts and modified them, depending on their level of experience, the surgeon's preference, and the individual patient's status. Table 10-9 details this type of protocol.

Zones III to V. Injuries in zones III to V are also treated with the modified Duran protocol or EPM. Flexor tendon repairs in zone IV and proximally, which include the wrist and forearm, generally result in better range of motion in the digits than repairs distal to this area. Peritendinous scar adhesions are less likely to form in these regions. The tensile strength of repaired tendons in zone IV and proximally is substantial enough to tolerate AROM exercises starting at 3 weeks after surgery. AROM of the digits can begin in the dorsal block splint at 3 weeks after surgery

TABLE **10-9**

Flexor Digitorum Profundus Repairs in Zone I (Tendon to Bone): Modified Early Mobilization Program

Time Frame	Program Considerations
0 to 5 days	• *Splint:* Fabricate a static dorsal block splint: Wrist, 0-20° flexion; MCP joints, 30° to 50° flexion; IP joints extended. The DIP joint may be positioned in flexion up to 45° by the surgeon to prevent stress on the repair. Based on the surgeon's guidelines, the dorsal block splint may be padded, or a separate finger splint may be taped dorsally over the involved digit, positioning the DIP joint in flexion. • *Exercise program:* Instruct the patient in the following: passive flexion of all finger joints within the splint; passive DIP flexion to 75° within a static finger splint and dorsal block splint; active extension of the IP joints within the splint with the MCP blocked in full passive flexion. Exercises are performed as 10 repetitions, 5-6 times a day. • Initiate edema management.
1 to 2 weeks	• In addition to the previously described exercises, DIP extension is progressed in the splint weekly to tissue tolerance or to the surgeon's guidelines. Begin scar management when appropriate. • Begin passive modified hook position (hook with the MCP joints resting on the hood of the splint with full IP flexion to tolerance). • Begin modified place and hold within the splint once edema has decreased and full passive motion has been achieved. Passively flex the PIP joint of the affected finger while holding the uninvolved fingers to the hood of the splint to encourage differential FDS gliding from the FDP. Instruct the patient to gently contract to hold the PIP joint in this flexed position with minimum tension for 3 seconds. • These exercises should be performed in the clinic by the therapist: Remove the patient's splint. Passively extend the patient's wrist to 30° to 40° with the fingers passively held in composite flexion. Passively flex the wrist to 60° with passive hook fisting of the fingers.
3 to 4 weeks	• Continue as previously described. The individual finger splint or DIP extension block can be discarded. The patient can begin full composite flexion with place and hold with the wrist positioned in slight flexion to neutral. • Begin active finger flexion and extension with the wrist in slight flexion to neutral; also begin active hook fisting with the wrist in slight flexion to neutral. • Instruct the patient in active tenodesis wrist exercises.
4 to 6 weeks	• Gentle blocking exercises are initiated, with care taken not to apply resistance during flexion while blocking. • Instruct the patient in full active wrist flexion and extension; begin passive finger extension with the MCP joints flexed and then progress to stretching and splinting to restore motion if needed. • Low-intensity ultrasound (3 MHz) is initiated if appropriate.
6 to 8 weeks	• The dorsal block splint is discharged unless the patient needs splinting for protection in certain environments. Instruct the patient to use the affected hand for light ADLs but to avoid lifting, gripping, or heavy activities. Begin gentle resistance.
8 weeks	• Progress with the strengthening program as needed and tolerated. The patient can begin resisted blocking exercises to increase IP flexion.

MCP, Metacarpophalangeal; *IP,* interphalangeal; *DIP,* distal interphalangeal; *FDS,* flexor digitorum superficialis; *FDP,* flexor digitorum profundus; *PIP,* proximal interphalangeal; *ADLs,* activities of daily living.

and gentle blocking exercises of the PIP and DIP joints at 4 weeks. Unrestricted AROM of the wrist and fingers can begin at 4 to 4½ weeks after surgery, and gentle resistance can be initiated at 6 weeks, progressing with strengthening at 8 to 10 weeks; most patients are discharged at 12 weeks after surgery. Patients may develop extrinsic flexor tightness with repairs in these zones. The dorsal block splint is discontinued at 6 weeks, and a full extension resting splint may be indicated if extrinsic flexor tightness is present.[111,112]

Anatomical structures that may be involved with a laceration to the wrist and forearm include the FDS, FDP, FPL, PL, FCR, FCU, the medial nerve, the ulnar nerve, the radial artery, and/or the ulnar artery. All these structures must be repaired to ensure a positive functional outcome for the patient.[111] If an injury in zone IV or V involves a median and/or ulnar nerve repair, the wrist should be positioned in approximately 30° flexion in the dorsal block splint and, starting at 3 weeks after surgery, the amount of wrist extension should be increased by 10° each week. If the ulnar nerve has been repaired, the MCP joints must be positioned in flexion to prevent hyperextension and clawing of the digits. If the median nerve has been repaired, adding a thumb component to the dorsal block splint is recommended to prevent shortening of the first web space and to maintain abduction.[113] If repairs in zone V are the tendon to tendon type, early active motion can be initiated and can follow the zone II protocol. However, if repairs in zone V are at the musculotendinous junction, active motion should be delayed until 3 to 4 weeks after surgery.

Flexor Pollicis Longus Injuries of the Thumb

Surgical repairs of the FPL tendon can be challenging because the proximal end of the lacerated FPL tendon retracts more proximally than a lacerated digital flexor tendon, which is restrained by its interconnections. Delaying surgery even up to 48 hours can make pulling out the proximal tendon to its original length difficult because muscle shortening can occur quickly. Unfortunately, increased tension of the FPL tendon from muscle shortening puts the patient at risk of rupturing the tendon and/or of developing thumb IP flexion contractures. Tendon retraction can be addressed during surgery by lengthening the FPL tendon within the muscle with transverse divisions or Z-lengthening of the tendon at the musculotendinous junction, which reduces FPL tension.[114]

Factors that affect the outcome of FPL injuries include retraction of the proximal tendon, the zone of injury, and postoperative management. Patients with proximal stump retraction have a higher incidence of unsatisfactory results. FPL lacerations in zone II can involve the A1 pulley, which is important for FPL function because it prevents the tendon from bowstringing. Excessive scarring in this area can lead to loss of tendon gliding. A study by Kasashima et al.[115] showed that passive flexion and active extension exercises using rubber band traction significantly reduced the risk of unsatisfactory results in patients with FPL repairs, particularly in those with a zone II laceration or retraction of the proximal tendon stump.

Many of the concepts and methods discussed for postoperative management of finger flexor tendon repairs apply to repairs of the FPL. Therapists and surgeons may use immobilization or EPM or EAM protocols, depending on their experience, preference, the type of repair, and the patient's age and compliance. Splint position and treatment protocols can vary; therefore communication is essential between the surgeon and the therapist.

Young children or patients who are noncompliant may benefit from an immobilization program. Cooperation is reported to be poor in children younger than 5 years of age, and some advocate immobilizing these injuries in an above-the-elbow cast (with the wrist and the MCP and IP joints in flexion and the thumb abducted) for 4 to 6 weeks, at which time motion can begin. No significant formation of adhesions was found using this method with this age group.[116] Older children and adults involved in an immobilization program after FPL repair generally are splinted with a forearm-based dorsal protective splint with the wrist in approximately 15° to 25° flexion, the thumb abducted, the CMC joint in 10° flexion, and the MCP joint in 20° to 30° flexion.

The thumb IP joint is in neutral, although this position could vary, depending on the type of repair and the amount of tension on the FPL tendon (Figure 10-58). If tendon shortening occurred or if approximating the tendon ends was difficult, the IP joint may need to be positioned in slight flexion.[112] Patients are immobilized for 4 weeks and then can begin gentle AROM exercises.

Figure 10-58 Dorsal protective splint for a flexor pollicis longus repair. The wrist is held in flexion, and the thumb is also placed in flexion to protect the healing tendon repair.

Proponents of the Kleinert method use rubber band traction to position the thumb in flexion for active extension/passive flexion exercises for the first 3 to 4 weeks before starting active thumb flexion.[115] The modified Duran protocol is also used for FPL repairs, and the patient is instructed to passively flex the thumb and then actively extend to the confines of the dorsal block splint for the first 3 to 4 weeks after surgery. As described earlier, with finger flexor tendon rehabilitation, some protocols treating FPL repairs combine elements of the modified Duran method with a place and hold component. The Evans MAMTT technique recommends using an active hold component with the thumb positioned in 15° of CMC joint flexion, 45° of MCP joint flexion, and 40° of IP joint flexion with an external force of 15 to 20 g, measured with a Haldex pinch gauge and string held perpendicular to the thumb.[96] Table 10-10 details the guidelines and most widely used protocols for the postoperative management and rehabilitation of FPL injuries in zones I and II.

Elliot and Southgate[114] have reported an EAM regimen for FPL repairs in zones I and II performed with a four-strand core suture with a Silfverskiöld circumferential suture. They recommended splinting the patient with the wrist in 10° extension and 10° ulnar deviation, the thumb abducted to 30°, the CMC joint flexed to 10°, the MCP joint flexed to 30°, and the IP joint at 0° extension. The patient is positioned in ulnar deviation at the wrist to reduce the turning angle of the FPL as it passes from the carpal tunnel into the thenar muscles. All remaining digits are also strapped into the dorsal hood of the splint with the fingers in neutral. The rationale for splinting the fingers is to prevent inadvertent increased strain on the FPL tendon with free finger motion.[114] This protocol is detailed in Table 10-11.

Extensor Tendon Injuries of the Hand

Extensor tendon rehabilitation involves many of the same concepts that apply to flexor tendon rehabilitation. Communication between the surgeon and the therapist is crucial, and the therapist must have a thorough understanding of the patient's injury and the type of surgical repair performed. Just as flexor tendon management has moved from immobilization toward EPM and EAM, so has the management of extensor tendons.[88] A variety of

TABLE **10-10**

Flexor Pollicis Longus Repairs in Zones I and II: Guidelines for Kleinert, Modified Duran, and Place and Hold Programs

Time Frame	Program Considerations
0 to 1 week	• *Splint:* Fabricate a dorsal protective splint: wrist, 15° to 30° flexion; CMC joint, 0° to 10° flexion; MCP joint, 20° to 30° flexion; IP joint, 0° (unless otherwise specified by the physician) to position in flexion. • *Exercise program:* Begin postoperative day 2-5; communicate with surgeon to determine the most appropriate program for the specific patient: o Modified Duran: Begin passive flexion of the IP, MCP, and CMC joints and allow active extension to meet the confines of the splint. o Kleinert traction: Begin passive flexion with a rubber band and active extension against the rubber band traction to meet the confines of the splint. o PROM and AROM to all noninvolved digits, with care taken not to actively flex the thumb. Instruct the patient to avoid all functional use of the injured thumb at this time (i.e., no lifting or gripping with the noninvolved digits). Instruct the patients to do the exercises frequently (i.e., 10 repetitions every 1-2 hours). o Place and hold should begin only with the physician's orders and once edema has diminished and the patient demonstrates good passive thumb flexion. Instruct the patient to place the thumb in limited flexion, exert a minimum amount of tension, and hold the position for 2-3 seconds. The degree of restriction of motion may be determined by the surgeon. • Begin edema management and scar management when the incision has healed.
3 to 4 weeks	• Discharge Kleinert rubber band traction unless the patient does not have full passive flexion. Continue with modified Duran exercises. Progress to place and hold with full range of motion. • Begin active thumb flexion in the splint with caution because FPL repairs have a higher rate of rupture. The wrist position of the splint may be changed to neutral.
4 to 6 weeks	• AROM of the thumb out of the splint, AROM of the wrist. • No resistance or gripping is allowed; light, functional, nonresistive activity of the thumb is allowed at week 6. • Ultrasound can be used at weeks 4-6 if indicated. • Gentle IP joint blocking with no resistance can begin.
6 to 8 weeks	• Dorsal block splint is discontinued unless protection is needed in a high-risk environment or circumstance. • Minimal resistance with a soft sponge or putty can begin. • Light functional use but no forceful pinching or gripping is allowed. • Progress with strengthening activities over 8-12 weeks.

CMC, Carpometacarpal; *MCP,* metacarpophalangeal; *IP,* interphalangeal; *FPL,* flexor pollicis longus; *PROM,* passive range of motion; *AROM,* active range of motion.

early motion protocols have been developed for zones III through VII, including thumb zones T-I to T-III.

The strength of the repaired tendon, the ability of the tendon to glide, and tendon excursion in relation to the position of the wrist all affect the treatment of extensor tendon repairs. The extensor tendon is smaller and flatter than the flexor tendon and therefore is not as suitable for more complicated, multistrand suture techniques. However, some suture techniques have been developed for extensor tendon repairs that allow for early controlled motion (ECM).[117]

Factors That Affect the Strength of a Repaired Extensor Tendon

- Ability of the tendon to glide
- Tendon excursion in relation to wrist position
- Wrist position
- Metacarpophalangeal joint position

Studies done by Newport and Tucker[117] have reported that finger extension strength varies significantly, depending on the wrist and MCP joint positions, because of the tenodesis effect the wrist has on the extensor tendons. The extensor tendons have less excursion than the flexor tendons because of the linkage between them known as the *juncturae tendinae.*[117] Evans and Burkhalter[118] have determined that 5 mm of EDC excursion is generated when the MCP joints of the index and middle fingers are flexed to 30° and when the MCP joints of the ring and little fingers are flexed to 40°. This amount of gliding is considered to be sufficient to prevent the formation of adhesions after an extensor tendon repair.[118]

Zones I and II (Mallet Finger Injuries). Mallet finger injuries involve a disruption of the terminal tendon and are treated with immobilization by splinting the DIP joint of the finger in 0° extension. The length of time in the splint depends on the classification of the injury (see previous descriptions of the four types of mallet injuries). Closed mallet injuries without fractures are treated by

TABLE **10-11**

Flexor Pollicis Longus Repairs in Zones I and II: Guidelines for the Elliot and Southgate Program[114]

Time Frame	Program Considerations
Week 1	• Instruct the patient to actively flex and extend the fingers only 25% of their full motion • Limit active flexion of the thumb to touching the tip of the middle finger • After 1 week the patient can passively flex the fingers fully
Week 2	• Increase finger active range of motion to 50% • Limit active flexion of the thumb to touching the tip of the ring finger • Begin passive flexion of the thumb
Week 3	• Full active range of motion of the fingers is allowed • Full active flexion of the thumb is allowed*

* The authors did not discuss resistive activity, strengthening exercises, and functional activity; however, they concluded that the repair they chose was strong enough to allow early active mobilization and to avoid the risk of rupture.

splinting the DIP joint in extension with a stack splint, a custom-molded thermoplastic splint, or aluminum foam splint. The splint should not interfere with PIP flexion and should be checked regularly to ensure proper positioning, especially if the swelling in the patient's finger is declining. Proper alignment at 0° extension is important because it prevents hyperextension of the DIP joint, which can cause blanching of the dorsal skin and lead to skin necrosis. The patient wears the splint continuously for 6 to 7 weeks; then gentle AROM can begin. If an extension lag occurs at the DIP joint, the splint may need to be applied for an additional 2 to 4 weeks. Patients are gradually weaned out of the splint during the day, although they may need to continue with night splinting if a lag persists. Open lacerations to a terminal tendon or those with associated fractures may be repaired and the DIP joint pinned in extension with a K-wire. Patients are instructed in AROM at approximately 6 weeks after surgery but continue to wear a static extension splint for several more weeks between exercises and at night.[119]

Swan neck deformities, which cause hyperextension of the PIP joint with flexion of the DIP joint, can occur if a significant mallet injury goes untreated (Figure 10-59). This deformity occurs as a result of unopposed tension of the central slip, dorsal migration of the lateral bands, and laxity of the volar plate. Swan neck deformities can be treated with a figure-of-eight splint that allows for PIP flexion but blocks hyperextension of the PIP joint. Splinting helps with functional grasp and prevents the finger from locking in hyperextension, but this is not a long-term or permanent solution for severe deformities, which may require surgical intervention (Figure 10-60).

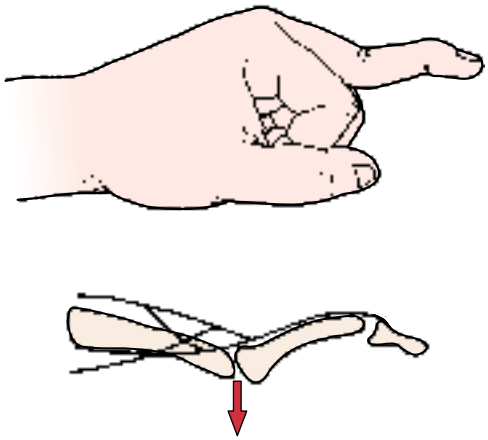

Figure 10-59 Swan neck deformity. Note the hyperextension at the proximal interphalangeal joint. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 440, St. Louis, 2014, Saunders/Elsevier.)

Zones III and IV. Zone III extensor tendon injuries occur at the PIP joint and involve the central slip. Zone IV extensor tendon injuries occur at the level of the proximal phalanx and involve the lateral bands. If these injuries go untreated, a boutonniere deformity can develop, causing flexion of the PIP joint and hyperextension of the DIP joint. Early intervention is important to prevent a flexion contracture of the PIP joint. If a closed rupture has occurred, the recommended course is to splint only the PIP joint in full extension and leave the DIP joint free to move. The patient is instructed to passively and actively flex the DIP joint with the PIP splint on. This allows the lateral bands, which have migrated anteriorly, to return to their proper anatomical position and also assists the central slip in moving distally to heal in the correct position. Closed boutonniere injuries are splinted anywhere from 2 to 6 weeks, depending on the severity of the injury. Patients should be checked frequently and instructed to remove the splint to perform gentle AROM, with active-assistive extension exercises. Passive PIP joint flexion should be avoided for 6 weeks. The patient may be weaned out of the splint gradually to wearing it at night as needed.[119]

Complete extensor tendon lacerations in zones III and IV are treated with surgical intervention. Postoperative treatment consists of immobilization (Table 10-12), ECM (Table 10-13), or EAM protocols.

Immobilization After Extensor Tendon Repair. Immobilization is considered the "safest" treatment because it limits motion altogether, thereby minimizing tension on the repaired tendon; however, it unfortunately leads to adhesion formation, loss of joint flexion, and extensor tendon lag. Despite these disadvantages, immobilization programs may be most appropriate for young children or for patients who are unable to comply with ECM methods.[117]

Effect of Immobilization on a Repaired Extensor Tendon

- Limit movement
- Lead to the formation of adhesions
- Decrease joint tension on the tendon
- Lead to extensor tendon lag

Early Controlled Motion After Extensor Tendon Repair. ECM programs that incorporate various combinations of dynamic splinting and tendon gliding, when used after extensor tendon repair, have resulted in significant improvements in the outcome of these injuries. ECM programs for extensor tendon repairs limit active flexion but allow passive extension of the digit, provided by rubber band traction attached to an outrigger (Figure 10-61). Based on the same rationale as that for flexor tendon studies, controlled stress combined with early motion has been shown to have a positive outcome on the healing extensor tendon.[120] Studies have reported that the protocol presented in Table 10-13, using a hand-based dynamic splint with ECM for repairs in zones III and IV, provides excellent results with fewer treatment visits and a shorter duration of treatment.[121,122]

Extensor tendon repairs in zones III and IV can also be treated with a dynamic extension assist splint with a

Figure 10-60 Figure-of-eight splint (Oval 8 Splint) for a swan neck deformity prevents PIP hyperextension while allowing full PIP and DIP flexion.

TABLE **10-12**

Extensor Tendon Repairs in Zones III and IV: Immobilization Protocol

Time Frame	Program Considerations
0 to 1 week	• *Splint:* PIP joint in 0° extension; if only zone III was repaired, leave the MCP and DIP joints free. If zone IV repair or lateral bands were involved, include the DIP joint in the splint at 0° extension for 4-6 weeks. • *Exercise program:* Begin 10-14 days after repair. If zone III was repaired, instruct the patient to actively flex the DIP joint every 2 hours. • Manage edema.
3 to 6 weeks	• Isometric extensor exercises can begin with the splint on; continue with DIP flexion exercises. • At weeks 4-6, remove the splint to begin gentle AROM exercises (hook and composite fist) but instruct the patient to wear the splint between exercise sessions. • Begin scar management if needed.
6 to 8 weeks	• Progress with gentle AROM and AAROM to increase flexion; progress to gentle flexion exercises. Incorporate a dynamic flexion splint, if needed, and alternate with the extension splint. • Begin resistive activity and progress as needed.

PIP, Proximal interphalangeal; *MCP,* metacarpophalangeal; *DIP,* distal interphalangeal; *AROM,* active range of motion; *AAROM,* active-assisted range of motion.

TABLE **10-13**

Extensor Tendon Repairs in Zones III and IV: Early Controlled Motion with Dynamic Splinting

Time Frame	Program Considerations
0 to 1 week	• *Splint:* ○ Fabricate a dorsal hand-based splint with the wrist free, the MCP joint in 0° to 20° flexion (surgeon's preference), and a Velcro strap around the proximal phalanx. ○ Apply dynamic traction to hold the PIP joint in 0° extension or slight hyperextension (surgeon's preference). The DIP joint is left free. ○ Apply a stop bead to the dynamic traction to limit PIP flexion (which is determined by surgeon) (see Figure 10-61). • *Exercise program:* ○ Allow the patient to actively flex the PIP joint against the rubber band traction, with limited flexion because of the stop bead (generally 30° if the repair is strong) and with passive extension back to neutral through dynamic traction. ○ Zone III repairs: If the patient is reliable, in the clinic the therapist can remove the strap around the proximal phalanx and perform limited MCP flexion with the PIP joint held in 0° extension. ○ Active DIP flexion can be performed with the PIP joint positioned or held in 0° extension. Begin edema management if indicated. ○ Week 2: With the physician's approval, adjust the stop bead to allow 40° of active PIP joint flexion. Continue with active flexion, passive extension, and previous exercises. • Begin scar management when incision heals.
3 weeks	• With the surgeon's approval, adjust the stop bead to allow 50° of active PIP flexion. Continue with previous exercises.
4 to 6 weeks	• Discharge dynamic traction. Instruct the patient to begin active extension and full active flexion exercises (composite fist, hook fist). Educate the patient about light use of the hand for functional, nonresistive, light tasks at week 6. • Begin blocking exercises to increase PIP flexion. Continue use of the static extension splint at night and for protection between exercises if needed.
6 to 8 weeks	• Begin PROM or dynamic flexion splinting or strap to increase flexion only if no extensor lag is present. • Continue use of the night extension splint if needed. Begin resistive flexion exercises and progress with strengthening program.

MCP, Metacarpophalangeal; *PIP,* proximal interphalangeal; *DIP,* distal interphalangeal; *PROM,* passive range of motion.

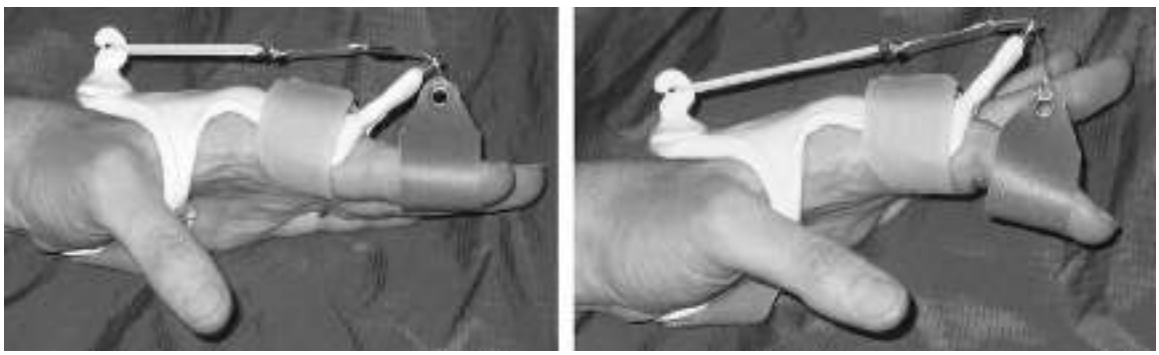

Figure 10-61 Hand-based dynamic extension splint for extensor tendon repairs in zones III and IV.

spring coil, referred to as a modified Wynn Parry splint or Capener splint. The advantages of this splint are that it is finger based and low profile, and it allows the MCP joint to be free.[123] The disadvantages are that it requires a longer splinting period before AROM out of the splint begins; it can be difficult to fit, especially if edema is present; it can cause pressure sores; and the duration of the treatment is longer than with dynamic splinting.

Early Active Motion for a Zone III Extensor Tendon Repair. Evans and Thompson[124] have defined the parameters for an early active SAM protocol

for a repaired central slip. The patient begins controlled active finger extension and limited flexion within 24 to 48 hours immediately after surgery. These researchers showed that 30° of PIP active motion allows 3.75 mm of EDC excursion. This provides enough gliding to allow healing but prevents the formation of adhesions in zones III and IV. The patient is splinted with the PIP and DIP joints in 0° extension and wears the splint at all times except when exercising. The patient uses two other static volar splints for an exercise program. One splint limits PIP flexion to 30° and DIP flexion to 20° to 25°. The patient is allowed to perform active extension of the digit and then flexes to meet the splint, but the MCP joint must be positioned in 0° extension and the wrist in 30° flexion. The second exercise splint positions the PIP joint in extension and allows DIP flexion. If the lateral bands have been repaired, DIP flexion is limited to 30°; if the lateral bands are not involved, the DIP is allowed to flex fully. The patient is instructed to perform each exercise 20 times every hour.[124,125]

Two weeks after surgery, if no extensor lag is present, the exercise splint that limits PIP flexion is adjusted to limit PIP flexion to 40°; 3 weeks after surgery, it can be adjusted to 50°; by the end of the fourth week, it can be adjusted up to 70° to 80° of PIP flexion if no extension lag exists. Patients can begin composite flexion exercises and gentle strengthening at 5 weeks after surgery, and some are discharged at 6 weeks after surgery. If the PIP joint is stiff, intermittent flexion splinting is recommended at approximately 4 weeks, alternating with night static extension splinting, which may need to continue for 5 to 6 weeks after surgery.[124,125] Evans[96] also recommended the MAMTT technique combined with dynamic splinting for more proximal extensor tendon zones.

Early Protected Motion with Passive Flexion. Crosby and Wehbe[126] advocate an early protected motion program that combines dynamic splinting with early passive flexion. This method is recommended for extensor tendon repairs in zones III to VII and all thumb zones (T-I to T-III), as well as in zones VI and VII. Their study included incomplete, complete, and complex extensor tendon lacerations. Surgical repairs were performed with mattress, figure-of-eight, or modified Kessler sutures, depending on the level of repair and the thickness of the tendon. Repairs in zones III and IV were treated with a dorsal hand-based dynamic splint with the MCP joint at 0° extension and the PIP joint held in 0° extension with traction from the splint. Some patients were allowed to flex the PIP joint with no limitations in the splint. In other patients, PIP flexion was limited with a block, as determined by the surgeon based on the integrity and status of the repair. Patients were instructed to perform, on an hourly basis, active hook fisting within the confines of the splint, allowing the dynamic traction to passively extend the finger back to extension.[126]

This protocol introduced the concept of tendon mobilization, performed by the clinician, which involves holding the affected digit and the wrist in maximum extension while passively ranging only one joint at a time. The PIP joint is passively flexed to its specified block while the MCP and DIP joints and the wrist are all held in maximum extension. If there is no flexion block, the clinician applies gentle gradual force until full range of motion is obtained or until resistance or pain is encountered.[126]

Dynamic splinting and tendon mobilization are initiated 1 to 5 days after surgery. After 4 weeks, the patient is instructed in AROM and tendon gliding exercises and weaned out of the splint over a few days. If an extension lag is present, the patient uses a static volar splint for extension. After removal of the splint, the patient begins a gentle, graded strengthening program. Grip and pinch strength are measured at 8 weeks after surgery with a Jamar Dynamometer and pinch meter. A flexion strap is used at 8 weeks if IP flexion is limited.[126]

This method is used with extensor tendon repairs performed in zones V through VII. These patients are splinted with a dorsal forearm-based dynamic splint that positions the wrist in 20° extension and holds the MCP joints at 0° extension with dynamic traction. The use and degree of MCP joint flexion blocks are determined at the time of surgery, depending on the strength of the repair and how well the tendon is able to glide without tension. These zones are also treated with an early protected mobilization program, and excellent to good results have been reported.[126]

Zones V to VIII

Immobilization Program. Zone V involves the area over the MCP joint, and zone VI is located over the dorsal aspect of the metacarpals. Zones VII and VIII, which are found at the extensor retinaculum and the musculotendinous junction, often are associated with scar adhesions that lead to extrinsic tightness and loss of finger flexion. Debate exists over whether patients treated with immobilization in zones V to VIII may not do as well as with ECM, resulting in extensor tendon lag and limited flexion. Proponents of immobilization programs for extensor tendon zones V to VIII report that equally good functional results can be achieved using static splints that are simpler, less labor intensive, and less expensive than programs that use dynamic splinting.[127] Many experts seem to agree that immobilization methods may be indicated for young children or noncompliant patients.

The position for immobilization depends on the level and complexity of the injury and whether other associated structures have been involved. The patient generally is splinted with the wrist in 30° extension and the MCP joints in 20° to 30° flexion. The IP joints may be included at neutral or left free to move. Patients who are allowed to actively flex and extend the IP joints without compromising the repair do better than patients whose IP joints are

splinted.[127] Three to 4 weeks after surgery, the patient can remove the splint only for gentle AROM exercises, with the wrist extended during finger flexion and care taken to avoid full wrist and finger composite flexion. Tenodesis exercises for the wrist can begin 4 to 6 weeks after surgery, with composite AROM of the wrist and fingers at 6 weeks after surgery. Gentle passive finger flexion can be initiated at 4 to 6 weeks after surgery, or gentle dynamic splinting alternating with extension splinting may be used if needed. A gentle strengthening program can begin at 6 weeks and progress to 8 weeks after surgery.[125]

Early Controlled Motion. Early motion protocols consisting of dynamic splinting and tendon gliding have become widely accepted and successful in treating zones V to VIII (Table 10-14). Protocols for treatment vary, depending on the position of the wrist and the MCP joints; they also may be determined by the surgeon at the time of surgery based on the status of the repair. More proximal zones often can tolerate more composite flexion within the confines of the dynamic splint, especially if the wrist is extended beyond 20° extension (Figure 10-62). However, excessive wrist extension may cause the extensors to buckle in the more proximal zones and interfere with tendon gliding.[117]

Chow et al.[120] presented a study of ECM for extensor zones IV through VII. The authors used a dorsal forearm-based splint with dynamic traction to passively extend the MCP joint to 0° extension, allowed limited MCP flexion, and provided unrestricted active flexion of the PIP and DIP joints. During the first week after surgery, the MCP joint of the involved finger was allowed to flex to 30°; during the second week, this was increased to 45°; during the third week, to 60°, and during the fourth and fifth weeks, full flexion was allowed with the splint on. Patients were instructed to actively flex within the confines of the splint 10 times every hour. The splint was discontinued by the end of the fifth week, and AROM out of the splint was initiated. Resistive exercises and strength were not discussed in this study, but patients had no restrictions after 8 weeks.[120]

Some protocols advocate positioning the MCP joint in 0° extension, whereas others suggest blocking the MCP

TABLE **10-14**

Extensor Tendon Repairs in Zones V to VIII: Early Controlled Motion with Dynamic Splinting

Time Frame	Program Considerations

0 to 1 week	• *Splint:*
	  ○ Fabricate a dorsal forearm-based dynamic splint with the wrist in 20° extension and the MCP joints in 0° to 20° flexion (depending on the surgeon's preference and the repair performed).
	  ○ The surgeon may order an MCP flexion block, or the MCP joint may be allowed to flex fully. The IP joints may be unrestricted, or the surgeon may request that loops from dynamic traction support them in neutral position. Adjacent fingers may or may not be included, depending on the level and location of the injury.
	  ○ Some surgeons may request a separate volar resting splint that blocks MCP flexion and supports the IP joints in extension. This splint is worn with the dorsal dynamic splint for exercises (see Figure 10-62).
	  ○ Some patients may find sleeping while wearing the dorsal forearm-based dynamic splint difficult; these patients may benefit from wearing a volar static resting splint at night, which positions the wrist and fingers in extension. (The IP joints may or may not be included in the splint, depending on the repair zone and the surgeon's orders.)
	• *Exercise program:*
	  ○ Begin active MCP flexion within the confines of the splint with passive MCP extension through the dynamic traction of the splint. If loops are not restricting IP motion, the patient is instructed to perform active flexion and extension of the PIP and DIP joints in the splint (i.e., active hook fisting) 10 times every hour.
	• Begin edema management.

2 to 3 weeks	• Continue with the previous exercises. The therapist can begin gentle passive IP flexion with the MCP joints and wrist in extension. • Begin scar management when appropriate.
4 to 6 weeks	• The patient can begin AROM and tendon gliding out of the splint, taking care with full composite wrist and finger flexion. Instruct the patient to keep the wrist extended with gentle finger flexion. • The patient can also begin tenodesis wrist and finger motion. Continue use of the night static extension splint if extension lag is present. Gradually wean the patient out of the dynamic extension splint for daytime.
6 to 8 weeks	• Full wrist and finger composite flexion and extension can be performed. The patient should wean out of the dynamic splint and continue with a night static splint if needed. • Instruct the patient in gentle PROM exercises. A dynamic flexion splint or strap can be used if flexion is limited. • Begin a gentle strengthening program and progress as needed. No restrictions are necessary after 10-12 weeks.

MCP, Metacarpophalangeal; *IP,* interphalangeal; *PIP,* proximal interphalangeal; *DIP,* distal interphalangeal; *AROM,* active range of motion; *PROM,* passive range of motion.

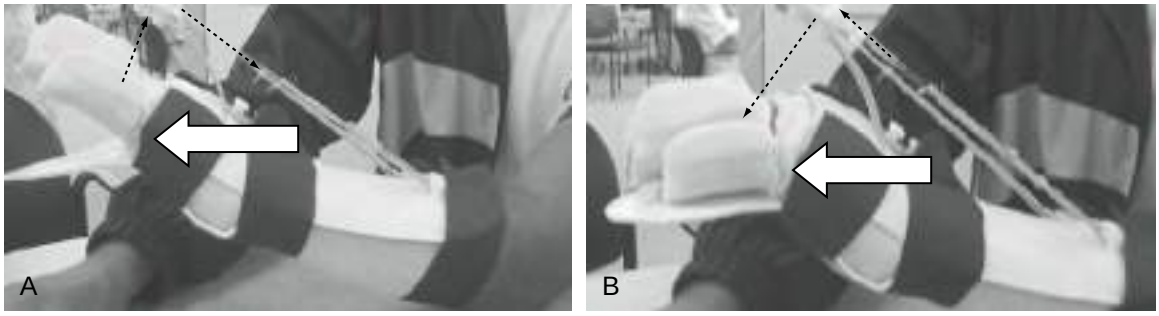

Figure 10-62 **A,** Dynamic forearm-based extension splint with elastic band assistance for passive finger extension. **B,** This splint allows active MCP flexion into a volar resting splint, blocking MCP flexion to approximately 30° for zone V extensor tendon repairs in the index, long, ring, and little fingers. The injuries, caused by a table saw accident, required open reduction and internal fixation of metacarpal fractures in the index, ring, and long fingers. The PIP and DIP joints are held in extension in finger troughs, which are attached to the elastics by opaque fishing line *(dotted lines and arrows)*.

joints at 5° to 10° flexion to prevent hyperextension and extensor activity, which has been detected through electromyographical (EMG) studies when the extensor tendons are at rest in 0° extension.[122] Active MCP flexion may also be limited with early motion protocols, depending on the repair and the ability of the tendon to glide freely.[126]

Immediate Controlled Active Motion for Zones IV to VII After Extensor Tendon Repair. Early mobilization programs vary among clinicians, surgeons, and clinics, depending on their experience level, the patient's presentation, and the extent of the injury. Just as there are trends toward early active flexion with flexor tendon rehabilitation, a trend has arisen for early active extension after extensor tendon repairs.

Immediate controlled active motion (ICAM) has been used to treat extensor tendon repairs in zones IV to VII. Howell et al.[128] designed an EAM program that consists of three phases and uses a low profile, two-part splint. The patient wears two static splints. One is a static volar wrist cock-up splint that positions the wrist in 20° to 25° extension. The second splint, called the ICAM yoke splint, links the injured digit to the noninjured digits to unload the repair and harness extension forces during active motion. The yoke is positioned across the proximal phalanges of the fingers and allows active flexion and extension of the fingers but positions the involved MCP joint in 15° to 20° more extension relative to the uninjured MCP joints (Figure 10-63).[128] The EAM program consists of three phases (Table 10-15). The authors had a 30% noncompliance rate, but they did not know of any complications or ruptured tendons. One hundred and forty patients completed the program. Categorization of an excellent outcome was based on the occurrence of no extensor lag or loss of terminal flexion. Of the 140 patients, 81% of the patients had no extensor lag and 79% of the patients had no loss of terminal flexion. The timing of strengthening and resistive exercises was not discussed, but grip strength was reported to be 85% of the opposite, uninjured hand at the time of discharge, which averaged 7 weeks after surgery.[128]

Figure 10-63 The immediate controlled active motion (ICAM) splint (third version) with wrist positioned in 20° to 25° extension. The yoke component positions the involved MP joint in 20° to 25° hyperextension relative to the MP joints of the noninjured digits. (From Howell JW, Merritt WH, Robinson SJ: Immediate controlled active motion following zone 4-7 extensor tendon repair, *J Hand Ther* 18:183, 2005.)

Rehabilitation of the Extensor Pollicis Longus in the Thumb

Immobilization Program After Extensor Pollicis Longus Tendon Repair. EPL tendon repairs can be treated with immobilization or ECM programs. Treatment programs vary, depending on the level of injury, the clinician's expertise, and the individual patient. Injuries in zone T-I are referred to as a *mallet thumb* and can be treated by splinting the IP joint of the thumb in 0° extension for 6 to 8 weeks for a closed injury or 5 to 6 weeks for an open repair. Gentle AROM can begin after the immobilization period, using caution if an extensor lag is present, and the

TABLE **10-15**

Extensor Tendon Repairs in Zones IV to VIII: Immediate Controlled Active Motion

Time Frame	Program Considerations
Phase 1 (0 to 21 days)	• Within 48-72 hours after surgery, splints are fabricated and the ICAM program begins. • The patient begins full active composite finger flexion and extension within the confines of the splint. • The splint must be worn at all times. • The patient is instructed in edema and scar management.
Phase 2 (22 to 35 days)	• Before the patient can begin phase 2, full active motion must be achieved within the limits of the ICAM splint. The patient continues to wear the ICAM yoke splint, but the wrist splint is removed to begin AROM exercises to the wrist with the finger held in a relaxed position. • The patient is instructed to wear the wrist splint and yoke if doing medium to heavy activity. If no extension lag is present, the patient progresses to wrist flexion with finger fisting in the yoke and wrist extension with finger extension. • Once the wrist is moving freely, the patient can discontinue the wrist splint for light tasks but should be instructed to wear the wrist splint and yoke if performing medium to heavy tasks.
Phase 3 (36 to 49 days)	• The wrist splint is discharged. • To prepare the patient for yoke-off activity, the yoke is removed for AROM of the digits. • The finger yoke or a buddy strap is worn during activities. • Full composite wrist and finger flexion and extension without the splints should be achieved during phase 3.

ICAM, Immediate controlled active motion; *AROM,* active range of motion.

patient continues to wear a static extension splint between exercises and at night. Patients can progress in active IP joint flexion slowly and begin resistive exercises at 6 to 8 weeks.[125]

Zone T-II injuries are also treated by immobilizing the MCP and IP joints in 0° extension in a hand-based splint with the thumb in radial extension. Limited AROM begins at 3 to 4 weeks, and over the next 3 weeks, the patient can increase joint motion gradually. If an extension lag is present, an extension splint should be used. Patients should use the splint for protection between exercises for a total of 6 weeks.[120]

EPL repairs in zones T-III and T-IV are treated by splinting the thumb MCP joint at 0° extension and slight abduction with the wrist in 30° extension for 3 to 4 weeks before starting AROM exercises. The MCP joint may become restricted from hyperextension or from prolonged splinting in extension, requiring dynamic flexion splinting at 4 to 6 weeks. Injuries in zone V are susceptible to the formation of dense adhesions, which can limit the excursion of the EPL at the retinacular level. Extension contractures of the thumb MCP joint, thumb web space contracture, and restrictions in the joint capsule and on tendon gliding are all problems that can occur at this level with immobilization.[125]

Immobilization programs can result in loss of thumb motion after repair of the EPL tendon. Scar tissue causes the extensor tendon to adhere to bone or skin. In addition, the scar tissue causes a thickening of the dorsal joint capsule. Even if no actual injury has occurred to the dorsal joint capsule, it can play a role in the loss of motion at these levels. The potential for loss of IP joint motion is greatest for zone T-I injuries, and loss of MCP joint motion is greatest for zone T-III injuries, which can be caused by tendon tethering. Scar tethering of the small branches of the superficial radial nerve of the thumb not only results in loss of thumb IP motion but also can cause dorsal thumb pain.[114]

Early Mobilization Programs After Extensor Pollicis Longus Tendon Repair. Early mobilization programs have been designed to reduce the potential for loss of thumb motion caused by scar formation and decreased tendon gliding. Most early mobilization programs used to treat EPL tendon repairs involve the use of a dynamic extension splint that allows for active flexion and provides passive extension of the thumb to neutral. This splint is used for approximately 4 weeks and then can be removed so that the patient can begin AROM out of the splint. Graded strengthening exercises begin at 6 to 8 weeks after surgery, and a static extension splint may be necessary if an extensor lag is present. The amount of active thumb IP or MCP flexion may be determined at the time of surgery and may depend on the level of injury. Protocols can vary among clinicians, surgeons, and clinics, depending on the surgical repair, the clinician's experience, and the patient's presentation.

Elliot and Southgate[114] have described an early mobilization program for EPL repairs in zones T-I to T-IV that allows the IP joint to be free in zones T-II to T-IV and to partly flex in zone T-I. Patients underwent primary repair, and splinting and exercises began 3 to 4 days after surgery using the protocol (Table 10-16).[114]

Early Active Motion to Zones T-IV to T-V After Extensor Tendon Repair. For extensor tendon repairs in zones T-IV and T-V, Evans[125] described the use of a dorsal forearm-based dynamic extension splint and a volar component that

TABLE **10-16**

Extensor Pollicis Longus Repairs in Zones T-I to T-IV: Early Controlled Motion with Dynamic Splinting

Time Frame	Program Considerations

0 to 1 week	• *Splint:*
	  ○ Zones T-II to T-IV are splinted with a forearm-based dynamic extension splint with the wrist in 30° extension and the thumb MCP joint held in neutral by the dynamic traction with the loop supporting the proximal phalanx. The IP joint is free to move. Only partial MCP flexion is allowed in the splint.
	  ○ Zone I is splinted in the same way except the traction loop should support the IP joint in neutral; it also should restrict full IP active flexion slightly but allow passive extension of the MCP and IP joints with dynamic traction.
	• *Exercise program:*
	  ○ Injuries in zones II through IV allow partial MCP active flexion with the IP joint held in extension within the confines of the splint. Full MCP flexion is restricted for the first 2 weeks. The dynamic traction passively extends the MCP joint back to neutral. Instruct the patient to perform exercises 10 times every hour.
	  ○ Also instruct the patient to manually support the MCP joint in neutral and actively flex and extend the IP joint of the thumb 10 times every hour.
	  ○ Rehabilitation of zone I repairs follows the same regimen of active MCP flexion except that the patient is allowed only slight flexion of the IP joint.
	• Begin edema management.

2 weeks	• Patients with repairs in zones II through IV are allowed to synchronously flex the MCP and IP joints of the thumb in the splint to oppose the tip of the middle finger. Patients with a zone I repair do the same, but full IP flexion is restricted. • Continue previous exercises. • Begin scar management if needed.
3 weeks	• Patients with repairs in zones II through IV are allowed to flex and oppose the thumb MCP and IP joints in the splint to oppose the tip of the ring finger. • The regimen for zone I repairs is the same, although with limited IP flexion.
4 to 5 weeks	• Patients with repairs in zones II through IV are allowed to flex and oppose the thumb MCP and IP joints in the splint to the base of the little finger. The regimen for zone I repairs is the same, although with the IP joint restricted from full flexion. • The splint is worn at all times until the end of the fourth week. The patient then can begin AROM of the MCP and IP joints out of the splint. • Ultrasound is initiated at 4 weeks if needed. • The patient can wear the splint only for protection during the fifth and sixth weeks at night and in crowded places.
6 to 12 weeks	• PROM can begin at 7 weeks. Begin gentle resistive flexion exercises and progress to 8 weeks. Patients can return to driving at 8 weeks. • No restrictions are necessary at 12 weeks.

MCP, Metacarpophalangeal; *IP,* interphalangeal; *AROM,* active range of motion; *PROM,* passive range of motion.

supports the MCP joint in neutral and the wrist in extension, with a cutaway at the IP joint that enables the dynamic traction to support it in neutral (0° extension) but allows the IP joint to flex only 60°. The author added the component of active hold (MAMTT), which is done after protected passive exercise. The patient's wrist is placed in 20° flexion while the CMC, MCP, and IP joints are held in extension, and the patient is asked to gently maintain this position. The patient can come out of the splint for exercises during the third and fourth weeks but must continue to wear the splint for protection. Composite thumb flexion and opposition exercises are initiated by the fifth week, and resistive exercises can begin at 6 to 8 weeks.[125]

SPECIFIC INJURIES OF THE WRIST

Radial Fractures

General Considerations

Distal radial fractures are extremely common and account for about 10% to 25% of all fractures,[129] and about 17% of all fractures treated in the emergency department. In the United States, 1 person in 500 is treated each year for a distal radial fracture. These also are the most common physeal fractures in children. There is a bimodal preponderance of immature patients with physeal injuries and older patients with osteoporotic bone (6 to 10 and 60 to 69 years of age).[130]

The alignment requirements for a good functional outcome are still a subject of controversy for the fracture named after Abraham Colles, who said, "[despite] the distortion… the limb will at some remote period again enjoy perfect freedom in all its motions and be completely exempt from pain.[131] It is remarkable that this common fracture remains one of the most challenging of all fractures [with] no consensus regarding description, outcome, or treatment."[132]

Anatomy

The distal radius consists of two intra-articular surfaces with three concave facets. The resting plateau for the carpal bones is the radiocarpal joint, which consists of two concave surfaces: the scaphoid and lunate fossae (Figure 10-64). The scaphoid fossa is a concave triangular space with the radial styloid as its apex. A ridge running dorsally to palmarly separates it from the lunate fossa. The lunate fossa is concave in both dorsal to palmar and radial to ulnar directions, making it more of a quadrangular space than the scaphoid fossa. The lunate therefore is nearly always congruently aligned within the joint, unlike the scaphoid, which can easily become incongruent within its fossa when it is rotated out of position.

The second intra-articular component, which is often overlooked in the evaluation of distal radial fractures, is the distal radioulnar joint. It consists of a concave fossa, the sigmoid notch, which has well-defined distal, dorsal, and palmar margins. This joint allows the radius, along with the attached hand, to rotate about the stationary ulnar head in pronation and supination.

Injury Classification

Any classification system ought to accomplish several tasks. It should make organizing data and communicating the information to other health care providers simple; in addition, it should provide insight into the treatment of and prognosis for the injury. At best, the system enables the user to better understand the injury by clearly explaining the mechanism, graphically depicting the fracture fragments, or revealing the concomitant injuries.

Figure 10-64 Model of the distal radius showing both the distal radioulnar joint and the radiocarpal joint. The radiocarpal joint has a fossa for the lunate and one for the scaphoid.

Over the years, multiple systems have been devised to categorize wrist fractures. Some are based on historical eponyms (a person's name), others on the mechanism of injury, and still others on the number of fracture fragments and the location of the fracture. Many of these systems remain in use today, and each has its strengths and weaknesses. Although it is tempting to choose one that works well, clinicians should examine and develop an understanding of several to gain the knowledge that each imparts.

Of all the fracture classification systems, those based on eponyms impart the least insight; they require the health care provider to memorize a fracture pattern and assign a name to it. Frequently misnamed by the casual user, the systems impart limited information as to prognosis and treatment.

The most common eponyms used to describe distal radial fractures are *Colles' fracture, Barton's fracture, Smith's fracture,* and *Chauffeur's fracture*. Colles' fracture is a transverse metaphyseal fracture with dorsal comminution that results in radial shortening, dorsal tilt, and loss of radial height. Classically, it does not enter the radiocarpal joint but may enter the distal radioulnar joint. Barton's fracture is a shear-type fracture that involves either the volar or dorsal rim of the radius. Smith described three fractures that are in essence either Colles' or Barton's fractures.

Archetype classification systems work by organizing known fracture patterns from simple into more intricate models with a concomitantly worse prognosis and more complex treatment algorithms. The *Frykman classification system* is an excellent example.[133] This system, which was based on biomechanical and clinical studies, was presented in 1967 (Figure 10-65). It distinguishes between extra-articular radial fractures and three types of intra-articular radial fractures (radiocarpal, distal radioulnar, and radiocarpal–distal radioulnar fractures). This leads to four possible fracture patterns; however, each pattern is further differentiated based on whether the ulnar styloid is also fractured. The fractures get more intricate as the system progresses from type I to type VIII, with worsening prognoses. The strength of this system is that it reveals multiple intra-articular fracture patterns and the importance of the ulnar styloid (and ulnar carpal ligaments) to the prognosis for the injury. Its weakness lies in the fact that not all fractures within one class behave the same way. In other words, the treatment and prognosis for a minimally displaced intra-articular fracture of the radiocarpal joint are very different from the treatment and prognosis for a fracture in the same location that is massively comminuted and displaced.

Melone's classification system,[134] introduced in 1984, identifies four possible major fracture fragments of the radius: the radial styloid, the radial shaft, and the medial

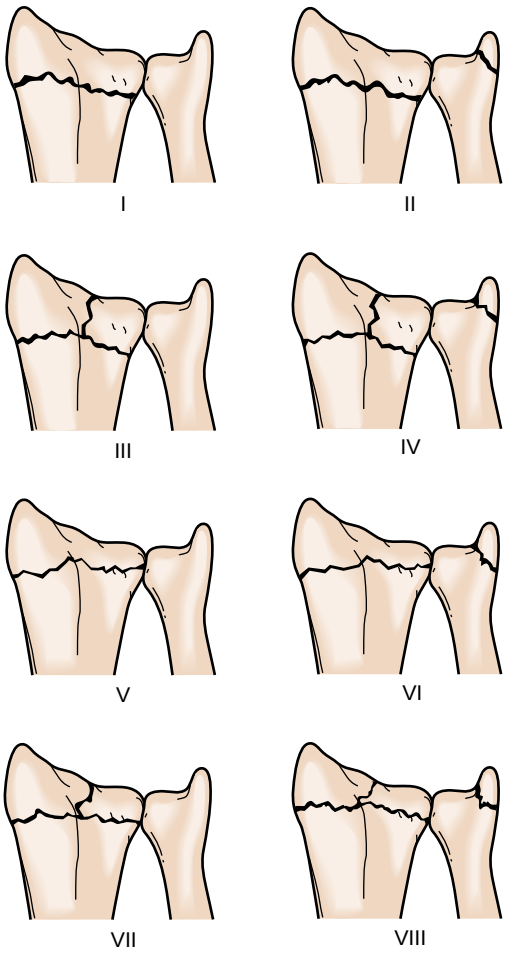

Figure 10-65 Frykman classification of distal radial fractures: types I to VIII. The higher numbers in the classification system indicate a poorer prognosis. (From Frykman G: Fracture of the distal radius including sequelae—shoulder-hand-finger syndrome, disturbance in the distal radio-ulnar joint and impairment of nerve function. A clinical and experimental study. *Acta Orthop Scand* 108: 1-155, 1967.)

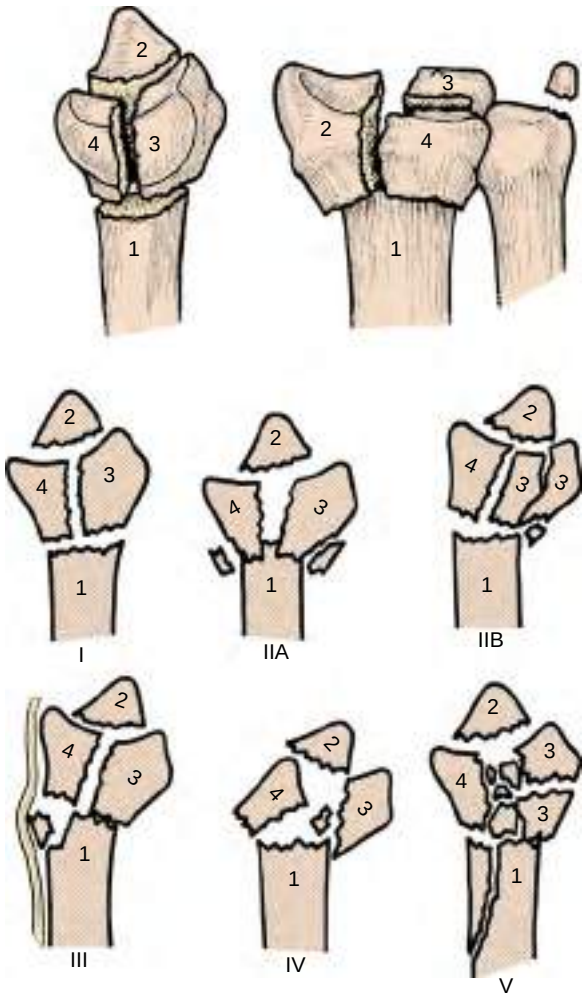

Figure 10-66 Melone's classification of distal radial fractures. (From Fernandez DL, Wolfe SW: Distal radius fractures. In Green DP, Hotchkiss RN, Pederson WC, Wolfe SW, editors: *Green's operative hand surgery,* ed 5, Philadelphia, 2005, Churchill Livingstone.)

aspect of the radius (the lunate facet), which frequently is split coronally into two fragments (Figure 10-66). Fractures can have one component or all four, and they become more complex and worsen prognostically as the number of fragments increases. This system of categorizing complex fractures has regained popularity with the advent of newer, more aggressive open fixation techniques. Its strength lies in its accurate depiction of complex fracture patterns and its emphasis on the lunate facet fragments, which affect the distal radioulnar articulation and therefore subsequently affect forearm rotation.

Fernandez[135] described a fracture classification system based on the mechanism of the injury. This system links the pattern of the break to the forces that caused it to occur. For instance, a shearing mechanism results in an unstable, oblique fracture off the volar or dorsal rim of the radius that requires open reduction and internal fixation. Although this system can be cumbersome, it relates the force that caused the injury to the relative stability of the fracture and makes treatment recommendations. This train of thought should start the clinician thinking about what other soft tissue injuries occurred with the osseous insult that will affect the overall outcome for the patient.

Diagnosis

The diagnosis of wrist fractures begins with a careful history to discover the mechanism of damage to the bone and the surrounding soft tissue envelope and to uncover any previous wrist injuries and concurrent damage. Likewise, it is important to get to know some things about the patient that will help determine the approach to this specific wound and to treatment in general. Important questions include: What does the patient do for work and hobbies? Which is the dominant hand? Does the patient live alone or with family and friends? What other health concerns does the patient have that may affect treatment?

The physical examination is conducted not only on the fractured wrist but on the entire upper extremity and any other body part the patient may have injured. Special consideration is warranted with patients who have fallen

without an obvious reason (e.g., they cannot remember slipping on ice or tripping). This should alert the examiner to the fact that the patient may have passed out briefly because of cardiac or neurological reasons that require further workup. Patients often are not forthcoming with this information. For them, it is a momentary blackout of memory, often filled in with the assumption that they simply tripped over something but cannot recall what it was. At this point, it is frequently helpful to note whether anyone else witnessed the injury.

The extremity then should be gently examined to evaluate the skin integrity, the overall alignment of the hand on the forearm, and the amount of swelling and discoloration. All these factors give insight into the amount of energy absorbed by the soft tissue and bone as a result of the trauma. Vascular and neurological examinations need to be performed carefully to verify brisk capillary refill in each digit and subjectively normal sensation. Wrist fractures have been known to cause injury to the median nerve or to worsen or create carpal tunnel syndrome. This possibility should be carefully evaluated. Tendon function for the digital flexors and extensors should be checked as well. The patient may be reluctant to move the digits because the gliding of the tendons past the injury zone is painful; however, the clinician must remember that tendon rupture can occur even with nondisplaced fractures, especially rupture of the long extensor to the thumb.[136] Displaced wrist fractures frequently have a similar appearance. The classic "silver (or dinner) fork" deformity has been used to describe the dorsal tilt created by the fracture. In addition, the clinician might note the loss of normal ulnar deviation of the hand at rest and a slightly pronated position of the hand on the forearm compared with the opposite side. If the swelling is not substantial, the distal ulna will look much more prominent because the radius has shortened and the ulna has not (Figure 10-67). Gentle palpation causes pain at the fracture site, and a palpable area of cortical incongruity and crepitus often is noted.

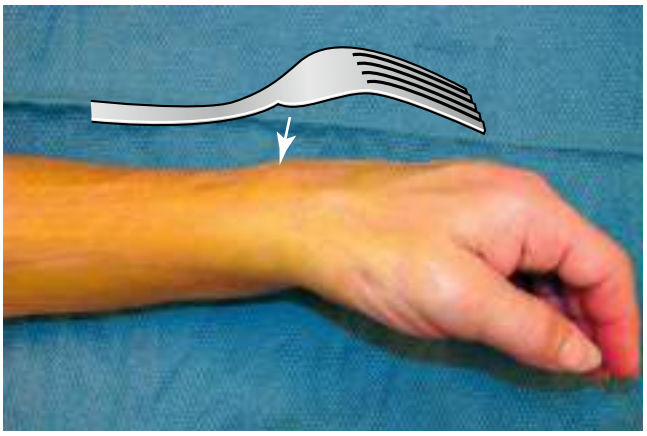

Figure 10-67 Displaced distal radial fracture (Colles fracture) with a classic "silver fork" or "dinner fork" deformity. Note the pronation and dorsal angulation of the hand on the forearm.

Imaging of the wrist usually confirms the diagnosis. Plain x-ray films taken in at least two planes, AP and lateral, should show most fractures. Oblique views can show additional fragments. Special x-ray views have been created to highlight joint incongruity, and these can be useful in determining the need for operative intervention. Occasionally, x-ray films are not sufficient to find an occult fracture or to depict the damage of a complex fracture accurately. In these cases, CT scanning can aid the clinician. If an occult fracture is suspected, a CT scan, MRI study, or bone scan is useful.

X-ray imaging can do more than confirm the diagnosis. The x-ray films help determine the character of the fracture, such as whether it is displaced or nondisplaced, stable or unstable, intra-articular or extra-articular, and, if intra-articular, whether joint alignment is acceptable or a incongruity is present that must be managed surgically. Determination of all these factors leads to the proper treatment.

Medical Treatment

Wrist fractures range from stable and nondisplaced to intra-articular, displaced, comminuted injuries. The treatment modalities chosen must reflect this continuum, as well as consider the patient's requirements of the hand and the skill of the surgeon and rehabilitation team.

Myriad treatment options are available for distal radial fractures. Splinting and casting, percutaneous pinning with x-ray or arthroscopically assisted reduction, external fixation, and internal fixation with plates or fragment-specific fixation devices are all currently in use. Recent advances in fragment-specific fixation and plate design, with the introduction of locking plates, has allowed hand surgeons to surgically repair extremely comminuted fractures in which such repair might not have been previously attempted.

When the clinician is deciding among this variety of options, clearly experience, preference, and the availability of equipment have an impact; however, certain principles guide treatment. The clinician must first determine whether the fracture is acceptably aligned. Knirk and Jupiter[137] reported that 90% of patients who had a healed intra-articular distal radial fracture with more than 1 mm of step-off went on to have symptomatic arthritis in the radiocarpal joint.[137] Multiple studies of extra-articular fractures have been done to determine the biomechanical changes that result from displacement. One study reported that a 12° loss of palmar tilt increases the ulnar load by 35%.[138] Another study reported that a loss in radial length of 2.5 mm increases the load on the ulna by almost 45%.[139] Increased ulnar loading is presumed to lead to an increased incidence of ulnar-sided wrist pain. Other effects of radial malunion include secondary midcarpal alignment changes and the possibility of early onset of degenerative joint changes in both the radiocarpal and distal radioulnar joints.[140]

If the fracture currently is acceptably aligned, the clinician must try to determine whether it is likely to stay in that satisfactory position as it heals. Good epidemiological studies are available describing what usually constitutes a stable fracture. The amount of displacement and comminution of the fracture and the patient's age are excellent predictors of subsequent redisplacement despite what initially might be a perfect closed reduction.[141–143]

If an injury requires operative intervention, either to prevent loss of reduction or to treat bony incongruence that cannot be resolved by closed methods, the surgeon must choose the method of treatment. Surgeons must have in their arsenal as many tactics or techniques as possible from which to choose. The surgeon must perform the appropriate surgery for the fracture *and the patient* to obtain the best outcome.

Pin Fixation. Pin fixation is percutaneous surgery that requires no dissection and causes very little additional soft tissue swelling. It relies on relatively good bone to hold the fixation around the pins and cannot correct extensively comminuted intra-articular fractures, nor can it reliably correct all of the volar tilt. This technique is most useful in older patients with shortened, dorsally tilted, minimally comminuted fractures because it holds better than a cast and does not require formal surgical dissection. Pin fixation also is useful in young patients with open growth plates who require reduction. With careful application of the pins, the growth plate can be avoided, and the small amount of volar tilt correction can usually be counted on to remodel with normal bone growth over time. Intrafocal dorsal pin application corrects length and volar tilt, and the addition of supplemental radial styloid K-wires provides stability. Pins require casting for supplemental stability; therefore motion cannot begin for 6 weeks or longer until the bone unites and the cast is removed. Pins are easily removed in the office and leave little scarring (Figure 10-68).

External Fixation. External fixation is a technique that uses ligamentotaxis to pull the fracture fragments into better alignment. The surgeon dissects and drills threaded pins into the radius proximal to the fracture and into the index finger metacarpal distal to the fracture and spanning the carpal joint. The surgeon attaches to these pins a mechanical frame with gears, which can be used to apply traction in different directions to pull on the hand to reduce the fracture fragments. This technique has recently begun to fall out of favor among hand surgeons as improved internal fixation technologies have become available. It still has a variety of indications that make it the procedure of choice. For fractures with extensive bone disruption, plate application may not be possible. Also, crush injuries may damage the soft tissue envelope such that the surgeon does not want to dissect extensively to apply a plate and screws to obtain rigid fixation. In this case an external fixator is the ideal choice. Finger motion should be started early because a potential drawback of the technique is stiff fingers as a result of overdistraction with the device. However, wrist motion must wait for removal of the device.

Internal Fixation. Internal fixation with a single locking plate and screws or with multiple small fragment-specific fixation components has been the most recent advance in the treatment of distal radial fractures. Previous attempts to apply plates to the distal radius had not been entirely successful because of the poor quality of the distal bone and the subsequent inability of the screws to obtain purchase and any type of holding strength. The new designs have successfully addressed these concerns and enabled anatomical repair of markedly comminuted unstable fractures in a stable configuration. The techniques differ in dissection and complexity, with the locking plate being far simpler to apply. However, in some instances the single locking plate will not obtain anatomical fixation of the joint surface, and the individual

Figure 10-68 **A,** X-ray film of a displaced Salter II fracture. **B,** The fracture was treated with closed reduction and percutaneous pin fixation. The pin avoids the growth plate but helps maintain alignment while healing occurs in a cast over a few weeks.

fracture fragments need to be addressed and repaired with the fragment-specific technique. These approaches require a surgeon who is experienced and comfortable with operating around the wrist. They should result in a stable reduction that allows motion in the early postoperative period. Ideally, because both the dissection and the initial injury will cause scarring, aggressive therapy to obtain mobility should be started in the first 7 to 10 days (Figures 10-69 and 10-70).

Complications. Treatment of distal radius fractures, both operatively and nonoperatively, has associated complications. Tendon irritation and rupture can occur secondary to plate position for operatively treated fractures. Tendon rupture, specifically EPL, has also been associated with nonoperative management of these fractures.[129] **Carpal tunnel syndrome** and **complex regional pain syndrome** are examples of nerve dysfunction that can result from operative and nonoperative management of wrist fractures and should be recognized and treated adequately to improve patient outcomes.[129]

As the operative techniques evolve, so must the rehabilitation protocols. New expectations for recovery of function in these injuries are being developed. Along the way, pitfalls and setbacks undoubtedly will be encountered and must be overcome. Hand surgeons and therapists must work more closely than ever to accomplish these tasks.

Scaphoid Fractures

General Considerations

The scaphoid is the most commonly fractured carpal bone, accounting for nearly 80% of all wrist bone injuries.[144] Fractures of the other carpal bones are much more rare, accounting for about 1.1% of all fractures.[145] The mechanism usually is a fall onto an outstretched hand (FOOSH injury), which creates a forced dorsiflexion of the wrist. The injured person may not have much pain, thinking the injury is little more than a sprain. Frequently, little swelling or ecchymosis is present except in the anatomical snuffbox. Young men are the most frequently affected. The injury can be associated with ligamentous injuries of the wrist, particularly scapholunate dissociations[146] or perilunate dislocations.[140]

Anatomy

The carpus consists of eight bones that are best thought of biomechanically as existing in two rows. The scaphoid traverses and links the two rows. This unique feature makes fractures of the scaphoid particularly important because the injury, in essence, unlinks the two rows, allowing them to function independently. It has been reported that, over time, chronic scaphoid fracture nonunions produce arthritis of the wrist in a reproducible and predictable pattern.[147,148]

The scaphoid is the most mobile bone in the wrist, bridging the midcarpal joint and providing three planes of motion. It is subject to the same deforming forces that cross the midcarpal joint, which in the fractured state causes the distal pole to flex with the distal carpal row, whereas the proximal pole tends to extend with the lunate and triquetrum. This creates foreshortening of the bone and the "humpback," or flexion, deformity. Simulated wrist motion has shown that healing of a 5° flexion deformity of the scaphoid leads to a 24% loss of wrist extension.[149]

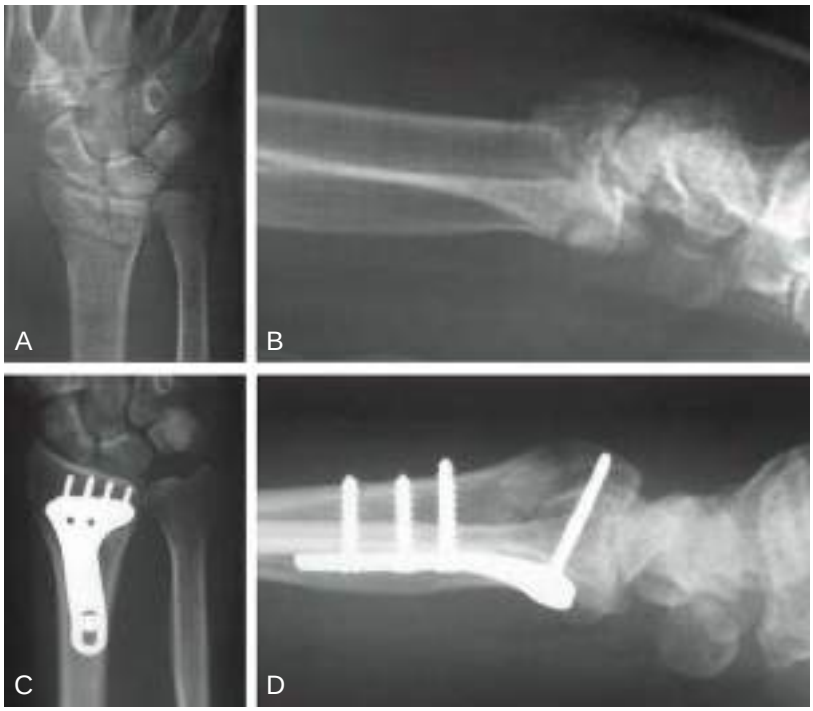

Figure 10-69 **A** and **B,** Comminuted intra-articular radial fracture. **C** and **D,** The fracture is repaired with a fixed-angle locking plate.

Figure 10-70 Complex intra-articular distal radial fracture. The fracture is treated with fragment-specific fixation. Anatomical restoration can be obtained, but this technique requires more extensive dissection than the fixed-angle volar plate.

The shape of the scaphoid is complex, and its orientation makes visualizing fracture lines with plain x-ray films difficult. The bone is described in thirds: the distal tubercle; the midportion, or waist; and the proximal pole. The scaphoid has multiple ligamentous attachments, both intrinsic (within the carpus) and extrinsic (between the radius or metacarpals and carpus). The scaphoid is nearly entirely covered with articular cartilage, which means that few areas are available for vessels to enter the bone. The blood supply is quite tenuous, which directly affects the bone's ability to heal. The scaphoid receives blood through a set of dorsal and volar arteries. The most important of these is the scaphoid branches of the radial artery, which enter the bone dorsally through foramina at the scaphoid waist. These dorsal ridge vessels supply blood to the proximal half of the bone. Because they enter the waist or distal third of the scaphoid, retrograde flow is required for blood to reach the proximal portions of the bone. This means that the proximal one third of the scaphoid is analogous to the femoral head or the talus in that it has little or no direct vascular input and it receives its blood through intraosseous flow. A fracture that displaces the waist or especially the proximal pole can disrupt this blood supply and prevent fracture healing or cause avascular necrosis of the proximal portion of the bone. The second group of vessels arises from the palmar branches of the radial artery and enters the distal end of the scaphoid. The scaphoid tubercle and the distal 20% to 30% of the bone are perfused by this arterial leash. The increased supply of blood at the distal pole of the scaphoid helps account for its more rapid fracture healing (Figure 10-71).

Injury Classification

The *Russe classification system*[150] is relatively straightforward and is based on the relationship of the fracture line to the long axis of the scaphoid bone. The horizontal oblique and transverse fracture types are considered stable and are not expected to displace with immobilization. The third type, the vertical oblique fracture, is considered far more unstable and requires longer immobilization with a higher potential for late instability.

Critical Elements in the Classification of a Scaphoid Fracture

- Location of the fracture
- Chronicity of the fracture
- Type of fracture (i.e., displaced or nondisplaced)
- Fracture pattern (i.e., stable or unstable)

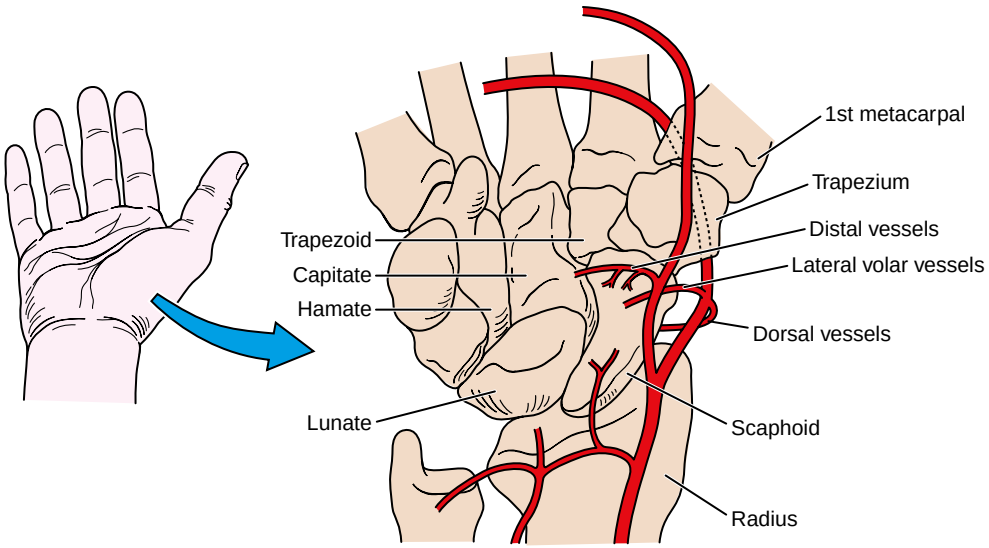

Figure 10-71 Blood supply to the scaphoid bone. Note how the blood supply to the scaphoid enters the bone proximally and distally in most people. If avascular necrosis occurs, it is primarily seen in the proximal fragment.

The *Herbert classification*[151] is a more complex alphanumeric system that rates the injury based on fracture anatomy, stability, and history (e.g., delayed union, fibrous union). By combining these several factors, a prognostic grade can be assigned to each injury.

Diagnosis

Scaphoid fractures can easily be missed, often with serious consequences; therefore it is imperative that clinicians have a high index of suspicion for this fracture in making the diagnosis. The patient's age (the fracture is uncommon in very young patients) and the mechanism of trauma should alert the clinician to the possibility the injury exists. Any tenderness on careful examination at the anatomical snuffbox should be presumed to indicate a scaphoid fracture until proven otherwise.

Radiographic imaging is the mainstay in confirming the diagnosis. However, plain films frequently can fail to detect acute nondisplaced fractures. Initial x-ray films should include a posteroanterior (PA) view, a PA view with ulnar deviation to extend the bone in a plane more parallel with the x-ray film, and lateral and oblique views (Figure 10-72). If the clinical examination leads to a high level of suspicion for a fracture but the plain films are negative, the patient should be treated with cast immobilization and the plain films repeated in 2 to 3 weeks. At that time, resorption of bone around the fracture line may be sufficient to allow positive identification of the injury on plain x-ray films. If an urgent need exists to rule out the fracture before 2 to 3 weeks has elapsed (e.g., professional athletes), imaging with MRI or a thin slice CT scan can be performed. The cost of these imaging modalities may make them prohibitive for routine applications.

CT scanning gives the highest resolution images of the bone and the trabeculae and is useful for evaluating the healing of treated fractures. It frequently is used after surgery or cast immobilization to confirm that bridging trabeculae are crossing the fracture site, indicating healing. In chronic nonunion, CT scanning is useful preoperatively to plan for bone grafting of deformities that are frequently encountered.

MRI does not depict the cortical bone well, but it gives an excellent image of the cancellous bone. It is both a highly sensitive and specific method of detecting occult scaphoid fractures. With gadolinium contrast, MRI is the best means of evaluating the blood supply to the proximal pole of the scaphoid if avascular necrosis is suspected.

Medical Treatment

For an acute, nondisplaced scaphoid fracture, treatment traditionally has consisted of cast immobilization. Healing time depends on the level of the fracture; distal fractures heal most quickly, and those that are most proximal take longest. Proximal fractures sometimes require 3 to 6 months of immobilization to heal, whereas fractures of the distal third generally heal in 6 to 8 weeks. Some studies have reported a slightly faster time to union if the initial casting is done above the elbow for the first several weeks.[152]

More recent techniques have become available that allow limited incision or even percutaneous compression screw placement in the scaphoid (Figure 10-73), which can obviate the need for prolonged cast immobilization while the fracture heals.[153] This has the obvious benefit of returning patients to work or sports much more quickly.

In one study in which 12 athletes were treated surgically for minimally displaced or nondisplaced fractures, the average time for return to sports was within 6 weeks. Only one fracture in the study failed to unite.[154] A recent meta-analysis also determined that surgical management for nondisplaced and minimally displaced scaphoid fractures gave better patient results with respect to functional

Figure 10-72 An AP x-ray film may fail to show a scaphoid fracture *(arrows)*. Ulnar deviation extends the bone and may help reveal the fracture.

Figure 10-73 Percutaneous compression screw fixation of a scaphoid fracture. This allows early removal from a cast and return to function.

outcome and time off work, although there was an increased risk of complications.[155]

Fractures that are unstable and/or displaced are associated with a nonunion rate of 50% and an avascular necrosis rate of 55%; these fractures therefore need to be treated operatively.[156,157] Displacement (and subsequent instability) is considered present if a gap of more than 1 mm is present at any point along the fracture, if the scapholunate angle exceeds 60°, or if the radiolunate angle is more than 15°.[158] If the fracture is acute and does not require bone grafting, a limited approach from either a volar or a dorsal direction (i.e., manipulation of the fragments into alignment and placement of a compression screw) can be used. However, if the fracture requires bone grafting or cannot be manipulated into alignment, a more traditional open reduction and internal fixation should be performed. For waist and midthird fractures, a volar approach may be favored, as this typically requires less dissection, while still allowing enough screw threads to pass the fracture site (Figure 10-74). Unfortunately, with the volar approach, it is more difficult to place the screw in line with the central axis of the scaphoid, although this does not seem to affect healing. A recent cadaveric study has reported that the percutaneous transtrapezial volar approach to the scaphoid may have the benefit of placing the screw more in line with the central axis of the scaphoid, which theoretically may affect healing.[159] With proximal third fractures, a dorsal approach is recommended, as this approach allows the screw to be placed for optimum compression of the usually small proximal fragment.[160]

Nonunions of the scaphoid that have not progressed to arthritis and do not require any type of salvage surgery require operative treatment to achieve a bony union. The fracture needs to be opened, bone grafted, and then rigidly fixed so that it can heal.[161,162] With fractures of the proximal third of the scaphoid or if sclerosis of the proximal pole of the bone is seen on plain x-ray films, the surgeon must consider that the blood supply to the proximal fracture fragment may have been disrupted. A preoperative

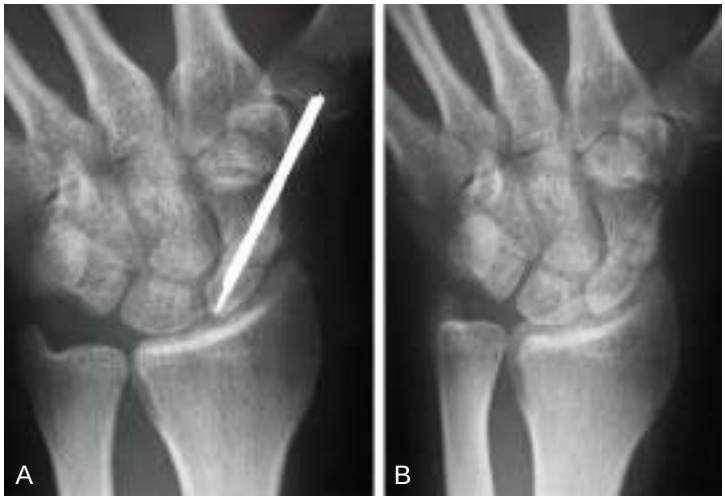

Figure 10-74 **A,** AP x-ray films of a chronic scaphoid nonunion that was treated with bone grafting and pins. **B,** After the fracture healed, the pins were removed.

Figure 10-75 MRI scan of the scaphoid showing avascular changes in the proximal pole *(arrow)*.

MRI scan should help determine whether this is the case (Figure 10-75). If, in fact, the bone is avascular, a vascularized bone grafting procedure may be chosen in an effort to increase the likelihood of successful union.[163,164] This procedure is more technically demanding than traditional fracture repair. A dorsal approach is used, and a segment of bone with its intact blood vessel is elevated from the radius and directly inserted into the scaphoid.

The treatment of scaphoid fractures that have gone unrecognized is a problem that frequently plagues clinicians. Some studies[165] have suggested that a scaphoid fracture that is left untreated for longer than 4 weeks is at increased risk of nonunion. For this reason, fractures of the scaphoid that are delayed in coming to treatment should be considered more readily for operative repair.[165]

Triangular Fibrocartilage Complex (TFCC) Injuries

General Considerations

A common problem clinicians encounter in patients is ulnar-sided wrist pain. Previously considered the "low back pain" of the upper extremity, this is an area of exciting new developments and understanding. Although still a significant diagnostic challenge, a better understanding of the anatomy and biomechanics of the ulnar side of the wrist has enabled clinicians to more accurately screen and treat patients with injuries that previously might have meant vocational retraining or limited sports activity.

The triangular fibrocartilage complex (TFCC) is one of several structures on the ulnar side of the wrist that can be injured, leading to debilitating pain and mechanical changes. Discussion of the more than three dozen recognized causes of ulnar-sided wrist pain is beyond the scope of this text. However, by understanding the function and pathology of the TFCC, the clinician can develop an appreciation of one common cause of ulnar-sided wrist pain and gain knowledge of some of the other structures in which injury can lead to pathology on the ulnar side of the wrist.[166]

Anatomy

The TFCC is described as a composite of ligaments and fibrocartilage that originates from the ulnar border of the distal radius at the articular surface. It inserts onto the base of the ulnar styloid and the fovea of the ulnar head.[167] This horizontal portion, considered the TFCC, or the articular disc proper, is fibrocartilaginous and relatively avascular. The periphery of this horizontal portion is composed of highly vascular ligaments, both dorsally and volarly, that connect the distal radius and ulna. These radioulnar ligaments are oriented perpendicular to the long axis of the forearm. In contrast with this are additional

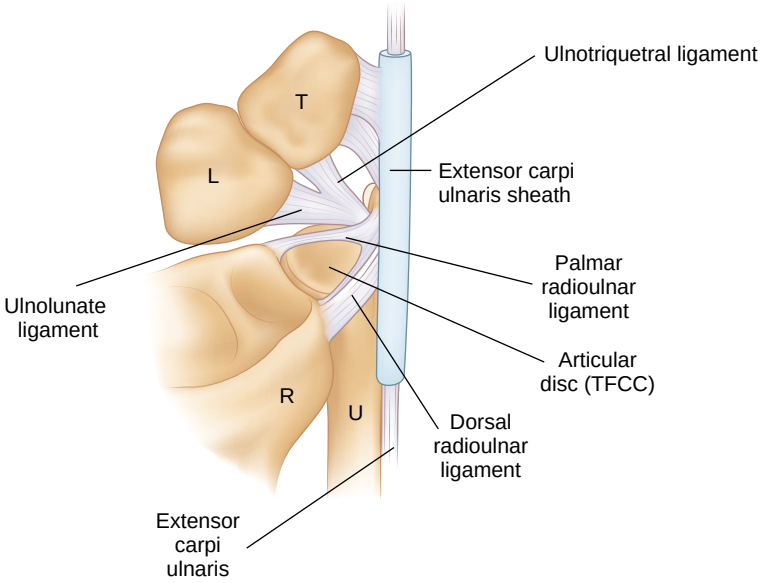

Figure 10-76 Ulnocarpal joint and triangular fibrocartilage complex (TFCC). Triquetrum (*T*), lunate (*L*), ulna (*U*), radius (*R*). (From Skirven TM, Osterman AL, Fedorczyk JM: *Rehabilitation of the hand and upper extremity*, ed 6, Philadelphia, 2011, Mosby.)

ligaments still considered part of the TFCC that arise from the base of the ulnar styloid to insert on the lunate, triquetrum, hamate, and base of the fifth metacarpal (Figure 10-76).[168] The distinct anatomical structures composed of differing biomaterial and oriented in several planes should alert the reader that the TFCC is both complex and multifunctional.

As the forearm moves through pronation and supination, the TFCC ligaments stabilize the distal radioulnar joint. As it arcs over the ulna in pronation, the radius becomes shorter relative to the ulna, resulting in positive ulnar variance, while in supination the radius is out at its maximum length relative to the ulna, resulting in a relative negative ulnar variance. These changes in relative ulnar height in relation to the carpus produce significant changes in the load borne by the TFCC.[169–176]

Major Roles of the Triangular Fibrocartilage Complex

- The triangular fibrocartilage complex (TFCC) creates a shock absorber for the ulnar carpus. The ulnar side of the lunate and the triquetrum do not articulate with the ulna, as the scaphoid and lunate do with the radius. The TFCC transfers about 20% of the axial load between the hand and the forearm.
- The dorsal and volar radioulnar ligaments are the primary stabilizers of the distal radioulnar joint. This arrangement allows stable pronation and supination of the forearm. The ligaments become taut at the end range of rotation in either direction.
- The ligaments that arise from the ulna and insert onto the lunate, triquetrum, hamate, and fifth metacarpal serve as stabilizers for the ulnar carpus. Their function is similar to that of the extrinsic wrist ligaments on the radial side of the wrist.

Injury Classification

In 1989, a classification system was devised that described TFCC lesions based on the mechanism of injury, the location of the injury, and the involvement of surrounding structures. This system is widely accepted as the standard for describing these injuries.[177]

Lesions of the TFCC are divided into two major types, traumatic and degenerative (Table 10-17). Traumatic (type I) lesions have four subtypes based on the location of the injury in the TFCC. Degenerative

TABLE **10-17**

Classification of Triangular Fibrocartilage Complex (TFCC) Tears

Type	Subclassification
Type I: Traumatic	IA: Central perforation IB: Ulnar avulsion (with or without a styloid fracture) IC: Volar tear ID: Radial avulsion
Type II: Degenerative	IIA: TFCC wear IIB: TFCC wear plus lunate or ulnar articular wear (chondromalacia) IIC: TFCC perforation plus lunate or ulnar chondromalacia IID: TFCC perforation plus chondromalacia plus lunotriquetral ligament tear IIE: TFCC perforation, chondromalacia, lunotriquetral ligament tear, and ulnocarpal arthritis

lesions are the result of chronic loading on the ulnar side of the wrist (ulnar carpal impaction syndrome). This leads to chronic deterioration of the TFCC and surrounding structures. These lesions are therefore subclassified by the extent of injury to the surrounding bones and ligaments.

Classification of Traumatic Lesions of the Triangular Fibrocartilage Complex

- *Type IA* lesions consist of a perforation of the horizontal portion of the triangular fibrocartilage complex (TFCC) in its avascular region. The tear usually is 1-2 mm wide, anterior to dorsal in orientation, and about 3 mm ulnar to the radial side attachment of the TFCC proper. These lesions cause mechanical pain on the ulnar side of the wrist but are not usually associated with instability (Figure 10-77).
- *Type IB* tears represent injury to the dorsal aspect of the TFCC or its insertion into the ulna. These tears may be accompanied by an ulnar styloid fracture, and they are frequently seen with displaced distal radial fractures. Type IB lesions can cause instability at the distal radioulnar joint.
- *Type IC* injuries are tears of the anterior aspect of the TFCC at its periphery. The lesion often occurs with avulsion of the attachment of the TFCC to the lunate or the triquetrum. This can result in ulnocarpal instability, which is manifested as palmar translocation of the ulnar carpus.
- *Type ID* lesions are traumatic avulsions of the ligament proper from its origin at the radius just distal to the sigmoid notch (Figure 10-78).

Diagnosis

Patients often are seen months after the initial symptoms have started. They frequently cannot remember any specific trauma. When an injury is recalled, it is regularly a fall onto a pronated and outstretched hand or a traction or rotation injury. We have treated several patients injured by rotating power tools that became bound and forcibly rotated the forearm. They also have treated several golfers who injured the nondominant wrist when they inadvertently struck a tree root or made a deep divot.

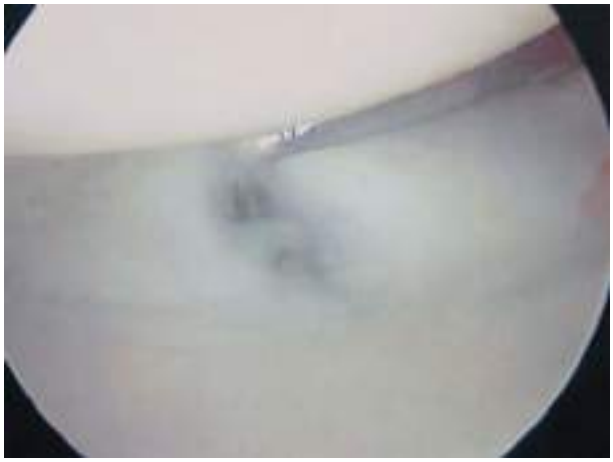

Figure 10-77 Arthroscopic view of a type IA tear in the TFCC (indicated by the probe).

Patients generally complain of ulnar-sided wrist pain, although not all can readily localize the pain to the ulnar side of the wrist without the prompting of an examination. Clicking and mechanical symptoms are sometimes encountered but are not nearly as reliable as pain. The symptoms seem most evident with rotational activities such as turning a key or the steering wheel of a car.

Pain can be elicited in the ulnar-sided snuffbox, the space just beyond the distal ulna between the extensor carpi ulnaris (ECU) and FCU tendons. This is a sensitive area to palpate, and the patient's opposite wrist should be used for comparison. The **TFCC load test** is used to detect ulnocarpal abutment or TFCC tears. It is performed by ulnarly deviating and axially loading the wrist while rotating the forearm. A positive test elicits pain, clicking, or crepitus.[178] The **ulnomeniscal dorsal glide test** increases the motion between the ulna, the TFCC, and the triquetrum to elicit symptoms. The examiner places the thumb of the right hand on the dorsum of the right ulnar head of the patient; the radial aspect of the examiner's right index finger PIP joint then rests on the patient's pisiform. The examiner compresses the pisotriquetral joint dorsally while pushing the ulnar head volarly by reproducing a key pinch maneuver. This increases the stress on the TFCC and ulnocarpal ligaments and should produce pain if a lesion or laxity is present in this region.[179] Evaluation of the distal radioulnar joint for laxity may reveal torn ligaments of the TFCC. This can be accomplished by moving/gliding the distal ulna head while stabilizing the radius in neutral rotation, pronation, and supination and comparing the findings to those of the patient's opposite wrist.

Imaging studies should always be part of the workup of ulnar-sided wrist pain. These begin with a series of plain x-ray films, including a PA and a gripping PA view taken in neutral rotation, as well as lateral views. These films aid the evaluation for distal radioulnar joint arthritis, ulnar variance, lesions consistent with ulnar abutment syndrome, ulnar styloid fractures, and wrist instability consistent with intrinsic ligament lesions.

However useful x-ray films are, they fail to visualize the ligaments of the wrist. Therefore other diagnostic imaging modalities are used if questions remain as to the diagnosis of the patient's ulnar-sided wrist pain. Wrist arthrography is useful for assessing the integrity of the TFCC complex and the other intrinsic ligaments of the wrist, including the lunotriquetral joint. Arthrography is accomplished by injecting dye into the radiocarpal joint and radiographically looking for leaks of the contrast material into the other compartments of the wrist, each of which should be watertight. If no contrast is seen to leak, the examination is repeated by injecting dye into the distal radioulnar joint and then the midcarpal joint and looking for dye leaking back into the radiocarpal joint. This three-phase arthrogram is more sensitive than a single-phase study for detecting small ligament tears (Figure 10-79).

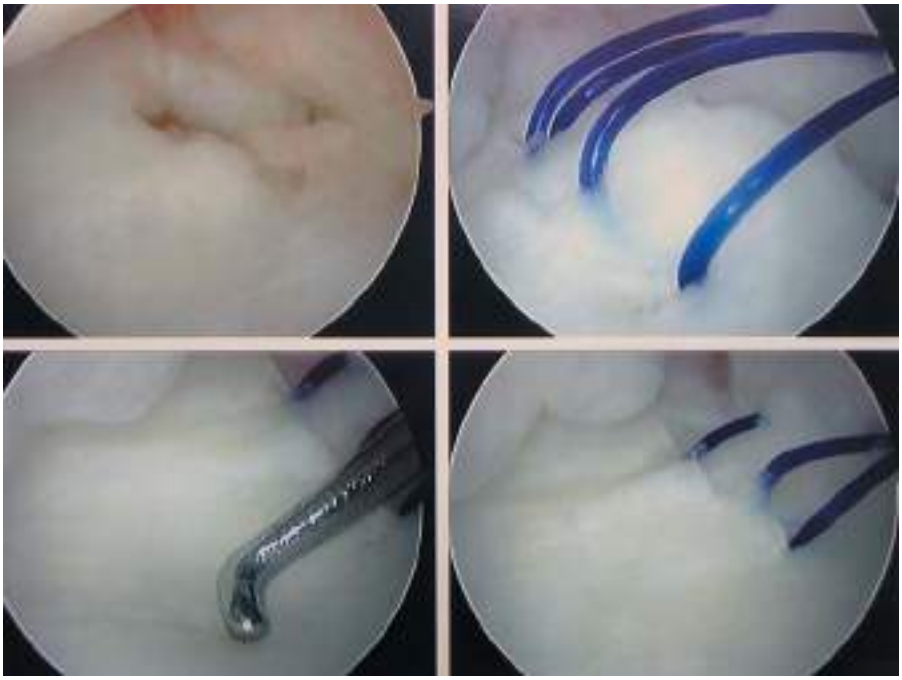

Figure 10-78 Peripheral TFCC tear (i.e., type ID lesion). Tears such as this cause instability and require fixation, which can be done arthroscopically.

Figure 10-79 Arthrogram showing dye leaking between the radiocarpal joint and the distal radioulnar joint, an indication of a TFCC tear.

MRI, both with and without arthrographic dye injection, has also been used to visualize the ligaments of the wrist, including the TFCC. It has proved to be a highly sensitive modality, with up to 95% correlation with arthroscopic findings when positive.[180] However, it is not as useful in patients in which the MRI is found to be normal. In this case Skahen et al.[181] reported its sensitivity to be 44% and the specificity only 75%. These same authors reported that the clinical examination could be more sensitive than MRI, with up to a 95% correlation with arthroscopic findings. Therefore a patient with a strongly positive clinical examination should not be assumed to have an intact ligament if the MRI results are normal. As the clinician gains more experience and confidence in wrist examination, the need for MRI for correlation diminishes.

Medical Treatment

The treatment of acute TFCC lesions initially is conservative. Long arm cast immobilization is used if the patient does not have a fracture of the ulnar styloid or instability of the distal radioulnar joint. If the tear is peripheral and acute, the highly vascular tissue is likely to scar together over a 4- to 6-week period. If the tear is more central, it is not expected to heal, although the synovitis associated with it may diminish and the symptoms of wrist pain may abate. Central tears do not cause instability and require treatment only if they are painful. Patients who present acutely but have instability of the distal radioulnar joint should undergo ligament repair.

When conservative treatment fails or a patient presents months after the onset of injury, arthroscopic evaluation is the gold standard for diagnosis of TFCC pathology. This modality also affords the possibility of treatment. Open treatment of TFCC tears is possible but creates more scarring postoperatively, and visualization of the ligament structure may not be as good as can be obtained arthroscopically.

Central (type IA) tears of the TFCC do not cause instability as long as the outer third of the TFCC remains intact. In patients with ulnar neutral or negative variance, debridement of the central tear to a stable rim of tissue (leaving at least 2 mm of the volar and dorsal ligaments of the TFCC) should resolve the pain. Several studies have reported that, with ulnar positive variance, simple ligament debridement will fail to give long-term pain relief in many patients, and the procedure should be combined with ulnar recession either in the form of a wafer-type procedure or formal ulnar shortening.[182,183] Postoperatively,

no immobilization is required, and patients are encouraged to begin using the hand and wrist immediately. Pain relief is fairly rapid, usually within a few weeks.

Peripheral TFCC tears can cause instability and a change in the load distribution between the hand and the forearm. These injuries need to be repaired to restore normal mechanics and reduce pain. TFCC tears can be best visualized through the arthroscope. Small instruments are used to remove inflamed synovium and scar and debride torn ligaments to fresh, healing tissue. Also, sutures are placed arthroscopically in one of several described methods to recreate the preinjury anatomy (see Figure 10-78). In the case of ID-type tears in which the ligament is avulsed from the radius, sutures are passed through drill holes made in the radius to reattach the TFCC to its point of origin. IC-type tears can be difficult to repair arthroscopically and may require a small open incision to safely place sutures. After suture repair of a peripheral TFCC lesion, patients are immobilized for the first 3 to 4 weeks in a long arm cast, followed by a well-molded short arm cast that limits forearm rotation for an additional 2 to 3 weeks. Pain relief is not as rapid as it is with treatment of IA-type tears. Immobilization can lead to stiffness and loss of strength, which respond well to therapy. Studies report that 95% of patients who undergo surgery for a torn TFCC return to work and sports, and grip strength can be expected to return to 85% of normal.[183]

Scapholunate Dissociation

General Considerations

Instability of the scaphoid and lunate secondary to a traumatic ligamentous disruption has been described many times, beginning with Vaughan-Jackson and Russell in 1949.[184,185] The characteristic symptoms of pain, clicking, and loss of motion at the radioscaphoid joint, along with the radiographic findings of scaphoid flexion, pronation, and lunate extension, have been well documented. Despite this, patients frequently fail to be diagnosed with this injury until months or often years after the onset. This can have unfortunate consequences in that the instability, given enough time, causes arthritic changes. This has been clearly borne out in the hand literature and is referred to as **scapholunate advanced collapse**.[186,187] With an understanding of the relevant anatomy, common mechanisms of injury, and clinical signs and symptoms, clinicians can be more prepared to make the diagnosis in patients at an earlier stage, perhaps preventing or at least delaying the onset of painful arthrosis of the wrist.

Anatomy

The wrist joint is made up of eight bones, best thought of biomechanically to exist in two rows. The lunate is located in the center of the proximal carpal row and articulates distally with the capitate, which is in the center of the distal carpal row. The scaphoid bone articulates with the radial side of the lunate and is the single bone in the wrist that bridges the proximal and distal rows. Both scaphoid and lunate bones move on the radius in their respective fossae. What is important to note is that the lunate fossa has a spherical shape and the scaphoid has an elliptical shape.

The ligaments of the wrist are considered intrinsic ligaments if they both begin and end on carpal bones. In contrast, extrinsic wrist ligaments attach on one side to the carpal bone and on the other side to the radius, the ulna, or one of the metacarpal bones of the hand. The scapholunate ligament complex is thought to have both intrinsic and extrinsic components.

The intrinsic portion of the complex consists of the scapholunate interosseous ligament, which connects the radial side of the lunate to the ulnar side of the scaphoid. This component is thought to be the primary stabilizer of the SL joint and contributes to the overall stability of the carpus.[188] It is composed of three distinct regions. The thick dorsal portion is the strongest and is composed of short transverse fibers that are biomechanically the most important for stability. The proximal section is composed primarily of fibrocartilage and is the least important stabilizer of the three sections. The volar ligament is thinner than the dorsal ligament and consists of obliquely oriented fibers that allow some movement to account for the differences in the arcs of motion between the scaphoid and lunate. Isolated cutting of the scapholunate ligament in cadaver models has not caused instability patterns that mimic those seen clinically, which has lead clinicians to believe that more than an isolated injury to the intrinsic ligament is needed to produce a scapholunate dissociation.[189]

The extrinsic portion of the scapholunate ligament complex is made up of ligaments that originate from the radius and insert on various carpal bones. The radioscaphocapitate (RSC) ligament extends from the radial styloid through a small groove on the volar aspect of the scaphoid to insert onto the palmar portion of the capitate. It serves as a rotational fulcrum around which the scaphoid can revolve. The long radiolunate ligament runs parallel and just ulnar to the RSC ligament from the radius to the volar radial portion of the lunate. The short radiolunate ligament originates from the palmar portion of the radius and inserts onto the palmar portion of the lunate. Both the intrinsic and extrinsic ligaments described can be partly visualized during routine wrist arthroscopy.

On the dorsal surface of the wrist capsule are some thickenings considered to be ligamentous; these provide additional stability to the wrist. They are not easily seen during routine wrist arthroscopy. The dorsal radiocarpal (DRC) ligament originates on the dorsal radial portion of the radius and runs ulnarly and distally to insert onto the lunate, lunotriquetral ligament, and dorsal portion of the triquetrum. The dorsal intercarpal (DIC) ligament originates from the triquetrum and runs radially and distally to insert onto the lunate, scaphoid, and dorsal aspect of the trapezium (Figure 10-80).

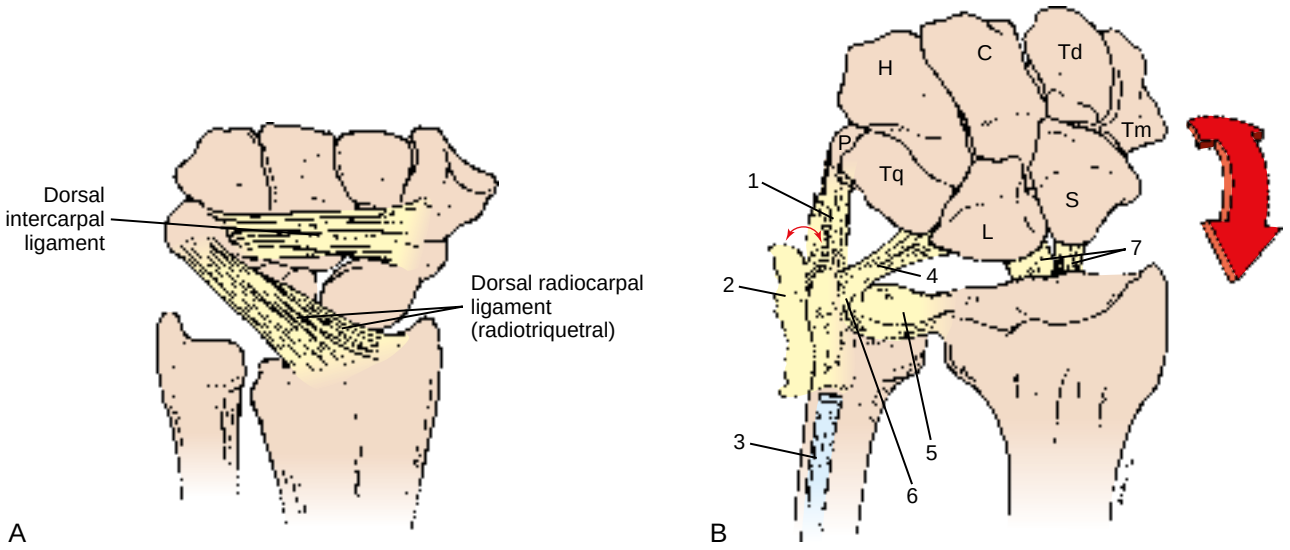

Figure 10-80 **A,** Posterior (dorsal) aspect of the wrist. **B,** Anterior (volar) aspect of the wrist. *1,* Ulnar collateral ligament; *2,* retinacular sheath; *3,* tendon of extensor carpi ulnaris; *4,* ulnolunate ligament; *5,* triangular fibrocartilage complex (TFCC); *6,* ulnocarpal meniscus homologue; *7,* palmar radioscaphoid lunate ligament. *P,* Pisiform; *H,* hamate; *C,* capitate; *Td,* trapezoid; *Tm,* trapezium; *Tq,* triquetrum; L, lunate; S, scaphoid. (From Fess E, Gettle K, Philips C, Janson J: *Hand and upper extremity splinting principles and methods,* ed 3, St Louis, 2005, Mosby.)

The importance of understanding the complexity of the extrinsic ligaments is twofold. First, these ligaments are used or reconstructed in the soft tissue operations that have been developed to treat scapholunate dissociation injuries. Second, some have reported that injury to the extrinsic ligaments is required to produce the radiographic results seen clinically in patients with scapholunate dissociation patterns.[190]

Injury Classification

Classification of scapholunate dissociative injuries can be based on several factors: the time since the injury, the presence or absence of radiographic abnormalities, the extent of ligamentous disruption, and the presence of additional carpal abnormalities or arthritic changes.

Injuries sustained within 6 weeks of diagnosis are classified as acute. Those that have happened beyond 6 weeks but before degenerative changes in the wrist have occurred are considered to be subacute. After degenerative changes have taken place within the wrist, the injury is best thought of as chronic and the treatment options differ considerably.

The chronic condition of scapholunate dissociation is referred to as **scapholunate advanced collapse**, or a **SLAC wrist**. It is a progression of arthrosis that occurs in the wrist because of the scapholunate instability and rotatory subluxation of the scaphoid. The arthritic changes begin at the radial styloid and progress into the radioscaphoid articulation. Over time, the midcarpal joints become arthritic, specifically in the scaphocapitate and lunocapitate joints. The radiolunate joint is spared in all but the most severe cases of pancarpal arthritis.

The injury is also classified according to whether it is apparent on x-ray films at rest or requires some provocative maneuver. With a less severe ligament injury, a stress x-ray film is required to uncover the changes caused by the instability. The stress can be created by asking the patient to tightly grip and/or ulnarly deviate the hand on the PA view. A wrist that can be seen to be unstable at rest is classified as having static instability, whereas a wrist that requires stress to uncover the instability is considered dynamically unstable. A third group is thought to exist: those that are predynamically unstable. In this case the wrist cannot be shown to be unstable radiographically by any means, but the patient is clinically believed to have the beginnings of instability secondary to ligamentous injury.

Diagnosis

The typical patient describes the mechanism as a FOOSH (Fall On an OutStretched Hand) injury, which causes a dorsiflexion and pronation injury at the wrist. A less common mechanism of injury is a rotational injury to the hand and wrist from a twisting force. Pain and swelling often are not severe and generally subside with rest after a few days. Frequently, little ecchymosis or edema is present, and no obvious deformity makes the diagnosis clearer to the patient, sports trainers, or coaches or to the uninitiated health care worker. Because these patients often do not seek treatment in the acute phase, they may not recall the inciting injury when, at some later time, they present for evaluation of the wrist pain.

Physical findings are related to the degree of instability of the scaphoid. In the least severe cases, pain is present over the dorsal scapholunate ligament and the radioscaphoid joint. Dorsal wrist pain usually can be elicited by applying dorsal pressure to the volar pole of the scaphoid. In addition, pain often is elicited at the anatomical snuffbox secondary to synovitis of the radial side of the wrist joint.

The stability of the scaphoid can be checked in the manner described by Watson et al.[191]; dorsal pressure is applied to the volar pole of the scaphoid while the wrist is moved from ulnar to radial deviation in an effort to sublux the proximal pole of the scaphoid out over the dorsal rim of the radius. This is known as a **scaphoid shift test**, and it can produce pain either from the instability or from compression of the scaphoid in its fossa in the presence of chronic synovitis. In a patient with an unstable injury, a discernable, painful clunk occurs when the examiner releases pressure on the scaphoid, allowing the subluxed proximal pole to reduce back into the scaphoid fossa of the radius.

A patient with long-standing instability who has progressed to arthritis of the joint may have a fixed subluxation of the scaphoid. This can be palpated as a firm dorsal prominence at the distal edge of the radius. Severe limitation of wrist motion and significant tenderness are indicative of the degenerative changes that have occurred at the radiocarpal joint. Osteophyte formation on the radial side of the wrist can lead to a deformity that is observable and palpable.

Plain x-ray films are the most important imaging study and should accompany the history and physical examination whenever a ligamentous injury of the wrist is suspected. Many articles have been devoted to the way the x-ray films should be obtained. It has been our practice to obtain a PA, a clenched fist PA, and a lateral view. In obtaining the PA films, a foam block is used that elevates the ulnar side of the wrist 10° to 15°, which allows a more perpendicular view of the scapholunate articulation. Abnormalities seen on the PA films include a widened scapholunate gap, usually greater than 3 mm in adults. The clinician can see signs of the flexed scaphoid by noting its loss of length and the appearance of the "signet ring sign," which is indicative of the cortical projection of the distal pole seen through the long axis of the bone as it becomes more vertical (Figure 10-81).[192]

The lateral projection views require more experience to read but generally provide even more information than the PA views. The scaphoid flexes and creates a bigger angle in relation to the long axis of the radius. In addition, the lunate tends to extend, pointing dorsally and translating volarly. The angle between the axial long axis of the lunate and scaphoid normally is 30° to 60°, with the average being 47°. As the scaphoid flexes and the lunate extends, that angle increases to more than 60° and often approaches 90° (Figure 10-82).

Clinicians occasionally can see the proximal pole of the scaphoid sitting dorsal to the center of its fossa on the radius. As the lunate extends, the capitate translates proximally and dorsally, and the normal collinear relationship of the radius, lunate, and capitate is disrupted.

Arthrography can confirm loss of the watertight compartment between the midcarpal and radiocarpal joints. This indicates a tear of some portion of the scapholunate interosseous ligament. Communication can be seen if a small perforation exists in the membranous portion of the ligament; this perforation is not biomechanically important, but it increases the potential for false positive results. In addition, some tears flow only unidirectionally; therefore, if the dye is injected into only one compartment, it may fail to reveal a substantial tear, leading to false negative results. Detection can be improved by injecting dye into all three compartments of the wrist over the course of the test.[193]

Figure 10-81 AP x-ray film of a wrist with a scapholunate tear. The scaphoid is flexed and shortened, and the lunate is extended. A gap is created between the scaphoid and the lunate as the scaphoid rotates away from the lunate. The scaphoid no longer lies correctly in its fossa in the radius, and over time this will cause joint degeneration.

MRI can visualize the different sections of the scapholunate ligament. Edema, thickening, tortuosity (twisting), and lengthening of the ligament indicate injury and possible disruption. Joint fluid flow through the ligament indicates a tear as much as arthrography does, without the need for an injection before the examination. In addition, the MRI can help visualize the bony alterations between the radius, capitate, lunate, and scaphoid that occur with scapholunate instability.

Medical Treatment

With acute or subacute injuries in which the scaphoid flexion deformity is still flexible and no joint destruction has occurred, the preferable course is to attempt a soft tissue reconstruction of the wrist. This retains the most mobility of the radiocarpal and midcarpal joints while attempting to regain stability. By restoring appropriate carpal alignment and improving the kinematics of the wrist, the surgeon attempts to prevent or delay the onset of arthritic changes that would occur if no treatment were given.

Many surgical solutions have been proposed for acute and subacute scapholunate dissociation. Many surgeons

Figure 10-82 **A,** Lateral x-ray film of a patient with a scapholunate dissociation. The lunate is tilted dorsally, and the scapholunate angle is nearing 90°. **B,** Lateral x-ray film of the same patient after repair of the ligament and capsulodesis of the scaphoid. The lunate is no longer tilting backward, and the scaphoid is more extended. This creates a more normal angle between the two (approximately 45°). *R,* radius; *L,* lunate; *S,* scaphoid; *C,* capitate.

attempt to restore the normal anatomy by repairing the scapholunate interosseous ligament back to the ulnar side of the scaphoid from which it usually detaches. This can be done through bone tunnels drilled into the scaphoid or with various suture anchors. However, this repair does not address the flexion and rotation deformity of the scaphoid. To do so, ligamentous tissue from the dorsal capsule of the wrist is rerouted to the distal pole of the scaphoid to act as a tether that prevents the scaphoid from flexing and rotating.

Additional soft tissue repairs have been created using various tendons, including the extensor carpi radialis longus (ECRL) and FCR ligaments. Tunnels are drilled through the scaphoid in a dorsal-volar direction, allowing one of these tendons to be passed through the bone, in an attempt to correct the position of the scaphoid in relation to the lunate.

The alternative to soft tissue procedures is partial wrist fusion or proximal row carpectomy. The scaphotrapeziotrapezoid (STT) fusion has been advocated in cases that have not progressed to arthritis at the radiocarpal joint. The scaphoid is brought out of its flexed position and locked in place by its fusion across the midcarpal row. This allows motion to continue at the radiocarpal joint. Criticism of this procedure relates to the increased load borne on the radial side of the wrist between the scaphoid and radius after the fusion, in the area at risk for arthritic changes secondary to the initial injury.

If arthritis has developed within the radioscaphoid joint but left the midcarpal joint intact, a proximal row carpectomy can be considered. In this instance the scaphoid, lunate, and triquetrum are excised, allowing the capitate to articulate in the lunate fossa of the radius. This changes the wrist from a complex link joint to a simple hinge joint with concomitant loss of motion. This procedure is criticized for the fact that the capitate is not an exact fit in the lunate fossa of the radius and that the relative shortening of the wrist leads to some weakness of grip.

As arthritis progresses in chronic scapholunate instability, the midcarpal joint between the scaphoid, lunate, and capitate is affected. In many surgeons' eyes, this midcarpal arthrosis, especially of the proximal capitate, is a contraindication to the proximal row carpectomy. In this case they favor removal of the arthritic scaphoid and fusion of the ulnar midcarpal joint (four-corner fusion). This stabilizes the midcarpal joint in the absence of the scaphoid. Again, the link joint has been turned into a hinge joint, with subsequent sacrifice of 30% to 50% of flexion and extension, as well as radioulnar deviation. The operation succeeds because, despite the progression of arthritis with scapholunate advance collapse, the surface between the lunate and the radius usually is preserved. This occurs because the radiolunate articulation is spherical; therefore, when the lunate tips backward because of ligament instability, the congruency between the two bones is maintained. This is not true of the radioscaphoid fossa, which is elliptical and becomes incongruous and eventually arthritic, as the scaphoid flexes and pronates.

Rehabilitation Principles and Considerations for Wrist Injuries

Rehabilitation of wrist injuries requires an understanding of carpal anatomy, force distribution, and wrist kinematics.[194] An optimally aligned, stable but mobile wrist is capable of the precise interaction needed between bone and soft tissues to produce pain-free, functional motion. Restoration of alignment, stability, and pain-free motion poses a challenge to the treating clinician.

Key Therapeutic Considerations in Management of Wrist Injuries

- Soft tissue injury accompanies bony injury[140]
- Disruption of ligaments can lead to altered mechanics, instability, degenerative changes, and pain[140,186,187]
- Nerve irritation or injury contributes to pain syndromes[195–199]
- Motor and sensory loss can occur as a result of nerve injury

Distal Radial Fractures

Understanding normal force distributions at the wrist and the impact of altered mechanics is essential in initiating therapy regimens. When the distal ulna is equal in length to the distal radius, this is termed **ulnar neutral variance**. Changes from ulnar neutral variance can occur as a result of injury, and they alter the mechanics of the wrist joint (Figure 10-83). Shortening of the distal radius during fracture healing, with no change in the position of the ulna, results in **ulnar positive variance**. This change increases the force distributed to the ulna and potentially results in ulnar-sided wrist pain.[175,200–203]

In a typical ulnar neutral wrist, 80% of the force is borne by the radius, with only 20% through the ulnocarpal joint. However, even a small change in height results in the ulna absorbing 40% of the load if the ulna is 2 mm ulnar positive or 4% of the load if it is 2 mm ulnar negative.[139,175,203–205] Loading the wrist, which occurs during weight bearing and gripping, places stress on the primary ligamentous stabilizers of the wrist. Evaluation for ligamentous injury should be considered in the event of persistent pain with loading of the wrist.[206] The **push-off test** measures upper extremity weight bearing, using a grip dynamometer, and may be useful to measure progress as patients recover strength and heal from their wrist injuries.[207]

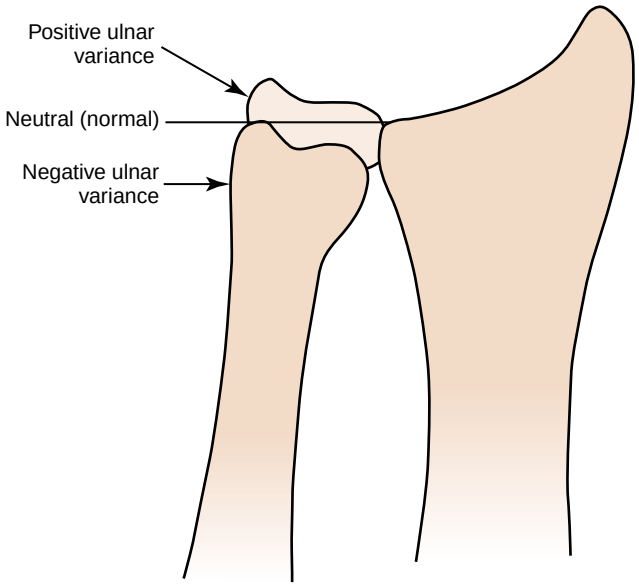

Figure 10-83 Differences in ulnar variance. (Redrawn from Frykman GK, Krop WE: Fractures and traumatic conditions of the wrist. In Hunter JM, Mackin EJ, Callahan AD, editors: *Rehabilitation of the hand: surgery and therapy*, ed 4, p 325, St Louis, 1995, Mosby.)

For the clinician charged with the rehabilitative management of a patient with a wrist injury and pain, the key considerations regarding force distribution at the wrist are summarized below.

Key Therapeutic Considerations in Force Distribution at the Wrist

- Ulnar-sided wrist pain may result from a change in mechanics and may not be limited to a healing ulnar styloid fracture. For example, a radial compression fracture that shortens the radius changes the relationship between the radius and the ulna, causing ulnar-sided wrist pain from ulnar positive variance.
- Care must be taken when loading the wrist to protect healing structures on the radial side of the wrist (e.g., with scaphoid fractures) or the ulnar side of the wrist (e.g., with tears in the triangular fibrocartilage complex).
- Loading the wrist stresses many of the carpal ligaments. Care must be taken when loading a wrist known to have or suspected of having a ligament tear. Wrist and grip strengthening may not be appropriate in patients with ligamentous instability. Appropriate diagnosis of the source of wrist pain is paramount in preventing further injury or degenerative changes of the carpus.
- Forearm position affects force distribution at the wrist. Activity modification, taking into account forearm position, should be considered in patients with persistent ulnar-sided wrist pain. Pronation shortens the radius and increases ulnar variance; this can increase ulnar-sided wrist pain.

The dynamics of wrist motion are important for the rehabilitation strategy. Wrist kinematics is described by the direction in which the proximal carpal row moves.[208,209] Normal kinematics and wrist motion are detailed in Table 10-18. Normal values for AROM at the wrist compared with what is needed for light activities of daily living (ADL) tasks are presented in Table 10-19. Of note, 40% to 60% of wrist flexion and extension occurs at the radiocarpal joint, and the remaining motion occurs at the midcarpal joint. As well, 60% of radial and ulnar deviation occurs at the midcarpal joint and 40% at the radiocarpal joint.[210,211]

Key Therapeutic Considerations for Wrist Kinematics and Wrist Motion

- Optimization of motion depends on restoration of wrist kinematics. Specific joint mobilization techniques can be used to improve wrist kinematics.[214]
- Surgical procedures or conditions in which the midcarpal joint is fused or significantly limited reduce motion 40% to 60% (except pronation/supination, which remains unaffected).
- Light activities of daily living can be performed without restoration of full motion.
- Optimization of pain-free motion is essential and should be based on individual activity requirements and realistic goals. The goals should consider the status of the joints comprising the wrist, including alignment.

TABLE 10-18

Normal Wrist Kinematics and Motion

Physiological Motion	Carpal Movement
Wrist flexion	The proximal carpal row shifts dorsally in relation to the radius
Wrist extension	The proximal carpal row shifts volarly in relation to the radius
Ulnar deviation	The proximal carpal row extends and shifts radially
Radial deviation	The proximal carpal row flexes and shifts ulnarly

TABLE 10-19

Degrees of Normal Active Range of Motion Compared with Active Motion Used in Light Activities of Daily Living (ADLs)[212,213]

Active Motion	Normal (degrees)	Light ADLs (degrees)
Wrist flexion	80	30-40
Wrist extension	70	30-40
Ulnar deviation	30	20
Radial deviation	20	20
Pronation	80-90	40-50
Supination	80-90	60

In a postoperative or postinjury therapy regimen, the clinician should consider the ultimate goals for motion and strength. Joint mobilization should focus on restoring normal kinematics.[214,215] Surgical procedures with any partial fusion of the wrist reduce motion 40% to 60%. However, most ADLs can be completed without full motion. Optimizing pain-free motion is essential. The clinician must perform a realistic evaluation of the patient's needs and expectations.

Newer philosophies for therapeutic intervention consist of an accelerated rehabilitation program. A recent study has reported that patients who underwent ORIF of a distal radius fracture, with stable fixation, had better mobility, strength, and DASH scores in the early postoperative period, after engaging in a rehabilitation protocol that emphasized early motion and strengthening.[216] Another newer philosophy is that there may be a role for wrist proprioception reeducation in the therapeutic plan for recovering wrist function and stability and preventing further injury.[217] The literature in this field is growing, and early success is promising.

Although some literature fails to support a therapist-governed exercise program as being more beneficial than a home exercise program,[218] it is clear that some patients benefit from having the motivation and supervision of a trained therapist.

In summary, the wrist is a complex structure with key specific considerations for the treating clinician. Direct communication between the surgeon and the therapist is essential. The overall rehabilitation strategy must account for the type and location of injury, possible concomitant ligament disruption, fixation methods used for fracture stabilization, overall fracture stability, and joint alignment (Figure 10-84). Table 10-20 presents rehabilitation

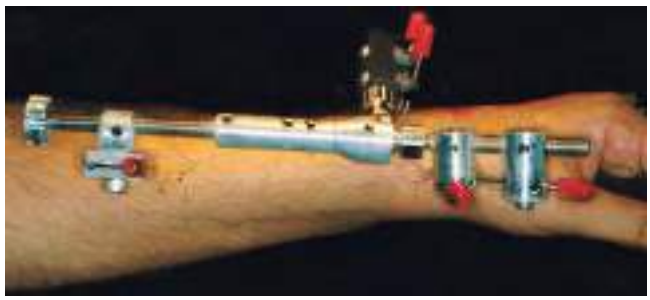

Figure 10-84 Use of an external fixator to stabilize a distal radial fracture. (From Slutsky DJ: Nonbridging external fixation of intra-articular distal radius fractures, *Hand Clin* 21:381-94, 2005.)

TABLE 10-20

Rehabilitation Guidelines for Wrist Fractures[27,219–225]

	Closed Reduction	External Fixation	ORIF with Plate and Screws	ORIF with Fixed-Angle Locking Plate
Description	• Fracture is manually reduced • Reduction is maintained in cast support for 6 weeks	• Fracture is reduced through distraction provided by external fixation in which pins are inserted into the radial shaft proximal to the fracture and distal to the fracture in the second metacarpal • Fixation is removed at 6 weeks	• Fragments require internal stabilization to hold reduction and achieve alignment • Plate and screws still allow slight motion at the fracture site • Casting is required for additional stability for 6 weeks	• Fragments require internal stabilization to hold reduction • Technique provides optimal anatomical realignment and stabilization of the fracture fragment • Procedure allows for early motion

(Continued)

TABLE **10-20**

Rehabilitation Guidelines for Wrist Fractures—cont'd

	Closed Reduction	External Fixation	ORIF with Plate and Screws	ORIF with Fixed-Angle Locking Plate
Healing Stages				
Stage I: Inflammatory stage (weeks 0 to 2)	• Casting; elbow may or may not be included in the cast • AROM of the uninvolved joints, with emphasis on the fingers and shoulder • Tendon gliding exercises • Blocking exercises to maintain flexor tendon gliding and encourage extensor tendon gliding • Edema management of the fingers with Coban • Soft tissue mobilization of the fingers	• AROM of the uninvolved joints: emphasis on the fingers and shoulder • Tendon gliding exercises • Blocking exercises to maintain flexor tendon gliding and encourage extensor tendon gliding • Edema management with Coban or a compression sleeve • Soft tissue mobilization	• Casting • AROM of the uninvolved joints; emphasis on the fingers and shoulder • Tendon gliding exercises • Blocking exercises to maintain flexor tendon gliding and encourage extensor tendon gliding • Edema management of the fingers with Coban	• Splinting between exercises and at night • AROM of the wrist and forearm (per physician guidelines) • AROM of the uninvolved joints; emphasis on the fingers and shoulder • Tendon gliding exercises to prevent adhesions • Blocking exercises to maintain flexor tendon gliding and encourage extensor tendon gliding • Scar management • Soft tissue mobilization • Edema management • Activity modification: no lifting, pulling, or pushing
Stage II: Fibroplasia and repair stage (weeks 2 to 6)	• As above • Nerve symptoms, color changes, and extreme swelling should be reported to physician because they may indicate the cast is too tight	• As above • Stretch to thumb web space • Median nerve symptoms or findings should be reported to the physician; distraction placed by the fixator may compromise the nerve	• As above • Nerve symptoms, color changes, and extreme swelling should be reported to physician because they may indicate the cast is too tight or that an infection may have developed	• As above • Stretch to thumb web space • Progress to PROM, gentle stretching at weeks 3-4 • Progress to light activities
Stage III: Remodeling and maturation stage (weeks 6 to 8+)	• Joint mobilization • Stretching • Splinting for motion • Static wrist splint for comfort during the day and support at night, worn for 2 weeks • Strengthening as tolerated at weeks 6-8 • Functional progression	• Joint mobilization • Stretching • Splinting for motion • Strengthening at weeks 8-12 as tolerated • Static wrist splint for comfort, to be worn during the day and at night as necessary • Functional progression • After removal of the fixator, structures shift slightly because the distraction from the fixator has been removed; patient's performance may be reduced as the tissues adjust	• Joint mobilization • Stretching • Splinting for motion • Strengthening at weeks 8-12 as tolerated • Static wrist splint for comfort to be worn during the day and at night as necessary • Functional progression • New onset of pain with active finger or thumb flexion and extension may be a sign of soft tissue shearing against the hardware and should be reported to the physician	• Joint mobilization • Stretching • Splinting for motion • Strengthening at weeks 8-12 as tolerated • Static resting splint usually is discontinued • Functional progression • New onset of pain with active finger or thumb flexion and extension may be a sign of soft tissue shearing against the hardware and should be reported to the physician

ORIF, Open reduction and internal fixation; *AROM,* active range of motion; *PROM,* passive range of motion.

strategies the clinician can use with patients who have suffered a wrist injury. Successful therapeutic intervention and its progression must incorporate all stages of the healing process.

Scaphoid Fractures

Rehabilitation of scaphoid fractures depends on the location and healing of the fracture. General casting guidelines for nondisplaced fractures at the distal pole is 4 to 8 weeks in a thumb spica cast. Midscaphoid (waist) fractures are immobilized longer (6 to 12 weeks). Proximal pole fractures are protected the longest (12 to 20 weeks).[152] During the casting phase, emphasis is placed on maintaining normal ROM of the fingers. After the cast is removed, the goals of therapy are joint mobilization and strengthening at the wrist and fingers.

Compression screw fixation of scaphoid fractures allows for earlier motion and return to activities. Generally, the thumb and wrist are immobilized for 1 to 4 weeks after compression screw fixation of minimally displaced fractures. After the cast has been removed, gentle motion is initiated. Weight bearing, gripping, and loading of the wrist should be avoided for the first 3 weeks. Between weeks 3 and 6, return to sports with casting or splinting is possible. Strengthening is initiated at week 8, after fracture healing allows for an increased demand. After 8 weeks, return to normal activities generally is permissible.

Displaced fractures that require ORIF are immobilized for 4 to 12 weeks, depending on the type of fixation. After the cast has been removed, active motion begins. If the scaphoid vascular supply is a concern, no weight bearing or strengthening can begin until CT scanning has confirmed fracture healing. Return to sports usually begins at 4 to 6 months.

Complications from scaphoid fractures include nonunion and malunion. Either of these causes kinematic disturbance within the wrist that can cause pain, instability, loss of motion, and eventually arthritic degeneration.[152,222,226–228]

Triangular Fibrocartilage Complex (TFCC) Injuries

Splinting in an ulnar gutter splint for stable TFCC sprains and strains to prevent ulnar deviation can be helpful for reducing inflammation and preventing repetitive stress to the region. Activity modification is essential. Activities that require ulnar deviation or forceful gripping should be avoided. Splinting during these activities prevents the incriminating wrist motions of ulnar deviation with or without terminal wrist flexion and extension. The splint often acts as a reminder to the patient to avoid the positions or activities that irritate the TFCC. Weight bearing, such as yoga or cycling, should be avoided regardless of the wrist position used. A splinting approach is used until the pain diminishes (approximately 4 to 6 weeks), at which time a strengthening to tolerance regimen can be initiated in all wrist positions. As previously mentioned, if pain persists after a 4-week period of splinting and activity modification, the patient should return to the referring physician.

Cast immobilization in a long arm cast as an initial treatment for peripheral and central tears has been reviewed previously and is used for 4 to 6 weeks. After cast immobilization, the goal of therapeutic strategies is restoration of pain-free motion and function. Strengthening is initiated when full AROM has returned. Weight bearing is avoided for 6 to 12 weeks and should be pain free before the patient returns to aggressive weight-bearing activities. If pain limits progression of the rehabilitation course, further evaluation is required.

Debridement of the central portion of the TFCC requires little or no immobilization. The patient wears a wrist or ulnar gutter splint for 1 week when not exercising. Occasionally, the splint time is extended to respect patient comfort. AROM is initiated during the first week to pain tolerance. At 2 to 4 weeks, light functional tasks can be resumed with limited ulnar deviation and weight bearing. Strengthening and functional progression begin at 6 to 8 weeks, during which a gradual return of ulnar deviation and weight-bearing activities is initiated. If pain limits progression of the therapeutic intervention, a mechanical issue (e.g., positive ulnar variance) may be contributing to the patient's pain and TFCC irritation.

Repair of the peripheral portion of the TFCC is treated with an initial casting period of 3 to 4 weeks in a long arm cast, followed by a short arm cast for an additional 2 to 3 weeks. Casting times can vary. At 6 to 8 weeks, restoration of motion begins with the initiation of AROM. Ulnar deviation and forearm rotation are avoided. A wrist or ulnar gutter splint is worn between exercises and at night for comfort. Progression of motion, including forearm rotation and ulnar deviation, occurs between 8 and 12 weeks. Strengthening is initiated at week 12, with a gradual return to sports and weight-bearing activities as tolerated.[229,230]

Scapholunate Dissociation

As noted, surgical solutions for scapholunate dissociation include both soft tissue repairs or reconstructions and fusions. The period of cast immobilization after soft tissue repairs or reconstructions varies and can last up to 12 weeks.[210]

After cast immobilization, an AROM program is initiated, as well as scar management, edema control, and activity modification, avoiding weight bearing and gripping. At 12 weeks, gentle stretching and strengthening and functional progression are begun. A wrist splint can be worn for comfort. Taking care to avoid stretching out the repair is a prime postoperative concern. Motion limitations of approximately 30° of flexion and 50° of extension are to be expected in procedures such as the Blatt technique,[231] in which a portion of the dorsal wrist capsule is used to correct the rotation and flexion deformity of the scaphoid (Figure 10-85). Return to high-demand activities and/or competitive sports occurs at 6 to 9 months after surgery.[210,231]

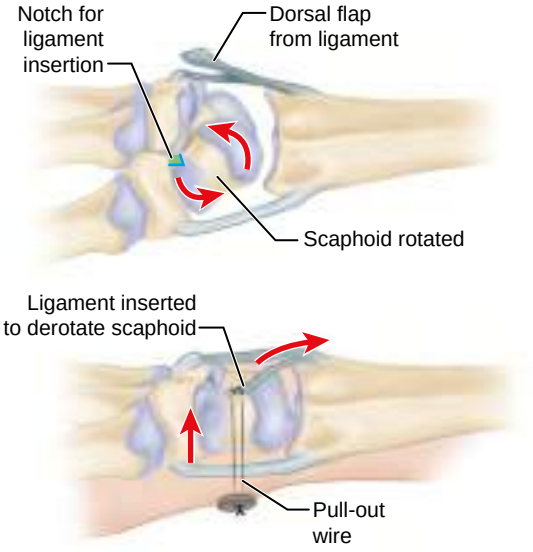

Figure 10-85 Blatt capsulodesis. (From Canale ST, Beatty JH: *Campbell's operative orthopaedics*, vol. 6, ed 12, Philadelphia, 2013, Mosby.)

The surgical fusion procedures (proximal row carpectomy, STT fusion, and four-corner fusion) follow a similar rehabilitative course (Figure 10-86). The wrist is immobilized for up to 6 to 12 weeks. After immobilization, AROM is initiated, along with scar management, edema control, and activity modification and splinting for comfort. At 12 weeks, stretching, strengthening, and functional progression begin. A reduction in motion is to be expected. Return to high-demand function and competitive sports may occur at 6 to 9 months after surgery.

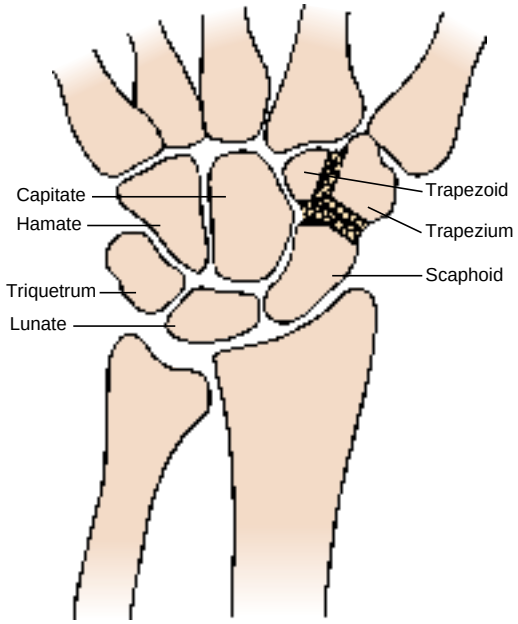

Figure 10-86 STT joint fusion with pinning and bone grafting. (From Frykman GK, Krop WE: Fractures and traumatic conditions of the wrist. In Hunter JM, Mackin EJ, Callahan AD, editors: *Rehabilitation of the hand: surgery and therapy*, ed 4, p 330, St Louis, 1995, Mosby.)

Persistent problems with scapholunate dissociation can include wrist pain despite surgical intervention to correct the instability.

TENDONITIS, TENOSYNOVITIS, AND ENTRAPMENT

Trigger Finger or Thumb (Stenosing Tenosynovitis)

General Considerations

Stenosing tenosynovitis of the digits and thumb, also known as *trigger finger* and *trigger thumb*, is a common cause of hand pain and dysfunction. The problem arises from a size disparity between the flexor tendon and the annular pulley portion of the tendon sheath through which the tendon should glide smoothly. The two types of stenosing tenosynovitis are nodular stenosing tenosynovitis and diffuse stenosing tenosynovitis. Patients present with a catching or snapping sensation (which often is quite painful) that occurs with finger or thumb motion. If this problem progresses, the affected finger or thumb may become locked in flexion and the patient may lose the ability to actively extend the digit. Treatment of this disability ranges from conservative nonoperative management to surgical release of the constrictive A1 pulley.

Anatomy

The flexor tendons are enveloped in a synovial sheath that glides through a series of pulleys, which function to keep the tendon closely apposed to the bone during bending. Damage to critical portions of the pulley system leads to bowstringing of the tendon away from the bone, which causes finger flexion contracture and loss of motion (Figure 10-87). The two types of pulleys in the flexor system are the annular pulleys and the cruciate pulleys. Two annular pulleys (A2 and A4; see Figure 10-49) cover the flexor tendons over the proximal and middle phalanges and are the most critical in preventing bowstringing. The three remaining annular pulleys (A1, A3, and A5) are closely associated with the volar plates of the MCP joint, the PIP joint, and the DIP joint, respectively. The three cruciate pulleys (C1, C2, and C3) provide additional support to the flexor tendon as it crosses the MCP, PIP, and DIP joints, but they are more flexible by design than the annular pulleys (Figure 10-88).

Pathophysiology

During finger flexion, the annular pulleys are under the greatest degree of stress from the flexor tendons. Flexion of the proximal phalanx, especially with power gripping, induces high angular loads across the most proximal pulley (the A1 pulley). Hypertrophy of the A1 pulley occurs in response to the increased stress. Microscopic examination of an A1 pulley involved in trigger digits shows degeneration, cyst formation, fiber splitting, and the

Figure 10-87 MRI scan of a closed rupture of the A2 pulley over the proximal phalanx. This injury led to bowstringing of the flexor tendon *(black structure)* away from the bone.

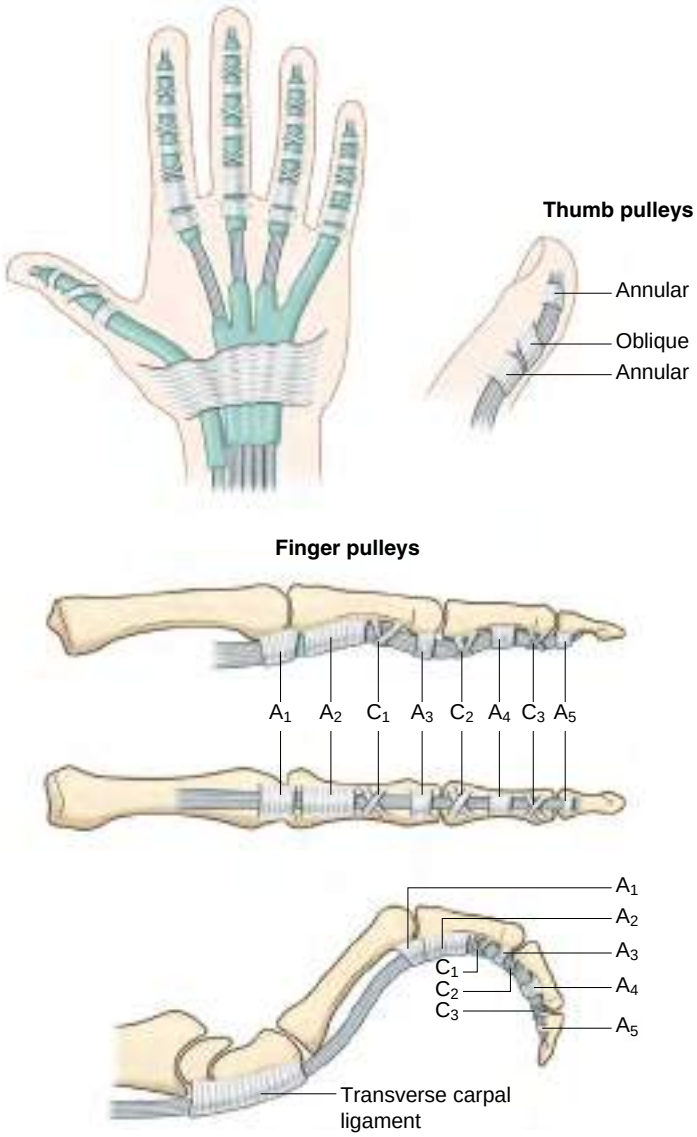

Figure 10-88 Synovial sheaths and retinacular and annular pulleys of the fingers and thumb. (Redrawn from Chase RA: *Atlas of hand surgery*, vol 2, Philadelphia, 1984, WB Saunders.)

presence of inflammatory cells. Inflammation and thickening also occur in the associated area of the flexor tendon. In nodular stenosing tenosynovitis, the thickening of the flexor tendon occurs in a localized area, just distal to the A1 pulley, where the increased friction between the pulley and tendon causes a thickened nodule to form. In diffuse stenosing tenosynovitis, the inflammation in the flexor tendon is not localized but rather extends beyond the region of the A1 pulley. No discrete nodule develops in this form of trigger finger. In both types of stenosing tenosynovitis, because of the inflammation noted in both the A1 pulley and the flexor tendon, a size disproportion develops, and the flexor tendon is no longer able to glide smoothly through the pulley. The patient experiences this as a snapping sensation when attempting to extend the affected finger. The etiology of this process is unclear, but it may be associated with repetitive activity that causes trauma to the hands. Activities that require increased finger flexor activity, such as cutting or sewing, may exert excessive stress across the A1 pulley, resulting in the inflammatory process of stenosing tenosynovitis. However, in most cases of trigger finger or thumb, no inciting activity can be identified. The majority of trigger digit cases are thought to be idiopathic in nature, but there is a known relationship between diabetes and the development of trigger digits, and there is also a more recently established association between the development of a trigger digit after a surgical carpal tunnel release.[232]

Diagnosis

Patients with a triggering finger or thumb may feel a click or snapping sensation as they attempt to extend the affected digit from a flexed position. Although the pathology of this process usually occurs at the A1 pulley, at the level of the MCP joint, the patient generally believes the mechanical problem exists at the level of the PIP joint. Initially, this triggering may not be painful. As the stenosis becomes worse, the patient may report increased pain and decreased ability to actively extend the affected digit. The digit may become locked in a flexed position, and the use of the other hand to passively extend the digit may be required to "unlock" the flexed digit. The thumb is the most frequently affected digit, followed in declining order by the ring finger, the middle finger, the small finger, and the index finger.

The medical history and physical examination can assist with the diagnosis of stenosing tenosynovitis. Trigger digits have been associated with other medical conditions, including rheumatoid arthritis, diabetes, gout, carpal tunnel syndrome, De Quervain's tenosynovitis, Dupuytren's contracture, and hypertension.[233] On the physical examination, the patient has tenderness at the level of the A1 pulley over the palmar aspect of the MCP joint. A catching sensation may be felt over the A1 pulley when the patient is asked to extend the affected digit from a flexed position. In severe cases the patient is unable to extend the digit. A tender nodule sometimes may be palpable on the flexor tendon at the level of the A1 pulley. This is associated with the nodular type of stenosing tenosynovitis. Usually the diagnosis of trigger digit can be based on the history and physical examination.

Medical Treatment

Treatment for stenosing tenosynovitis ranges from nonoperative management to splinting and cortisone injections to surgical management, including release of the A1 pulley. If a patient presents with a mild form of trigger finger or thumb, initial management may consist of splinting the MCP joint of the involved digit. The splint should allow free motion at the PIP and DIP joints.[234] Splinting has been successful, mostly in the four fingers, excluding the thumb, and in fingers that have mild triggering. However, the patient may need to spend up to 4 months in the splint. Because of this, patients may be less compliant with this treatment regimen. This method is an alternative for patients with mild disease who are hesitant to accept a steroid injection.

Steroid injections into the flexor tendon sheaths can be a successful treatment option for some patients with trigger fingers. Studies have reported that corticosteroid injections into the flexor tendon sheath tend to be more successful in women, in patients who have had symptoms for less than 6 months, in patients who have the nodular rather than the diffuse form of tenosynovitis, and in patients in whom only one digit is involved.[235,236] Usually two corticosteroid injections may be given for an attempt at successful therapy; if triggering symptoms continue or recur after three injections, operative management should be considered because the efficiency of further injections seems to decrease.[235]

Surgical management of stenosing tenosynovitis involves release of the A1 pulley, resulting in the return of the smooth gliding mechanism of the flexor tendon. Opening the pulley resolves the size disproportion between the pulley and the flexor tendon. Two different techniques are used for this purpose: percutaneous release and open release.

Percutaneous release of a trigger digit can be done in the office with administration of a local anesthetic. A needle or other cutting device is used to transect the A1 pulley longitudinally. The needle is placed through the skin into the A1 pulley at the level of the metacarpal head. The pulley is opened by sweeping the needle or cutting device back and forth in a longitudinal direction. After the cutting utensil is removed, the patient is asked to flex and extend the affected digit. Release of the pulley is confirmed when the patient can demonstrate this motion without any triggering.

Open release of a trigger digit typically is performed in the operating room and involves a skin incision proximal to the palmar digital crease. Blunt dissection is carried out by moving the neurovascular structures out of harm's way. The A1 pulley then is longitudinally transected with a scalpel or scissor tips under direct visualization.

Possible complications associated with surgical release of the A1 pulley include injury to the closely associated digital nerves. These nerves travel parallel to the flexor tendon on either side of the A1 pulley in the fingers. In the thumb,

however, the radial digital nerve crosses from the ulnar to the radial side of the digit at the level of the palmar digital crease, just proximal to the A1 pulley. The proximity of these digital nerves to the A1 pulley, especially in the thumb, puts the nerves at risk during pulley transection. Inadvertent release of the A2 pulley, resulting in bowstringing of the flexor tendon, has been reported with both open and percutaneous techniques.[237] Incomplete release of the A1 pulley and injury to the underlying flexor tendon can occur and seem to be more prevalent with the percutaneous technique.[238]

For the most part, surgical management of this problem results in successful resolution of symptoms, and the chance of recurrence is low.

De Quervain's Disease

General Considerations

De Quervain's disease is a stenosing tenosynovitis of the first dorsal compartment in the wrist. It causes pain over the radial aspect of the wrist that worsens with thumb motion as well as wrist radial and ulnar deviation.

Anatomy

Extension of the wrist, fingers, and thumb is controlled by a group of muscles that originate in the proximal half of the forearm. The tendons of these muscles course over the dorsal aspect of the wrist and hand before inserting on their target of motion. As these tendons approach the wrist, their outer covering forms a synovial sheath, which provides lubrication for the tendons as they glide back and forth. As the extensor tendons cross the dorsal aspect of the wrist, they are covered by the extensor retinaculum, a ligamentous structure that prevents bowstringing of the extensor tendons, allowing the tendons to stay closely approximated to the bones despite changes in wrist position.

The extensor retinaculum also organizes the tendons into six distinct anatomical compartments. The first compartment lies over the radial aspect of the wrist and contains the multiple slips of the APL and EPB tendons, both of which control thumb motion (Figure 10-89). The APL inserts on the dorsal base of the thumb metacarpal. The EPB inserts at the proximal dorsal aspect of the first phalanx of the thumb. Pathology of these tendons is the cause of de Quervain's tenosynovitis. The second dorsal compartment contains the ECRL and extensor carpi radialis brevis (ECRB) tendons, which provide wrist extension and radial deviation of the hand. The third compartment contains the EPL tendon, which extends the distal joint of the thumb. This tendon travels ulnar to Lister's tubercle and can be ruptured in distal radial fractures, particularly those that are nondisplaced. The fourth compartment contains the EDC and extensor indicis propius (EIP) tendons, which control finger extension. The fifth compartment contains the extensor digiti minimi tendon, which extends the small finger, in combination with EDC to the small finger. The sixth compartment contains the ECU tendon, which extends and ulnarly deviates the wrist and hand.

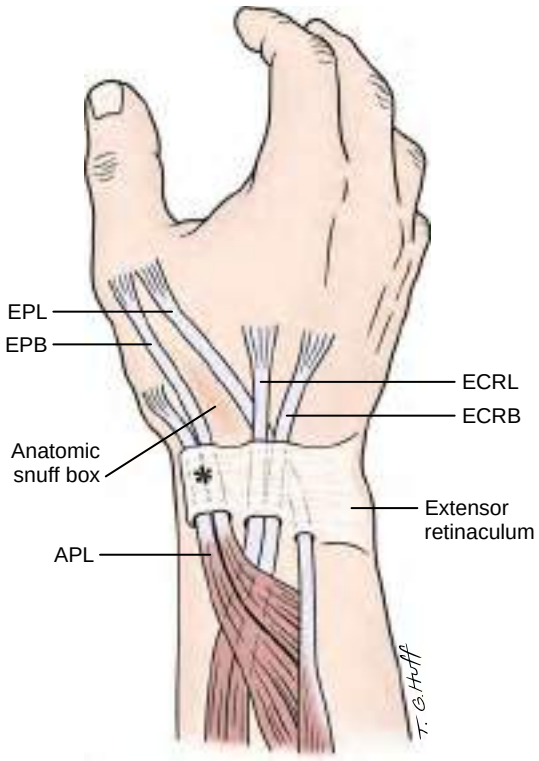

Figure 10-89 De Quervain's disease. Tenosynovitis (*) of tendons of abductor pollicis longus (APL) and extensor pollicis brevis (EPB). *ECRB*, extensor carpi radialis brevis; *ECRL*, extensor carpi radialis longus; *EPL*, extensor pollicis longus.

Also relevant to the anatomy of the dorsal wrist is the presence of the radial artery and branches of the radial sensory nerve that travel close to the first dorsal compartment. The radial artery travels from the volar to the dorsal wrist through the anatomical snuffbox. The tendons of the first dorsal compartment (APL and EPB) form the volar border of this space, and the EPL tendon forms its dorsal portion. The radial artery lies deep to these tendons as it moves to pass between the heads of the first dorsal interosseous muscle on its way to become the deep palmar arch. Branches of the radial sensory nerve lie superficial to the first dorsal compartment, providing sensation in this region. Just volar to the first dorsal compartment tendons, in the subcutaneous layer reside the terminal branches of the lateral antebrachial cutaneous nerve. Either nerve can easily be injured in the surgical approach to release the first extensor compartment, resulting in a painful neuroma.

Pathophysiology

Normally, the extensor tendons glide smoothly through the fibro-osseous compartments of the extensor retinaculum with finger and thumb motion. De Quervain's disease is a stenosing tenosynovitis that occurs because of a thickening of the tendons in the first dorsal compartment and a narrowing of the compartment itself. This disproportion in size between the tendon and the canal results in the

loss of the smooth gliding motion, which leads to significant pain with any wrist and thumb movement. The cause may be repetitive thumb abduction and ulnar deviation motions, leading to increased tension on the first dorsal compartment tendons. This increases the friction at the extensor retinaculum sheath, causing swelling of the tendons and narrowing of the compartment. Anatomical variations of the first dorsal compartment may also contribute to the development of de Quervain's disease, as well as to the success or failure of the treatment of this disorder. In up to 80% of patients, the first compartment may be divided by a longitudinal septum, resulting in separate canals for the APL and EPB tendons.[239,240] Separate canals may even be present for the multiple tendon slips of the APL. The possibility of these variations must be recognized because it may influence management.

Diagnosis

Patients present with increasing pain of insidious onset. The tenderness generally is described as involving the thumb and wrist and, on examination, may be localized to the area of the radial styloid. This pain radiates in a longitudinal fashion along the first extensor compartment from the metacarpal or proximal phalanx of the thumb onto the distal third of the forearm. Aching usually accompanies thumb motions, as well as grasping with the thumb and ulnar deviation of the wrist.

Examination of a patient with de Quervain's disease may demonstrate tenderness with palpation at the radial styloid and pain with active or passive stretching of the APL and EPB tendons. Finkelstein's test is pathognomonic for the diagnosis of de Quervain's tenosynovitis. This test is performed by passively adducting the patient's thumb into the palm of the patient's hand and then providing an ulnar deviation force to the wrist. Replication of the patient's pain with this action is a positive **Finkelstein's sign** and leads to the diagnosis of de Quervain's disease (Figure 10-90). The clinician must take care to rule out arthrosis of the thumb as the primary source of pain because this condition can easily mimic or even coexist with de Quervain's tenosynovitis.

Medical Treatment

The management of de Quervain's stenosing tenosynovitis ranges from immobilization to steroid injection therapy to an operative procedure. Immobilization in a cast or a splint may be attempted for a patient who is hesitant about having an injection or undergoing an operative procedure. This may alleviate symptoms for a short period, but pain tends to recur after the cast is removed. Overall, the failure rate for immobilization alone is 70%.[241]

A corticosteroid injection is a useful treatment option for patients with de Quervain's tenosynovitis. An injection is given into the two separate tendon sheaths of the first dorsal compartment, which is located approximately 1 cm (0.4 inch) proximal to the radial styloid. It is important to recognize that subdivisions may be present in the first dorsal compartment; therefore some of the injection solution should be redirected in a more dorsal direction to permeate a separate EPB sheath. The success rate for alleviating de Quervain's disease with corticosteroid injections can be as high as 80% after two injections.[239]

If nonoperative management has been unsuccessful for a patient with de Quervain's tenosynovitis, a surgical procedure may be necessary to release the stenotic fibro-osseous canal and restore smooth gliding of the tendons through the first dorsal compartment. The procedure involves incising the extensor retinaculum that covers the first dorsal compartment, and allowing decompression of the residing tendons. It is important to visualize the compartment fully and to incise any septa that may be subdividing the compartment. Each tendon slip should be identified and proven to glide smoothly before the procedure is completed. Some surgeons elect to widen and repair the extensor retinaculum, whereas others simply leave the compartment open after the release. A tenosynovectomy of the tendons can be performed at the time of surgery.

Complications

Both the operative and nonoperative management of de Quervain's disease can have complications. Corticosteroid injections have been associated with depigmentation in the area of the injection, fat necrosis, and subcutaneous

Figure 10-90 The Finkelstein maneuver is performed by placing the patient's thumb inside the palm and then gently deviating the wrist ulnarly. This maneuver causes severe discomfort in a patient with de Quervain's tenosynovitis. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 472, St. Louis, 2014, Saunders/Elsevier.)

atrophy. Also, the risk of infection or nerve injury, although remote, is still present.

Operative treatment for de Quervain's disease risks injury to the lateral antebrachial cutaneous or superficial sensory branch of the radial nerve because they both lie close to the tendons and can easily be injured in the surgical approach. If these branches are not identified and preserved, injury may result in a painful neuroma. Incomplete release of the first dorsal compartment leads to ongoing painful symptoms. Incomplete release most often results from failure to recognize a septum separating the APL and EPB tendons into different compartments or multiple compartments for the slips of the APL tendons. Failure to release this separate subsheath has been associated with persistent pain and unfavorable outcomes.[242] Persistent pain also may be the result of a secondary diagnosis (e.g., arthritis of the CMC joints) that was overlooked during the patient's workup. A more major complication of surgical release of the first compartment without its repair is the painful volar subluxation of the tendons from their usual position with wrist and thumb motion. This causes a painful snapping of the tendons as they slip volarly away from the radius. This generally requires reconstruction of a retinacular sling for tendon stabilization.

Carpal Tunnel Syndrome

General Considerations

According to Kerwin et al., carpal tunnel syndrome is the most frequently encountered peripheral compressive neuropathy.[243] Because of the frequency of this condition in the United States, approximately 500,000 operations to decompress the median nerve are performed each year.[244]

To understand carpal tunnel syndrome, it is necessary to appreciate the response of a peripheral nerve to injury, specifically the effect of compression and ischemia. Then the clinical manifestations that enable diagnosis and treatment will become clear.

Peripheral Nerves. Peripheral nerves consist of cell bodies that project axons to the extremities. The cell body resides in the anterior horn of the spinal cord for motor neurons and in the dorsal root ganglion for sensory neurons. Axons are surrounded by an outer layer, called *myelin*, which is produced by Schwann cells. Together, the axon and the surrounding Schwann cells constitute what is commonly referred to as a nerve.

The myelin sheath produced by the Schwann cells functions as insulation so that the axons can more efficiently transmit electrical impulses, a phenomenon known as *saltatory conduction*. These nerve fibers transfer sensory information from the periphery to the cell body in the dorsal root ganglion (i.e., afferent conduction). They also conduct motor orders from the brain and spinal cord to the extremities to dictate muscle function (i.e., efferent conduction).

Microscopically, the smallest unit of the nerve is a fiber called a *fascicle*. These fibers are often bundled together in groups that are surrounded by a strong connective tissue layer called the *perineurium*. Groups of fascicles, each bundled within its perineurial sleeve, travel together within a loose connective tissue known as the *internal epineurium*. This material is believed to function as a mechanical insulator to shock and pressure, and different nerves have various amounts of internal epineurium. The groups of fascicles lying in the internal epineurium are ultimately surrounded by the external epineurium, which defines the periphery of the nerve (Figure 10-91).

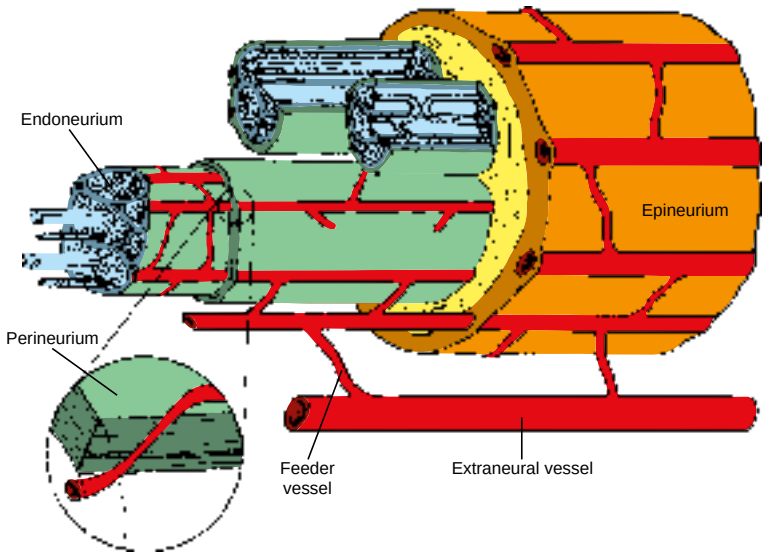

Figure 10-91 Cross section of a peripheral nerve and its blood supply. (Adapted from Lundborg G: Nerve injury and repair, Edinburgh, 1988, Churchill Livingstone. In Magee DJ, Zachazewski JE, Quillen WS, editors: *Scientific foundations and principles of practice in musculoskeletal rehabilitation*, p 178, St Louis, 2007, Saunders.)

The blood supply to the peripheral nerves runs from superficial epineurium to the deep endoneurial layer. A plexus of vessels runs longitudinally with the nerve at the level of the epineurium. These vessels send perforating arterioles into the perineurium. At the level of the endoneurium is a thin capillary network that is supplied by the vessels of the perineurial matrix. For the median nerve, the blood supply arises from branches from the radial and ulnar arteries. Nutrient vessels from these two major arteries accompany the median nerve through the carpal tunnel.

Peripheral nerves are subjected to different types of injury mechanisms, including compression, ischemia, stretching, chemical injury, and complete transection. Injuries to peripheral nerves are commonly classified by one of two systems. The simpler system, devised by Seddon,[245] describes three levels of nerve injury: the neuropraxia, the axonotmesis, and the neurotmesis. Sunderland[246] subsequently devised a more complex classification that describes injuries in terms of degrees, ranging from first degree (least severe) to fifth degree (most severe). Sunderland's system, although more involved to learn, appears to correlate better with clinical and pathological findings.

A first-degree Sunderland injury (classified as a neuropraxia by Seddon) is localized damage to the myelin sheath without injury to the axon. In this situation, the electrical impulses carrying the sensory and motor information are temporarily interrupted, but the nerve fiber architecture remains intact. This is a reversible injury, with full recovery of nerve function anticipated within 3 months. Most patients with carpal tunnel syndrome fall into this category.

A second-degree Sunderland injury (Seddon classification: axonotmesis) involves injury to the axon. Traction or a severe crush to the nerve disrupts the axonal fibers; however, the endoneurial tubes in which they travel remain intact. In this situation the axon undergoes degeneration (i.e., wallerian degeneration) at the time of the injury and must regenerate if function is to be regained. Surgical intervention is not required and return of function is anticipated, although it may not be complete.

In third-degree Sunderland nerve injuries, both the axon and endoneurium are disrupted, which increases the difficulty of regeneration. Therefore recovery of nerve function usually is incomplete.

In a Sunderland fourth-degree injury, the perineurium is disrupted along with the axon and endoneurial tubes, and in a fifth-degree injury (Seddon classification: neurotmesis), the nerve is completely transected and the epineurium is cleaved. Degeneration occurs, and regeneration is limited because of the large amount of scar tissue that forms and, in the case of complete transection, the physical separation of the cut nerve ends. In these cases, nerve damage is irreversible and surgical nerve repair is necessary to regain function.

Compression Injury. Carpal tunnel syndrome is a chronic compressive injury to the median nerve caused by increased pressure within the carpal canal at the wrist. Compression causes mechanical deformation of the nerve. Chronically this pressure compromises the neural blood flow, resulting in nerve ischemia. This creates an inflammatory response within the nerve. The connective tissue of the endoneurium and perineurium becomes edematous and eventually fibrotic. Demyelination occurs, resulting in less efficient signal conduction and compromised nerve function. If compression continues, axonal degeneration can occur. This manifests itself clinically on a continuum, depending on the degree of nerve damage. Initially a patient may complain of pain and sensory disturbances ranging from intermittent paresthesia to constant numbness. With progression of the compression, the patient loses the ability of two-point discrimination. Symptoms of motor disturbance may begin as pain and progress to muscle atrophy as more diffuse nerve damage occurs.

Anatomy

The carpal tunnel (Figure 10-92) is a relatively rigid structure, open ended at both the proximal and distal margins, which allows structures to pass through it from the forearm to the hand. The carpal bones border the tunnel on the dorsal, radial, and ulnar sides. The ulnar border consists of the hook of the hamate, triquetrum, and pisiform. The scaphoid and trapezium make up the radial border. The volar surface or roof of the tunnel is the flexor retinaculum, which extends from the distal radius to the metacarpal bases. The flexor retinaculum is made up of three structures: the deep forearm fascia, the transverse carpal ligament, and the aponeurosis between the thenar and hypothenar muscles. The median nerve, along with nine tendons (four from the FDS, four from the FDP, and the FPL) pass through the carpal tunnel. The median nerve usually branches at the distal edge of the flexor retinaculum, giving rise to the recurrent

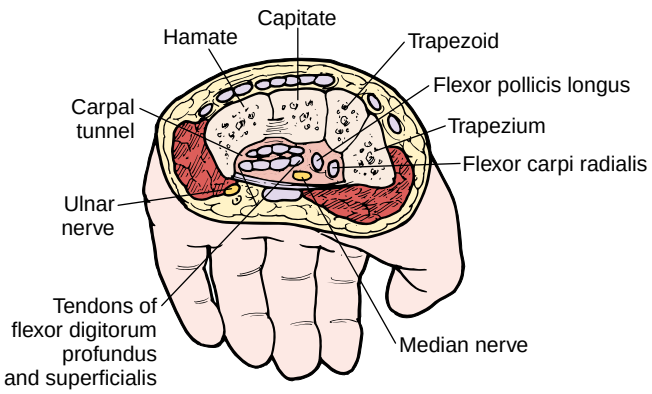

Figure 10-92 Cross section of the wrist showing the carpal tunnel. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 447, St. Louis, 2014, Saunders/Elsevier.)

motor branch, which supplies the APB muscle and the digital nerves to the radial three and one-half fingers. Variability in the anatomy of both the median nerve and the branch point of the recurrent motor nerve are common and must be considered during surgical treatment of carpal tunnel syndrome. In most cases the recurrent motor nerve branches distal to the distal edge of the flexor retinaculum (extraligamentous), putting it at low risk during carpal tunnel releases.

Etiology

Several possible reasons can account for the development of increased pressure within the carpal tunnel.

Conditions that alter fluid balance in the body may cause increased edema and pressure within the carpal tunnel, resulting in compression of the median nerve. Pregnancy, hypothyroidism, renal disease, and hemodialysis all have been associated with the onset of symptoms. Inflammatory conditions, such as rheumatoid arthritis, lupus, and infection, may also cause increased pressure within the carpal tunnel. Traumatic injuries such as distal radial fractures or carpal dislocations can directly injure the nerve and lead to increased pressure in the carpal tunnel. Space-occupying lesions, arthritic spurs, or ganglions also can compress the median nerve at the wrist.

Neuropathic factors, such as diabetes, alcoholism, or nutritional deficiency, may affect the median nerve directly without ever altering the fluid pressure within the carpal canal. It is imperative that, during the workup, the clinician differentiate these intrinsic nerve processes from extrinsic pressure that is compromising median nerve function.

Despite this list of multiple etiologies, which is far from complete, most cases of carpal tunnel syndrome are idiopathic. Patients with this type of carpal tunnel syndrome usually are women between the ages of 40 and 60, and in half of the cases, the carpal tunnel syndrome is bilateral.[247] Currently, the cause of the nerve compression in this situation is unclear. It may be associated with hormonal factors, changes in the tenosynovium in a person with an anatomically small tunnel, or vascular sclerosis. A well-established myth exists that carpal tunnel syndrome is directly correlated to the workplace environment and is associated with repetitive motion, typing, and work activities. There is little scientific evidence to support this popular belief.[248]

Determining the etiology of the carpal tunnel syndrome is important because the etiology influences the treatment options. If carpal tunnel syndrome results from an underlying disorder, resolution of the condition sometimes can alleviate the median nerve dysfunction. For example, if carpal tunnel syndrome results from the fluid shifts induced by pregnancy, operative treatment usually can be avoided. Delivery of the child frequently resolves the compression quite quickly; therefore steps to alleviate symptoms during the pregnancy may be all that is required.

Diagnosis

The diagnosis of carpal tunnel syndrome is made primarily on the patient's experience of symptoms. However, a number of physical examination findings, if positive, can help confirm the diagnosis.

A patient usually presents with a complaint of pain and/or paresthesia along the median nerve sensory distribution in the hand. This encompasses the palmar aspect of the thumb, index finger, middle finger, and the radial border of the ring finger. Symptoms increase insidiously over time from activity-related paresthesia and pain to constant, unrelenting numbness. Patients complain that these usually are worse at night, and this is believed to be related to the flexed position of the wrists during sleep, resulting in narrowing of the carpal tunnel and increased pressure on the median nerve.[249] Patients report worsening of symptoms during activities that cause prolonged wrist flexion or wrist extension, such as driving and talking on the telephone. If compression continues, weakness and atrophy of the thenar muscles may develop, resulting in loss of dexterity, difficulty grasping and holding objects, and an overall compromise in hand function.

The patient's history is critical in making the diagnosis. Provocative clinical tests, such as **Durkan's carpal compression test** (compression directly over the carpal tunnel), **Phalen's wrist flexion test** (wrist flexion for 60 seconds), and **Tinel's nerve percussion test** (tapping along the course of the median nerve), attempt to reproduce symptoms in the median nerve. Reproduction of the pain, numbness, or tingling is considered a positive finding and supports the diagnosis of carpal tunnel syndrome. However, if the tests are negative, this does not rule out the condition. Threshold sensory tests using Semmes-Weinstein monofilaments can elucidate the degree of sensibility the patient has lost secondary to nerve compression.

Electrodiagnostic tests (e.g., nerve conduction) and electromyographic studies provide objective evidence of impaired nerve conduction and intrinsic muscle function, which can be useful adjuncts to the clinical examination. These tests establish nerve conduction velocity, latency, and intrinsic muscle activity. They are helpful in isolating the location of a nerve lesion or injury and the degree of conduction block. This is important in cases in which the compression of the median nerve occurs at a level more proximal than the carpal canal.

Medical Treatment

Treatment options for carpal tunnel syndrome are varied, ranging from noninvasive splinting and cortisone injections to operative release of the transverse carpal ligament either by open or endoscopic techniques. Initially, attempts at nonoperative management are emphasized. The use of splints to maintain the wrist in a neutral position, which reduces the pressure in the carpal canal, is a

standard option for patients with low-grade symptoms. The patient may wear the splint at night while asleep or during activities that provoke symptoms.

If wrist splints are unsuccessful, a steroid injection into the carpal tunnel is another treatment option. This reduces the inflammation in the carpal tunnel, creating more space for the median nerve. In a select group of patients this results in complete alleviation of symptoms; however, 50% to 70% of patients have a return of their symptoms months after the injection. Care must be taken during the procedure to avoid needle injury or, even worse, injection into the nerve, which has long-term negative effects.

Surgical management of carpal tunnel syndrome is useful for patients who have thenar muscle weakness, who have failed nonoperative therapy, or who have numbness and tingling that is constant and no longer intermittent. Operative management consists of opening the roof of the carpal tunnel by incising the flexor retinaculum. This allows the carpal canal to increase its volume, relieving the pressure on the median nerve. Currently, two major surgical options are available. The first is the open release procedure, and the second is the endoscopic release procedure. Both accomplish the same goal, incising the transverse retinacular ligament to release the carpal tunnel.

The open carpal tunnel release begins with a vertical skin incision at the proximal aspect of the palm. Dissection continues through the subcutaneous tissue and the palmar fascia, ultimately leading to transection of the transverse carpal ligament. Care must be taken to preserve all cutaneous nerve branches and to visualize and preserve any branches of the median nerve, specifically the recurrent motor branch, which innervates the thenar muscles. Possible postoperative problems associated with open carpal tunnel release are scar tenderness and pillar pain. **Pillar pain**, which is discomfort that extends along the thenar and hypothenar borders of the hand, may be related to the release of the thenar-hypothenar fascia, which is necessary to reach the transverse carpal ligament through the open approach. If this develops, pillar pain typically resolves by 3 months.

With endoscopic carpal tunnel release, the palmar incision and dissection are avoided. Instead, an endoscope and cutting instrument are placed into the carpal canal and used to visualize and transect the transverse carpal ligament from its undersurface (Figure 10-93). During this procedure, care must be taken to avoid injury to the recurrent motor branch of the median nerve because this nerve occasionally has an anomalous course. The procedure is technically demanding and, in the hands of

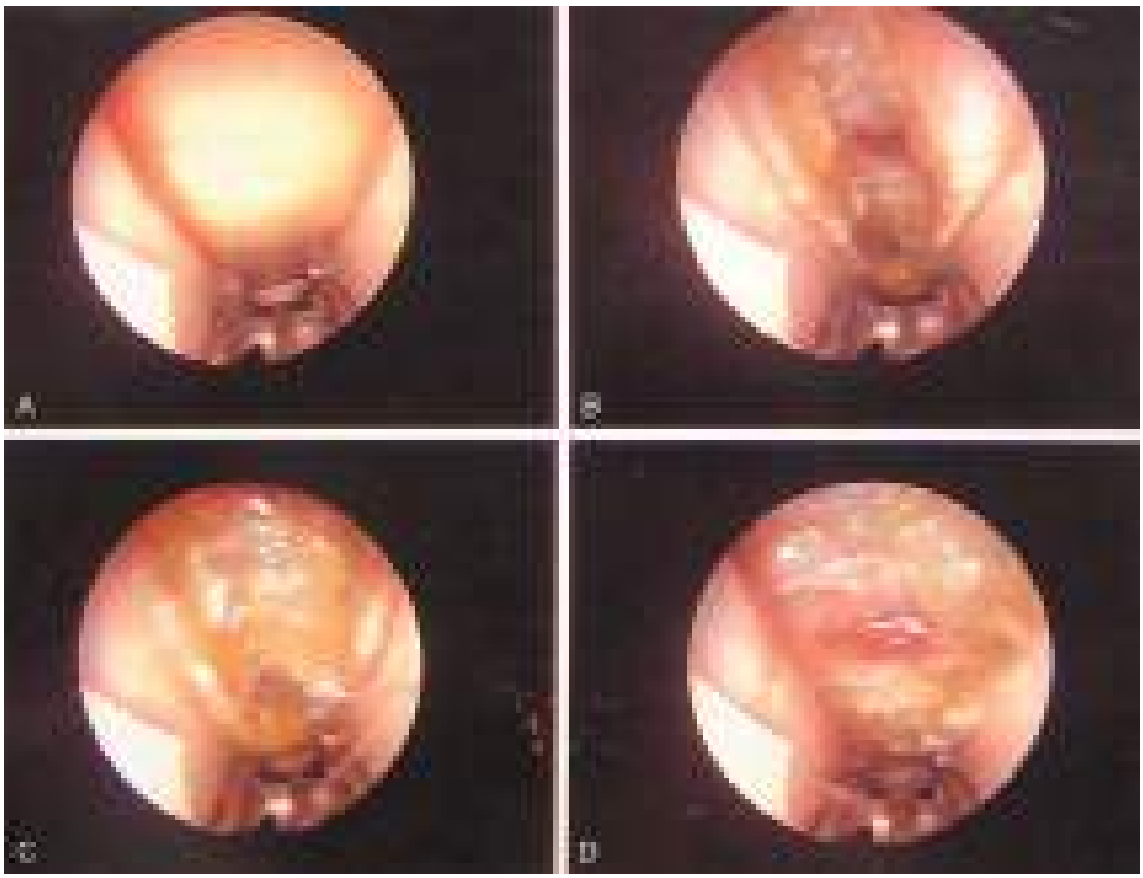

Figure 10-93 Endoscopic carpal tunnel release. **A,** Intact ligament. **B,** Partly incised ligament. **C** and **D,** Ligament is completely divided and "pops" widely apart. The overlying normal muscle and fascia are left intact.

an inexperienced surgeon, poses risks to neurovascular and tendinous structures.[250] Some studies have reported that postoperatively, patients have fewer complaints of discomfort, and they return to work sooner than with the open procedure.[251] Although outcomes at 3 months for both procedures are the same.

Each technique has its advocates. However, the final result with either procedure, the transection of the transverse carpal ligament, releases the pressure within the canal and alleviates the patient's symptoms of pain and paresthesia. A recent study has reported that 88% of patients were satisfied with their outcomes of open carpal tunnel release at a minimum of 10 years.[252]

Rehabilitation Principles and Considerations for Tendonitis, Tenosynovitis, and Entrapment

Trigger Finger

Rehabilitation for trigger digit begins after the involved digit is splinted in extension and if the patient experiences pain or stiffness, or both. It is important that the splint allow free motion at the PIP and DIP joints, with a hooked flexed position and full extension (Figure 10-94). Flexion of the IP joint with the MCP joint extended allows the flexor tendon to glide without stressing the A1 pulley. Splinting in extension prevents PIP flexion contractures and assists maximal glide of the flexor tendons.[234] The splint should be hand based and can be limited to the involved digit. A recent study published in the *Journal of Hand Therapy* demonstrated an 87% success rate with the use of a trigger splint.[253] Although there were limitations to this study, this treatment option may be beneficial to some patients.

Postoperative referral for therapy is indicated if pain, diminished AROM, scar adhesion, and tissue tightness persist. After inflammation has diminished, night extension splinting is implemented to aid in prolonged stretching of the flexors, if shortening has occurred. Emphasis is placed on differential flexor tendon gliding with blocking exercises. Edema and scar management, to improve gliding of the soft tissues, is often necessary. Strengthening and prolonged grasp activities are avoided until full healing and the return of pain-free motion have been achieved.

Figure 10-94 Anterior (volar) based trigger finger splint. The MCP is supported in extension, allowing PIP and DIP flexion. An alternative dorsal splint can be made, depending on the patient's preference.

De Quervain's Disease

In the early treatment of de Quervain's disease, intervention through immobilization may be initiated in the acute inflammatory cycle. In this case a thumb spica splint with the IP joint free reduces stress to the tendons by resting the tissues. Soft tissue mobilization may help reduce inflammation and tissue guarding. Extensive patient education is essential to protect the tissues from overuse. Splinting can be attempted for 4 to 6 weeks. Once the patient has reduced pain from splinting, education for positioning of the thumb and wrist during ADLs is important to avoid further recurrence of the pain.

There is some evidence that modalities such as iontophoresis, noxious level stimulation, and transverse friction massage may be useful in treating tendinopathies such as de Quervain's tenosynovitis. These may help to alleviate pain and allow the treating clinician to progress patients to eccentric exercises and strengthening protocols.[254]

Patients should be advised to modify activities after a corticosteroid injection for 1 to 2 weeks. These patients may also benefit from wearing a thumb spica splint for 1 to 2 weeks after the injection.

Postoperatively, emphasis should be placed on differential tendon gliding, edema and scar management, and modalities to improve soft tissue glide. Desensitization for nerve irritability is often also needed. Strengthening and prolonged pinching are avoided until healing is complete and the patient is pain free.

Carpal Tunnel Syndrome

Nonsurgical intervention for carpal tunnel syndrome consists of splinting the wrist in a neutral position, tendon and nerve gliding exercises, and extensive patient education, including activity and work site modification and positions to avoid to prevent irritation of the median nerve. Splints are worn at night to prevent the wrist from resting in flexion and/or extension.[249] Splinting may also be recommended for day use if the symptoms are not improving. Patients may benefit from wearing a splint for 1 to 2 weeks after a corticosteroid injection.

Postoperative referral to therapy is indicated if pain, hypersensitivity, AROM deficits, and reduced soft tissue mobilization, including scar tissue, persist. Emphasis is placed on scar management, differential tendon gliding exercises, and modalities (ultrasound) to improve the soft tissue mobility and function. Acetic acid iontophoresis is a treatment modality that may be beneficial for helping patients recover function that is lost secondary to impairment caused by recalcitrant scar tissue.[255] Desensitization is included if nerve irritability is present. Activity modification (e.g., avoiding prolonged grasping) is indicated if inflammation is present.
