Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

To Suzann K. Campbell and the 126 contributors who have been instrumental to the success of the five editions of Physical Therapy for Children

PREFACE

What makes an outstanding textbook on pediatric physical therapy? First and foremost is the emphasis on clinical reasoning, decision making, family-centered services, and application of knowledge and research to practice. Pediatric physical therapists make numerous clinical decisions, including eligibility and need for services, goals and outcomes, prognosis, intensity of services, and intervention plans. The reasoning and evidence for clinical decisions are emphasized throughout *Campbell's Physical Therapy for Children*. Chapter 1 presents frameworks to guide clinical reasoning and decision making, such as the International Classification of Functioning, Disability and Health (ICF) and the Guide to Physical Therapist Practice, strategies for finding evidence, and criteria for appraisal of evidence. Terms used throughout the book such as *Background* and *Foreground* information are defined.

The editors believe that the priorities, concerns, and aspirations of children and families are integral to pediatric physical therapy practice. Accordingly, the chapters not only address direct interventions, but also child and family goals and information needs; communication and coordination of services as members of healthcare and education teams; and consultation to community agencies, instructors, and coaches. Families of children with disabilities have expressed the importance of planning for the future. To address this priority, key considerations for physical therapy management are presented for infants, children, and adolescents, including the transition to adulthood.

The ability to effectively apply knowledge and research to practice is a characteristic of expert practitioners. Since the publication of the first edition, research pertinent to pediatric physical therapy has dramatically increased. The authors of each chapter have effectively appraised this aspect of pediatric physical therapy, including emerging technologies. Chapters in Sections 2 to 4 feature case scenarios and videos that illustrate application of knowledge and research to practice. Additionally, the cases demonstrate how child and family strengths and preferences, environmental context, and therapist practice knowledge all inform clinical reasoning and the decision making process. These cases and videos are found on the Expert Consult site that accompanies this text (discussed below).

Several new and extensively revised chapters are included in this edition. Chapters have been added on children with autism (Chapter 24), children with cancer (Chapter 16), and measurement (Chapter 2). Content on concussion has been expanded and includes a new case scenario on post-concussion rehabilitation (Chapter 15). Chapter 3, *Motor Development and Control*, integrates content from two previously separate chapters and expands application to practice.

The **45 case scenarios** and **80 videos** on Elsevier's Expert Consult platform are distinctive features of this fifth edition. The cases actively engage readers in clinical reasoning and decision making. The phrase *Pause and Reflect* followed by a question is inserted several times within a case to encourage readers to stop and reflect on what they would do before continuing to read the case. The phrase *Evidence to Practice* is followed by the rationale and evidence for a decision.

We are pleased to provide readers access to videos that illustrate children in their daily lives, examination procedures, and physical therapy interventions. Many of the case scenarios include an accompanying video. Additionally, there are videos on motor development, development of gait, tests and measures, practice in special settings, and transition to adulthood. An introduction to the case scenarios and videos is provided at the end of each chapter. A table of contents for the case scenarios and videos for each chapter is provided for easy reference. We strongly encourage readers to take advantage of these outstanding resources on the Expert Consult website, a user-friendly platform for easy access.

Edition 5 retains the five sections included in previous editions. Section 1, *Understanding Motor Performance in Children,* provides foundation knowledge for pediatric physical therapy practice, including evidence-based decision making, measurement, motor development and control, motor learning, musculoskeletal development and adaptation, and physical fitness. Sections 2 to 4 contain 22 chapters on the management of children with musculoskeletal, neuromuscular, and cardiopulmonary conditions. Chapters are organized by two main headings: *Background Information* (knowledge of the health condition, medical, and pharmacologic management) and *Foreground Information* (evidence-based recommendations for physical therapy management). Text boxes and tables are used to summarize recommendations for tests and measures and evidence for interventions. Section 5, *Special Settings and Special Considerations,* includes chapters on the neonatal intensive care unit, early intervention, the educational environment, transition to adulthood, and assistive technology. Throughout the book, chapters are cross-referenced to integrate content.

ACKNOWLEDGMENTS

The fifth edition of *Campbell's Physical Therapy for Children* is dedicated to Suzann K. Campbell and the 126 contributors to one or more editions. Adding Sue's name to the title acknowledges her vision for a comprehensive, evidence-based textbook on pediatric physical therapy and having guided *Physical Therapy for Children* from inception through edition 4. Sue's fingerprints grace the pages of edition 5. Hard to believe (especially for contributors to all five editions) that more than 20 years have passed since publication of the first edition. The key to success has been the expertise of the contributors, including the 73 contributors to edition 5. The contributors are an eclectic mix of pediatric clinical specialists, educators, and clinical researchers. They are distinguished not only by their expertise and leadership but also their commitment to excellence. Contributors have graciously devoted countless hours to their chapters to ensure content is of the highest quality. Collectively, they have made possible a high-quality textbook that spans the breadth and depth of pediatric physical therapy. Their contributions have enriched the education and professional development of countless students and pediatric physical therapists worldwide.

I am extremely grateful to Margo Orlin and Joe Schreiber (co-editors) for their collaboration and innovation in planning and editing the fifth edition. A comprehensive, 34-chapter textbook with extensive resources is a major undertaking—definitely a three-person effort! The editors are appreciative of the support provided by Kathy Falk, Courtney Sprehe, Rich Barber, and the rest of the Elsevier production team. Kathy and Courtney were receptive to the changes we proposed for the fifth edition and made them a reality.

TABLE OF CONTENTS – CASE SCENARIOS

CHAPTER 7

- Case 7-1: "Reading" the diagnostic-classification from motor-behavior in very young children
- Case 7-2: Severe refractory polyarticular juvenile idiopathic arthritis in a 14-year-old girl

CHAPTER 8

- Case 8-1: Spondylolysis and spondylolisthesis in a young athlete

CHAPTER 9

- Case 9-1: Initial examination and follow-up of an infant with congenital muscular torticollis and deformational plagiocephaly

CHAPTER 10

- Case 10-1: Young man with arthrogryposis followed from birth through adolescence
- Case 10-2: Young man with arthrogryposis followed from birth to age 7 years

CHAPTER 11

- Case 11-1: 11-year-old girl with type III/IV osteogenesis imperfecta

CHAPTER 12

- Case 12-1: 9-year-old boy with dystrophinopathy and probably Duchenne muscular dystrophy
- Case 12-2: Ambulatory changes 7-year-old girl with spinal muscular atrophy Type III

CHAPTER 13

- Case 13-1: 7-year-old girl with proximal femoral focal deficiency
- Case 13-2: 6-year-old boy with cancer (osteosarcoma of the right distal femur)
- Case 13-3: 14-year-old boy with traumatic amputation

CHAPTER 14

- Case 14-1: 12-year-old boy diagnosed with Sever Disease
- Case 14-2: 14-year-old girl with diagnosis of vascular malformation of the left leg presenting with an ankle sprain

CHAPTER 15

- Case 15-1: Post-concussion rehabilitation management in a 16-year-old swimmer
- Case 15-2: 10-year-old boy with stable osteochondritis dissecans lesion in the medial femoral condyle
- Case 15-3: Postoperative management of anterior cruciate ligament reconstruction in a young female athlete

CHAPTER 16

- Case 16-1: 10-year-old girl with vincristine-induced peripheral neuropathy

CHAPTER 17

- Case 17-1: 5-year-old child with developmental coordination disorder who has developed methods of avoiding school-based tasks with motor demands
- Case 17-2: 8-year old girl with motor challenges and some of the secondary consequences that can arise with motor coordination issues
- Case 17-3: 13-year-old boy with attention issues and coordination difficulties

CHAPTER 18

- Case 18-1: 6-year-old girl with Down syndrome

CHAPTER 19

- Case 19-1: Girl with asymmetric quadriplegic cerebral palsy
- Case 19-2: Girl with cerebral palsy

CHAPTER 20

- Case 20-1: Girl with brachial plexus injury to the left arm

CHAPTER 21

- Case 21-1: Girl with complete tetraplegia
- Case 21-2: Boy with diagnosis of T10 paraplegia
- Case 21-3: Teenage boy with incomplete paraplegia

CHAPTER 22

- Case 22-1: 6-year-old boy hit by a car with acquired brain injury (from time of injury to discharge)

CHAPTER 23

- Case 23-1: 6-year-old girl with L4 level paraplegia from myelomeningocele
- Case 23-2: 6-year-old girl with S1-S2 level paraplegia from myelomeningocele

CHAPTER 24

- Case 24-1: 30-month-old boy with a diagnosis of autism spectrum disorder receiving services through the Early Intervention System

CHAPTER 25

- Case 25-1: 2-year-old boy with chronic lung disease and history of dependence on mechanical ventilation

CHAPTER 26

- Case 26-1: Boy with cystic fibrosis followed from 2 months through age 16

CHAPTER 27

- Case 27-1: Boy with exercise-induced asthma and pectus excavatum

CHAPTER 28

- Case 28-1: 10-year-old child with cardiomyopathy receiving outpatient physical therapy
- Case 28-2: Child with complex cyanotic congenital heart disease presented from birth through age 26

CHAPTER 29

- Case 29-1: Boy born extremely pre-term, spent over 4 months in NICU
- Case 29-2: Girl born full-term with Down syndrome

CHAPTER 30

- Case 30-1: 22-month-old both with global developmental delay and failure to thrive
- Case 30-2: 26-month old boy with right hemiplegia

CHAPTER 31

- Case 31-1: Young girl with spastic diplegic and ataxic cerebral palsy in a school setting

CHAPTER 32

- Case 32-1: 22-year-old man recently transitioned from high school to part-time community employment
- Case 32-2: Physical therapist working in the public schools, expanding her role to service youth with physical disabilities transitioning from high school to postsecondary education
- Case 32-3: Doctoral candidate Matt Freeman shares his thoughts on the transition process as someone who lived the experience as an individual with cerebral palsy

CHAPTER 33

- Case 33-1: 37-year-old woman with spastic quadriplegia cerebral palsy and how her assistive technology needs have changed as she matures
- Case 33-2: 17-year-old man with cerebral palsy, spastic quadriplegia and learning disabilities and how his family's advocacy for assistive technology from early childhood helped his development
- Case 33-3: 10-year-old boy with cerebral palsy and quadriplegia and the multiple assistive technology devices he uses to achieve independence

TABLE OF CONTENTS – VIDEOS

CHAPTER 3

- Video 3-1: Development of mobility from 3-14 months
- Video 3-2: Postural control from 3-10 months
- Video 3-3: Repetition of movements
- Video 3-4: Inability to break free of symmetry: 10 weeks
- Video 3-5: Righting/equilibrium reactions: 10 weeks
- Video 3-6: Accommodating grasp to the environment: 8.5 months
- Video 3-7: Mature and immature running
- Video 3-8: Responses to sound in prone
- Video 3-9: Effects of movement on stability: 8.5 months
- Video 3-10: Head and trunk control: 10 weeks
- Video 3-11: Trunk control: 8.5 months
- Video 3-12: Skip, hop, gallop, jump
- Video 3-13: Object manipulation stages
- Video 3-14: Stair-climbing: 3 years
- Video 3-15: Irish dancing
- Video 3-16: Hopping strategy development
- Video 3-17: Stages of play
- Video 3-18: Teaching prone play: 10 weeks
- Video 3-19: Reaching in supine

CHAPTER 4

- Video 4-1: Motor learning practice examples

CHAPTER 7

- Video 7-1: "Reading" the diagnostic-classification from motor-behavior in very young children (see Case 7-1)
- Video 7-2: Severe refractory polyarticular juvenile idiopathic arthritis in a 14-year-old girl (patient from Case 7-2)

CHAPTER 8

- Video 8-1: 12-year-old soccer player with spondylolysis

CHAPTER 9

- Video 9-1: Examination and intervention
- Video 9-2: Treatment activities for 9-month-old infant with left congenital muscular torticollis

CHAPTER 10

- Video 10-1: 21-month-old boy with arthrogryposis multiplex congenita

CHAPTER 11

- Video 11-1: 5-year-old girl with Type III/Type IV osteogenesis imperfecta

CHAPTER 12

- Video 12-1: 9-year-old boy with dystrophinopathy and probably Duchenne muscular dystrophy (Derek from Case 12-1)
- Video 12-2: Ambulatory changes in a 7-year-old girl with spinal muscular atrophy Type III (Ava from Case 12-2)

CHAPTER 13

- Video 13-1: 14-year-old boy who sustained a mutilating injury to his right leg (Anthony from Case 13-3)
- Video 13-2: 4-year-old girl with congenital longitudinal deficiency of the tibia complete

CHAPTER 14

- Video 14-1: 12-year-old boy diagnosed with Sever disease (Jesse from Case 14-1)
- Video 14-2: 14-year-old girl with diagnosis of vascular malformation of the left leg presenting with an ankle sprain (McKenzie from Case 14-2)

CHAPTER 15

- Video 15-1: Functional performance tests for athletes

CHAPTER 16

- Video 16-1: 10-year-old girl with vincristine-induced peripheral neuropathy (Rachel from Case 16-1)

CHAPTER 17

- Video 17-1: 6-year-old boy with developmental coordination disorder (Bill from Case 17-1)
- Videos from Missiuna C, Gaines R, Soucie H: Why every office needs a tennis ball: a new approach to assessing the clumsy child, CMAJ 175(5): 471-473, 2006. - http://www.cmaj.ca/content/175/5/471/rel-suppl/1d9a234c1fa41f96/suppl/DC2

CHAPTER 18

- Video 18-1: 6-year-old girl with Down syndrome (Liz from Case 18-1)
- Video 18-2: 20-month-old girl with spinal muscular atrophy
- Video 18-3: Teenage boy with spinal muscular atrophy

CHAPTER 19

- Video 19-1: Demonstration of all five levels of the Gross Motor Function Classification System
- Video 19-2: 13-year-old girl with spastic cerebral palsy (Noelle from Case 19-1)

CHAPTER 20

- Video 20-1: 2-year-old girl with brachial plexus injury of the left shoulder

CHAPTER 21

- Video 21-1: 4-year-old boy with T3-4 spinal cord injury
- Video 21-2: 15-year-old boy with T1 ASIA D spinal cord injury

CHAPTER 22

- Video 22-1: 6-year-old boy hit by a car and suffering from acquired brain injury (Said from Case 22-1)
- Video 22-2: Boy with ependymoma

CHAPTER 23

- Video 23-1: 6-year-old girl with S1-S2 level paraplegia from myelomeningocele (Megan from Case 23-2)

CHAPTER 25

- Video 25-1: 22-month-old girl with Moebius syndrome, central respiratory dysfunction, and long-term mechanical ventilator dependence (see also Case 25-1)

CHAPTER 26

- Video 26-1: Pulmonary function test in 15-year-old boy with cystic fibrosis
- Video 26-2: Parent instruction in postural drainage and percussion on infant with cystic fibrosis
- Video 26-3: Parent instruction in postural drainage and percussion on 3-year-old girl with cystic fibrosis
- Video 26-4: Exercise testing with 15-year-old boy with cystic fibrosis
- Video 26-5: Positive expiratory pressure (PEP) therapy with a 15-year-old boy with cystic fibrosis

CHAPTER 28

- Video 28-1: 10-year-old child with cardiomyopathy receiving outpatient physical therapy (same patient from Case 28-1)

CHAPTER 29

- Video 29-1: Boy born at 28 weeks, now at 40 weeks, being prepared for discharge (see also Case 29-1)
- Video 29-2: Bayley Scale of Infant Development
- Video 29-3: Harris Infant Neuromotor Test
- Video 29-4: Test of infant motor performance (TIMP)

CHAPTER 31

- Video 31-1: Young girl with spastic diplegic and ataxic cerebral palsy in a school setting (Adrianna from Case 31-1)

CHAPTER 32

- Video 32-1: Doctoral candidate Matt Freeman shares his thoughts on the transition process as someone who lived the experience as an individual with cerebral palsy (see also Case 32-3)

CHAPTER 34

- Video 34-1: Initial contact
- Video 34-2: Loading response
- Video 34-3: Mid stance
- Video 34-4: Terminal stance
- Video 34-5: Pre-swing
- Video 34-6: Swing phase
- Video 34-7: Patient with internal twist in the femur demonstrating a walk with excessive internal rotation through the hip joint
- Video 34-8: Patient demonstrating crouched gait

Evidence-Based Decision Making in Pediatric Physical Therapy

Joseph Schreiber, Robert J. Palisano

Pediatric physical therapists make multiple complex and challenging clinical decisions on a daily basis. These include determining eligibility and need for services, selecting intervention techniques and strategies to engage and motivate children, deciding the frequency and duration of services including when to discontinue services, and selecting outcome measures and interpretation of findings. An essential aspect of decision making in pediatric physical therapy is effective collaboration with families and children to determine the best course of action for an individual child at a particular point in time. On what basis do we make these important decisions with children and families? Evidence suggests that physical therapists make clinical decisions based primarily on knowledge gained from entry-level education, continuing education conferences, and from peers.[4,6,25,27,53,54,38,24] Although this reliance on professional craft knowledge has historically served us well, it is an expectation in today's health care environment that physical therapists also integrate the best available research evidence into valid and reliable clinical decision making and that decision making be systematic and consistent. The purpose of this chapter is to provide guidance on optimal clinical decision making for pediatric physical therapists. Several overarching frameworks are presented, including the International Classification of Functioning, Disability and Health (ICF), the American Physical Therapy Association (APTA) Guide to Physical Therapy Practice, evidence-based practice, and effective and efficient strategies for knowledge acquisition, analysis, and integration. These frameworks are integrated into a collaborative evidence-informed decision-making model that should serve to optimize outcomes for children and families.

INTERNATIONAL CLASSIFICATION OF FUNCTIONING, DISABILITY AND HEALTH

One important framework to guide clinical decision making is the International Classification of Functioning, Disability and Health (ICF; World Health Organization[55]), which aids in the identification of child and family strengths and needs, along with home and community/environmental considerations, including family resources and availability and accessibility of services. The ICF was developed to provide a scientific basis for understanding and studying health and health-related states, outcomes, and determinants. The ICF also is intended to provide a common language in order to improve communication among people with disabilities, health care providers, researchers, and policy makers. The ICF emphasizes "components of health" rather than "consequences of disease" (i.e., participation rather than disability) and environmental and personal factors as important determinants of health. The ICF model is available on the World Health Organization website (www.who.int/classifications/icf/en). A children and youth version (ICF-CY) was published by the World Health Organization in 2007.[56] The model is the same as the ICF but codes for components of health, personal, and environmental factors were modified and new codes added to reflect development and environments of children and youth from birth to 18 years. A resolution was passed in 2012 to merge the ICF-CY into the ICF. The ICF framework has been incorporated into the third edition of the *Guide to Physical Therapist Practice*[2] and is used throughout this text.

The diagram of the ICF model is presented in Fig. 1.1. The ICF has two parts. Part 1, Functioning and Disability, includes three components of health: body functions and structures, activities, and participation. Part 2, Contextual Factors, includes environmental and personal factors that influence components of health. For example, the impact of activity (ability to walk) and participation (ability to travel with classmates at school when going to lunch) may be influenced by the environment (distance from classroom to cafeteria and time to travel this distance) and personal factors (the child's motivation to walk). The bidirectional arrows in the ICF model are inclusive of all possible relationships. The challenge when applying the ICF is to identify the relationships that are most relevant for an individual child and family.

Body functions are the physiologic and psychological functions of body systems. Physiologic functions include respiration, vision, sensation, muscle performance, and movement. Psychological functions include attention, memory, emotion, thought, and language. *Body structures* are the anatomic parts of the body such as the brain, organs, bones, ligaments, muscles, and tendons. *Impairments* are problems in body functions and structures. Examples of impairments are limited ability to plan and execute movement, poor processing of sensory information, reduced cardiorespiratory endurance, lack of sensation, muscle weakness, balance difficulties, skeletal deformity, and joint contracture. *Activity* is the performance of a task or action by an individual. Activities represent the integrated use of body functions and vary in complexity. Examples of activities are maintaining and changing body positions, walking

and moving around, lifting and carrying objects, fine hand use, and self-care. *Activity limitations* are difficulties in performing age-appropriate tasks or actions. *Participation* is involvement in a life situation. Most children participate in home life, school, community activities and organizations, and social relationships with friends. Participation is highly individualized. What is important to one child may be of little consequence to another child. *Participation restrictions* are problems in involvement in life situations. *Environmental factors* make up the physical, social, and attitudinal environments in which people live and conduct their lives. *Personal factors* are the particular background of the individual's life and living that *are not* part of a health condition or disorder. These factors may include gender, race/ethnicity, age, fitness, lifestyle, habits, coping styles, and past and current experiences.[55] Box 1.1 lists considerations for applying the ICF to clinical decision making.

For each of the three components of health and the environment factor, the ICF lists domains, categories within domains, and qualifiers to record the presence and severity of the problem. For example, one domain for Activity and Participation is Mobility, and among the categories of Mobility are Walking and Transportation. Core sets of categories that are considered most relevant for particular health conditions have been developed and include cerebral palsy and autism (http://icf-research-branch.org).

An example of a child with cerebral palsy spastic diplegia, Gross Motor Function Classification System level II, illustrates application of the ICF for clinical decision making (Fig. 1.2).

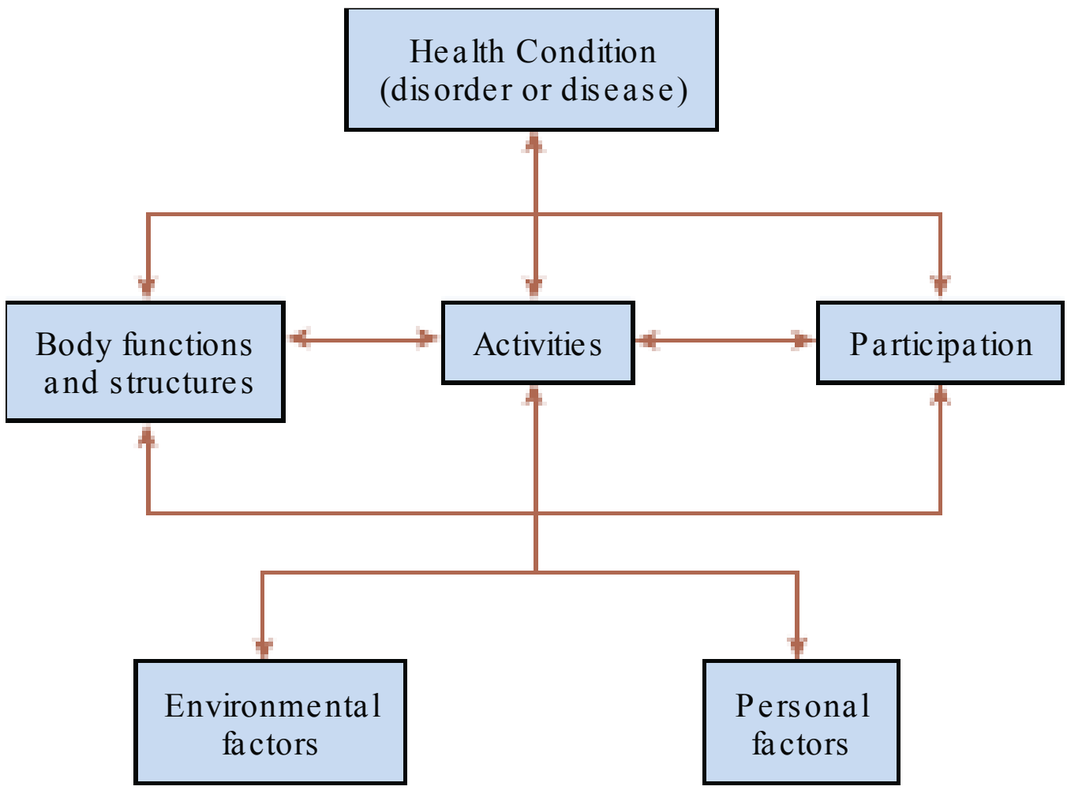

FIG. 1.1 Interactions between the components of the International Classification of Functioning, Disability and Health (IFC). (Courtesy of the World Health Organization: International classification of functioning, disability and health. Geneva, Switzerland: WHO; 2002.)

BOX 1.1 Considerations for Using the International Classification of Functioning, Disability and Health as a Framework for Clinical Decision Making

Body Functions and Body Structures

Not all impairments are modified by physical therapy
Not all impairments cause activity limitations and participation restrictions
Relate impairments to activity limitations and participation restrictions
Impairments are identified from examination and evaluation of body functions and structures

Activities

Relate activity limitations to participation restrictions
Activity limitations can cause secondary impairments
Activities are often measured by norm-referenced and criterion-referenced assessments

Participation

Reflects child and family perspectives
Is context dependent (environmental and personal factors)
Is one aspect of health-related quality of life
Is measured by child and parent self-report
Is measured by observations in natural environments as well as parent and child self-report

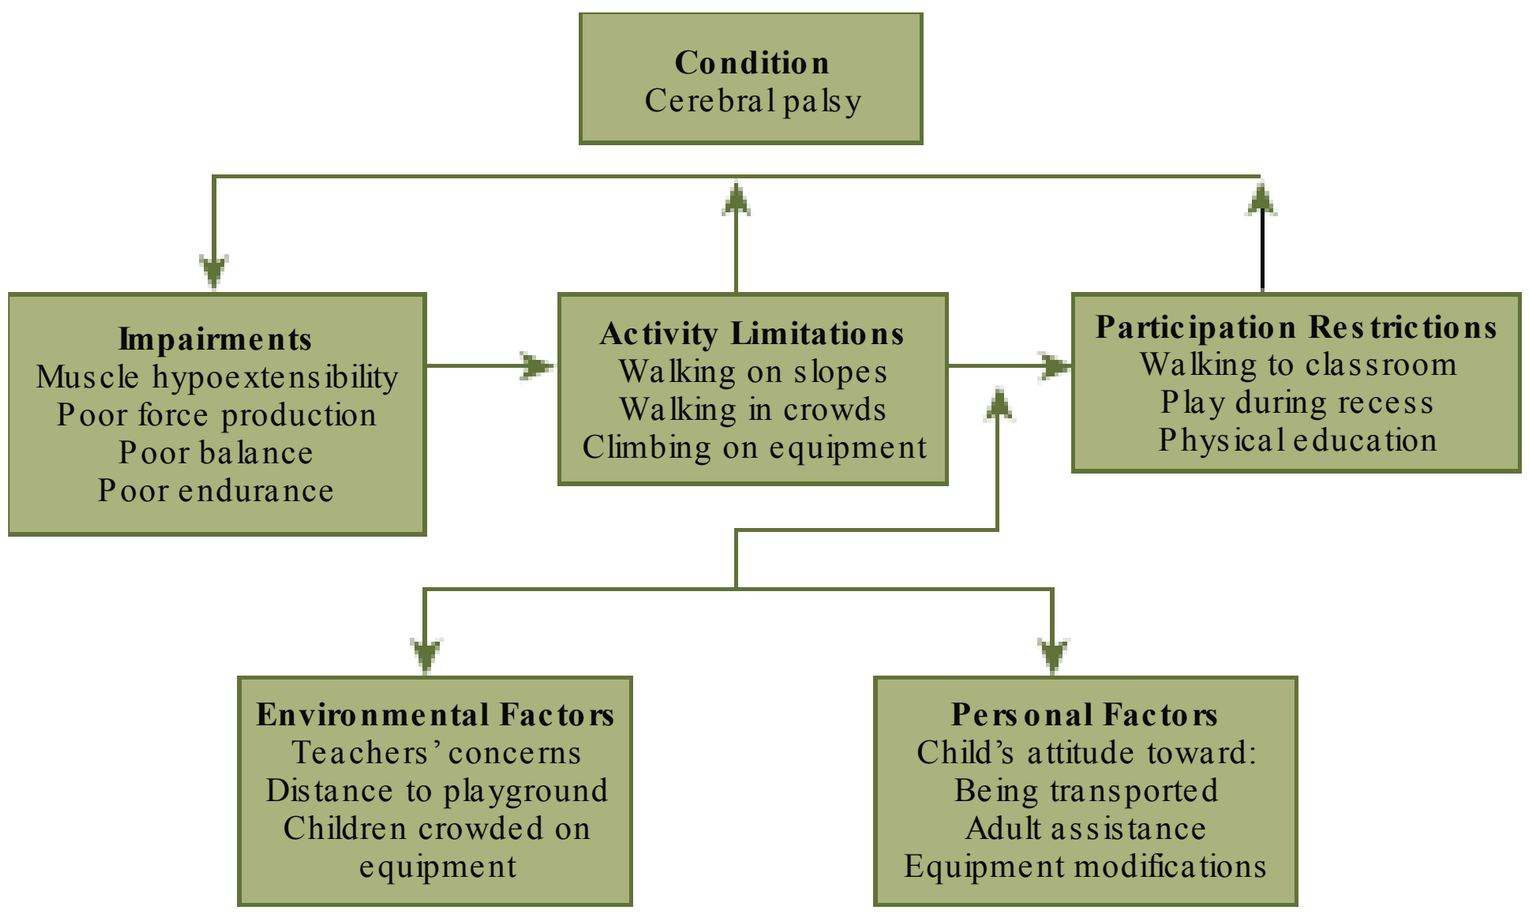

FIG. 1.2 Example of application of the International Classification of Functioning, Disability and Health to clinical decision making.

The child's impairments in the neuromuscular and musculoskeletal systems include hamstring and gastrocnemius muscle hypoextensibility, reduced muscle force production, poor balance, and limited muscular endurance. The child's activity limitations include difficulties in walking on a sloping surface, walking amid people, and climbing playground equipment. At school, the child occasionally falls when walking from the bus to the classroom. Although the child has several friends and enjoys physical activity, participation in recess and physical education is restricted. Social and physical environmental factors that may contribute to restricted participation include the following: teachers are concerned that the child will get injured; the child's classroom is located at the end of the school most distant from the playground; the terrain of the school yard is uneven; and students are crowded on the playground equipment.

When applying the ICF framework, the therapist is encouraged to identify what the child does (strengths) in addition to impairments, activity limitations, and participation restrictions that limit or restrict what the child wants to or needs to do. The challenge is to hypothesize cause-effect relationships. For example, what are the possible causes of a student's restricted participation during recess and physical education? Will instruction and practice in walking in varied settings and climbing on playground equipment (motor learning) improve participation? A systematic review of interventions for children with cerebral palsy by Novak et al. (2013) reported evidence of effectiveness of interventions that are goal directed and provided in natural environments.[36] Collaboration with the teachers to discuss their safety concerns and the feasibility of modifications to playground equipment are environmental considerations. The child's feelings about energy conservation (e.g., being transported to the playground), modifications of playground equipment, and support from adults are examples of personal factors to consider in formulating an intervention plan. Note that in Fig. 1.2, only the hypothesized interactions are depicted. The arrow from the participation restrictions and activity limitation to impairments represents a secondary impairment.

APTA GUIDE TO PHYSICAL THERAPIST PRACTICE 3.0

The *Guide to Physical Therapist Practice 3.0* (Guide 3.0) provides a framework to inform clinical decision making for patient/client management.[2] At the time this chapter was published, Guide 3.0 was available online at no cost to members of the APTA or by paid subscription for other users. The second edition of the Guide (2001) was designed as a resource not only for physical therapists but also for health care policy makers, administrators, managed care providers, third-party payers, and other professionals. Guide 3.0 is a description of practice intended primarily for physical therapists and physical therapist assistants. The language of the Guide has been modified to be consistent with the ICF, and Review of Symptoms has been added to the Examination. The Preferred Physical Therapist Practice Patterns from earlier editions have been removed. The purposes of Guide 3.0 include description of: a) the roles of physical therapists and physical therapist assistants in different practice settings, including roles in prevention and the promotion of health, wellness, and fitness; b) standardized terminology; c) the clinical decision-making process that occurs as part of patient and client management, including the examination and evaluation process focusing on tests and measures and selection of interventions; and d) measuring outcomes.

Patient/Client Management Model

The model of patient/client management presented in Guide 3.0 is designed to maximize outcomes through a systematic and comprehensive approach to decision making. The model includes six elements: examination, evaluation, diagnosis, prognosis, intervention, and outcomes. The elements are used to organize content throughout the text.

Examination

The physical therapist is required to perform an examination before providing any intervention. The examination consists of the history, systems review, and selected tests and measures. The history is an account of the child's past and current health status, which is obtained through an interview with the child and caregivers and review of medical and educational records. As part of the history, the physical therapist identifies child and family expectations and desired outcomes of physical therapy. A useful means for documenting and quantifying family expectations is the Canadian Occupational Performance Measure.[36] The physical therapist then considers whether these expectations and outcomes are realistic in the context of examination and evaluation data.

The systems review is a brief screening that is intended to help focus the subsequent examination and identify possible health problems that require consultation with or referral to another health care provider. A thorough systems review is critical for managing clients who have direct access to physical therapy services. After analyzing information from the history and systems review, the physical therapist examines the child more closely, selecting tests and measures to obtain sufficient data to make an evaluation, establish a diagnosis and a prognosis, and select appropriate interventions.

Evaluation

Evaluation is a process in which the physical therapist makes judgments about the status of the child based on the information gathered from the examination. Evaluation refers to the process by which the results of the examination are analyzed and interpreted in order to determine a diagnosis within the scope of physical therapist practice; the prognosis, including goals for physical therapy management; and a plan of care. The evaluation process includes judgment of the relationships among impairments in body functions and structures, activity limitations, participation restrictions, and the influence of environmental and personal factors. We encourage therapists to consider child, family, and community strengths as part of the evaluation process. Strength-based and ability-focused interventions build on the strengths and resources of the youth, family, and community.[44]

Diagnosis

The definition of diagnosis as it pertains to physical therapist practice is evolving. Guide 3.0 states: "Physical therapists use labels that identify the impact of a condition on function at the level of the system (especially the movement system) and at the level of the whole person. Physical therapists use a systematic process (sometimes referred to as differential diagnosis) to classify an individual into a diagnostic category."[2] The aim is to identify the capacity of an individual to achieve the desired level of function (achieve goals) and whether this can be accomplished by physical therapy. Physical therapists, therefore, may need to obtain additional information (including diagnostic labels) from physicians and other professionals.

Prognosis

Perhaps the greatest challenge to patient/client management is determination of the likelihood that an individual child or youth will achieve the desired goals of intervention. Prognosis refers to the predicted optimal level of improvement in function and the amount of service needed to reach that level (frequency and duration of intervention). A trend in managed health care is to use periodic and episodic intervals of therapy services based on specific functional problems. This approach is a marked departure for children with developmental disabilities for whom ongoing services have traditionally been reimbursed based on medical diagnosis.

If the examination and evaluation support the need for physical therapy, the therapist's next important decision is the plan of care. What interventions should be implemented, how often, and for how long? Presently, research evidence to guide decisions on amount of service is limited. Outcomes are the changes that are anticipated as a result of implementing the plan of care. Expected outcomes should be measurable and time limited. Outcomes of therapy include changes in health, wellness, and physical fitness, emerging areas of pediatric practice.

Intervention

Intervention is the purposeful and skilled interaction of the physical therapist with the patient/client and, when appropriate, with other individuals involved in patient/client care. Various physical therapy procedures and techniques are used during intervention to enable the child and family to achieve goals and outcomes that are consistent with the child's diagnosis and prognosis. Physical therapy intervention has three components: (1) coordination, communication, and documentation; (2) patient/client instruction; and (3) procedural interventions.

Coordination, communication, and documentation. These services are provided for all children and their families to ensure appropriate, coordinated, comprehensive, and cost-effective care and efficient integration or reintegration into home, community, and work (job/school/play). Services may include (1) case management, (2) coordination of care with family and other professionals, (3) discharge planning, (4) education plans, (5) case conferences, and (6) documentation of patient/client management. Children with disabilities are managed in a variety of settings, from public schools to private offices or rehabilitation facilities to specialty clinics for orthotics, surgery, and assistive technology. Therapists in each of these settings often express frustration regarding the lack of coordination of services and the paucity of effective and timely information sharing among health professionals, teachers, and families.

Patient/client-related instruction. These services are provided for all families to provide information about the child's current condition, the plan of care, and current or future transition to home, work, or community roles. Methods of instruction include demonstration; modeling; verbal, written, or pictorial instruction; and periodic reexamination and reassessment of the home program. The educational backgrounds, needs, and learning styles of family members must be considered during this process. As part of family-centered services, therapists collaborate with children and families to identify how to incorporate exercise and practice of functional movements in daily activities and routines.

Procedural interventions. In the Guide 3.0, physical therapist interventions are organized into 9 categories:

Patient or client instruction (used with every patient and client)
Airway clearance techniques
Assistive technology
Biophysical agents
Functional training in self-care and domestic, work, community, social, and civic life
Integumentary repair and protection techniques
Manual therapy techniques
Motor function training
Therapeutic exercise

The child's response to intervention is closely monitored, and the intervention plan is revised as appropriate. Throughout the text the authors provide recommendations supported by research and best practices for specific procedural interventions based on children's age and health condition.

Outcomes

Outcomes are the results of implementing the plan of care; they indicate the impact of the intervention on functioning (body functions and structures, activities, and participation). Outcomes are essential to evaluate the effect of physical therapy for individual children and evaluate services and programs within a health care organization or education system. Outcome measurement is addressed in Chapter 2, and recommendations are provided in the chapters on management of children with musculoskeletal, neurologic, and cardiopulmonary conditions.

EVIDENCE-BASED PRACTICE

Evidence-based practice is the standard for pediatric physical therapy. Evidence-based physical therapy practice has been defined as "open and thoughtful clinical decision making about the physical therapy management of a patient/client that integrates the best available evidence with clinical judgment and the patient's/client's preferences and values, and that further considers the larger social context in which physical therapy services are provided, to optimize patient/client outcomes and quality of life."[26] This open and thoughtful clinical decision-making paradigm implies a defensible, transparent, and reflective process and requires that practitioners know about and are capable of effectively sharing the best available evidence with patients/clients and caregivers.

Pediatric physical therapists engage in lifelong learning and professional development as ways to know about current best evidence and therefore are faced with an almost constant need to acquire and integrate knowledge. There are a number of challenges and barriers that may impact these processes, including significant time constraints, lack of awareness of the evidence, limited confidence in interpreting and applying research results, disagreement with practice guideline recommendations, and the presence of economic, administrative, and interprofessional constraints.[11,38,41,48] In addition, entrenchment of existing practice behaviors or habits may also limit practice change despite the presence of new knowledge.[16,43,47]

Background and Foreground Information

An essential first step in efficiently acquiring new knowledge occurs during and after interaction with the child and family. Questions naturally arise regarding the best course of action to address problems and concerns. Questions may also arise related to the child's health condition or age group. One way to organize these questions and to guide subsequent searching strategies is to determine whether there is a need for background or foreground information. *Background information* is

most often related to a specific diagnostic condition and may include pathology and pathophysiology, etiology, prognosis and natural evolution of the condition, and medical and pharmacologic management. Background information may also include human anatomy, physiology, kinesiology, and neurology. Efforts to gather background information reflect a desire to understand the nature of a patient's/client's health condition, problem, or need. Novices and those lacking experience and expertise with a specific condition are more likely to gather this type of information, but it can also be useful for more experienced practitioners interested in ensuring that knowledge and understanding are up to date.[26,18]

A number of different types of resources may be used to search for and acquire background information. These include consulting with peers or practice leaders, continuing education courses, textbooks, web-based resources, and informal and formal in-services and practice/workshop sessions with colleagues and peers.[50] Research articles often contain information relevant to background questions in their introductory paragraphs.[26] Government agencies, professional societies, and national patient advocacy groups often vet this type of information and publish it for clinicians and consumers in written and electronic formats.[26] In an effort to enhance the organizational structure and to support efficient knowledge gathering for the reader, the chapters in *Physical Therapy for Children* that focus on a health condition are organized by "Background Information" and "Foreground Information." Each background information section includes pathology and pathophysiology, etiology, prognosis and natural evolution, and medical and pharmacologic management, in addition to any other relevant background information pertaining to specific pediatric health conditions.

Practitioners are likely to seek out *foreground information* on a frequent basis. This is due to the ongoing need to acquire new knowledge about the physical therapy management of children who present with specific movement challenges or diagnoses. Foreground information can aid practitioners in identifying, selecting, implementing, and interpreting the most appropriate diagnostic and prognostic tests and measures. In addition, continually building foreground information ensures that practitioners are aware of the most effective intervention strategies and procedures and can therefore collaborate optimally with caregivers and patients/clients to identify the most appropriate intervention for an individual child. Gathering this type of knowledge may be more helpful for practitioners after having acquired background knowledge about a specific health condition.[18,26] In this text, each Foreground Information section includes evidence-based recommendations on physical therapy examination strategies, optimal tests and measures for diagnosis and prognosis, and on physical therapy intervention planning including procedural interventions, coordination and communication, and patient/client/caregiver instruction. Where appropriate, both the Background and Foreground Information will address the implications of life span changes as infants and children grow up and become adolescents and adults.

Declarative and Procedural Knowledge

An interrelated way to organize clinical questions and knowledge gathering is to determine whether there is a need for additional declarative knowledge or procedural knowledge. *Declarative knowledge* can be thought of as "knowing what." The ability to name the bones in the wrist, describe the typical characteristics of an adolescent with Down syndrome, and explain the process of serial casting to a student or novice physical therapist are examples of declarative knowledge. A second type of knowledge is *procedural knowledge,* which involves knowing how and knowing when to apply various procedures, methods, theories, styles, or approaches. For pediatric physical therapists, this might include implementation of standardized testing procedures, modulation of amount of assistance during gait training, and strategies to motivate a child to complete a challenging task.[1] It is common for students and novices to know facts and concepts but not now how or when to apply them. In contrast, practitioners may also be able to perform procedural tasks without being able to articulate a clear understanding of what they are doing and why.[1]

Evidence-Based Resources for Acquiring Knowledge

As noted previously, thoughtful reflection on practice often leads to identification of clinical questions. If the question necessitates obtaining foreground information, an important next step to aid in focusing the search process is to configure the clinical problem into a PICO format, which involves four elements: P = patient, I = intervention, C = comparison intervention, and O = outcome. Examples of PICO questions (or PIO questions, where only one intervention is being investigated) are included in Box 1.2.

Once the question has been refined, the 6S model is a means to enhance efficient knowledge gathering to address the question (Fig. 1.3).[8] This model reflects the evolution over the past decade toward creation and use of "preappraised" resources that facilitate ready access to high-quality research. Preappraised resources can increase the efficiency of searching for and analyzing research evidence because they have undergone a filtering process to include only those studies that are of higher quality. In addition, ideally the resources are updated regularly, which ensures that the evidence is current.[8] The 6S model can aid in gathering background information about a health condition. For foreground information, decision makers should use a PICO question to search for evidence starting at the highest level of the pyramid, and therefore the most synthesized form of evidence, as opposed to beginning the search at the bottom of the pyramid, representing the least synthesized form of evidence. It becomes necessary to move to lower levels in the pyramid only when no evidence exists at a higher level.[42]

At the top of the pyramid are *Computerized Decision Support Systems* that match information from specific clients

BOX 1.2 Examples of Clinical Questions Written Using the PICO Format

For (P) children with developmental coordination disorder, is (I) cognitive motor learning more effective than (C) sensory integration in improving (O) motor function?

For children (P) with hemiplegia, is (I) bimanual coordination therapy more effective than (C) constraint-induced movement therapy in improving (O) arm and hand motor function?

For (P) infants with torticollis, what (I) physical therapy interventions improve (O) head and neck alignment and range of motion?

For (P) children with Duchenne muscular dystrophy, is (I) resistive exercise effective in (O) maintaining the ability to walk?

For (P) parents of infants born preterm, does (I) support, education, and instruction in the neonatal intensive care nursery improve (O) confidence and skill in handling and caring for their infants upon discharge to home?

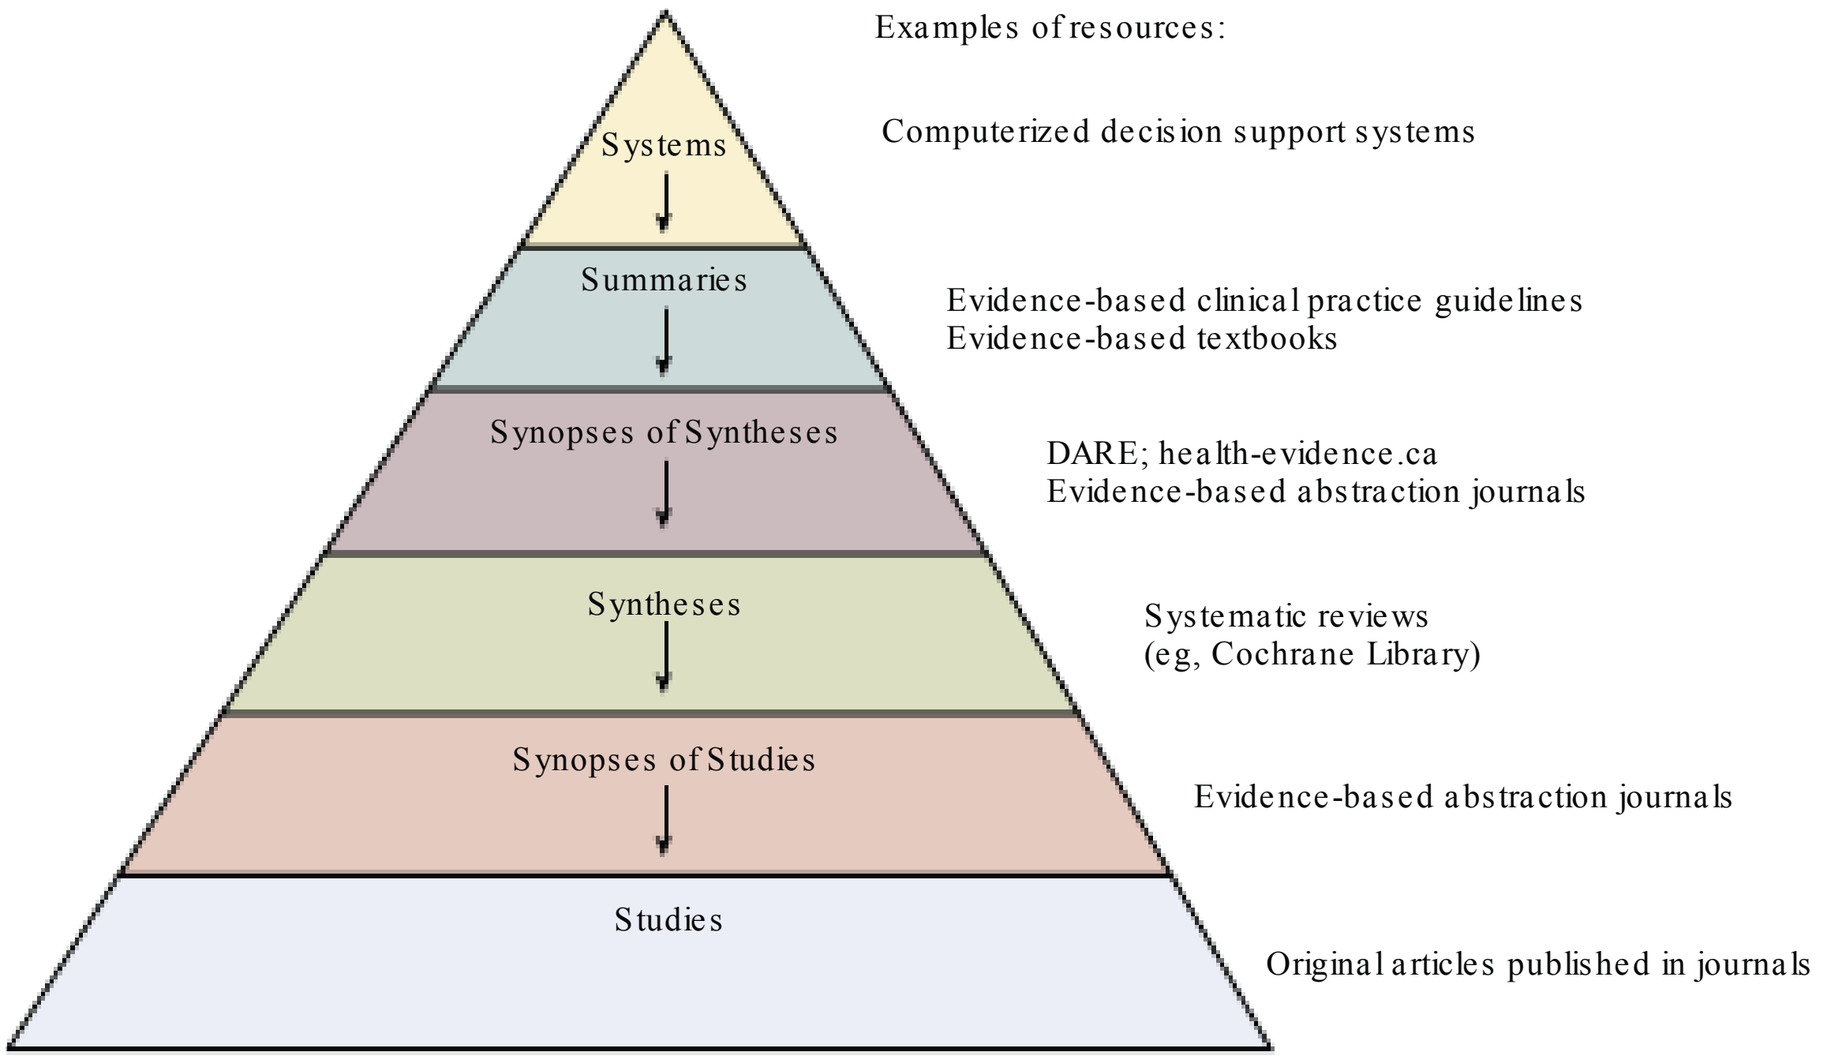

FIG. 1.3 6S hierarchy of preappraised evidence. (From DiCenso A, Bayley L, Haynes RB: Accessing pre-appraised evidence: fine-tuning the 5S model into a 6S model. Evid Based Nurs 12(4): 99-101, 2009.)

(individuals, groups, or populations) with the best available evidence that applies. These systems provide suggestions to the clinician for management of the specific patient.[8] Ideally the decision support is provided automatically as part of daily work flow, at the time and location of decision making, and with specific actionable recommendations. Systems represent the ideal resource for evidence-informed decision making because they contain all the research evidence about a specific client or population circumstance, linked to individual client records and to a synopsis of the existing relevant research literature with direct links to the original studies and/or reviews.[42] Although there are efforts currently under way to develop systems level data, it is not expected that these will be readily available in the near future.[42]

The next level of the 6S pyramid is *Summaries,* which integrate the best available evidence from the lower levels (drawing on syntheses [e.g., systematic reviews] as much as possible) to provide a full range of evidence concerning management options for a given health condition.[22] Examples include evidence-informed clinical practice guidelines (CPGs) and electronic textbooks, which can easily be made universally available (e.g., via the Internet), and are more feasible to keep up to date and provide some level of passive decision support. A well-known source for evidence-informed clinical practice guidelines is the National Guidelines Clearinghouse (NGC) (http://guideline.gov). The NGC, an initiative of the Agency for Healthcare Research and Quality (AHRQ), is a repository of clinical practice guidelines. The APTA, in collaboration with a number of sections including the Section on Pediatrics (SOP), also actively supports the development of clinical practice guidelines in order to reduce unwarranted variation in care. An example is a CPG for congenital muscular torticollis published in *Pediatric Physical Therapy* in 2013[28] and also available through the NGC website.

Practitioners accessing CPGs and other summary documents should ensure that they meet the following criteria[15]:

- Based on a systematic review of the existing evidence
- Developed by a knowledgeable, multidisciplinary panel of experts and representatives from key affected groups
- Considers important patient subgroups and patient preferences, as appropriate
- Based on an explicit and transparent process that minimizes distortions, biases, and conflicts of interest
- Provides a clear explanation of the logical relationships between alternative care options and health outcomes and provides ratings of both the quality of evidence and the strength of the recommendations
- Reconsidered and revised as appropriate when important new evidence warrants modifications of recommendations

An additional resource for appraisal of clinical practice guidelines is the Appraisal of Guidelines for Research and Evaluation (AGREE II) collaboration. This collaboration includes members from Denmark, Finland, France, Germany, Italy, the Netherlands, Spain, Switzerland, the United Kingdom, Canada, New Zealand, and the United States. AGREE II is a reliable and valid instrument to assess clinical practice guidelines developed by local, regional, national, or international groups and government organizations and can be used by physical therapists deciding whether to implement recommendations in a practice guideline or pathway. The instrument provides guiding questions and a response scale to assess the scope and purpose of a guideline, the people involved in development, rigor of development, clarity and presentation of recommendations, applicability, and editorial independence. The instrument and training manual are available on the AGREE website (http://www.agreetrust.org).

The next level on the 6S pyramid is *Synopses of Syntheses,* which are defined as succinct descriptions of systematic reviews

or meta-analyses that aim to provide the right amount of evidence (not too much nor too little) to inform an intervention.[22] Ideally, these synopses describe the research question, the study groups, the outcomes, and the measure of effect or other results of a body of evidence. These summaries often discuss the methodologic quality of the synthesis and the relevance of the findings to health practice, program development, and policies. Given that many busy clinicians do not have the time to review detailed systematic reviews, a synopsis that summarizes the findings of a high-quality systematic review can often provide sufficient information to support clinical action. One example is the Database of Abstracts of Reviews of Effectiveness (DARE) of the Centre for Review Dissemination (CRD) at the National Institute for Health Research in the United Kingdom. DARE assists decision makers by systematically identifying and describing systematic reviews, appraising their quality, and highlighting their relative strengths and weaknesses.[42]

At the next level, *Syntheses* are synonymous with systematic reviews and meta-analyses and are found in peer-reviewed journals. Syntheses combine, using explicit and rigorous methods, the results of multiple single studies to provide a single set of findings.[22,42] The Cochrane Library (www.thecochranelibrary.com/) houses syntheses about the effectiveness of health care interventions and some diagnostic tests and also includes the DARE database of systematic reviews.[8]

In a well-conducted systematic review, all relevant research is analyzed in an effort to determine the overall evidence. The process involves: (1) a focused clinical question, (2) identification of criteria for inclusion of a study in the review, (3) a comprehensive literature search, (4) appraisal of the internal validity (methodologic quality) of each study included in the review, (5) a description of how results were analyzed, and (6) interpretation of findings in a manner that enhances application to clinical practice.[10] Just as in a research report, therapists must critique a systematic review. A systematic review is only as good as the quality of each study included. Meta-analysis is a mathematical synthesis of the results of two or more research reports. A meta-analysis can be performed on studies that used reliable and valid measures and report some type of inferential statistic (e.g., t-test, analysis of variance). Effect size, odds ratio, and the weighted mean difference are examples of statistics used for meta-analysis.

Effect size is the mean difference of the outcomes of interest between subjects in experimental and comparison/control groups. The most basic measure of effect size is the *d-index*. The d-index is the mean difference between groups divided by the common standard deviation. Cohen[5] provided the following guidelines for interpretation of the d-index: d = 0.2 represents a small effect, d = 0.5 represents a medium effect, and d = 0.8 represents a large effect. Fig. 1.4 and Table 1.1 present the overlap of scores between subjects in the experimental and control group for selected effect sizes. The overlap in distribution of scores has important implications for clinical decision making. A finding that the mean score on the outcome measured was significantly higher for subjects in the experimental group does not indicate that all subjects or even most subjects in the experimental group had better outcomes than subjects in the comparison/control group. As illustrated in Table 1.1, even for a large effect size (0.80), there is a 53% overlap in scores of subjects in the experimental and control groups. Consequently, when applying the evidence to clinical decisions for an individual child, the therapist would not be certain of that child's outcome.

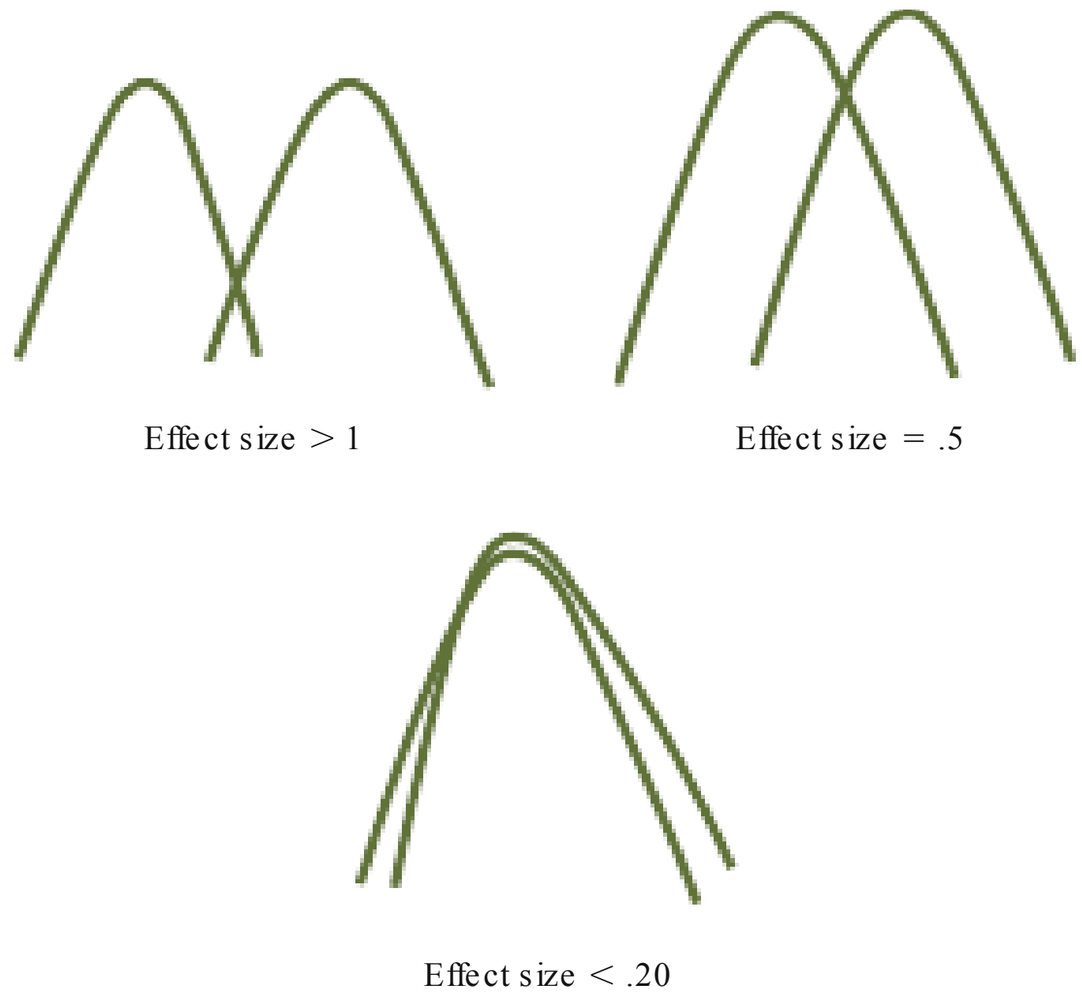

FIG. 1.4 Distribution of scores of subjects in the experimental and control groups for small-, medium-, and large-effect sizes (illustrations not drawn to scale).

TABLE 1.1 Interpretation of Effect Size Based on Cohen's Criteria[5]

Effect Size	Interpretation	Overlap of Scores[a]
0.00	No effect	100%
0.20	Small	85%
0.50	Medium	67%
0.80	Large	53%
1.70		25%

[a]Overlap in individual scores of subjects in the experimental and control groups.

The *Forest Plot Diagram* is used to graphically present the results of a systematic review. Results may be presented as an effect size, weighted mean difference, or odds ratio; however, interpretation is the same. Fig. 1.5 illustrates a Forest Plot Diagram for a meta-analysis of four randomized controlled trials. The odds ratio is used to present the results of each study and the meta-analysis. The odds ratio is presented on a scale of 0.10 to 10.0; 1.00 is the line of no effect. Each study is represented on the graph by a horizontal line. The vertical mark in the middle of the line is the odds ratio, and the diamonds at the far left and right indicate the boundaries of the 95% confidence interval. If a horizontal line crosses the line of no effect, the odds ratio is not significantly greater than 1 ($P > 0.05$). When the horizontal line is to the right of the line of no effect, the odds ratio is significantly greater than 1 ($P > 0.05$). In Fig. 1.5 the odds ratio for only one study is significantly greater than 1 (top study). The horizontal lines for the remaining three studies cross the line of no effect, indicating the odds ratio is not significantly greater than 1. The thicker horizontal line at the bottom is the overall odds ratio for the four studies. The overall odds ratio is 0.90 ($P > 0.05$), indicating that subjects who received the experimental intervention were not more likely to improve compared to subjects who did not receive the experimental intervention (control group). Miser[34] suggested that

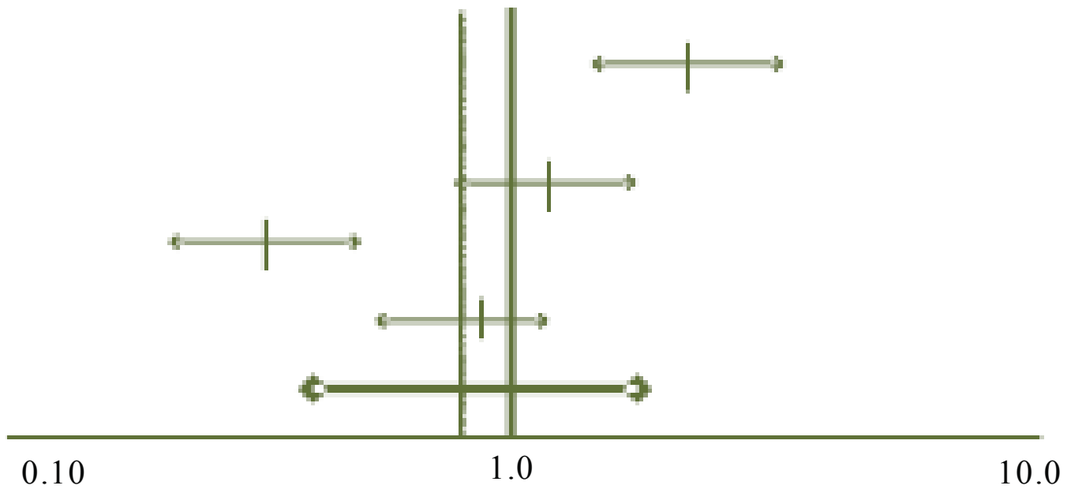

FIG. 1.5 Graph of meta-analysis using the odds ratio.

an odds ratio of 2.0 or greater represents a strong intervention effect. An odds ratio of 2.0 indicates that subjects who received the intervention are two times more likely to have improved on the outcomes measured compared with subjects who did not receive the intervention.

Educators and researchers have responded to the need for systematic reviews and meta-analyses of research on children with developmental conditions. Simple Medline searches in which "cerebral palsy" and "developmental coordination disorder" were each combined with "systematic review" identified 14 systematic reviews of research on children with cerebral palsy and 5 reviews of research on children with developmental coordination disorder published between 2010 and 2015 judged to have application to pediatric physical therapy practice. In most databases, searches can be limited to systematic reviews. This is a good strategy for determining whether a systematic review has been published on the clinical question of interest.

An intermediate level on the 6S pyramid is the *Synopses of Studies*. The synopsis of a single study provides a brief, but often sufficiently detailed, summary of a high-quality study that can inform clinical practice.[8] These synopses will also often include a brief commentary about the clinical applicability of the results of the study. Some relevant resources to obtain these synopses include *Rehab+*, which is a part of McMaster University's evidence-based practice initiative and a subset of *Evidence Updates*. *Rehab+* provides selected abstracts from 130 clinical journals. Each registrant to *Rehab+* receives email alerts with links to the article abstract along with the article's relevance and newsworthiness ratings. In addition, both *Physical Therapy* and *Pediatric Physical Therapy* feature a "Bottom Line" commentary that accompanies many of the clinical research articles in those journals. This commentary asks and answers a number of pertinent questions about the research. A final possible resource for clinicians is to create their own synopses by following a systematic appraisal and documentation process. There are a variety of resources available to aid clinicians in working through this process based on the clinical question and the relevant type of research.[18] The critically appraised topic (CAT) is a one- or two-page summary of a research study that includes implications for practice, the "clinical bottom line." The format is intended to facilitate transfer of research to practice.[10]

The foundation of the pyramid, and the final stop in searching for evidence if none exists at higher levels, is *Individual Studies*. The individual study, published in a peer-reviewed journal, is the most common form of evidence available. Electronic databases are the most efficient method for finding individual studies in peer-reviewed journals. Electronic databases provide bibliographic references to thousands of peer-reviewed journals and can be searched from a personal computer via the Internet. In addition to the complete reference, databases provide links to the abstract and, increasingly, the full text of published articles. Many journals provide online access to articles before publication in print. Box 1.3 summarizes several commonly used electronic databases. Tutorials are available on each database to aid in conducting efficient and successful searches. Typically, the PICO question provides keywords and phrases that guide the initial search. Each keyword can be used individually or in combination and, depending on the database, can be modified in ways that either expand or narrow the focus of the search.

As with higher levels of the 6S pyramid, physical therapists must use critical analysis skills to ascertain the strength and quality of evidence from individual studies and to determine whether that evidence justifies a change in clinical practice. For example, Harris[20] posed several thought-provoking questions for professionals to ask themselves when analyzing the scientific merit of an intervention. A negative response to one or more of these questions is a warning sign that an intervention is not evidence based.

- Is the theory on which the intervention is based consistent with current knowledge?
- Is the population for whom the intervention is intended identified?
- Are the goals and outcomes of intervention consistent with the needs of the intended population?
- Are potential adverse effects of the intervention identified?
- Is the overall evidence critiqued?
- Are advocates of the intervention open to discussing its limitations?

If these criteria are satisfied, there are a number of strategies to further assess the strength and quality of any evidence.

APPRAISAL OF RESEARCH FROM INDIVIDUAL STUDIES

The paramount questions for applying research evidence from individual studies are whether findings generalize to children who were not in the study and are applicable to the particular child for whom the intervention is a consideration. These are complex issues. To assist practitioners in decision making, systems have been developed to rate the strength of research evidence, methodologic quality (how well the study was conducted), and grade of recommendation.

Strength of Evidence

The levels of evidence framework proposed by Sackett, refined by the Centre for Evidence-Based Medicine (CEBM) at the University of Oxford in 2009 (http://www.cebm.net) and revised in 2011 (Oxford Levels of Evidence 2; http://www.cebm.net), are often used to report the strength of evidence of research on prognosis, diagnosis, differential diagnosis/symptom prevalence, intervention, and economic and decision analyses.[46] Using the CEBM Levels of Evidence (2009) to rate the strength of evidence for therapy interventions, a systematic review of randomized controlled trials (RCTs) provides the strongest evidence (1a), whereas a single RCT of high quality provides 1b evidence. The strength of evidence for studies using observational designs (also referred to as nonexperimental designs) is rated as level 2 or 3. Level 4 evidence is associated with case series (multiple case reports) and poor-quality observational designs. Level 5 evidence is based on expert opinion, general scientific knowledge, or basic science research.

The randomized controlled trial is an experimental design that provides evidence of efficacy (results of interventions provided under randomized and controlled conditions). The feature that distinguishes the RCT from observational designs is random group assignment; subjects have an equal chance of being in the experimental or comparison/control group. In theory, random group assignment controls for variables not measured that may influence intervention outcomes. The RCT therefore provides the strongest evidence of a cause-effect relationship between the experimental intervention (independent variable) and the outcome (dependent variable). Another distinguishing feature of the RCT is that inclusion criteria are usually restrictive in an effort to obtain a sample without characteristics such as co-morbid health conditions that might adversely influence the outcomes. The parameters of the intervention are also specified by the researchers, and the intervention is intended to be provided in the same manner to all subjects.

Although the RCT provides the strongest evidence of a cause-effect relationship between the intervention and outcomes, trials are costly and challenging to implement with children with developmental disabilities. To adhere to the rigor of an experimental design, the intervention is often provided under conditions that are not representative of many practice settings. Consequently, when attempting to apply the results of an RCT, therapists must consider whether subject characteristics generalize to children on their caseloads and whether the intervention is feasible within their practice settings. The *pragmatic clinical trial* is intended to meld the advantages of efficacy and effectiveness research. The pragmatic clinical trial is characterized by random group assignment; however, interventions are clinically feasible, subjects are from diverse populations and practice settings, and a wide range of outcomes are measured.[52]

Observational designs provide evidence of effectiveness (interventions provided under conditions more typical of clinical practice). Cohort, case control, and case series are examples of observational designs. Level 2 evidence is associated with cohort designs, sometimes referred to as quasi-experimental designs. Subjects *are not* randomly assigned to the experimental or comparison/control group. Additionally, subject inclusion criteria and the intervention are usually not controlled by the researchers to the same extent as in the RCT. Level 3 evidence is associated with observational designs where there is no control group or the intervention is not specified by the researchers or both. A *practical clinical trial* refers to a prospective, cohort study designed to analyze variability among patients and interventions on the outcomes of interest.[13]

Clinical practice improvement (CPI) methodology is a type of observational research that is intended to identify specific intervention strategies and procedures that are associated with outcomes and determinants of outcomes.[23] Horn contends that the RCT is designed to investigate a single procedural intervention as opposed to the combination of strategies and procedures that constitutes a typical physical therapy intervention. In clinical practice improvement, standardized forms are created to document intervention strategies and procedures and time spent on each activity. Data are also collected on variables that potentially influence outcomes. Variables might include child characteristics (age, severity of condition, interests, cognition, and communication), family characteristics (family dynamics, interests, resources, supports), and features of the physical, social, and attitudinal environment. Multivariate statistical analyses are used to identify among all of the interventions documented those that are associated with favorable outcomes and child, family, and environment variables that are determinants of outcomes. This type of information is appealing to physical therapists because it informs the decision-making process. Although clinical practice improvement is feasible to implement in practice settings, multivariate analyses require large numbers of subjects.

The CEBM Levels of Evidence 2 differ from the original framework in the definition of levels 1 and 2, removal of subcategories (i.e., 1a, 1b), less technical wording, and the acknowledgement that a "lower level" study with a "dramatic effect" can provide stronger evidence than a "higher level" study. Inclusion of *n*-of-1 trials as level 1 evidence is a marked change from the original framework, which did not address single-subject research designs. The *n*-of-1 trial is similar to the single-subject design; each subject serves as his or her own control. Descriptions of how to conduct *n*-of-1 trials are generally more rigorous that is typical of single-subject designs published in pediatric physical therapy and potentially less feasible to implement in clinical practice.[29]

In the *single-subject design,* outcomes are measured repeatedly during baseline, intervention, and follow-up phases. Within-subject variability between phases is analyzed. This is in contrast to the group design, where between-subject variability is analyzed. The single-subject design is experimental; therefore results can provide evidence of a cause-effect relationship for the subject. Findings, however, should not be generalized to other children. Replication of single-subject designs across subjects and practice settings provides initial evidence of generalizability. Generalization of findings from *n*-of-1 trials is not addressed in Levels of Evidence 2.

Qualitative and Mixed Methods Research

Qualitative and mixed methods of inquiry have been used in nursing and occupational therapy and increasingly more often in physical therapy.[19] Qualitative research is well suited for understanding processes associated with effective communication, coordination, and documentation and child-and family-related instruction, two components of physical therapist interventions. The experiences and values of consumers (e.g., children and families), practitioners, and administrators are integral components of health services research that are too often missing in clinical research. Qualitative research is not addressed in the CEBM Levels of Evidence.

Phenomenology and grounded theory are two qualitative approaches that are frequently used in health care research. Both are concerned with understanding the lived experiences of the population of interest. Themes or theory emerge from analysis of data that are grounded in the social world of the people being studied. This is in contrast to experimental and quantitative research that is based on the researcher's preconceived hypothesis. Participatory action research is a qualitative approach that involves collaboration of consumers, practitioners, and researchers to address specific questions or issues. Children, families, and practitioners are participants or co-researchers who provide input about the questions or issues to address, feasibility of proposed practices, and dissemination of information in usable formats. The preferences and values of consumers and practitioners therefore are incorporated into the design and implementation of research. Schreiber et al.[48] used participatory action research to collaborate with pediatric physical therapists to identify strategies for implementation of evidence-based practice.

Qualitative methods are distinct from those used in experimental research, especially with respect to sample size. Data collection typically involves interviews and focus groups that are recorded and transcribed verbatim. Interviews include neutrally worded, open-ended questions followed by prompts and follow-up questions to encourage participant reflection. Other methods of data collection include observation and examination of artifacts such as medical records and clinical documentation. Data analysis is an iterative process. Procedures to ensure credibility and trustworthiness are used to ensure the themes or therapy that emerges represents the perspectives and lived experiences of study participants. The textbook by Creswell[7] provides a more extensive understanding of qualitative research.

Mixed methods designs, which incorporate both quantitative and qualitative methods, are increasingly being used in rehabilitation research.[39] Depending on a study's aims, the qualitative dimension may proceed or follow the quantitative phase. In outcomes research, qualitative interviews following the intervention are useful in understanding how children, parents, and therapists experienced the intervention and whether the intervention was feasible and acceptable.

Finally, although not a research design per se, the *case report* is a valuable means of communicating practice knowledge including in-depth description of a new, interesting, or unique case and implications for clinical decision making. A case report may also describe innovative approaches to coordination of services, methods of service delivery, and issues germane to a practice setting. McEwen[33] has published an excellent manual for clinicians on how to write case reports.

Methodologic Quality in Individual Research Studies

Methodologic quality is not a primary consideration in systems for rating strength of research evidence in the system developed by the CEBM. Controversy exists as to whether the strength of evidence is greater for a cohort design of high methodologic quality compared with a RCT of poor methodologic quality. The Physiotherapy Evidence Database (PEDro) scale (http://www.pedro.org.au/) is widely used to evaluate the methodologic quality of RCTs. Ten criteria on internal validity (e.g., random allocation to groups, whether subjects, therapists, and assessors were masked to group assignment) and interpretation of results (e.g., between group statistical comparisons, intention to treat analysis) are rated "Yes" or "No." A Pedro scale score of ≥ 5 or ≥ 6 has been proposed as adequate methodologic quality.[35] Maher et al.[31] reported that the reliability of the PEDro scale varied from "fair" to "substantial" for each criterion and "fair" to "good" for the total score. Macedo et al.[30] found evidence of content and construct validity for 8 of the 10 criteria. The exceptions were "blinding of all therapists" and "blinding of all assessors." Authors are strongly encouraged to report the methodologic quality of each study included in a systematic review and exclude studies with poor methodologic quality. The CONSORT (http://www.consort-statement.org/) and STROBE (http://www.strobe-statement.org/) statements were developed to improve reporting of the results of RCT and observational research respectively. Many peer-reviewed journals require authors to complete the respective checklist when submitting a manuscript to ensure that methodologic strengths and limitations of the study are addressed. Intention to treat analysis is a criterion for rating methodologic quality that has important implications for interpretation of results. Subjects who are enrolled in a clinical trial but do not complete the intervention are included in statistical analysis (potentially reducing the effect size). Not including all subjects in the statistical analysis introduces bias if subjects' reasons for not completing the study are related to group assignment or perceived lack of benefit or progress, compromising the intent of randomized group assignment.

GRADES OF RECOMMENDATIONS

Once new knowledge has been acquired, the GRADE system (Grading of Recommendations Assessment, Development, and Evaluation) is a tool to aid practitioners in determining whether practice change is warranted.[17] An important advantage to this system is that it includes explicit, comprehensive criteria for downgrading and upgrading quality-of-evidence ratings. To achieve transparency and simplicity, the GRADE system classifies the quality of evidence in one of four levels—high, moderate, low, and very low. High-quality evidence indicates that further research is very unlikely to change confidence in the estimate of effect, whereas with low-quality evidence, further research is very likely to have an important impact on confidence in the estimate of the effect and is likely to change the estimate. Evidence from randomized controlled trials may begin as high-quality evidence, but confidence in the evidence may be decreased for several reasons, including study limitations, inconsistency of results, indirectness of evidence, imprecision, and reporting bias. Observational studies start with a low-quality rating, but grading upwards may be warranted if the magnitude of the treatment effect is very large or if there is evidence of a dose-response relation.[17]

An additional important aspect of the GRADE system is that it incorporates a clear separation between quality of evidence and strength of recommendations. Two grades for strength of recommendation are possible: *Strong* and *Weak*. When the desirable effects of an intervention supported by high-quality evidence clearly outweigh the undesirable effects, or clearly do not, this leads to a strong recommendation. On the other hand, when the trade-offs are less certain—either because of low-quality evidence or because evidence suggests that desirable and undesirable effects are closely balanced—weak recommendations are provided. Other factors affecting the strength of recommendation include uncertainty in patient values and preferences and uncertainty about whether the intervention

represents a wise use of resources.[17] In the GRADE system a "strong recommendation" implies that all or almost all informed people would make the recommended choice for or against the intervention (*Do it* or *Don't do it*); a "weak recommendation" implies that most informed people would choose the recommended course of action but a substantial number would not (*Probably do it* or *Probably don't do it*)[3]

Novak[37] proposed an *Evidence Alert Traffic Light Grading System* for recommendations on physical therapy and occupational therapy interventions. Based on the amount and quality of evidence, one of three recommendations is made: *Green GO:* High-quality evidence; use this approach. *Yellow MEASURE:* Low-quality or conflicting evidence; measure outcomes carefully to ensure the goal is met. *Red STOP:* High-quality evidence that intervention is ineffective; do not use this approach.[37]

KNOWLEDGE TRANSLATION

If a specific aspect of pediatric physical therapy practice is worthy of a strong recommendation based on the GRADE system, all pediatric physical therapists should strive to integrate this into an evidence-informed decision-making process. In contrast, if there is a strong recommendation to *not* use a specific intervention, this should also be integrated into the evidence-informed decision-making process. If either of these scenarios requires a substantial change from standard practice, either at the individual level or within a group of clinician colleagues, implementing this change is likely to be challenging.

The concept of *knowledge translation (KT)* has recently emerged as a strategy to address this challenge. Knowledge translation is defined as a dynamic and iterative process that includes synthesis, dissemination, exchange, and ethically sound application of knowledge to improve health, provide more effective health services and products, and strengthen the health care system.[40] Graham et al.[14] developed a schematic representation of the knowledge-to-action process (Fig. 1.6). The funnel symbolizes knowledge creation, and the cycle represents the activities and process related to application of knowledge (action).[14] As such, the activities and process cycle is likely to be of more direct relevance to practitioners and others who are attempting to change their own practice behaviors or those of professional colleagues. In an effort to illustrate how this action cycle may be implemented, Table 1.2 presents each phase along with the relevant activities of a recent KT project implemented in a pediatric outpatient facility.[49] The outcomes of this project demonstrated that a comprehensive approach to KT can be effective at supporting behavior change in pediatric physical therapists practicing in an outpatient setting.[49]

EVIDENCE-INFORMED CLINICAL DECISION MAKING

Ultimately, a clinical decision for an individual child and family is guided by a model of evidence-informed decision making.[21] This model, adapted from Haynes et al.[21] and modified for pediatric physical therapy, is presented in Fig. 1.7. Although *evidence-based practice* is a more common term (and is used in the title of this chapter), opinion varies on what constitutes evidence. Initially evidence referred to research. Thus the term *evidence-informed* is used in the model presented in Fig. 1.7 and applied throughout the book to emphasize that factors in addition to research inform decision making. Each of the overarching decision-making frameworks previously described in this chapter contributes to the optimal application of this model. When a clinical question arises, the process must include identification of the child's and family's strengths and needs. This involves systematic data collection at the impairment, activity, and participation levels along with identification of key personal and environmental factors. This data collection may occur during the history, systems review, or tests and measures sections of the physical therapy examination or during the ongoing evaluation of outcomes during intervention within patient/

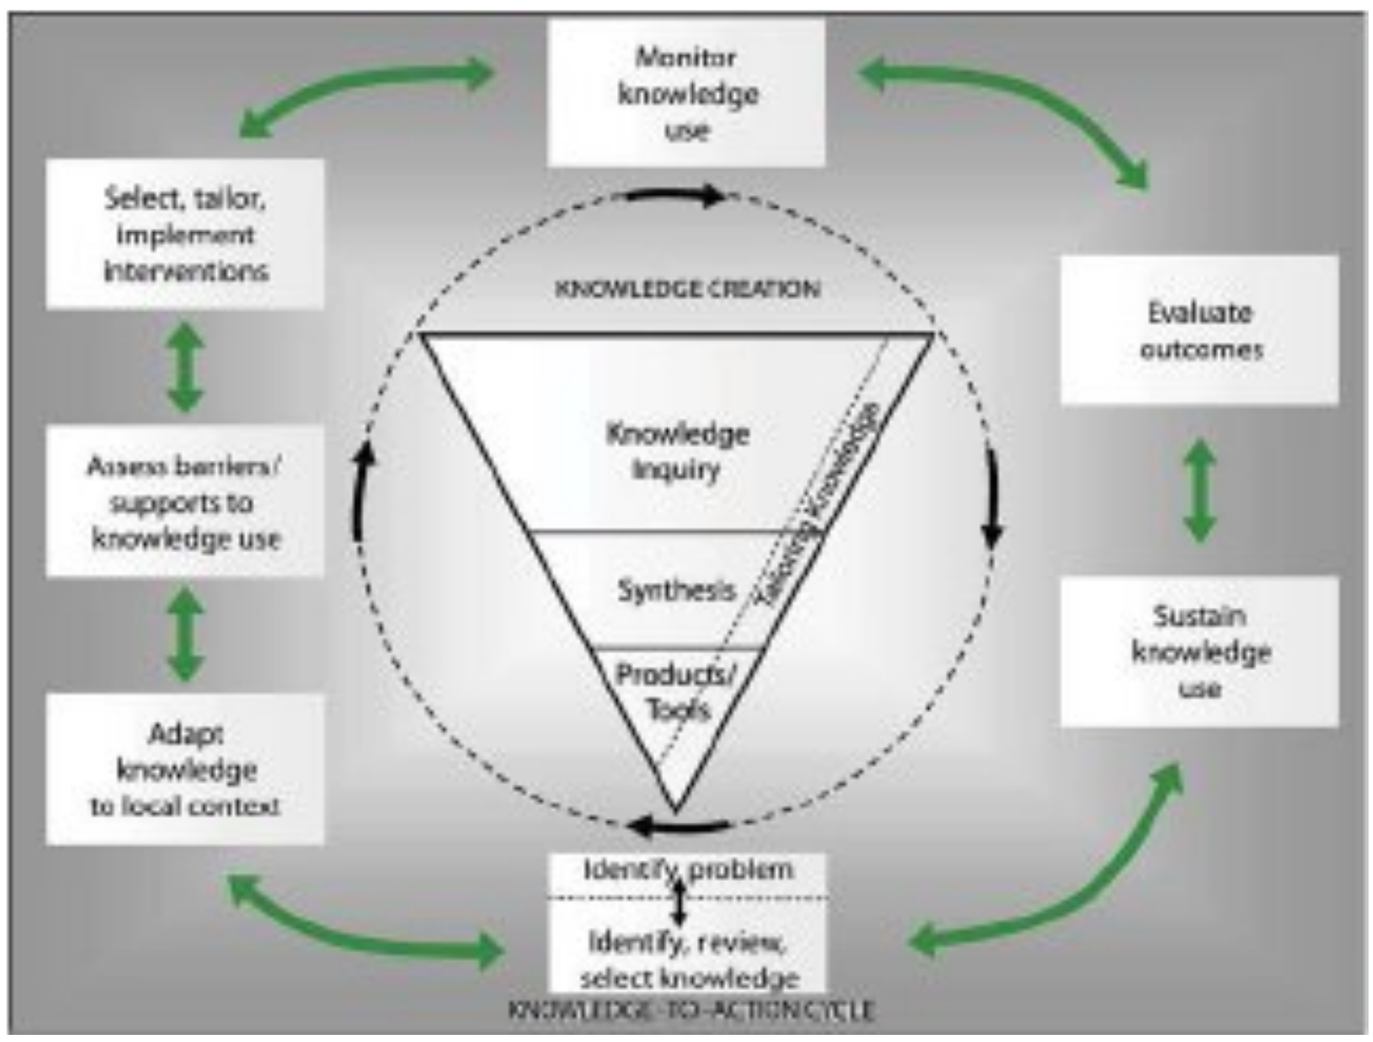

FIG. 1.6 Knowledge-to-action process. (Redrawn from Graham I, Logan J, Harrison MB, et al.: Lost in Knowledge Translation: Time for a Map? J Contin Educ Health Prof 26(1):13-24, 2006.)

TABLE 1.2 Knowledge Translation Example

Knowledge-to-Action Cycle Phase	Project Implementation[49]
Identify problem: Group or individual identifying a problem or issue that deserves attention or a group or individual becomes aware of knowledge, and then determines whether there is a knowledge-to-practice gap that needs filling with the identified knowledge	Key stakeholders identified inconsistent clinical decision making among staff physical therapists related to frequency and duration of outpatient physical therapy services as a significant clinical problem and that improved selection, administration, interpretation, and sharing of results of pediatric outcome measures was critical to addressing that problem
Identify, review, select knowledge; adapt to local context: A search for knowledge (background) or research (foreground) that might address the problem; this typically will encompass database searches for relevant clinical practice guidelines, systematic reviews, and research articles, appropriate continuing education courses, and reliable web-based resources. Critical appraisal of all evidence then determines validity and usefulness for the identified problem.	Collaboration among senior staff and department administrator to identify appropriate tests/measures for practice setting; database search to ascertain strength of evidence and appropriate use for each outcome measure Note that "adapting to local context" also was incorporated into the intervention stage, where staff members actively practiced with the outcome measures in their workplace and adapted the tests where appropriate to fit within the constraints of each clinic workspace.
Assess barriers to knowledge use so that these may be targeted and hopefully overcome or diminished by intervention strategies; also identify supports or facilitators to address barriers	Lack of knowledge among staff regarding administration and interpretation of key outcome measures; configuration of electronic medical record; access to test/measure materials and equipment; variable space and layout across four separate satellite clinics
Select, tailor, implement interventions based on the identified barriers and audiences; change is more likely to occur with planned and focused interventions	Two-hour workshop led by knowledge broker[45] at each satellite; one-hour follow-up workshop; hard copy and online resource manual (including video demonstrations) with all relevant information about key outcome measures; online discussion board and periodic newsletter updates regarding practice change
Monitor knowledge use to determine how and the extent to which it has diffused among the group; can be used to determine whether interventions have been sufficient or if additional intervention is necessary	Follow-up workshops; mandatory discussion board postings by staff; informal ongoing interaction between knowledge broker, department administrator, and staff; monitoring of data from electronic medical records related to key outcome measures; integration into annual goals for staff
Evaluate outcomes to determine the impact on health and well-being of patients/clients, practitioners, and/or systems	Knowledge assessment related to key outcome measures; a self-report measure of knowledge and performance; electronic medical record review for frequency of test/measure usage before and after the intervention
Sustain knowledge use	Follow-up data collection on outcomes at 10 months post–project implementation date

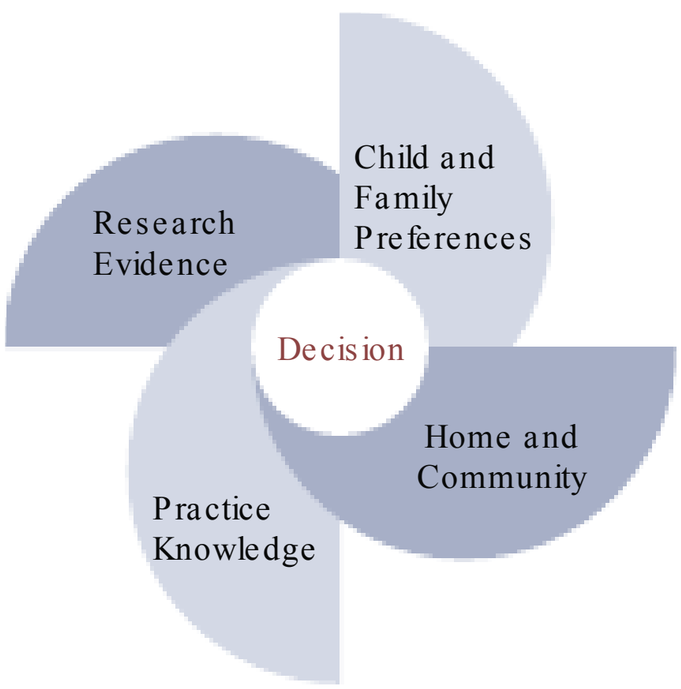

FIG. 1.7 Model of evidence-informed decision making. (Adapted from Haynes RB, Devereaux PJ, Guyatt GH: Clinical expertise in the era of evidence-based medicine and patient choice. Evid Based Med 7(2):36-38, 2002.)

client management. The use of valid and reliable tests and measures is an essential aspect of the data collection process.

The practitioner must also identify any additional background and foreground information that may be necessary to address this clinical question and whether additional declarative and procedural knowledge must be obtained. If foreground information is required, practitioners should use the 6S model and the GRADE system to seek out, gather, and evaluate research evidence in order to develop a clinical recommendation. At that point, sharing the findings from the examination or evaluation of outcomes and offering a GRADE recommendation should incorporate the therapist's practice knowledge and should occur in a way that empowers children and families to integrate their own personal preferences and values to make the best decision at that point in time for that individual child. The statement, "Evidence alone does not make decisions, people do," by Haynes et al.[21] reflects the integral role of the physical therapist in translating and applying research to evidence-informed clinical decisions to achieve optimal participation level outcomes for children and families.

Embedded in the practice knowledge aspect of evidence-informed decision making is clinical reasoning, which has been conceptualized as the process of deciding on the appropriate action for an individual patient at a particular time. Knowledge is viewed as a starting point but not as a strict plan for action. As part of the process of individualizing clinical decisions, the therapist makes judgments and improvises in moving from general practice guidelines to the requirements of a specific situation.[32] Mattingly suggested that judgment and improvisation are often guided by knowledge that is embodied in the therapist's hands or eyes.[32] Part of the therapist's practice knowledge therefore is reflected in implicit thought processes that are translated into habitual ways of observing and interacting with children and families. Pediatric physical therapists are encouraged to strive for better understanding of their thought processes, not only to enhance their own professional development but also to serve their clients and educate physical therapy students more effectively. Understanding how best to integrate child and family strengths and preferences, research evidence, and practice knowledge is essential for the implementation of evidence-based decision making that reflects the broad scope and complexity of

BOX 1.4 Evidence-Informed Decision Making

Clinical Question:

DeMarco is a 5-year-old with a diagnosis of cerebral palsy, level II on the Gross Motor Function Classification System (GMFCS). He has been receiving outpatient physical therapy (2×/week) for the past 2 years. He will be attending kindergarten in the fall. The clinical question is whether DeMarco would benefit from a trial of intensive (5×/week for 4 weeks) outpatient physical therapy this summer in order to maximize his ability to participate in his kindergarten classroom.

Child and Family Strengths, Needs, and Preferences:

Recent re-evaluation data suggest that DeMarco has improved with gross motor function and performance on activity level tasks but that he is well behind age-matched peers in gait velocity and ability to ascend and descend stairs.

DeMarco is willing and able to participate in intensive bouts of activity during weekly physical therapy sessions.

Parents are concerned that DeMarco is becoming isolated from age-matched peers and are strongly invested in doing everything possible to help him succeed both socially and academically in his neighborhood and at school. DeMarco's mother saw a brochure for the intensity program in the waiting room and inquired as to whether this might be an option for him. She expresses some concern that transporting DeMarco to the outpatient clinic 5 days per week would be difficult due to work and family obligations.

Research Evidence:

Two synopses of studies documents were identified.[9,12] The low-quality evidence and the lack of evidence for adverse events suggest a weak recommendation for intensive outpatient therapy for DeMarco.

A synthesis of the evidence suggests that intervention strategies most likely to be effective are goal-directed training/functional training, task-specific practice of child-set goal-based activities using a motor learning approach, and fitness training for improving fitness.[36]

Home and Community:

The family lives in a row home in a city neighborhood. The bathroom and bedrooms are on the second floor. There are two nearby parks within walking distance, and the family frequently visits these parks. DeMarco has one younger sister, age 3 years 2 months.

DeMarco will need to take a school bus to his neighborhood school in the fall. The school building is accessible and all of the kindergarten activities are on one floor. Kindergarten is a full day, and the class has two separate gross motor/free play sessions during the day, either in the school gym or on the playground.

Practice Knowledge:

DeMarco's physical therapist has been working with him for the past 9 months and possesses the knowledge and skills to implement the intensive program with him. She has been in practice for 11 years and is board certified as a pediatric clinical specialist. She has had some success with intensive intervention with other similar children, but most recently one child did not experience any meaningful improvement after participating in this program.

Information Sharing and Decision Making:

A synthesis of the evidence suggests that patients are more likely to understand the research evidence when it is presented in a way that is tailored and interactive.[51] Therefore DeMarco's physical therapist prepared a one-page document that summarizes his current status and recent progress toward goals, along with a bulleted summary of evidence for intensive physical therapy programs. The summary indicated that there is no evidence to date to support a change in participation level outcomes following an intensive program and that the overall recommendation is weak. Several potential adverse events were included.

After some reflection and discussion, the parents decided to continue with DeMarco's 2×/week outpatient program and to reconsider the intensive program at a later date.

pediatric physical therapy. A description of evidence-informed clinical decision making is presented in Box 1.4.

SUMMARY

Pediatric physical therapists continually make difficult, complex clinical decisions as part of their daily routine. Historically, most of these decisions were based primarily on experience and practice knowledge. Although there has been an ongoing effort toward incorporating research evidence into clinical decisions, practitioners have benefited recently from the development of a number of overarching frameworks aimed at enhancing efficiency and effectiveness with this process. Thoughtful reflection on practice leads to questions that guide ongoing knowledge acquisition, and critical analysis of that new knowledge determines whether and to what extent it is appropriate to integrate that new knowledge into clinical decisions and recommendations. The PICO format may be used for framing clinical questions. Electronic databases and other web-based resources allow the practitioner to efficiently obtain the highest-level evidence available. The 6S system, CEBM levels of evidence, the GRADE recommendation process, and KT strategies aid in ascertaining whether the evidence merits a change in practice and then in implementing that change. Finally, clinical reasoning strategies allow pediatric physical therapists to effectively integrate new knowledge, practice-based expertise, child and family preferences, and the clinical presentation of the individual child and his or her family into an optimal, collaborative, shared decision that should lead to excellent outcomes for that child.

Measurement

Robin Lee Dole, Joseph Schreiber

INTRODUCTION

Pediatric physical therapists make numerous clinical decisions each day that should be guided by information gathered from standardized outcome measures. Accurate and reliable data collection regarding an individual child and family is essential for optimal decisions about eligibility for services, intervention strategies, meaningful and appropriate goals, and intensity and duration of services. This data should be shared with children and families in a way that encourages and supports collaborative decision making. Pooled data collection from multiple children can also inform decisions about program effectiveness and need for systemwide practice change.

Despite the availability of a wide variety of outcome measures to guide clinical decisions, pediatric physical therapists are not confident with the selection, administration, and interpretation of standardized outcome measures.[30,37,67] This lack of confidence is due to barriers that include lack of time to learn and administer tests, limited knowledge about measures and measurement principles, and inadequate training.[41,66] The purpose of this chapter is to guide clinicians on the effective use of tests and measures in pediatric physical therapy practice. Information will be provided on measurement principles and psychometrics as critical components of the selection, administration, interpretation, and sharing results of appropriate tests and measures. A variety of single and multi-item tests and measures will be presented to aid in identification of body structures and function impairments, activity limitations, and participation restrictions in children. Special emphasis will be placed on use of technology to enhance the feasibility of tests and measures within the daily work routine.

The American Physical Therapy Association's (APTA's) *Standards for Tests and Measurements in Physical Therapy Practice* states that a *measurement* is the "numeral assigned to an object, event, or person, or the class (category) to which an object, event, or person is assigned according to rules."[65] *Tests and measures* are the means of gathering reliable and valid cellular-level to person-level information about the individual's capacity for, and performance during, movement-related functioning. The appropriate selection of tests and measures for a specific child depends on the goals of the child and family, purpose of the testing, and the psychometric properties and clinical utility of the test.[3]

Outcomes are the actual results of implementing the plan of care that indicate the impact on functioning. At the level of pathology, body function, and body structure, outcome measures indicate the success of individual interventions during an episode of care. Outcome measures directed toward activity and participation demonstrate the value of physical therapy in helping individuals achieve their identified *goals,* which are measurable, functionally driven, and time limited and represent the intended results of a plan of care.[3] *Standardized outcome measures* are based on formal descriptions of a conceptual framework and documentation of the development, application, and scoring processes. They are applied within a defined context (e.g., condition, patient characteristics, setting, etc.) and have been reported, critiqued, and substantiated in peer-reviewed forums.[61] Throughout this text, the term *outcome measures* is used synonymously with *tests and measures* and *standardized outcome measures.*

The purpose of testing is a key consideration for pediatric physical therapists when selecting outcome measures. For example, for some children it is necessary to determine eligibility for physical therapy or other services. This is most often based on comparing the child's performance to same-aged peers, which would therefore require administration of a discriminative, norm-referenced outcome measure. A score on a norm-referenced outcome measure is usually expressed as a percentile rank or z-score and therefore identifies children with delays in a specific set of skills as compared to age-matched peers.

In other circumstances, eligibility for services has been established, and the focus of testing is on determining a baseline level of performance related to child and family goals. The child can then be retested over time to identify any change that has occurred and whether goals have been achieved. In this scenario, an evaluative, criterion-referenced outcome measure would be most appropriate. A score on a criterion-referenced outcome measure is most often expressed as a percentage or raw score, or as a scaled score. It is also critical that this type of outcome measure be responsive to change and therefore sensitive to the effects of intervention.

In addition to determining eligibility and accurately measuring change over time, pediatric physical therapists use outcome measures to predict future performance. The results from these tests aid practitioners in anticipating child and family needs and can provide critical support for clinical decisions related to placement, intervention planning, goal setting, environmental adaptations, bracing and orthotics, adaptive equipment, and child and family educational needs. For example, evidence suggests that the Test of Infant Motor Performance (TIMP)[14,33] can predict Peabody Developmental Gross Motor Scale (PDMS-2)[56] scores at preschool age and scores on the Bruininks-Oseretsky (BOT-2)[10] scores at school age.[23,40] Therefore clinicians might expect that infants who score lower on the TIMP are at greater risk for activity and participation restrictions due to suboptimal motor skills. Motor growth curves have been established for children with cerebral palsy based on scores from the Gross

Motor Function Measure (GMFM-66).[26] These growth curves help clinicians and families estimate a child's future motor capabilities including how much independence is likely to be achieved.[63] Practitioners would need to consult the scientific literature and the test manual to determine whether specific outcome measures might be used for prognostic purposes.

Finally, outcome measures may be used to contribute to minimal data sets and score aggregation as part of program evaluation and health services research. Frequently, these measures are based on self- (or parent/caregiver) report, in contrast to performance-based measures that are based on child performance of a particular skill or task.[3] One example of an outcome measure that may be used in this manner is the Patient Reported Outcome Measurement Information System (PROMIS), which is a psychometrically validated, dynamic system to measure patient reported outcomes. The PROMIS initiative is part of the NIH goal to develop systems to support NIH-funded research supported by all of its institutes and centers. PROMIS measures cover physical, mental, and social health and can be used across chronic conditions.[12] A similar tool, Outpatient Physical Therapy Improvement in Movement Assessment Log (OPTIMAL), has been developed by the APTA. This tool integrates patient identification of a primary goal of physical therapy. In addition, OPTIMAL's scoring of the patient's perceived difficulty and confidence in performing a specific activity can help the physical therapist make a clinical judgment on the severity of the impairment limitation restriction.[4] There is potential for use of patient-reported outcome measures to improve quality of care and disease outcomes, to provide patient-centered assessment for comparative effectiveness research, and to enable a common metric for tracking outcomes across providers and medical systems.[12]

MEASUREMENT PRINCIPLES

Norm- Versus Criterion-Referenced Outcome Measures

The two main types of standardized tests or measures, with regard to their scoring and interpretation, are those that are norm referenced and those that are criterion referenced.[11] When the purpose for using a standardized outcome measure is to compare children to a reference group, for example the child's same-aged peers, a norm-referenced test will provide such a comparison. When a therapist desires to know how well a child performs on a specified set of knowledge, skills, or abilities, a criterion-referenced test may be most appropriate. Typically, when the desired information is whether the child performs at, below, or above expectations based on their age, a norm-referenced test is required.[59] Such tests are commonly used to establish eligibility for therapy services when such qualification standards require that a child be below a certain cut-off score when compared to his or her peers. For example, one way to qualify for early intervention services in the United States under Part C of the Individuals with Disabilities Education Act is to have performance that is well below average for age. For some tests and measures this may be defined as a score that is greater than two standard deviations below the mean for a given age.[62]

In the case where a child has a known disability and deficits in knowledge, skills, and abilities have already been established or if eligibility for intervention is based on meeting a set of specific skills, a criterion-referenced test may be of benefit. A criterion-referenced test may also be an appropriate choice when the purpose of testing is to show whether a child's performance of a set of knowledge, skills, or abilities has changed over a specific period of time.[11] Such an example would be when a therapist desires to document the changes in functional mobility skills for a child who has been receiving intervention to address these skills.

Norm-referenced tests also may be sensitive to changes in knowledge, skills, and abilities over time, but one has to keep in mind that the scores from those tests are always referenced back to the normed group, which in pediatric practice is typically by age. In a situation where the therapist expects the child to "catch up" to same-aged peers with respect to his or her motor skills, changes in scores on a norm-referenced test may be an appropriate way to make that determination. Conversely, when a child who initially scores lower than average for age when compared to peers and on follow-up testing demonstrates no change in standard score performance, it could be evidence that the child is "keeping pace" with their typical peers even if no progress toward catching up to the age-expectations is made. That child has not made progress toward catching up with his or her peers but has not lost any additional ground either. This type of finding may also be an indication that additional data from a criterion-referenced measure is needed to document whether the child has made progress on important skills without reference to age expectations.

Test Development

A brief discussion of how standardized tests are constructed can help illustrate the differences between norm-referenced and criterion-referenced outcome measures. For a more comprehensive review of test development, the reader is referred to the *Standards for Educational and Psychological Testing*[2] and the *Handbook of Test Development*.[20] A measure is considered norm referenced because the test developers seek to create a measure that has enough items to capture the full range of performance on a particular set of knowledge, skills, or abilities and then provide a comparison of how children from the norming group achieve that knowledge, skill, or ability. Test developers also seek to obtain a large enough norming group to record the full range of performance across a variety of relevant demographic variables. Such variables may include age or grade level, gender, ethnicity, race, culture, and level of function. Scores from the norming group are ranked highest to lowest in order to identify average performance based on, in this example, the child's age.[11]

Items for criterion-referenced measures are selected because they are well representative of the domain of content to be measured. For example, for a criterion-referenced measure of gross motor function, the test developers may be less interested in what skills are achieved by a particular age and more concerned about the various elements that contribute to the functional mobility skills of rolling, crawling, cruising, standing, walking, and running. Criterion-referenced measures that are linked to age may do so through standard setting, where individual judgments of or information on expected ages of achievement are the criterion, rather than comparison to a norming group.[22] Both norm-referenced and criterion-referenced measures result in scores that may be interpreted in a diagnostic, predictive, or evaluative manner. Only norm-referenced measures can be used to compare performance to a population or determine difference when compared to same-aged peers through

scores referenced to the normal curve, yielding standard scores, T-scores, z-scores, and percentile ranks (Fig. 2.1).[11]

Psychometric Properties

A standardized outcome measure has a specific set of standards for administration, scoring, and interpretation. By adhering to such standards, the stability of the score or outcome is greatly increased. Stability within one test administrator is considered *intrarater reliability* and across multiple administrators is termed *interrater reliability*. The ability of a measure to capture accurately and assess the domain of interest is part of the psychometric property of validity. Both the concepts of reliability and validity, when considering test development, have several levels of complexity. For a more thorough discussion of these concepts the reader is referred to *Foundations of Clinical Research: Applications to Practice*.[59] For consumers of standardized outcome measures, valid use of a test or measure can be ensured when the subject undergoing testing is most like the reference group used in the norming process or population of individuals used to develop and validate the test. According to the test developers, the Gross Motor Function Measure-66 item version (GMFM-66)[26] should only be used with children who have a diagnosis of cerebral palsy. The test developers issue this caution because, at the time of publication of this text, the GMFM-66 has been validated for use only with this population and this measure has been used to develop gross motor curves to assist with making prognoses regarding motor skill abilities based on a child's Gross Motor Function Classification Scale Level (GMFCS).[68] It is important to know how well one's clinical situation fits with the design and purpose of the test as well as the population for which the test was intended.

Another clinical consideration for test validity is the manner in which tests are administered. It is critical for test validity that standardized outcome measures be administered as they were intended, including closely following instructions, using the designated materials, and providing the permitted demonstrations and number of trials that are required of the test.[35] Making modifications to a standardized test diminishes the ability to make judgments from the scores obtained, both for comparison to a reference group and for detecting change in performance of the same individual over time. Therapists may feel compelled to make such modifications because they believe the child's true abilities could be uncovered with such adaptations or that a child's diagnosis or co-occurring condition prevents the child from showing their true performance given the constraints of the test. One way to address this clinically is to administer the test according to the test specifications, including scoring it appropriately, and if the therapist desires to know how well a child could perform on the same item with some form of modification or additional trials, provide that opportunity after the standardized administration of the item or the test is complete. Do not include the performance of this modified item in the scoring and interpretation of the child's performance on the test. The information that has been gathered from modification is less a reflection of how well that child performs on the standardized outcome measure than an indication of how that child might respond to intervention or a method of identifying appropriate strategies to address the child's challenges with a particular skill or ability. One caution here is to refrain from taking specific items from a test and repeatedly practicing those items in therapy or adopting the items as therapy goals for measuring success. Such a practice could also jeopardize the ability to

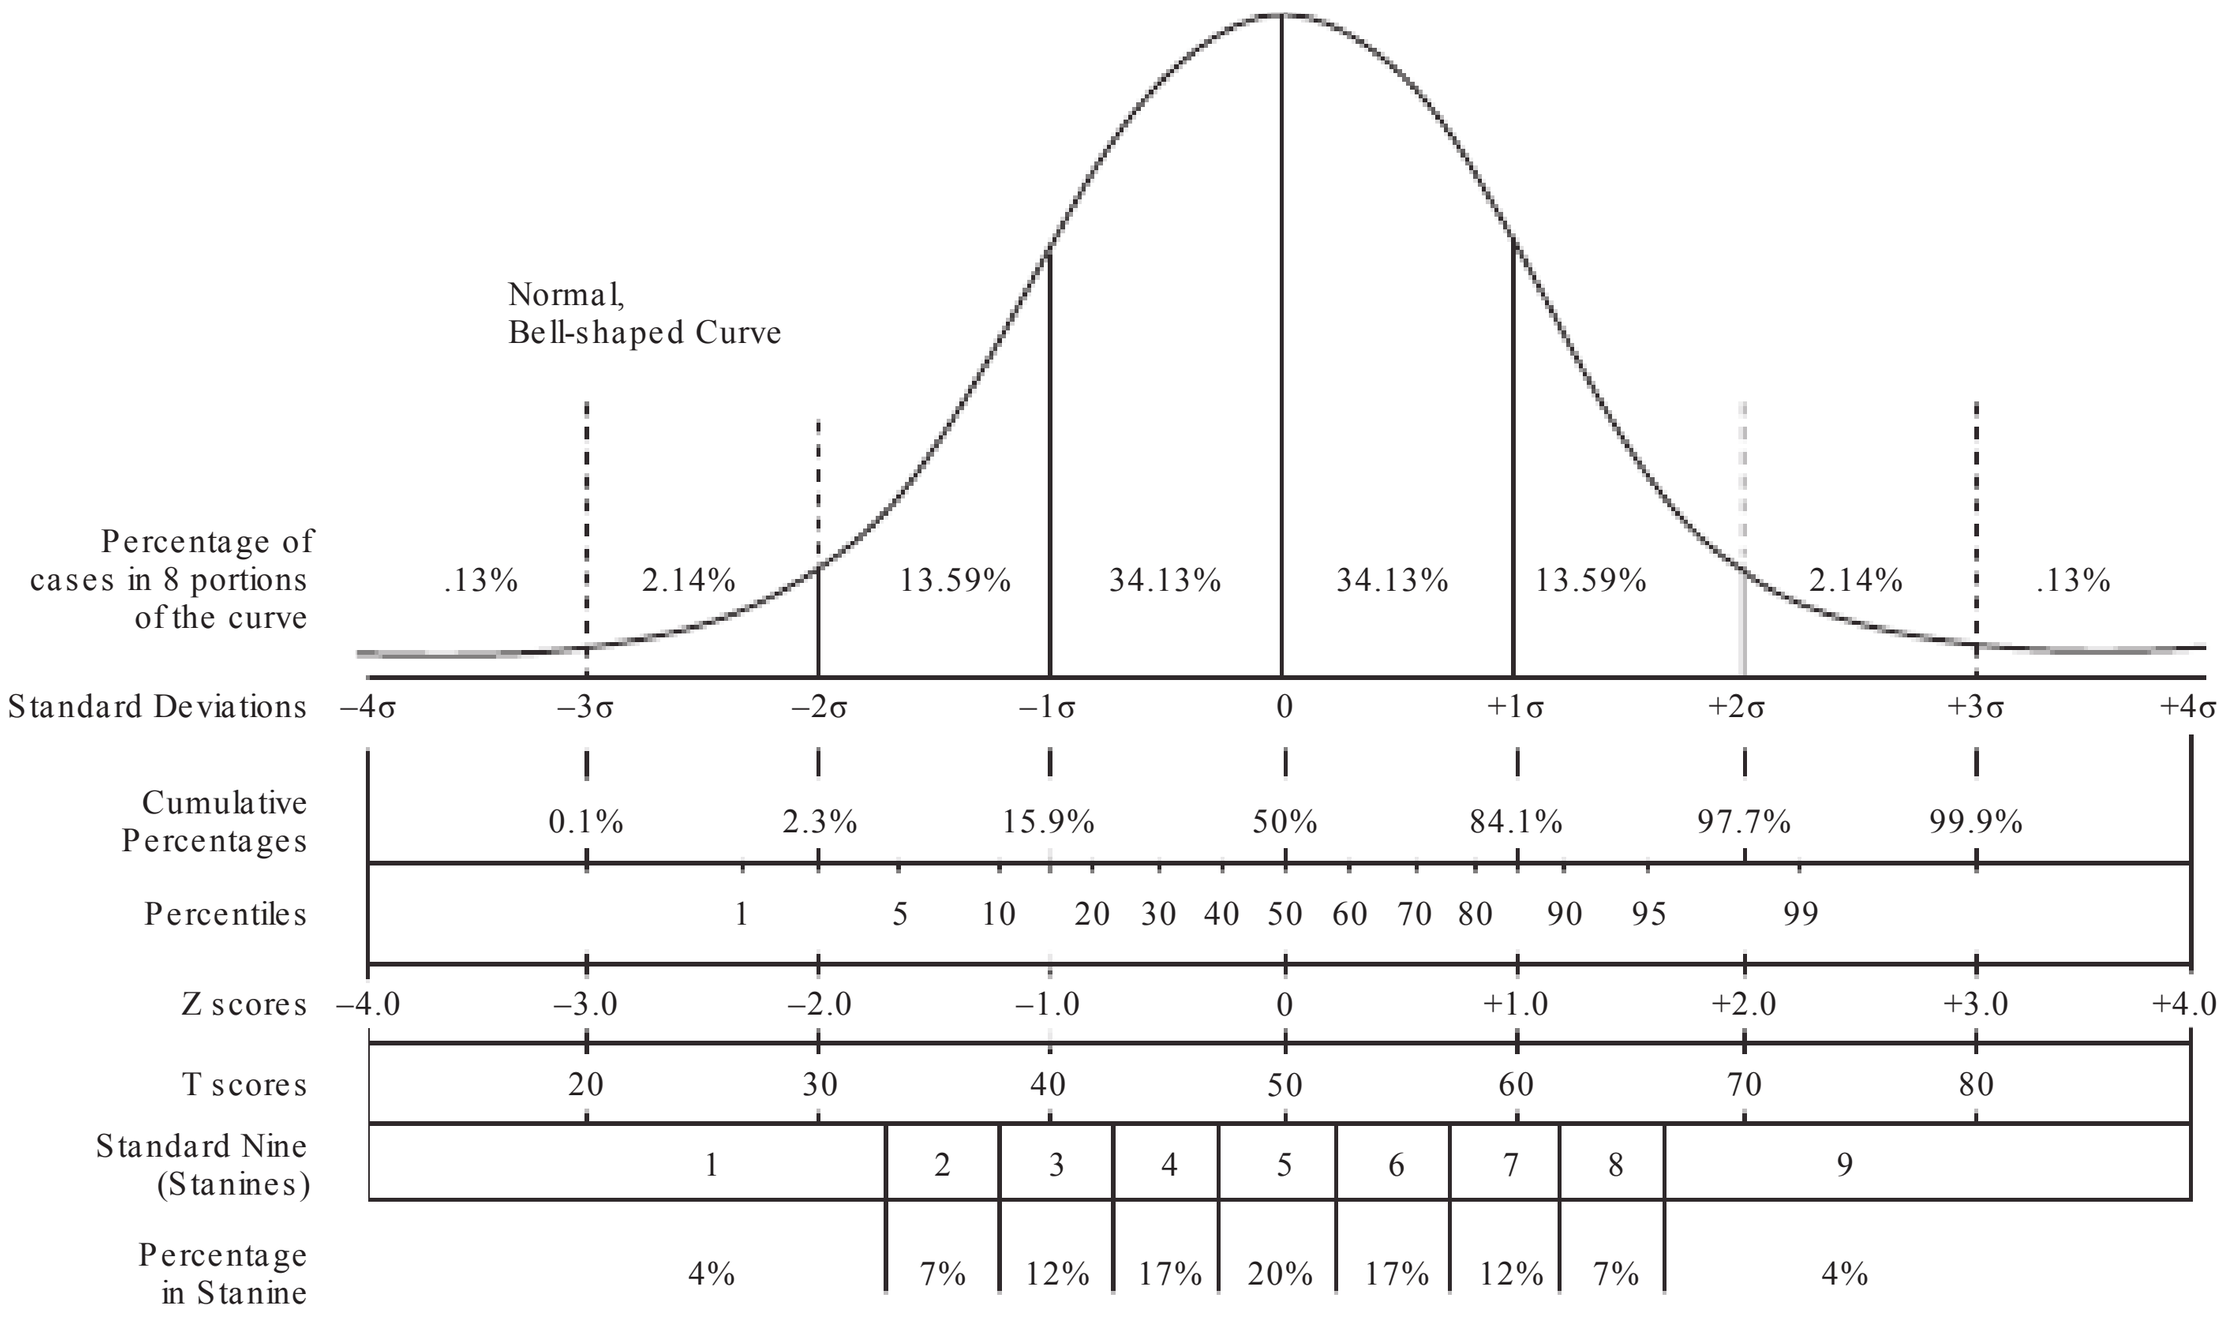

FIG. 2.1 The Normal Distribution.

validly measure performance for comparison to a normed population or to a specific skill criterion. The "Clinical Measurement Practical Guidelines for Service Providers" available through the CanChild Centre for Childhood Disability Research (www.canchild.ca) is a helpful resource for clinicians regarding these issues and their effect on effective use of clinical outcome measures.[29]

For outcome measures designed to screen to predict a condition or diagnosis, the properties of specificity, sensitivity, positive and negative predictive values, and likelihood ratios are important factors to consider for selection and interpretation. Two mnemonics that can be helpful for understanding the importance of specificity and sensitivity are SpPIN: measures with high levels of specificity (true positive rate) indicate that a positive test result will rule in the condition or diagnosis; and SnNOUT: measures with high levels of sensitivity (true negative rate) indicate that a negative test result will rule out the condition or diagnosis.[20] Ideally, measures designed to predict a later outcome should have acceptable measures of specificity and sensitivity; however, how a measure is used can shed light on interpreting the importance of these properties. For example, clinicians using screening measures to help identify those premature infants who would most likely be diagnosed with motor impairment or cerebral palsy at some later point might be willing to accept lower levels of specificity but desire higher levels of sensitivity. This risk of overidentifying children (high false positive rate, 1 – specificity) who may later demonstrate motor impairment and therefore be given early intervention is preferable to having high numbers of children for whom the test incorrectly rules out the likelihood of developing cerebral palsy (false negative rate, 1 – sensitivity) and then are not identified or referred for intervention.[59] The risk of this happening, of course, is low because it would mean that only the score on a single test would be used to identify a condition or diagnosis when clinically it is best practice to use multiple sources of clinical information for decision making. There is the potential, however, that infants may not meet the threshold for developmental differences and still be at risk for later challenges, and early identification and intervention is desired.

Positive and negative predictive values provide an estimate of a test's feasibility in actually identifying that a child who tests positive or negative actually does or does not have the diagnosis or condition of interest. Positive and negative likelihood ratios indicate how much more likely it is that a child may have a particular diagnosis or condition *after* testing positive or negative on a predictive test.[59] These concepts will be discussed further via an example in the section Analysis and Interpretation.

Computer- and Technology-Aided Measures

As computer technology has advanced, options for utilizing more sophisticated test administration and interpretation have been applied to existing pediatric outcome measures and the development of new outcome measures. One way in which technology has enhanced the use of standardized testing is in computer-aided scoring. In this situation, raw scores from a measure are entered into a software program that calculates standard scores, scaled scores, z-scores, percentile ranks, confidence intervals, item maps or other relevant data for interpretation. Such analysis software is specifically applicable to norm-referenced tests and helps to reduce the potential for human error in reading and interpreting scoring tables from a particular test or measure.[69] Some software packages will also print out a report that provides a description of the test, a table of data, and a first-level analysis of the data. Readers should be cautioned that such reports are based solely on the data that are provided and therefore lack the additional clinical data and impression that can only be provided by the therapist administering the test or measure. Examples of commonly used measures that have this computer-aided scoring are the Peabody Developmental Motor Scales-2 (PDMS-2)[56] and the Bruininks-Oseretsky Test of Motor Proficiency-2 (BOT-2).[10]

Computer-adaptive tests are constructed in such a way as to minimize the number of items that need to be completed in order to arrive at an accurate score that would be comparable to the score achieved if the entire test was administered. The test therefore "adapts" to the responses and performance of the individual being tested.[11] All items on the assessment are ordered by level of difficulty, and the first item administered is in the middle range of difficulty. From there items are selected for administration and scoring based on the response or performance on the item tested, progressing by either increased or decreased difficulty level as appropriate. These measures also have the benefit of computer-based scoring and first level of interpretation of the data. The United States military has heavily supported the development of computer-adaptive testing. It has been using this method for their Armed Services Vocational Aptitude Battery since 1996.[11] Computer-adaptive testing has also been applied to common pediatric assessment tools. An example is the Pediatric Evaluation of Disability Inventory Computer Adaptive Test (PEDI-CAT), which captures functioning in the four domains of daily activities, mobility, social/cognitive, and responsibility.[27] The test developers indicate that the PEDI-CAT is appropriate for all populations of children between the ages of 1 and 21 years and across all settings. The test can be completed by parent or caregiver report or by a practitioner familiar with the child. The PEDI-CAT produces both normed standard scores (percentile and T-scores) and criterion-referenced scaled scores for analysis. The precision version provides a precise score in the quickest fashion and delivers the fewest number of items delivered per domain, and the comprehensive version delivers more items per domain to ensure a more balanced number of items from each domain. The comprehensive version is required if the production of an item map is desired. Item maps show the test items ordered by level of difficulty, which can aid in interpretation and program planning.[27]

Another interesting application of computer technology in testing is the Gross Motor Activity Estimator (GMAE), which can be used in conjunction with the GMFM-66.[26] The GMFM-66 is a criterion-referenced measure and, as such, the scores derived are considered ordinal in nature. The scores have an order to them in that higher numbers indicate better performance but the intervals between the scores are not necessarily equal distance apart.[68] The GMAE provides a manipulation of the scores derived from the GMFM-66, converting those scores to an interval scale. Scores that are considered to be interval can be interpreted differently than scores that are ordinal. When the intervals between two scores are equal distance, it is possible to apply statistical analysis to them and compare scores across individuals.[59,68] See the case of Sophia on Expert Consult for an example of interpretation of the GMFM-66 and GMAE scores.

ANALYSIS AND INTERPRETATION

When choosing tests and measures, therapists should consider the purposes for which they are testing (What type of decision

is to be made?), the types of data to be gathered (What information is needed to make that decision?), and the methods to be used to gather the data (How best is the information gathered: by observation, direct assessment of performance, or through self- or caregiver report?). The purpose of testing and the outcome measures that are selected and administered will have a direct impact on the type of analysis and interpretation of results for clinical decision making. Therapists are encouraged to consider collecting data, as appropriate, at all levels of the International Classification of Functioning (ICF).[77a]

Screening and Prediction

When the purpose of testing is to detect the potential for a certain condition or diagnosis either now or in the future, a standardized measure that has been validated for screening or prediction is necessary. Such measures should report the strength of related psychometrics in sensitivity, specificity, positive and negative predictive values, and likelihood ratios. These properties of the measure play a role in selecting appropriate tests to rule or rule out a condition and give an assessment of the strength and quality of the decisions that are made through interpretation of the test results.

Spittle et al[71] investigated the predictive abilities of two motor-related outcome measures, the Alberta Infant Motor Scale (AIMS)[1] and the Neuro-Sensory Motor Developmental Assessment (NSMDA).[48] These tools were used to examine preterm infants at 4, 8, and 12 months (corrected age) and the ability to predict a later diagnosis of cerebral palsy as determined by child's pediatrician and confirmed by a physical therapist. The outcomes were also reviewed for their ability to identify motor impairment based on performance at age 4 years (corrected age) on the Movement Assessment Battery for Children (MABC-2).[46] The specificity related to identification of impairment on both outcome measures assessed during infancy was high for motor impairments at 4 years as assessed by the MABC-2 and for diagnosis of cerebral palsy at 4 years (ranging from 88% to 95%). Sensitivity for predicting motor impairment on the MABC-2 was low (ranging 38% to 56% depending on the cut-off score used), whereas sensitivity for predicting later diagnosis of cerebral palsy was very high (83% at 4 months and 100% at 8 months and 12 months of age). Recall the earlier discussion of sensitivity and specificity. These measures were highly specific for identifying cerebral palsy and later motor impairment, a positive test resulting in a correct identification of children with the condition or impairment. These measures were also highly sensitive for predicting a later diagnosis of cerebral palsy, a negative test resulted in correct identification of the children who did not have the condition. The lower sensitivity for the MABC-2 is concerning in that there may be children who go unidentified. One has to consider that there are limitations, perhaps, with the MABC-2 as a diagnostic tool because all tests have limitations. The authors of the study note that false positives did occur and that serial outcome measurements during follow-up with children at high risk for motor impairment are important.

Positive and negative predictive values (PPVs and NPVs), positive (+LR) and negative likelihood ratios (−LR), and diagnostic accuracy were also reported. Because PPV and NPV take into account the prevalence of the condition under study, these properties provide insight on the clinical utility of the screening measure.[59] In the Spittle et al[71] example, the NPVs for the AIMS and NSMDA are high (82% to 100%) for their probability in identifying infants who did not have motor impairment as tested on the MABC-2 and did not have diagnosis of cerebral palsy (CP) at age 4. The PPVs, or probability of identifying infants who did have motor impairment as identified by the MABC-2, were higher (54% to 73%) than the PPVs for identifying infants who had a later diagnosis of CP at age 4 (32% to 45%). The study analyzed data on 82 children, of whom only 6 were eventually diagnosed with CP. Just over a quarter had confirmed motor impairment at <15th percentile on the MABC-2. The lower PPVs for the AIMS and NSMDA to estimate the likelihood for an infant who tests as delayed at 4, 8, and/or 12 months to later be diagnosed with CP could have been impacted by a low prevalence for CP among the infants in the study. The positive predictive value answers the question: If the child is identified as positive for the condition on the predictive test, what are the chances that they actually have that condition? However, in studies of predictive tests, if the prevalence of a condition in the general population is low (in this case CP and the overall number of children with identified CP in this sample was low), the positive predictive value will be low as well regardless of how good the sensitivity and specificity of the test. In this study, likelihood ratios (LRs) are independent of prevalence and provide information of the confirming power or certainty of a measure's diagnostic ability. The calculation of positive and negative LRs takes into account sensitivity, specificity, and true and false positive rates (LR+) and true and false negative rates (LR−).[59] In the example discussed here the 11.3 LR+ found for diagnosis of CP indicates that it was 11.3 times more likely that infants with impairment at 4 months would have CP at 4 years than for infants without impairment at 4 months to be later be diagnosed with CP at 4 years.[71]

Determining Difference

Tests and measures may be used in the process of determining whether a child has a motor impairment and may contribute to the determination of a specific diagnosis or determination of eligibility for services. One example where measures of motor skill or impairment may be used to establish evidence for a diagnosis and determine difference is in developmental coordination disorder (DCD). The Developmental Coordination Disorder Questionnaire (DCDQ '07) is a criterion-referenced measure that collects information about a child through parent report to screen for characteristics associated with DCD.[76] In addition, other norm-referenced direct assessments of performance on motor tasks, like the MABC-2 or the BOT-2, may help identify children who perform below their same-aged peers in areas of motor performance that are typically challenging for children with DCD.[8] Measures like these may help to identify whether a child meets the diagnostic criteria for DCD within the *Diagnostic and Statistical Manual of Mental Disorders,* 5th edition (DSM-5).[5,7] When the decision to be made is related to difference, diagnosis, discrimination, or eligibility determination by screening for and confirming a diagnosis, outcome measures that can distinguish those with impairment from those without impairment are needed.[70,74] Parent report measures help to capture the perspective of the parent and may help to ascertain the child's typical performance, whereas direct measures help to identify and quantify which skills may be problematic for the purpose of diagnosis and establishing a baseline of performance for later comparison. The same psychometric properties that were applicable to the screening and predictive measures described earlier are also applicable to measures used for diagnostic or discriminative purposes.[59]

Missiuna and colleagues[45] studied a "staged" approach for the identification of children with DCD, which included using one parent-report measure (DCDQ'07) and one child-report measure (Children's Self Perception of Adequacy in and Predilection for Physical Activity Scale [CSAPPA])[32] as an initial, first-step screening for DCD in over 3000 children. The second stage involved further testing for only those children whose scores on either the DCDQ '07 or CSAPPA were below the 5th percentile as an indication of probable DCD. They also included children known to have ADD/ADHD regardless of their scores on the first step screening due to the high co-incidence of these conditions with DCD. Presence of ADD/ADHD was confirmed using the Conner's Parent Rating Scales (CPRS)[16] during the second stage of the process. Stage 2 also involved direct assessment for motor impairment with the MABC, estimation of cognitive skill with the Kaufman Brief Intelligence Test-2 (KBIT-2),[36] and a structured home interview to assess impact of impaired motor skill on self-care and academic activities. Each of these measures and procedures connected back to one of the diagnostic criteria for DCD set forth in the DSM-5. Children determined to meet criteria for DCD would have motor impairment evidenced by MABC scores below the 15th percentile, typical intelligence evidenced by > 70 on the KBIT-2, and parent confirmation of the impact of motor impairment on daily activities. The results showed that almost 30% of the children initially identified with probable DCD did not go on in stage 2 to demonstrate a significant motor impairment, and about 16% of the children that were not identified during the screening process were later identified as having DCD. Screening processes are not without error and should be used as a part of a system of measurement that identifies difference or diagnosis. The staged approach studied by Missiuna and colleagues[45] also helps to illustrate how important it is to collect information from a variety of measures and perspectives in order to enhance clinical decision-making.

EVALUATING CHANGE

If the decision of interest is whether a child has changed in performance over a specified amount of time, either to track the child's rate of progress or to evaluate the effectiveness of a particular intervention, test results from before and after intervention can be analyzed to help identify change. A measure's ability to detect such change is often referred to as its *responsiveness to change*.[28] To determine if the change in scores from one administration to another is different enough to be true change, it is important to know the minimal detectable change (MDC) for the measure or the smallest amount of change that is reflective of true change and not that which can be accounted for by measurement or test error.[45] Statistical measures are applied to determine the MDC, and most often are reported relative to the confidence interval applied. The MDC90 reflects use of the 90% confidence interval (z score of 1.65); the MDC95 reflects use of the 95% confidence interval (z score of 1.96) in the calculation. The MDC calculation also takes into consideration the coefficient of the measure's established test-retest reliability and the standard error of the measure.[28] The standard error of the measure is a reflection of variability or error in estimating a true score from the observed score on a particular measure. When calculating the 90% or 95% confidence interval, the standard error of the measure is a component of that calculation. If the change in scores from two administrations of a measure exceeds the MDC for that measure, one can conclude that the amount of change beyond the MDC is true change from a statistical point of view. Therapists should consult the relevant literature for reports of the MDC when available for the outcome measures they commonly use in practice.

Another measure of change is one where clinical meaningfulness is the benchmark for change. The minimal clinical important difference (MCID) has been defined as smallest amount of change that is meaningful from the perspective of a relevant individual, for example a patient or a practitioner. There are multiple ways to determine the MCID; therefore there are some concerns with its use as a measure of meaningful change. The anchor-based method determines the average change of those who have been defined as having improved. The distribution-based method typically takes into consideration effect size. A single measure could have more than one MCID reported in the literature, so when applying this analysis, it is vitally important that the method used to determine the MCID be considered because it can be diagnosis, setting, and population specific.[17]

Iyer, Haley, Watkins and Dumas[34] retrospectively reviewed the inpatient rehabilitation charts from 53 children in order to establish the MCID for the original version of the Pediatric Evaluation of Disability Inventory (PEDI).[57] An anchor-based method was used with the mean change in scores as identified by clinicians as important when comparing admission and discharge summaries. Each clinician rated the level of improvement noted for each subject on both a 0- to 15-cm visual analog scale (VAS) and a 15-point Likert scale. Both scales had extremes from a great deal worse (−7 on the Likert scale) to a great deal better (+7 on the Likert scale) with the middle (0 on the Likert scale) indicating no change. The results of this study identified an 11-point change in a scaled score on the PEDI as the minimal change that can be deemed important in an inpatient rehabilitation setting. For the same measure Haley and Fragala-Pinkham[28] reported the MDC90 to be a 5.1-point scaled score change. It should make sense that the minimal change beyond error is smaller (MDC90 of 5.1 points) than that which might account for clinically important change (MCID of 11 points) A caution with the MCID is that it is likely baseline dependent, meaning that children whose baseline scores are lower performing may need less of a change to be considered meaningful by parents, clinicians, or patients than children whose baseline scores are at the higher end of the performance scale of the measure.[75] A caution with the MDC is that measurement error may not be consistent at all levels across the measure's scaled scores. The standard error of the measure is a component of the 90% confidence interval and therefore a part of the MDC90. Measures that report the standard error of the measure at each point or level of the scale may help offset this concern.[28]

Examples of how to apply analysis and interpretation with outcome measures at the body system and function, activity, and participation levels of the ICF are provided in the case studies on Expert Consult.

SELECTION

A difficult challenge for pediatric physical therapists is the selection of appropriate tests and measures. As noted above, this selection must be based on the purpose of testing and the goals of the child and family. The history and systems review portions of the physical therapy examination process narrow the focus of the examination and guide practitioners in prioritizing tests and measures to obtain data that will inform collaborative clinical decision-making with the child and family. The ICF also provides an organizational framework for this

data collection process. The Tests and Measures tables (eTables 2.1 to 2.4) are organized (based on the ICF) into impairment, single-task, multi-item activity, and multi-item participation outcome measures. Relevant information is provided regarding the appropriate clinical circumstances when a specific test might be used, along with information to support accurate analysis and interpretation. Links for many of the tests are also included and allow the reader to obtain more detailed information to guide selection and interpretation.

One additional consideration in selection of tests and measures is the integration of individualized outcome measures into this process. Pediatric physical therapists regularly write individualized outcomes as a way to measure progress toward child and family goals. These outcomes may be at any level of the ICF and should all be related to the parent and child- identified goals at the activity and participation level. Both the Canadian Occupational Performance Measure (COPM)[72] and Goal Attainment Scaling (GAS),[38,39] included in eTable 2.4, Multi-Item Participation Level Tests and Measures, may be used to more precisely measure change in performance on these outcomes. The COPM requires the child and/or family to rank satisfaction and performance on individualized outcomes on a 0–10 scale. With GAS, each individualized outcome is scaled to five levels of attainment: expected level, two outcomes that are less favorable and two outcomes that are more favorable. In addition, with multiple outcomes a T-score can be calculated such that a score > 50 indicates better-than-anticipated performance. Examples of how the COPM and GAS can be integrated into clinical decision making are included in the case studies on Expert Consult.

REPORTING AND SHARING RESULTS

A key responsibility of therapists when using outcome measures in practice is the obligation to report and share results with a variety of stakeholders and through multiple communication methods. Therapists may report results officially in writing as part of documentation, and these reports are likely shared with other professionals, families and caregivers, third-party payers, and (when appropriate) the child. Therapists are often called on to report verbally at team meetings in early intervention, school, hospital or clinic settings. Whenever reporting and sharing results, therapists should adhere to the responsibilities of test users identified in the Standards for Tests and Measurements in Physical Therapy Practice, including using all relevant and available data with appropriate justification for decision making, recognizing the limitations of tests and measures, and identifying any irregularities in the testing protocol or conditions.[65] As routine best practice, therapists should include and share information in ways that are easily understandable by those who will hear or read the report and that allow for collaborative decision-making.[77] Reports should include information about the outcome measures administered, tables or narrative outlining the results, and interpretation of the results within the context of the child and family's needs and goals. Trevena, Davey, Barratt, Butow, and Caldwell[73] found that communication tools in most formats (verbal, written, video, provider delivered, computer based) will increase patients' knowledge and understanding but are more likely to do so if the tools are structured, tailored, and/or interactive. One additional consideration is that some outcome measures may provide age equivalents as a component of analysis of the test results. Therapists should refrain from using age equivalents as a unit of analysis and basis for decision making because age equivalents have significant limitations, including that these scores are ordinal rather than interval, are based on raw scores and not normative or scaled scores, and the likelihood that this data is value laden and therefore easily misinterpreted by children, families, and caregivers.[44]

CASE ILLUSTRATIONS OF ANALYSIS AND INTERPRETATION OF EXAMINATION DATA

This section presents two separate clinical cases to illustrate the use of outcome measures to support evidence-informed and collaborative clinical decision making. The first, Sophia, focuses on the early life span beginning in the neonatal intensive care unit and continuing into early intervention and the elementary school years. The second, Jacob, focuses on the use of outcome measures to make clinical recommendations for intervention, episodes of care, and referral to other health care providers. The case spans Jacob's life between ages 4 years 8 months and 14 years, and many of the outcome measures are appropriate for adolescents and adults as well.

Case 1: Sophia

Sophia was born at 30 weeks gestational age (GA) via emergency C-section and weighing 3 pounds (1361 grams). She spent 8 weeks in the neonatal intensive care unit (NICU), the first week on mechanical ventilation. At 14 days an ultrasound screening revealed a grade II intraventricular hemorrhage (IVH). The first signs that there may be neuromotor challenges were identified when the NICU team assessed Sophia at 34 weeks postmenstrual age (PMA) using the Qualitative Assessment of Generalized Movements (GM).[21,60] This assessment, which requires the tester have formal training, follows a specific protocol for observing infant movements via videotape and classifying those movements (http://general-movements-trust.info/). Sophia's team also administered the Test of Infant Motor Performance (TIMP) as part of its program to identify infants early who may be at risk for later motor impairment.[13,14,33,40,] The TIMP assesses functional infant motor behaviors related to posture and movement and can be administered to infants from 34 weeks postconceptual age to 4 months postterm age (or corrected age, CA).[14] Sophia's developmental progress was followed further with the Alberta Infant Motor Scale (AIMS) during NICU follow-up visits at 6 and 12 months.[58] Information on later testing with the Peabody Developmental Motor Scales (PDMS-2), a multi-item assessment of gross and fine motor development, is provided to demonstrate or confirm the presence of motor impairment by age 4 (Table 2.1).[14,24]

Screening and Prediction

How likely is it that Sophia will go on to develop motor impairment? Should intervention be provided?

Eligibility Decisions

Is Sophia's development different enough for her age to warrant the initiation and continuation of early intervention services?

Depending on her state's interpretation of the Individuals with Disabilities Education Act, Sophia may qualify for early intervention services based on her being at risk due to prematurity. If she did not have such a diagnosis, Sophia might qualify based on her developmental status as measured by a standardized outcome measure or by the informed clinical opinion of a practitioner.[62] A targeted evaluation team met with the family at their home and administered the Battelle Developmental Inventory, 2nd edition (BDI-2), a

ETABLE 2.1

Test	Who Should this Outcome Measure be Used With?	What is Important to Know About Administering this Outcome Measure?	Norm Referenced Info for Interpretation	Criterion Referenced Info for Interpretation
Muscle strength-dynamometry	Children > age 3.5 with cognitive and behavioral capability to cooperate with test instructions	Standardized procedures for each muscle group	See tables below from Hebert et al[1] and Macfarlane et al[2]	
Spasticity- Modified Ashworth Scale and Modified Tardieu Scale	Children with spasticity; limited use due to inconsistent reliability	Each is based on passive movement of a limb through available range of motion	Intraclass correlation coefficients of both scales are < 0.75. Caution should be used when these scales are applied.[3,4]	
Selective Control Assessment of the Lower Extremity (SCALE)[5]	Children with CP > 4 years of age with cognitive and behavioral capability to cooperate with test instructions; assesses selective voluntary motor control in the LEs	Health care professionals; should take less than 15 minutes		Validity, inter and intra rater reliability established[5]
Pain- self report	Children > age 3.5 with cognitive and behavioral capability to understand test instructions	If possible, screen the child's cognitive and communication skills to ensure that they will be able to understand the tool. Administer the tool to the children when they are not in pain. Let the child practice using the tool by providing hypothetical situations or by rating previous pain experiences. Identify and remove potential consequences for high or low ratings of pain.[6]	Self-report measures can be verbal, such as structured interviews, questionnaires, self-rating scales, and pain adjective descriptors, or nonverbal behaviors, such as facial expression scales and drawings. Aspects of pain that may be assessed through self-report include location, intensity, duration and quality, affective reactions, situational factors that increase pain, and pain related disability.[6] A 30% reduction of pain can be considered clinically significant. This level corresponds with a "much improved" or "very much improved" response from patients on a global impression of change, or 2 points on a 0 to 11 pain intensity numerical rating scale -mm visual analogue scale indicates a satisfactory result for the patient.[7]	
Pain- Behavioral	Children experiencing or at risk for experiencing pain	Talk to the caregivers to determine typical pain behaviors. Observe child under pain-free circumstances if possible. When possible, obtain several ratings over time and observe variations depending on pain free, pain-inducing, and pain-relieving interventions. Consider the environmental and social context in which the behavioral observation is occurring.[6]		
Pain- physiological	Children experiencing or at risk for experiencing pain	Obtain baseline measurements under stress-free circumstances. Correlate measurements with environmental circumstances and with other measures such as behavioral pain distress scales. Consider medications, age, cardiorespiratory status, chronicity of pain, and previous pain experiences.[6]	Heart rate- Increase Blood pressure- Increase Respiratory rate- Increase or decrease Oxygen consumption- Increase Oxygen saturation- Decrease Mean airway pressure- Increase Intracranial pressure- Increase Hormonal secretions (cortisol, catecholamine, glucagons, growth hormone, renin, aldosterone, and antidiuretic hormone)- Increase Hormone secretion (insulin)- Decrease Observable autonomic responses: Mydriasis, sweating, flushing, pallor.[6]	
OMNI Rating of perceived exertion (OMNI-RPE)[8]	Children, including those with cerebral palsy, ages 6-18 who are ambulatory and have either age-appropriate or mild impairments in social/ cognitive skills; Valid, feasible and low cost measure of exercise intensity	Displays both pictorial descriptors and semantically consonant verbal descriptors distributed along a numerical category response range	Validated for use with typically developing children ages and children with cerebral palsy ages 6-18	No evidence to date on responsiveness, MDC or MDIC

Test	Who Should this Outcome Measure be Used With?	What is Important to Know About Administering this Outcome Measure?	Norm Referenced Info for Interpretation	Criterion Referenced Info for Interpretation
Range of Motion (ROM)	See Chapter 5 for Normal values	Full-body goniometric measurements are very time-consuming to conduct and do not result in a meaningful summary score that is required for some purposes[9]		See Chapter 5: Variances of +/- 10 to 28 degrees (depending on joint) in ROM over time do NOT signify a meaningful change in children with spastic CP
Spinal Alignment and Range of Motion Measurement (SAROMM)	A reliable and valid method to estimate limitations of range of motion to support clinical decisions about individual prognosis and management for individuals with cerebral palsy. Can be used as a discriminative and responsive tool.[8] Especially suited for use in those who are uncooperative and in young children. Analytical results provide a benchmark for clinical decision-making while managing musculoskeletal difficulties in children with CP.[10]	Trained rehabilitation professionals; 15 minutes with cooperative clients; 30 minutes might be required for those with more severe physical and cognitive impairments. To administer the measure, one needs 1) a firm sitting surface such that the individual is able to sit with the hips and knees both at approximately 90 degrees of flexion and 2) a floor or raised mat or other surface for testing in the supine position. If an individual is unable to attain or maintain bench sitting independently, two people might be required to administer the measure.[9,10]		MDC 90 = 3.22 MCID = 4.53 to 4.62 [10]
Segmental Assessment of Trunk Control (SATCO)	A systematic method of assessing discrete levels of trunk control in children with motor disabilities; 3 aspects of trunk control: (1) static (or steady state) control, (2) active (or anticipatory) control, and (3) reactive control (maintaining or regaining trunk control following a threat to balance produced by a brisk nudge).[11]	Need for bench with strapping system[11]	Evidence that this tool discriminates between children with varying levels of trunk control[11]	No evidence to date on sensitivity to change[11]

ETABLE 2.2 Single Task Activity Level Outcome Measures

GAIT VELOCITY

Test	Who Should This Outcome Measure be Used with?	What is Important to Know About Administering This Outcome Measure?	Norm Referenced info for Interpretation	Criterion Referenced Info for Interpretation
30 Second Walk Test	5-17 years; appropriate for use in clinical settings including schools	Marked course for distance; verbal cues for elementary school children to "walk as a line leader" and for older children to walk in a "natural and comfortable pace"	Ages (years)– Distance (feet) 5 – 135 +/- 11.6 6 – 133.9 +/- 12.9 7 – 152.9 +/- 16.8 8 – 158.2 +/- 17.2 9 – 162.6 +/- 20 10 – 164.6 +/- 17.9 11 – 156.3 +/- 17.8 12 – 159.7 +/- 18 13 – 155.2 +/- 16.6 14 – 151.5 +/- 20.5 15 – 146.4 +/- 23 16 – 138.5 +/- 17 17 – 135.8 +/- 20.9[1]	
10 meter walk test (or other standardized distance up to 10 meters)	Ambulatory Children > 1 year		107.38 ± 5.14 meters/ minute[2] Walking velocity (m/min) 38.4 (1 year) 42.6 (1.5 years) 51.6 (3 years) 68.4 (7 years)[3] Gait speed over 4 m, m/s 5th 25th 50th 75th 95th percentiles, high school students 0.84 1.09 1.19 1.29 1.46 (standing start) Gait speed over 6.1m, m/s 1.03 1.23 1.32 1.44 1.69 (walking start)[4]	Adults: MCID .10 to .20 m/sec appears to be accurate for a variety of adult populations[5] For children with CP, MCIDs for gait speed are identified for small and large effect sizes, and at Level I, II, and III of GMFCS. Measures are all percentage of normal[6] Level I GMFCS 8.7 and 13.9 Level II 6.8 and 10.9 Level III 5.5 and 8.8 Overall 5.7 and 9.1

ENDURANCE & CARDIORESPIRATORY

Test	Who Should This Test be Used with? (Age/ Diagnosis)	Procedures/ Administration	Norm Referenced Info7		Criterion Referenced Info
6 minute walk test	Ambulatory children > 4 years, with goals related to increased participation with age-matched peers; children with progressive disorders (e.g. Duchenne Muscular Dystrophy), as a predictor for decreased ambulatory capability[8]	Instructions: walk up and down corridor, covering as much distance as possible; self-paced and allowed to rest as needed (clock keeps moving); standardized words of encouragement ("keep going" "you are doing fine" "everything is going well")[7]	4 yrs 5 6 7 8 9 10 11	383 meters +/- 41 420 +/- 39 463 +/-40 488 +/- 35 483 +/- 40 496 +/- 53 506 +/- 45 512 +/- 41 [8]	MDC90 = 54.1 meters (post stroke)[9]
Energy Expenditure Index (EEI)	Ambulatory children ages 5-18; cognitive and behavioral capability to cooperate with and understand instructions; A convenient means of estimating differences in energy expenditure associated with ambulation at different velocities EEI may be a useful clinical indicator of oxygen consumption index at self-paced ambulation speeds in children with spastic diplegia CP[10]	Ambulation at self-paced velocity for six minutes; exercise HR calculated as average HR during the 4th and 5th minute; velocity calculated as meters per minute; EEI calculated as Exercise HR – Resting HR, all divided by gait velocity; final unit is beats per meter.	0.3 to 0.4 for self- selected walking[10-12]		No evidence to date for responsiveness, MDC or MCID

ETABLE 2.2 Single Task Activity Level Outcome Measures—cont'd

RUNNING

Test	Who Should This Test be Used with? (Age/ Diagnosis)	Procedures/ Administration	Norm Referenced Info	Criterion Referenced Info
4 X 30' shuttle run	Ambulatory children > 3 years, with goals related to increased participation with age-matched peers	Standing start; run to a line 30' away, pick up a block, return to starting line and place block there, run back to the 30' line and pick up another block, and then run back through the starting line.	Ages 5 – 18 years; values are estimates based on graphed data from the Motor Performance Study of Michigan State University.[13] 5 years: 15.8 seconds 10 years: 12.2 seconds 15 years: 10.5 seconds 18 years: 9.5 seconds	
10 X 5 meter shuttle run	Ambulatory children > 3 years with goals related to increased participation with age-matched peers	10 runs of five meters at a maximum pace; distance (5 m) marked by two taped lines on the floor and by cones. The subject runs as fast as possible to each line, places at least one foot on each line, make a turn and run back as fast as possible	Level I of GMFCS = 27.5 +/- 5.6 seconds Level II of GMFCS = 38.5 +/- 9.9 seconds[14]	
Running speed-30 yards	Ambulatory children > 3 years with goals related to increased participation with age-matched peers	5 yard running start	Ages 5 – 18 years; values are estimates based on graphed data from the Motor Performance Study of Michigan State University.[13] 5 years: 6.7 seconds 10 years: 5.0 seconds 15 years: 4.2 seconds 18 years: 3.8 seconds	

MOTOR SKILLS AND BALANCE

Test	Who Should This Test be Used with? (Age/ Diagnosis)	Procedures/ Administration	Norm Referenced Info	Criterion Referenced Info
Standardized Walking Obstacle Course (SWOC)	Ages 4-11 for typically developing children Ages 6-21 for children with Disabilities	39.5 feet long by 36 inches wide; negotiate three directional turns (30 degrees right, 90 degrees left, and 70 degrees right), stepping over an axillary crutch, walking across a visually stimulating mat, stepping around a trash can, walking across a shag rug, and transitioning from sitting to standing and standing to sitting from a chair with arm rests and a chair without arm rests. Note that Figure 1 in this article provides a schematic of this obstacle course.	7.8 seconds (+/- 1.4 sec) 11.6 seconds (+/- 2.8 sec) while carrying cafeteria tray 6 to 21 for children with disabilities 12.7 sec (+/- 4.8 sec) 19.7 (+/- 9.3 sec) while carrying cafeteria tray[14] *Note: can also count # of stumbles and # of steps off	
Standing Long Jump	Ambulatory children > 3 years with goals related to increased participation with age-matched peers	Feet together, jump forward; measure from line to heel of foot closest to line Data are means for each age for TD children (*note: values are extrapolated from graphed data)	Ages 5 – 18 years; values are estimates based on graphed data from the Motor Performance Study of Michigan State University.[13] 5 years: 99 cm 10 years: 140 cm 15 years: 165 cm 18 years: 170 cm (girls); 225 cm (boys)	
Vertical Jump	Ambulatory children > 3 years with goals related to increased participation with age-matched peers		Ages 5 – 18 years; values are estimates based on graphed data from the Motor Performance Study of Michigan State University.[13] 5 years: 15 cm 10 years: 26 cm 15 years: 32 cm (girls); 40 cm (boys) 18 years: 38 cm (girls); 53 cm (boys)

ETABLE 2.2 Single Task Activity Level Outcome Measures—cont'd

MOTOR SKILLS AND BALANCE

Test	Who Should This Test be Used with? (Age/ Diagnosis)	Procedures/ Administration	Norm Referenced Info	Criterion Referenced Info
Timed up and go (TUG)	Ambulatory children > 3 years with goals related to increased participation with age-matched peers, balance, and functional mobility	Modified test for children (ref Williams): Walk and touch a wall; seat at 90 degrees of knee flexion with feet flat; instructions to walk (no qualitative instructions to walk as fast as you can)- use consistent instructions; start timer as soon as child leaves seat and stop when returned to sitting[15]	Age ranges in years 3-5: 6.59 (1.36) 6-9: 5.69 (8.3) 10-13: 5.57 (.75) 14-18: 4.97 (.87)[16] Down Syndrome[17] (organized by percentage scores in dimension E of GMFM): 50-69%: 11.24 (2.47) 70-89%: 9.42 (1.16) 90-100%: 8.17 (1.84) D'Agostini reference Cerebral Palsy GMFCS level I (mean 8.3s, SD 1.8), level II (mean 10.8s SD 1.8) level III (mean 28.1s, SD 13.5).[1616]	MCID Estimate[16] = 2.07 (exceeds 2.0 standard deviations)
Timed Up and Down Stairs	Ambulatory children > 3 years with goals related to increased participation with age-matched peers, balance, and functional mobility	Quickly, but safely go up the stairs, turn around on the top step (landing) and come all the way down until both feet land on the bottom step (landing). The subjects were given the cues "ready" and "go." The TUDS score was the time in seconds from the "go" cue until the second foot returned to the bottom landing. Shorter times indicated better functional ability. Subjects allowed to choose any method of traversing the stairs. This included using a step-to or foot over foot pattern, running up the stairs, skipping steps, or any other variation. However, all subjects faced in the direction of the movement (faced up and down stairs, not to the side) as they traversed the steps.[17]	Norms ages 8-14: 14 stairs, 9.5 cm/stair 8.1 sec (+/- .27) GMFCS Level I 15.5 (+/- 2.4) GMFCS Level II/III 24.5 (+/- 3.83)17	
Functional Reach Test	Children > 7 years of age with goals related to increased standing balance and participation with age-matched peers	Level measuring stick at height of shoulder; Consider 1 arm versus 2 arm reach; consider finger to finger measure versus toe to finger measure; the 2-arm toe to finger is the most reliable measurement strategy[18]	Fist to fist[18] 3 yrs: 11.4 cm (+/- 2.6 cm) 4.5 inches (+/- 1") 4 yrs: 13.6 cm (+/- 3.0 cm) 5.4 inches (+/- 1.2") 5 yrs: 15.7 cm (+/- 4.4 cm) 6.2 inches (+/- 1.7") Finger to finger measures (one arm)[18] 7-8 yrs: 24.69 cm (+/- 4.52 cm) 9.7 inches (+/- 1.8") 11-12 yrs: 33.68 cm (+/- 5.08 cm) 13.3 inches (+/- 2") 15-16 yrs: 36.52 cm (+/- 7.09 cm) 14.4 inches (+/- 2.8") Toe to finger (two arms)[18] 7-8 yrs: 63.73 cm (+/- 5.12 cm) 25 inches (+/- 2.1") 11-12 yrs: 77.88 cm (+/- 5.47 cm) 30.7 inches (+/- 2.2") 15-16 yrs: 88.42 cm (+/- 5.82 cm) 34.8 inches (+/- 2.2")	> 5 cm (2 arm toe to finger method) difference indicates meaningful change[18]

ETABLE 2.3 Multi Item Activity Level Measures

Test	Who Should This Test be Used with? (Age/ Diagnosis)	Procedures/ Administration	Interpretation Information

Alberta Infant Motor Scale (AIMS)	• 0–18 months
	• Typically developing; at risk for developmental delay; diagnosed with conditions that present with immature development
	• Not appropriate for diagnoses like cerebral palsy or myelomeningocele
		• Who – anyone with a background in infant motor development
		• Time – 20–30 minutes
		• Setting – warm, quiet room; infant alert & active, parent present
		• Sequence – observation in each developmental position
			• Norm-referenced
			• Items scored as "observed" or "not observed"; 0 or 1
			• Raw scores for 4 developmental positions are summed converted into percentile ranks
			• Predictive validity at 8 months (cut off at 5th percentile) for later motor impairment at 18 months (as determined by pediatrician):[1]
			  • Sensitivity: 80%
			  • Specificity: 90%
			  • Positive Predictive Value: 70%

Ages and Stages Questionnaire (ASQ-3)	• 1–66 months
	• At risk for developmental delay; identifies children (screening) who would benefit from further evaluation
	• 21 questionnaires (2 month intervals) assess communication, gross and fine motor, problem-solving, personal-social
	• ASQ Learning Activities to help educate families on developmental expectations
		• Who – parents/caregivers complete questionnaire; interpreted by early child educator or health care professional
		• Time – 10–15 minutes
		• Setting – home, clinic, online or phone interview
		• Sequence – complete each item as directed
			• Norm-referenced
			• Items scored yes (10pts), sometimes (5pts), not yet (0pts)
			• Cut-off scores for each age questionnaire; represent performance >2 standard deviations below mean for age
			• Concurrent Validity with BDI[2]
			  • Sensitivity: 86.1%
			  • Specificity: 85.6%
			  • Percent agreement: 85.8%

Assessment, Evaluation and Programming Systems for Infants and Children (AEPS-2)	• 0 to 6 years (0–3, 3–6)
	• With a known disability or at risk for delay
	• Assess fine and gross motor, cognitive, adaptive, social-communication, social development
	• Links assessment, goal development, intervention and evaluation
		• Who – professionals who work with children and their families
		• Time – 30–120 minutes
		• Setting – home, clinic, online via the AEPSinteractive
		• Sequence – test organized by areas, strands, goals, and objectives; Notes related to assistance, modification, behavior, etc.
			• Criterion-referenced
			• Item scored 0, 1, 2
			• Raw scores by area; percent score (% of total possible score by area); cut off scores by age interval for eligibility or differentiate from typically developing child's performance
			• Ability to correctly identify "eligible" vs "ineligible" toddler-aged children[3]
			  • Sensitivity: 100%
			  • Specificity: 89%

Continued

ETABLE 2.3 Multi Item Activity Level Measures—cont'd

Test	Who Should This Test be Used with? (Age/ Diagnosis)	Procedures/ Administration	Interpretation Information

Bayley Scales of Infant and Toddler Development (3rd edition) (BSID-III)	• 0–42 months
	• At risk for delay
	• 5 subscales meet requirements for IDEA (cognitive, receptive and expressive language, fine and gross motor)
	• Parent/Caregiver Questionnaire also available (social-emotional, adaptive)
		• Who – professionals with training and experience with developmental assessment
		• Time – 50–90 minutes
		• Setting – child's natural environment
		• Sequence – establish basal and ceiling for each subscale, administer items within the window of the basal and ceiling
			• Norm-referenced
			• Items scored as 0 or 1
			• Raw scores convert to scaled scores, composite scores, percentile ranks, confidence intervals
			• Predictive validity of BSID-III motor scale (cut off 1 sd, 2 sd below mean) at 2 years for MABC-2 total motor score (5th and 15th centiles) at 4 years
			  • Sensitivity: 18–37%
			  • Specificity: 97–100%
			• And for predicting diagnosis of CP at 4 years[4]
			  • Sensitivity: 67–83%
			  • Specificity: 94–100%
			• Caution for identification of motor delays – not able to differentiate gross and fine motor; BSID-III motor scale has acceptable concurrent validity with PDMS-2 locomotion subscale with age equivalents but not standard scores[5]

Batelle Developmental Inventory (2nd edition) (BDI-2)	• 0–7 years, 11 months
	• identification of disability or developmental delay; evaluating programs
	• Seven domains: adaptive, personal-social, communication, motor, cognitive
	• BDI-2 screening test and BDI-2 data manager and mobile data solution versions for computerized scoring and reporting
		• Who – teachers, special educators, infant intervention providers
		• Time – 10–30 minutes (screening test); 60–90 minutes (full test)
		• Setting – home, clinic
		• Sequence – three administration options: structured, observation, interview; identify basal and ceiling, administer items in the window
			• Norm-referenced
			• Item scored 0, 1, 2
			• Raw scores converted to domain and subdomain standard scores, z scores and percentiles; a change sensitive score is sensitive to change over two administrations
			• BDI-2 screening test accurately classified children with and without delay as identified by the BDI-2[6]
			• The manual reports overall concurrent validity with a variety of developmental assessments including the BSID-2[7]
			  • Sensitivity: 72–93%
			  • Specificity: 79–88%

Bruninks-Oseretsky Test of Motor Proficiency (2nd edition) (BOT-2)	• 4–21 years
	• At risk for motor impairment, to determine need for intervention, evaluate motor training programs
	• Fine motor (fine manual control, manual coordination); Gross motor (body coordination, strength and agility)
	• Computerized scoring and reporting available
		• Who – OTs, PTs, psychologists, adaptive PE, others with training in tests and measures
		• Time – 40–60 minutes (short form 15–20 minutes)
		• Setting – classroom or clinic with chair/desk and large floor space
		• Sequence – all items administered; can administer and interpret Fine Motor or Gross Motor Composite subscales separately; short-form can be used for screening
			• Norm-referenced
			• Raw scores convert to point scores, administer trials as indicated in administration easel; composite standards scores and percentiles based on combined, male, or female norms; 90% and 95% confidence intervals
			• Discriminative validity: able to differentiate typically developing children from those with DCD, intellectual disability, and autism/ Asperger's[8]
			• Responsiveness to change in children with intellectual disability:[9]
			  • MDC90 for Total Composite: 4.18
			  • MID (minimal important difference) for Total Composite: 6.53[9]

Carolina Curriculum for Infants and Toddlers with Special Needs (3nd edition)	• 0–5 years • Two versions, one appropriate for children birth to 3 years, the other for 2 to 5 year olds • Children with mild to severe disabilities; document change over time; track developmental progress • Assess personal-social, cognition, communication, fine and gross motor,	• Who – those with general experience and education in child development • Time – 60–90 minutes • Setting – child's natural environment • Sequence – 24 teaching sequences across 5 domains; suggested adaptations; observation of play session; can give opportunities to practice	• Criterion-referenced • Items scored as mastery/generalization (+), emerging or inconsistent (+/-), unable to demonstrate (-), A (can demonstrate with assistance – only for cognitive/language skills)

ETABLE 2.3 Multi Item Activity Level Measures—cont'd

Test	Who Should This Test be Used with? (Age/ Diagnosis)	Procedures/ Administration	Interpretation Information
Developmental Assessment of Young Children (DAYC)	• Age • At risk for developmental delay or disability • 5 areas assessed: physical development, adaptive, cognitive, social-emotional, communication	• Who – parent/caregiver completes form, • Time – 50–100 minutes • Setting – home or clinic • Sequence – parent reports on developmental milestones, then items are observed and/or challenged	• Norm-referenced • Items scored 0 (not passed), 1 (passed) • Children born pre-term or late pre-term infants (NICU graduates) who were later diagnosed with CP by 3 years had significant decreases in DAYC motor scores between 6 and 12 months; decreases in scores of >10 with C-index of .89 (highly predictive); potential for early identification and intervention[10]
Gross Motor Function Measure (GMFM)	• All ages (validation sample was 5 months to 16 years) • GMFM-66 children with cerebral palsy • GMFM-88 children with cerebral palsy, Down syndrome, osteogenesis imperfecta, developmental delay, brain injury • 5 dimensions include typical motor skills developed by children by 5 years • basal-ceiling and item-set versions of the GMFM-66	• Who – pediatric PTs experienced in assessing motor skills • Time – 45–60 minutes • Setting –floor space with mat, bench, access to stairs • Sequence – GMFM-66 orders items by level of difficulty; dimensions can be administered and scored separately; can be administered with and without orthoses/ aids to assess effectiveness	• Criterion-referenced • Items scored 0, 1, 2, 3 with descriptors; summary score for each dimension and overall • GMFM-66 scores can be entered into the Gross Motor Activity Estimator (GMAE) computer program to convert performance scores to interval scores with standard error for confidence intervals, item maps • Comparison to gross motor curves[11] and percentiles comparing performance to children with CP by GMFCS level[12] • MCID for medium and large effect sizes for GMFM-66 by GMFCS level are available[13]
Hawaii Early Learning Profile Checklist (HELP)	• 0-6 years • Two versions, one 0–3 years, 3–6 years • Areas: regulatory/sensory, fine and gross motor, self-help, cognitive, language, social • Home activity sheets; curriculum	• Who – OT, PT, Nurse, teacher • Time – variable • Setting – child's natural environments • Sequence – organized by area, strands, skills	• Criterion-referenced • Items scored as present (+), emerging or inconsistent (+/-), not present (-)

Miller Function and Participation Scales (M-FUN)	• 2 years, 6 months-7 years, 11 months
	• Known or risk for developmental delay; determine need for intervention
	• Performance (visual motor, fine motor, gross motor games), Participation (checklists for home observation, school observation, test observations)
		• Who – OT, PT
		• Time – 40–60 minutes performance component; 10 minutes participation component
		• Setting – classroom or clinic with chair/desk and large floor space
		• Sequence – visual motor, fine motor, gross motor unless adaptations are needed and recorded; complete behavior ratings for each section
			• Norm-referenced (Performance Component – motor games)
			• Criterion-referenced (Participation Component - checklists)
			• Scoring and points as specified in each game and checklist
			• Can utilize scores from individual sections separately
			• Performance scores converted to standard scores and percentiles, standard error for confidence intervals; performance plots and progress scores
			• Ability to discriminate those with and without motor delays:[14]
			  • Sensitivity: 38–60% (> -2sd from mean); 69–89% (-1sd from mean)
			  • Specificity: 80–100%

Continued

ETABLE 2.3 Multi Item Activity Level Measures—cont'd

Test	Who Should This Test be Used with? (Age/ Diagnosis)	Procedures/ Administration	Interpretation Information

Movement Assessment Battery for Children (2nd edition) (MABC-2)	• 3–16 years (four age bands: 3–6 years, 7–10 years, 11–16 years)
	• With motor/coordination difficulties; aids in identifying DCD
	• 3 sections: manual dexterity, ball skills, static and dynamic balance
	• Checklist (5–12 years) on home and school tasks; completed by OT, PT, teacher, other adult familiar with child; parent input
		• Who – PT, OT, SLP, psychologist, special educator, those with training in assessment
		• Time – 20–40 minutes (checklist 10 minutes)
		• Setting – classroom or clinic with chair/desk and large floor space
		• Sequence – administer all 8 items for age band in order, allow specified practice attempts and trials; best performance is scored
			• Norm-referenced
			• Raw scores converted to component standard scores and percentiles for each component, an overall standard score and percentile; standard error for confidence intervals
			• Recommended cut-off scores: 6th-15th percentile indicate at risk of motor difficulty; below 5th percentile indicate significant motor difficulty[15]
			• Responsiveness to change in 6–12 year old children with DCD:[16]
			  • MDC90 = 1.21 points on Total Score
			  • MID = 2.36 to 2.50 points on Total Score
			  • All scales except balance were sensitive to change in performance

Pediatric Balance Scale (PBS)	• 5–15 years
	• With motor/balance deficits
	• Items related to static and dynamic balance skills
		• Who – pediatric therapists
		• Time – 15 minutes
		• Setting – clinic, school, home
		• Sequence – 14 items scored from 0-4
			• Criterion-referenced
			• Normative values and cutt off scores by age available[17]
			• Responsiveness to change in children with CP[18]
			  • MDC = 1.59 points on Total Score
			  • MDC = 0.79 points on Static items
			  • MDC = 0.96 points on Dynamic items
			  • MCID = 5.83 points on Total Score
			  • MCID = 2.92 points on Static items
			  • MCID = 2.92 points on Dynamic items
			• Predictive validity in children with CP[18]
			  • PBS with GMFM-66 = 0.90-0.92
			  • PBS with WeeFIM = 0.43-0.76

Peabody Developmental Motor Scales (2nd edition) (PDMS-2)	• 0–71 months
	• Suspected to have motor difficulties/ delays
	• Gross motor (reflexes, stationary, locomotion, object manipulation), Fine motor (grasping, visual motor integration)
	• Motor activities program based on the test available for use in intervention
	• Computerized scoring and reporting available
		• Who – OTs, PTs, psychologists, adaptive PE, others with training in tests and measures
		• Time – 45-60 minutes
		• Setting –classroom or clinic with chair/desk and large floor space
		• Sequence – predetermined starting points by age; establish basal and ceiling; administer items within the window of the basal and ceiling
			• Norm-referenced
			• Items scored 0, 1, 2, with descriptors; summary score for each subtest converted to standard score and percentile; subtest standard scores summed and converted to Fine Motor Quotient, Gross Motor Quotient, and Total Motor Quotient; z scores and standard error for confidence intervals
			• Responsiveness to change in 2–5 year old children with CP:[19]
			  • Average Percentage* change score TMQ subtests of at least 2.2%
			  • Average Percentage* change score on GMQ subtests or FMQ subtests of at least 2.6%
			* percentage scores were obtained from raw scores – the percentage of the total score achieved for a quotient area

ETABLE 2.3 Multi Item Activity Level Measures—cont'd

Test	Who Should This Test be Used with? (Age/ Diagnosis)	Procedures/ Administration	Interpretation Information

Pediatric Evaluation of Disability Inventory PEDI-CAT	• 6 months-7 years 6 months (PEDI); 0–21 years (PEDI-CAT)
	• Identify and describe functional impairment; monitor progress and outcomes
	• PEDI: self-care, mobility, social function; each assessed on 3 scales – functional skills, caregiver assistance, modifications
	• PEDI-CAT: daily activities, mobility, social/cognitive, responsibility
		• Who – parents/caregivers/ practitioners; scoring and interpretation: should have familiarity with tests and measures
		• Time – 45–60 minutes (PEDI); 10–25 minutes (PEDI-CAT)
		• Setting –structured interview with parent/caregiver (PEDI); via parent/ caregiver/ practitioner via computer or tablet (PEDI-CAT)
		• Sequence – PEDI – administer questions in order for each area; PEDI-CAT – computer starts with a question in middle range of difficulty and adjusts based on the respondents' answers; two versions: speedy and content balanced
			• Norm-referenced (standard score, T score, percentile)
			• Criterion-referenced (scaled score) – for the PEDI, if child is >7.5 years of age but functional skills are at or below that age
			• Items on the PEDI: functional skills scored 0 (unable) or 1 (capable); caregiver assistance on a 6 point scale, modifications by the number of devices used; PEDI-CAT:
			• Standard error for confidence intervals, Fit score, item maps
			• Responsiveness to change:
			  • MCID for PEDI (inpatient rehab): 11 points[20]
			  • Effect size and SEm (standard response mean): >.8; higher responsiveness noted with children with younger than 4[21,22]

School Function Assessment (SFA)	• Children attending kindergarten through 6th grade • With a variety of disabilities that impact school participation • Functional tasks that support participation in elementary school; 3 components (participation, task supports, activity performance)	• Who – one or more school personnel familiar with the child • Time – 1.5–2 hours • Setting – adults rate child based on observations on multiple occasions in school • Sequence –	• Criterion-referenced • Separate rating scales (Likert) with descriptors for each component of the test • Criterion score generated each for participation, task supports, and activity performance; standard error for confidence intervals
Transdisciplinary Play Based Assessment (TPBA-2)	• 6 months-6 years • At risk for developmental delay; helpful with children who can't b assessed in other ways • To determine eligibility and develop intervention plans • Assesses sensorimotor, emotional and social, communication, and cognitive • Strengths-based, family-focused	• Who – transdisciplinary team members; includes family and child • Time – variable • Setting – child's natural environments • Sequence – observation of play; qualitative assessment; structured and unstructured facilitation of skills	• Criterion-referenced; uses multiple sources of information across multiple settings • 1-9 point scale • Determine skill level with age tables (not norms), learning style, interaction patterns,
Test of Gross Motor Development (2nd edition) (TGMD-2)	• 3–10 years • suspected or have gross motor difficulties or delays • Two subtests: Locomotor (run, hop, gallop, leap, horizontal jump, slide) and Object Control (strike ball on tee, dribble, catch, kick, overhand throw, underhand roll)	• Who – PTs, adaptive PE, others with knowledge of motor skills and test and measures • Time – 15–20 minutes • Setting – classroom or clinic with large floor space and wall • Sequence – demonstrate and describe each item prior to administration; two test trials per item, both trials are scored and used in the raw scores	• Norm-referenced • Ratings (dichotomous, 0 or 1) for each item are based on the quality and maturity of the skill; two trials per item are added together (highest score per item within a skill is 2); total scores for skill and subtest; subtest raw scores converted to standard scores; subtest standard scores summed for the Gross Motor Quotient with percentiles

Test of Infant Motor Performance (TIMP)	• 34 weeks postconceptual age-4 months post-term
	• Assess functional motor behavior: posture and movement skills, identify infants at risk for later motor impairment; evaluate effectiveness of intervention
	• Online version available
		• Who – practitioners experienced with handling fragile infants
		• Time – variable
		• Setting – warm, quiet area
		• Sequence – observation during infant spontaneous activity, head control in supported sitting, postural control in a variety of positions
			• Criterion-referenced
			• Age standards, percentiles established through research[23]
			• Predictive validity, at 3 months, TIMP cut off z score at >.5:
			  • Predict AIMS score at 12 months[24]
			  • Sensitivity: 92%
			  • Specificity: 76%
			  • Predict PDMS score at 4 years[25]
			  • Sensitivity: 72%
			  • Specificity: 91%

ETABLE 2.3 Multi Item Activity Level Measures—cont'd

Test	Who Should This Test be Used with? (Age/ Diagnosis)	Procedures/ Administration	Interpretation Information

Functional Independence Measure for Children (WeeFIM)	• 6 months to 7 years; 0–3 year old module completed by parents
	• Assess self-care, mobility, cognition
	• Can be used with children >7 if functional abilities are at or below what is expected for a typical 7 year old
	• National database available; training required; subscription
		• Who – trained practitioners; must pass certification process
		• Time – 20 minutes
		• Setting – any – commonly used in acute care, rehabilitation
		• Sequence – observation and/or direct interview; rate performance on 7 level ordinal scale of range of functioning and independence
			• Norm-referenced
			• Responsiveness to change by GMFCS level in children with CP (Mobility scale noted here – see full reference for self-care and cognition)[13]
			  • MCID (large effect sizes) GMFCS level I = 3.0
			  • MCID (large effect sizes) GMFCS level II = 7.1
			  • MCID (large effect sizes) GMFCS level III = 4.3
			  • MCID (large effect sizes) GMFCS overall = 3.9

ETABLE 2.4 Standardized Multi Item Tests at the Participation Level of the ICF

Test	Who Should This Test be Used with?	What is Important to Know About Administering This Test	Criterion Referenced Info for Interpretation
Canadian Occupational Performance Measure (COPM) http://www.caot.ca/copm/index.htm.	Ages 8 – adult *(Note- can be used with younger children and children with cognitive delays, but this requires inclusion of caregiver to aid in test administration); establishes client self-perception of occupational performance over time; areas include self-care, productivity, and leisure.	Typically administered by occupational or physical therapists; identify through interview process, occupations that the client needs or wants to perform, but which are not done satisfactorily- Client self-rates on performance and satisfaction with each of the 1-5 goal areas (on a 0 – 10 scale from not able/ satisfied to extremely able/ satisfied). Scores are totaled and then that score is divided by the total number of problem areas	Change score of 2 or more is clinically important[1,2]
Activities Scale for Kids (ASK) Self report questionnaire (Children under age 9 may require parental assistance) http://www.activitiesscaleforkids.com/.	Children 5-15 years of age with limitations in physical activity due to musculoskeletal disorders	Two versions: Performance (what the child "did do" in the past week) and Capability (what the child "could do" in the past week;) leads to single summary score	Valid, reliable, and responsive to change[3,4]
Children's Assessment of Participation and Enjoyment (CAPE) and Preferences for Activities for Children (PAC) http://www.pearsonclinical.com/therapy/products/100000481/childrens-assessment-of-participation-and-enjoyment-cape-and-preferences-for-activities-of-children-pac-capepac.html?Pid=076-1606-432&Mode=summary.	Children and youth ages 6-21; involvement in the day to day formal and informal activities of childhood; activities outside of mandated school curriculum; the PAC taps into children's preferences	Self-administered booklet- activities within the past 4 months; takes 30-45 minutes	Participation dimensions- did the child perform the activity? How often the child did the activity; with whom, where, and enjoyment; Five activity types: recreational, active physical, social, skill-based, self-improvement; Responsiveness remains unknown[2]
Child and Adolescent Scale of Participation (CASP) http://sites.tufts.edu/garybedell/measurement-tools/.	Children 5 years of age and older with traumatic and other acquired brain injuries; also appropriate for children with other diagnoses;	Self-administered questionnaire or interviewer administered; 20 items- takes about 10 minutes; total or subsection summary scaled scores	4 subsections: home participation, community participation, school participation, and home and community living activities; useful for individualized intervention planning; no evidence to date for responsiveness
Pediatric Outcomes Data Collection Instrument (PODCI)	A patient self-report or parent-proxy measure of functional ability in children with orthopedic limitations.	Primary scales of the measure include upper extremity function, transfers and mobility, sports and physical function, comfort and pain, happiness and satisfaction, and expectations for treatment. Each with a possible range from 0 – 100; lower scores indicate better functioning	MCID[5]: Parent Global Function: GMFCS Level I = 7.2 Level II = 7.9 Level III = 4.5 Parent Sports: Level I = 7.3 Level II = 9.7 Level III = 9
Assistance to Participate Scale (APS) http://www.canchild.ca/en/measures/assistance_participate_scale.asp.	measures the assistance that a school-aged child with a disability requires to participate in play and leisure activities at home or in the community, from the primary caregiver's perspective;	Questionnaire designed for mothers/ caregivers of children with disabilities ages 5-18; three different scores: APS-Home alone; APS-Community social and APS-Total; higher scores = less assistance required; scores can be converted to interval scores (0-100)	An outcome measure and to evaluate and predict the amount and type of additional assistance families need to facilitate their child's participation in an important aspect of the child's daily life and development: play and recreation.
Participation and Environment Measure for Children and Youth (PEM-CY) http://participation-environment.canchild.ca/en/participation_environment_measure_children_youth.asp.	Measures participation in the home, school and community, along with environmental factors within each of these settings	For parents of youths ages 5-17, with and without disabilities; takes 25–40 minutes; 25 types of activities grouped into three settings: home, school, and community; for each setting there are questions about participation and the environment	Electronic version Includes a feature that produces a participation profile for the child based on the information provided

ETABLE 2.4 Standardized Multi Item Tests at the Participation Level of the ICF—cont'd

Test	Who Should This Test be Used with?	What is Important to Know About Administering This Test	Criterion Referenced Info for Interpretation
Goal Attainment Scaling (GAS)	Individualized outcomes- may be based on baseline performance on impairment, single task activity level measures and/or specific participation level goals for the child and family	Each outcome is scaled to 5 levels of attainment: expected level, two outcomes that are less favorable and two outcomes which are more favorable- therefore measures amount of change and not just whether goal was attained; T score can be calculated for multiple goals (mean = 50, SD = 10) * see below) [6,7]	Evidence for content validity and responsiveness[2]
GAS T Score Calculation[7] Xi = level of attainment (–2, –1, 0, +1, +2) 2 goals: T= 50 + 6.20 (X1 + X2) 3 goals: T = 50 + 4.57 (X1 + X2 +X3) 4 goals: T= 50 + 3.62 (X1 + X2 +X3 + X4) 5 goals: T= 50 + 3.02 (X1 + X2 +X3 + X4 + X5)			
MPOC http://www.canchild.ca/en/measures/mpoc.asp.	Self-report measure of parents' perceptions of the extent to which the health services they and their child(ren) (ages 0–17 years) receive are family-centered	MPOC 56 and a shorter MPOC 20 version are available. The MPOC 56 takes about 15-20 minutes to complete	Very useful tool for program evaluation and a theoretically sound measure of family centered care [8]
Patient Reported Outcome Measurement System (PROMIS)[9] http://www.medicaljournals.se/jrm/index.php?option=com_content&view=article&id=9&Itemid=18.	Patient (or parent proxy) reported outcomes in a variety of areas including pain, fatigue, and mobility		
Peds Quality of Life Measure (PEDS QL) 4.0 http://www.pedsql.org/index.html.	Ages 2–18 years; Assesses health-related quality of life in children in various diseases areas. Applicable for healthy school and community populations, as well as pediatric populations with acute and chronic health conditions; domains include physical, emotional, social, and school function	Parent proxy and child report versions	Used with multiple pediatric populations; reliability and validity demonstrated in healthy and patient populations[10]

TABLE 2.1 Various Assessments of Sophia During NICU and Follow-up

Age	Measure	Overall Results	Analysis and Interpretation
34 weeks (PMA)	GM	Cramped synchronized general movements	This movement pattern during the preterm period is associated with a higher likelihood of later diagnosis of motor impairment including cerebral palsy.[9,19,51]
36 weeks (PMA)	TIMP	35 (95% CI 17–53) z score: −.93	TIMP at 3 months (CA) is predictive of motor development on the AIMS at 12 months (CA). Standard error of the measurement (SEM) of the TIMP is 9[18]; 95% CI around the TIMP score is +/− 18 (1.96 × SEM). For scores at 2 and 4 months, even at the high range of the 95% CI the z score is < the −.05 cutoff point suggested for predictive ability of the TIMP.[13,40] Even though her scores improved over time, there is evidence that her progress is not keeping pace with expected developmental progress over time. There is ample evidence to make a referral for and continue intervention and follow-up.
2 months (CA)	TIMP	60 (95% CI 42–78) z score: −1.83	
4 months (CA)	TIMP	90 (95% CI 72–108) z score: −1.88	
6 months (corrected age)	AIMS	20 (95% CI 18.5–21.5) Percentile: between 5th–10th z score: −1.5	AIMS predictive validity at 4 months (cutoff 10th percentile) and 8 months (5th percentile) for identifying infants with poor motor performance at 18 months.[18] Predictive validity studies of the TIMP used AIMS scores <5th percentile at 12 months as an indicator of motor impairment.[13] Sophia's performance on the TIMP suggested she might have motor impairment at 12 months on the AIMS, which indeed was confirmed. There is continued evidence in support of intervention, and further investigation into a diagnosis of motor impairment may be likely given her inability to keep developmental progress as noted by declining z scores over time.
12 months (corrected age)	AIMS	43 (95% CI 41.75–44.25) Percentile: below 5th z score: −2.12	
2 years (corrected age)	PDMS-2 (TMQ)	79 (95% CI 73–85) Percentile: 8th z score: −1.40	Sophia's performance is below her same-aged peers with a z score of −1.4 indicating that she performs at 1.4 standard deviations from mean performance for children her age, which equates to the 8th percentile (92% of children perform better than she does at this age). Her performance compared to peers decreased significantly from 2 years to 4 years (SEM for 24–35 and for 48–59 months = 3; 95% CI = 1.96 × SEM). There is no overlap in the two confidence interval ranges, so we can be sure that this difference in performance is not due to potential error or variability of the measure. She continues to perform below her peers and qualifies for therapy services. Should the z score of >1.5 be a cutoff for services, despite her performance at age 2, her therapist can use the 95% CI (the lower bound score of 73 is a z score of −1.8).
4 years (corrected age)	PDMS-2 (TMQ)	66 (95% CI 60–72) Percentile: 1st z score: −2.27	

Unless otherwise reported from the literature, z scores, percentiles, and SEM to calculate the 95% CI are available in the measure's manual.
AIMS, Alberta Infant Motor Scale; GM, Prechtl's General Movements; PDMS-2, Peabody Developmental Motor Scales (2nd edition); TIMP, Test of Infant Motor Performance; TMQ, total motor quotient.

comprehensive assessment of developmental status in a variety of relevant domains (Table 2.2).[49]

Evaluation of Change of Time

How has Sophia's motor function changed over time? What has been the result of intervention?

By the time Sophia reaches school age and enters elementary school, she has officially been diagnosed with cerebral palsy, Gross Motor Classification System level II.[54] She qualifies for special education and related services under the Individuals with Disabilities Education Act based on her diagnosis. Her motor function continues to be below age expectations, and that has a direct impact her participation in school. Results of those outcome measures related to motor function as she progresses through elementary school are presented in Table 2.3.

Case 2: Jacob

Jacob is a 4-year 8-month-old male with a diagnosis of Down syndrome (DS). He has been referred to outpatient physical therapy by the physical therapist at his preschool due to concerns about his gross motor skill in preparation for his attendance at kindergarten within the next 12 months. Jacob's mother and father identify improved running, jumping, and ability to safely and efficiently walk up and down the stairs as primary goals. During the initial examination the tests and measures collected are shown in Tables 2.4 to 2.7.

Clinical decision: A 6-month episode of care with an emphasis on parent goals.

Measures collected during the initial episode of care are shown in Tables 2.8 to 2.10.

Measures collected during this time are shown in Tables 2.11 to 2.13

The decision to continue with a consultation level of service is based on a comparison of scores to previous performance and to norms for DS where appropriate. It is important to continue to collaborate with the family on goals and to identify community resources and fitness options.

Measures collected during this episode of care are shown in Tables 2.14 to 2.16

This category reflects the decision for a 6-week episode of care, referral for nutrition counseling, focus on fitness-related goals, and preparation for high school.

TABLE 2.2 Results from Two Administrations of the Battelle Developmental Inventory, 2nd Edition (BDI-2), One Year Apart

Age	BDI-2 Domain	Raw Score	Standard Score	Percentile Rank	Z score	Analysis and Interpretation
10 months (7.5 CA)	Adaptive	0	55	0.1	−3.00	Eligibility for EI in Sophia's state: ≤2 standard deviations (SD) below the mean in one domain or 1.5 SDs in two domains; she qualifies based on her motor performance alone but also has significant deficits in adaptive function. Z scores reflect the number of SDs from the mean (see Fig. 2.1).
	Personal-social	31	100	50	0.00	
	Communication	24	89	23	−0.73	
	Motor	24	69	2	−2.07	
	Cognitive	26	90	25	−0.67	
	Total	105	80	9	−1.33	
22 months (19.5 CA)	Adaptive	21	75	5	−1.67	Sophia received intervention for 12 months; increased adaptive function has been noted; new deficits are noted especially in the area of communication that warranted additional evaluation; motor skills have not improved when compared to age, but she has gained skills. Sophia continues to qualify for EI and additional services are provided.
	Personal-social	36	80	9	−1.33	
	Communication	30	63	1	−2.47	
	Motor	60	71	3	−1.93	
	Cognitive	30	77	6	−1.53	
	Total	177	67	1	−2.20	

TABLE 2.3 Results of Outcome Measures through Elementary School

Age Measure	Overall Results	Analysis and Interpretation
4 years PDMS-2 (TMQ)	66 (95% CI 60–72) Percentile: 1st z score: −2.27	• A TIMP cutoff z score of <−0.5 at 3 months correctly identified 87% of children who would later be classified as having motor impairment via a z score of <−2 on the PDMS-2 at 4 years.[40] • Sophia's performance is well below same-aged peers (z score of ≥ −2 at 4 and 5 years). • Her performance compared to peers did not decrease between 4 and 5 years of age and may not have improved enough to be significant; she kept developmental pace with other children her age, but she did not "catch up" to her peers. • 95% confidence intervals (1.96 × SEM) were calculated from the reported SEM (TMQ 48–59 months = 3, 60–71 months = 2); since the 95% CI ranges for 4 years and 5 years overlap, it is possible Sophia's true score could fall in each of those ranges, so these scores do not statistically differ from each other.
5 years PDMS-2 (TMQ)	70 (95% CI 68–74) Percentile: 2nd z score: −2	
4 years GMFM-66 using the GMAE	54 Percentile: 50th	• GMFM-66 scores were converted to interval scores using the GMAE. • Performance on GMFM-66 can be plotted on growth curves for children with CP[64]; changes in percentile scores can vary over time and may not reflect true change in ability; the GMFM-66 score change is a more appropriate assessment of motor ability, as the percentile compares Sophia to other same-aged children with GMFCS level II.[31] Note these percentile ranks are not like others reported for Sophia, as the others compared her to same-aged children without motor impairment. • MCID for large effect sizes for the GMFM-66 with children at GMFCS level II is 1.5[52]; the 6-point change from 4 years to 6 years exceeds the MCID and moves the child from the 50th percentile to 45th when compared to other level II peers; one could argue that the change, though clinically important, also demonstrates that the child kept pace with peers with CP—still very close to "average" expectations given her diagnosis and GMFCS level. • The 1-point change in GMFM-66 score from 6 years to 8 years does not exceed the MCID and the child actually appears to have lost ground when compared to other level II peers, dropping from the 45th percentile to the 25th percentile.
6 years GMFM-66 using the GMAE	60 Percentile: 45th	
8 years GMFM-66 using the GMAE	61 Percentile: 25th	
8 years PEDI-CAT	Daily Activities: • T score: 40 • Percentile: 18 Mobility: • T score: 30 • Percentile: <5	• Daily Activities and Mobility domains of the PEDI-CAT were followed over time as Sophia progressed through elementary school to middle school. • Progression in her skills with respect to how she compares to her peers in daily functional activities are noted in her improvements from a T score of 50 (1 SD below the mean, and just under the 20th percentile for age) to 50 (within average expectations for age at the 50th percentile). • While making marked improvements in her daily activities, Sophia's mobility function was relatively stable from 8 years to 10 years, and a movement from a T score of 30 to a T score of 35 shows a movement from 2 SDs below the mean for age to 1.5 SDs below the mean. • The PEDI-CAT manual[27] notes that T scores between 70 and 30 represent 2 SDs above or below the mean and are within averaged expectations for age. If using T scores or percentiles to qualify for services, either can and should be used in decision making. • Sophia experienced her adolescent growth spurt early and has had challenges with her weight since she entered her preteen years. She has also experienced a decrease in her overall activity level (increase in sedentary time as she became more focused on school and was less involved in recreational activities). These are factors to be considered when interpreting her scores. The fact that her mobility did not decrease but remained stable or slightly increased over time may be attributed to her continued involvement with intervention and home activity programs to maintain her overall fitness and mobility.
10 years PEDI-CAT	Daily Activities: • T score: 45 • Percentile: 32 Mobility: • T score: 30 • Percentile: <5	
12 years PEDI-CAT	Daily Activities: • T score: 50 • Percentile: 50 Mobility: • T score: 35 • Percentile: 7	

Unless otherwise reported from the literature, z scores, percentiles, and SEM to calculate the 95% CI are available in the measures manual.

TABLE 2.4 Jacob Baseline-Impairment Level Data

	Baseline Score	Interpretation
Quad Muscle Strength- Dynamometer (Newtons)	49	Well below age- and gender-matched norm[6]
Height (cm)	95	50th percentile
Weight (kg)	12.5	25th percentile
BMI (kg/m^2)	13.8	10th percentile

Note: Percentiles are based on the population of children with DS.[47]

TABLE 2.5 Jacob Baseline-Single Task Activity Level Data

	Baseline Score	Interpretation
5× Sit to Stand (sec)	14	
5× Step-ups (sec)	30	
6-Minute Walk (m)	Refuses due to behavior and cognitive limitations	N/A
Standing Broad Jump (cm)	Unable	N/A
30-Yard Running Speed (sec)	16 seconds	Slow, immature, disorganized pattern; norm for age-matched peers is approximately 7 seconds[43]
Timed Up and Down Stairs (sec)	32 seconds for nine stairs (1.78 seconds/stair) Intermittent reciprocal pattern when ascending, step to pattern when descending, with railing	Mean TUDS for chronologic age 8–14 years = 0.58 s• step-1[79]
Timed Up and Go (sec)	13.5 seconds	Norm for age-matched peers = 6.59 +/− 1.36 seconds[50] Norm for children with Down Syndrome who score 50%–69% on Dimension E of the GMFM = 11.24 +/− 2.47 seconds[50]

TABLE 2.6 Jacob Baseline- Multi Item Activity Level Data

	Baseline Score	Interpretation
GMFM 88	73%*	Low for age and diagnosis[55]
Pediatric Balance Scale	34	> 2 standard deviations below mean for age- and gender-matched peers[25]

*GMFM score allows determination of a 34% conditional probability that Jacob will be able to walk up at least two steps from the base of the stairs (alternating feet, without holding on) by age 5 and a 41% conditional probability that he will jump forward (at least 2 inches, both feet simultaneously) by age 5.[55]

TABLE 2.7 Jacob Initial Episode of Care- Goal Attainment Scaling Information

Goal	−2 Score	−1 Score	0 Score	+1 Score	+2 Score
Improve TUDS to 1.4 second/ stair (total)	1.77 (32 seconds)	1.6 (29 seconds)	1.4 (25.2 seconds)	1.25 (22.5 seconds)	1 (18 seconds)
Improve 30-yard running speed to 12 seconds	16	14	12	10	8
Improve standing broad jump to 2 cm	Unable	2-foot take-off and landing	2 cm	4 cm	6 cm

TABLE 2.8 Jacob Initial Episode of Care- Impairment

	Baseline Score	6-Month Score	Interpretation
Quad Muscle Strength-Dynamometer (Newtons)	49	53	Remains well below age- and gender-matched norm[6]
Height (cm)	95	97	50th percentile
Weight (kg)	12.5	13	25th percentile
BMI (kg/m^2)	13.8	13.8	10th percentile

Note: Percentiles are based on the population of children with DS.[47]

TABLE 2.9 Jacob Initial Episode of Care- Single Task Activity

	Baseline Score	Biweekly Scores						6-Month Score	Interpretation
5× Sit to Stand (sec)	14	15	21	17	19	16	15	15	No change in this outcome
5× Step-ups (sec)	30	27	26	28	24	22	19	18	Approximately 30% improvement reflects improved motor control with this task
6-Minute Walk (m)	Refuses–due to behavior and cognitive limitations								
Standing Broad Jump (cm)	Unable	0	0	0	0	3	3	4	Achieved this skill; requires continued practice to refine and improve GAS score: +1
30-Yard Running Speed (sec)	16	16	17	16	15	15	14	13	Approximately 20% improvement; still slow compared to age-matched peers[43] GAS score: −1
Timed Up and Down Stairs (sec)	32 Intermittent reciprocal pattern when ascending, step to pattern when descending, with railing	32	31	27	28	31	27	23	Approximately 28% improvement; GAS score: +1
Timed Up and Go (sec)	13.5 seconds	13.5	12	13.1	11.4	12	11	10.8	Approximately 20% improvement exceeds MCID estimate of 2.07 seconds; score is within normal range for age, diagnosis, and current level of gross motor function[50]

TABLE 2.10 Jacob Initial Episode of Care- Multi Item Activity

	Baseline Score	6-Month Score	Interpretation
GMFM 88	73%*	84%	Significant improvement beyond MCID[52]; age-appropriate score for diagnosis[55]–justifies decision to discontinue PT and address GM skills through community-based and age-appropriate programs (e.g., TOP-Soccer, swim club).
Pediatric Balance Scale	34	44	MCID for children with CP = 3.66–5.83.[15] A 30% improvement appears to represent meaningful change; however, the score is approximately 1.5 standard deviations below the mean for age- and gender-matched peers.[25]

*Improvement in goal areas (stairs, running, jumping; GAS T score = 54.57 [score > 50 = better than anticipated change]) along with improvement on GMFM and Pediatric Balance Scale support a change to the consultation service level. Data are provided to the family to share with the school PT; the family is comfortable with the child engaging in community and age-appropriate fitness and recreational opportunities (play in the neighborhood, community swim club, TOPSoccer).

TABLE 2.11 Jacob 6 to 8 Years- Impairment

	Baseline Score: Age 6	Baseline Score: Age 8	Interpretation
Quad Muscle Strength- Dynamometer (Newtons)	79	90	Improving, but still >2 standard deviations below age- and gender-matched norms[6]
Height (cm)	110	120	50th percentile
Weight (kg)	17.5	22.5	25th percentile
BMI (kg/m^2)	13.8	14	10th percentile
			Note: percentiles are based on population of children with DS[47]

TABLE 2.12 Jacob 6 to 8 Years- Single Task Activity

	Baseline Score: Age 6	Baseline Score: Age 8	Interpretation
5× Sit to Stand (sec)	15	14	Performance does not merit PT intervention due to ongoing improvement and participation in age-appropriate family and community fitness and recreational activities
5× Step-ups (sec)	16	13	
6-Minute Walk (m)	400	440	
Standing Broad Jump (cm)	20	50	
30-Yard Running Speed (sec)	11	10	
Timed Up and Down Stairs (sec)	18	14	
Timed Up and Go (sec)	9.8	8.5	

TABLE 2.13 Jacob 6-8 Years- Multi Item Activity

	Baseline Score: Age 6	Baseline Score: Age 8	Interpretation
GMFM 88	80	90	Ongoing improvement and performance at level expected for age and diagnosis, thus there is no need for an episode of care
Pediatric Balance Scale	48	55	Ongoing improvement; score at 6 years of age remains 2 standard deviations below the mean for age and gender-matched peers; score at 8 years is at the mean for typically developing children > 7 years of age[25]

TABLE 2.14 Jacob 14 Years- Impairment

	Baseline Score	Interpretation	6-Week Score	Interpretation
Quad Muscle Strength- Dynamometer (Newtons)	150	Improved but > 2 standard deviations below age- and gender-matched norms[6]	152	Focus of episode of care was on aerobic fitness; continue to monitor leg muscle strength and encourage incorporation of resistance exercises into ongoing fitness/exercise program
Height (cm)	155	BMI is at the 90th percentile for age, gender, and diagnosis[47]; physical therapy intervention is appropriate to address this impairment; referral to a nutritionist also initiated	155	BMI remains at the 90th percentile, but the patient and family are committed to regular fitness and improved nutrition; will monitor at follow-up visit in 6 months[47]
Weight (kg)	66		66	
BMI (kg/m^2)	27.4		27.4	

TABLE 2.15 Jacob 14 Years- Single Task Activity

	Baseline Score	Interpretation	Biweekly Scores			6-Week Score	Interpretation
5× Sit to Stand	———	———	—	—	—	—	———
5× Step-ups	13	Similar to previous scores	12	12	13	12	Focus of episode of care was on aerobic fitness and collaborating with Jacob and his family to establish a sustainable fitness program
6-Minute Walk	420 (Jacob reports an OMNI RPE[31] of 9 at the conclusion of this walk)	Decreased distance (compared to previous years) and high OMNI RPE indicate concern with level of aerobic fitness	425	435	450	455 (OMNI-RPE = 7)	Steady progress, 30-meter increase, and reduction in OMNI-RPE indicate meaningful improvement
Standing Broad Jump (cm)	55	Skill has plateaued—not an area of emphasis during this episode of care	55	54	55	53	Skill has plateaued—not an area of emphasis during this episode of care
30-Yard Running Speed (sec)	9.8	Limited by fatigue	9.9	12	11.5	9	Approximately 20% improvement, perhaps due to improved endurance; performance is variable due to inconsistent motivation with this task
Timed Up and Down Stairs (sec)	14	Limited by motor control especially when descending	13	13	12	10	Focus of episode of care identified as a goal area by Jacob and his family; improvement on this skill necessary for safety and participation in high school with age-matched peers
Timed Up and Go (sec)	8.5	Norm for age-matched peers = 4.99 +/− 0.87 seconds Norm for children with Down syndrome who score 70%–90% on Dimension E of the GMFM = 9.42 +/− 1.15 seconds[50]	8.7	9	8.5	8.5	Not a focus of episode of care

TABLE 2.16 Jacob 14 Years- Multi Item Activity and Participation

	Baseline Score and Interpretation	6-Week Score and Interpretation
GMFM 88	———	———
Pediatric Balance Scale	———	———
Canadian Occupational Performance Measure (COPM)	Priorities: • Better on stairs satisfaction = 2/10 performance = 3/10 • Better fitness satisfaction = 2/10 performance = 1/10 Faster running speed satisfaction = 2/10 performance = 3/10 • Total satisfaction = 2 • Total performance = 2.3	• Better on stairs satisfaction = 5/10 performance = 6/10 • Better fitness satisfaction = 3/10 performance = 6/10 Faster running speed satisfaction = 4/10 performance = 5/10 • Total satisfaction = 4 Improvement ≥ 2 on satisfaction indicates meaningful change • Total performance = 5.4 Improvement ≥ 2 on performance indicates meaningful change[42]
Activities Scale for Kids (ASK)[78]	70 Not participating in team sports or other community recreational opportunities	85 Some improvement here as a result of collaboration with Jacob and his caregivers on options for participation in the community

Improvement on COPM and ASK following 6-week intervention program justifies resumption of a consultative level of services.

Motor Development and Control

Regina T. Harbourne, Stacey Dusing

"Development, then, can be envisioned as a changing landscape of preferred, but not obligatory, behavioral states with varying degrees of stability and instability, rather than as a prescribed series of structurally invariant stages leading to progressive improvement."

Esther Thelen, p 77, Mind as Motion, 1995[313]

Movement expresses our needs, preferences, desires, successes, and interactions with the world. As physical therapists, we are often asked questions about early movement that begin with the word "when." When will my child walk? When will my son sit up by himself? Alternatively, as time passes, the question may be modified from time-based to an absolute: Will my child ever learn to ride a bike? However, as a movement expert the physical therapist must understand much more than the timing of developmental motor milestones. Our questions need to focus on the "how" so that we can provide explanations of *how* a child learns to sit, crawl, stand, and walk. Understanding how a skill emerges benefits us in three ways. First, our predictions become more exact. Knowing the factors contributing to change over time sharpens our estimate of when the next increment of change will occur. Second, understanding how skills emerge allows a therapist to analyze gaps in the contributions to a skill and thus formulate a plan to fill the gap. Finally, understanding the multiple variables that contribute to skill advancement allows versatility in creating intervention suitable to the individual child. In this chapter we will examine in detail the when, how, why, and what of developing motor skill, toward the ultimate goal of building understanding that contributes to effective physical therapy for children with motor needs.

To understand motor development, movement needs to be placed in a context. Motor skill does not develop in a vacuum; motor development depends on individual child factors (physiology, temperament, cognition), and environmental factors such as the immediate microsystem environment (womb, family, home, surroundings, peers), the exosystem environment (extended family, neighborhood, school), as well as the macrosystem environment (community, economic system, culture).[42] Thus the pediatric therapist must consider the layers of influence that build behavior, and she must understand that not all behavior is displayed in every context. For example, a shy child may be unwilling to display her ability to jump or kick a ball in a strange clinical setting, even though she skillfully and delightfully exhibits these skills in her backyard. A hungry infant arching his back and refusing a toy during a testing session might easily sit independently and engage with the same toy once his physiologic needs are met. An infant raised in a culture that does not practice floor play may not exhibit prone skills, even though there is nothing wrong with his extensor musculature. All of these individual, contextual, and cultural factors contribute to wide variability in motor skill development and the variable acquisition of motor control throughout childhood.

Although extensive evidence supports the existence of general developmental trends in motor skill development (Fig. 3.1), strong evidence also reveals wide variability in the acquisition of functional motor skills. What contributes to this variability, and how can therapists capitalize on the flexibility and adaptability of the developing system to build skill within a therapy program? In this chapter we begin by laying a theoretical base for understanding developmental change, with an eye toward historical influences that contribute to ideas that have been evaluated and accepted, rejected, or modified over time based on advances in child development research. We then discuss a current framework for therapeutic motor intervention, which incorporates multiple external factors thought to influence change in children, or the "how" of development. We follow these external factors by detailing the internal factors that influence the child's motor skill: variables within the motor control realm that may be important to consider in determining the "why" questions regarding selection of strategies by children over time. In the third section we describe the acquisition of specific motor skills in greater detail: the "what" and "when" of development. And finally, we provide exemplar stories of children at different ages, with the how, what, why, and when used as a guide to maintain a global view of development within therapeutic practice, yet tailoring that practice toward the needs of the individual child within his or her world.

THEORETICAL BACKGROUND: PERSPECTIVES LEADING TO UNDERSTANDING THE BASICS OF HOW AND WHY MOTOR SKILLS CHANGE OVER TIME

Our understanding of theories of development leads to deeper knowledge of the "how" questions we ask when watching an infant perform a new skill or when we ask "why" a child may not be skillful at a task as we try to create an intervention leading to progress in motor development. Theory drives the way we think and creates the space in which we search for problem solutions. In this section we discuss some major theoretical steps that brought us to currently think in complex ways about development. Importantly, developmental theory springs from contributors outside the motor realm. In fact, much developmental research comes from psychologists and other scientists who are interested in the development of cognition and language and how motor skills contribute to learning.[5] However, early

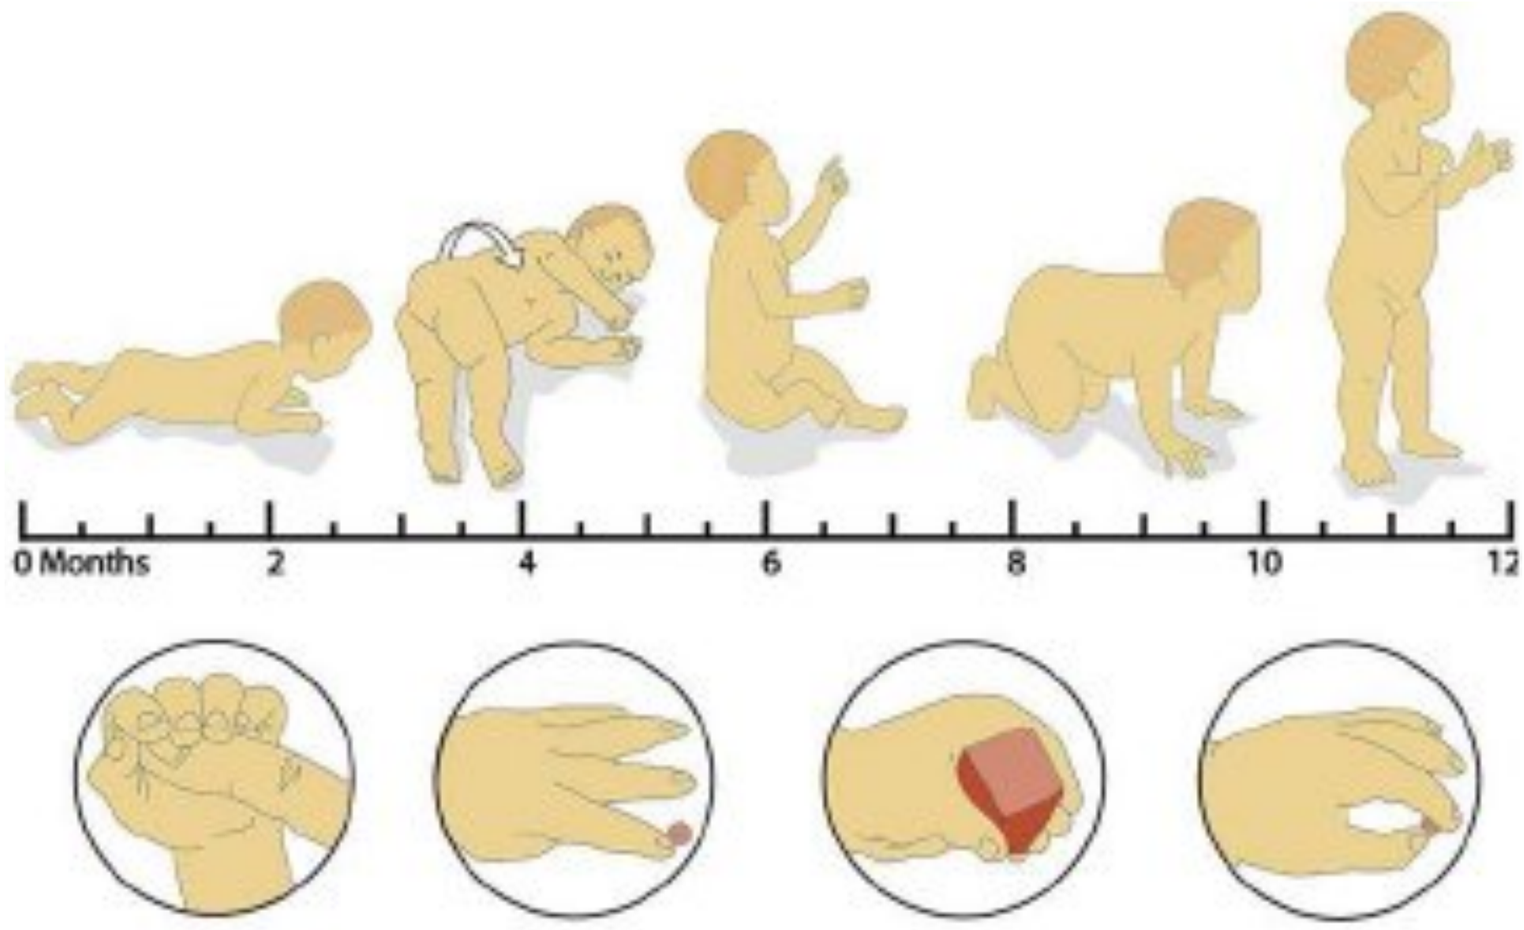

FIG. 3.1 Developmental timeline for several gross and fine motor milestones. (Drawing courtesy Ricardo Solis, Costa Rica.)

theorists used movement and motor skills as a primary means of studying development in all domains. Through movement a child expresses knowledge of the world (cognition), knowledge of how he or she can affect the world (adaptive skills), the exchange of ideas (language), and the connections to others (social/emotional). Thus motor skill reveals much more than simply musculoskeletal information. Movement reveals information about the child's overall development and the effects of other areas on motor skills in a cyclical and ever-changing relationship.

Thelen and colleagues[317] summarized the major theoretical approaches to developmental change as encompassing three world views: (1) neural-maturationist, (2) cognitive, and (3) dynamical systems. Each contributes to a history revealing the strong role that changing biases contribute to the accumulation of new knowledge and the way this knowledge is subsequently interpreted and applied clinically.[19,80,313,314] These theories are reviewed briefly in this chapter, with their major distinguishing features summarized in Table 3.1.

Neural-Maturationist Theories

The neural-maturationist point of view was pioneered by Arnold Gesell,[123,124,125,127,128,126] Shirley,[285] and others. This view proposed that the ontogeny of behavior is "an intrinsic property of the organism, with maturation leading to an unfolding of predetermined patterns, supported, but not fundamentally altered by the environment".[317] According to this approach, functional behaviors appear as the nervous system matures, with more complex behaviors reflecting the activity of progressively higher levels of the nervous system. This theory, therefore, depends on the assumption of a hierarchic maturation of neural control structures. Taking the core concept of the neural-maturationist viewpoint a bit further, one realizes the viewpoint focuses mainly on the child and the child's nervous system. One might even extend the idea to the genetic background of the individual. Thus the roots of this viewpoint, which started in the early 1900s, stem from a worldview that sought to categorize and classify organisms and to predict in a linear fashion what that organism would be like in the future. These neuromaturational views from developmentalists were linked to discoveries about the way the nervous system controls movement and resulting correlations between changes in behavior and changes in the nervous system.

At the same time neuromaturational theory was prominent advances in techniques to stain neuronal cells helped to shed light on the structures of the motor control system.

The notion of "structure-function" and the maturational-based theory of motor control are two theoretical products of the neuron doctrine. Using staining techniques, anatomists found that structural features distinguish subpopulations of neurons within and between regions of the nervous system and that morphologic changes occur during development. The array of morphologic findings led to the view that structural organization of the nervous system determines behavioral function (structure-function). Physiologists provided evidence for structure-function control of behavior by isolating portions of the nervous system that produced stereotypic movements such as the stretch reflex, the brisk contraction of a muscle in response to a quick stretch of the muscle stimulating its proprioceptors. Based on his many studies of reflex function in the spinal cord of cats, dogs, and monkeys, Sherrington espoused the view that behavior is hierarchically organized and the simple reflex (composed of a receptor, conductor, and effector organ) is the fundamental unit of neural integration.[284] Furthermore, he proposed that motor behavior is the composite coordination of simple reflexes (e.g., reflex chaining) as excitatory and inhibitory actions are summated at the synapse. Sherrington's notion of reflex chaining so dominated the study of physiology in the first half of the 20th century that physiologists gave little attention to other views of motor control in explanations of behavior.[121]

Structure-function organization and reflex chaining were commonly employed rationales in studies of motor development because of timing linkages between emerging stimulus-evoked behavior and anatomic changes in neural pathways.[174] Thus early studies identified the neuroanatomic changes occurring around

TABLE 3.1 Comparison of Developmental Theories

	Neural-Maturationist	Cognitive: Behavioral	Cognitive: Piagetian	Motor Learning Theory	Dynamical Systems
View on "stages"	Stages of motor development occur as a result of CNS maturation	Stages are merely empirical descriptions of behavior	Stages represent alternating periods of equilibrium and disequilibrium	No specific developmental stages. Stages of motor learning: cognitive, associative, and autonomous	Apparent stages of development are actually states of relative stability arising from the self-organizing, emergent properties of a multitude of systems, each developing at its own continuous rate
Driving forces for development	Development spirals with alternating periods of flexor vs. extensor dominance and symmetry vs. asymmetry based on maturation of the CNS	Development occurs through interaction of the individual with the environment	Development occurs through interaction between cognitive-neural structures and environmental opportunities for action	Trial and error practice leads to the development of motor programs	The individual develops as the organism recognizes the affordances of the environment and selects (self-organizes) the most appropriate available responses to tasks
Building blocks of development	Reflexes	Pavlovian and operant responses to environmental stimuli	First actions using reflexes and later from voluntary actions	General motor programs, recall schemas, and recognition schemas are the building blocks of learning that contribute to development	Multiple cooperating systems with individual rates of development and self-motivated exploration of the environment

CNS, central nervous system.

the time a new behavior emerged without considering whether other variables such as environmental enrichment or experience[314] contributed to the behavioral change. Consequently, scientists proposed that certain predictable changes during neural maturation cause behavioral change,[165,226] establishing the foundation for maturational theories. Concurrent with these developments, theories of hierarchic reflex chaining evolved to include the notion that reflex behaviors are expressions of an animal's phylogenetic origins, leading to the use of the term *phylogenetic* for basic and early motor skills in the first year of life, such as rolling and crawling.[174] Such views merged into the notions that the earliest movements are primitive behaviors controlled by phylogenetically older neural structures and that these movements eventually disappear or are inhibited by later differentiating neural structures that are phylogenetically more recent.[319] These notions suggested that the development of control of movement is primarily a reflection of internal neural development. It appears there was little or no scientific challenge of these neuromaturational views into the latter half of the 20th century, perhaps because students of development took little notice of other directions in neurobiologic research that were emerging at the time.[121]

In addition to Sherrington, maturationists such as Gesell were influenced by Darwin[223] (evolution theory, natural selection) and Coghill[72] (general movements are intrinsically driven to differentiate into specific behaviors). These influences led Gesell to his study of detailed descriptions of behaviors as they naturally occurred and an appreciation of the relationship between behaviors and the maturation of the nervous system.[314] Thus the neural-maturationist model reflects the idea that the child's nervous system drives changes in behavior, diminishing any consideration of the role of the external environment.

Gesell's point of view and research findings resulted in the development of important tests of motor milestones and other adaptive behaviors that have had, and continue to have, a monumental influence on practice in the area of diagnosis of developmental delay or deviance.[80,314] Virtually all subsequent tests of development contained items derived from Gesell's work. Item examples that appear in current developmental tests include observations of head in midline at 4 months in supine, head control during pull-to-sit maneuver at 5 months, and pulling a dangling ring to the mouth at 4 months. Gesell emphatically believed in stages of development as biologic imperatives. He ultimately observed that there are individual differences among children and toward the end of his career came to recognize the role of environmental factors in development, particularly for their influence on cognitive development. In spite of that realization, he never completely resolved the paradox between the role of environment and his insistence on maturation as the predominant force driving development.

Pediatric physical therapy originally developed based primarily on a neural-maturationist theoretic model. As a result, emphasis was placed on the examination of stages of reflex development and motor milestones as reflections of increasingly higher levels of neural maturation.[167] Examination of reflexes and motor milestones actually continues to dominate clinical tools of a neurologic exam.[266] The presence or absence of reflexive responses to specific stimuli contributes to decision making about the necessity for further testing or possible follow-up for intervention because of suspected neurologic problems.[303] Treatment of the child with central nervous system (CNS) dysfunction in early approaches was organized around inhibition of primary reflexes that were believed to persist and produce activity limitations, along with facilitation of righting

and equilibrium reactions that were supposedly the underlying coordinative structures for development of skilled voluntary motor behavior. It was generally assumed that functional outcomes would naturally follow. However, the utility of examining reflexes to predict future function has been shown to be limited and the evaluation of spontaneous movement to be more accurate in evaluation and prediction of function.[234]

Early pediatric physical therapy approaches to analyzing and treating movement delays or dysfunction, including the Bobath approach, the Rood approach, and the Ayres approach to sensory integration,[322] arose from the neural-maturationist model. The key to recognizing the influence of these approaches lies in their focus on the movement patterns of the child and resulting classification of movement as "primitive" or "abnormal" versus normal. Abnormal movement patterns are interpreted as springing from the excessive influence of an immature, or lower (more primitive), level of the nervous system. Although our purpose here is not to describe therapeutic approaches, an example may clarify the influence of early maturationist theory on the selection of a therapeutic strategy. Imagine a 9-month-old infant being evaluated because of a delay in developing independence in sitting and reaching for toys. The evaluator notes an asymmetrical posture of the infant, such that head turning to the right occurs concurrently with extension of the right arm (a notable tonic reflex in infants around 2 months old). This may be interpreted as an undue influence of a lower level of the brain stem on the infant's movement, blocking the ability of the child to sit and reach (which are considered "higher" level skills in the nervous system). The intervention may be to try and help the infant, through equipment or positioning, to block or inhibit the asymmetrical posture and maintain more midline postures to provoke or stimulate "higher" levels of movement control. These higher levels of the nervous system would inhibit the asymmetrical posture and thus allow the infant to develop sitting and reaching skills over time. From a neural-maturationist viewpoint, milestones would be addressed sequentially, and thus a skill such as standing or walking would not be addressed until "earlier" skills such as sitting and crawling were apparent. This same example of a young child with movement challenges will be used as we briefly review other theoretical viewpoints to illustrate the influence of theory on therapeutic intervention.

Around the same time as Gesell, Skinner[217] popularized his theories of behaviorism. This theory was in opposition to Gesell's because Skinner posited that the environment, via positive or negative reinforcement, was responsible for behavioral change. The driving force was seen as external to the child, rather than the neurologic change within the child. The behavioral approach represented the viewpoint that "nurture," or the external influences on the child, drove changes in behavior and that development was not preordained by genetics or maturational influences, considered "nature." From the behavioral perspective, a child would repeat a movement or action if that action was positively reinforcing in some way. Likewise, if the action elicited a negative reinforcement, the action would be less apt to be repeated. Thus behavioral shaping occurs over time as the environment positively or negatively reinforces specific actions. The behavioral approach of Skinner lies at the roots of approaches currently used today with children diagnosed on the autism spectrum to effect behavioral change.[88] The behaviorist approach does not clearly fit under the neuromaturationist umbrella and could be viewed as a "learning" approach, which may seem to fit under the cognitive umbrella. However, behaviorists did not credit the cognitive system or the nervous system specifically, rather specifying that behavior could be shaped without indicating the mechanism behind the shaping process. As such, behaviorism pushed the boundaries of the maturationist camp, while still noting changes in behavior, but with an external driving force that somehow caused a change, but without directly addressing the mechanism creating that change.

Another person who pushed the boundaries of the maturationist viewpoint was Myrtle McGraw, who was generally considered a member of the maturationist school. However, she developed a theory of motor development in the 1930s that contained the rudiments of many of the components of the modern dynamical systems approach to understanding motor skill development because she actually considered the maturation of the child together with the effect of environment and experience.[19,80,226] Thus she moved beyond the maturationist views of Gesell and the behaviorist view of Skinner. McGraw was a psychologist who famously studied the effects of intensive longitudinal intervention, beginning at 20 days of age, with Johnny, the weaker of twin boys named Johnny and Jimmy. Her research was conducted at the height of the nature-nurture controversy between maturationists (represented by Gesell) and behaviorists (represented by Skinner). In summary, her work showed that providing up to 7 hours a day of exercise of newly emerging developmental skills in the first year of life did not increase the rate of motor development. Her anecdotal comments, however, indicated that the exercised twin had better coordination of movement than the twin whose movements and exploration had been restricted to a crib for much of the day, with no interaction with people other than for needed care.

McGraw's work was interpreted at the time as supporting the neural-maturationist theory that the environment had little effect on child development. In the second year of his life, however, McGraw provided Johnny (the exercised twin) with a stimulating and challenging environment and extensive practice opportunities (3 hours per day) for developing motor skills that were not otherwise likely to develop in a child younger than 2 years, such as roller skating, climbing inclines of 70°, and jumping off high pedestals. Under these conditions, Johnny excelled in physical growth, problem solving of difficult motor control situations, and attainment of skills that Jimmy refused even to try during the periodic testing sessions that occurred. McGraw also noted the remarkable persistence in tasks demonstrated by Johnny, as well as his extensive visual review of the situation before embarking on a task. Films of the twins at age 40 years, moreover, demonstrated that the twin who exercised intensively during the first 2 years had an impressive physique and elegantly coordinated movement compared with those of his twin. Experience practicing novel motor skills, as well as problem solving, likely enhanced the physical development of the trained twin, and the enhanced skillfulness lasted into adulthood.

Although the results of an analysis of two individual cases cannot be accepted as leading to fundamental laws of motor development, McGraw's study makes it clear that we have little idea of the possibilities inherent in the very young child who is seldom stimulated to achieve the full potential of early motor skill development. By analogy, we can assume that we have barely scratched the surface in our understanding of how therapeutic intervention might be used to mitigate the effects of conditions causing motor dysfunction.

McGraw also described the uneven nature of development, in which a given behavior pattern has a period of "inception, incubation, consummation, and decline".[226] The results of her longitudinal studies on the intratask course of development of important motor patterns were published in 1945 and remain highly informative today. Because of her daily observations, she often saw a movement pattern appear only once or twice (examples of beginner's luck) and then disappear before becoming a stable part of the infant's repertoire. When first becoming stable, the activity seems overworked and exaggerated. Furthermore, she noted that "as the child begins to get control over a pattern or an aspect of a pattern, the activity itself becomes the incentive for repetition".[226] Thus, early in life, movement for the sake of movement is a functional activity. The daily observations of infant development conducted by Adolph and colleagues,[7] generally considered in the dynamic systems camp, confirmed that multiple daily transitions in performance skills are present before a stable new pattern emerges. For example, an individual infant may experiment with different versions of crawling (belly crawling forward, pivoting on belly, rocking on hands and knees and lunging forward) within a day, even from cycle to cycle.[7]

McGraw suggested that a stable movement pattern might seem to disappear as a part of the child's repertoire, becoming superseded by some rapidly developing new behavior. Eventually the "disappearing" movement will reappear and be utilized in its most economic form. She was among the first to note the presence of normal regressions in motor behavior and has been credited as one of the first developmental psychologists to recognize the bidirectionality of neural and behavioral development.[19,27,237,256] A behavior may also become integrated with other behaviors to form a complex activity; thus McGraw noted that the developmental course of a behavior may look quite different during different stages of its maturation. For example, an infant with the new skill of walking may become more bilateral in arm use temporarily during early practice of the walking skill.[74] On the other hand, an infant who has developed some skill in walking may insist on walking during a cognitively challenging task when crawling would be a more efficient choice.[21] Although McGraw discussed regressions in development as well as consuming use of a new skill as normal, recent research reveals that a complex interplay of cognition, perception, and movement may explain an ongoing reallocation of resources for the child. Changing allocation of the child's resources during skill acquisition likely contributes to the apparent temporary regression or stubborn use of a particular skill.[20]

Because McGraw noted these various characteristics across many developing movement patterns, she believed that fits and starts, spurts and regressions, and overlapping of patterns undergoing emergence, development, and decline were firm developmental principles and that snapshots of development, such as motor milestone tests, could not adequately reflect the underlying processes of development.[19] The current work of Adolph and colleagues[7] confirms this belief. McGraw firmly believed that there were sensitive periods (she actually used the term "critical period" but later regretted it because of its "use it or lose it permanently" interpretation in biology) in which interventions could produce the most influence on developing behavioral patterns.[14] During a sensitive period, certain experiences have particularly influential effects on development, although these effects may be modified with subsequent experience.[43] McGraw believed that the period of greatest susceptibility to exercise was one in which a behavior pattern was entering its most rapid phase of development. Delay did not mean that intervention could no longer affect the behavior pattern (the concept of critical period) but rather that the interference of other ongoing developmental programs, including changes in anthropometric configuration of the body with growth, can decrease effectiveness. McGraw famously detailed progressions of skill within various milestones, such as prone development, sitting development, and standing/walking, which are still utilized today in describing the sequence of development. However, even though McGraw was insightful about the way that environment can change the course of motor development, these progressions of movement were displayed "in air" as though the support surface or any external context, including gravity, did not exist. Thus the interpretation of her contribution to this day focuses on sequences of movement without the advantage of context that supports and shapes motor skill.

In summary, the neuromaturationist perspective provides us with a detailed description of motor milestones in time, or the description of "what" skills change and "when" they change. This knowledge is useful for determining whether a child is progressing in a typical fashion over time. However, to understand the "how" and "why" of motor skill change and provide appropriate intervention, we must delve into other aspects of development. Cognitive theories, in the next section, begin the story of motor skill interaction with other areas of development, an important step toward providing effective developmental care, and determining why skills progress in typical ways.

Cognitive Theories

Movement is observable behavior, prompting early developmental researchers to focus on developmental motor milestones (Gesell, Shirley, McGraw) and relegating specific behaviors and motor acts to a point in developmental time. Perhaps because these motor skills were so carefully mapped to time, the influence of other factors on motor acquisition was ignored as developmental researchers focused on other, "invisible" skills, such as cognition, perception, social understanding and motivation.[246,348] In this section we review two types of cognitive theory. The first originated specifically in regard to a child's development of basic motor skills, or phylogenetic functions (e.g., rolling, sitting, walking). The second, motor learning theory, was developed to explain the basis of new skilled movements in the older child or adult, called ontogenetic skills (e.g., riding a bike, hitting a baseball, shooting a basket). Both perspectives contribute to an overall contemporary knowledge base and theoretical point of view. In addition, both illustrate the intersection of cognition and movement in functional activity.

Developmental Cognitive Theories

Perhaps the most significant contributor to developmental cognitive theory was Jean Piaget (1896-1980).[246] Piaget observed infants in a context and utilized movement to explore what children were thinking. He pioneered the idea of "stages" of development, linking infant overt behavior to stages of cognitive constructs available to the infant. His focus was on understanding how infants think by watching their interaction with objects in the world. Although movement inherently supports the tasks he documented related to cognitive development, the interrelatedness of movement skill to cognition was not described. Piaget described four stages of cognitive development. The

first is the sensorimotor stage (0–2 years), followed by the preoperational stage (2–7 years), then the concrete operational stage (7–11 years), and finally the formal operations stage (11+ years). Each of these stages has substages describing a continuum of constructs that the child understands. Physical therapists likely have application primarily to the sensorimotor stage because of the "motor" influence, but an understanding of the progression of cognitive change through childhood contributes to investigating the "how" of motor skill acquisition at all ages.

In the sensorimotor stage, reflexive schemes are notable in the first month of life, followed by primary circular reactions from 1–4 months, which are simple movements around the infant's own body. Stage 3, labeled secondary circular reactions (4–8 months), focuses on infants' repeating interesting effects of their own movements. This is the stage of repeated movements, such as banging and shaking. And because the infant is fascinated with his or her own movement effects, he or she may shake or bang everything, whether or not the object was meant for that purpose. From 8–12 months infants switch to intentional, goal-directed behavior and develop the concept of object permanence, or the ability to know that an object still exists even when it is out of sight.

Piaget suggested that the experience of acting on the world (assimilation) with whatever sensorimotor schema is currently dominant was frequently met with resistance because the objects of interest were not easily adapted to the current schema (e.g., gently handling a soft cookie when the motor activity of crumpling or shaking is the current schema).[246] This misfit between the child's current sensorimotor functioning and the response of handled objects leads to disequilibrium, which drives developmental progress through the child's persistence in gradually accommodating to the properties of objects eliciting interest. In so doing the child eventually develops a different approach to handling the cookie and thereby alters the cognitive structure as well. Examples of assimilation can be applied to many motor skills. When infants have a stable hand preference at 2 years of age, they persist in using the preferred hand for tool use, even when that might not be the most efficient approach for the task.[77] Infants who are new crawlers plunge recklessly down slopes too steep to negotiate safely toward their waiting mothers at the landing.[1] As they gain more experience in crawling, failures on risky slopes gradually lead to the accidental use of a different, but successful pattern (one that an infant already knows from previous activities), such as sliding down the slope backward or in sitting. The alternative method then becomes one that the child purposely selects for descending slopes perceived to be risky, in a prospective manner. Transitions such as learning about slopes described above are not well explained by developmental theories that suggest that children immediately perceive the affordances of the environment and act on them,[104,105,247,311] but Piaget recognized this type of function and included it in his principle of assimilation.[109] This principle states that when cognitive structures develop a particular schema, it is applied indiscriminately to objects in the environment, assimilating them to the existing cognitive structure. Piaget also posited that repeated experiences with attempted assimilations of inappropriate objects result in gradual *accommodation* to their properties and the appearance of both new behaviors and new cognitive structures.

Piaget's extensive work in the development of cognitive constructs forms the basis of tests and research paradigms used today. Some examples are searching for a hidden object (object permanence concept) and pulling a cloth to obtain a toy (means-end concept).[16] However, the principles of accommodation and assimilation are not applied on a consistent basis to intervention paradigms. Researchers are now beginning to tease apart and understand the interdependence of cognitive change and motor development, an important interaction for the pediatric therapist to understand.[212]

Application of Theory: Recall the 9-month-old infant who presented with a delay in developing independence in sitting and reaching for toys with an asymmetrical posture. From a cognitive theory perspective this infant's lack of exploration of the world through her sensorimotor system prevents advancing to the next stage of development, assimilation (acting on objects in the world). A therapist might provide a variety of sensory experiences to encourage the child to interact with the environment, which the therapist assumes would lead to the next level of motor engagement with the world, handling objects. Alternatively, the therapist might try to engage the child in motor-based interaction with objects by providing direct, hand-over-hand physical guidance to show the child a strategy for interacting with the world and encourage transitions from the assimilation stage to the accommodation stage.

Another theorist in the cognitive camp provides a linkage to sociocultural aspects of learning. Lev Vygotsky[347]championed the important concept of social scaffolding to developmental learning, heralding the necessity of social interaction as a driving force for child learning.[347] He emphasized how social forces shaped the way children think, based on their interaction with more knowledgeable members of the group. At the core of his theory is the construct of the "zone of proximal development," in which a parent supports the child to accomplish skills at successive and slightly advanced levels.[348] This social scaffolding builds incremental skill both cognitively and motorically, as well as socially and emotionally. Thus in our example of a 9-month-old child with delays in sitting and reaching, the adult caregiver constitutes a critical feature of the scenario. The adult's actions to provide an imitative model, the social cues of encouragement given via facial expression and voice, and the ultimate reward of engaging in a joint play experience all drive a child's behavior to new levels. Of course, these same types of social experiences that drive function pertain to siblings, extended family, schoolmates, friends, and the more distant community as the child ages and encounters more challenging functional tasks.

Motor Learning Cognitive Theory

While motor learning theory is covered in depth in Chapter 4 of this text, "learning" in the case of motor skill change certainly falls within the realm of child development. Typically developing infants take over 9000 steps per day and walk over many different surfaces within their home and community.[4] This massive dose of practice allows infants to learn from their experiences. Although the word "learning" was not used as a key component in many developmental theories, learning is implied even in the neuromaturational approaches of Gesell, Skinner, and McGraw. The word *learning,* defined as "the activity or process of gaining knowledge or skill by studying, practicing, being taught, or experiencing something" (*Merriam Webster Dictionary* online), can be applied to the developmental process in multiple ways, including the gradual acquisition of motor skill. The "learning" definition has been used by some to imply a strictly cognitive process, but the actual mechanism of acquiring and improving a skill may involve processes that are not explicitly cognitive.

For example, early neuroscience researchers such as Thorndike extended the notion of response chaining to address how motor skills are learned, and in the law of effect he proposed that skills emerge as we repeat actions that are rewarded, an idea that might sound familiar when considering the ideas of Skinner, McGraw, and Piaget.[277] Fitts and Posner[108] proposed that the first stage of motor learning was cognitive, followed by an associative phase to link component parts into a coordinated whole, culminating in an autonomous, or automatic, stage that frees cognitive processes such as attention.

The importance of repetition of actions is a component of schema theory, one of the most widely embraced of the motor learning theories. Schema theory proposed that motor skill acquisition is a process of learning rules to evaluate, correct, and update memory traces for a given class of movements.[275] This theory extended the idea of learning a specific movement or task to something more general and abstract, which is a set of rules. It is helpful to envision the type of movement imagined within this theoretical approach as a motor act that is goal driven, such as a child trying to bat a ball or learning to hit a target. These higher-level skills were the frequent examples or tasks used to examine the tenets of schema theory; therefore early infant skills such as learning to roll or crawl were not considered, partly because these early skills had been perceived as emerging or developing, rather than being a specific goal-directed task of the infant. Early developmental skills (rolling, sitting, etc.) are likely to be examples of general motor programs from this perspective, and these skills will later be refined within higher level skills.

Schema theory assumes the presence of three constructs: general motor programs and two types of memory traces, recall schema and recognition schema. General motor programs are loosely defined as sets of instructions that are responsible for organizing the invariant or fundamental components of a movement. Recall schemas are defined as memories of relationships between past movement parameters, past initial conditions, and the *movement outcomes* they produced. Recognition schemas are defined as memories of relationships between past movement parameters, past initial conditions, and the *sensory consequences* they produced. It is theorized that recall schemas function to establish rules regarding the relationship between movement parameters of a general motor program, such as force or velocity, and the movement outcome for a given set of initial conditions that can be used to plan similar movements under anticipated conditions. Recognition schema, in turn, are proposed to compare sensory consequences with movement outcome in light of initial conditions to form a second set of rules. The second set of rules can be used to predict the expected sensory consequences for similar movement outcomes during anticipated initial conditions. The expected sensory consequences are proposed to serve as a perceptual memory trace for evaluating new movements. When movements are generated too quickly (ballistically) to be corrected by feedback during the movement (i.e., open loop), it is theorized that after the movement a feedforward motor command is compared with the expected sensory consequences. Schema theory holds that the initial feedforward command given to initiate the movement links to expected sensory consequences. If these expected sensory consequences do not match actual sensory information at the end of the movement, the next attempt will utilize the error information to correct the movement. In this manner the schema are established and refined as a function of practice.

Application of Theory: Recall the 9-month-old infant who presented with a delay in developing independence in sitting and reaching for toys with an asymmetrical posture. From a motor learning–based motor control perspective this child has not developed the motor pattern for sitting. Therapy would focus on providing ample opportunities for trial-and-error learning in a sitting position with as little support as possible, while encouraging symmetry. Intervention would encourage the child to try to sit and expect some variation in sitting control. The assumption would be that the child who practices sitting and reaching would build on a motor program he or she already has, like head control, and develop a new motor program for sitting through the trial-and-error practice. However, in motor learning theory, the context (including the child's motivation to sit, the room, location of nearby toys or siblings) would not be considered.

Schema theory does not attempt to explain the establishment of general motor programs, nor does it attempt to ascribe them to specific neural structures. The term *motor program* is employed in a variety of ways by researchers from a variety of disciplinary backgrounds, which may help explain why there is no consensus as to what constitutes a motor program.[268,283] In motor learning literature, motor programs are commonly invoked to explain the stereotypic attributes of a complex movement pattern that persists as movement parameters or context is altered.[366] For example, it has been suggested that a general motor program for writing our name exists, and its instructions consist of features common to signing our name under different conditions with different tools, different parameters of movement, even different sets of muscles.[258] Motor learning literature also ascribes to motor programs the ability to generate complex movements without benefit of concurrent feedback, such as reaching for a target after administration of a local anesthetic or tourniquet, as well as ballistic movements that may be completed before feedback can contribute to the movement.[276] Although in each of these instances motor programs are viewed as learned sets of instructions, one can see how this idea appears similar to reflexes because of its focus on a pattern of movement that does not require extensive time for processing and that can be "pulled up" immediately for quick access and ease of managing multiple degrees of freedom and limited resources. However, unlike reflexes, motor programs imply learning or the capacity for modification.

Based on more recent motor learning research, the definition of and the presence of general motor programs have been suggested to be outdated.[283] Rather a "scalable response structure" that is not necessarily invariant has been suggested as the more appropriate construct.[283] The notion is that rather than a "memory state" (motor program), we have a "processing mechanism" (scalable response structure) that serves to provide a basic movement that can be altered according to current conditions. Research involving the observation of infant development of walking when presented with various obstacles such as inclines, cliffs, and bridges has supported this notion, suggesting a process of "learning to learn" or a continual process of online problem solving.[2,3]

Although the idea that motor programs account for higher-level behaviors is being challenged, it may be that some basic networks exist. In neurobiology "motor programs" are called "pattern generators" and are viewed as genetically inherited sets of instructions that control the stereotypic features of innate behaviors such as mating, defense, and locomotion.[200] Some

of the strongest arguments in neurobiology for the existence of general motor programs refer to the many examples of an animal's ability to execute functional movements in the absence of feedback.[203,250,304,310] Where the movement instructions are stored is yet to be determined, but some investigators implicate the sensorimotor cortex,[12] primary motor cortex,[163] and cerebellum[202,272] for motor learning and the prefrontal association cortex,[120,281] basal ganglia,[280] and subcortical areas[304] for motor memory and planning. Even the spinal cord is implicated as a location for neural circuitry for locomotion patterns.[229]

As theories are tested, the outcomes reveal their shortcomings, clarify the boundaries of our understanding, and raise a new generation of questions. In contrast to maturationist theories, learning-based theories suggest that development of motor skill is the consequence of learning to solve problems by trial and error, in order to master and sequence units of action that are goal directed. Cognitive theories provide additional information to the "what" and "when" of development and begin to answer "how" and "why" skills develop. In the next section, other systems provide building blocks toward a deeper understanding of how functional motor skills are built.

Dynamic Systems

The dynamic systems approach departed from previous theories in a fundamental way. Each prior theoretical viewpoint, although admitting multiple influences on development, stated strongly the existence of a primary driver of the developmental process. For neural-maturationists the nervous system drove change. For cognitive theorists the mind, either via innate learning processes or the external influence of social scaffolding, drove the developmental process. For motor learning theories, trial and error practice modified predetermined motor programs. But in dynamic systems, no primary driving influence leads the developmental charge. Multiple systems engage to produce skill change, and the primary driver role fluidly transfers between systems to allow the emergence of a new behavior. Thus the musculoskeletal system, the environment, social influences, physiologic needs, or many other systems interact to produce behavior, and any system could take the lead in changing the trajectory of development or shifting to a new level of performance.

Any driving influence or factor in the dynamic systems theory is called a control parameter, and these influences or factors may change over time. For example, the stepping movements of a child may cease if the weight of the legs increases too quickly or if weight increases faster than accompanying strength increases.[316] Later in development, increasing height may drive the ability for a child to be able to ascend stairs in a step-over-step fashion because the child's legs reach a critical point of length-to-step-height ratio. Although strength is a critical component of ascending stairs successfully, strength may not be the control parameter depending on the height of the child or the stairs, and the control parameter role may be the height/length of the lower extremities. From a different point of view the control parameter could be step height, a factor external to the child. This is the critical point of the dynamic systems approach: different systems or parameters dynamically interact to adapt the organism to its environmental context and the task at hand.

Along with the idea of multiple systems affecting change, the idea of nonlinearity in development, as part of the dynamic systems approach, challenged the idea of predictable linear milestones occurring in a nonvarying sequence. Wide age ranges of normality of skill acquisition provide a hint that milestone achievement is nonlinear. By nonlinear, we mean that developing motor skills are not smoothly attained on a predictable timetable. Our motor milestone tables average together data from individuals who show great interindividual variability in skill emergence. Although across cultures and generations there is a general pattern of skill achievement (e.g., rolling before sitting, sitting before walking), that pattern appears macroscopically. With microscopic examination, researchers find that infants come into new behavioral states with varying strategies and time scales. There is both intraindividual and interindividual variability, which may average globally to the developmental sequence that appears on norm-referenced tests but which do not explain how novel behaviors emerge in an individual child. Dynamic systems theory posits that factors available to build a level of skill in one position do not transfer to another posture automatically.[22] For example, a body of research by Karen Adolph and colleagues has demonstrated that infants do not use their experience crawling on slopes to alter their approach to walking on slopes until they have experienced walking on the slopes. Differences in the base of support, the forces and joints necessary for the new action, and perception of affordances of the environment require the child to "relearn" the impact of the slopes (environment) on the task (walking). Massive amounts of variable practice, errors, and problem solving are thought to be involved in the transference of skilled navigation when the body posture changes. An example of infants learning to navigate novel surfaces such as slopes in new postures demonstrates a systems approach to skill development and transference because the environment plays just as strong a role in the change of skill over time as the infant's motor skill. Maturation of the nervous system is not the driving force in this theoretical approach, rather it is equal to all other systems.

Adolph's research supports a dynamic systems selectionist view of what infants learn from experience with everyday problem-solving challenges (see following section for more on selectionist theory). Her research paradigm presented young infants with emerging walking skills varying slopes and gaps to navigate. Each new presentation of a slope to the infant presented a choice: to go with the currently preferred mode of locomotion, to choose an alternative (presumably safer) mode of locomotion, or to avoid the situation, using a detour attempt or simply sitting down and waiting for the caretaker to come to the rescue. Notably, the latter was seldom selected with slopes that were moderately risky; it seemed that infants were goal oriented rather than safety oriented. Their choice was made based on, first, visual information and then if still uncertain, tactile and proprioceptive information. The choice was usually their preferred mode of locomotion (walking) until they had many weeks of experience and had, usually accidentally, discovered an already familiar motor strategy (crawling) to be safer or more successful. As they gained experience crawling or walking, their choice was made more and more quickly; after many weeks of practice, a short glance was enough for making a decision. However, near their ability boundary (slopes that generated less than predictable success in descending without falling), they appeared to have less than adequate knowledge of their own motor capabilities and instead made the decision based on their desire to achieve the goal of returning to their caregiver and a quick judgment of whether or not to go based on visual or haptic information. Failure (e.g., falling) did not

predict whether infants would choose to go on a subsequent trial, so they appeared to learn little between trials based on successful or unsuccessful outcomes. Adolph concluded that infants have extensive capability to use sensory inputs to make decisions about choice of motor actions, although they are not always right about their motor capabilities for solving the problem at hand. They choose to act rather than avoid a challenging situation, demonstrating the influence of motivation to achieve the goal. At the edge of their abilities, infants do not engage in trial-and-error learning but rather continue to rely on their visual-haptic analysis of whether or not to engage in risky behavior. When useful motor synergies happened serendipitously, however, they seemed to recognize the adaptability of such patterns and used them on subsequent trials as alternatives to generally preferred modes of locomotion that were riskier to use in a given situation. Goldfield[131] summarized Adolph's findings[1] by indicating that "inexperienced infants tend to be drawn inexorably toward the goal, rather than stopping at a choice point, and apparently do not notice the available affordances. Conversely, the experienced infant who has explored the available affordances may be overly conservative because the affordance information about slopes is inherently inhibitory; that is, it specifies ways for slowing, stopping, and changing direction". Thus, it seems that infants generate information visually, use their preferred mode of locomotion if the choice is to go, and then over time learn, accidentally or through a general wealth of experience with variable-level surfaces, to select from a variety of possible choices the most efficacious method of traversing risky terrain. One must conclude that adaptive locomotion (i.e., selecting the most appropriate method for the task at hand) requires exploratory movements to obtain information and a repertoire of available movement synergies from which to select.[1]

Adolph's research once again emphasizes that advances in motor behavior depend on having a variety of movement patterns from which to choose when faced with challenging new opportunities for action. As a result, children with disabilities, who generally have a limited repertoire of movement strategies, are constrained in their motor development by a lack of experience with variable movement and may also have limited perceptual capabilities for making online judgments about the likelihood of successfully accomplishing a motor task even when they have an intense interest in the goal.

Application of Theory: Using the dynamic systems theory viewpoint, the 9-month-old infant with sitting and reaching delays would be analyzed to determine the control parameter most affecting her strategy for reaching. The physical surround would likely be the first factor to be analyzed, and the distance of the object to be reached may be a determining factor in her strategy. If placing objects closer to her body elicited a strategy that was successful, increased practice while slightly varying the placement of the object would be the first suggestion. The child would be allowed to make mistakes, but it would be assumed that the child would eventually stumble upon strategies that worked for her body parameters. Immediate success would not be expected because building the new strategy may take hundreds of attempts.

Neuronal Group Selection Theory

Neuronal group selection theory, or neural Darwinism, is a popular theory that ranges through many disciplines, including psychology, developmental biology, and physiology.[94] The theory is useful because it helps explain the relationship of brain to behavior. Put simply, the theory utilizes Edelman's prior work in immunology as a framework for understanding nervous system function, based on the concept that a local event and local feedback can create a complex adaptive system. Because the theory incorporates multiple systems, adaptation, and dynamic changes over developmental time, we include it under the general heading of dynamic systems theory.

Edelman argues that popular models describing the brain as analogous to a computer with hardware (neurons) and software (motor programs) bear only superficial resemblance to the actual operation of the brain. He postulates that the nervous system is more akin to the immune system because the immune system must create weapons to attack infectious agents that have not been encountered previously. Thus, like the immune system, the nervous system must continuously solve novel problems. Edelman's theory, called the *neuronal group selection theory,* has three basic tenets. These tenets describe how the anatomy of the brain is produced during development, how experience selects for strengthening certain patterns of responses from the anatomic structures, and how the resulting maps of the brain give rise to uniquely individual behavioral functions through a process called reentry. Sporns and Edelman further described how such a system solves the problem of managing movement in an organism with multiple degrees of freedom.[298]

In Edelman's theory, neuronal groups from various maps throughout the region and the nervous system as a whole combine to produce a particular behavior. The behavior is unique to the individual in whom it occurs because of variations in neuronal maps caused by the effects of individual experience on their development. The combination of neuronal groups used from multiple maps allows the production of a movement that is precisely tuned to the environmental demands for functional performance yet unique to the individual's capacity for processing sensory inputs and his or her individual regional neuronal maps. This neuronal group selectionist system with distributed functions requires a repertoire of variable actions in order to provide adaptability: that is, a variety of means for responding to environmental demands and internal changes such as growth must be available.

Neuronal group selection theory does not hold that preexisting programs are executed by the nervous system; rather, dynamic loops are created that continually match movements and postures to task-related sensory signals of multiple kinds. Functioning is based on statistical probabilities of signals, not coded signals or preformed programs. Edelman further theorized that the system has biologic "values" that are species-specific and drive the selective strengthening of synaptic activities based on experience.[94] These values influence adaptive processes by linkage between the global mappings and activity in pleasure centers and the limbic system of the brain in a way that fulfills homeostatic needs of the organism. For example, in a computer model of Neural Group Selection Theory (NGST), Oztop and colleagues[238] included a variable labeled by the authors "joy of grasping," which modeled the sensory feedback received by the infant from achieving a successful stable grasp and that, in turn, strengthened the future selection of grasping strategies. In a computer model of a visual system with a set "value" that prefers light to no-light conditions in the center of a "visual" field (similar to that produced in humans by evolution), initially nondirected movements of an "arm" were shaped to target an object.[94] If one appreciates that newborn infants possess

a primary repertoire that includes moving the hand to the mouth, seeking light, and producing head turns or arm projections in response to moving objects in the visual field, it is not difficult to understand the theory of neuronal group selection as an explanation for the gradual process of learning to reach successfully. In fact, newborn infants will move their hand into a light beam,[327] and early reaching is more likely to be made to a moving object,[345] indicating potential innate value system for neonates. The research of Oztop and colleagues produced the first successful computational model of the process of learning to grasp.[238]

Neuronal map creation through an individual's use of movement to drive brain plasticity can go awry. Byl and colleagues, for example, reported that monkeys trained and reinforced for performing a stereotyped movement thousands of times, using the simultaneous activation of muscles and tactile-kinesthetic receptors, developed degraded primary sensory cortex maps.[48] Neurons in the cortical area related to hand function become responsive to stimulation almost anywhere on the hand (even the back of the hand), a condition Byl and colleagues describe as a dedifferentiation of the normally exquisitely organized response patterns of the sensory cortex. They believe that this animal model may reflect the process of repetitive strain injury with focal dystonia in humans and that the findings support use of a sensorimotor retraining approach to treating this disorder in order to redifferentiate sensory maps in the cerebral cortex. If we think of the constrained and repetitive movements used by infants with CNS dysfunction, it is not hard to conceive of the possibility that they also have a poorly differentiated sensory cortex. The key to understanding and treating this type of problem is recognition that maps are formed connecting various areas of the brain based on the simultaneous activity of sensory and motor systems. We learn (and train the brain to select) what we do. Stereotyped activity leads to poorly differentiated brain maps, whereas learning to use a variety of flexible patterns to accomplish common tasks leads to rich, complex brain organization compatible with adaptability to environmental demands and the internal changes accompanying growth. Thus neuronal group selection theory provides a template for understanding "how" motor skills build over time, as well as how they may be unbuilt or degraded.

Embodied Mind Concept

Another concept that fits within dynamic systems theory and NGST is the concept of the embodied mind. Because the brain is plastic and responds to experience and information gained through movement, the viewpoint that the mind is built via the physical activities of the body within the environment is defined as embodiment. Evidence from infant studies suggests that the mind is embodied, meaning that a strong linkage exists between what we know and what our bodies can do.[50,290] In essence, the interplay between acting on the environment and gathering information about how the world works creates the intellect. Additional research across the life span confirms that movement builds the brain and increases brain volume.[346] The embodied mind concept involves both action and perception, both of which are required to build the brain. Researchers are also investigating the use of models of motor control based on developments in the fields of robotics and neural networks. Both approaches seek to incorporate perception and action to explain control of movement. Robotic models are based on the physics of perception and movement, assigning mathematical values to known neural and biomechanical relationships to explain movement outcome. For example, as a child begins to explore movement of the arms, he will encounter objects and pick up information about these objects, such as texture, firmness, and shape. The child may grasp the object and wave it around, gaining knowledge about its weight and the forces of the arm required to bring the object into view. In this way, the child's body builds the brain to handle and understand, incrementally, more about the body and the object. Imagine if the child could not reach and handle the object: this rich experience diminishes drastically. Currently, in the area of autonomous robotics there is interest in simulating principles of dynamic systems using a new method called computational neuroethology. The method attempts to account not only for the neural and biomechanical elements of a robot but also for environmental context and any new phenomena that may emerge during action within that environment.[69,220,363] Neural network models are based on the assumption that no simplistic, predictable relationship exists among nerve cells to explain movement, but rather it is the phenomenon of their complex interactions that creates the movement outcome. Thus neural networks focus primarily on specifying the array of cellular and network properties that may govern how a population of neurons will self-assemble under a given set of conditions. Robotics actually utilizes concepts from infant learning and the embodied mind framework to advance artificial intelligence in robots and computing.[290]

Within the dynamic systems theory and embodied mind models, motor control functions are not assumed at successively higher hierarchic levels, leaving behind previously used primitive behaviors and control centers; rather, many levels of the nervous system cooperate in the production of movement behaviors. Typically, no single active site for any particular behavior can be identified; behavior is, rather, an emergent property of the cooperation of various subsystems, with task characteristics organizing the response.[318,24] That is, the characteristics of the task lead the nervous system with its distributed functions to select from a variety of currently available options for assembling a task-related action.

Application of Theory: For our 9-month-old child, NGST adds background justification for allowing the child to find her own unique solution to functional problems. This can be interpreted in multiple ways, and in fact, NGST is used by groups with opposing intervention strategies as justification for an intervention approach. On the one hand, those who utilize NDT have adopted NGST as a theory supporting intervention that discourages "abnormal" movement patterns and encourages "normal" movement patterns in various ways. This justification basically supports the same therapeutic activities seen in the neuromaturational hierarchical approach example. Opposing this viewpoint, NGST can also be used to support an intervention strategy that allows discovery of movements that are unique to the individual, even though the movement may look abnormal. This second interpretation is more in line with the NGST basic theory. Using this second interpretation, the therapist would allow the asymmetrical movement but add supports and environmental cues that continue the basic value-driven behavior while eliciting incrementally variable deviations from that singular strategy to build adaptation and long-range connections between the movement, sensory information, and the accomplishment of the task with the child's own solution (and not a preconceived notion of a normal movement pattern).

Perception Action Theory

Perception-action theory, expressed and researched by Gibson[131] and others, focuses on the relationship between self-generated movement and the child's understanding of properties of the environment in a cyclical pattern that builds skills. No action can be performed without resulting perception, and nothing can be perceived without action. Thus movement plays a central role in what we know and can perceive. Taking an early example, an infant sees a cube in front of him; however, this cube will be a two-dimensional square until it either is touched, to feel the sides and back of the object, or the infant must change the orientation of his body or move the cube to see all sides of the cube. Anyone who has watched an infant grasping a new object delights in the way the baby turns, gazes at, mouths, and touches the object with fasciation in exploiting the details of the object's characteristics. As each action allows a new perception, further exploration is elicited to expand that perception. In fact, Soska and colleagues showed that infants do not understand the spatial properties of an object (such as recognizing a toy from the back versus the front) until they can call upon action to move and handle the object.[292] Thus perception is strongly linked to action, a linkage that should be exploited within physical therapy intervention to advance both motor capacity and the understanding of linkages between movements and perception of how the world works. From a perception-action perspective the focus is on building the perception of affordances, allowing discovery of new actions that inform and build perception of new options.

Application of Theory: In our example of the sitting child with asymmetrical posture with poor reaching ability, the therapist would take some time to explore and understand the strategy the child is using. If the child can reach using an asymmetrical tonic neck reflex (ATNR), the therapist would start there, with a toy that might be mobile, like a small ball with noise and textures to explore. The therapist would encourage small, incremental changes (child initiated) in hand, arm, or head posture, allowing the building of the many actions and postural changes needed to perceive "roundness," the affordance of the chosen surface and gravity to assist or resist movement.

Ecological Theory

Ecological theory is closely related to perception-action theory but takes a broader view by examining behaviors across species and within multiple levels of the environment. Some ideas that evolved from this theory relate specifically to our understanding of prospective control: in other words, how we plan movements based on our understanding of spatial configurations in our world and the medium in which we move.

Ecological theory includes Bronfennbrenner's ideas of the roles of different levels of environmental influence on a child.[42] The theory attempts to explain progressive and mutual accommodations made between an active, growing human and the changing properties of his or her immediate and distant surroundings. This theory also relates to ecological perception and Gibson's[130] ideas of perception being built (as opposed to being innate) as the child experiences the environment. But more importantly, ecological theory presents the idea of an affordance, something in our environment that affords action or a certain type of action or movement. Because we evolved within our environment, ecological theory posits that function stems from the relationship between our body and the properties of things in the world.

Application of Theory: Why is this important to the pediatric physical therapist? Take our earlier example of a 9-month-old infant with an asymmetrical posture and difficulty sitting and reaching. Unlike the hierarchical approach, which would seek to reduce the effect of a "primitive" or lower-level reflex, the ecological approach would examine the affordances available to the child and the current relationship of the child to those affordances. Let's say the child is positioned in a high chair with a flat back, flat tray, and seat belt. The hard back affords pushing against, and flat tray affords leaning on a straight arm, which then supports stability of the child's head and gaze to one side. The ecologic approach, instead of building supports to hold/force the child to midline, might put an inclined, contoured surface in front of the child to afford or invite the child forward and reduce the back of the chair to afford less leaning (or pushing) back. The forward surface also provides a stable base, with gravity assisting, for the child to lean on both arms and learn about the stability that the new orientation lends to the head and gaze. In this way the child discovers and perceives new affordances of a different body configuration.

Theory Summary

In summary, theories of motor learning, motor control, and motor development attempt to explain complex and changing motor behavior and, as theories go, are also not static notions. Theory terminology, which stems from different fields of study, is often obtuse and difficult to understand without intense study. There is no one unifying theory of motor control related to motor development, and there are some overlapping tenets among the broad theoretical positions presented. This likely is influenced by the fact that we may control our movement in a different manner dependent on the type of movement we need. For instance, movements that repeat periodically (e.g., walking) may emerge and evolve differently from skills acquired by following a set of external rules that are learned (e.g., playing a piano) and may not develop from an evolutionary base.[191] Theories, however, guide research and should guide our problem solving when assessing and determining interventions for children with motor dysfunction.

Although no one theory unifies the field of pediatric physical therapy, a blend of dynamic systems, neuronal group selection, perception-action, motor learning, and ecological theories dominate new intervention approaches. This blended theoretical approach supports the use of infant-initiated and infant-directed movements, high dosage and early active experiences, and respect for all the systems that contribute to the acquisition of new skills.

Application of Theory: Take our example of the 9-month-old who has motor asymmetries and is learning to sit. From a blended approach of the various dynamic-based theories, the therapist might present the child with a toy of interest, while using changes in the seat surface (or an adult's lap) and the position of the toy to encourage the child to shift her weight just beyond her current comfort level, increasing the weight borne on one arm while reaching with the other hand. In addition to providing opportunities for new perceptual information and new motor skills, the experience, if repeated in a variable way through infant-directed play, could change the neuronal map used to accomplish this task over time. This would support the infant's development of multiple movement strategies for changing task demands. In the next section, we present a

framework that has evolved from the previous perspectives to help therapists build a competent and evidence-based approach to intervention.

CURRENT FRAMEWORK FOR DEVELOPMENTAL INTERVENTION

The most recent approach to theory, under the dynamic systems umbrella, appears compatible with updated research findings in general. Consistent with the dynamic systems approach, therapists should consider the role of both intrinsic and extrinsic factors in the development of each child. Each child presents with different factors influencing his or her particular course of development. Although there is extensive variation in the "typical" course of development, physical therapists play a role in evaluating the influence of intrinsic and extrinsic factors in the development of any child they assess, taking into account not only the what and when of developmental change but also guiding us to answer the how and why questions about skill acquisition.

Although use of dynamical systems theory to drive therapeutic theory and practice in physical therapy is still in its infancy with no large efficacy studies reported to date (Blauw-Hospers et al., 2007; Morgan et al., 2015), it is already clear that this model focuses the attention of the therapist on a number of important aspects of the therapeutic process of facilitating functional activity and participation.[32,227] These aspects include (1) search for the constraints in subsystems that limit motor behavior, such as contractures or weakness, leading to treatment goals related to reduction of impairments; (2) creation of an environment that supports or compensates for weaker (rate-limiting) components of the systems that contribute to development of motor control with a goal of promoting activity and participation; (3) attention to setting up a therapeutic environment that affords opportunities to practice tasks in a meaningful and functional context, especially in the child's home and community, with a high value placed on parent and family interaction for goal setting, activity construction, and social encouragement, as well as a high dosage of practice; (4) use of activities that promote exploration of a variety of movement patterns that might be appropriate for a task; (5) search for control parameters, such as speed of movement or force production, that can be manipulated by intervention to facilitate the attainment of therapeutic goals, especially during sensitive periods of development during which behavior is less stable[104,105,157]; and (6) extensive practice (high dose) to drive developmental learning (Spittle et al., 2015).[297] Thus parents and caregivers must be encouraged and coached in how to provide the multiple and varied repetitions of infant-directed practice needed to advance motor skills. Here we will present some examples of the factors influencing child development. The impact of each factor will vary between children and within one child at various times, which will contribute to the course of development, as do all components within this systems approach.

Factors External to the Nervous System

In the current view of developmental processes, factors external to the nervous system contribute significantly to the emergence of a behavior. These factors may be rate limiting or rate enhancing, depending on other factors within the system of the child and depending on the developmental time being considered.

Anthropometrics, Body Mass, and Nutrition

The emergence of locomotion during development is determined by the interaction of anatomy and the environment during movement. The weight of the child or the child's body parts may be one of those external factors that can affect functional movement. One famous example of the intersection of weight and movement involves infant stepping. Typically, infant stepping is not readily elicited beyond the first to second postnatal month under standard testing conditions, and it was long argued that the behavior disappears as a consequence of encephalization processes (the taking over of control) by maturing higher motor centers.[226] However, the postnatal decreases in rate of stepping temporally correlate with rapid weight gain, suggesting that morphologic changes in body mass may contribute to the "disappearance" of infant stepping. Two lines of evidence support this hypothesis. One, when infants are submerged in water up to chest level, both stepping rate and amplitude increase in comparison with stepping out of water.[315] Two, if weights equivalent to the weight gains at 5 and 6 postnatal weeks are added to the ankles of infants at 4 postnatal weeks, both stepping rate and amplitude decrease in comparison with stepping without ankle weights.[315] Thus buoyancy appears to diminish the dampening effect of body mass and gravitational interactions, whereas added weight appears to augment the effect of these interactions. Additionally, weight gain in an infant may not only affect a behavior such as stepping but generally affect the progression of motor development. Infants who are overweight have greater likelihood of delayed motor development,[289] and children classified as overweight are more likely than their normal-weight peers to have motor and mental developmental delays.[57] On the other hand, infants who are premature benefit by additional subcutaneous fat gain; subcutaneous fat addition in premature infants at 3 and 6 months correlated with greater advances in motor skill as infants matured.[186] Thus weight is a factor that interacts with motor skill development at both ends of the spectrum. Related to weight gain, nutrition can be an important factor, with critical nutrients playing a part in overall development. For example, infants with iron deficiency have negatively affected motor skill attainment.[282] Iodide and iron deficiency in early life are linked to impaired brain development affecting both cognitive and motor skills, which may not be reversible.[252]

Musculoskeletal System Factors

In children younger than 4 years of age, some biomechanics can constrain the possible movement options. Most notably, in the first postnatal year, the center of mass is proportionately higher than at any other age because of the combination of a large head and short limbs, requiring large force generation and regulation by neck and upper trunk musculature to counter the inertial forces created by displacements of the head. Likewise, the skeletal alignment of the lower extremity changes significantly between 2 and 10 years of age in typically developing children.[30] Infant growth displays irregularities, and is not a continuous process; there are spurts of growth followed by periods of no growth.[201] These spurts of growth may confound the infant's use of emerging motor skills, either adding to or decreasing difficulties in coordination. Infants who start to pull to stand and walk must generate adequate strength to lift and hold their body up against gravity, which gradually changes the alignment of the hip. It is the interaction between the experience of the child and the developing musculoskeletal system that results in the change in skeletal alignment.

Cultural Differences/Influences on Motor Skill Development

Milestone charts used in all clinics in the United States spring primarily from a European cultural background and grew from the original work by Gesell and McGraw (see theory section). These timetables reflect development of children from a limited scope of cultures. Handling practices for infants and young children vary widely between cultures, and these parenting practices provide for varying amounts of practice of specific motor skills.[166] Some cultures, including some parts of Africa and the Caribbean, do specific exercises with young infants that include practice with sitting and upright postural tasks, as well as stepping and walking. One example is the difference in sitting independently; infants in Cameroon routinely sit well at 5 months such that their parents leave them unattended on elevated surfaces.[187,188] No parent in the United States would assume, at 5 months of age, or even 7 months, that their child would be safe perched alone on an elevated surface. Therefore our milestone guidelines from standardized tests that put independent sitting at 7 months must be understood in the context of our own predominant cultural experience, which stems from the US and Western European culture.[34]

The "Back to Sleep" program, instituted in 1994, was initiated to reduce the numbers of sudden infant death syndrome (SIDS) and is now known as the Safe to Sleep program.[271] The program encouraged parents to position their infants in supine for sleeping, which reduced the incidence of SIDS by 50%. However, infant delays in developmental milestones were suspected as these parenting practices changed.[216] This example shows that a national effort to change one aspect of sleep positioning for infants can affect motor development. Overall, motor skills appear to have changed little due to the supine sleep program.[82] However, deformational plagiocephaly has increased significantly, as well as appearing earlier, related to the supine sleep program.[40]

Some cultures use restrictive positioning in infancy such as swaddling. One such practice is the Ghavora, used in Tajikistan. Infants are bound tightly in the supine position, and as they get older, they have more hours per day out of the restriction. These infants have delayed motor skills compared to our Western norms, with sitting independently occurring at about 1 year of age and walking at about 2 years.[187] Overall, cultural practices may change the trajectory of infant achievement of motor milestones, but these practices do not appear to have long-term consequences. Maternal expectations, related to culture, may affect infant development as well.[195] Pediatric therapists should note these differences in parenting practices and handling and consider culture in assessment and intervention for young children in varying cultures.

Task Demands

Task requirements, which are external to the child, can also be considered to be distinct motor control variables. Task requirements may include any variable that can contribute to or in some way alter movement, including biomechanical requirements, meaningfulness, predictability, or any other variable associated with a given movement context. Physiologic recordings from several sensorimotor centers of the brain indicate that the participation of brain areas in a task is context specific.[78,129,52] Task requirements shape motor strategies. For example, when a person slips, his or her response selection (step/reach/fall) is likely to be contingent on the task he or she was trying to accomplish, (carrying a tray/stepping onto an escalator/playing in a pool).[44,171] Task requirements can also result in the gating of reflexes; for example, a noxious stimulus applied to the foot may produce a flexor withdrawal response if the leg is in the swing phase of gait, but an extensor "contact" response if the leg is in the stance phase.[270] Evidence suggests that the meaningfulness of the task may enhance or mask performance.[332] The role of meaningfulness is demonstrated by comparing performance when a child is asked to complete a relatively abstract task (e.g., to repetitively pronate and supinate as far as possible) versus a concrete task (e.g., to strike a tambourine, a task requiring repetitive pronation and supination). Children with cerebral palsy (CP) generate larger movement excursions following the concrete instructions than after the abstract instructions.[332] In summary, task requirements, like all other variables we have considered, appear to play a crucial role in the control of movement. There may be multiple possible behavioral outcomes for a given set of centrally generated movement instructions depending on external factors.

For therapists using learning- or dynamic-based theories, thoughtful analyses of task requirements can generate both a deeper understanding of the minimal requirements for completing a task and an array of hypotheses as to why a client cannot complete the task. Analysis can also assist in determining how to modify and reduce task requirements so that a child can successfully complete the modified version of the task.

Internal Child Factors (Related to the Nervous System)

Children have their own personalities and goals from the time of birth. First displayed with the demand for food, caregiving, and sleep, infants express their goals. Some infants are demanding while others are calm with fewer demands. Infants are driven to move and control their bodies, often in an attempt to reach a destination, hold a pacifier in their mouth, roll over to get a toy, or sit up so they can see the world with a different vantage point. The infant's internal drive to achieve movement-related goals can influence development. In this section we discuss subsystems within the child pertaining to neuromuscular control affecting functional movement. These factors can be classified as motor control components, or strategies of control by the nervous system to coordinate the many degrees of freedom of the body, acting in the environment, toward functional movement.

Cognitive and Behavioral Factors

Cognitive factors may include variables that are dependent on conscious and subconscious processes such as reasoning, memory, or judgment to optimize performance. Such variables might include arousal, motivation, anticipatory or feedforward strategies, and the selective use of feedback, practice, and memory. Variations in arousal can probably modify any other control variable, such as pattern generation,[316] or even whether a behavior is demonstrated.[35] Motivation may make multiple contributions to the control of movement and thus development. In some instances motivation may serve primarily to trigger activity, and in other instances motivation may determine the form of the consequent movement.[136] For example, it has been suggested that hand path is straighter during reaches for a moving target than for a stationary one because the infant or child is more motivated to reach and make contact with a moving target.[340] Cognitive-related variables likely emerge with and assist in skill mastery; toddlers as young as 13 to 14 months of age having only a few weeks of standing experience

can selectively determine when to use manual assistance for maintaining postural control while standing on an array of support surfaces[301] or when challenged with various obstacles.[2] Cognitive processes associated with action are also important for acquiring spatial maps (memories) of the movement environment,[225] are apparent in the earliest anticipatory behaviors during infancy (such as the anticipatory head and eye turning during games of peekaboo), and may be delayed or differently configured in children with Down syndrome.[11]

Cognitive processes for predicting the postural requirements and selecting timely anticipatory strategies, also called feedforward strategies, are a select form of anticipatory behavior characterized by movement adjustments time locked to voluntary movements.[222] Typically, as we become expert in a movement task, we learn to recognize those sensory cues most reliable for predicting how the environment may change during movement execution, and we learn to ignore less useful cues. Simultaneously, we learn to predict how our movements will change our relationship with respect to a more or less predictable environment and therefore determine the postural requirements for the task. In the control of posture, anticipatory strategies work to minimize equilibrium disturbance and may also assist in completing the desired movement. In other acts, anticipatory strategies minimize the amount of attention dedicated to monitoring feedback and making corrections after initial movement execution. In the adult, for example, when asked to rise onto tiptoes (from a plantigrade to digitigrade posture), ankle dorsiflexor muscles are activated nearly 200 ms before ankle plantar flexors, apparently to shift the center of pressure (COP) at the foot-floor interface a sufficient amount forward before onset of postural elevation.[170] Although anticipatory strategies are not usually conscious cognitive processes, they involve subconscious forecasting processes[222] that are essential for minimizing movement errors during perceptuomotor tasks[334] and sometimes require considerable training such as the anticipatory postural adjustments (APAs) observed in dancers.[228] Indeed, it is argued that anticipatory strategies are learned, that they are relatively fixed under stable conditions, and that they are adapted in less fixed situations only by learning from past movement experiences.[222] Anticipatory strategies are observed in postural adjustments before the onset of whole body movements,[231] postural adjustments prior to onset of arm movements,[170] shaping and orientation of the hand before contact with an object to be grasped,[178] and strategies to time body movements with timing demands of the environment.[334] Anticipatory strategies during preparation to grasp can also be observed as early as 9 months of age[113,334] and appear to be present by 4 postnatal months, as evidenced by postural adjustments in neck and trunk musculature when infants are about to be pulled to sit or picked up from supine[16] and adjustments in gaze as they anticipate an object's trajectory (van der Meer et al., 1994).[328] These anticipatory strategies are built over time through experience and active engagement with the environment.

The amount of attention dedicated to monitoring a movement is also viewed as a variable that can be modified to perfect a motor skill. It has been suggested that during development, children initially execute new movements in a ballistic manner, ignoring feedback, then swing to the opposite extreme attempting to process excessive amounts of feedback, before finally learning to selectively attend to feedback. An example of this transition proposed by Hay[154] is described in the Reaching section later in this chapter and shown in the videos of the development of reaching on Expert Consult. It is generally thought that once the child (or adult) learns to selectively attend to feedback, more attention (or mental processing) can be assigned to reading the environment and predicting the environmental changes and movement outcome as the movement is executed.[192] Other cognitive variables related to learning, such as form and quantity of practice and the role of memory, are addressed within the context of motor learning in Chapter 4.

Sensory Factors

Infants are born with functional visual, vestibular, auditory, and somatosensory apparatus. However, the use of sensory information likely required practice and is context specific. Thus an infant's ability to look at and track a toy may depend on where she is positioned, how much support she has, and her previous practice with this skill. From a dynamic systems perspective, the sensory system has an equal role in development as all other developing systems. From a motor control perspective, sensory systems have an impact on our ability to control our posture and react to task demands. In this section we will briefly review the role of important sensory systems in typical development.

Vision. The relationship between eye movement and vision is present prior to birth with spontaneous fetal eye movements linked to networks in the frontal and visual cerebrum.[279] At birth vision begins to affect development in multiple systems including: socialization, object interaction, cognition, motivation, and postural control. Infants have the ability to track an object or face and orient to sound within the first hours of life. The opportunity to visualize a face and begin to interact with a caregiver builds early social skills. Infants who are shown toys, even before the onset of reaching, will change their movements in the presence of the toy.[28] Vision can drive complex movement, as when an infant sees a toy just out of reach and transitions to another position to obtain the toy. In relation to movement, vision has been primarily studied for the role it plays in posture.

Vision is perhaps the most powerful sensory system functioning to regulate posture, both for feedback correction and for selection of anticipatory postural strategies.[47,153,207,305] The first to ascribe a proprioceptive function to vision, Gibson[130] suggested that as light from the visual field strikes the retina, changes in light associated with movement create "optical flow patterns" interpreted by the brain to determine the position of the head and body with respect to the surrounding environment. It is argued that the large-amplitude postural sway observed in blind individuals is due to the absence of this optical flow information,[206] although adult individuals blind from birth show little difference in postural adjustments when compared to sighted individuals.[230] This may be due to the dynamic ability of the postural system to adapt during the developmental process. Optical flow patterns can evoke dramatic postural responses in both children and adults. Children begin to demonstrate distinct postural responses to optical flow patterns very early in development, even prior to walking.[47,207,305] Then, they go through several visual dependence periods as they first develop sitting and standing control. Table 3.2 outlines this developmental process. It appears that if children lack visual information during development, they may not minimize their postural sway to the same degree as sighted children.[251,253] Prechtl and colleagues suggested that the visual system exerts a

TABLE 3.2 Typical Development of Postural Control: Sensory System

Components	Age	Skills/Behaviors
Vision	4 to 6 days to 2 months	Activation of neck muscles following visual stimuli from looming visual stimulation in supported sitting[362]
	5 to 13 months	Scaling of postural responses to visual stimulation from moving room[26]
	5 months	Postural response to looming visual stimulation in stance[117]
	13 to 17 months and < 7 months walking experience	Apt to fall in looming moving room[47]
	2 to 10 years	Decreased falls and reaction to eyes closed conditions in moving room, moveable platform, SOT[111,305,358]
Somatosensory		
	> 6 months	Can control head and sitting balance using somatosensory input[207,287]
	4 to 6 years	Beginning ability to use somatosensory input for sensory conflict in standing during SOT[287]
	4 to 10 years	Ability to reweight within visual and somatosensory stimuli of various amplitudes by 4 years old; ability to reweight between visual and somatosensory input by 10 years[287]
	7 to 10 years	Adultlike ability to use somatosensory input to balance during sensory conflicts during SOT[118,287]
Vestibular		
	7 to 10 years	Adultlike ability to use vestibular input to balance during sensory conflict during SOT[67,359]
	12 to 16 years	Adultlike ability to balance during sensory conflict SOT[295,300]

SOT, Sensory Organization Test.

calibrating effect on the proprioceptive and vestibular systems that, when missing in children who are blind from birth, may contribute to early differences in postural control.[253]

In standing and walking the role of vision for posture and control in infants and children is significant. Infants who have recently learned to walk demonstrate an increased gastrocnemius response when perturbed without vision compared to with vision. However, same-aged infants who cannot take independent steps do not demonstrate any change in muscle response without vision.[305] In a now classic set of studies, Lee and Lishman demonstrated that when an adult stands inside a closed space formed by three walls and a ceiling, a forward or backward movement of the wall facing the person (center wall, Fig. 3.2) will trigger a larger sway amplitude (S) than under static visual conditions: a so-called "moving room" paradigm.[208] The effect is greater if the postural task is made more difficult (e.g., standing on one leg) and if the visual stimulus moves along the anterior-posterior (AP) axis of vision (referred to as a looming visual stimulus [A]), and it is least effective if it moves tangential (side to side [B]) to the visual axis. In general, if the subject faces the center wall as it is slowly moved toward the subject, the subject will sway backward; if the wall is moved away from the subject, the subject will lean forward. If the entire enclosure is moved sideways from the subject's left to right (or vice versa), however, little or no change in posture is detected. Clinically, and in research, the Sensory Organization Test (SOT) first suggested by Nashner and colleagues is used to assess the subject's response to visual, vestibular, and proprioceptive feedback, and the visual portion utilizes a "moving room" or "visual surround" to provoke postural responses (Fig. 3.3).[111]

Vision is linked to stability also in terms of perception of stability. In young walkers the actual distance between floor contact and the center of mass is small and results in much higher frequencies of postural sway with relatively larger arcs of motion than at later ages.[260,323] Consequently, younger children sway faster and closer to their limits of stability than older children and adults. Although younger children can produce

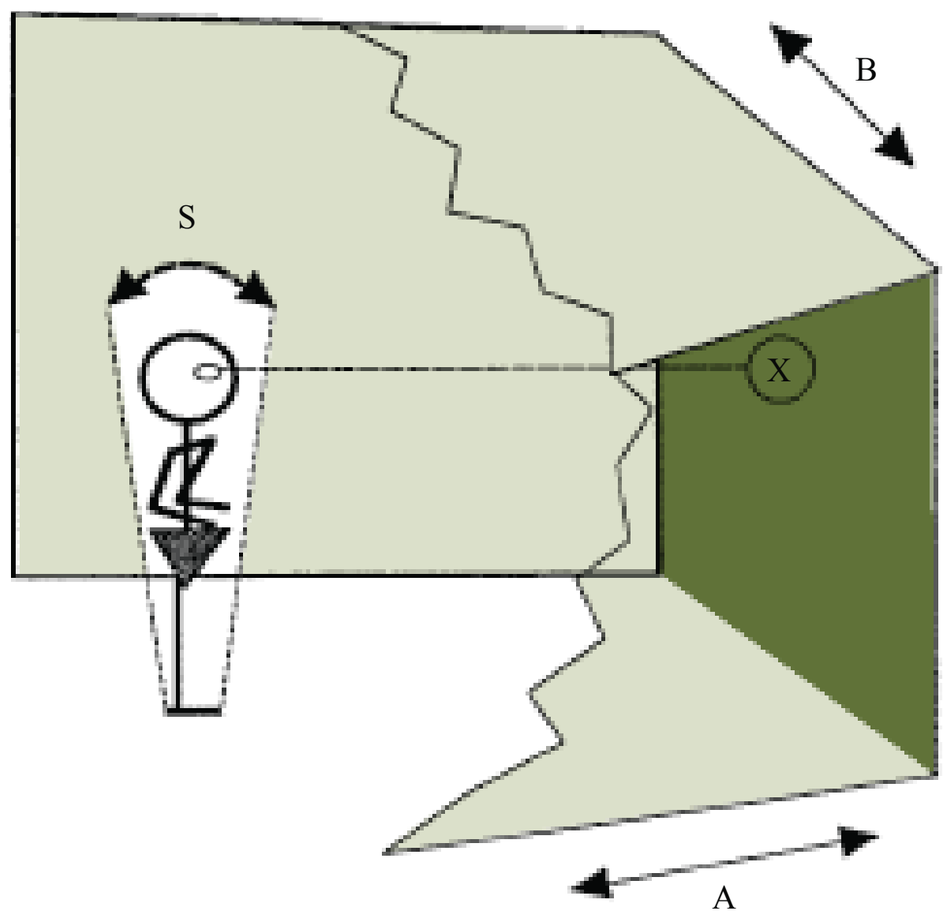

FIG. 3.2 The subject is placed in the center of a partial room formed by three walls and a ceiling that can be slid along in direction A or B. When the subject is facing wall X, room motion in direction A creates a looming visual stimulus and triggers an increase in the magnitude of sway (S) in the anterior-posterior plane. Younger children are likely to sway closer to their limits of stability (dashed lines) when presented with a looming visual stimulus but not when the visual stimulus moves side to side (direction B). (Adapted from Lee DN, Aronson E: Visual proprioceptive control of standing in human infants. Percept Psychophys 15:529-532, 1974.)

adultlike muscle synergies for postural correction at latencies similar to adult values, given the aforementioned biomechanical constraints, adultlike responses may be too slow for regaining upright posture. Infants learning challenging postures exhibit frequent falls, both in sitting[152] and in standing,[8] which does not appear to deter attempts to continue upright

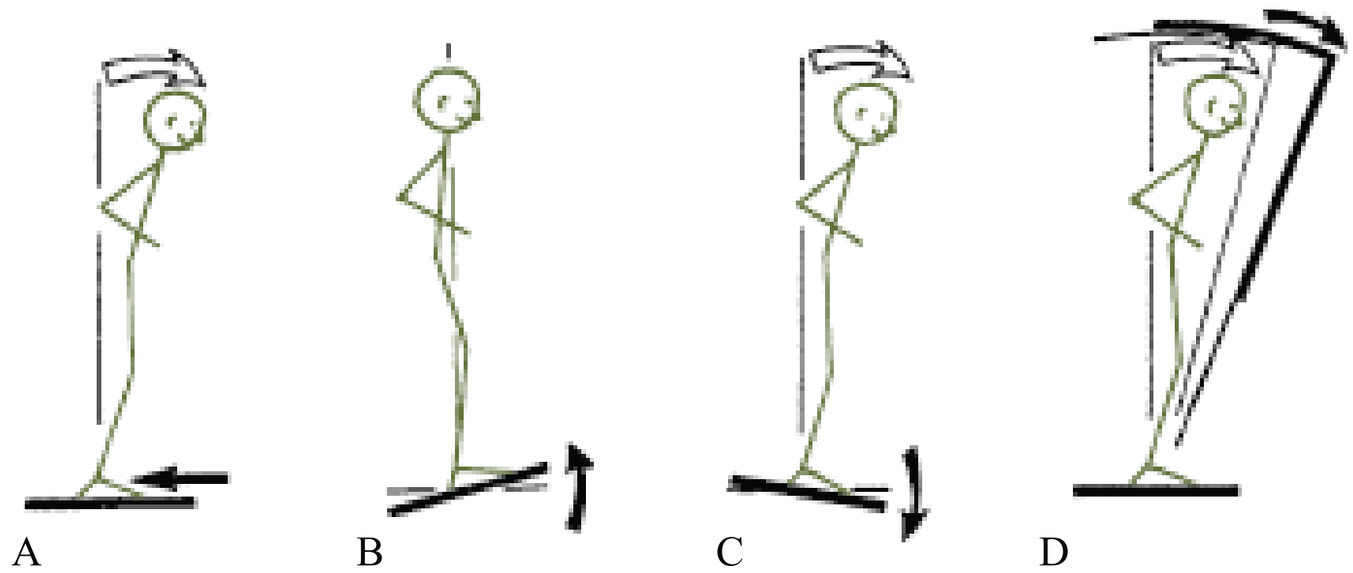

FIG. 3.3 When a child is placed standing on a movable platform that is then displaced in the posterior direction at a fixed rate and duration (computer driven), the child sways forward and the posterior synergy is activated in a distal to proximal sequence over time to realign the head and trunk over the base of support (A_1). Conversely, displacement of the platform in the anterior direction produces a posterior sway that is corrected by activation of the anterior muscle synergy, also in a distal to proximal sequence (A_2). In both conditions illustrated, normal visual, vestibular, and somatosensory inputs are available. If the platform is rapidly rotated to produce ankle dorsiflexion (B) or plantarflexion (not shown), visual and vestibular inputs remain relatively stable throughout the perturbation, whereas somatosensory receptors register displacement. If, however, the platform is rapidly rotated in the same direction and synchronous with normal sway (C), somatosensory input remains relatively stable because the ankle angle changes little during the perturbation, whereas vestibular and visual receptors register the postural sway. Visual information regarding sway can be altered during testing by closing the eyes or by placing a dome around the head to provide a stable visual field (D). If vision is stabilized during platform translations, as in (A), visual inputs will be in conflict with normal vestibular and somatosensory information. If vision is stabilized during platform rotations, as in (B), both visual and vestibular inputs will be in conflict with somatosensory information. Finally, if vision is stabilized during platform rotations synchronized to normal sway (C), visual and somatosensory inputs will be in conflict with normal vestibular information. (Adapted from Nashner LM, Shumway-Cook A, Marin O: Stance posture control in select groups of children with cerebral palsy: deficits in sensory organization and muscular coordination. Exp Brain Res 49:393-409, 1983; and Horak FB, Nashner LM: Central programming of postural movements: adaptation to altered support-surface configurations. J Neurophysiol 55:1369-1381, 1986.)

activity. Falling from a self-achieved and gaze-directed attempt may assist in calibrating postural adjustments and mapping the child's own parameters for dynamic stability. Thus vision may assist in learning appropriate postural control for the individual child's system.

Vestibular and somatosensory system variables. The vestibular system is activated and drives postural activity to regulate head control and to reference gravitational forces to prevent slow drift of the trunk during complicated postural control tasks early in the first year of life.[58,169,172] The somatosensory system primarily triggers postural activity related to body positioning and righting. When both head and body movement occur, as is common in many functional movements, the two sensory systems appropriately influence the motor outcome based on the various head/body configurations. The location of somatosensory input (i.e., the weight-supporting structure and the use or not of hands to support or balance the body) also greatly influences the postural muscle activity in reaction to or in anticipation of perturbations.[179,257] Further details on the role of the vestibular and somatosensory systems in postural control appear in the following section on motor control of posture.

VARIABLES OF MOTOR CONTROL THAT INFLUENCE DEVELOPMENT

Characteristic of contemporary motor control research is the notion that multiple variables contribute to the initiation and execution of a movement. Thus, it is generally assumed that to understand how movements are controlled, one must be able to identify which variables are important and determine how they interact during movement. Knowledge of this information could be very important for focusing assessment and intervention for children with motor dysfunction. However, one of the challenges of motor control research is that in order to investigate the role of one variable, the others must be held constant, which is not representative of the natural developmental process. Thus when considering the role of motor control in development, the evidence must be interpreted within our contemporary developmental theory of dynamic systems.

We now turn to theory that relates to the older child who has developed basic movements and skills. This section identifies some current hypothesis in motor control followed by motor control variables and research that relate to skill development. Although we describe each variable separately, we encourage the reader to reflect on the role of each variable and the interaction between variables that influence development. For additional motor control theory and background, we encourage the reader to review Shumway-Cook and Woollacott (2011).[286]

Current Hypotheses of Motor Control

While related to development, much of the motor control literature is driven by the implications for adult and older child rehabilitation rather than the generation of new skills during the course of typical development. In addition, many motor control theories exist without a unifying theory. Rather, each theory's hypotheses of motor control attempt to identify controlling variables for specific types of movement. Briefly, we will discuss a few of the most prominent motor control theories that relate to pediatric rehabilitation and development.

A common view of motor control is that movement synergies are the nervous system's solution to controlling the multiple degrees of freedom inherent in coordinating a multisegmented body.[25] Research has supported this hypothesis because relatively few synergies have been identified in frogs' unrestrained kicking[79] and in human movements such as squats, walking, and going up and down a step.[302] Although synergies, such as flexor and extensor synergies, have long been viewed as the stereotypic motoneuron patterns inherent in spinal neural circuitry, current views suggest that movement synergies can be context specific and highly individualistic[193] and can change during the acquisition of coordination.[53]

Current hypotheses of motor control attempt to identify controlling variables for specific types of movement. Central pattern generators (CPGs) are proposed to account for the basic neural organization and function required to execute coordinated, rhythmic movements, such as locomotion, chewing, grooming (e.g., scratching), and respiration, and have been specifically identified in animal models.[221] CPGs are commonly defined as interneuronal networks located in either the spinal cord or brain stem that can order the selection and sequencing of motoneurons independent of descending or peripheral afferent neural input. Under normal conditions, however, neural input from select supraspinal regions, such as the brain stem reticular nuclei, activate CPGs, and peripheral afferents, propriospinal regions, and other supraspinal regions modulate the output of CPGs and adapt the behavior to the movement context. Work in invertebrate species suggests that CPGs can even alter their own configurations (i.e., intrinsic modulation) to produce more than one pattern associated with the same or different behaviors.[190] CPGs can also modulate the inputs they receive, gating potentially disruptive reflex actions such as nociceptive activation of the flexor withdrawal reflex when a limb is fully loaded during the stance phase of locomotion (further review of pattern generators is available in Guertin and Steuer, 2009).[139] A growing body of literature examining the continuum of stepping behaviors in fetuses, premature infants, term infants, and young infants is beginning to make a strong case for the view that human locomotion is also governed by CPGs.[36] Promising research in humans to substantiate the presence of CPGs for locomotion has centered around locomotor recovery studies in adults with spinal cord lesions and hemiplegia.[89,215] Research on infants and children with CP,[81,353] Down syndrome,[321,360] and spinal cord injury[18] who train on treadmills with partial body weight support has also shown positive improvements in these individuals' ability to ambulate faster and without assistive devices, to start walking at a younger age, and to demonstrate some facility in upright ambulation, respectively. Newer studies are documenting changes in cortical activity via functional magnetic resonance imaging[84,245] and changes in short-latency reflexes in the peripheral nervous system.[162] However, evidence of the success of intervention capitalizing on the potential modification of the CPG, such as treadmill training for children with CP, has yet to be produced.

To better understand current concepts of motor control as applied to children, we examine the functions of postural control, reaching, and locomotion.

Postural Control

Postural control is achieved via the cooperative interaction of sensory (e.g., visual, vestibular, and somatosensory systems), musculoskeletal, and motor control systems so as to meet the behavioral goals of postural orientation and stability.[168,170] Although each of the three sensory systems is considered essential to optimal control of both static and dynamic posture, each system can compensate to some extent for the other two, and the relative importance of each system appears to vary with contextual or task demands.[170,288]

The vestibular and somatosensory systems contribute to the generation of directionally appropriate responses in the trunk and legs following anterior posterior displacements in infants and toddlers in sitting[148,159] and in stance.[308] Commonly used testing methods and leg responses are illustrated in Fig. 3.3. It is likely that vestibular and somatosensory systems participate in these postural responses during infancy because directionally appropriate muscle responses are generated even when infants are blindfolded.[358] Variable responses also may be attributed to the availability of vision, for when vision is occluded infants produce more reliable vestibular and somatosensory-evoked neck responses following AP displacements in sitting than when vision is available.[358] These early responses to perturbation are considered by some to be innate building blocks for orientation to vertical and postural skill. However, it is not clear how these early responses to perturbation are related to active, self-initiated movement. Complete developmental information related to use of these systems for postural control is outlined in Table 3.2.

Achievement of postural control is often described in terms that emphasize the closed-loop or sensory feedback aspects of balance correction or reactive postural adjustments (RPAs). Adaptive postural control, however, also employs open loop or anticipatory postural adjustments (APAs). These anticipatory strategies function to minimize potential postural perturbations arising with movement initiation and to assist in achieving the desired movement.

As young infants are exposed to gravity in the extrauterine environment, they must learn to control their bodies and respond to specific task demands. Several common postural control strategies can be observed over the first years of life that many people describe as postural reaction or reflexes. Righting reactions occur when the infant or child moves his or her head to keep his or her eyes on the horizon. Although this reaction has a common goal across tasks, the movements are not stereotypic. When an infant moves from prone to sitting, the infant demonstrates orienting the head to horizontal as the torso moves through a multitude of positions, which we refer to as head righting. The control of the head position is vital to gaze stability and orientation to the environment. However, it is not reflexive because the response is not stereotyped, can be easily interrupted with volitional movement, and may vary from trial to trial or from one child to another. An equilibrium reaction can be observed when the center of mass shifts outside the base of support. In a classic equilibrium reaction the torso elongates on the weight-bearing side and laterally flexes on the non–weight-bearing side. The upper and lower extremity often abduct on the non–weight-bearing side as well. Although this may be the classic description, in daily function equilibrium reactions rarely display the classic pattern because they are not stereotypic movements or typical response-stimulus reflexes. As such the development of the visual, vestibular, and proprioceptive systems, as well as the task or context of the activity, will adapt the degree of equilibrium reaction observed. Equilibrium reactions can be elicited as either a response to an external stimulus such as losing balance on a slippery surface (RPA) or in preparation for a movement such as going into single-limb stance (APA). If a child is unable to maintain his or her balance in response to an external stimulus, a protective reaction results in which the child steps, places a hand down, or grabs for a support. This type of RPA is present in children once they have experience in a position and can determine where their limits of stability are. Righting, equilibrium, and protective reactions can be observed in infants, children, and adults and are often related to the amount of experience the person has controlling his or her center of mass within a given base of support and the speed of movement. For example, a child may be able to stand well while playing with a toy on a flat surface without need for equilibrium or protective reactions. Yet when asked to complete the same task on a dynamic surface, equilibrium reactions are likely to be observed while the child is maintaining his or her balance and protective reactions when the child weight shifts too quickly and cannot maintain his or her balance.

Some mention should be made regarding the failure of researchers to find distinct sequences of development in postural motor responses to RPA.[244] This probably reflects the fact that complex neuromuscular responses are available early in development, and a child's ability to select the most favorable strategy is still developing.[93] In addition, the task requirements and the immediate context in question are critical determinants of any postural response. Infants demonstrate slow and variable reactive muscle responses in sitting, which speed up and become more consistent during development.[143,156,309] The developmental course of RPA in standing is variable, with periods of increasing latency in some children between 4 and 6 years of age and adultlike reactions by 7 to 10 years of age.[287] It has been suggested that the greater variability observed in children 4 to 6 years of age in standing may reflect a period of transition as vision becomes less important and somatosensory information becomes more important in the control of posture.[287,286] During this transition, children may be trying to process excessive amounts of information rather than selectively attending to the most pertinent sensory information, as has been suggested for other types of motor skill acquisition.[154] Children may also attempt to process excessive amounts of information as a strategy for coping with limited ability to anticipate change in the environment.[192] Yet another possible explanation for the variations in children's muscle response patterns may be found in variations in behavioral variables such as restlessness, fatigue, apprehension, and novelty during laboratory testing.[148,161] Finally, several studies have noted that reactive postural responses are task dependent, supporting the idea of a second phase of development.[64,156] See Table 3.3 for detailed developmental information.

Anticipatory activity can be observed in infants when reaching from various lying and sitting positions.[325] Recent research on anticipatory postural control during infancy suggests the importance of exploring variability during the development of optimal postural control.[92] Both too little variability and too much variability may be detrimental to flexible and adaptive control.[149] Sitting development in five infants was examined from the time the infants could prop in sitting using arms on the support surface until they could sit freely using their arms to play.[150] Analyses indicated that, as sitting balance improved, the infant first moved from instability to a period of constraint of the degrees of freedom (i.e., more stability using very consistent unchanging motor coordination patterns). Then the infants moved to a period of releasing the degrees of freedom or using more variable motor coordination patterns, indicating a complex chain of control development. A similar pattern of early postural variability followed by constraint of postural sway was observed during the development of reaching and midline head control in supine as well.[93] Harbourne and Stergiou hypothesized that the increased variability in selection of motor coordination patterns reflects specific individual solutions to solve specific individual problems.[150]

Chen and colleagues examined nine infants' development of standing balance longitudinally from age 6 months until they had been walking for 9 months, while standing with and without support on a forceplate.[65] They found rate-related changes in the children's postural sway. Sway developed toward a lower frequency and a slower, less variable velocity, but the infants did not show overall less amplitude of sway as they developed. This was hypothesized to be due to the child not just controlling sway to remain upright but also using sway to explore the limits of stability and learn about postural control. During the time the infants were tested, they also experienced both growth and development of sensorimotor control mechanisms.[65]

Overall, developmental studies suggest that there is a progression and refinement or modulation of APAs that improves with experience in movement. See Table 3.3 for details on development of the APA. The overlap in refinements of feedback (perturbation-triggered corrections) and feedforward postural

TABLE 3.3 Typical Development of Postural Control: Motor System

Components	Age	Skills/Behaviors
Reactive Postural Adjustments (RPAs)		
Sitting		
	3 to 5 months	Single postural muscle groups activated or antagonist activated rather than an identifiable RPA sequence[141]
	5 to 6 months	Activation of directionally specific motor coordination patterns (agonists opposite to the side the child is falling) Slow and variable timing (cocontractions and reversals of proximal to distal patterns) Poor adaptation to task-specific conditions[41,161]
	7 to 10 months	Decreased timing variability of directionally specific motor coordination patterns (activations of leg, trunk, neck muscles)[141]
	9 months to 3 years	Invariant use of directionally specific motor coordination patterns, some use of co-contractions Good modulation of pelvic muscles at base of support for adaptations to task-specific conditions[141,144] (Hadders-Algra et al., 1998)
	3 years	Variability in directionally specific motor coordination patterns Less co-contraction and use of neck muscles to improve variability of postural control[144] (Hadders-Algra et al., 1998)
Standing		
	7 to 8 months	Infants who pull-to-stand show beginnings of ankle strategies[141,309]
	10 to 12 months	Adultlike RPA with grossly directionally specific (distal to proximal) motor coordination patterns[309] (Hedberg et al., 2007;
	12 to 16 months	More consistent directionally specific motor coordination patterns although onset latencies longer[141]
	3 months walking experience	Compensatory stepping balance responses emerge[267]
	4 to 6 years	Increased variability of motor coordination patterns occurs (perhaps resulting from growth spurts or sensory integration changes)[111] (Shumway-Cook and Woollacott, 2007)
	7 to 10 years	Adultlike use of directionally specific motor coordination patterns (Shumway-Cook and Woollacott, 2007)
Anticipatory Postural Adjustments (APAs)		
Movement in Sitting		
	6 to 8 months	APA in trunk muscles before lifting the arm in sitting[325] (van der Fits et al., 1998) Can adapt to different sitting positions and velocities of reaching movement
	12 to 15 months	Consistent APA, particularly in neck muscles (van der Fits et al., 1998)
	2 to 11 years	APA variable and incomplete by age 11 years when compared to adults[326]
Movement in Standing		
	10 to 17 months	APA activity in gastrocnemius muscles (to counteract the reach and pull movements with arms) in 10- to 13-month-old infants More consistent and temporally specific APAs in 16- to 17-month-olds[356]
	3 to 5 years	APA response variable, with immature as well as adultlike activity[278] Anterior shifts in COP are present before raising an arm while standing, but these are less well coordinated[155] (Raich and Hays, 1990)
	4 to 6 years	APAs recorded in the following tasks: lever pull[115] Voluntary drop weight; raise arm[155,159,160] APA may shift from a supporting function to movement to a compensatory function of postural stability
	6 to 8 years	More continuous, systematic, and harmonious APA during a reaching movement APAs show greater variability of muscle coordination patterns than in 9- to 12-year-olds[351]
	9 to 10 years	Some children exhibit insufficient APA before movement into digitigrade stance[140] APA shown only when postural control disturbances reached "perilous" limits[155] APA less variable during stand and reach[351] Modulation of APA in weighted and unweighted wrist reach task
	12 years	APA with forward leg raising similar to adults and both affected by segmental acceleration (slow vs. fast movement) and sensory context (eyes open vs. closed)[239]
Movement During Gait Initiation		
	1 to 17 months walking experience	Inexperienced walkers use gait initiation APAs involving lateral rather than posterior COP shifts and use both the upper and lower body to make the shifts[13]
	1 to 2.5 years	Variable APA in reaction to a perturbation (holding the limb back) during gait initiation (Woollacott and Assaiante, 2002) APA (posterior COP shift) present, but not coordinated with the velocity of the step forward[205]
	4 to 6 years	Adultlike APA patterns of anterior tibialis activity and posterior COP shifts during gait initiation[218] APA (decrease in latency and increase in amplitude of muscles for push-off) in reaction to a perturbation (holding the limb back) during gait initiation (Woollacott and Assaiante, 2002) With 4 to 5 years walking experience, postural control motor coordination patterns move distally with ability to control gravitational forces with leg muscles during gait (Breniere and Bril, 1998)
	6 to 8 years	APA (posterior COP shift) present and coordinated with the velocity of the step forward[205]

COP, center of pressure.

TABLE 3.4 Age-Related Reaching Development

Age	Skills/Behavior
Newborn period	Arm movements appear to be purposeful (van der Meer et al., 1995) and spatiotemporally structured (von Hofsten and Rönnqvist, 1993) Reaching is visually triggered but not guided (von Hofsten, 1982) Hand is typically open during forward extension of the arm
7 weeks	Rate of reaching briefly decreases Infants seem more interested in looking at the object Hand posture is more likely to be fisted (von Hofsten, 1984)
12 weeks	Frequency of reaching increases Hand prepared for reaching (von Hofsten, 1984; Bhat and Galloway, 2006) Infants acquire ability to visually determine realistic reaching distances (Field, 1977)
12 to 18 weeks	Acquire skill in aiming reaches (von Hofsten and Rönnqvist, 1993) Infants can contact a moving object in as much as 90% of trials Between 15 and 18 weeks, contact shifts from just touching to catching the moving object (von Hofsten, 1979)
19 weeks	Reaches include more movement units that are seen in adults Reaching path is not straight (von Hofsten, 1991)
31 weeks	First movement unit is longer and functions as the transport unit similar to adults Reaching path is straighter (von Hofsten, 1991)
5 to 9 months	Variability in reaching path and movement units while reaching for a stationary object (Fetters and Todd, 1987)

control in children between 1 and 10 years of age suggests that they are two distinct processes that emerge in parallel during development.

Reaching

Reaching is one of the first motor skills infants perform and provides an early window into their motor control and their interactions with the world. (See the video on Expert Consult on the development of reaching from 2 weeks to 6 months.) Table 3.4 is provided to summarize the development of reaching. A growing body of work suggests that arm movements of the neonate, like kicking movements, are rudimentary expressions of skilled reaching that emerge during the first postnatal year. Supported in a semireclined posture, newborns demonstrate rudimentary eye-hand coordination in response to a moving target.[344,329] When infants from 1 to 19 weeks of age are presented with a slowly moving object, they display interest in the object. Prereaching or flapping of the arms during the first months of life is visually guided and often resembles early functional reaching. As infants become more interested in looking at objects, visual attention may inadvertently extinguish neonatal reaching efforts for a brief period of about 1–4 weeks.[23,342] Vision functions to elicit reaching but does not guide the trajectory or help orient the hand during early reaching.[204,213,355] In fact, infants do not appear to require vision of their hands for initiating reaching or contact and grasp of an object.[71] These findings seem to suggest that younger infants initiate reaching using a ballistic strategy to aim the hand toward the target and then switch to a feedback strategy (vision, proprioception, or both) to make corrective movements for grasping once the object is contacted.[71] At 4 to 5 months of age, reaches are as good with vision as when vision is removed after onset of the reach,[71,355] and infants begin to adjust their gaze, anticipating the future trajectory of an object.[328]

During the period from 12 to 36 postnatal weeks, several major changes occur in the form of reaching that suggest the development of a new control strategy.[340] Adult reaches are characterized by 1 to 2 movement units, meaning that there are one or two periods of acceleration and deceleration in a mature reach. The first unit functions to transport the hand 70% to 80% of the distance to the target and is relatively long in duration, and the second unit functions to home in on the object and is relatively short in duration.[178] Between 19 and 31 postnatal weeks, infants progressively restructure reaches for a moving object reducing the number of movement units from an average of 4 movement units per reach to 2 movement units.[340] The sequencing of movement units is also modified. In the younger infant when there are more than 2 movement units per reach, the transport unit can occur as one of the middle movement units rather than the first. In 19-week-old infants, the transport unit is the first movement unit in only half of the reaches, extending an average distance of 80 cm, whereas at 31 weeks, it is the first unit in 84% of reaches and extends 137 cm. Finally, the hand path trajectory straightens with age suggesting that, by 31 weeks, improved spatial planning contributes to advances in aiming skill as the hand is now transported closer to the target in a more efficient manner during the first movement unit, requiring fewer subsequent units to correct for errors.[340] Note the differences in trajectory and movement units between a 9-month-old infant and an adult during reaching in Fig. 3.4.

Experience in reaching is frequently found to be related to an infant's age. But in a series of studies investigating changes in arm movements with and without a toy present, it was found that infants alter the joint kinematics of their spontaneous arm movements in the presence of a toy months before the onset of reaching.[28] Clear stages of prereaching movements can be identified in the coordinated movement patterns of these healthy infants based on their reaching experience, not just their age. Carvalho found that infants with less ability in reaching demonstrated fewer reaching attempts resulting in less practice reaching compared with more skilled reachers of the same age.[55] Thus age alone is not a good indicator of reaching ability; experience must be considered as well.

Another factor influencing the improvements in typical infants' reaching is postural control.[84] As postural control improves in supine between 12 and 24 weeks of age, a decreased number of reaching movement units, a decreased length of the displacement path of the hand, and an increase in the length and duration of the first movement unit have been shown to be correlated.[102] Research on the APAs in preparation for reaching has demonstrated the presence of organized muscle activation patterns before infants are able to successfully reach and during the onset of reaching.[85,325] Muscle activation patterns were less variable by 6 months of age, and infants with a "top-down" or cephalic-caudal temporally ordered recruitment pattern demonstrated a larger percentage of successful reaches than those using a less organized pattern of muscle activation.[85] Although age, reaching experience, posture, and developmental

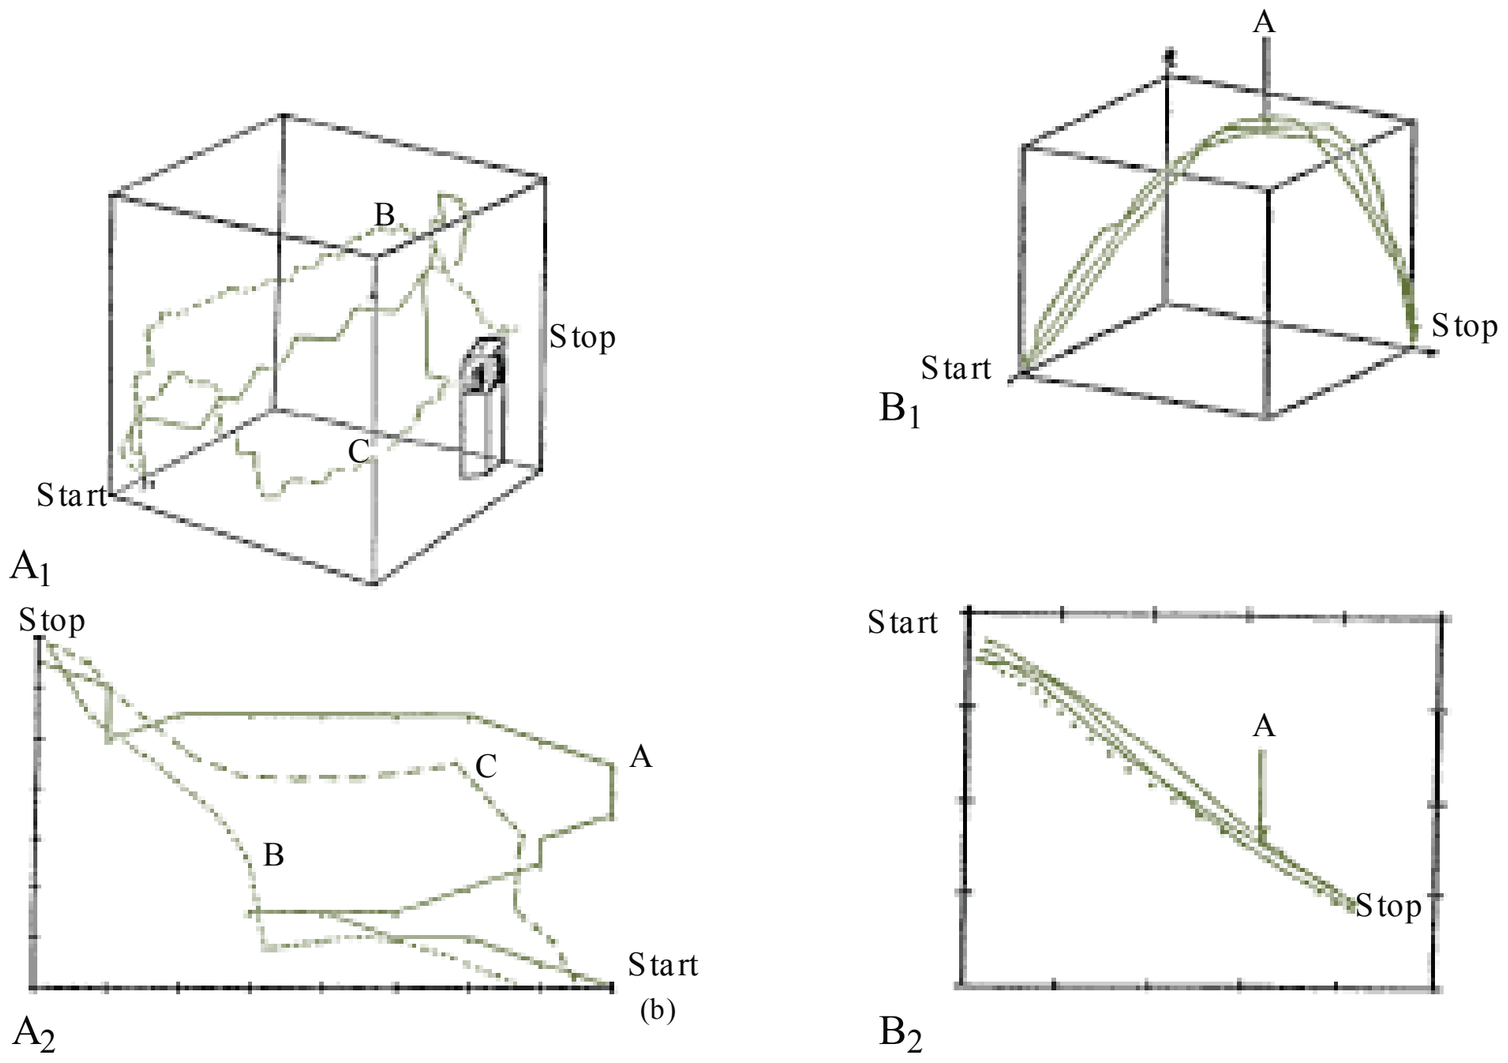

FIG. 3.4 When reaching for a stationary object, infants exhibit reaches containing multiple movement units similar in duration. Three reaches are shown for a 9-month-old infant from a side view (A_1) and an overhead view (A_2). Note the irregularities both within and between reaches as compared with adult performance from the side view (B_1) and overhead view (B_2). (Adapted from Fetters L, Todd J: Quantitative assessment of infant reaching movements. J Mot Behav 19:147-166, 1987. Reprinted with permission of the Helen Dwight Reid Educational Foundation. Published by Heldref Publications, 1319 Eighteenth St., NW, Washington, DC 20036-1802. Copyright © 1987.)

delay influence reaching abilities, task demands or extrinsic factors of the task may result in changes in reaching strategies as well.

During the period from 5 to 9 months, infants begin to use visual information at the end of the reach as the hand approaches the target to correct for errors in hand path trajectory.[336] Before 5 months of age, they take little notice of the hand during flight, but thereafter, if vision of the hand is blocked, as when infants reach for a virtual (mirror image) object, performance is frequently disrupted.[204] Although infants continue to use a ballistic reaching strategy well into childhood, withdrawal of visual feedback begins to impair reaching skill at 6 to 7 months of age.[204,355]

During the first postnatal year, interlimb coordination of the arms and hands during reaching is characteristically variable. In a longitudinal case study of one infant from 3 to 52 weeks of age, instances of bimanual reaching appeared to correlate with more variable kinetics, greater limb stiffness, and greater reaching velocities in the following arm as compared with the leading arm. These findings led the investigators to conclude that bimanual reaching predominates until infants learn to differentially control the following arm at approximately 6 to 7 months of age.[76] The degree of coupling between arms during reaching also appears to depend on the complexity of bimanual cooperation required (task demands): that is, whether one hand can remain relatively passive or must produce complementary movement patterns such as when holding a box lid up with one hand while extracting a toy with the other.[100] Complementary bilateral reaching skill emerges at 9 to 10 months of age.[101]

A recent study comparing adults with Down syndrome to typical adults and children found that the individuals with Down syndrome were able to demonstrate stable bimanual coordination during a circle-drawing task that appeared adult-like.[262] In contrast, their unimanual ability was less coordinated and similar to the children examined in the study. This suggests that the individuals with Down syndrome have more mature bilateral reach and fine motor skill and less mature unilateral ability. This may be due to improved postural control via using both sides of the body during the bimanual activity, but this is yet to be examined experimentally.

The influence of object properties on grasping has been well documented (see the next section), but the properties of objects also influence infants' reaching strategies.[75] Infants between 6 and 9 months of age frequently have a preferred reaching strategy, but they may be able to alter that movement strategy based on the task demands. In a study comparing the reaching and grasping strategies of 6- to 9-month-old infants for small balls, large balls, and large pompoms, Corbetta and Snapp-Childs described the infants' ability to use sensorimotor information to alter their preferred reaching strategy.[75] Older infants were better at altering their reaching strategy between unimanual and bimanual based on the task demands than were the younger infants. In addition, handling the object provided more cues to the infant than vision alone, leading to more appropriate changes in reaching strategy.[75]

Reaching in infants is routinely studied in a semireclined seated posture, but several groups have compared the development of reaching among infants in supine, upright, and semireclined postures. An early comparison of reaching in supine

and upright sitting at 12 to 19 weeks of age and 20 to 27 weeks of age found that position had little impact on reaching abilities or quality between 20 to 27 weeks of age. Infants in the younger age group, however, demonstrated fewer reaches and grasps, and they had poorer quality of movement in supine.[273] Consistent in the research literature is the finding that younger, less experienced reachers are more influenced by changes in body position that those who have more experience and are older.[54,55,273] Carvalho and colleagues suggested that the similarity of reaching performance of the more experienced reacher in either body position is an indication of the adaptability of the system to new constraints, which is not observed in the less adaptable, less experienced infant.[55]

Locomotive Control

Stepping movements and walking have been studied extensively in both human infants and in developing animals. Animal studies add to our understanding of the control systems for walking as infants develop a more adultlike pattern of movement.

The presence of stepping movements in the human fetus, early onset of infant stepping in premature infants, and rhythmic leg movements of infant kicking provide argument for development of basic stepping circuitry for locomotion in humans during embryogenesis as in other animals.[36] The presence of some potential for locomotion at birth raises the question of whether that potential is established early in fetal development. Here again a parallel may be drawn with animal studies. Ultrasound studies of human fetal movement indicate that isolated kicks are initiated during the 9th embryonic week, and alternating leg movements, reported to resemble neonatal stepping, are initiated with postural changes ("backward somersaults") in utero during the 14th embryonic week.[87] Thus human fetuses appear to exhibit stepping during the first half of the gestational period, about the same portion of the embryonic period when chicks exhibit organized electromyography (EMG) and kinematic features during spontaneous motility.[37,62] Given that low-risk preterm infants born at 34 weeks of gestational age demonstrate orderly kinematic patterns similar to those of full-term newborns and that those features differing from full-term infants appear to be attributable to dynamic interactions emerging during movement,[122,158,180,181,344] the parallel between human fetuses and chick embryos appears reasonable (Fig. 3.5). In other words, the neural foundations for locomotion in humans may be assembled during neurogenesis, as they appear to be in other animals.[37,46]

Several parallels can also be drawn between studies of neonatal animals and rhythmic, locomotor-like leg movements in human infants. When supported on the treadmill, infants perform repetitive leg movements characterized by several kinematic features similar to adult locomotor behavior.[315,320,361] Although infants 6 to 12 months of age become more reliable in producing a sustained pattern of alternating steps that are timed to the treadmill belt speed, even infants as young as 10 days of age occasionally demonstrate these features.[361] Neonatal infant stepping shares many features with early treadmill stepping. Most notably, hip, knee, and ankle joints are synchronously flexed during the swing phase and synchronously extended during the extensor phase; the excursions are accompanied by nonspecific EMG patterns; and there is an absence of both heel strike and push-off at the transitions between swing and stance.[110] These features are also characteristic of infant kicking within the first 1 to 3 postnatal months, further suggesting that some of the mechanisms controlling treadmill stepping, and therefore locomotion, are already functional at birth.[182,183]

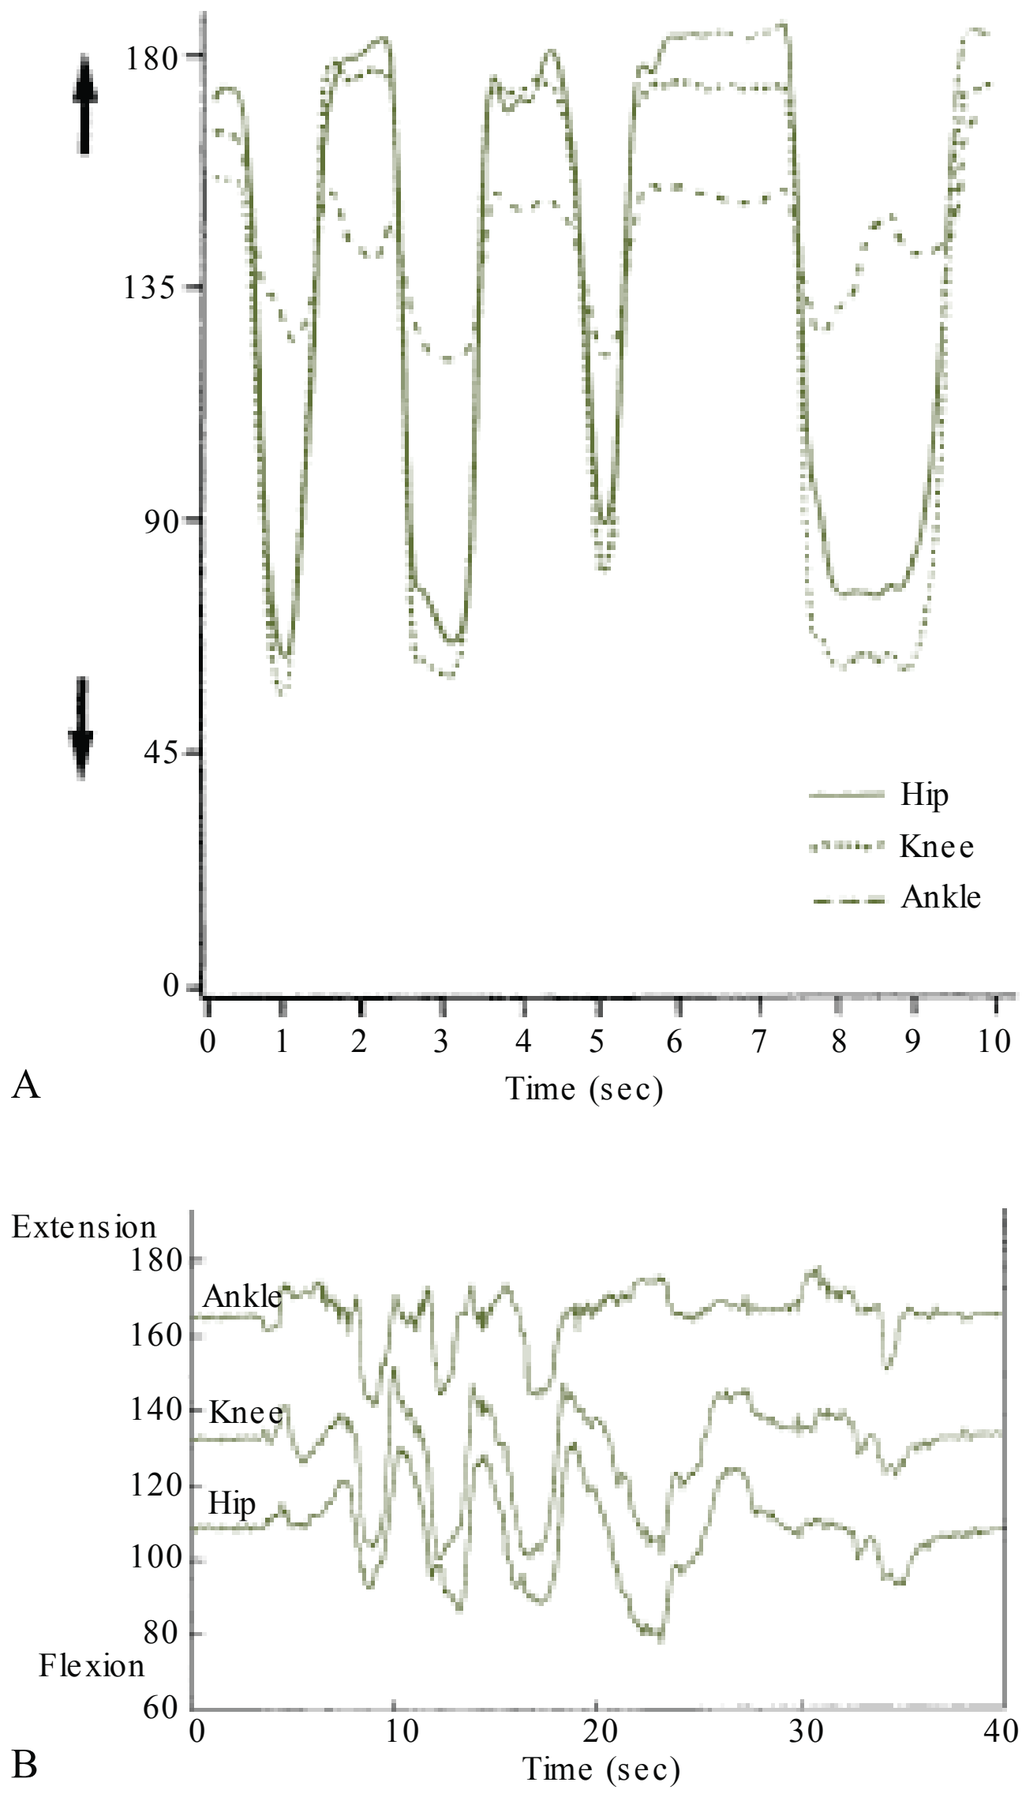

FIG. 3.5 Kinematic analyses indicate that lower extremity movements are organized very early in development. When preterm infants initiate a sequence of several kicks at 40 weeks of gestational age, the alternation of flexion and extension at the hip is synchronous with motions of the knee and ankle in the same direction (A) and is similar to kicking movements during spontaneous motility in chick embryos in ovo at 9 embryonic days of age (B). (Adapted from Heriza, CB. Comparison of leg movements in preterm infants at term with healthy full-term infants. Phys Ther 68:1687-1693, 1988.)

Until recently, it was believed that infant locomotion lacked adultlike features typically observed in EMG recordings. Failure to observe adultlike EMG patterns was often attributed to late myelinization of descending paths at caudal spinal levels,[307] late maturation of cortical structures,[110] or late myelination of peripheral nerves.[306] In a study of treadmill locomotion, however, infants as young as 10 days of age occasionally produced steps characterized by alternating activation of antagonist muscles, and the extent of coactivation decreased with practice.[361] The relative duration of flexor and extensor burst durations also

varied with treadmill speed in a manner similar to that in adults. Furthermore, it has been demonstrated that prewalking infants, age 4 to 12 months, can respond with adultlike interlimb coordinated responses when given unilateral leg perturbations while supported to walk on a treadmill.[240,241] The failure to observe adultlike EMG patterns for locomotion in previous studies of prewalkers and early walkers may have been the result of adaptive strategies that masked this potential. For example, infants may have coactivated antagonist muscles to increase joint stiffness and stabilize limb posture as a compensation for insufficient postural control or control of force generation for supporting and transporting body mass.[38,236] Also, testing conditions may have masked the potential to generate adultlike locomotor EMG patterns: that is, support in stance or movement against gravity in supine likely altered the task requirements,[320] necessitating a different EMG pattern. Conversely, the testing conditions may have lacked key features for expressing locomotor EMG patterns. For instance, in cats the velocity of limb movements contributes to the generation of certain EMG patterns.[364]

Although there is wide support for the view that basic features of locomotion are spinally mediated,[46,173] some argue that uniquely human features of gait emerge as spinal neural networks are transformed with maturation of higher neural centers.[110] Specifically, it is argued that the basic patterns of alternating flexion and extension observed during neonatal stepping persist with development of locomotion but that maturing sensorimotor input suppresses activation of ankle extensor motoneurons to permit heel contact at the onset of stance. Also, the absence of heel strike in children with CP is thought to occur because cerebral injury impairs development of higher-center control over spinal neural networks for locomotion.[110] As further support for this view, Luo and colleagues studied infants who were born prematurely, compared to a similar group born at full term, in their ability to walk while supported on a treadmill.[214] The factors that contributed across the whole group to earlier attainment of independent walking were a higher percentage of alternating stepping pattern, a decreased association in hip/knee coupling, and an increased association in hip/ankle coupling during swing phase as well as increased interlimb symmetry during stance. A small number of preterm infants were classified as "late walkers," and authors hypothesize that the presence of periventricular leukomalacia—i.e., a neural control deficit and/or chronic lung disease (either linked to muscle weakness and/or to a neural deficit related to poor oxygenation of the brain)—affected the infant's coordination and delayed the development of locomotion.

Conversely, many researchers now speculate that attributes of gait, such as heel strike, need not be specifically dictated by higher neural centers because they may emerge from the inertial interactions and associated feedback among body segments during different types of movement exploration from many practice sessions.[31,63,68,145,164,176,199] For example, when cats walk at relatively fast speeds, the sartorius muscle produces a two-burst pattern, one during late stance and one during late swing, but the second burst does not consistently occur at slower walking speeds. Kinematic and kinetic analyses suggest that the burst in late swing functions to counteract extensor forces at the knee during faster walking speeds, but it is not required and therefore not recruited at slower speeds because viscoelastic properties of knee flexors are sufficient to counter these forces. In adult humans, examination of muscle actions during the walk-to-run transition demonstrates lower swing-related ankle, knee, and hip flexor muscle activation and higher stance-related activation of the ankle and knee extensors during running than walking.[255] It is suggested that the exaggerated sense of effort in lower extremity flexors during swing of a fast walk may trigger the locomotor pattern to change from the walk to run pattern.

Whether the muscle activity associated with heel strike or other attributes of gait is due to centrally organized neural commands or is an emergent property of movement exploration and motion-dependent feedback has recently received more focused study related to the development of walking in infants. A study of treadmill training in a premature infant who sustained a left grade III/IV intraventricular hemorrhage demonstrated that the infant changed the right and left initial foot contact from a toe touch to either a flat foot or heel strike after 4 months of practice.[33] This improved motor pattern continued for a time after the treadmill training ended, then it reverted to the previous pattern. This finding might suggest that the absolute velocities or rate of change in velocity typically achieved during early over-ground locomotion is insufficient to force the infant to express adultlike ankle control in the step cycle. However, when given the higher velocities of the treadmill to stimulate the walking pattern, the appropriate heel strike pattern emerges even though the infant had early brain damage. From study of early walking development in infants, researchers have demonstrated that the infant's walking pattern related to EMG control,[63] net joint moment control,[146] and coupling of AP and medial-lateral oscillations seems to emerge in a nonlinear manner, requiring cycles of perception and action to self-organize and stabilize.[198]

Heel strike may not be observed until independent walking is established because of immature morphologic characteristics of the infant foot interacting with a support surface. Given the considerable structural change the foot undergoes during the first postnatal year or more, it is conceivable that initial biomechanical features of the foot do not readily afford initiation of heel strike or push-off in the young infant. Recent study would also suggest that strength of the foot/ankle muscles plays a role. Vereijken and colleagues have examined manipulation of body weight during the first 6 months of independent walking.[333] They placed ankle, waist, or shoulder weights on the infant and observed changes in the infant's gait patterns. Ankle weights affected the gait most over these months of development, causing continued slower and shorter stepping patterns. This was hypothesized to occur due to immature strength and control at the ankle.

The gradual refinement of gait is described by Stout in Chapter 34: Development and Analysis of Gait (on Expert Consult).

In summary, during the first several months of walking experience, creeping is gradually abandoned and heel strike in gait develops, allowing faster walking with longer strides. As children become bigger, older, and more experienced, steps become longer, narrower (reflecting a narrowing of the base of support), straighter (reflecting increasing control over the path of progression), and more consistent.[7] Walking practice is a stronger predictor of improvement in walking skill than age and duration of walking experience.[8]

DETAILS OF DEVELOPMENT: WHEN AND WHAT SKILLS ARE ACQUIRED

Because a large number of researchers have documented that the behavior of children varies based on characteristics of

tasks and environments,[15,22,211] it has become clear that the apparently invariant sequence of development of motor skills is an artificial creation of the particular tasks chosen by early investigators such as Gesell. Nevertheless, information on when children achieve various skills is of continuing importance in physical therapy and other fields because information about ages and stages of appearance of motor milestones is used in developmental diagnosis of delayed motor performance. Thus this section elaborates on the observable "stages" of gross and fine motor development that represent milestones of developmental progress toward achieving the goals of upright posture, mobility, and manipulation: essential elements of environmental mastery and control. As infants attain and perfect these major developmental motor skills, they are incorporated into functional activities such as self-care, feeding, and play. Important milestones of motor development in later years of childhood will also be briefly addressed.

The major gross motor milestones of the first 12 to 18 months include achieving an indefinitely maintained upright head posture, attaining prone-on-elbows position, rolling from supine to prone, independent sitting, belly crawling, attaining hands-and-knees position, moving from sitting to four-point position and prone, creeping on hands and knees, pulling to a stand, cruising along furniture, crawling up and down stairs, standing independently, and walking independently.[17] As each position or skill is attained, further development will entail the perfecting of postural control in these positions and the ability to make rapid, effortless transitions from one position to another. Table 3.5 compares results for a US sample from Indiana, Pennsylvania, and New York City[22] with those for children from five countries, including Ghana, India, Norway, Oman, and the United States (WHO multicenter growth study, 2006).[352] Ranges for accomplishment of early milestones are narrower than for later milestones, and neither study noted gender differences. Of note, however, is that the order of attainment of mobility skills can vary a great deal. Berger and colleagues found that 64% of their sample used 1 of 8 variations in the order of attainment of skill from belly crawling to stair descent, but in the sample as a whole 57 different orders of attainment were recorded.[22]

Early Development: First Year of Life

The motor skills described in this section are likely to be the most important to a pediatric physical therapist. Changing positions, reaching and attaining objects, and mobilizing through the world are all phylogenetic (basic in all animals) skills needed for survival and self-preservation. Thus pediatric PT is considered necessary if a child is not performing these skills at the expected time, has difficulty with these functions, or has a limited repertoire of movements in the first year of life that may limit exploration and skills development. In addition, early motor delays, reduced strategies of movement, or altered quality of movement may predict future problems in other developmental areas. For example, children with autism often show motor delays that precede delays in communication or social skills.[29,233] Children with developmental coordination disorder (DCD), usually not diagnosed until school age, may display atypical early motor skill in infancy.[296]

Early Neonatal Movement

Skill acquisition starts in utero when a fetus starts to bring hand to mouth, foot to foot, and pushes on the uterine wall. Infants have been observed in utero during real-time ultrasound imaging to perform hand-to-mouth activities, touch other parts of their own bodies, and explore the uterine walls: all, of course, without visual guidance.[294] The first movements are notably general and cause the entire body to move, with lateral bending being the first to appear at around 7 weeks.[86] Isolated arm and leg movement begin around 9 weeks, and breathing movement as early as 10 weeks. Fetuses explore their own body, the umbilical cord, and the uterine wall with their hands.[294] However, there are individual differences, with a wide range of occurrence of any specific movement pattern. As the fetus develops, movement increases so that the child is moving on average of 30% of the day at the height of activity.[86] As the infant reaches the last trimester and becomes constrained by available space, movement decreases and complete positional changes occur infrequently from 26–30 weeks onward.[248] Thus the environmental conditions of the womb also afford ease of movement because of the fluid medium in which the infant resides when size and space allow but then restrict movement toward the end of the pregnancy. Movement in utero not only informs

TABLE 3.5 Average Ages and Ranges of Attainment of Gross Motor Milestones From Two Studies

	BERGER ET AL., 2007 (N 732) (UNITED STATES)		WHO GROWTH STUDY, 2006 (N 816) (GHANA, INDIA, NORWAY, OMAN, AND THE UNITED STATES)	
	Mean Age (mo.)	Range (mo.)	Mean Age (mo.)	1st, 99th Percentile (mo.)
Sitting without support			6.0	3.8, 9.2
Belly crawl	6.8	2.7–11.7		
Stand with assistance			7.6	4.8, 11.4
Hands/knees crawl	8.1	4.6–12.7	8.5	5.2, 13.5
Cruise	9.3	4.3–14.1		
Walk with assistance			9.2	5.9, 13.7

Descend stairs	12.5	7.0–20.0		

the infant of consequences of activity but also provides neural feedback that appears to help perpetuate the movement. For example, in experiments with rats, tethering the legs together with a small thread changes kicking patterns from alternating to synchronous. When the thread is removed, the synchronous kicking continues, indicating some type of learning or adaptation within the fetal nervous system.[264] In addition, the musculoskeletal system depends on fetal movement for adequate shaping of the joints; poverty of early fetal movement is associated with congenital joint malformation.[90]

General and variable movement are pervasive in the fetus and young infant, even before goal-directed movements are apparent.[293] In fact, observational tests that focus on detecting variable movement in the early months of life are useful in predicting whether an infant is likely to be diagnosed with cerebral palsy at a later age.[253] This is because a lack of variability of movement, or poverty of movement, is not normally seen in infancy. Following a healthy full-term birth the infant's movements will continue and closely resemble his or her movements in utero. In the extrauterine environment infants must learn to modify their movement in response to gravity and are bombarded with new sensory feedback. Infants engage in many small shifts and wiggles of the body and thus change and shift the weight-bearing surface (even though the infant is unable to support himself in upright postures). This provides a wide array of possibilities for selecting movement strategies for emerging functions.[93] Infants gain experience with postural control and learn to deal with sensory stimulation through their active movements.

Neonatal and Infant Reflexes

Infants are born with the ability to actively select their movement patterns. However, some stereotypic movements, often referred to as primitive or neonatal reflexes, can be elicited in neonates and young infants. In neonates the presence or absence of a reflex may help estimate the infant's gestational age.[91] Neuromaturational theorists assumed that early reflexes diminish as cortical structures take control of active movements. From a dynamic systems perspective, multiple systems contribute to the increasing difficulty in eliciting reflexes with increasing age in infancy. Increased weight, increased engagement with the environment, neural maturation, and increased control of body segments all impact the observation of reflexes. The persistence of reflexes beyond the typical range may indicate a system is not developing typically. Thus many physical therapists and physicians assess primitive reflexes during examinations. Some of the most common primitive reflexes are rooting, plantar and palmar grasp, and stepping. Tonic reflexes including the asymmetric tonic neck reflex (ATNR) and symmetric tonic neck reflex (STNR) and labyrinthine reflex also remain prominent in many children who have neurologic dysfunction. In the section above on postural control is a brief review of the postural control reactions sometimes described as reflexes. Although the functional impact of obligatory reflexes should be documented in physical therapy assessments, treatment based on the current theoretical approaches should not attempt to integrate reflexes. Rather, active movement variability and function are viewed as factors that build motor skill in the child.

Functional Head Control

As an integral component of head control, eye control should be considered in early development. Eye movement early and often contributes to the emergence of movement. Considering that gaze shifts appear at birth and lead the interest of the child even before head control is complete, eye movement should be of interest to anyone hoping to improve a motor skill. Strangely, physical therapists who are concerned with developmental skill building rarely consider the ability of the eyes to shift gaze quickly as necessary groundwork for higher-level skills. In supine, or with the head supported in a reclining position, head turning to either side of midline can usually be elicited by attracting the infant's visual orientation to a moving object. Shifts of gaze are typically preceded by rapid bursts of body movement.[263] Smooth visual pursuit is present by 6 weeks of age and is adultlike by 14 weeks.[341] The ability to move the eyes contributes to cognitive as well as motor advancement and may shift to less skillful levels when a new motor task is emerging. For example, infants learning to sit take longer looks at objects, possibly because they are allocating resources to attending to postural control.[151]

At birth, infants already have the capacity to lift the head from either full flexion or full extension when they are supported in an upright position. A stable vertical head position, however, cannot usually be sustained for more than a second or two, if at all. At about 2 months the infant can sustain the head in midline in the frontal plane during supported sitting but often appears to be looking down at his or her feet so that the eyes are oriented about 30° below the horizontal plane as in Fig. 3.6 (Campbell SK, Kolobe TH, Osten E, Girolami G, Lenke M, unpublished research, 1992). Turning of the unsupported head in the upright position is not usually possible. If the child can be enticed to lift the head to the vertical position, oscillations are typically seen with inability to maintain a stable upright posture. Finer control of neck flexor and extensor muscles typically appears in the third month, when the head is indefinitely stable in a vertical position and can be freely turned to follow visual stimulation, although sometimes with brief oscillations and loss of control. This developmental progression is the product of improving postural control and experience and the use of sensory information such as visually attending to environmental cues. Evidence suggests infants are able to keep their head in midline 2 weeks earlier when an object is in their line of sight.[93] Early complexity supports development of motor behaviors in the first months of life.

When stabilizing control of the head in the upright position has been attained, the infant can typically organize head and trunk activity so that, when placed prone, the child assumes the prone-on-elbows position by lifting the head and extending the thoracic spine while simultaneously bringing both arms up to rest on the forearms (Fig. 3.7). Given the large weight of the head relative to the rest of the body at this age, a stabilizing postural function of the legs and pelvis must provide a stable base of support for simultaneous neck and trunk extension with arm movement. Green and colleagues demonstrated that the developmental progression in both supine and prone positions involves a gradual shifting of the load-bearing surfaces in a caudal direction.[138]

Turning the head to either side while prone on the elbows may still be difficult to coordinate at this stage, and lateral head righting also remains imperfect. Nevertheless, by the end of the third or fourth postnatal month, the head, in conjunction with organized trunk and lower extremity extension, has largely perfected the maintenance of stable positioning in space appropriate for the further development of eye-head-hand control and of

FIG. 3.6 Early head control in space is characterized by the ability to stabilize the head in midline but with eyes angled downward from the vertical. (A) The infant receives support at the trunk in order to exhibit head control. (B) The infant receives support from her mother through the infant's arms to stabilize her upper trunk; she is also assisted by the social interaction and encouragement from her mother, whose face is likely a preferred object of attention for the infant. Notice the slightly rounded trunk in both pictures, indicating a lack of active trunk extension in this position and a reliance on external support from the parent. ([A] From van Blankenstein M, Welbergen UR, de Haas, JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p 26. [B] From iStock.com.)

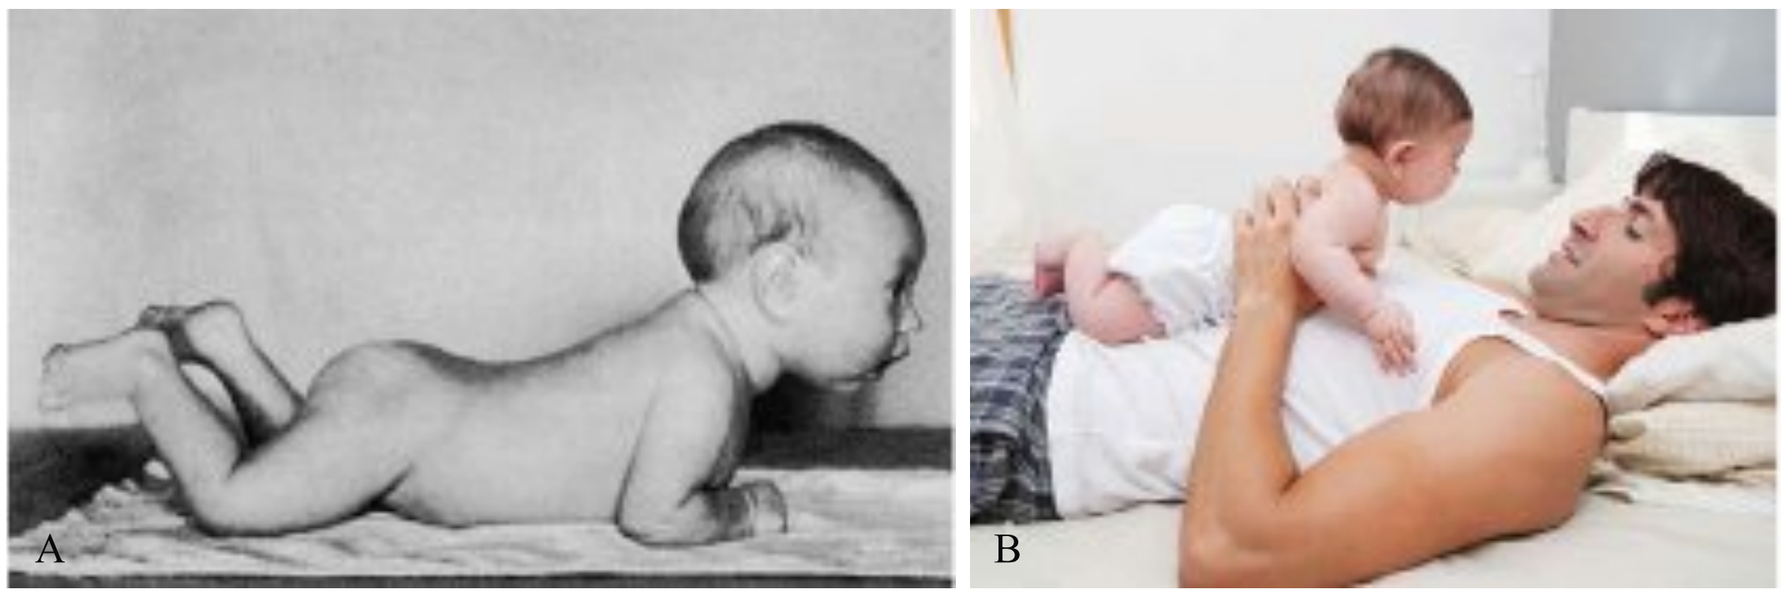

FIG. 3.7 Early stage of prone-on-elbows posture with stable neck extension, elbows close to trunk, and flexed hips and knees. (A) You can see the curvature of the infant's back, which is less than in Figs. 3.8 or 3.9. Also note the significant hip flexion that still exists, driving the pressure at the base of support cephalically. (B) The father assists the infant to shift the weight caudally, allowing for better head lifting, which is also encouraged by the face-to-face interaction of father and child. ([A] From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p 25. [B] From Shutterstock.com.)

independent sitting to come (Fig. 3.8). Bushnell and Boudreau believe that a stable head is a prerequisite for initial ability to perceive depth cues from kinetic information (movement of an object relative to its surroundings or to self), which is present by 3 months of age.[45] Once established by 4 or 5 months of age, binocular vision is used to identify depth cues.

Commensurate with acquisition of functional control of head positioning are important developments in control of the arms that are also related to positioning. For example, the prone position was effective in eliciting hand-to-mouth behavior in 0- to 2-month-old infants, whereas this behavior was elicited more often in sidelying when infants were 3 to 4 months old.[265] During the second and third months, generalized movements of the arms and body have altered their earlier writhing quality.[254] Small, fidgety movements appear throughout the body, the arms and legs may show oscillations during movement, and ballistic swipes and swats with legs or arms appear for the first time.[142] For example, if the legs are flexed up to the chest and then released while the infant is supine, the legs may extend so that the heels pound the supporting surface, or when excited, the infant may make large arm-swiping movements in the air. The first evidence of reciprocal activity of muscular antagonists

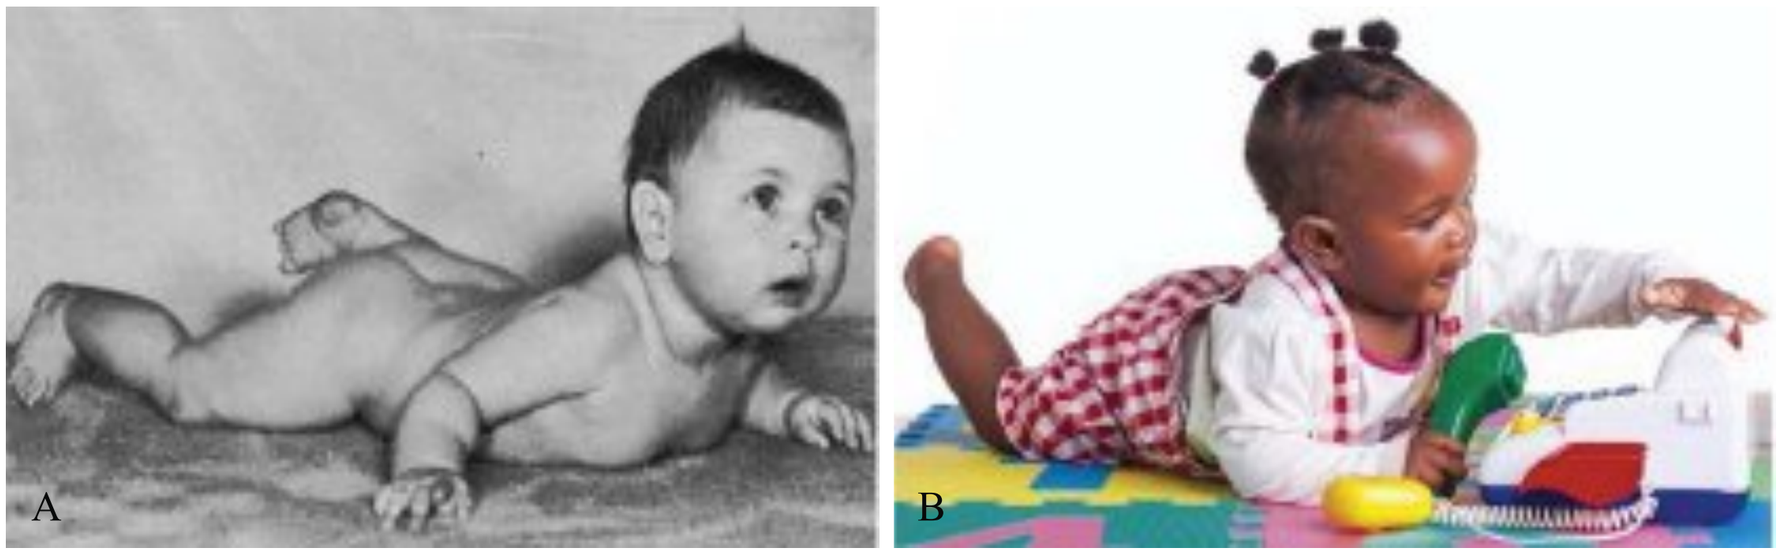

FIG. 3.8 Advanced stage of prone-on-elbows posture, with free movement of head and arms and extended lower extremities. (A) Note that the infant's arms are free to move because the weight of the upper trunk and head is shifted more caudally than in Fig. 3.7. Thus as depicted in (B), infants at this level of skill begin to shift weight to one side and reach to manipulate toys in prone. ([A] From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p 34. [B] From iStock.com.)

about the shoulder underlies the ability to perform these ballistic movements.[142] Ferrari and colleagues suggested the importance of these developing qualitative changes in spontaneous movement by demonstrating that they herald the appearance of goal-directed reaching and by indicating that they do not appear in children destined to be diagnosed as having CP.[103] Children with CNS dysfunction resulting in spasticity also tend to move in tight ranges characterized by simultaneity of activity in multiple limbs, referred to as cramped synchrony, and general movements that tend to repeat monotonously. The characteristics of children with dyskinetic CP are different.[95] Until the second postterm month, these infants displayed a poor repertoire of general movements, circling arm movements, and finger spreading. These movements remained until 5 months, when they became associated with lack of arm and leg movements toward the midline.

It is notable that typically developing infants have an abundance of movement with large variability when awake and alert. Movement is constant, with small shifts of weight and constant orienting to different events or aspects of the environment. This constant self-generated action provides a rich pool of sensory information from which the infant can gain an understanding of the consequences of particular movements and build concepts about the world around him.

Sitting and Transitioning Toward Mobility

Infants are supported in the sitting position by caregivers and in equipment starting at birth. It is not surprising that caregivers encourage sitting, considering the amount of time sitting functions to support everyday activities such as eating, playing, manipulating objects, or just looking and thinking. Sitting "propped" on extended arms after being placed in position by a caregiver begins around month 4 or 5. Prior to maintaining prop sitting, many infants begin to initiate movement toward a more vertical sitting posture when they are in a supported, reclined position, such as in an infant seat or on a parent's lap. Thus head orientation and positioning the arms to access environmental information appears to drive the infant toward sitting. The initial ability to maintain sitting independently on propped arms when placed also co-occurs with the ability to extend the head and trunk in prone position such that the legs and pelvis become load-bearing surfaces (Fig. 3.9). At this time the infant is also able to control the pelvis and lower extremities while using the arms or moving the head in the supine position, indicating the ability to stabilize the body segments to counteract internally generated forces caused by movement.[138]

Harbourne and Stergiou described the development of sitting independence in three stages.[150] Stage 1 is the prop sitting phase, when the infant begins to explore the limits of the body segments (trunk and head primarily) over a static base of support. The legs are positioned in wide abduction, external rotation, and flexion in a "circle" sit posture. At this point the infant exhibits many "wiggly" movements of the trunk, which appear to be attempts to control the many degrees of freedom of the pelvis, spine, and head. EMG reveals that there is no singular postural pattern of motor control as the infant is placed into the prop sitting position, and variable muscle synergies (muscles that contract in a fixed time sequence) are utilized as the infant goes through a trial-and-error process to find a strategy that successfully controls the posture.[148] Infants at this stage of sitting may attempt to lift the arms to reach, but the effort disrupts the tripod stability of the posture, and the reach appears as primitive batting that does not go above the level of the shoulder.

Typically, in about a month at around 5 months of age, infants progress to Stage 2 of sitting, described as the ability to sit without use of the arms for short periods of time (a minute or two), but the child lacks the skill to maintain the posture while performing ongoing activity such as manipulating objects or looking around the room (Fig. 3.10). Sitting at this time is quite variable as the child attempts to control the body segments from the pelvis on up over the static legs. Trunk movement occurs often in wide excursions, in the infant's attempt to bring his or her center of mass under control. Even turning the head quickly can cause the child to lose balance. During this stage, parents often surround the infant with pillows because movement errors are frequent and falls are inevitable. However, infants persistently reach both within their cone of stability and outside of their stable range, falling and learning with each new reach challenge.[152] Reaching, although expanded to areas outside of the leg boundary of the child and over the level of the shoulder, is now linked to trunk and pelvic movement as the infant freezes degrees of freedom to accomplish the exploration of the surrounding environment. Fewer bilateral reaches are

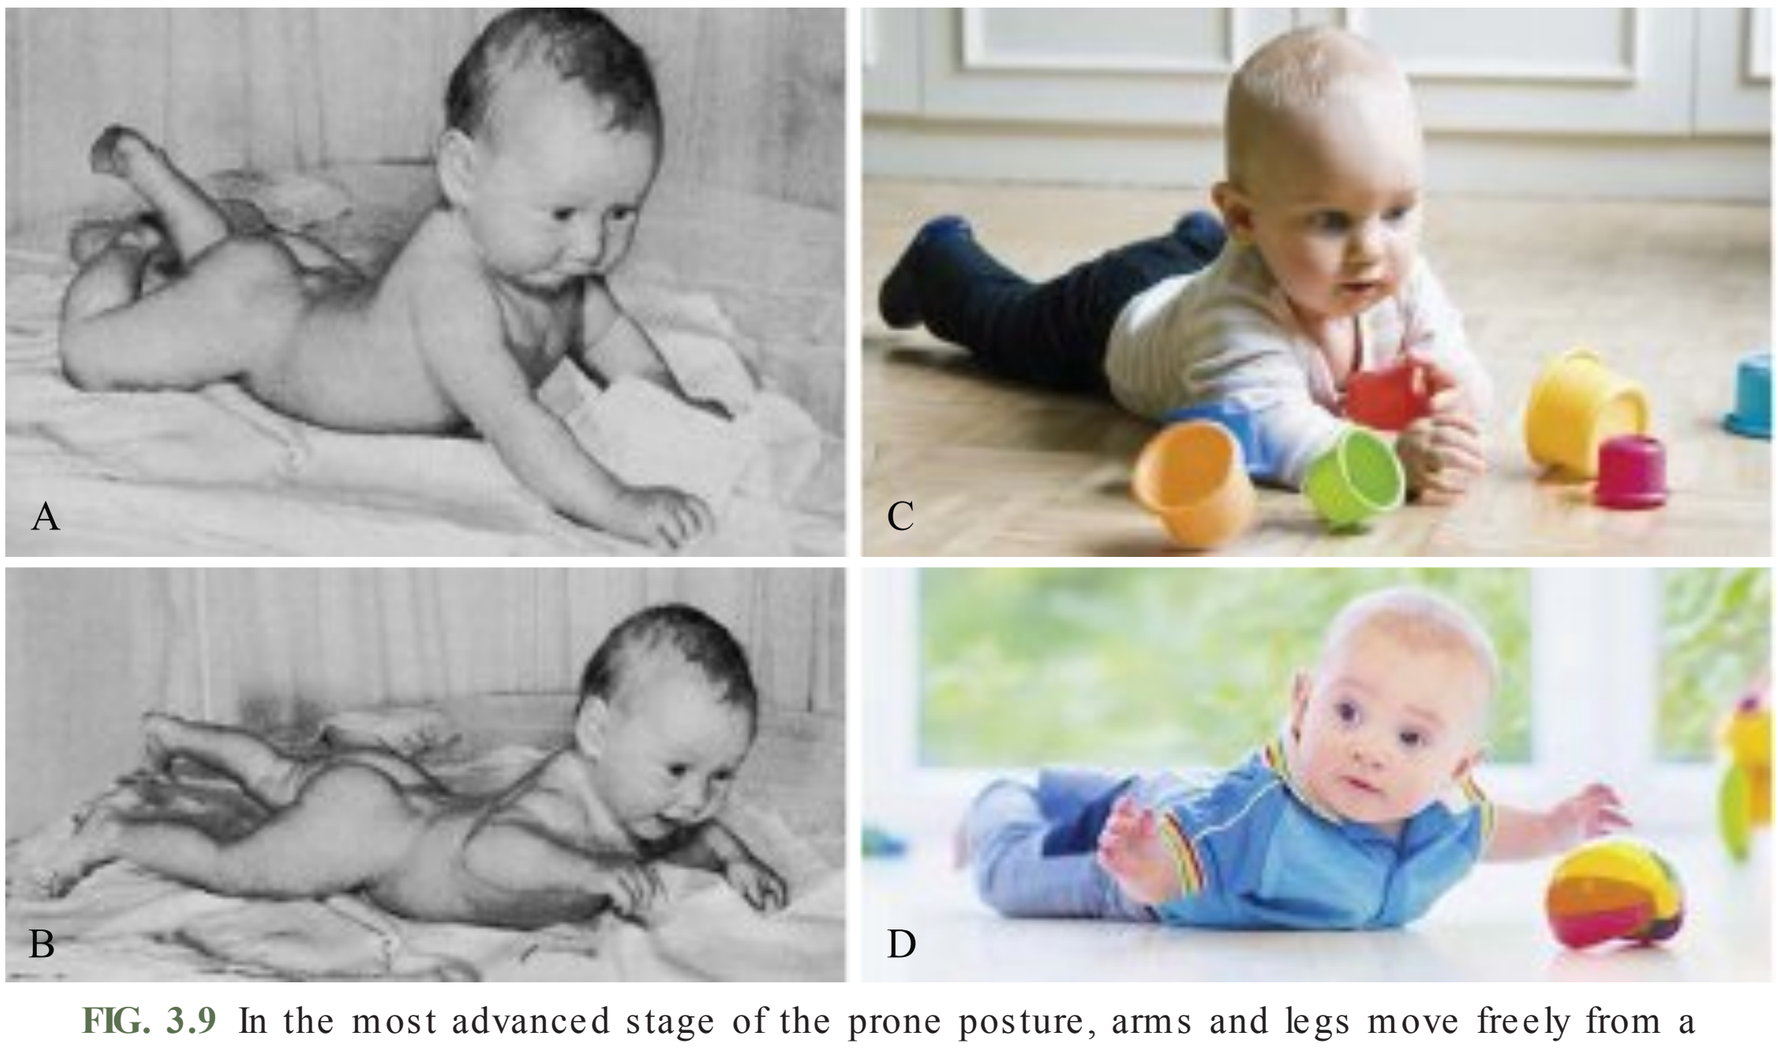

FIG. 3.9 In the most advanced stage of the prone posture, arms and legs move freely from a stable trunk. The skillful control of trunk and hip extension in this position allows the infant to push far up on the arms (A), or to elevate the upper trunk, arms, and legs off the surface in a "superman" pose (B). (C–D) This emerging ability to gain elevation and come off the surface allows engagement with toys and greater visual regard of the environment. ([A–B] From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p 37. [C–D] From iStock.com.)

present at this stage of sitting because the child will attempt to somehow stabilize the body with one arm while reaching with the other. However, once an object is brought close to the center of mass, infants will again resort to bilateral exploration.

Midway through the first year, at about 6–7 months, the average child achieves the ability to sit alone. In this third stage of sitting, infants no longer need to be surrounded by pillows and can sit for extended periods of time without falling. They can reach in all directions and above their head without excessive trunk movement, unless the trunk movement is necessary to extend the reach. The infant can successfully manipulate an object with one hand while the other hand holds it, although sitting and manipulating at once may still be a challenge. Poking fingers explore crevices and crumbs and herald the fine, selective digital control that characterizes the human organism. Strong extension throughout the body in the prone position and caudal shift of the load-bearing surfaces allow significant freedom of action for the arms and head. Bushnell and Boudreau believe that ability to perceive the characteristics of objects through their manipulation now allows the child to use configural cues from objects in depth perception.[45] Despite these developments in arm control, the child in sitting lacks the fine pelvic and lower extremity control needed for moving into and out of the position or for turning the trunk freely on a stable base. However, the legs are no longer fixed in a circle sit position, and infants exhibit variable leg postures, not necessarily symmetrical. The legs can be adjusted to accommodate a shifting center of mass, such as when the infant reaches far beyond his or her base of support. EMG at this stage of sitting reveals that the numerous and widely variable strategies exhibited when in Stages 1 or 2 of sitting have been trimmed to "preferred" or selected strategies that provide a directionally appropriate response to a perturbation.[143,148] EMG also reveals that when infants initiate a forward reach for a toy, they prepare for the disruption to balance by activating the hamstrings and trunk extensors prior to activating arm muscles. Thus the infants have learned, over the past few months of trial and error, the appropriate muscles to activate in the service of efficient reaching and exploration with the hands, a form of anticipatory postural control. Pelvic control notable in sitting is also exhibited in rolling segmentally from the supine to the prone position (Fig. 3.11), pivoting while prone, and playing with the legs and feet while supine.

During the end stage of sitting development, the infant has great variability in arm, trunk, and leg movement. It is during this time that the transition from sitting to prone begins, as the infant leans forward, reaching with one arm while bearing weight on the other arm.[132] The combination of rocking movements, unilateral hand preference for reaching, and increased ability to orient the head and trunk in all directions appears to co-occur with the transition from sitting to crawling. This coalescing of multiple factors fits into the dynamic systems theoretical viewpoint because various systems can contribute to the self-organization of a new pattern of movement.[133]

Upper Extremity Use: Grasping and Object Manipulation

So far we have addressed the use of trunk and lower extremity control in exploratory motor control, but the upper extremity is crucially important to motor exploration. From fetal movements including hand to hand, hand to mouth, and hand to umbilical cord, fetuses are controlling their upper extremity and hand to learn about the world and their own bodies. Following delivery, infants must learn to control their upper extremity and hand in the new environment with gravity, increased visual and auditory stimulus, and more diverse objects to interact with.

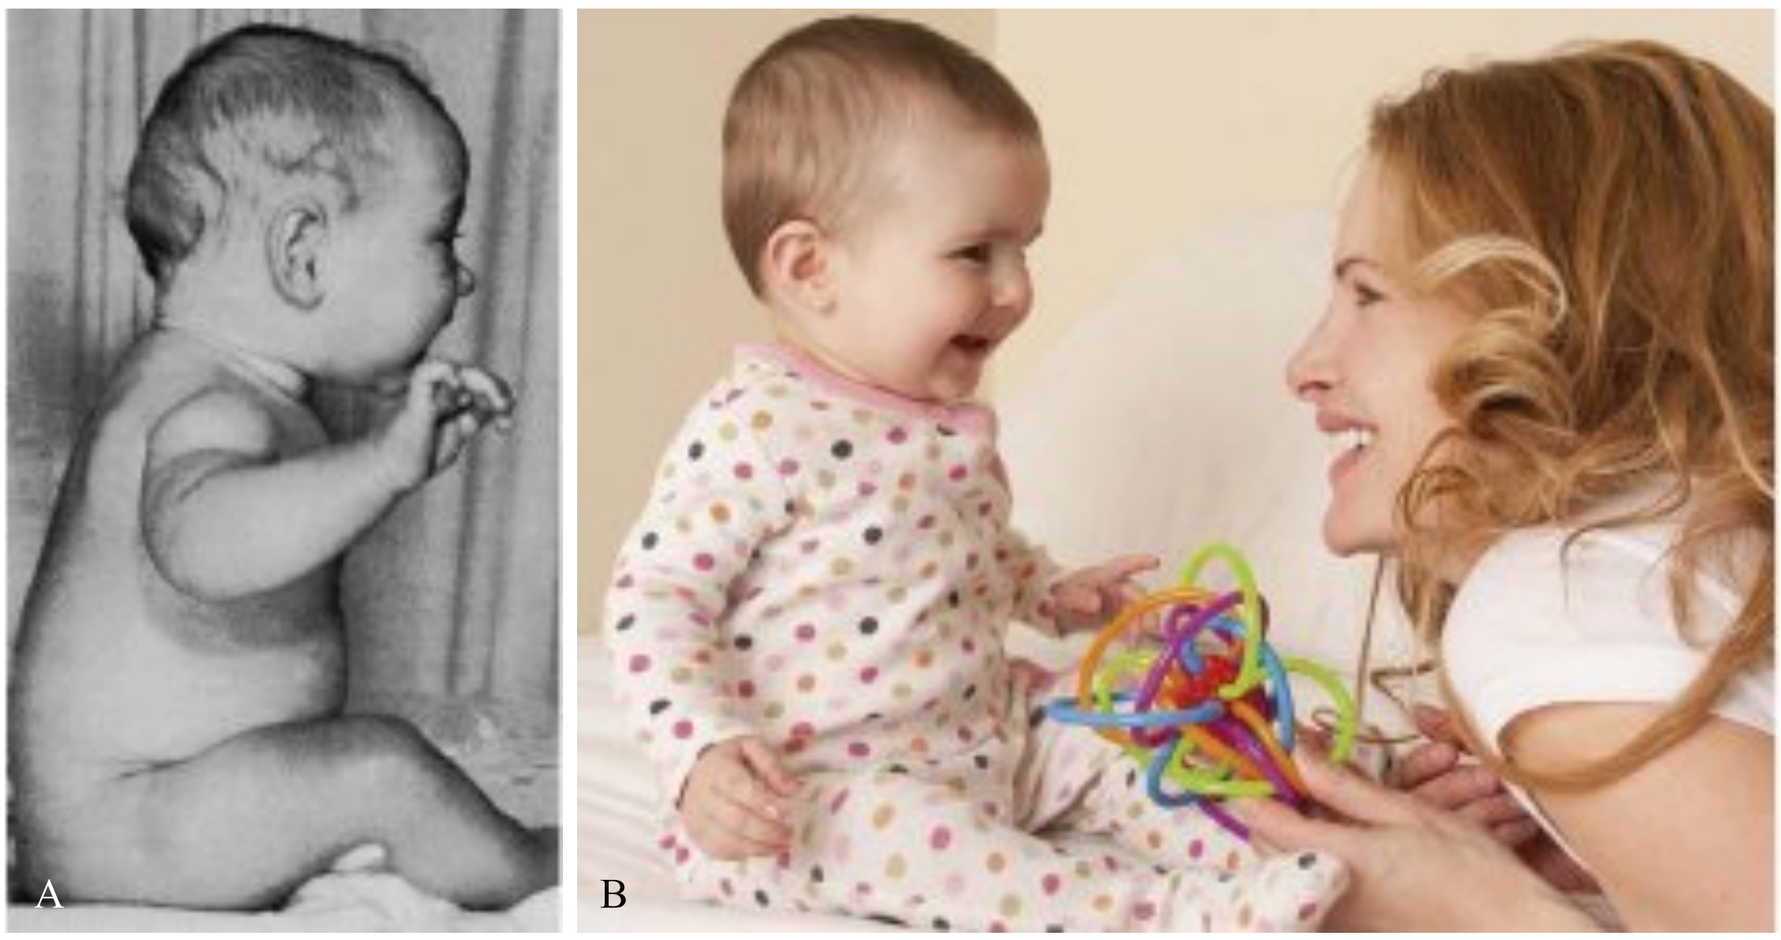

FIG. 3.10 Early stage of independent sitting, with arms used for balance. (A) The infant raises his arms in a "high guard" posture to stabilize the trunk and head; note the trunk is not as curved as in Fig. 3.6. (B) The infant shows his ability to gaze at and interact socially with his mother, as well as having the potential to reach for the toy because the arms are not needed as much for stability. ([A] From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p. 39. [B] From iStock.com.)

While postural control, strength, visual acuity, cognition, and motivation all play a role in the development of reaching and grasping, here we will focus on the control of the upper limb. Upper limb control can be broken into three sections of control development: reaching, object manipulation, and anticipatory grasping. Reaching control was covered in the previous section on motor control; here we move to greater detail about hand use.

As discussed previously, the infant's initial upper extremity goal is to bring the hand to an object or to his or her mouth. Yet the hand's interaction with the target is the true driver of perceptual development, not the reach alone. Early grasping behaviors can be observed in infants during spontaneous movements between 1 and 5 months of age.[350] Infants are observed to open and close their hands and to grasp their clothing and other objects that are near their hands during spontaneous movements. Fisting decreases while preprecision and precision grasp[112] emerge around 2 to 4 months of age. Self-directed grasping and self-exploration increase around 4 months of age in typically developing children.[350] These early grasping behaviors may provide experience and help infants learn to anticipate grasping following reaching at older ages.

Infants use four grasping patterns in the first 5 months, including fisted grasps, preprecision grips (thumb to side of index or middle finger), precision grips of objects, and self-directed grasps of their own body or clothing to explore objects and their own bodies.[350] While Karniol suggested infants move through invariant stages of spontaneous object manipulations,[189] research of Thelen,[311] Thelen and colleagues,[318] Oztop and colleagues,[238] and Keshner and colleagues[194] hypothesizes that, although functional hand use develops in a regular, invariant sequence when tested with a standardized series of tasks, it is likely that each infant uses unique coordinative patterns and kinetics. Each infant's pattern is developed with a specific manipulative goal circumscribed by individual variations in body structure, experiences, and rate of neural and physical maturation. Karniol suggested that parents and others who choose toys for infants have two important functions: (1) helping infants to master the abilities of each stage by providing objects that are appropriate for emerging skills and (2) facilitating infants' developing sense of capability to control their world by providing objects that are responsive to current manipulative abilities.[189]

Thus the stages of object manipulation presented here as described by Karniol are now considered to be flexible and overlapping, as noted from the dynamic systems perspective.[189] They typically progress from rotation (angular displacement) to translation (movement parallel to the object itself) to vibration (rapid periodic movements of either translation or rotation). Later stages involve combinations of these actions and bimanual activities.[39] One factor that has been shown to affect skill in managing multiple objects during the age range from 7 to 13 months is hand preference.[197] Infants with stable hand-use preference used more sophisticated sequences of activity when presented with multiple objects. Because the task characteristics structure the infant's unique response, parents play an important role in providing opportunities that support development.

Stage 1, rotation of held objects—by 2 months. With improvements in head stability and visual perception, holding objects becomes an intentional act. Objects are first held when they come directly into the infant's reach and are later (by 3 to 4 months) twisted while being held. Karniol indicated that through this action infants learn that objects can be held and their appearance transformed by rotation.[189]

Stage 2, translation of grasped objects—by 3 months. Typical of this stage is reaching for an object while in the prone posi-

FIG. 3.11 Rolling from supine to prone with head righting. (A–C) These photos depict head righting, or the raising of the head off the surface in the course of rolling over to keep the head aligned to vertical. (D) This photo depicts goal-directed rolling: that is, rolling to interact with a person or an object, as a means of mobility. Note how the infant is reaching toward his father, which would assist the rolling movement as well as provide important interaction with others and with the environment. ([A–C] From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p 36. [D] From ThinkStock.com.)

tion and bringing it to the mouth. The object may also be rotated. What the infant learns through these types of action is that he or she can translate objects in order to look at, or mouth, them and that it is not possible to reach objects farther away than the length of the arm.

Stage 3, vibration (shaking) of held objects—by 4 months. In this stage infants learn that they can make interesting noises by rapidly flexing and extending their arms and can make the noise stop by holding still. If the object does not produce a noise, it may be translated or rotated and examined before being dropped, but visual attention is not a dominant part of this activity.

Stage 4, bilateral hold of two objects—by 4.5 months. The infant may hold an object in one hand and shake an object held in the other; infants thereby learn that it is possible to do more than one thing at a time (Fig. 3.12).

Stage 5, two-handed hold of a single object—by 4.5 months. First use of bimanual holding is to hold an object, such as a bottle, steady, but it rapidly advances to holding (and often rotating) large objects that require the use of two hands. These actions allow the child to learn that two hands can steady and rotate objects better than can one hand, as well as permit the holding of large objects.

Stage 6, hand-to-hand transfer of an object—at 4.5 to 6 months. Transfer is usually followed by repeated actions on the object with the second hand; infants thereby learn that whatever can be done with the right hand can also be done with the left.

Stage 7, coordinated action with a single object in which one hand holds the object while the other manipulates or bangs it—at 5 to 6.5 months. A quintessential example of this type of activity is holding a toy in one hand while picking at it with the other (Fig. 3.13). Displacements of the object caused by handling are followed by rotational readjustments of the hand that holds it. These activities teach the infant that two hands can do more than can one hand alone and that noise can be produced from striking objects that do not respond to vibrating. Infants at this age tend to be unimanual reachers with reaching being space dependent rather than object dependent, and it is not until 6 to 8 months of age that infants can take possession of two objects at the same time.

Stage 8, coordinated action with two objects, such as striking two blocks together—at 6 to 8.5 months. Through these actions, the infant learns to produce interesting effects by moving one object toward another.

Stage 9, deformation of objects—at 7 to 8.5 months. At this stage, the infant learns that it is possible to alter the way things look or sound by ripping, bending, squeezing, or pulling them apart.

Stage 10, instrumental sequential actions—at 7.5 to 9.5 months. These activities involve the sequential use of two hands for

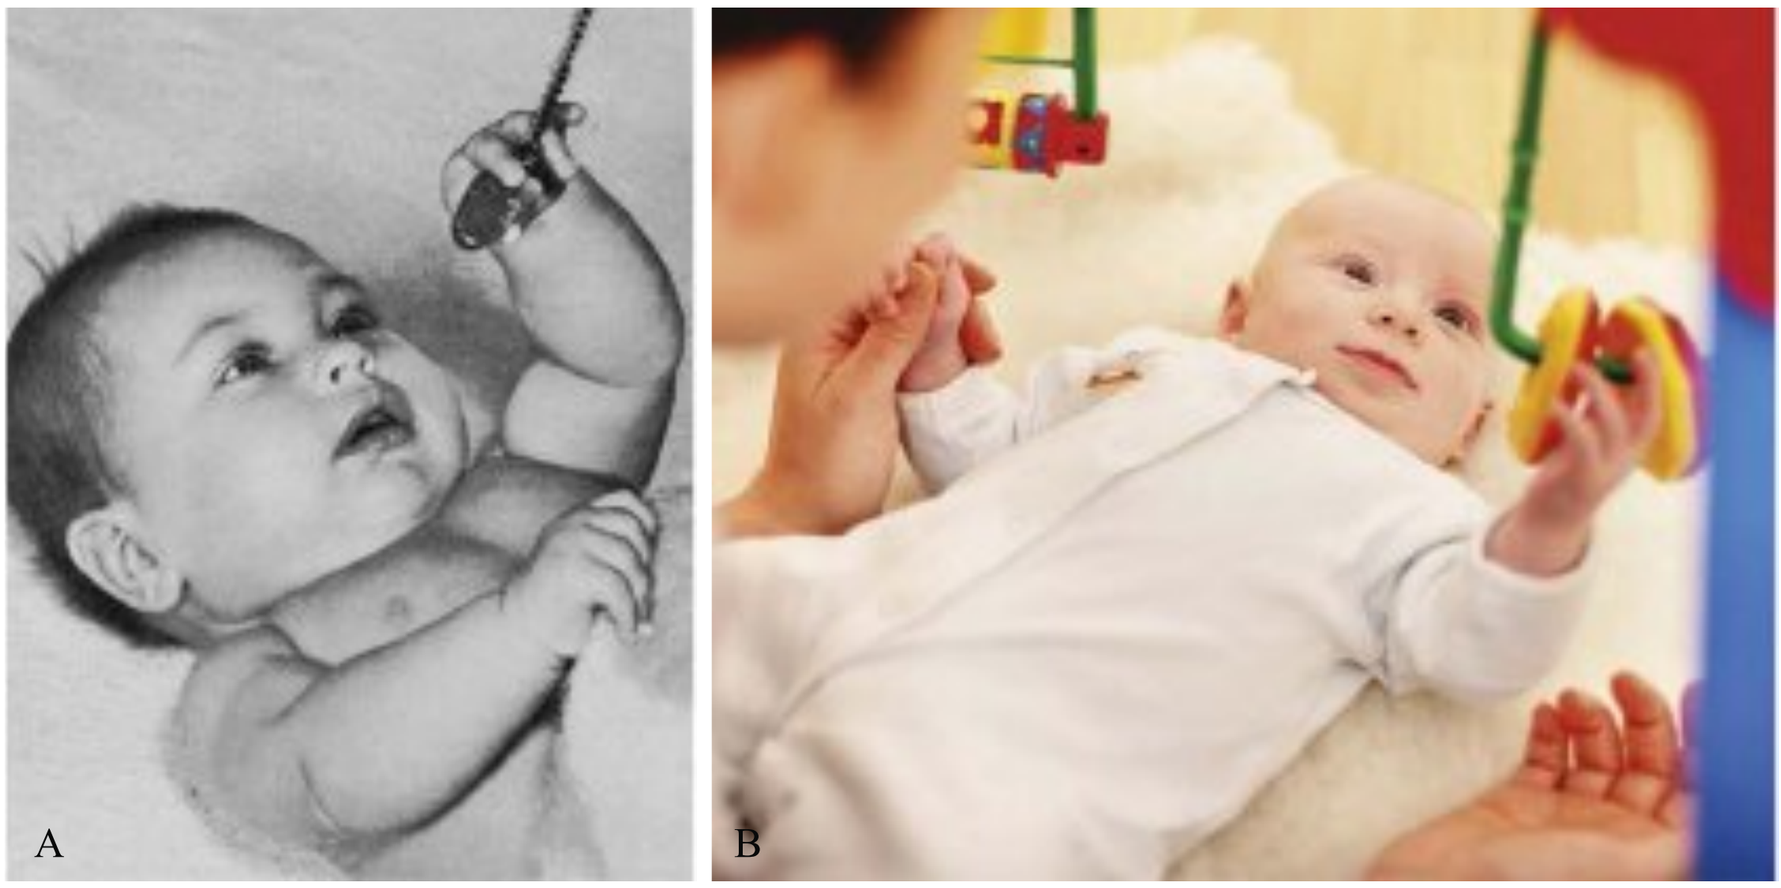

FIG. 3.12 Bilateral hold of two objects. (A) One hand holds the blanket, the other reaches for a keychain (stage 4 of Karniol).[160] Both pictures show bilateral holding action of the infant, but (B) includes the mother within the visual field of the infant. Importantly, the infant can begin to experience joint attention to objects with his mother in such a setup, a critical step in communicating ideas as the infant looks back and forth between mother and object and she reacts with commentary. ([A] From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p 91. [B] iStock.com.)

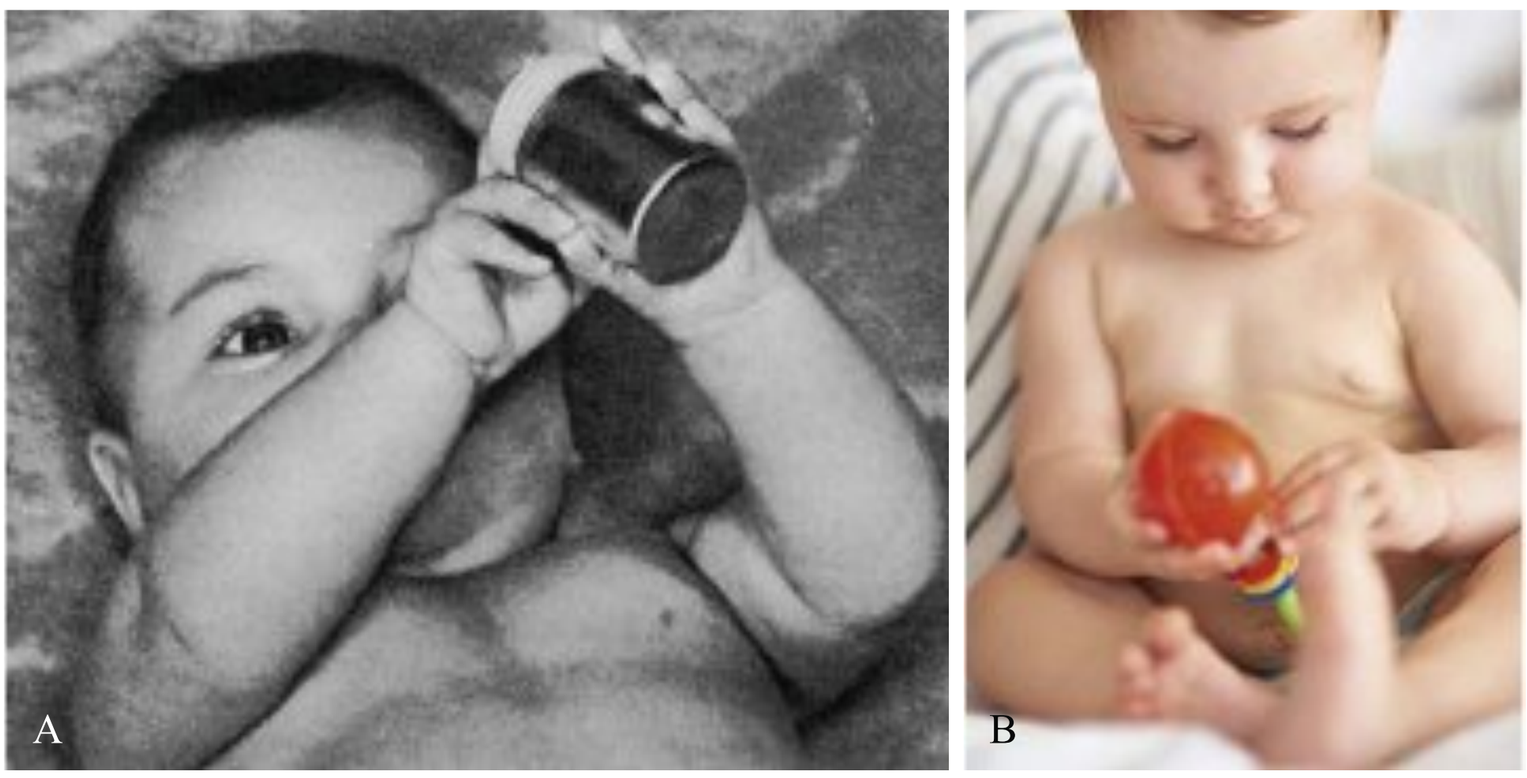

FIG. 3.13 Coordinated action with a single object: holding a toy with one hand while poking at it with another (stage 7 of Karniol) (A).[160] Note in both pictures the infant's visual regard and focus are to the toy and her hands, as eye-hand coordination emerges as the infant learns skillful manipulation of objects. (B) The infant has found an interesting part of the toy that slides and proceeds to explore the sliding motion. ([A] From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p. 93. [B] From iStock.com.)

goal-oriented functions so that the infant learns that coordinated use of the hands leads to desired outcomes. The infant may, for example, open a box with one hand and take out its contents with the other.

Anticipatory Control of the Hand During Grasping

In addition to reaching for or grasping an object placed in front of them, infants must learn to prepare their hand using anticipatory control to grasp an object and learn to grip smaller objects like pencils. Case-Smith and colleagues have shown that the characteristics of objects, such as differences in size and presence of moveable parts, lead to immediate use of distinct actions when grasping that are appropriate to the object's characteristics.[56] For example, a given infant might display more mature patterns of grasp when handling a toy with movable parts than when handling a pellet, so even infants seem to have

some capability to recognize the affordances for manipulation offered by different objects despite having preferred modes of operating on items in the environment. Recently Barrett and Needham showed that 11- and 13-month-old infants used visual information from the shape of an object to grasp an asymmetrical object further from its center of mass than a symmetrical object.[15]

As with the development of object manipulation, a general pattern of development can be described that is flexible to the abilities of the child and the constraints in the task. As shown in walking and crawling experiments, we see that infants have extensive capability to use sensory inputs to make decisions about choice of motor actions, although they are not always right about their motor capabilities for solving the problem at hand.[8] They choose to act rather than avoid a challenging situation, do not engage in trial-and-error learning, but rather continue to rely on their visual-haptic analysis of whether or not to engage in risky behavior. While presented with the typical ages of onset, the descriptions of anticipatory control of the hand during grasping are variable, just as many other motor skills vary with experience in the task.

At the onset of functional reaching, infants are not inclined to reach for objects that are placed at the perimeter of their reach.[106] At 5 months of age, they begin to orient their hand toward the object, either just before or at the beginning of the reach,[224] as well as shape the hand in anticipation of object size constraints during manipulation.[232] At this age, infants primarily rely on contact with the object to orient and successfully grasp the object, but over the next 3 months, infants begin to use visual information to both anticipate contact and orient their hand with respect to the object.[213,15]

When adults reach to grasp an object, the distance between index finger and thumb is set with respect to object size at the onset of reaching.[177] Anticipation of object size is similarly observed in the hand posture of 9- to 13-month-old infants during reaching,[344] suggesting that young infants quickly learn to preprogram reaches for object size, location, and distance on the basis of visual information. The grasp of infants older than 9 months continues to exhibit some immature features, one being the relatively constrained range in hand opening when infants are presented with an assortment of objects varying in size.[210]

The infant's hand may open in exaggerated postures. Infants may open the hand widely as a strategy to compensate for limited ability to estimate the task requirements for grasping an object.[344] Finally, this exaggerated hand opening in the infant could be due to the small size of the hand in relation to the object. A body-scaled relation of the grip configuration, based on an equation including the size and mass of the object to be grasped and the length and mass of the grasping hand, has been demonstrated to be invariant across young children (6 to 12 years of age) and adults.[59,60] The force applied during grasp, the duration of the grasp, and displacement phases of prehension have also been shown to adhere to the same body-scaled relationship.[61] These findings support the idea that mature grasp and displacement are ultimately controlled within a single action that relates to body size and object perception.

Becoming Mobile

During the third quarter of the first year, around 7 months, infants begin to explore movement through space and develop movement, freeing them from positioning by others. As infants explore the parameters of their bodies and the affordance of the environment, new movements emerge. There are many possible patterns of moving within the environment, and not all children choose the same strategy. Some infants drag the belly on the floor in a "combat crawl" style, and other infants scoot along on the bottom in a sitting position alternating with a hands and knees position. Other infants crawl with a reciprocal alternating pattern of the arms and legs. At least 18 different "styles" of crawling have been documented, and some infants use several over the course of becoming mobile.[6]

Context can also dictate a crawling pattern. An infant who normally belly crawls may be forced to crawl on hands and knees if he or she is trying to move in only a diaper on a hot, sticky day when frictional forces prevent dragging the belly on the normally slick tile floor. Although there are many forms of crawling, generally infants converge on a diagonal pattern of limb movement shortly after they have enough control to get their abdomen off the floor.[119] Control of lower trunk and pelvis, combined with previously achieved upper body skills, provides new mobility when prone (Fig. 3.14), crawling and creeping (Fig. 3.15), pulling to a stand, moving from supine to four-point and sitting positions, and moving down to hands and knees or prone position from sitting (Fig. 3.16). Inherent in each activity are freedom from a strong midline symmetry that previously characterized postural control and the continued refinement of rotational abilities within the axis of the trunk.

The presence of oscillations also continues to herald new developments. Rocking on four limbs before launching into creeping[6] and bouncing while standing before beginning to cruise along furniture are examples of self-induced actions that appear to be important precursors of functional skills. These repetitive movements may be a way that the child calibrates the forces needed to control body mass in new positions or a process of perceiving the result of actions that are self-produced.

Once the child has attained competence at standing and cruising along furniture, the legs and feet move toward perfection of selective control because the trunk and pelvis are increasingly reliable supports that permit freedom of lower extremity activities. In creeping, pelvic swiveling motions give way to reciprocal hip flexion and extension activity, and creeping velocity increases because an arm and a leg on the same side of the body can be placed in simultaneous flight. The child can lower himself or herself from standing (Fig. 3.17); bear-walk with dorsiflexed ankles, flexed hips, and partially extended knees (Fig. 3.18); ascend stairs by crawling up at an average age of 11 months with descent several weeks later, usually by backing down;[22] and stand and walk independently at 9 to 15 months of age (Fig. 3.19). As an example of typical regressions in the course of development, the early stage of walking is accompanied by a return to two-handed reaching, which declines again in frequency as balance control improves.[74] Chen and colleagues have also shown that learning to walk affects infants' sitting posture as the internal model for sensorimotor control of posture accommodates to the newly emerging bipedal behavior.[66] Increased postural sway in sitting just prior to or at the onset of walking is commensurate with the idea that new motor behaviors arise during periods of high instability.

Motor Development Beyond the First Year

Functional Motor Skills and Activity Levels in Preschoolers

We turn now to a description of the functional skills of preschool children, combining information on both gross and fine motor function in practical use. Toddlers operate with different

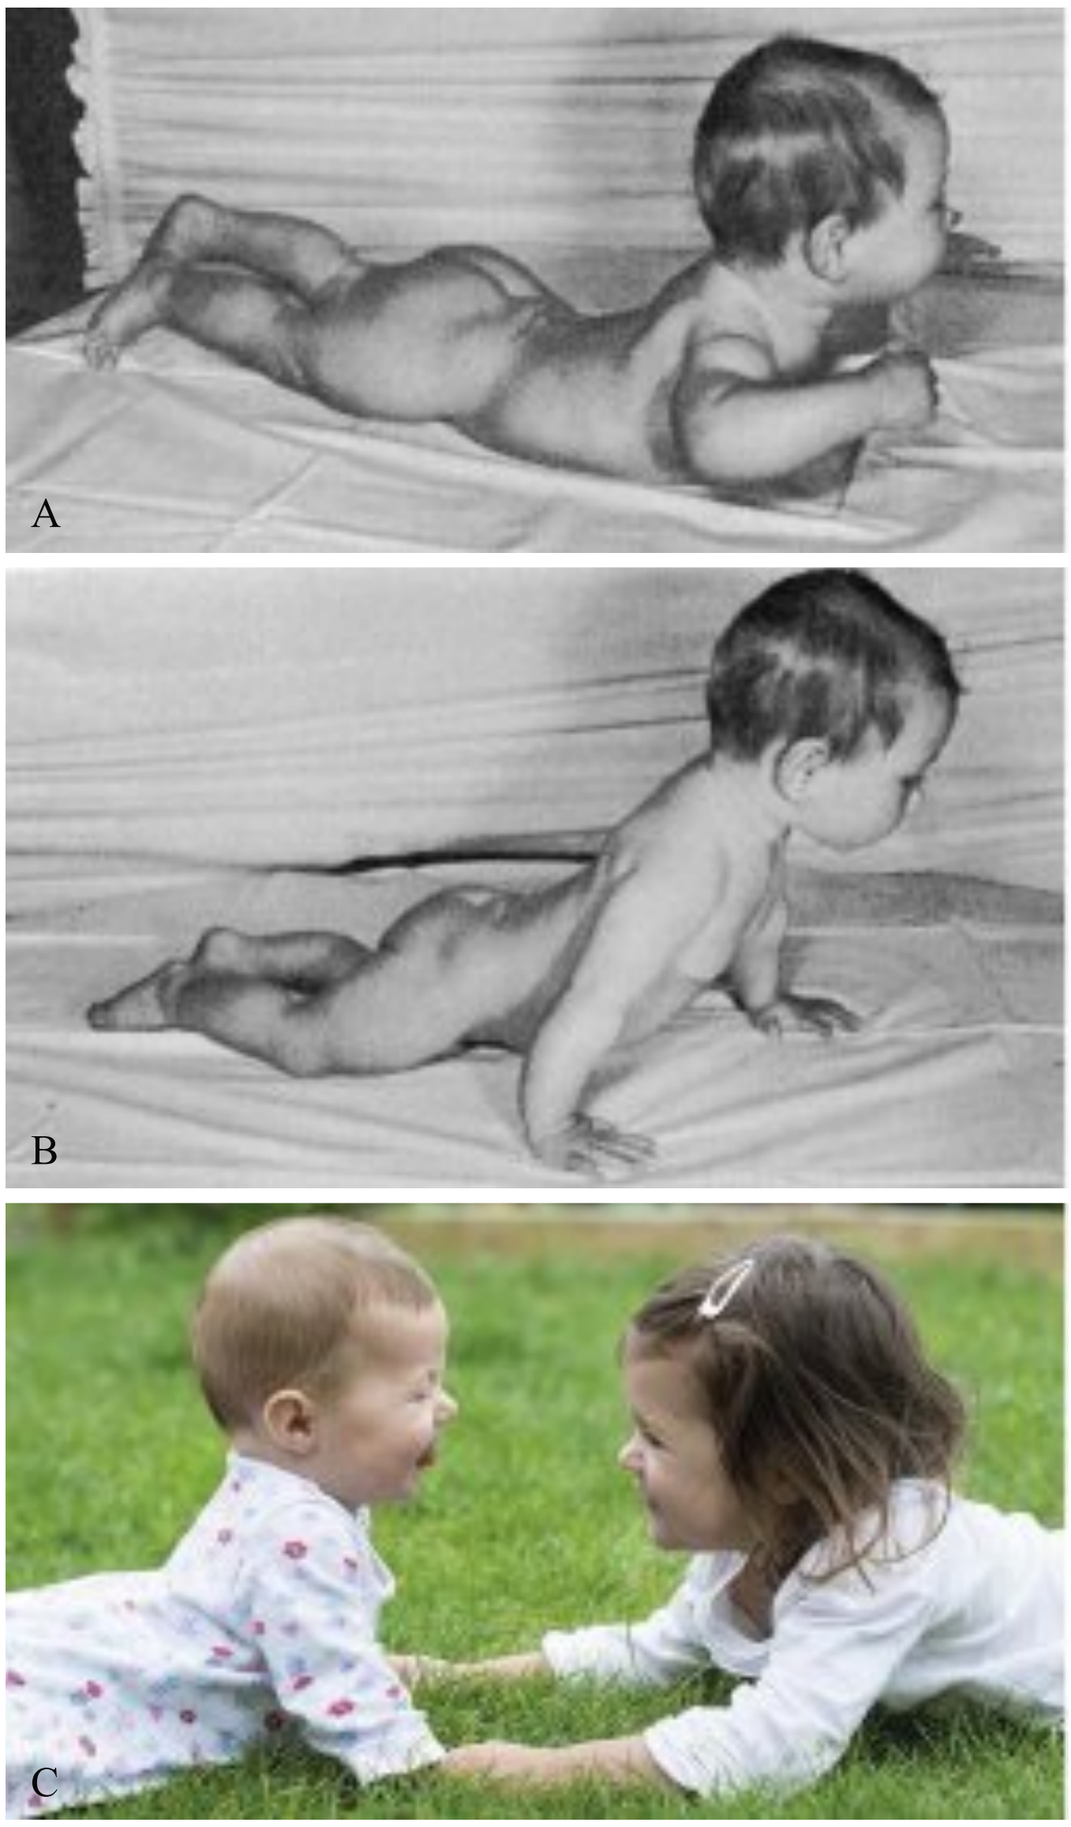

FIG. 3.14 (A–B) Dynamic play in prone position includes "flying" and push-ups on extended arms with strong trunk extension and scapular retraction. These types of movements are often immediate predecessors to rocking in the all fours position. (C) This emerging ability to gain elevation and come off the surface allows eye-to-eye engagement with a sibling and advances social interaction for future communication. ([A–B] From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p 47. [C] From iStock.com.)

anthropometric characteristics than infants. Toddlers gain about 5 pounds in weight and 2.5 inches in height each year, the latter resulting mostly from growth of the lower extremities.[73] Fifty percent of adult height is reached between the ages of 2 and 2.5 years. Children now walk well (although steps are still short and constrained) and enjoy the sheer pleasure of movement through running, climbing up and down stairs independently, and jumping off the bottom step.[10]

The 2-year-old child can kick a ball and steer a push-toy, and by 2.5 years the child can walk on tiptoes, jump with both feet, stand on one foot, and throw and catch a ball using arms and body together. Galloping may appear, but only leading with the preferred foot.[261] The more practical pleasures of dressing independently (pulling on a simple garment at 2 years and pulling off pants and socks by 2.5 years) and eating with a spoon with little spilling also develop.[10] Food preferences can become a touchy subject by around 2.5 years; nevertheless, the toddler is gradually developing impulse control.[73]

Roberton and Halverson hypothesized the following temporal sequence of further development of foot locomotion patterns: walking; running; single leap, jumping down or bounce-jumping, and galloping (in uncertain order, but generally at about 2 to 2.5 years); hopping on dominant foot (seldom before age 3) and then nondominant foot; and skipping and sideways galloping or sliding.[261] Although some children may manage a skip by age 4, many reach an early level of proficiency only by age 7. A rhythmic step-and-hop movement is even more difficult and does not appear until well into the primary school years, when it may be used in many dance forms.

The 3-year-old child can alternate feet easily when ascending stairs, can control speed of movement well, and takes pleasure in riding a tricycle.[10] Hopping may emerge, although it is often a momentary, single hop on the preferred foot.[154] Surprisingly, however, by 3.5 years the child may seem less secure and physically coordinated, stumbling frequently and showing a fear of falling.[10] Hands may show excessive dysmetria during block stacking. Nevertheless, typical 3-year-olds feed themselves well and can hold a glass with only one hand.

At 3.5 years, mealtime may again become trying because the food must be put on the plate in a certain way and the sandwich has to be cut just so. The same may be true of the dressing process, with special objection being expressed against clothing that goes over the head. The typical 3-year-old can put on pants, socks, and shoes, but buttoning may be difficult. Nearly all 3-year-olds are consistently dry during the daytime, and bowel training is well established as the physical skills and the emotional willingness to participate in toilet training come together.[73] The ability to delay gratification is developing, and toddlers strive for autonomy while continuing to intermittently seek reassurance from caregivers to whom they are securely attached.

Despite these generalizations, preschoolers exhibit a variety of individual behavioral styles.[73] About 10% of children are considered "difficult" because of increased levels of activity, emotional negativity, and low adaptability. Another 15% of children are described as "slow to warm up" because they take a long time to adapt to new situations.

Ames and colleagues have described typical 4-year-olds as characteristically out-of-bounds in their exuberance.[10] Behavior in all spheres is frequently wild, and self-confidence and bragging seem endless. The 4-year-old can walk downstairs with one foot per step, catch with hands only, and learn to use roller skates or a small bicycle. (But remember McGraw's experiments demonstrating that learning these skills is possible much earlier.) Athletic activities are particularly enjoyed, especially running, jumping, and climbing. Four-year-olds can button large buttons and lace shoelaces, feed themselves independently except for cutting, and talk and eat at the same time. The average Chinese child can use chopsticks to finish more than half the meal at 4.6 years.[357] Most children can take responsibility for washing hands and face and brushing teeth as well as dressing and undressing without help except

FIG. 3.15 Creeping on hands and knees. (A–B) Coordinated extension of the trunk and head while the legs and arms alternate in flexion. (C–D) This new found mobility allows the child increased exploration and social engagement with people, objects, surfaces, and even pets, providing ample learning situations. ([A–B]From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p 53. for tying their shoes or differentiating front from back of some garments.[10]

Early School Years

Five-year-olds tend to be more conforming than the exuberant 4-year-old.[9] Children begin to learn to dodge well at 5 years and can skip, long jump about 2 feet, climb with sureness, jump rope, and do acrobatic tricks.[261] Handedness is well established, and overhand throwing is accomplished.[10] Current research suggests that hand preference is already stable by 12 to 13 months in most children.[101] The 5-year-old likes to help with household tasks, play with blocks, and build houses. Eating is independent, including using a knife except for cutting meat, although dawdling and wriggling in the chair may be trying to parents. The challenge of dressing oneself is past, so children age 5 may ask for more help than they need (usually only for tying shoes or buttoning difficult buttons), and overall, undressing is generally easier than dressing.

At age 6, children are constantly on the go, "lugging, tugging, digging, dancing, climbing, pushing, pulling"(p 49).[10] Six-year-olds seem to be consciously practicing body balance in climbing, crawling over and under things, and dancing about the room. They swing too high, build too tall, and try activities exceeding their ability. Indoors, awkwardness may cause accidents, and the child seems less coordinated than during the previous year. Despite excellent eating skills, falling out of the chair or knocking over full glasses is not uncommon.

Although children may begin to ride a bicycle at age 6, there is wide variability on acquiring this skill due to factors such as access to equipment, location, and child or family interest. Even though a child may learn to ride a bike at this age, even at 12–14 years the child does not have adultlike perception of self versus objects in complex moving environments such as a traffic intersection.[137]

Because of the epidemic levels of obesity in the US population, concern about children's activity levels as an aspect of health has been heightened. In a study of the activity levels of 493 3- to 5-year-old children in 24 preschools, children were found to engage in moderate-to-vigorous physical activity during less than 3% of observations conducted with the Observational System for Recording Physical Activity in Children-Preschool Version.[242] Children were sedentary in more than 80% of the observation intervals. Boys were more active than girls, and younger boys were more active than older boys. An important observation was that activity levels varied by preschool, highlighting the importance of environmental

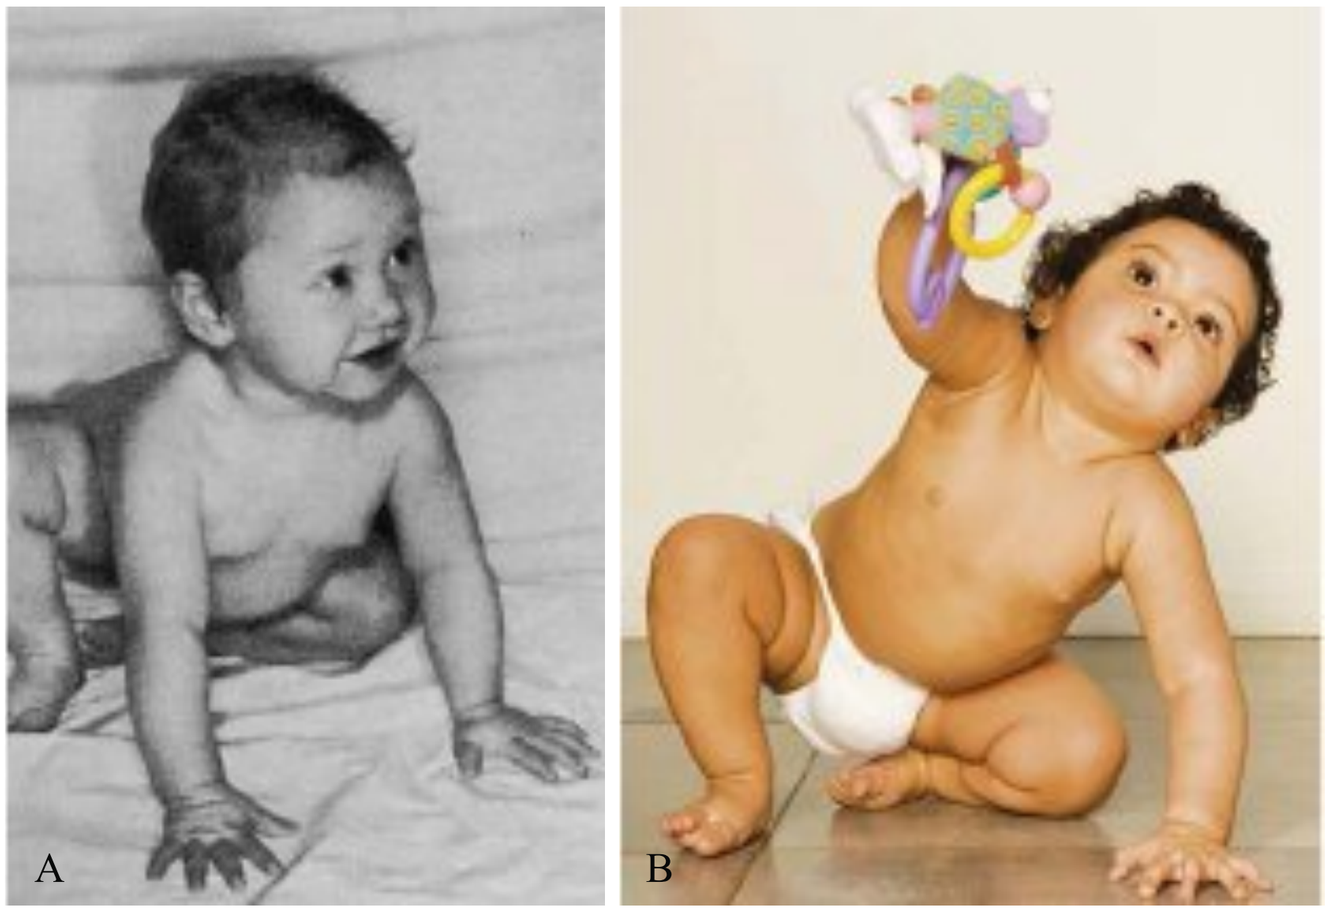

FIG. 3.16 (A) The infant moves from sitting to the four-point position over one leg. Infants transition frequently from sitting to crawling and back to sitting, generally by rocking over one leg and catching or pushing on the arms. (B) This transition comes in handy when the infant wants to socialize with a parent by showing a toy found while crawling or to move quickly out of sitting to reach an object. ([A] From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p 57. variables in children's opportunities to engage in vigorous activity.

Steps in Motor Skill Development for Older Children

In the various motor skills developed in the preschool and elementary school years, each body segment has its own developmental trajectory within the overall coordinative structure; one part can be at a different level of skill than another, although all parts tend to be at a primitive level early or at an advanced level when skills are well learned.[261] Furthermore, when demands of the task change (increased height, distance, or accuracy requirements) or when fatigue sets in, one body component may regress in its action while another continues to perform at an advanced level of skill. Thus task requirements are once

FIG. 3.18 "Bear-walking" on hands and feet. (A) Similar to crawling on hands and knees, this posture is often an option used when the surface either is rough or has added friction. (B) The child obviously enjoys the outing with the family and will adapt his mobility option to his comfort level to play. ([A] From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p 54. FIG. 3.19 (A–B) The infant walks and carries a toy, with wide-based gait and hands in "guard" position. (C) Early walking is motivated by parental encouragement and by the affordance of being able to carry objects toward and away from others. ([A–B] From van Blankenstein M, Welbergen UR, de Haas JH: Le développement du nourrisson: Sa première année en 130 photographies. Paris: Presses Universitaires de France; 1962. p 64–65. [C] From iStock.com.)

again seen to be influential in determining the characteristics of motor responses. For hopping and other skills, such as catching, throwing, and jumping, Roberton and Halverson provided detailed analyses and photographs of the intratask developmental steps for each critical body component, instruction in how to make detailed observations to categorize the level of skill of body segments, and advice for guiding the learning of these childhood skills.[261]

Physical therapists would find this information useful in planning intervention for children with mild physical disabilities or clumsiness. For example, as children learn to throw, the trunk goes through similar stages of development as those found in early developmental motor activities. The trunk is initially passive, then increasingly a stabilizer for the function of the extremities, and finally a participant in actively imparting force to the flight of the ball. Jumping changes from a functional activity characterized best as falling and catching to one of projection, flight, and landing, each with components that add force and speed or shock absorption to lend elegance and style to the activity.

Although many tests of motor development include assessment of hopping skills, most therapists probably would not view

this as a particularly functional activity because children seldom hop spontaneously.[261] Physical educators, however, believe that hopping is an important developmental skill because a hop is often required in situations such as controlling momentum during sudden stops and in handling unexpected perturbations to balance, as well as for pleasurable play activities such as skipping. Hopping is also an excellent activity for describing the development of various strategies leading, finally, to skillful action.

Skillful hopping requires projected flight off the supporting leg and a pumping action of the swinging leg that assist in force production. Initial prehop attempts involve extension of the supporting leg as the child tries to lift off with the nonsupporting leg raised high. The first successful strategy, however, is usually a quick hip-and-knee flexion that pulls the supporting leg off the floor and into momentary flight (actually falling off balance and flexing the leg) while the swing leg remains inactive. At the next level of skill, the supporting leg again extends but with limited range and early timing relative to the point of takeoff. In skillful hopping the swinging leg leads the takeoff, and extension of the supporting leg occurs late; thus the action becomes one of "land, ride, and extend."[261] Just as with infants learning to descend risky slopes, children learn through practice how to control their intrinsic dynamics to produce efficient movements that accomplish intended goals.[1]

Sports and playground games become increasingly important parts of children's motor activities when they enter school and when complex feats of coordination become possible. Children have, however, individual rates of development of the components of motor skill, some undoubtedly innate, some based on cultural characteristics and family interest in development of physical skills. McGraw's work demonstrates, for example, that toddlers can develop motor skills that are usually considered inappropriate, primarily because of safety issues. Furthermore, research has supported the belief that African American children in grade school have superior motor skills, specifically the speed and agility skills on the Bruininks Oseretsky test, relative to white children.[70,249] Most authors have explained these differences on the basis of SES and differences in strategies of child rearing.[51]

Reaching Strategies in School-Age Children

Studies in older children suggest that reaching strategies change very little from 9 months until approximately 7 years of age, at which time there appears to be a transitional period leading to an adult reaching strategy. Five-year-olds continue to use ballistic strategies much like those of older infants, whereas 7-year-olds constantly monitor their movements in a closed-loop strategy to control their reaches. Between 9 and 11 years of age, children begin to combine these strategies to increase the efficiency of their movements and to reduce the amount of attention required.[154,192] These changes in reach strategy appear to coincide with developmental changes in how children utilize sensory information for guiding and adjusting arm position during reach. Based on these studies, the child's ability to understand and utilize sensory information for reach correction continues to develop through at least the first 11 years.[154,196]

In a related vein, one current view of the clumsiness seen in children with mild to moderate movement dysfunction is that a sensory or attention problem hinders the ability of these children to identify or selectively attend to the most pertinent information during a reach.[99,219,274,365] For example, study of hand paths during movement between two buttons in a repetitive tapping task in 8- to 10-year-olds with minimal neurologic dysfunction (DCD) suggests that these children must constantly monitor and correct their actions. It is believed that using this closed-loop strategy leaves little opportunity to attend to information for executing anticipatory adjustments and minimizing the amount of error correction required. In comparison with age-matched controls, children with minimal neurologic dysfunction also appear to execute more movement units per reach. The first movement unit is less likely to be the longest unit or to achieve the greatest acceleration, and each unit tends to contain more acceleration irregularities.[274] When asked to reach from a starting point to a stationary target, 8- to 10-year-old children with DCD were less accurate than typical peers as a result of spending less time in the deceleration phase of the reach.[291] When the visual conditions were manipulated (vision removed after reach began or only target or target and hand visible), the group with DCD did not seem to take advantage of the visual information available.[330] Similarly, when children with DCD were asked to reach for a target with and without a visual perturbation (prism goggles), they used longer and more curved movement paths than a control group, demonstrating that their response to altered vision was different from typically developing children.[365]

In a different task, manual tracking of a continuously moving stimulus (a coincident-timing task) with a predictable path, children with motor coordination dysfunction (ages 6 and 11 years) were slower than age-matched controls.[330] Their movement distance during an acceleration phase was more variable than that of control children, their tracking motions were more delayed, and they performed more trials with apparently suboptimal attention. As an adaptive strategy, 7-year-olds with minimal brain dysfunction gave themselves more time to cope with less efficient reaching skills by planning a hand trajectory that would intercept a moving target further along its trajectory.[116] When these children were presented with an unpredictable tracking task, they had greater difficulty attending to the task than age-matched controls, perhaps because they could not identify a compensatory strategy.[99,331]

As was suggested for the infant during development, postural control may also affect the reaching behavior of children with DCD. Johnston and colleagues documented differences in the APAs of shoulder and trunk muscles in 8- to 10-year-old children with and without DCD during a goal-directed reaching movement.[185] The children with DCD demonstrated longer reaction times and movement times of their reach as compared to children who were typically developing. From a postural muscle perspective, the DCD group used earlier onsets of shoulder and posterior trunk muscle activity and later than typical activations of the anterior trunk muscles. Johnston and colleagues hypothesized that the altered timing of postural muscle activation influences the speed and quality of the reach movement.[185] Children with myelomeningocele, who frequently have atypical postural control and sensory deficits, used a different strategy for a similar task. The children with myelomeningocele did not alter their movement time while demonstrating a significant decrease in accuracy.[235] Whether the altered postural movements are part of the primary problem or a compensation for difficulty with necessary sensory integration to complete the task is yet to be determined.

In summary, the variables and processes that contribute to an emerging control of reaching skills during infancy and

childhood are similar to variables contributing to those for posture and locomotion. In each instance, rudimentary aspects of control can be observed in very young infants if optimal conditions are provided, suggesting that precursors to functional skills may be established at very young ages. Each of these early skills, however, undergoes important transformations as children learn to perceive the task demands, monitor their movements, predict the potential consequences of their actions for a given context, and develop anticipatory strategies for efficient movement execution. As shown in the following section, these variables also contribute to the development of grasp control.

Maturation of Precision Grip and Load Force Control in Preschool and School-Age Children

Once a child's hand comes in contact with an object, he or she must coordinate normal (grip) and frictional (load) forces to grasp and lift an object.[184] Adults coordinate these forces synchronously, whereas infants and young children coordinate them sequentially.[113] To quantitatively examine grip control, infants are encouraged to pick up a toy that is equipped with force transducers to measure the grip forces of the opposing thumb and index finger and the load force necessary to lift the object off the table. During the preload phase (initial contact with the object), infants as young as 8 months contact the object with one finger before the other, creating a latency to onset of grip force that is significantly greater than in infants 18 months of age or older. Infants and young children also tend to press down on the object, creating a negative load force before reversing the direction of force to successfully lift the object off the table. Infants and young children generate a significant portion of the total grip force (often twice the magnitude of adult grasps) for grasping before initiating the load force, and during the load phase they typically exhibit multiple peaks in records for both of these forces. Adults, in contrast, scale the increases in grip and load forces in an economic, synchronous, and nearly linear manner with only a single peak near the middle of the load phase.[113] These findings suggest that the smooth execution of an adult grasp is the consequence of anticipating the object's weight so as to select an appropriate target force magnitude and scaling over time.[184] This anticipation of necessary grip-force adjustments for precision grip to lift, hold, and replace an object has been shown in adults to be related to experience with a predictable stimulus.[354] This collective experience, called central set, appears to affect the response gain of both voluntary and triggered rapid grip force adjustments to be set to a certain extent before perturbation onset in a similar manner as the effects of central set on lower extremity RPAs to platform perturbations. This suggests that in motor control there may be a general rule governing anticipatory processes.

The studies on control of grasp are consistent with a recurring theme of this chapter: infants appear to possess the neural substrate to execute skilled motor patterns early in development, but demonstration of this potential is unreliable.[113,114,115] First, these studies indicate that by 6 to 8 months of age infants can produce each of the actions required for a precision grip, and by 12 months of age infants can occasionally assemble all the components to produce adultlike force patterns, but there is considerable variability in performance across trials.[59] These studies also indicate that infants and young children use far more force than required, a common finding in studies of motor development.[192] Children as young as 2 years of age are able to adjust grip and load forces with respect to the degree of friction or potential slip during repeated lifts of the same object, but when the coefficient of friction is randomized over trials, they cannot adapt grip and load forces effectively. Thus with sufficient practice they can formulate rules for more adultlike performance, but if confronted with uncertainty, they do not know how to draw from limited previous experience.

When typical children 6 to 8 years of age are asked to grasp and lift a 200-g object repeatedly, they initiate nearly synchronous, linear increases in grip and load forces with a single peak in magnitude, as do adults. Children with CP (diplegia or hemiplegia) and autism, in contrast, tend to initiate the forces sequentially, as do younger children with typical development.[83,96] Specifically, it appears that at least some children with CP and autism can produce the requisite forces, but they have difficulty selecting or executing efficient grasp strategies. Available data indicate that these children have difficulty regulating the timing and magnitude of force during both dynamic and static phases, and they tend to bear down on the object before lifting it. When these children are asked to grasp and lift objects of two different weights, presented in blocked and randomized trials, they also have difficulty scaling forces with respect to object weight during both nonrandom and random presentation of the two weights,[97] but if they are given a sufficient number of practice trials, they can anticipate and scale grasp force parameters[98,299] and learn better precision isometric grip force, but not to the same extent of children of the same age who are typically developing.[324] Children with CP may also have difficulty stabilizing their gaze so that they can effectively use the available visual information.[209] Given that the normal acquisition of grasp control has a protracted period of development,[113,114] it is also probable that these children do not experience sufficient amounts and variety of practice to use available information for developing efficient strategies, an issue previously raised by Goodgold-Edwards.[134]

Refinements in the control of grasping continue to occur well into late childhood. Examination of the fine details of grip force amplitude and timing control has suggested that children age 7 to 8 years still do not exhibit finger force components typical of adult skill.[175] By 12 years of age, children approximate adult patterns of control and accuracy of bimanual isometric finger force production for both in-phase (both hands pinching a load cell device at the same time) and antiphase (one hand pinching, then the other) activation.[147] When coordinating grasp and lift of objects, young children execute grasps characterized by multipeaked variations in grip and load forces and do not execute the smooth, coincident increases and decreases in these forces characteristic of adult grasping until approximately 8 years of age.[113] Transitions to smooth, single-peak force patterns may in part be due to gradual improvements in anticipatory strategies.[114] It appears that the scaling of grip and load force rates continues to change until approximately 8 to 15 years of age, depending on the order of presentation of the weights, suggesting that anticipatory skills do not achieve adult levels until some point in this age range.[135]

Collectively, the studies described in this section demonstrate that grasping is a complex skill involving many different aspects of sensorimotor control. Rudimentary skills, biomechanics, experience, and other context-dependent variables probably contribute to the rapid changes in motor control observed in the first year of life. Even during earliest exercise of skill, infants are probably building a database of information

for transforming their skills as they become increasingly more intent on shaping their experiences. Probably one of the views enjoying the greatest consensus among researchers in the field of motor control today is that all aspects of movement execution, including the basic physiology, biomechanics, perceptual processing, and development of strategies, must be closely examined under varying movement conditions to better understand the acquisition of motor control during typical development and when it goes awry.

The Role of Play in Development

Research on children's activity memory, or ability to explicitly recall activities they observe or create, is helpful in considering how to structure therapeutic exercise to promote memory regarding what has been experienced. Ratner and Foley reviewed the literature on activity memory and suggested that children remember activities better if (1) there was a clear outcome of the activity, (2) actions within the activity were logically sequenced such that cause and effect were obvious throughout the activity, and (3) the child engaged in planning of the actions involved in the activity in advance of carrying it out (not just mental imaging of it) or was asked to plan to remember what happened.[259] Young children do not always profit from external memory cues, at least not until 3 years of age or older, depending on the type of cue.

Nevertheless, children's behaviors show that they both consciously and verbally anticipate the unfolding and outcomes of activities by at least 2 years of age, even telling themselves "no, no" when about to perform some forbidden action.[259] At this point, imaginary play with objects that are not present appears, and children express surprise when outcomes of actions are not what they expected. Play then provides the opportunity for children to voluntarily act out intentions and to learn the difference between plans and outcomes. By 20 months of age, children are able to work toward a concrete goal, such as building a house from blocks, exhibiting checking behaviors, correcting mistakes, and acknowledging successful achievement of the goal. Repetition of an activity typically enhances memory of it when recall support is provided, and even infants 4 to 6 months of age can be shown to have some retrospective processing of events in that experiments demonstrate that they actively notice properties of an activity that were previously not noticed. Preschoolers allowed to demonstrate what happened will recall far more of an activity than if only verbal recall is elicited. Therapists should consider the mental ages of the children they treat with a mind toward creating therapeutic activities that provide children with disabilities the opportunity to develop cognitive skills such as planning and activity memory as they engage in exercise to reduce impairments.

When seen in its functional context as a learning device, motor activity can also be seen to have a stagelike character. Physical activity play (i.e., play with a vigorous physical component) has three developmental stages.[243] In infancy, babies engage in what Thelen has called rhythmic stereotypies or repetitive gross motor activities without any obvious purpose, including body rocking, foot kicking, and leg waving.[312] Whole-body, self-motion play is also called peragration, and Adolph suggested that such activities are the most direct route to knowledge: infants plunge in and obtain important information as a result.[1] These behaviors peak around the midpoint of the first year of life with as much as 40% of a 1-hour observation at 6 months being composed of such play.[243]

A second stage called exercise play begins at the end of the first year.[243] Such play can be solitary or with others, increases from the toddler to the preschool periods, and then declines during the primary school years. It accounts for about 7% of behavior observed in childcare settings. Activities included in exercise play include running, chasing, and climbing. Children with physical disabilities may need alternatives for participating in such play, particularly with other children.

The third phase of physical activity play is rough-and-tumble play such as wrestling, kicking, and tumbling in a social context. Often this type of play appears first in interaction with a parent, typically a father. Rough-and-tumble play increases through the preschool and primary school years and peaks just before early adolescence. No gender differences are noted in peragration activities, but males engage in more exercise play and rough-and-tumble play than females.

The functional benefits of physical activity play may be deferred or immediate. Pellegrini and Smith suggested that the benefits of rhythmic play in infants are immediate in improving control of specific motor patterns, that is, the primary repertoire in Edelman's terms.[243] Through active self-generated body movement, infants create perturbations to balance for which they gradually learn to accommodate or plan; such play also provides interesting visual and perhaps auditory spectacles for development of perceptual systems. Strength and endurance are also developed through such activities. Pellegrini and Smith posited that the function of exercise play is specifically to promote muscle differentiation, strength, and endurance. Chapter 6 provides further information on health-related physical fitness, which may have its roots in early play behavior. Pellegrini and Smith described animal research on the juvenile period, suggesting that it is a sensitive period for such development (recall McGraw's experiment with Johnny and Jimmy and their respective adult physiques).[243] Play may also have cognitive benefits in terms of providing a break from attention-demanding activities, thus leading to distributed practice and creating an enhanced arousal level of benefit to subsequent engagement in mental activities. Seen in this light, recess becomes something more than a meaningless break in the routine.

Pellegrini and Smith hypothesized that rough-and-tumble play serves a social function, especially for boys, related to establishing and maintaining dominance in social groups (girls are believed to use verbal skills more than boys in establishing dominance hierarchies).[243] As a by-product, children also may use rough-and-tumble play as a way to code and decode social signals. For example, in early rough-and-tumble play with parents, children learn that this is "play" and not aggression. Rosenbaum suggested that this view of motor activity raises the question of what goals we should pursue in therapeutic interventions.[269] Is it more important to provide opportunities to "travel" than to concentrate on improving gait? Do children with disabilities benefit from adapted recreational activities such as horseback riding in terms of social skills and cognitive function, as well as in motor skills per se? What is lost in terms of self-esteem or ability to decode social signals in children with disabilities if they are "protected" from rough-and-tumble play? Such "differentness" begins even in infancy as babies born prematurely are less likely to be included in play date activities in community centers or the homes of other families as much as other babies, in part because of concern for exposure to illness. For children in early intervention services, such isolation may

be reinforced by the current emphasis on home-based therapy for the 0 to 3 population.

EXAMPLES OF MULTIFACTORIAL NATURE OF MOTOR DEVELOPMENT: PULLING IT ALL TOGETHER

In this concluding section, we provide examples at different key ages for functional actions and the cooperation of multiple systems for the successful accomplishment of that action. As physical therapists, our understanding of the interaction of multiple systems builds our ability to help new actions emerge. Although understanding of the motor system is important, it is not enough to help build function. We focus here on the first year of life because of the accelerated changes occurring within the child's body during that time.

Nate is a 3-month-old infant who displays indications of need, possibly hunger. His motor system acts by wiggling and twisting toward his mother's breast, while his eye gaze and beginning social understanding get his mother's attention via looking and vocal fussing. As his mother assists him to the food source, early control of the oral system and early reach/grasp orient his body to latch on to eat. Suck and swallow coordinated movement allow successful feeding, which leads to calming of his motor system and beginning understanding of how his motor efforts result in positive reward both socially and physiologically. Think about how the experiences of an infant with movement problems would differ from this typical experience and how the connections between the motor system and other systems might be altered if the infant lacks movement. Alternatively, an infant who is bottle-fed instead of breast-fed may have a different movement strategy of expressing needs, which should be considered in problem solving to assist the development of motor skill.

Katie is a 6-month-old infant who amazes her parents with her newfound interest in objects. Her motor system allows her to reach persistently for objects with her hands and her feet, and her visual system can quickly note novel objects and the details of objects within her view. Her progressing visual, social, and cognitive skill invites adult engagement with her toward an object of interest, heralding the important skill of joint attention, a precursor to language and later speech. She may even vocalize for a toy that is out of reach or object vocally to a toy taken away. High variability in exploration with her motor skills interacts with cognitive skills to begin problem solving and memory of familiar things. She is easy to entertain because she likes to repeat movements like banging a toy, and handling novel objects seems to fascinate her. Imagine how reduced movement would limit the strategies for exploration and learning for Katie. Alternatively, consider the strong implications of environmental context for this child. Without opportunities for both exploration (variety of objects, surfaces, situations) and related movement, cascading effects on cognition and perception can be expected.

Sam is 9 months old and he hears the phone ring in another room. Because he is mobile now via crawling, he can seek the origin of the ringing noise. He expects his mother will begin talking due to his memory of what happens with a phone, and he knows she is in the other room because she just exited his room. He has the object permanence concept now, so he understands his mother still exists even if she walks out of his sight; this concept became solidified when he could move himself and find people and objects that disappeared behind a door. He has social skills, which have bonded him to close family and friends, and he drags a new toy with him as he crawls to engage in joint attention to the object when he finds his mother. As he finds his mother sitting on the couch, he pulls himself to stand and proudly shows her the toy with a squeal of delight and babbling of consonant-vowel sounds. His mom answers back by labeling the toy, "You found a car!" and they communicate with visual, tactile, and verbal exchanges. This rich learning experience would be significantly limited by a mobility restriction.

Sally is a 12-month-old infant who wants to carry a container of toys from her living room to her room. She has been walking for a couple weeks, and her newfound ability to carry objects with her free arms is a powerful tool. She now can walk on level surfaces easily because she practiced for hundreds of steps per day, and the pattern of stepping is quite automatic unless she comes to a change in surface. However, she knows the route to her room because of her improved memory and spatial skills, related to months of navigating and exploring her house. She can orient her arms and hands around the object (a small bucket of toys) and she has the postural control to maintain upright with this added weight and bulk to her frame. She has visual and prospective control to avoid the sides of the door and the cognitive skill to conceptualize the skill. When she comes to the obstacle of her family dog in the way, she vocalizes to solve the problem by getting her parent's attention. By combining environmental and child factors, Sally is beginning to be in control of her world; her motor development allows this growth to progress and learning to continue.

SUMMARY

Theories of motor development have evolved over time, but current thinking suggests that development is a complex outcome of the maturation of multiple physiologic systems in combination with demands placed on children by the environment and task-related experiences. In this chapter, we described developmental principles in combination with motor control theory to provide normative information as a reference for understanding the needs of children facing motor problems. The information provided in this and subsequent chapters will enable pediatric physical therapists to apply current concepts and research for the benefit of our clients—children with disabilities and their families.

Motor Learning: Application of Principles to Pediatric Rehabilitation

Andrew M. Gordon, Richard Magill

Increasingly, physical therapists are recognizing that effective training of motor function in children requires motor learning. Children need to be active learners to problem-solve how to accomplish a specific task, given their constraints.[2] Such task-oriented approaches[20] are becoming the predominant type of treatment in adult therapy. An important difference among children with disabilities, however, is that unlike adults, children are rarely trying to regain function, and thus they do not have a motor image of how the task should be performed. Rather, their learning must occur in the context of development, whereby age-appropriate skills must be learned for the first time. Such learning can be considered as part of a triad consisting of the person, the task (i.e., skill or activity), and the environmental context in which the child performs the task.

This chapter first discusses this triad and how it applies to adult motor learning, as well as the relevant learning principles derived from studies of adults without disabilities. Specifically, we discuss taxonomies of motor skills in relation to skill progression, types of knowledge gained during motor learning, different types and stages of learning, methods of instructions, feedback types and frequency, types of practice schedules, variability and specificity of training with whole and part practice, and benefits of mental practice. This information provides important theory and context for the training of motor skills in children. Oddly, there is a dearth of good studies on motor learning in typically developing children. We review what is known about motor learning in children and how learning in children may differ from that in adults. We discuss the implications of reduced information-processing capabilities and processing/memory in children and the implications for feedback, along with the type and amount of practice, and will show that skill emerges over enormous amounts of practice and extensive time periods. We continue by discussing the limited research on motor learning in pediatric rehabilitation, with emphasis on cerebral palsy (CP), the most common type of pediatric physical disability. We show that contrary to older notions, CP is not static, but rather motor function improves with development and practice. We provide examples of how intensity matters, models for providing intensive, task-oriented approaches (e.g., constraint-induced movement therapy, bimanual training), and information on how tasks and the environment can be used to optimize learning. We describe the importance of training specificity and provide important clues from the neuroscience literature on how to take advantage of and maximize neuroplasticity. Among these is the fact that neuroplasticity is enhanced when the tasks are meaningful to the performer. Increasingly, this means using video gaming to maintain salience and motivation and to target specific motor impairments. It is suggested that motor learning in the context of gaming can be an important complement to, but not a replacement for, salient task-oriented activities in the real world. Finally, we discuss gaps in the existing knowledge and project where pediatric rehabilitation research needs to be directed to fully incorporate motor learning into practice.

MOTOR LEARNING PRINCIPLES

One way to address the many complexities of the therapist–patient interaction is to consider principles on which to base decisions that must be made during this interaction. One set of principles relevant to this situation relates to learning processes that underlie physical rehabilitation. Patients present not only specific motor skill capabilities and limitations when they initially engage the services of a physical therapist but also future movement goals. The therapist is confronted with the need to determine a plan of action to enable the patient to attain achievable goals given the individual's capabilities and limitations. Implicit in this plan is an understanding of learning processes as they relate to the learning or relearning of motor skills. Accordingly, this section of the chapter provides a foundation on which the therapist can establish knowledge of these processes and apply that knowledge to developing and implementing effective intervention strategies.

Basic Assumptions

General Influences on the Learning of Motor Skills

When a person attempts to learn or relearn a motor skill, at least three sets of characteristics influence that process: the person, the task (i.e., skill or activity), and the environmental context in which the person performs the task (Fig. 4.1). These characteristics interact in ways that influence not only motor skill learning and performance but also the effectiveness of therapeutic intervention strategies. For the physical therapist, this interactive model should provide support for the view that

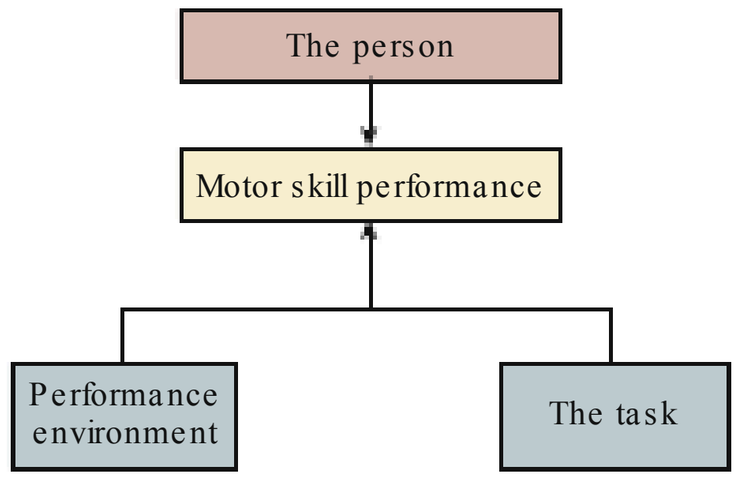

FIG. 4.1 Three influences on the learning and performance of motor skills.

there can be no "one size fits all" approach to creating interventions. As therapists are keenly aware, patients (the "person" part of the model) differ in their capabilities and limitations. However, the intervention planning process for a child must also incorporate specific characteristics of the skills or activities developed and the environmental contexts in which those skills will be performed.

Categories and Taxonomies of Motor Skills

Because the motor skill itself plays an important role in the learning and relearning process, it is important to understand key characteristics of motor skills that influence this process. Several categorization and taxonomy schemes have been developed to identify characteristics of motor skills that make them distinct or similar.[102] The taxonomy that is most relevant to physical therapy is one developed in the United States by A.M. Gentile at Teachers College, Columbia University, which was based on the view that certain characteristics of motor skills place different types and quantities of attention and motor control demands on the person.[57] The full taxonomy consists of the interrelationship of four general characteristics of skills. Rather than discuss all of these categories, we consider only three of the four general characteristics of skills that are especially relevant to the purposes of this chapter.

The first two characteristics concern the environmental context (i.e., all the components of the location and situation in which the skill is performed, such as the supporting surface, objects, and other people). The first of these relates to *whether the skill's regulatory conditions are stationary or in motion*. Gentile defined *regulatory conditions* as those features of the environmental context that specify the movement characteristics needed to achieve the skill's performance goal (note that Gentile used the term *action* goal).[57] Because a person could achieve a specific performance goal with different movement characteristics, the regulatory conditions specify the movement characteristics required to achieve the performance goal in a specific situation. For example, the regulatory conditions associated with walking from one location to another include the surface on which the child walks and the objects or other people in the pathway. These environmental context features influence the person's walking behavior by requiring him or her to alter certain movements to walk from one location to another. Consider, for example, how your movements differ when you walk on a concrete sidewalk, a sandy beach, a moving bus, or a treadmill. Also consider how your movements differ when you walk alone compared to when you walk on a sidewalk that is filled with people walking in various directions and at different speeds. As these examples illustrate, the regulatory conditions of the performance environment influence walking behavior in considerably different ways, depending on the specific characteristic of the regulatory condition and whether or not the regulatory condition is stationary or in motion. Skills for which the regulatory conditions are stationary are commonly referred to as *closed skills*, and skills for which the regulatory conditions are in motion are commonly referred to as *open skills*.

The second general characteristic of a motor skill concerns whether the regulatory conditions are the same or different on successive repetitions of performing the skill. Gentile referred to this characteristic as *intertrial variability*.[57] If the regulatory conditions are the same on successive repetitions, the skill has no intertrial variability. For example, stepping up a series of stair steps when each step is the same height requires repetitions of stepping with each repetition occurring in a performance context in which the regulatory conditions are the same for each repetition. In contrast, if the regulatory conditions are different on successive repetitions, the skill is classified as having intertrial variability. For example, when we drink a glass of water, each successive drink (i.e., repetition) removes some water from the glass, which means that the amount of water in the glass changes on each trial. Although both stair-stepping skills and drinking skills are similar because each is a closed skill, they differ in the demands placed on the performer on succeeding repetitions of the skill. The skill with no intertrial variability (stair-stepping) requires the person to simply repeat each trial's movement characteristics, but the skill with intertrial variability (drinking from a glass) requires the person to adjust specific movement characteristics on each repetition.

The third general characteristic is *whether or not an object must be manipulated* when performing the skill. The same motor skill can place distinctly different attention and motor control demands on the child simply by adding or taking away an object as part of the performance requirement. Consider, for example, the different attention and motor control demands of walking on a sidewalk while carrying or not carrying a book bag.

Gentile organized the taxonomy on the basis of the complexity of each skill.[57] She defined complexity in terms of the amount of attention and motor control demands the skill places on the person performing the skill. The simplest skill, which is the closed skill with no intertrial variability and no object to manipulate, involves the lowest number of these demands. Skill complexity increases with the addition of intertrial variability or an object to manipulate. Because of its systematic basis for identifying the complexity level of a skill, the taxonomy has practical value to the physical therapist. One use of the taxonomy is as a guide for evaluating a patient's movement capabilities and limitations. Another use is for systematically selecting a progression of activities to improve a child's functional capabilities.

Types of Knowledge Acquired During Learning

Learning of motor skills involves the acquisition of two types of knowledge: *explicit* (sometimes referred to as *declarative, or "what to do"*) and *implicit* (sometimes referred to as *procedural, or "how to do" a skill*).[56,57] These types of knowledge are commonly assessed on the basis of how accurately a person can verbally describe the knowledge. For example, if you were asked to provide evidence that you know how to tie your shoes, you could verbally describe how you do it, or you could physically tie them. The verbal description indicates an explicit knowledge of the skill of shoe tying. But if you had difficulty giving this verbal description, it could not be concluded that you do not know how to tie your shoes. Your knowledge may be in an implicit form and therefore difficult, if not impossible, to verbally describe. Evidence of this implicit knowledge of shoe tying would be revealed by physically performing the skill. Although some learning theorists typically view knowledge of how to perform a motor skill as implicit, or procedural, this view is too narrow to present a complete understanding of the knowledge structure underlying motor skill learning. In fact, motor skills involve the acquisition of both explicit and implicit knowledge.[160] Some researchers argue that the acquisition of explicit knowledge precedes that of implicit knowledge; others contend that the two types of knowledge are acquired simultaneously but that certain skill characteristics are acquired explicitly or implicitly.[56,160] Clear evidence that they are separate comes from

object rotation experiments. Subjects learn to grasp and lift an object with a symmetrical appearance but whose mass distribution is actually asymmetrical within one or two consecutive lifts by partitioning fingertip load forces asymmetrically before lift-off.[6,131,132] This involves learning to generate a compensatory moment in the opposite direction of the external moment, thus preventing object roll. However, despite subjects' explicit knowledge of the new center of mass (CM) location following object rotation, as determined by verbal cuing, they fail to generate a compensatory moment, resulting in object roll.[6,131,132,170] It is interesting to note that over repeated object rotations and lifts, subjects do reduce object roll through modulation of digit placement along the vertical axis (e.g., thumb lower than index finger when the center of mass is on the left side) but not tangential forces.[170] Thus the explicit knowledge influences the modulation of grasping kinematics but not kinetics. Much remains to be understood about these types of knowledge and their relationship to the skill learning process, but as explored later in the chapter, the type of knowledge acquired has implications for several aspects of the therapist–patient interaction.

Stages of Learning

An important characteristic of the motor skill learning process is that people go through distinct stages, or phases, as they learn. Although several models have been proposed to identify and describe these stages,[102] we consider here one that is especially relevant to physical therapy. Gentile proposed a model of skill learning involving two stages.[54,55,57] The first, which Gentile called the *initial stage,* involves the learner attempting to attain some degree of success at achieving the performance goal of the skill. To do this, the person develops movement characteristics that match the regulatory conditions of the skill. In addition, the person acquires a basic movement coordination pattern that results in reasonably successful achievement of the skill's performance goal, which means that the goal achievement will be inconsistent from trial to trial. In the initial stage, the learner produces movement characteristics that often match, but sometimes do not match, requirements of the regulatory conditions. This stage is therefore characterized by both successful and unsuccessful attempts. Eventually, the learner develops a movement coordination pattern that allows a reasonable amount of performance goal achievement, although the pattern is rather crude and inefficient. As Gentile described it, "Although the learner now has a general concept of an effective approach, he or she is not skilled. The action-goal is not achieved consistently and the movement lacks efficiency" p.[57] An important part of the initial stage is that the learner actively moves to determine the appropriate movements to achieve the action goal.

In the second stage, which Gentile called the *later stages,* the learner needs to acquire three general characteristics: (1) the capability of adapting the movement pattern acquired in the initial stage to specific demands of any performance situation involving that skill; (2) consistency in achieving the performance goal of the skill on each attempt at performing the skill; and (3) efficiency of performance in terms of reducing the energy cost of performing the skill to a level that allows an "economy of effort."[57]

A distinct feature of the second stage is that the learning goals depend on whether the skill being learned is closed or open. Closed skills require what Gentile called *fixation* of the basic movement coordination pattern acquired in the first stage. This means that the learner must refine this pattern so as to achieve the action goal consistently with little, if any, conscious effort and a minimum of physical energy. In contrast, open skills require what Gentile called *diversification* of the basic movement coordination pattern acquired in the first stage. This means that the movement pattern needs to be adaptable to the ever-changing spatial and temporal characteristics of the open-skill performance context.

Another characteristic of Gentile's learning stages model is the involvement of explicit and implicit learning processes in the two stages.[56] Although both types of learning processes occur in both stages, one type predominates in each stage. In the initial stage, explicit learning processes predominate, whereas implicit processes predominate in the later stages. The basis for which type of learning process predominates is the characteristic of the skill being acquired at each stage. For example, Gentile proposed that during the initial stage the learner acquires knowledge about the regulatory conditions that influence the movements required to achieve the skill's performance goal. These conditions and the movements the performer must learn are acquired through explicit learning processes. In contrast, the dynamics of force generation involved in performing a skill are acquired by implicit learning processes and become predominant in terms of what is learned in the later stages of learning.

Practice Conditions Considerations

Generalization: From the Clinic to the Everyday Experience

Physical therapists engage children in specific types of interventions because they want the interventions to ultimately allow patients to function in their everyday world. In the study of motor learning, this clinic-to-everyday-world relationship is known as *generalization,* or *transfer of learning.*[102] Because this type of generalization is such an essential goal of physical therapy practice, it is important to consider the factors that influence it.

The long-standing view is that generalization occurs due to the *similarity between the components of the skills or performance contexts* involved. More generalization occurs with increased amounts of skill or context similarity. Consider first the similarity of skills. If you analyze the movement components of skills or assess the movement goals of skills, you will find similarities as well as differences. For example, reaching for and grasping an object can involve a variety of skills that are distinct according to the characteristics of the object to be grasped and its intended use but are similar in terms of many of the movements required. The context in which a skill or activity is performed also must be considered as a factor influencing generalization, especially if the generalization involves performing a skill or activity in the clinic and then in the daily living environment. Again, more generalization occurs as the degree of similarity increases between these two contexts. Another aspect of why generalization occurs relates to the similarity between the cognitive processes required by the two situations. The more similar the cognitive demands of a practice situation are to the eventual situation, the more generalization can be expected. For example, if the eventual situation demands a high degree of problem solving, such as would be required when a child needs to navigate a crowded room to exit through a door, then the practice situation should require a similar high degree of problem solving. Children typically engage in many problem-solving situations in their everyday environments, which indicates the physical

therapy benefits of the inclusion of similar situations in a therapy context.

Taken to its logical conclusion, the greatest amount of generalization of skill performance from a clinical environment to the child's everyday living environment would occur when all the characteristics of the patient's everyday living environment are included in the intervention strategies, wherever they take place. Two implications for physical therapy practice of this view of generalization are the use of simulations in the clinic of a patient's daily living environment and the performance of functional daily living skills in the patient's own home or workplace.

Presenting Instructions About How to Perform a Skill: Demonstration and Verbal Instructions

If you wanted to teach a child how to perform a skill or activity, how would you do it? In any motor skill learning situation, the learner needs to know something about what he or she needs to do to perform the activity. The instructions can be as simple as a verbal description, such as "I want you to walk from this line on the floor to that table" or "I want you to pick up this coin and place it in the jar." This type of instruction works well for motor skills the child can already perform. But, if the person is not familiar with a skill or activity or does not know how to perform it, then some other type of instructions must be provided. The two most common ways therapists provide instructions are by demonstrating the skill or activity and by verbally describing what to do to perform the skill or activity. What do we know about these two forms of presenting instructions?

Demonstration. Sometimes referred to as *modeling,* demonstration is an effective way to communicate how to perform a skill or activity. It is especially effective when the skill or activity involves many movements that must be coordinated or sequenced in a way that the child has not experienced before or if he or she would have difficulty following a long verbal description of the sequence of movements. After demonstration of a complex activity, it is common to observe the person performing a reasonable approximation of the activity on the first attempt. Why does this happen? Most researchers agree that the observation of another person performing an activity engages a part of the brain that involves "mirror neurons."[84,140] These neurons are activated by vision as the person watches the activity being performed. In addition, when engaged in observing an activity, the visual system detects specific movement-related features of the activity that do not change from one performance of the activity to another. These features specify the coordinated movement patterns underlying performance of the activity. For example, if you observe another person walking and running, it is easy to distinguish each skill because each has a unique coordinated movement pattern. The combination of the mirror neurons registering the activity and vision detecting the specific movement pattern associated with the activity allows the observer to form a type of blueprint on which to base his or her own attempt to perform the activity.

Researchers also have shown that novice learners benefit from observing other novice learners.[102] The beneficial learning effect appears to be due to the cognitive problem-solving activity in which the observer engages while watching the novice practice the activity. This means that the observer sees what not to do as well as what to do. One strategy that implements this use of demonstration is the pairing or grouping of children where one of the pair or group practices the activity while the others observe. After a certain number of practice attempts or a specific amount of time, one of the observers practices the activity and the previous performer becomes an observer. This is consistent with the philosophy of conducting intensive therapies such as constraint-induced movement therapy in group or day camp settings,[25,38,61] as described later in the chapter.

Verbal instructions. An alternative to demonstrating how to perform an activity is providing verbal instructions. Although evidence supports the value of verbal instructions, two factors are important to consider. One is that the *amount of instruction* given must be within the limits of the person's capacity to remember and think about when he or she attempts to perform the activity. In general, this means that instructions should be few in number and concise in presentation, particularly when working with children or individuals with limited comprehension.

Another influential factor is where the instructions *focus the person's attention* while performing the activity. Researchers have compared the effects of focusing attention on the movements themselves (i.e., an *internal focus*), such as "be sure that your thigh is parallel to the floor before you place your foot on the step," versus focusing attention on the intended movement outcome (i.e., an *external focus*), such as "be sure to place your foot on the step." Typically better learning occurs with an external focus—that is, when the person's attention is directed to the intended movement outcome. (See Wulf et al.[167] for a review of this research.) Evidence of the benefits of instructing children externally came from a study conducted in Brazil[47] where 6- to 10-year-old children were learning a dynamic balance task, the Pedalo (developed in Germany; for a photo of the device, see Figure 1 in Totsika and Wulf[152]). The device consists of two wheeled platforms, with a foot on each, that moves by alternately pushing the upper platform forward and downward (like pushing the pedals on a bicycle). The typical performance measure is movement time for a specified distance. Internal focus instructions directed the children to push their feet forward to move the Pedalo; external focus instructions directed the children to focus on pushing the platform on which they stood forward. Results showed better learning by those who engaged in the external attention focus.

We commonly think of verbal instructions as words that describe how to perform a skill or activity. But another way to use verbal instructions is to describe a *visual metaphoric image* to help the person determine how to perform the skill. This type of image involves picturing in the mind what the skill or activity is like, rather than the skill itself. For example, the fundamental locomotion movement of hopping with two legs involves a complex array of movements that must be spatially and temporally coordinated. A verbal description of this array of movements may overwhelm the child. Although a demonstration of hopping would be an alternate way to provide information of what to do, telling the child to move from one place to another "like a bunny would move" presents a metaphoric image the child can use to determine how to hop. (For an excellent discussion about the use of imagery in physical therapy, see Dickstein and Deutsch.[34])

Presenting feedback during practice. When a person practices a skill or activity, he or she typically performs some parts correctly and some incorrectly. The therapist supplies essential information about these aspects of the person's performance by providing feedback. Although the term *feedback* is used

in various ways, we use it here to denote the information the therapist provides to the child during or after the performance of an activity (sometimes referred to as *augmented, external,* or *extrinsic* feedback to distinguish it from the feedback naturally available through the various sensory systems, such as visual, auditory, or tactile feedback).[102]

Feedback provided by the therapist can refer to the outcome of performing a skill (e.g., "you were 2 inches short of grasping the cup") or the movement characteristics that led to the performance outcome (e.g., "your elbow was not extended enough to allow you to reach the cup"). Motor learning researchers often refer to these two types of feedback as knowledge of results (KR) and knowledge of performance (KP), respectively.[102]

Feedback can play two roles in the motor skill learning process. One is to facilitate achievement of the skill's performance goal. Because feedback provides information about the degree of success achieved while performing a skill (e.g., the errors made or what was done correctly), the learner can determine whether what he or she is doing is appropriate and what he or she should do differently to successfully perform the skill. In this way, feedback can help the person achieve successful performance of the skill more quickly or easily than could occur without the feedback. The second role of feedback is motivational. Feedback can motivate the child to continue striving toward a specific performance goal. In this role, the child uses feedback to compare his or her own performance to a specified performance goal.[26] The person must then decide to continue to pursue that goal, to change the goal, or to stop performing the activity.

Feedback about errors versus correct aspects of performance. An often debated issue is whether the performance information conveyed by feedback should refer to the mistakes the person made or those aspects of the skill or activity that were correctly performed. The consensus appears to be that both types of information are valuable, especially because each relates to a different role of feedback. Research evidence consistently has shown that error information is more effective for facilitating skill learning, especially in the initial stage of learning, and information about correctly performed aspects of an activity serves a motivational role by informing the person that he or she is on track in learning the skill or activity, which should encourage the person to keep trying.[102]

Selecting the skill or activity component for feedback. When performing a skill or activity during a therapy session, a child will undoubtedly make many errors. The challenge for the therapist is determining which error, or errors, to give feedback about. The first step is to acknowledge that the feedback will relate to only one aspect or component of the person's performance. The rationale relates to a similar point made in our earlier discussion about the amount of instruction to present, which emphasized the need to stay within the child's memory and attention limits. To simplify the process of determining how much feedback to give, we recommend that the therapist focus on only one aspect or component of the child's performance.[102]

The therapist should focus on the part of the skill that is most critical for achieving the performance goal. For example, if a child were attempting to step over an object, the most critical part of the skill would be looking at the object. If the child is not looking at the object, the therapist would provide feedback to correct this error. Additional errors to be corrected would be based on a priority list of errors that are most critical for successfully performing the skill.

Frequency of giving feedback. It is not uncommon for therapists to want to give error correction feedback after every attempt a patient makes at performing a skill, or even during the performance itself. However, research shows that giving error correction feedback during or after every practice trial (referred to as 100% frequency) is not optimal for helping a patient to learn motor skills. Rather, a less than 100% frequency optimizes skill learning, at least in healthy adults.[101] The primary problem with 100% frequency is that it engages patients in a fundamentally different, and less effective, learning process than when they receive error correction feedback less frequently. According to the *guidance hypothesis,*[133,161] learners use feedback to guide performance and achieve success, which occurs rather quickly. But there is a negative aspect to this guidance. The benefit experienced during practice creates a dependency on the availability of feedback so that when feedback is not available the performance is poorer. In effect, the feedback becomes a crutch. In contrast, when feedback is available less frequently than on every practice attempt, the learner engages in more active learning strategies on trials. A concern here for pediatric physical therapists is the extent to which the guidance hypothesis, as it relates to feedback frequency, applies to children. As is discussed later in this chapter, some research suggests that the frequency conclusion may not apply to children in the same way as it applies to adults.

Although motor learning scholars have not identified an optimal frequency for giving error correction feedback, they have reported various techniques that reduce the frequency to less than 100%.[102] One is the *fading technique,* which systematically reduces the frequency from high to low as the person progresses in learning the skill. Another technique (referred to as the *self-selection technique*) involves the patient receiving feedback only when he or she requests it. It is interesting to note that research has shown that when novice learners are allowed to request error correction feedback when they want it, they request it at a frequency that is less than 100%. Another technique involves the *interspersing of motivational and error correction feedback* during practice trials. Unfortunately, research has not established an optimal ratio for the interspersing of these two types of feedback.

Practice Structure

In addition to selecting specific activities for each child, an essential part of the physical therapist's decision making involves scheduling the sequence of those activities. Scheduling involves not only the within therapy session activities but also the activities to be completed from the first to the last session. Specific motor learning principles can guide the therapist in making scheduling decisions.

Practice variability. A practice structure characteristic that increases the chances for future performance success is the variability of the learner's experiences during practices. This includes variations in the skill or activity itself, as well as variations in the context in which an activity is practiced. In the motor learning literature, inclusion of these variations is referred to as *practice variability*.[102] A common characteristic of theories of motor skill learning is their emphasis on the learning and performance benefits derived from practice variability. The primary benefit a learner derives from practice experiences that promote movement and context variability is an increased capability to perform a skill or activity in the future. This means that the person has acquired an increased capability not only

to perform a practiced skill or activity but also to adapt to performance context conditions that he or she may not have actually experienced.

Practice variability can be included in practice sessions in various ways. One is by directly requiring the child to perform multiple variations of a skill that necessitates different movement patterns or sequences to achieve the same action goal. For example, consider how in a child's daily activities he or she moves to achieve the goal of reaching, grasping, and drinking from a cup. The person may need to use various movement strategies to achieve this goal simply because of the location or shape of the cup, or various movement strategies will be required when the cup is completely full or almost empty. Another way to include variability in practice sessions is to modify the characteristics of the context in which the skill or activity is performed. Using the same reaching-grasping-drinking from a cup example, context characteristics can be varied by using different types and sizes of cups (e.g., cup with sippy cover, one or two handles, with a straw) or different types of contents in the cup. A method of incorporating increased amounts of practice variability in physical therapy sessions is to engage children in *movement exploration,* which some scholars have referred to as *discovery learning.* The benefits of this method for learning motor skills have been provided by much research with infants and children, especially by Adolph[2] and Thelen[147] and their colleagues.

Organizing practice variability. When variations of a skill or activity, or performance context, are included in therapy sessions, the therapist needs to determine how to organize or schedule those variations. Should each variation be practiced separately with a sufficient amount of time or number of practice trials for the person to demonstrate a desired level of improvement? Or should each variation be practiced in such a way that all variations are experienced within each session? Research comparing these organizational schemes has consistently shown the superiority of the latter versus the former approach in terms of learning benefits.[102]

Motor learning research comparing various practice variability schedules has demonstrated the *contextual interference (CI) effect*. The term *contextual interference* refers to the interference (i.e., memory or performance disruption) that results from performing variations of skills or activities within the context of a practice session.[102,103] The CI effect is that higher amounts of CI during practice result in better learning than occurs with lower amounts. In terms of variable practice schedules, this effect translates into schedules that involve more interspersing of skill or activity variations within a practice session, which results in better learning than occurs with schedules that involve less interspersing of variations. The most commonly compared practice schedules have been *blocked* and *random* practice schedules, which are the two extremes of the types of schedules that can be organized within the CI framework.[103] Blocked practice schedules create the lowest amount of CI by engaging the learner in nonrepeated sets of practice trials (or amounts of time) for each skill or activity variation. In contrast, random practice schedules create the highest amount of CI by engaging the learner in performing all skill or activity variations in random order throughout the practice session.

An important characteristic of the CI effect is that performance of the skills or activities is qualitatively different when compared during practice sessions and transfer tests (i.e., performance trials that differ in some way from those experienced during practice sessions). Typically, people perform the skills or activities better during practice in a blocked practice schedule. But an opposite result occurs on transfer tests when people who followed a random practice schedule during practice show superior performance.

Although there is some controversy within the physical rehabilitation community about the applicability of the CI effect to rehabilitation contexts, it is important to note that research in these contexts has been sparse and typically limited to comparisons of only blocked and random schedules. Many alternative practice schedule variations induce different amounts of CI. Unfortunately, too few of these schedules have been investigated to determine the specific application limits for clinical situations. An alternative schedule that shows learning benefits for children involves systematically increasing the amount of CI as practice progresses. This means that early practice involves blocked practice but then as practice continues, smaller block sizes are introduced until a random schedule is experienced when skill level is at a higher level (see an example in a study by Saemi and colleagues[127]).

Practice specificity. The earlier discussion of the generalization of learning emphasized the importance of the degree of similarity between practice conditions and future performance situations. This relationship, often referred to as *practice specificity,* emphasizes the need for comparable conditions in both practice and future performance situations. The practice specificity hypothesis is one of the oldest principles of human learning, with origins that can be traced back to the early 1900s.[149,150] Motor learning researchers since that time have accumulated sufficient evidence to show that practice specificity is especially applicable to the sensory/perceptual characteristics of practice and future performance contexts. According to Proteau, motor skill learning is specific to the sources of sensory/perceptual information available during practice.[120] This conclusion is especially relevant to the availability of visual feedback. Because people use and rely on visual feedback when it is available, it can become a potential problem in practice settings. For example, the use of mirrors as a source of visual feedback to help people learn to move in specified ways can lead to a dependence on the mirrors for performing the skill or activity. When the mirrors are not available, performance is typically poorer than if the mirror is available. In effect, the visual feedback from the mirrors becomes part of what is learned during practice.[100]

The practice specificity and practice variability hypotheses may appear to be at odds, but the two points are actually complementary. Both hypotheses propose that practice conditions can create a dependency on the availability of certain conditions during practice and future performance situations: the more specific the conditions during practice, the more dependent the person becomes on the availability of those conditions. And both hypotheses propose that varying conditions during practice can break this potential dependency.

Massed and Distributed Practice

Another practice structure issue concerns the amount of time to devote to various activities within and across sessions. Included are questions about the length of each session, the amount of engagement in each activity within a session, and the amount of rest between activities within and between sessions. Each of these issues can be addressed by determining whether to use massed or distributed practice conditions. The terms *massed* and *distributed* refer to the amount of time a person actively

practices and rests between and during practice sessions. Researchers have not established objective definitions for these terms with respect to amount of time or number of trials. As a result, these terms are operationally defined with respect to the context in which they are used. Massed practice involves longer active practice and shorter rest periods than distributed practice.[102]

One application of massed and distributed practice relates to the *length and distribution of practice sessions*—that is, if a specified amount of time (or number of practice trials) should be devoted to practicing a skill or activity, is it better to schedule longer (and fewer) practice sessions or shorter (and more) practice sessions? In physical therapy settings, this question is often answered by limitations imposed by health care management and financing systems. But when the therapist can set these limits, the decision is made on the basis of evidence from motor learning research. The general principle is that shorter and more practice sessions are preferred to longer and fewer sessions.

The second application of massed and distributed practice relates to the *length of the rest intervals between trials*. For example, if a child is supposed to perform 10 repetitions of an activity, how long should the patient rest between repetitions to maximize the benefit? The answer to this question is not as straightforward as it was for determining the length and distribution of practice sessions. Although the traditional view has been that distributed practice is better than massed, research indicates that distributed practice is better only for learning continuous skills, such as locomotion, cycling, and swimming activities, but massed practice is better for discrete skills, such as reaching, grasping, and limb positioning (e.g., range-of-motion exercises).[99] One factor influencing this effect of the type of skill is the role played by fatigue. Massed practice trials create fatigue problems for continuous skills more than for discrete skills.

Whole and Part Practice

Another of the many decisions the physical therapist must make in a therapy session concerns whether it is better to have the patient initially practice a skill or activity in its entirety or in parts. For example, if a child needs to learn to get out of bed and into a wheelchair, should the child initially practice the entire sequence of the parts of this activity as a whole, or should he or she practice the separate parts before trying the whole activity? One way to answer this question is to analyze the skill in terms of its complexity and organization characteristics. As originally proposed by Naylor and Briggs, *complexity* refers to the number of parts of the skill, as well as the amount of attention demanded by the performer.[109] Complexity increases as the number of parts and the amount of attention demanded increase. The *organization* of a skill is determined by the temporal and spatial relationships of the parts of the skill. Motor skills in which the parts are relatively independent in terms of temporal and spatial relationships between parts are considered to be low in organization. In contrast, skills in which the between-parts relationships are temporally and spatially interdependent have a high level of organization. According to the Naylor and Briggs complexity–organization model, skills that are low in complexity and high in organization should be practiced as whole skills, but skills that are high in complexity and low in organization should be practiced in parts.[109] To apply this model to the skills and activities in physical therapy, the clinician needs to analyze each skill in terms of its levels of complexity and organization before determining whether the child should initially practice the skill or activity as a whole or in parts.

Most of the functional skills and activities that a physical therapy patient must practice are relatively complex, which means that most of these skills should be practiced in parts before they are practiced as a whole. Now the question becomes which parts should be practiced separately and which should be combined? The answer is determined by the organization characteristic of the parts. Parts that are temporally and spatially interrelated should be grouped together as a natural unit within the skill. For example, research has shown that the reach and grasp components of reaching for and grasping a cup to drink from it are temporally and spatially related, which would indicate a high level of organization for these two parts of the skill.[81] The relationship between these two parts suggests that they should be practiced together as a single natural unit of the skill.

A common strategy for engaging people in practicing individual parts is known as the *progressive part method*. Rather than have people practice each part of a skill separately before performing the whole skill, the progressive part method involves practicing the skill in increasing sizes of sequences of parts. The first part is practiced separately until a certain level of success is achieved, then the second part is added so that the first and second parts are practiced as one unit. Each part is then added progressively until the whole skill is performed.

Reducing difficulty of a skill. For some skills or activities, it may be more desirable to reduce the difficulty of the skill and practice a modified version of the whole skill rather than to practice the skill by parts. This approach to practicing a skill involves at least a two-step sequence. The first step is practicing the simplified version of the skill, which is followed by practicing the actual skill without the modification. Whether additional modifications are needed between these two steps will depend on the skill or activity and the person learning it. Research has shown that several strategies effectively reduce a skill's difficulty and can be employed as an initial practice experience.[102] Each strategy relates to the characteristic of a skill or activity that makes it especially difficult to perform. In addition, each strategy simplifies the performance of the skill or activity in a way that allows the person to practice its basic movement coordination pattern, which is essential in the initial stage of learning. The following three strategies meet these requirements: (1) reduce the speed at which the skill is normally performed to a pace that gives attention to the movement pattern; (2) reduce the difficulty of the object that must be manipulated while performing the skill or activity (e.g., a research investigation in Australia with 6- to 8-year-old children learning a tennis forehand skill found that smaller racquets were superior to regular-sized adult racquets for improving hitting technique and performance[16]); and (3) reduce the attention demands required by the skill, such as by using the body weight support system for performing gait skills. Other effective methods for reducing the complexity and difficulty of skills include the use of virtual reality and simulators. Although physical therapists have increased their use of these devices, research concerning their use and effectiveness is lacking.

Mental Practice

The term *mental practice* refers to the cognitive or mental rehearsal of a physical skill in the absence of overt physical movement. When engaging in mental practice, people may

think about the cognitive or procedural aspects of the skill or activity or they may engage in visual or kinesthetic imagery in which they see or feel themselves actually performing the skill or activity. Research concerning the use of mental practice in motor skill learning has established its effectiveness in facilitating skill acquisition in adults and as a means of preparation just before performing a skill or activity.

As an aid to skill acquisition, mental practice is most effective when combined with the actual physical practice of the skill or activity. In some research, the inclusion of mental practice can reduce the need for physical practice by 25% to 50%.[7] This means that 50 physical practice trials combined with 50 mental practice trials are as effective for learning a skill as 100 physical practice trials. Numerous research studies have reported the effectiveness of mental practice in physical rehabilitation settings.[102,111,142]

As a means of skill or activity performance preparation, mental practice involves visually and kinesthetically imagining the performance of the skill in the few minutes or seconds before actually performing the skill. An example in a physical rehabilitation setting would be a situation in which a child must stand up from a seated position. While seated, the child visually sees and kinesthetically feels himself or herself performing the entire sequence of movements required to perform the skill. After engaging in this brief mental imagery experience, the child then physically performs the skill.

Why is mental practice effective for aiding motor skill learning and performance preparation? Researchers have proposed and provided evidence to support several hypotheses. One is the neuromuscular hypothesis, which states that the imaging or visualizing of motor skill performance creates electrical activity in the nerves and musculature involved in performing the skill.[35] Although this activity can be measured by electromyography (EMG), it does not reach a level of intensity that would produce the kind of muscle activity needed to generate observable movement. The brain activity hypothesis involves a similar notion of internal activity that simulates activity that occurs when the skill is actually performed. According to this hypothesis, which is based on the results of brain imaging studies, when a person imagines moving a body part, the brain activity is similar to what occurs when the person physically moves.[116] The third hypothesis, known as the cognitive hypothesis, proposes that mental practice engages the person in the type of cognitive processes in which a person engages before, during, and after physically performing a motor skill.[102] These processes may include cognitive activities such as decision making or developing strategies to correct performance errors. Together the research evidence supporting these three explanations for the effectiveness of mental practice establishes the potential roles that mental practice can play in physical therapy.

MOTOR LEARNING IN TYPICALLY DEVELOPING CHILDREN

Children learn motor skills with astonishing frequency. Functional activities (e.g., crawling, walking, grasping, manipulating), academic skills, and play increasingly involve complex, skilled actions that develop as various cognitive and social skills emerge. Children not only undergo motor learning repeatedly, they also experience changes in cognitive and physical constructs as their bodies change during their development. Thus it is important to consider learning in the context of motor development of age-appropriate skills. An important aspect is that learning occurs through individual movement exploration, with variations and errors being important features. Furthermore, this learning occurs through astonishing numbers of repetition, with intensive practice involving trial and error as key features of motor learning during development.[2]

Many of the principles derived from the adult studies discussed earlier hold true in children. Although oddly there is a paucity of motor learning studies in children, it is important to note that the nature and capacity of the learner may be quite different, and thus it is important to understand differences in motor learning between adults and children.[148] In this section, we describe key differences between motor learning in children and in adults and discuss how many of the above-described principles may or may not hold true in children.

Children Are Not Simply Little Adults

Perhaps the most important difference between children and adults relates to the concurrent changes in physical structure that provide the ability to learn and also force the child to relearn as his or her body changes. For example, learning to walk can occur only after suitable strength and balance capabilities emerge.[147] Precision grasping can emerge only after the development of finger individuation, which depends on the maturation of the corticospinal tract.[59] That is not to say that learning and development are purely driven by maturation. Rather it is likely epigenetic, where both maturation of physical and neuronal structures and environmental cues and practice influence each other and guide development,[48] just as the person, task, and environment affect adult learning. Furthermore, as changes in body mass and limb length occur, the dynamics required to produce skilled action also change. Thus learning activities must be planned and occur continually in the context of the developing child (see Chapter 3) and motor learning at one time point may not directly transfer to another.

Equally important is the increasing capacity to process and store information. Adults have amazing cognitive processing capabilities, but these emerge slowly throughout development. Children are known to have decreased information-processing capabilities compared with adults.[119,148] This limits the amount and type of information they can process. Children are slower at processing such information and have decreased selective attention to do so. Limited processing and reduced object recognition capabilities affect their ability to copy images.[96] Higher-level attentional focus,[90,104] spatial working memories,[135] and verbal learning and memories[29] all differ between children and adults. This means that the amount of information (e.g., feedback) that children can process and the rate at which they may do so may be limited, and thus many of the principles of motor learning discussed so far may need to be adjusted according to age expectations, as well as any cognitive limitations.

Feedback Schedules

These differences may also bring into question the applicability of some adult learning principles. In fact, in a number of cases, learning indeed has been shown to be quite different in children. One could imagine that slower feedback processing in children could result in information overload, which would interfere with learning; thus like adults, they would benefit from intermittent feedback as described earlier. In contrast, however, reduced feedback has been found to be *less* beneficial than feedback provided after every trial in children.[144] This effect is

illustrated in Fig. 4.2, which shows variability during acquisition and retention of an arm movement task in adults (Fig. 4.2, A) and children (Fig. 4.2, B). Specifically, performance accuracy during acquisition was similar in adults regardless of whether or not feedback was reduced. In contrast, reduced feedback in children resulted in more error. This could be due to the reduced attentional capabilities described previously, but it may relate to the fact that children have increased error and movement variability,[12] whereby their signal-to-noise ratio becomes much higher and intrinsic feedback is washed out. Errors may increase disproportionately as accuracy demands increase.[97] Children are also known to rely more on online adjustments during movement, and increased feedback may help calibrate these adjustments.[46,169] Children may require increased feedback to update internal representations, which may interact with information processing.

Early studies on feedback reduction suggested a similarity to adults whereby feedback fading was beneficial as learning progressed in children.[52,136] More recent evidence may suggest that fading of feedback beyond a critical point may in fact be detrimental to learning in children.[144] There may be a critical point in age or skill where feedback reduction interferes, and feedback may need to be withdrawn more gradually. Practice in children can be made more effective with feedback with optimal information without guiding to outcome.[108] Thus a key challenge for the therapist is to monitor how feedback is influencing performance and modify the frequency accordingly. Nevertheless even within a given patient, the optimal feedback frequency may vary, depending on the tasks being learned.

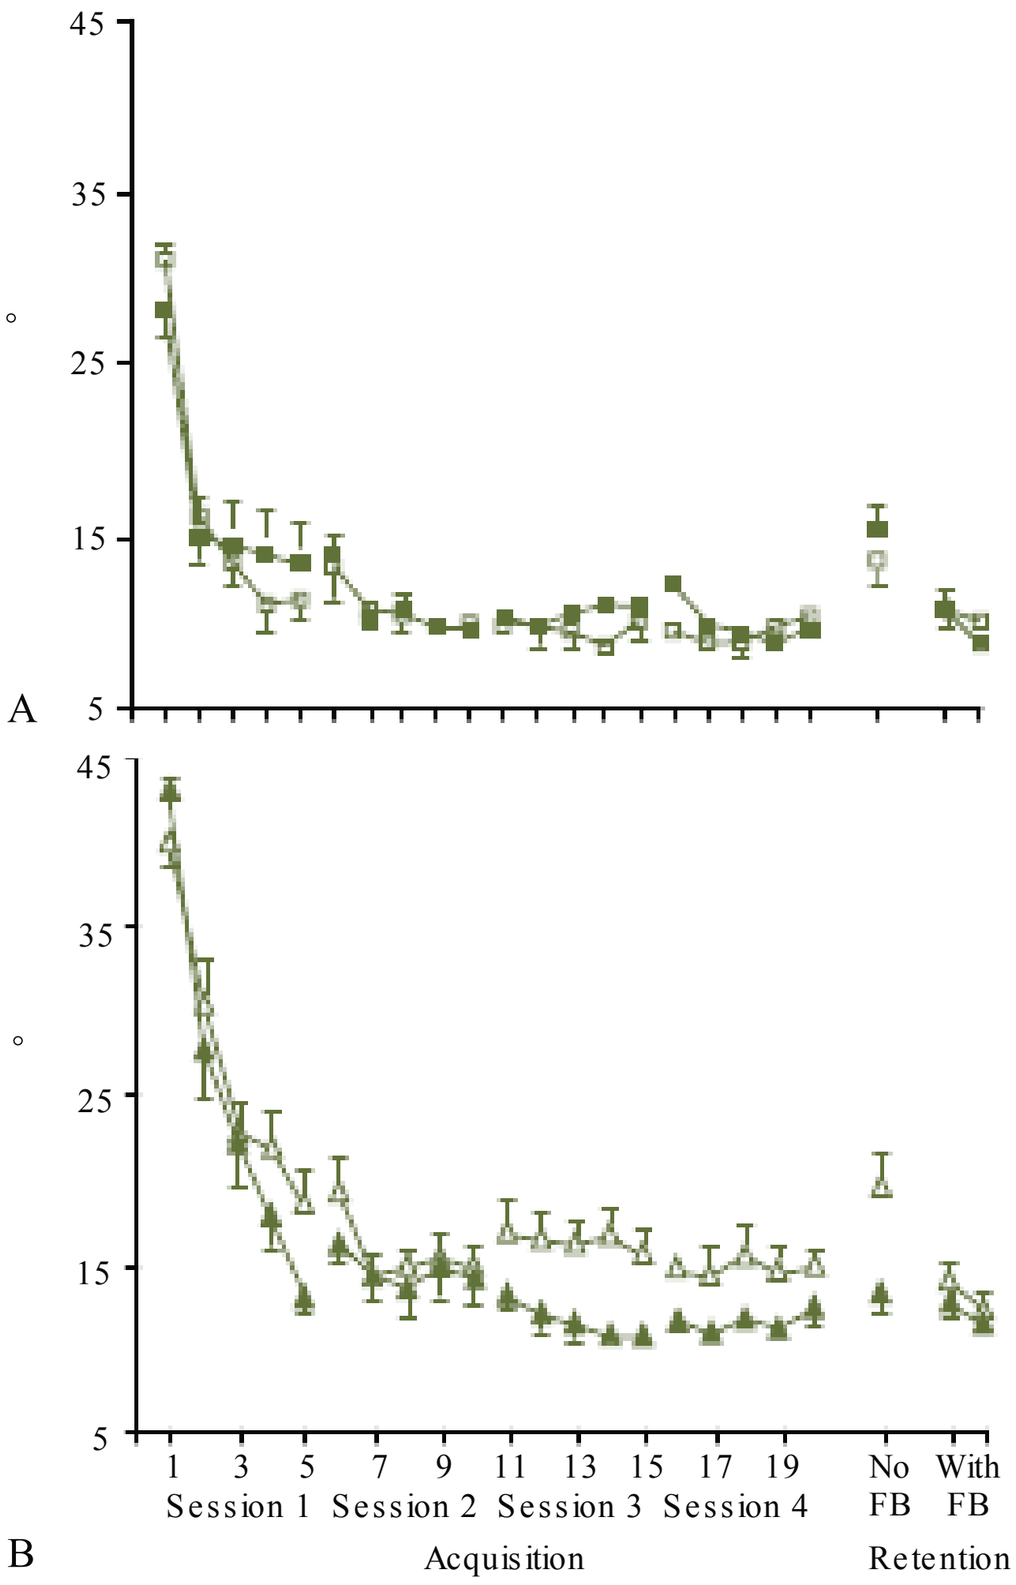

FIG. 4.2 Block means (SE) for root mean square error (RMSE) during acquisition, retention (no feedback), and reacquisition phases (with feedback) for young (A) adults and (B) children. Filled symbols denote feedback on all trials; unfilled symbols denote feedback on 62% of trials. (Modified from Sullivan KJ, Kantak SS, Burtner PA: Motor learning in children: feedback effects on skill acquisition. Phys Ther 88:720-732, 2008.

Types of Practice Schedules

The organization of practice variability to modulate contextual interference may also need to differ between children and adults. Some evidence suggests that for children, like adults, random practice is better for learning[88] and retention.[71,119] Yet blocked or mixed practice may be better for some tasks[70] and age groups.[168] Still other studies suggest no difference in practice schedules.[37,87] Blocked practice may be better for younger/less-skilled learners in terms of complex tasks.[76] In this case, random practice schedules may overload the system with too much information, given the reduced and slower information processing. Yet handwriting retention in elementary school kids was found to be better during random practice.[143] And the learning of overarm throwing for accuracy from different distances was best for elementary school children when the practice schedule involved systematically increasing the amount of CI as practice progressed.[127] This means that early practice involves blocked practice but then as practice continues, smaller block sizes are introduced until a random schedule was experienced when skill levels were at a higher level. Thus the type of practice schedule that is most beneficial may in fact depend on age, task complexity, and skill level.[88,168]

Learning Occurs Over Considerable Time and Practice

An important consideration is that unlike many of the laboratory-based tasks used in published research, complex functional motor skills are not learned over short periods. Even in adults, expert typists,[17] chess players, musicians, and athletes[43] engage in immense amounts of practice over long durations to acquire skill. Crawling infants have been shown to practice maintaining balance more than 5 hours per day, equal to approximately 3000 crawling steps.[1] Similarly, emerging (toddler) walkers undergo about 14,000 steps, 46 football fields, and 100 falls per day.[3] Thus hundreds of thousands of trials are spread out over weeks or months during infant development of mobility skills. The naturalistic practice in which these infants and children engaged is not continually the same (blocked); actually a rich variety of events, locations, and surfaces are experienced over an extended time period. This can be considered an exaggerated version of random practice. Thus rather than practicing a solution, this random experience may construct new solutions and dissuade infants from relying on simple stimulus-response learning and instead promote "learning to learn."[1,2,74] This generalization strategy would promote broad transfer of learning within perception action systems (e.g., walking on various surfaces) and narrow specificity between them (walking versus crawling). Rest between learning sets during the development of such skills is intermittent, which may promote the contextual interference effects described earlier in the chapter. Because in most cases physical therapists cannot be with patients over

such long durations, promoting strategies that will generalize to home environments should be used to facilitate practice in that environment. An example is to use strategies involving active problem solving.[144] Thus the involvement of caregivers is a crucial component of continued learning.

MOTOR LEARNING IN PEDIATRIC REHABILITATION

Although much of pediatric rehabilitation focuses on learning of motor skills, little is known about the learning processes in children with physical or neurologic disabilities. Motor learning in this case is further complicated by the physical constraints involved, as well as by potential sensory impairments that may diminish feedback and affect the updating of internal models used for movement.

In one study of motor learning in typically developing children and children with hemiplegic CP, children were assigned to 100% or reduced (62%) feedback subgroups as they practiced 200 trials of a discrete arm movement task with specified spatiotemporal parameters.[18] Children with hemiplegic CP used their less affected hand. Children in all groups improved in accuracy and consistency. Although typically developing children showed greater accuracy as expected, those who received 100% feedback performed with significantly less error than the 62% feedback group during all phases. In contrast, no statistically significant difference was found between feedback subgroups of children with CP, although the 100% feedback group consistently demonstrated less error. Thus children with CP use feedback in a similar manner as children with typical development when learning new skills with their less involved hand, but they demonstrate less accuracy and consistency.

In terms of efficacious rehabilitation approaches, reviews of all approaches for children with cerebral palsy showed just six with good levels of evidence supporting their implementation.[112,113] These approaches had two commonalities. First, they all involve active movement of the participant using a motor-learning approach to rehabilitation.[20] This approach uses the environment to elicit desired motor behaviors and requires active problem solving. Second, they are all intensive, requiring many hours of training.

The next section of the chapter provides examples of learning in children with physical or neurologic disabilities with a focus on cerebral palsy, which is the most common type of childhood neurologic disability and the focus of most research in pediatric motor learning.

Practice Makes Better

Cerebral palsy (CP) is a developmental disorder of movement and posture that causes limitations in activity and deficits in motor skills (see Chapter 19). CP is attributed to nonprogressive disturbances in the developing fetal or infant brain, and it is the most common pediatric physical disability. Spastic hemiplegia (unilateral CP), characterized by motor impairments mainly affecting one side of the body, is the most common subtype, accounting for 30% to 40% of new cases.[77] Through much of the 20th century, the motor impairments, especially in the upper extremity (UE), were thought to be static, with little potential for rehabilitation. Thus therapy efforts were largely directed at minimizing impairment (e.g., reducing spasticity, preventing contractures). In fact, as recently as the 1990s, studies were suggesting that individuals with CP could reduce unwanted motor activity or spasticity with visual tracking or biofeedback but that they had little ability to learn appropriate motor commands.[110,114] Early work studying prehensile force control reinforced this view, suggesting that children with CP retain infantile coordination strategies.[59] Subsequent studies, however, provided two separate lines of evidence that these impairments are not static and instead improve with sufficient practice.

First, developmental studies of children with CP have shown that motor function does improve over the course of development. For example, gross motor function has been shown to improve as children with CP get older.[124] Development of hand function has also been observed. For example, Holmefur and colleagues studied the longitudinal development of bimanual UE use in children with hemiplegic CP.[79] Children were followed for 4 to 5 years with the Assisting Hand Assessment (AHA), a Rasch-based measure that describes how the affected UE is used as a nondominant assist during bimanual activities. Investigators found that bimanual proficiency improves during the course of development but that the developmental rate and the subsequent plateau depend on the initial score at 18 months of age (Fig. 4.3, A). Children with hemiplegia with higher bimanual function in early childhood developed bimanual skills faster and reached their limit earlier than children with lower bimanual function. It is interesting to note that the development of bimanual UE use differs from that of gross motor activities in CP,[124] where milder children reach their limit later. During a 13-year follow-up study starting at the age of 6 to 8 years, it was found that hand function in children with CP improves with age.[39] Specifically, time to complete items on the Jebsen-Taylor Test of Hand Function improved in all children, and grip force coordination during grasp improved (Fig. 4.3, B). Thus both gross and fine motor functions do develop, although these two general types of skills seem to develop and reach plateaus differently.

A second line of evidence that motor function is not static in CP comes from systematic studies on the effects of extended practice that have demonstrated that motor performance can indeed improve with practice.[89] In one study, children with CP were asked to repeatedly lift an object of a given weight 25 times.[63] Even though motor learning was considerably slower than in typically developing children, impairments in fine manipulative capabilities and force regulation during grasp were partially ameliorated with this extended practice. This suggests that the initial impaired performance, at least in part, may be due to lack of use, and that many impairments in motor control previously documented may be due to the fact that insufficient practice was provided (i.e., early stages of motor learning rather than motor control capabilities were captured). Similarly, in-hand manipulation has been shown to improve with practice.[38] Such benefit of intensive training has also been documented in postural control in children with CP.[137] It is important to note that these findings suggest intensive practice may provide a window of opportunity for improvement. It is increasingly being recognized that reduction of unwanted tone (i.e., by the use of botulinum toxin) alone does not improve function[121] and that functional or task-oriented approaches and physical conditioning provided with sufficient intensity have the potential to improve motor function in CP.[4,69,91,159] Unlike adults, children with CP may benefit more from concrete instructions than from movement outcome information.[158] Motor learning in this case may require providing careful feedback on knowledge of performance, as well as cognitive strategies to achieve

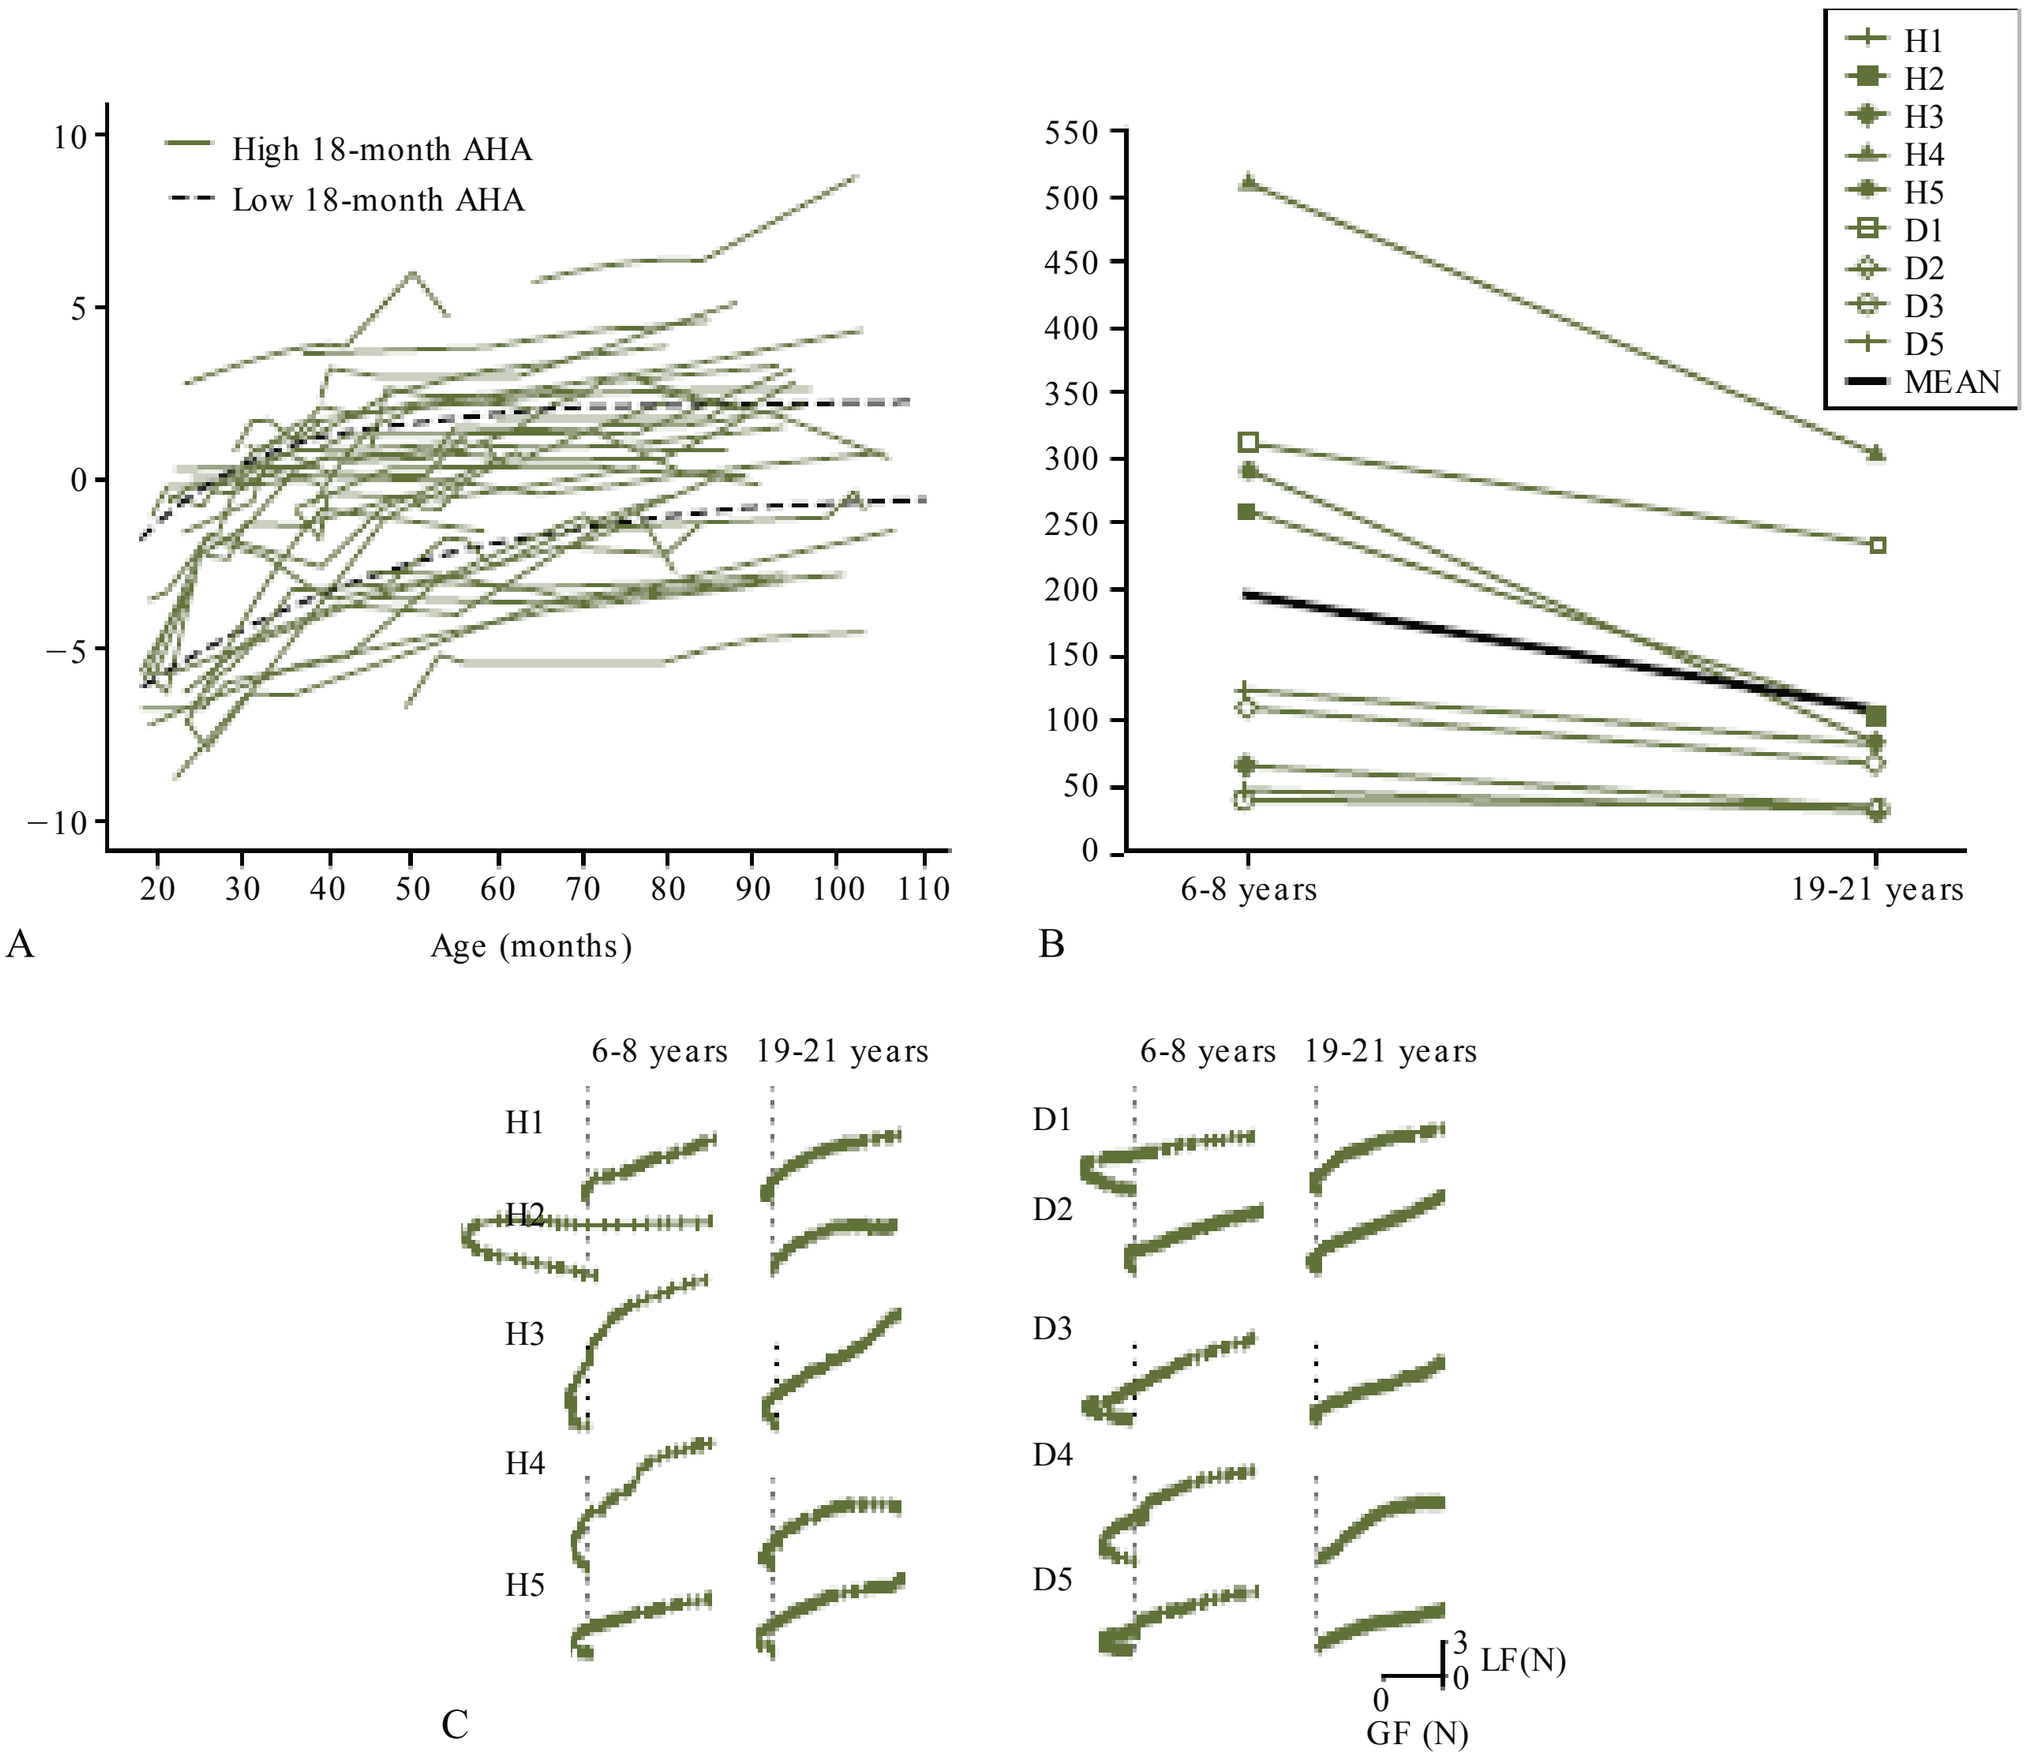

FIG. 4.3 A, Observed and predicted Assisting Hand Assessment (AHA) development. Groups have high (n = 27) or low (n = 16) 18-month score (above or below 3 logits) on the AHA at age 18 months in children with cerebral palsy. Higher scores mean better bimanual performance. B, Time to complete the six timed items (writing excluded) of the Jebsen-Taylor Test of Hand Function for individual participants, as well as mean (bold line) from the first (age 6 to 8 years) and second (age 19 to 21 years) data collection sessions. Faster times correspond to better performance. C, Mean grip-force/load-force trajectories for each subject (A, hemiplegic subjects; B, diplegic subjects) at the ages of 6 to 8 (left) and 19 to 21 (right) years. The x axis corresponds to load force (LF), and the y axis represents grip force (GF). Straighter lines indicate simultaneous increase in the two forces. Dn, diplegic; Hn, hemiplegic. (A, From Holmefur M, et al.: Longitudinal development of hand function in children with unilateral cerebral palsy, Dev Med Child Neurol 52:352–357, 2010. B and C, From Eliasson AC, Forssberg H, Hung YC, Gordon AM: Development of hand function and precision grip control in individuals with cerebral palsy: a 13-year follow-up study, Pediatrics 118:e1226-1236, 2006.)

better performance levels.[151] Thus it is not simply practice of movements, but practice of movements embedded in tasks. The exact dosage of training is unknown and is an important focus of future trials.[94]

Together, these lines of evidence contradict traditional clinical assumptions that motor impairments in CP are static. UE performance in children with CP may improve with practice and development. More important, this implies that hand function in particular may well be amenable to treatment.

So what type of practice schedules may be best for motor learning in children with CP? After a blocked practice schedule over several sessions, children with CP retain the ability to grade isometric grip force (using online visual feedback) after a 5-day delay.[157] Even within a single session of extended blocked practice, children with hemiplegic CP improved their ability to scale fingertip forces to the weight and texture of novel objects.[63] Similar to healthy adults, blocked practice resulted in better acquisition of force scaling to the grip of novel objects in

children with CP than did random practice.[37] But both practice schedules resulted in similar retention (Fig. 4.4). These findings suggest that children with CP can form and retain internal representations of novel objects for anticipatory control, irrespective of the type of practice schedule employed. It should be noted, however, that force scaling is a form of parameter learning as opposed to learning a new skill (such as how to grasp). In that sense, the findings are in line with the hypothesis that random practice would not provide an advantage over blocked practice for parameter learning.[103] Thus it is unknown whether one form of practice is more beneficial than the other in this population, although random or mixed practice may resemble naturalistic learning to a greater extent. Nevertheless, it is clear that intensity of practice matters in rehabilitation.[13] An important point is that usual and customary therapy delivery schedules may not be sufficient for providing such intensity. For example, a study of physical therapy and occupational therapy sessions for adults with hemiparesis post stroke showed that the numbers of repetitions of UE movement observed were relatively small.[98] Although it is not known how many repetitions occur in pediatric therapies, one could imagine that this number would be even smaller given the requirement to maintain the interest and attention of children. In fact, one study of intensive constraint-induced movement therapy showed that 4- to 8-year-old children were engaged in tasks over less than 60% of a 6-hour day.[25] This effort is even less than it appears, as this number does not reflect time between trials and time taken to redirect focus as needed. It is interesting to note that children who required less redirection of focus improved to a greater extent than those who required a lot of redirection. Next we consider models for the delivery of intensive practice schedules.

TASK-ORIENTED TRAINING

Unlike neuromuscular reeducation approaches traditionally focused on impairment-level disablement (body functions/structures in International Classification of Functioning, Disability and Health Resources [ICF] language), task-oriented training is a top-down approach that focuses on activity limitations (i.e., an important aspect of CP) rather than on remediation of impairments or correction of movement patterns. Task-oriented training can be considered a motor learning or goal-directed approach to rehabilitation.[20,154,162] The approach is based on integrated models of motor learning and control and behavioral neuroscience focusing on participation and skill acquisition. An important component is the active problem solving described earlier. The associated behavioral demands of the tasks and motor skill training may result in cortical reorganization[118] underlying concurrent functional outcomes. For optimal efficacy, task-oriented training must be challenging, must progressively increase behavioral demands, and must involve active participation. Skilled training in animals shows the plasticity of UE cortical representation, whereas unskilled training does not.[93] The tasks must also have salience to the performer to influence the person–task–environment triad. In fact there may not be a relationship between intensity and

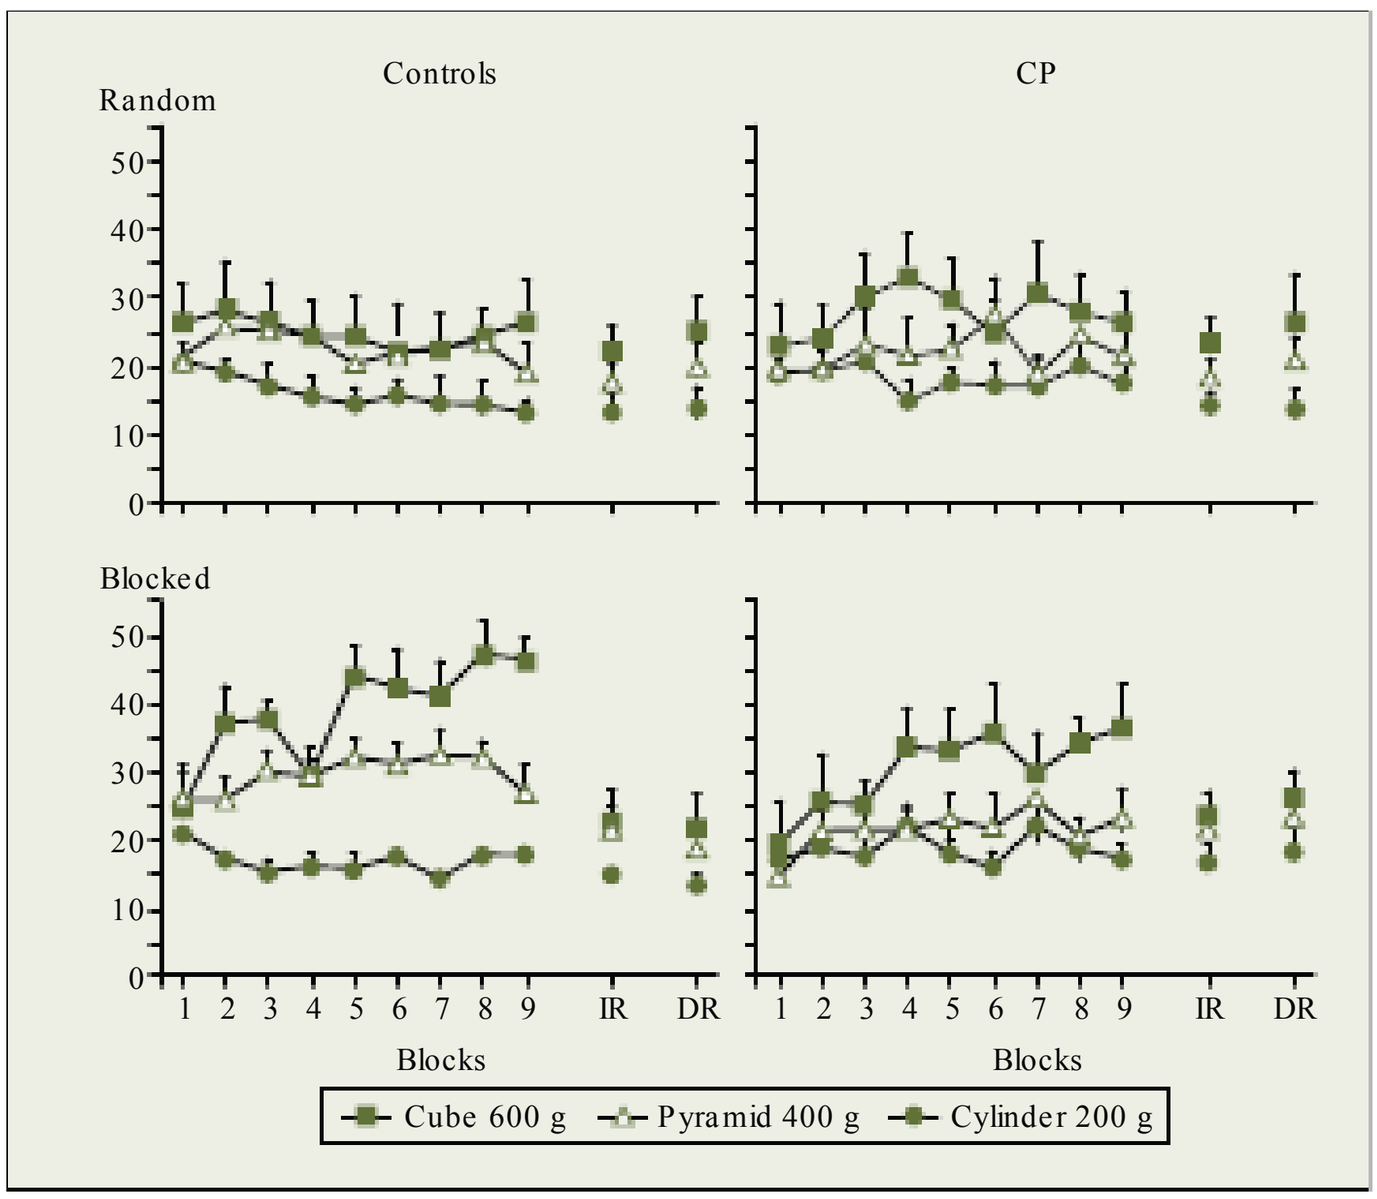

FIG. 4.4 Mean standard error of the mean (SEM) load force rate across nine blocks of acquisition, immediate retention (IR), and delayed retention (DR) during lifts with cylinder (circle), pyramid (triangle), and cube (square) for control children (left) and children with hemiplegic cerebral palsy (CP) (right). Insets show mean (SEM) single trials from first trial at immediate retention and first trial at delayed retention. Blocked practice resulted in better acquisition of force scaling, but retention was similar for both types of practice. (From Duff SV, Gordon AM: Learning of grasp control in children with hemiplegic cerebral palsy. Dev Med Child Neurol 45:746-757, 2003.)

outcome unless the nature of training is considered.[164] Thus at least beyond a certain point, time on task may be less important than what is practiced.

The importance of task-oriented approaches was highlighted in a randomized trial of 55 children with CP comparing functional physical therapy versus a reference group whose therapy was based on the principle of movement normalization (including some aspects of neurodevelopmental treatment [NDT] and the Vojta method).[91] The functional therapy model consisted of the establishment of functional goals, repetitive practice of problematic motor abilities in a meaningful environment, active problem solving, and involvement of caregivers in goal setting, decision making, and implementation in daily life (i.e., many of the motor learning principles described earlier).

Gross motor abilities in a standardized environment were measured with the Gross Motor Function Measure (GMFM).[126] The GMFM is a standardized observational instrument for children with CP, developed to measure change in gross motor function, including lying and rolling, sitting, crawling and kneeling, standing, and walking, running, and jumping. Motor abilities in daily situations were measured using the Pediatric Evaluation of Disability Inventory (PEDI).[73] The PEDI is a judgment-based assessment that uses parent report through a structured interview. Two domains of the PEDI were measured: self-care and mobility. These include independent toileting, brushing teeth, dressing, and so on.

Both measures were taken 6 months, 12 months, and 18 months after implementation of the training programs. Investigators found no group differences in improvement in basic gross motor abilities.[91] However, when examining functional skills in daily situations, they found that children in the functional therapy group improved more than children in the movement normalization group. Thus functional training had the additional benefit of improving motor abilities in the daily environment identified to be important to caregivers.

The efficacy of functional training in CP using varying protocols has been documented by a number of additional investigators.[4,69,159] Treadmill training is another form of functional training that focuses on massed practice of locomotor behaviors. Efficacy in Down syndrome is well established[155]; however, it is not yet clear whether this holds true in CP and other pediatric disabilities.[30,107]

Although evidence for functional and task-oriented approaches is accumulating, evidence for other approaches such as NDT is more limited. An evidence report for the American Academy of Cerebral Palsy and Developmental Medicine concluded that as of 2001, there was not consistent evidence in support of NDT.[19] More than a decade after their report, little evidence supports its efficacy.[112] However, when applied with greater intensity, NDT approaches may provide greater benefit.[9] It should be noted, however, that NDT has been evolving beyond the original concepts introduced by the Bobaths shortly after the Second World War, and more recent NDT approaches appear to incorporate some principles of motor learning.[80]

The examples of task-oriented approaches described earlier highlight the importance of motor learning principles such as intensity, specificity, and task salience. Next we provide several examples of contemporary task-oriented approaches focusing on the upper extremity that further incorporate motor learning approaches, which can be considered use-dependent training as they engage children in activities that necessitate the use to the more affected extremities.

Constraint-Induced Therapy

A rich history of theoretical constructs has been derived from the basic sciences (including neurosciences and motor learning) underlying the application of intensive practice-based models of rehabilitation. For example, it has long been noted that monkeys with unilateral lesions or deafferentation neglect to use their affected UE but indeed will do so if forced by restraint of the contralateral unaffected UE, and that this forced use led to improved use of the affected UE.[145,153] The idea that "residual (masked) capability" could potentially be tapped into by forced use of the deafferentated or impaired limb drove the development of intensive practice-based therapies in humans. This line of research began with studies of forced use in adults with hemiparetic stroke by conducted Wolf and colleagues in the 1980s.[115,163] Subsequently, Taub and coworkers added 6 hours of structured activities using principles of behavioral psychology (shaping).[146] Shaping involves approaching motor activities in small steps by successive approximation to the movement goal or grading of task difficulty based on the patient's capabilities[117,138]; it is similar to part practice described earlier in this chapter. The active intervention involving restraint plus structured practice evolved to become known as *constraint-induced movement therapy (CIMT)*.[146] CIMT can be considered to be a special class of task-oriented training because the triad among person, task, and environment is very much applied, although functional arm use is promoted more than skill. Strong evidence of efficacy has been obtained in adult patients following stroke.[165,166] Although it would be easy to misinterpret this work as suggesting that it is the restraint that is essential, it is important to note that optimal efficacy depends on employing the motor learning principles described so far. An example has been found using an animal model of hemiplegia.[50] One hemisphere of the cat motor cortex is transiently inactivated with muscimol, a GABA agonist, and the cat wears a restraint on the unimpaired limb with no training or receives training for 1 hour per day, 5 days per week, for 4 weeks, along with the restraint. An important finding is that only cats that receive active skilled training have normalization of functional and synaptic plasticity.[50] Thus the ingredients of training matter.

Constraint-Induced Therapy in Children with Hemiparesis

For CIMT to be conducted in children, the overall approach must be changed to focus on age-appropriate activities that sustain interest for long periods, as children are not as easily motivated to perform activities of daily living or part practice methods for sustained periods of time in the way that adults are. Often the duration of restraint wear must be modified along with the type of restraint. These studies differ in age of participants (ranging from 6 months to 18 years), inclusion criteria, duration and intensity of treatment (ranging from usual and customary care schedules to adult models of CIMT), restraint (gloves, mitts, slings, and casts), and outcome measures.[22,40,78] It should be noted that despite these methodologic differences,[42] nearly all of these studies have reported positive outcomes.[8,129]

An important point is that CIMT should not be viewed as a one-time opportunity whereby the less-affected UE is restrained as much as possible (e.g., with a cast) and the highest possible intensity is provided regardless of age. Despite the diversity of approaches, no evidence suggests that one type of restraint is more effective than another; thus comfort and safety should be key factors in restraint selection.[42]

Furthermore, improvements in UE performance in young children have been noted with just 2 hours per day three times per week.[41] Perhaps most important, repeated doses of CIMT have been shown to have an additive effect (Fig. 4.5).[24] This suggests that there is no advantage to maintaining the potentially invasive schedule and restraints, and instead, one could administer CIMT through repeated, and less intensive, bouts. Thus overall, CIMT is just a task-oriented method to induce intensive practice (use-dependent training); it can be considered as part of a child's long-term pediatric rehabilitative care.

CIMT utilizes a number of motor learning principles. These include use of both part and whole practice methods, modifying tasks to ensure success and progression of difficulty as success is achieved, active problem solving, optimal practice and feedback schedules, and the need to generalize learning to performance in everyday environments.

Despite the promise of CIMT, a number of conceptual problems have been noted in applying it to children that need consideration. First, CIMT was developed to overcome learned nonuse in adults with hemiplegia and to promote use over skill. These adults lost UE function and were often highly motivated to regain previously learned functional behaviors. Children, in contrast, must overcome *developmental disuse,* whereby they may have never learned how to effectively use their more affected extremity during many tasks and may need to learn how to use it for the first time. Thus treatment must be developmentally focused and must take into account the principles of motor learning described earlier.

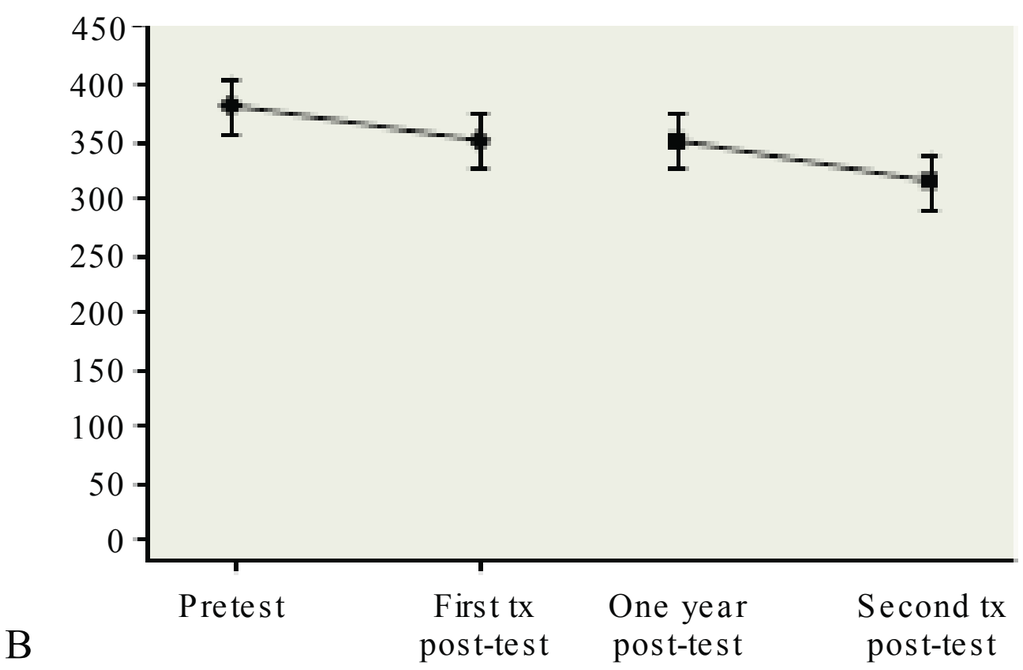

FIG. 4.5 A, Schematic diagram of child with the less-affected upper extremity (UE) restrained with a cotton sling sewn shut, while the more affected UE practices placing coins in a coin bank. B, Mean standard error of the mean (SEM) time to complete the six timed items (writing excluded) of the Jebsen-Taylor Test of Hand Function for eight children before and after 2 weeks of constraint-induced movement therapy (CIMT, 12 months later, and after a second dose of CIMT. Faster times correspond to better performance. The maximum allowable time to complete each item was capped at 120 seconds, resulting in a maximum score of 720 seconds. (B, Modified from Charles JR, Gordon AM: A repeated course of constraint-induced movement therapy results in further improvement, Dev Med Child Neurol 49:770-773, 2007.)

Second, restraining a child's less-affected extremity (especially with casts) is potentially psychologically and physically invasive and thus should not be performed on young or severely impaired children with the same intensity as in adults. It must be remembered that use of the less-affected side is still developing in children. Neuroanatomic evidence in developing kittens indicates that refinement and maintenance of corticospinal terminations in the spinal cord are activity dependent. Restriction of limb use on one side during a critical period in early development reduces the topographic distribution, branch density, and density of presynaptic boutons on the side of restricted use.[64,105,106] This suggests that there may be a substantial risk of damage to the less affected UE if it is restrained for long periods at too early an age. Thus a greatly modified protocol is required in young children.

Finally, CIMT focuses on unimanual impairments, which do not greatly influence functional independence and quality of life in that children with hemiplegia have a well-functioning (dominant) hand.[139] Training it as a dominant hand while restrained likely will improve manual dexterity, although it lacks specificity of training for how the hand will be used once the restraint is removed, for example, as a nondominant assisting hand during bimanual activities. Children with hemiplegia have impairments in spatial and temporal coordination of the two hands,[65,156] as well as global impairments in motor planning.[141] Constraint therapies cannot address these problems, and thus generalization of training may not be optimal.

Unconstraining the Constraint: Bimanual Training

Development of UE control is the consequence of activity-dependent competition between the two hemispheres, with the more active side winning out over the less active (damaged) side.[44,104] Balancing activity of the two hemispheres after unilateral brain damage may help restore motor function and may establish more normal anatomic organization of the corticospinal tract and motor representational maps in the primary motor cortex.[51] One way to do this is by using noninvasive brain stimulation (NIBS) such as repetitive transmagnetic stimulation (rTMS) and transcranial direct current stimulation (tDCS). These approaches may be used to inhibit activation of ipsilateral pathways and enhance activation of contralateral pathways. Such approaches are promising in adult stroke rehabilitation[49] and may even facilitate motor learning.[122] Evidence supporting NIBS in pediatric populations is more limited.[58,92]

From a functional perspective, principles of practice specificity would suggest that the best way to balance activity of the cerebral cortices and achieve improved bimanual control would be to directly practice bimanual coordination. Bimanual training may be efficacious in adults with hemiparesis.[21,123] A child-appropriate form of task-oriented intensive functional training, hand-arm bimanual intensive therapy (HABIT) was developed, which aims to improve the amount and quality of involved UE use during bimanual tasks.[23] HABIT is a highly structured form of training long used in pediatric rehabilitation, bimanual training that retains the two main elements of pediatric CIMT (intensive structured practice and child-friendliness). Similar to CIMT, this approach engages the child in bimanual activities 6 hours per day for 10 to 15 days in a day camp setting. It is important to note, however, that no physical restraint is used. Rather, bimanual UE coordination is elicited by modifying the environment. Similar to other functional training approaches often used in physical therapy and occupational therapy, HABIT involves task-oriented training to achieve meaningful goals. However, it differs from these approaches in that intensity is much greater, practice is far more structured, and children problem-solve and focus on how the UE performs at the *end point* of the movement. No attempt to normalize movement is made.

An initial randomized control trial of HABIT was conducted on 20 children with hemiplegic CP between the ages of 3.5 and 14 years.[60] Children who received HABIT had improved scores on the Assisting Hand Assessment, whereas those in the no-treatment control group did not. Frequency of UE use increased for the children who received HABIT. Bimanual coordination, as determined by analysis of the kinematics of a drawer-opening task,[83] showed that children improved temporal coordination of the movements of each extremity after receiving HABIT. Providing HABIT using a magic-themed based approach has also been shown to be efficacious.[72] Part-practice, scaffolding task complexity, and goal training did not have significant effects on unimanual or bimanual performance but did drive the motor learning necessary for improved goal performance.[15] More extensive randomized trials have since been conducted comparing CIMT and HABIT and other variations of bimanual training.[32,45,62,67,128] With small nuances,[14] all of these studies have shown similar improvements in unimanual capacity and bimanual performance.[68] At first glance, these would suggest a lack of training specificity because both approaches yielded unimanual and bimanual improvements. However, follow-up studies suggest caveats. Specifically, 85% of goals identified by children and caregivers were bimanual in nature,[67] and bimanual training (HABIT) resulted in greater gains in performance on these goals.[14,67] Second, kinematic analysis of the drawer-opening task showed greater improvements in spatiotemporal coordination of the two hands following HABIT.[83] It should be noted that although not yet tested, the same logic may hold true for CIMT: greater improvements in unimanual coordination and range of motion. Although these approaches have many similar aspects and may be combined as seen fit,[1,28] it is likely that there may be differential responders to each approach. For example, it has been suggested that children who have a brain reorganization early during development such that one side of the brain controls both hands (ipsilateral corticospinal projections to the spinal cord) appear to respond to a lesser extent than children who maintain normal brain organization.[42,95(but see 85)] Nonetheless, CIMT and bimanual training are not one-time approaches, and thus can each be performed over time on a given individual.

It should be noted that the intensive, motor learning–based approaches described earlier are expensive, logistically challenging, and not likely suited for all children with CP (e.g., younger children). A more distributed model, provided in alternative settings, may be more suitable for some children and families. Both CIMT and HABIT have been shown to elicit greater improvements than NDT-based approaches in a school environment when provided just 2 hours per day.[53] Individualized therapy augmented with a home training program may offer an effective alternative when provided at a sufficient dose.[130] Both CIMT[5,42] and bimanual training have demonstrated efficacy when provided in a home environment. However, this should not be seen as a way to replace therapy delivered by professionals, and its success will likely depend on quality training and supervision by such professionals.

TWO MORE LIMBS

It should be noted that all of the approaches with good levels of evidence are aimed at the upper extremities in children with CP, and there is no evidence yet supporting a given approach for the lower extremities.[113] However, an adaptation of bimanual training, hand-arm bimanual intensive training including the lower extremities (HABIT-ILE)[10] was shown to be promising.[11] This approach simultaneously engaged the upper and lower extremities, with the premise that both are typically performed together in everyday activities. Using a crossover design, children were initially randomized to 90 hours of HABIT-ILE or their usual and customary care as provided in Belgium. The latter largely focused on normalization of movement patterns (i.e., NDT or similar approaches). Each group was then crossed over to receive the other approach. It was found that children in the HABIT-ILE group initially had significant improvements in both upper and lower extremity function, whereas no such changes occurred in the usual and customary care group. When crossed over to HABIT-ILE, the control group then demonstrated improvements in function.

SALIENCE OF MOTOR ACTIVITIES

For rehabilitation to remain effective in light of the importance of task salience (especially protocols involving long hours), it must constantly evolve to include activities that are meaningful and enjoyable, including video gaming. Children play video games on average 8 hours per week.[27] Actional immersion in a video/virtual environment can potentially allow individuals to produce movements that are not feasible in the real world as a result of their motor impairments (e.g., weakness, limited range of motion). This possibility therefore may have novel intriguing consequences and may enhance learning[31] for functional training, as it is therefore possible to provide positive KR for appropriate efforts.

The choice of video game platforms, consoles, and software needs to take into account (1) the initial abilities of the performer, (2) the specific motor impairments targeted, (3) the extent to which therapy is directed to one or both UEs, (4) the ability to attain progress in movement difficulty, and (5) the age and interest of the performer. Although use of virtual reality-based and video gaming protocols is indeed gaining momentum in rehabilitation,[33] presently evidence of the considerable efficacy of gaming by itself is lacking. Like HABIT and CIMT, it is just one means of engaging task-oriented training, but one that is potentially beneficial in maintaining motivation and providing reward, which were shown earlier in the chapter to be important for motor learning and enhancing plasticity.

There are two general approaches to incorporating video-based or virtual reality (VR) training into pediatric rehabilitation protocols.[66] The first is to develop game platforms that target specific impairments or elicit certain movements. This may be particularly useful for eliciting successful movements by altering the gain of required movement to virtual movement provided as feedback. Thus specific impairments could be targeted (e.g., wrist extension) by creating games requiring such movement, again adjusting the gain required to displayed movements. Such approaches are promising and will likely constitute an important part of pediatric rehabilitation in the future. To be successful, however, these forms of pediatric rehabilitation must adhere to the same principles described earlier (especially salience). A large limitation, meanwhile, is the expense of building and programming devices that are enjoyable and flexible and can progress training suitably with improvements to maintain sufficient challenge. Such activities must address an array of movement impairments across a wide variety of ages. Often there is considerable delay between development and testing and implementation in clinical environments. Even as robotic-assisted therapy becomes more available, the tasks that are employed (often center-out tasks where participants must move a cursor on a screen in a straight line to concentrically arranged targets) are still often unmotivating and thus will not effectively maximize motor learning and generalization. Many robotic-assistive devices are focused on correcting movement patterns (providing templates), and in some cases, passively moving the extremities. Certainly technology does hold promise and will increasingly be part of or supplement therapeutic services. However, for these to work, they need to involve self-initiated movement, the mental and physical effort of the participant, a high intensity of training, and variability of practice including problem solving—all while continuing to be meaningful to the participant.

The second approach is to use or modify commercially available gaming systems (e.g., Nintendo Wii/Wii-Fit, Minami-ku, Kyoto, Japan; Microsoft Kinect, Redmond, WA). Although commercially available motion capture VR systems have been tailored specifically for rehabilitation, the cost may prevent wide-scale application in the near future. Thus commercial, mainstream gaming consoles have the distinct advantage of constantly being updated by game developers to maintain the interest of children and are familiar to most children; also, the initial financial investments are minimal compared with the diversity of devices and games available. A major limitation, however, is that these devices were not created to elicit specific movements that are necessarily impaired in children with disabilities and may not have sensors that are sensitive enough to translate subtle movement improvements into increases in game performance. During free play, children are likely to choose games or consoles that can be performed with one (nonparetic) UE or require minimal (stabilization) movement of the more affected UE.

Paradoxically, because children often already engage in video gaming at home, simply continuing to perform what they do at home may be neither rewarding nor specific enough to elicit movement changes and improvement in gaming ability. Thus therapists must be creative about how the games are used to target movement impairment and elicit motor learning during game play. Rules about how each UE will be used and challenges that progress difficulty of movement beyond speed and accuracy requirements of the game must be considered (e.g., adding wrist weights to promote UE strength, challenging balance by having children sit on a yoga ball while playing). Given these limitations, gaming should be viewed as complementary to, but not as a replacement for, salient task-oriented activities in the real world.

CONSIDERATIONS

It is important to note that an overwhelming majority of motor learning studies in both adults and children have been conducted in carefully controlled laboratory environments. This allows researchers to parcel out important factors that may relate to learning but has limitations in that we do not entirely know

what aspects of training transfer to the learning of functional complex tasks. Emphasis in adult motor learning has made use of technology to study center-out tasks or reaching perturbation studies, where subjects need to learn new movement gains. Such paradigms are useful for studying how subjects readapt learned patterns of movement under new conditions, but we do not know how they inform us about learning complex, skilled tasks, especially with the physical constraints present in pediatric patients.

Although training protocols have emphasized intensive practice, it should be noted that the practice of motor skills alone may undershoot the potential for rehabilitation, especially in developing infants. Four interrelated tenants have been suggested to broadly advance future abilities and meet early intervention goals of maximizing children's learning potential: (1) grounded perceptual-motor experiences within cultural/social contexts form cognition, (2) exploration through early behaviors facilitates development, (3) infants and children with limited exploration opportunities are at risk for global developmental impairments, and (4) early interventions targeting exploratory behaviors may be effective for advancing motor abilities. This rationale forms the basis for using mobility devices early during development.[82] Furthermore, through action observation and vigorous action experiences, infants gradually develop more complex action understanding capabilities.[75]

Finally, it should be emphasized that interventions need to be family centered. This approach recognizes that each family is unique, that the family is the constant in the child's life, and that family members are the experts on the child's abilities and needs.[125] Thus the family works in concert with professionals to make informed decisions about the treatments and supports the child and family receive. One such approach, Coping With and Caring for Infants with Special Needs (COPCA), a family-centered program, encourages family members in an equal partnership to discover their own strategies and to decide for themselves about priorities and interventions.[36]

SUMMARY

This chapter described a triad consisting of the person, the task, and the environmental context in which the child performs the task. We discussed this triad in relation to relevant motor learning principles derived from studies of adults and children, mostly without disabilities. This includes taxonomies of motor skills in relation to skill progression, types of knowledge gained during motor learning, different types and stages of learning, methods of instructions, feedback types and frequency, types of practice schedules, variability and specificity of training with whole and part practice, and the benefits of mental practice. We highlighted important differences in motor learning between children and adults. We discussed the implications of reduced information-processing capabilities and processing/memory in children and the implications for feedback and the type and amount of practice, where we showed that skill emerges over enormous amounts of practice and extensive time periods. We demonstrated that although there are certainly many similarities, the way children learn may differ from the way adults learn. More research is required to parcel out these differences.

In the context of rehabilitation, we showed that unlike in adults, learning in children must occur in the context of development, whereby age-appropriate skills are learned for the first time. We showed that intensity of training matters; provided models of intensive, task-oriented approaches such as constraint-induced movement therapy and bimanual training; and discussed how tasks and the environment as part of the triad can be used to optimize learning. We showed the importance of training specificity and provided important clues from the neuroscience literature on how to take advantage of and maximize neuroplasticity. In particular, we showed that neuroplasticity is enhanced when the tasks are meaningful to the performer. Finally we provided an example of a salient task—playing video games targeting specific motor impairments. We discussed the limitations of existing knowledge and projected where pediatric rehabilitation research needs to be directed to fully incorporate motor learning into practice.

Motor learning approaches were slow to gain popularity in pediatric rehabilitation, though there is now considerable evidence supporting their efficacy. Although therapists may be implicitly applying motor learning principles in their treatment protocols, explicit application of these principles is required to determine if this approach is effective. A challenge in coming years to therapists who work with children will be to determine how the principles of motor learning described in this chapter may or may not differ from results of studies performed in adults and void these characteristics. Although intensity of training is one variable that surely will be an important factor in future task-oriented approaches, determining the key intervention ingredients to include in planning intensity will be all the more important.[134]

Musculoskeletal Development and Adaptation

Linda Pax Lowes, Krystal Hay

Pediatric physical therapists routinely work with children whose clinical conditions influence the growth and development of the musculoskeletal system, either directly or indirectly. The musculoskeletal system demonstrates a remarkable ability to adapt to the physical demands, or lack of physical demands, placed on the system. Pathologic conditions may adversely influence the structure and function of any component of the system and may lead to impairments. For example, bone abnormalities due to congenital deformities, disease processes, or abnormal growth can disrupt the normal length/tension relationship of the muscle and result in weakness. Likewise, muscle pathology, such as Duchenne muscular dystrophy (DMD), often leads to secondary adaptations and impairments such as joint contractures. The normal process of adaptation can either enhance function or lead to impairment, activity restriction, and participation limitation.

The musculoskeletal system and the neurologic system are also intertwined. A neurologic insult such as cerebral palsy (CP) frequently leads to muscle contractures and weakness. See Chapter 19 for a complete discussion of cerebral palsy. Neurologic impairments such abnormal neural maturation, insufficient and disorganized motor recruitment, impaired voluntary control, impaired reciprocal inhibition, altered setting of muscle spindles, and reinforcement of abnormal neural circuits[105] can contribute to weakness in individuals with cerebral palsy. In addition to neurologic changes, individuals with cerebral palsy can present with altered muscle tissue and abnormal bone growth. Over time, there is selective atrophy of fast fibers and altered myosin expression, changes in fiber length and cross-sectional area, changes in the length-tension curve, reduced elasticity, and impoverished muscle tissue development.[105] Once considered an isolated neurologic impairment, cerebral palsy is now viewed as a multisystem disease.

Conversely, when a person with an intact nervous system is immobilized in a cast for a musculoskeletal injury such a fracture, the timing and sequencing of muscle activation can change following cast removal due to a newly acquired range-of-motion limitation. Therapeutic interventions are often designed to promote musculoskeletal adaptations in an effort to prevent or correct physical impairments with the hope of enhancing function and participation in daily life activities. Accordingly, knowledge of normal growth and development and of the principles of adaptation of the musculoskeletal system is essential for understanding the efficacy of interventions. This chapter describes (1) the growth and development of muscle and bone and (2) the adaptations of muscle and bone, including the effects of select interventions designed to promote desired adaptations.

MUSCLE HISTOLOGY AND DEVELOPMENT

In the developing vertebrate embryo, two masses of mesoderm cells, called somites, form along the sides of the neural tube. Somites eventually differentiate into dermis (dermatome), skeletal muscle (myotome), and vertebrae (sclerotome). Because the sclerotome differentiates before the other two structures, the term *dermomyotome* refers to the combined dermatome and myotome. Progenitor cells (cells with the ability to differentiate into many types of cells) migrate from the dorsal medial lip of the dermomyotome and differentiate to form primary or secondary myotubes.[9] The primary myotubes are first observed at approximately 5 to 7 weeks' gestational age (GA), and most will eventually differentiate into type I (slow-twitch slow-oxidative) fibers. The three types of fast-twitch fibers (fast-twitch oxidative glycolytic [2A], fast-twitch glycolytic fibers (2B), and fast-twitch intermediate [2X]) primarily develop from the secondary myotubes and are observed at about 30 weeks of gestation.[131] The myofibers are long, cylindrical, multinucleated cells composed of actin and myosin myofibrils repeated as a sarcomere, the basic functional unit of the cell, which is responsible for the striated appearance of skeletal muscle.

A motor unit, consisting of a motoneuron and the muscle fibers it innervates, begins with the development of the neuromuscular junction. The primary myotubes are preferentially innervated first. By 8 weeks of gestation, acetylcholine receptors are dispersed within the myotubular membrane.[63] At this stage in development, multiple motor axons originating from different somites (precursor cells) innervate the developing end plates. These early motor units provide the earliest fetal movement, which is observed in the intercostal muscles. From 18 weeks' GA until several months post term, synaptic elimination occurs until each neuromuscular junction is innervated by only one axon.[30] Synaptic elimination occurs in both the central and peripheral nervous systems and is believed to be influenced by activity.[30] The adult pattern of one axon per muscle fiber permits a reproducible and predictable increase in force during performance of a task. Why fetal muscles are innervated initially by several axons and later undergo the elimination of all but one axon is not well established. It does not appear that the reason is to ensure that every muscle fiber is innervated. In partially denervated muscles of animals, the few remaining muscle fibers still undergo synaptic elimination, thus further reducing the size of the motor unit.[46]

During the last half of gestational growth, the number and size of muscle fibers increase so rapidly that most of the skeletal muscle fibers have developed by birth. This suggests that infants born very prematurely have different muscles from full-term babies. This is also supported by a cohort study that showed that

there was a strong correlation between birth weight and adult strength, with other confounding variables accounted for.[83] By the end of the first year of life, the remaining muscle fibers are developed. From this point, new muscle fibers originate from either the division of existing cells or the differentiation of myoblasts into secondary myotubes.[106] During the growing years, muscles increase in length and cross-sectional area through the addition of sarcomeres within individual muscle fibers.[106] Their final size depends on many factors, including blood supply, innervation, nutrition, gender, genetics, and exercise.

The bulk associated with a mature muscle comes from the many multinucleated fibers. Next to these fibers, however, are quiescent satellite cells. Satellite cells are mononucleated, myogenic cells that proliferate in response to stress or injury to aid in muscle regeneration. The satellite cells themselves have the ability to regenerate after restoration of the damaged muscle fibers. In diseases such as DMD, the rate of muscle degeneration greatly exceeds the rate at which the satellite cells can repair tissue and regenerate themselves. This imbalance exhausts the supply of satellite cells, and muscle fibers can no longer be regenerated leading to progressive weakness.[73]

Structure and Function of the Normal Muscle-Tendon Unit

The normal muscle-tendon unit (MTU) is composed of muscle fibers, two cytoskeletal systems within the muscle fibers (exosarcomeric and endosarcomeric), the supportive connective tissues within and around the muscle belly (endomysium, perimysium, and epimysium), and the dense regular connective tissue of the tendon that connects the muscle to the bone. Total muscle force production achieved by an MTU is influenced by many factors, including the size of the muscle fibers, the firing rate of the motor unit action potentials, recruitment and de-recruitment patterns, muscle architecture, the angle of pull, the lever arm, and changes in the length of the muscle. The membrane at the muscle-tendon junction typically has a folded appearance that is thought to reduce membrane stress. With disuse atrophy the amount of folding is decreased and therefore under greater stress. This change is likely why atrophied muscles sustain increased tears.[131]

A passive length-tension curve is developed on the basis of muscle tension that is produced as the muscle is stretched from its resting length to its maximal length. The initial take-up part of the curve (left part of the curve) represents the resting length, and the end point of the curve (right part of the curve) represents the maximal length (Fig. 5.1). The force produced by the active component depends primarily on the amount of overlap of the actin and myosin filaments. The maximum isometric force is produced near the resting length (due to the optimal overlap of the actin and myosin filaments) of an isolated muscle; it decreases as the muscle is lengthened or shortened relative to the resting length. This force-length relationship forms the basis of the sliding filament theory of muscle contraction.[172] The force generated by the active component of the MTU also depends on the integrity of the central and peripheral nervous systems, the excitation-contraction coupling mechanism, and the cross-sectional area of the skeletal muscle tissues. In a completely relaxed skeletal muscle (i.e., when the central nervous system [CNS] is not intact or when no artificial stimulation occurs), no active tension exists.

Passive resistance, which is the equivalent of resting muscle tone, increases exponentially as the muscle is lengthened. When a resting muscle is passively stretched, the force produced by the passive component of the MTU is thought to be brought about by three mechanisms: (1) stretching stable cross-links between the actin and myosin filaments, (2) stretching proteins within the exosarcomeric and endosarcomeric cytoskeleton (series elastic component), and (3) deformation of the connective tissues of the muscle (parallel elastic component). The passive component accounts for the resistance felt during passive stretch of a fully relaxed muscle. Intracellular and extracellular components are now thought to contribute to passive stiffness. Numerous proteins are believed to play a role in muscle stiffness, but the exact mechanism is unknown.[97,131]

In contrast, tendons, which are made up of dense regular connective tissue, are generally considered noncontributory to the overall passive length-tension relationships of the stretched MTU. Dense regular connective tissues present exceedingly high stiffness and therefore are unlikely to stretch. Passive stiffness can be represented by the ratio of the change in passive torque to the change in the joint angle.

An intermediate-sized protein of the exosarcomeric cytoskeleton known as *desmin* is thought to help reduce passive muscle stiffness. Desmin is the major subunit of the intermediate protein filaments forming the Z-discs. Desmin connects the Z-discs with many cell organelles and also extends longitudinally from Z-disc to Z-disc outside the sarcomere.[172] Because of this longitudinal orientation, desmin lengthens as the sarcomere is stretched. In animal studies, when desmin is removed, the muscle becomes increasingly fibrotic and passive stiffness increases dramatically.[102] Many proteins are present in a sarcomere, other than those discussed here. The absence of or pathology of the sarcomere proteins is responsible for many of the muscular dystrophies.[157]

Adaptations of Muscle Fibers

Muscle fiber types are susceptible to both internal and external influences. In normal muscle, fiber types are randomly distributed to form a mosaic pattern, and little variation in fiber size is noted. In the presence of disease, this pattern is altered and

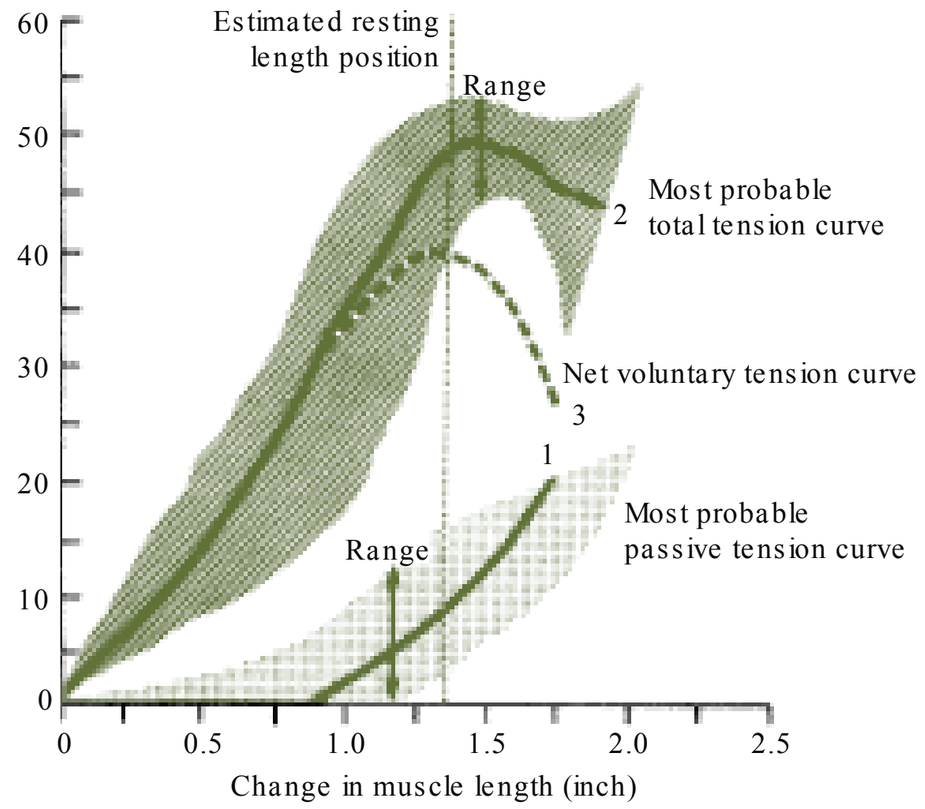

FIG. 5.1 Classic length-tension curves for skeletal muscle. Net voluntary active tension is predicted by subtracting passive tension from total tension. (From Astrand P, Rodahl K, Dahl HA, et al: Textbook of work physiology, ed 4, Champaign, IL, 2003, Human Kinetics.)

often well documented in adults. Evaluating muscle composition in children, however, is difficult because, unless the sample can be obtained as an adjunct to a surgery, elective biopsy is required. This usually results in small sample sizes, which likely are a cause of the lack of consensus among reports. With this limitation in mind, the following information is presented.

Spasticity is a common impairment seen by physical therapists. Previously, this excessive stiffness was thought to be attributable almost exclusively to a hyperactive stretch reflex. A wider focus is now the current thinking and includes (1) altered muscle fiber size and fiber type distribution, (2) proliferation of extracellular matrix, (3) increased muscle cell, and (4) inferior mechanical properties of extracellular material.[48]

The deep fascicle angle (angle at which fascicles arise from a deep aponeurosis) is also related to stiffness. It is generally believed that the fascicle length of the gastrocnemii and rectus femoris muscles is reduced in CP compared with age-matched peers, but the data are somewhat ambiguous.[98,107,137] It is hypothesized that this angulation contributes to muscle shortening.

Muscle histopathology reports can be inconsistent for children with CP (most likely due to small sample sizes), but researchers agree that spastic muscles vary considerably from typical muscles.[48,50,114,123,138,139] One consistent theme that arises from spastic muscle reports is that the muscles are overall smaller than typically developing peers.[57] In an animal model of young, hypertonic mouse muscles, longitudinal muscle growth has been shown to increase in length at only 55% of the rate of growing bone in contrast to the expected 100%.[180] To keep up with growing bone, the sarcomeres of the spastic muscle stretch to increase to the necessary length. It is generally agreed that this is an important contribution to the muscle weakness and contracture seen in children with cerebral palsy. The reduced growth rate leads to a lower than expected number of in-series sarcomeres and subsequent overstretched length of each individual sarcomere.[98] This shifts the muscle well past the optimal length/tension relationship resulting in a greatly reduced ability to generate force. Longer sarcomeres were also correlated with greater joint contracture. Longer sarcomeres also indicate that there is increased sarcomere strain, resulting in skeletal muscle injury. In turn, repeated strain-induced injuries drastically increase collagen content and fibrosis in skeletal muscle, which will increase stiffness.[140,161] This is an important consideration when intervening to correct a plantar flexion contracture. While lengthening the muscle through a serial casting, the practitioner must be cognizant of the possibility that he or she may be stretching the sarcomeres to an even greater mechanical disadvantage that could result in increased weakness.[98] The pathologic changes in muscle in children with CP also should be considered when contemplating an Achilles tendon lengthening. In many children with CP, the tendon is already longer and the gastrocnemius muscle shorter than in typically developing children.[177] A tendon lengthening will increase the child's range of motion but may decrease the amount of force the child can generate, because the muscles are placed at a decreased mechanical advantage.[177]

Varying degrees of atrophy and hypertrophy of type I and type II fibers have been reported and appear to be dependent on muscle group, severity of CP, and age of the child.[24,48,50,88,123] Moreau and colleagues[107] reported decreased cross-sectional area, muscle thickness, and fascicle length in children with CP compared with typically developing children. Booth[17] found excessive amounts of collagen and fibrous tissue in older children with CP. The author suggested that collagen and fibrous tissues are irreversible detriments to muscle performance.[17] It is not known whether this is a preventable change.

The clinical application of muscle histology could be enhanced by additional research. One example is the finding by Rose and colleagues[127] that children with spastic diplegia who had a predominance of type I fibers expended more energy and had more prolonged electromyograph (EMG) activity during walking than children with CP and a predominance of type II fibers. There is some evidence that targeted training programs can alter fiber type composition in adults.[37,43,70] Research in children is needed to determine if we could change the muscle composition of our patients and if this would translate to improved function.

FORCE AND LENGTH ADAPTATIONS IN THE MUSCLE-TENDON UNIT

Researchers have used length-tension curves to provide information about histologic and histochemical changes in muscles related to length and stiffness. After intervention, the position and steepness of the curve may change, indicating a change in muscle length or stiffness. For example, a shift of the curve to the left indicates a shorter muscle, and a shift to the right indicates a longer muscle. A steeper curve indicates that the muscle is less compliant (stiffer).

Studies have shown that even short-term casted immobilization can create significant losses in quadriceps strength and cross-sectional area.[41,164] Less than 1 week of immobilization led to a 3.5% to 10% reduction in size and a 9% to 13% strength reduction.[41,148] This was increased to an 8% to 20% decrease in size and a 20% to 23% reduction in strength after 14 days.[148,164] Immobilization for as little as 2 to 3 weeks has been reported to reduce muscle strength by 10% to 47%.[65,111] After 2 weeks of spontaneous activity, an 11% strength deficit was still noted.[65] Similar to casting, bed rest for 28 days or more also consistently shows reduced muscle strength and size.[14]

Although changes in immobilized muscle strength and resting length have been attributed to loss of sarcomeres, changes in passive stiffness following immobilization have been attributed to changes in the connective tissues.[54,173] Early in shortened-position immobilization, an increase in the concentration of hydroxyproline occurs in relation to the total volume of the muscle, indicating an increase in connective tissue. Reorganization of the collagen fibers of the perimysium into more acute angles to the muscle fiber axis was also seen.[71] This resulted in greater tension per unit of passive elongation, otherwise known as increased stiffness. The passive length-tension curves were shifted to the left and appeared steeper, indicating that the muscles were shorter and stiffer after immobilization in the shortened position (Fig. 5.2).

Conversely, animal research suggests that immobilization of muscles in lengthened positions can cause an increase in the number of sarcomeres and therefore in muscle length.[153] However, in animals, the number of sarcomeres will revert to the original number in 4 weeks.[153] The addition of sarcomeres was accompanied by muscle weight gain and increased protein synthesis after immobilization.[142] Similar to immobilization in a shortened position, the change in sarcomeres predominantly occurs at the ends of the muscle fibers, which appear to be the most responsive area, as most of the normal postnatal growth

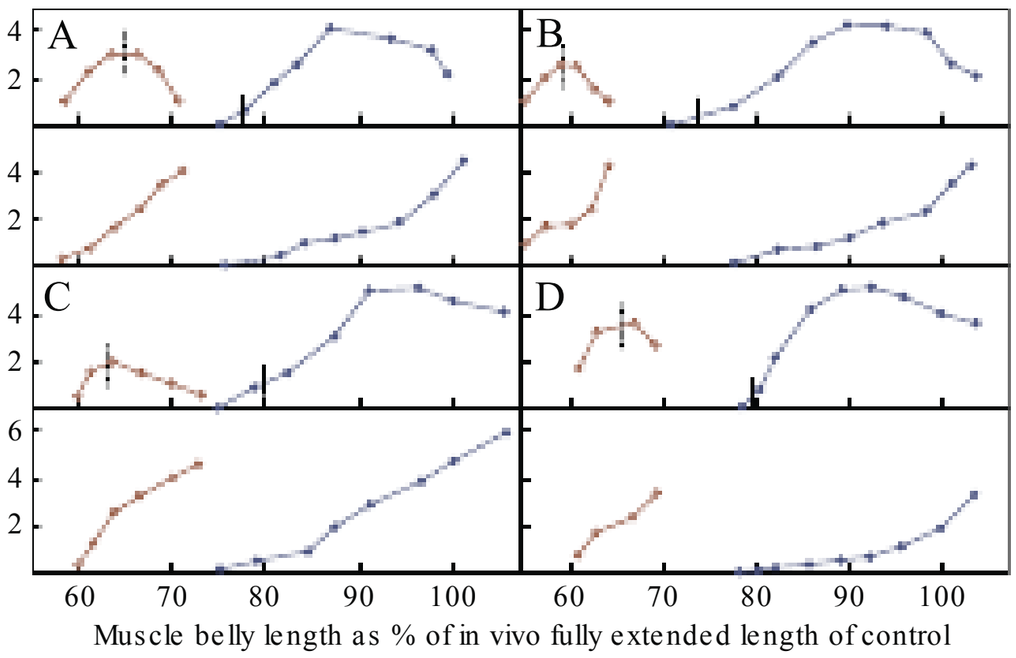

FIG. 5.2 Length-tension curves for young muscles (A to D) immobilized in the shortened position (red) and their controls (blue). (From Williams PE, Goldspink G: Changes in sarcomere length and physiologic properties in immobilized muscle. J Anat 127(Pt 3): 459–468, 1978.)

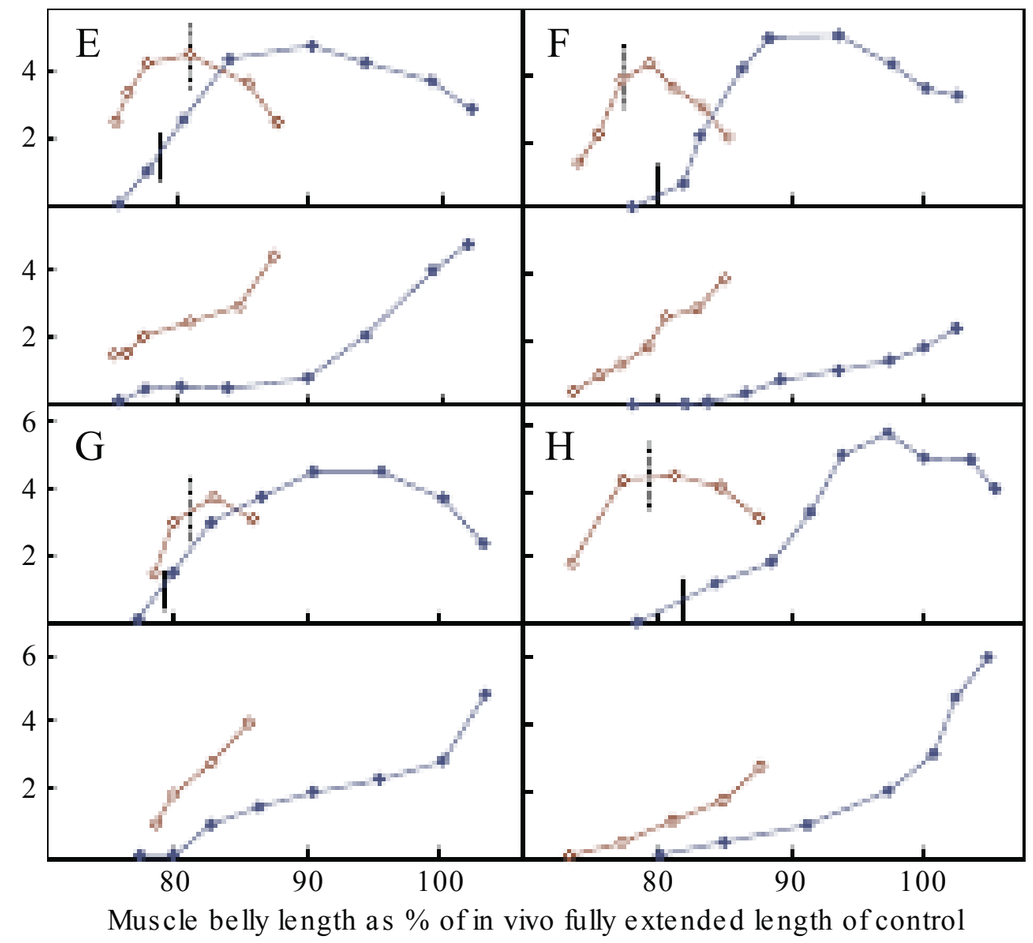

FIG. 5.3 Length-tension curves for young animals (E to H) immobilized in the lengthened position (red) and their controls (blue). (From Williams PE, Goldspink G: Changes in sarcomere length and physiologic properties in immobilized muscle, J Anat 127(Pt 3): 459–468, 1978.)

of young animals occurs here.[174] As with muscles immobilized in the shortened position, the sarcomere length adapts to maintain optimal actin and myosin overlap. Overall, animal research suggests that immobilization in a shortened position has a more profound change in sarcomeres (40% loss) than immobilization in the lengthened position (19% increase).[153]

Active and passive length-tension curves for adult muscles that were immobilized in a lengthened position were shifted to the right (indicating that they were lengthened) compared with those of adult controls (i.e., nonimmobilized muscle).[173] In young mice, however, muscles immobilized in the shortened or lengthened position resulted in an overall decreased muscle length, with a concomitant increase in tendon length.[173] This caused a shift in the length tension curve to the left, indicating a decline in strength[173] (Fig. 5.3). Evidence suggests that a tendon elongates more readily in young, growing animals than in adult animals. Although this work was performed in animals, it should still be considered when casting to increase range of motion (ROM).

Botulinum toxin (BoNT-A) injections inhibit the release of acetylcholine at the neuromuscular junction, which results in an immobilized portion of the treated muscle.[108] The affected nerve terminals do not degenerate, but the blockage of neurotransmitter release is irreversible. Similar to physical immobilization, this chemical immobilization leads to increased sarcomere length and decreased force production.[156] Initial muscle tissue recovery from a toxin such as BoNT-A is achieved by collateral sprouting from nerve terminals. Sprouting reaches a peak around 8 to 12 weeks post injection. After this time the original function of the neuromotor junction returns and synaptic elimination of excessive neurons begins. This process is similar to the synaptic elimination seen in postnatal development. In animals, the rate of synaptic elimination is dependent on the amount of use the muscle receives.[32] If human muscle responds similarly, this may explain why the addition of BoNT-A to serial casting frequently does not improve outcome.[75]

Skeletal and Articular Structures

Like muscle tissue, both skeletal and articular tissues arise from the mesodermal layer of the embryo (Fig. 5.4). Mesenchymal cells condense to form templates of the skeleton. From this point, two distinct processes of bone formation take place: (1) endochondral ossification and (2) intramembranous ossification. All bones, with the exception of the clavicle, mandible, and skull, are formed by endochondral ossification (also called intracartilaginous ossification).[106] During the early embryonic period, collagenous and elastic fibers are deposited on the mesenchymal models and form cartilaginous models. Bone minerals are deposited on these new models and gradually replace the cartilage via the process of ossification. Intramembranous ossification occurs directly in the mesenchymal model. Mesenchymal cells differentiate into osteoblasts that deposit a matrix called osteoid tissue. This tissue is organized into bone as calcium phosphate is deposited.[124] Ossification at the primary ossification centers, typically in the center of the diaphysis or body of the bone, commences at the end of the embryonic period (eighth fetal week).[106]

Bone development progresses most rapidly in the prenatal period. By the time of birth, the diaphyses are almost ossified. If a child is born prematurely, however, osteopenia is frequently seen. In the very premature, it may result in bone fragility and must be considered if therapy is being provided to the very young neonate. After birth, long bones grow in length at the epiphyseal plate, which is between the diaphysis and the epiphysis. This cartilaginous plate rapidly proliferates on the diaphyseal side of the bone. The resultant chondrocytes, arranged in parallel columns, become enlarged and are then converted into bone by endochondral ossification.[124] Eventually, the epiphyseal plate is ossified, the diaphyses and epiphyses are joined, and the growth of the bone in length is considered complete. The timing of complete ossification varies with each particular bone. Most bones are fully ossified by 20 years of age, but for a few bones, the process can continue longer into adulthood.[106]

Bone is increased in width through appositional growth, which is the accumulation of new bone on bone surfaces. To keep the bone from becoming too thick and therefore too

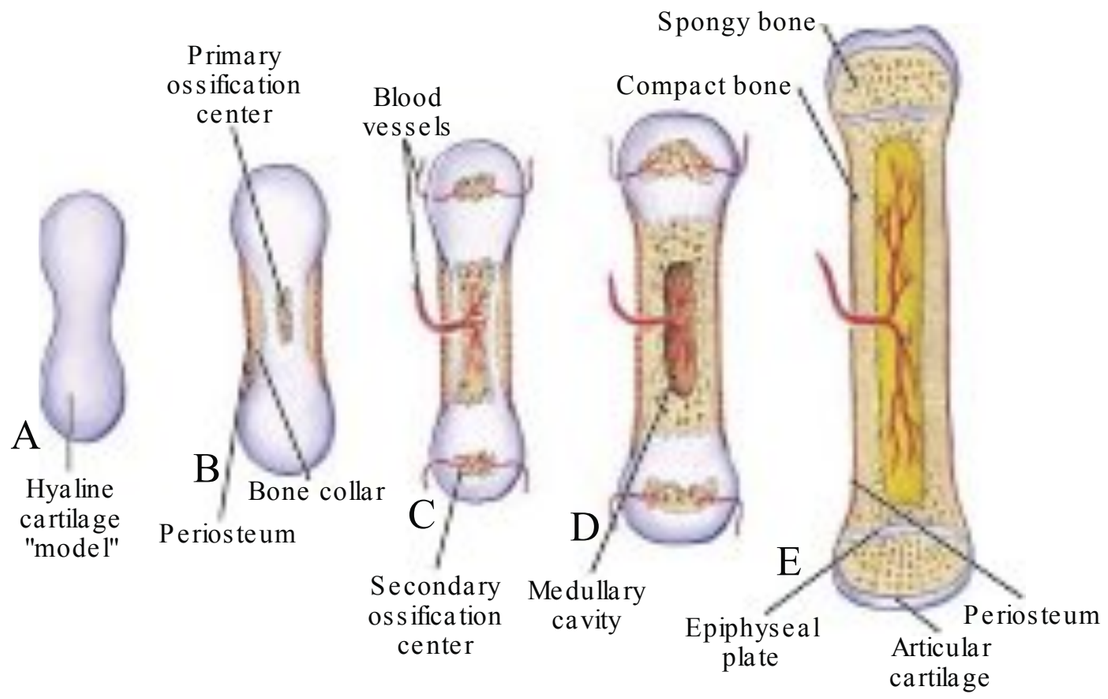

FIG. 5.4 Schematic diagram of progression of bone growth. (From Applegate E: The anatomy and physiology learning system, ed 4, St. Louis, 2011, Saunders.)

heavy, osteoblasts on the inside of the bone are reabsorbed as new bone is added on the surface. This results in an increase in thickness and density of the diaphysis without excess weight.

Joint formation also begins as the cartilaginous models are formed. In a specialized area between cartilaginous bone models, the interzonal mesenchyme differentiates to form the joint. The basic structures of the joint are formed during the sixth to seventh weeks of gestation, but the final shape develops throughout early childhood under the influence of the forces of movement and compression.[106] One example of the relationship between joint formation and movement is seen in children with brachial plexus injuries. Pearl and colleagues[117] examined 84 children between the ages of 7 months and 13½ years who had obstetric brachial plexus palsy that resulted in medial rotation contractures of the shoulder. Sixty-one percent had extreme glenohumeral deformities, including flat glenoids, biconcave glenoids, pseudoglenoids, and flattened, oval humeral heads. The mechanical forces created by the unopposed medial rotators had a profound effect on the development of this joint.

Hip joint development is another good example of changes during the fetal period. At 12 weeks of GA, the acetabulum is extremely deep, and the head of the femur is quite round and well covered (Fig. 5.5).[121] As the fetus increases in age, the relative depth of the acetabulum decreases as the head of the femur becomes more hemispheric. At birth, the acetabulum is so shallow that it covers less than half of the femoral head; this results in a relatively unstable hip and is thought to allow for easier passage through the vaginal canal. Because of the combination of shallow acetabulum, flattened femoral head, high neck shaft angle, and a large amount of anteversion, the hip is especially vulnerable to dislocating forces during the third trimester.[121] The risk of dislocation is greatest if the child is delivered in single-breech position (i.e., hips flexed and knees extended).[150] It was postulated that extreme hip flexion combined with knee extension caused the hamstrings to pull the head of the femur downward, stretching the compliant hip capsule. After birth, the femur may be dislocated by the upward pull of the iliopsoas muscle when infants are diapered and wrapped with the hips extended.[150]

During postnatal growth, the forces of compression and movement contribute to an increase in the depth of the acetabulum until the age of 10 years, when the adult level of femoral head coverage is reached.[8] The head of the femur also becomes

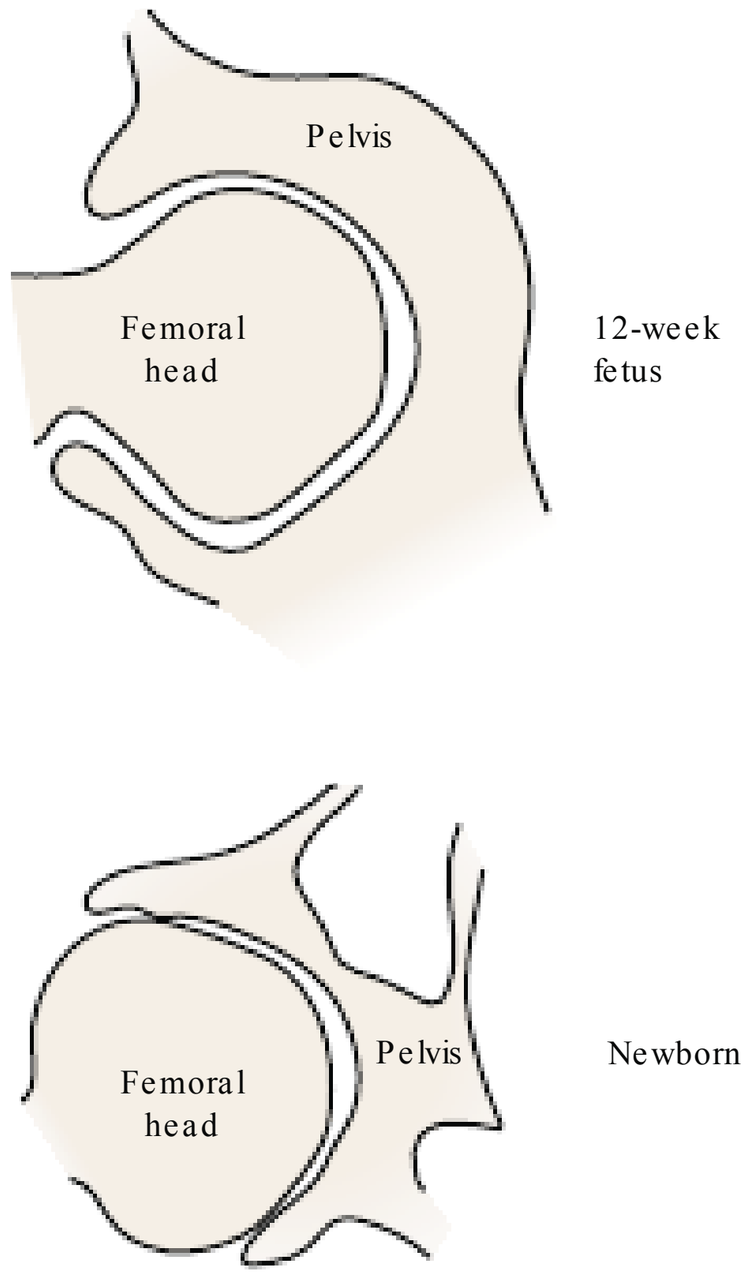

FIG. 5.5 Schematic diagram of the fetal and newborn hip joint, illustrating changes in acetabular coverage of the femoral head. Coverage is extensive in the 12-week fetus, but it is reduced in the newborn.

rounder, but it never achieves the roundness that it had during the early fetal period. A listing of reference values for changing range of motion from birth through 5 years of age can be found in Table 5.1.

Skeletal Adaptations

Although deformities can occur throughout the growing period, the skeleton is most vulnerable during the first few years of life (prenatal and postnatal), when the rate of growth is greatest.[22] Fetal position has been related to various deformities, especially

TABLE 5.1 Central Tendency Values of Lower Extremity Range of Motion Reported in Degrees for Children Born Full Term, From Birth Through 5 Years Old

	Birth	6 Weeks	6 Months	1 Year	3 Years	5 Years

those that occur toward the end of pregnancy when the neonate is outgrowing the space in utero. Factors that can increase the risk of prenatal deformities include decreased amniotic fluid, which further limits the space in which the fetus can move, multiple births, and excessive forces from tightly stretched uterine and abdominal walls. Associated deformities include congenital torticollis, plagiocephaly (asymmetrical head), and developmental dysplasia of the hip.[39,84]

After initial development, bone shape can be changed through a process of bone functional adaption, which uses resorption of old or immature bone and formation of new bone to determine its shape. Bone structure adapts in response to the mechanical forces that are placed on the bones.[129] The type of loading and stress (or force per bone area) in different situations affects bones differently.

Loading a bone longitudinally (parallel to the direction of growth) results in compression or tension. Either type of loading, applied intermittently with appropriate force, such as with weight bearing or muscle pull, stimulates bone growth. The *Hueter-Volkmann principle* describes the reaction of bone to excessive force and states that excessive static loading will cause bone material to decrease, which can be detrimental to bone integrity and strength.[124]

Shear forces, which run parallel to the epiphyseal plate, can lead to torsional or twisting changes in the bone. The columns of chondrocytes around the periphery of the plate veer away from the shear forces in a twisting pattern. The normal pull of muscles around a joint contributes to the shear forces, resulting in normal torsional changes in the long bones. For example, at birth, the tibia exhibits 0° to 5° of medial torsion but increases to around 25° of lateral torsion by adulthood.[87]

Just as normal forces shape bones, asymmetrical forces will lead to asymmetrical growth as the growth plates line up perpendicular to the direction of the forces. This can be advantageous during fracture healing, as the bone is able to straighten some degree of malalignment through a process known as *flexure drift*. This remodeling mechanism describes a process whereby strain on a curved bone wall applied by repeated loading tends to move the bone surface in the direction of the concavity to straighten the bone.[87] Bone is resorbed from the convex side and is laid down on the concave side. This process is seen in the femur and tibia as a normal part of development of the position of the knee in the frontal plane. At birth, the infant's knees are bowlegged (genu varum), but they gradually straighten until they reach a neutral alignment between the first and second years. The knee angulation then progresses toward genu valgum, reaching its peak between the ages of 2 and 4 years. After this time, the angle of genu valgum gradually decreases (Fig. 5.6).[130] The final knee angle differs slightly according to race and gender.[2,20] Typical values vary by author, but in general, by adolescence, Caucasian girls have a tibial angle of between 0° and 5.8° of valgus, and boys range from 5° of valgus to 5° of varus.[20,61] In contrast, Cheng and associates[28] found that Chinese children of both genders progressed to genu varus of less than 5° in the preteen years. The pediatric therapist should be aware that the presence of genu varus between the ages of 2 and 6 years may need a referral to an orthopedic specialist. Artificially applied asymmetrical compression of one epiphyseal plate of the proximal tibia by surgical stapling or a tension band can be used to correct these deformities.[72] For children with leg length differences, surgical staples are applied to both sides of the epiphyseal plate of the longer leg to slow its growth until the shorter leg catches up.[51] The Ilizarov and monolateral devices for limb lengthening use tension to facilitate bone growth.[51] With this technique, the diaphyseal cortex of the bone of the shorter leg is cut, and gradual incremental distraction is applied across the cut ends of the bone. Osteogenesis occurs in the space between the two ends of the cut bone.

Normal developmental changes in the femur illustrate the impact of the muscular system on bone. To understand these changes, the terms *version* and *torsion* require discussion. Torsion refers to the normal amount of twist present in a long bone (Fig. 5.7). Femoral torsion is the angle formed by an axis drawn along the head and neck of the femur and another through the femoral condyles. To visualize this angle, picture a femur with the posterior surfaces of the femoral condyles on a horizontal surface such as a table. When looking up toward the hip, you will notice that the head and neck of the femur are angled upward from the table approximately 15°. This is the angle of torsion.

Antetorsion occurs when the head and neck of the femur are rotated forward in the transverse plane relative to the femoral condyles. If the head and neck of the femur are rotated posteriorly, the femur is said to be in retrotorsion. At birth, the femur has its maximum antetorsion at approximately 30° to 40°.[143] This angle decreases rapidly during the infant's first year, more slowly between 1 and 8 years, and then rapidly again through adolescence to a mean of 16° by age 14 to 16 years.[143] The femur is said to "untwist" through the process of growth, muscle action, reduction of the coxa valga angle, and reduction of the hip flexion contracture. The femoral head, neck, and greater trochanteric areas are made of pliable cartilage and are attached to the rigid osseous diaphysis. As the infant develops, normal torsional forces about this point of fixation cause a decrease in femoral antetorsion. Bleck[12] speculated that the active external hip rotation and extension forces created during walking have a major impact on developmental changes in femoral antetorsion. If active hip motions are minimal or walking is delayed, as

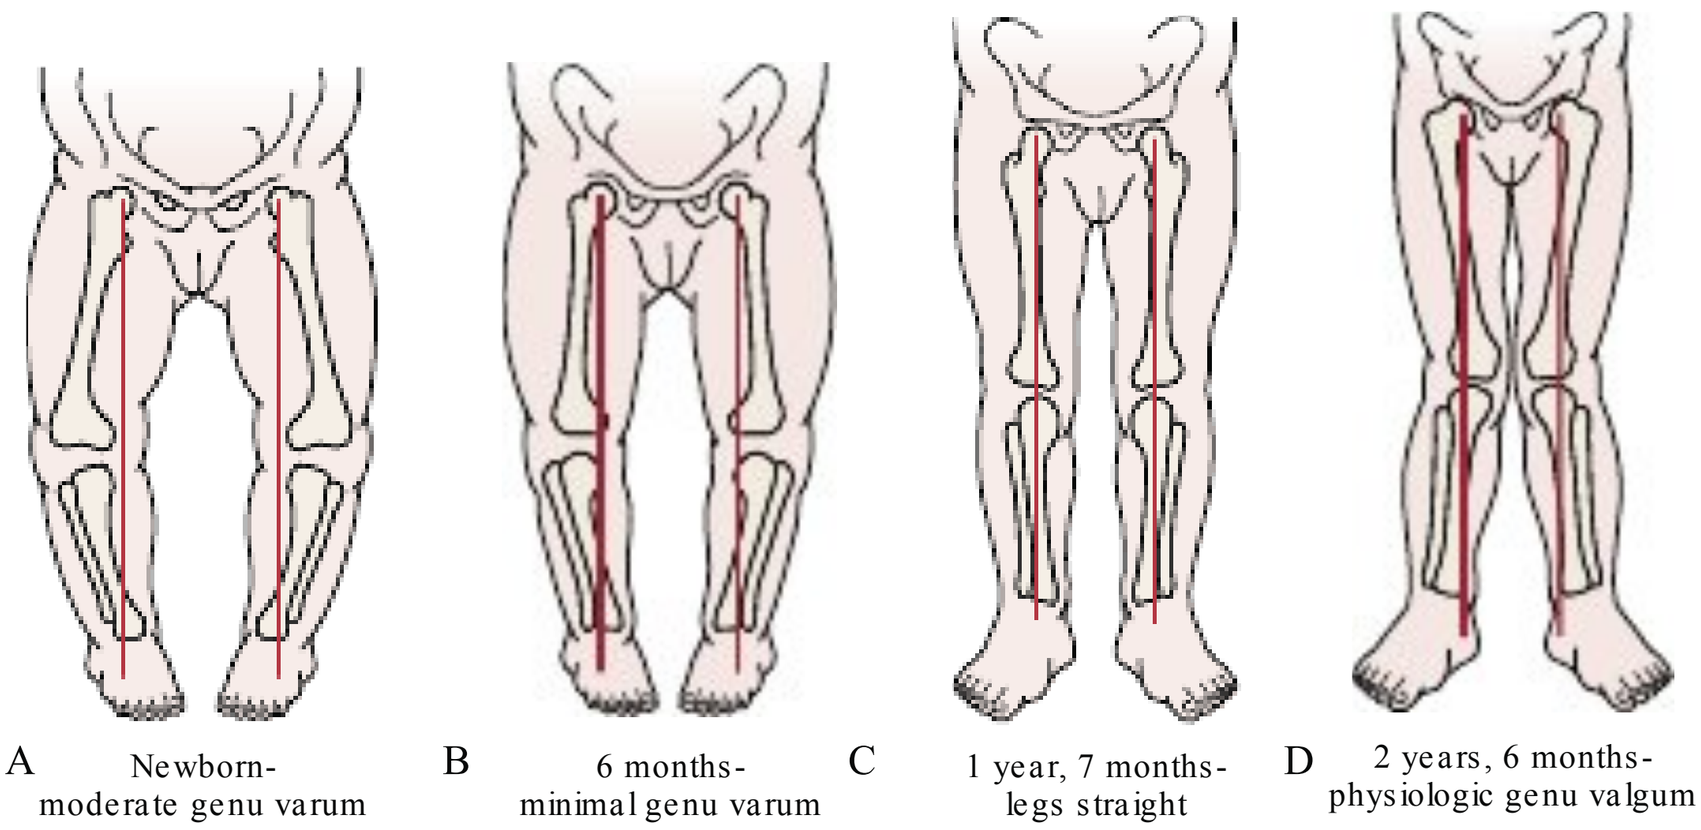

FIG. 5.6 A-D, Physiologic evolution of lower limb alignment at various ages in infancy and childhood. E and F, Alignment differences between teenage female (E) and teenage male (F). (A-D, Redrawn from Herring JA: Tachdjian's pediatric orthopaedics: from the Texas Scottish Rite Hospital for Children Tachdjian's pediatric orthopaedics, ed 5, Philadelphia, 2014, Saunders. E and F, Redrawn from Griffin LY: Rehabilitation of the injured knee, ed 2, St. Louis, 1995, Mosby.)

is frequently observed in children with CP, the infantile femoral torsion does not decrease as it should.

Version refers to a position of a segment relative to a plane. Femoral version refers to the position of the head of the femur in the acetabulum (see Fig. 5.7). When the pelvis is visualized in supine, the angle that the head and shaft create relative to the back of the pelvis aligned on the frontal plane is the amount of version. Anteversion positions the head of the femur anteriorly in the acetabulum and results in a position of thigh external rotation. Conversely, retroversion positions the head of the femur posteriorly in the acetabulum, which results in thigh internal rotation. At birth, a neonate has 40° to 60° of anteversion. This gradually resolves over time to 15° to 20° by age 8 to 10 years and down to 12° in adulthood. The externally rotated posture seen in newborns is attributed to the high amount of anteversion. At birth, anteversion (60°) is greater than antetorsion (30°) with a net result of an externally rotated posture.[165]

Excessive or persistent fetal antetorsion can lead to an in-toed gait pattern. In-toeing becomes apparent as the amount of hip external rotation decreases with age. A majority of otherwise healthy children with persistent fetal antetorsion will improve as the hips spontaneously realign by age 10 years. In less than 1% of these children, antetorsion fails to resolve by age 10 years, and the children warrant treatment.[143] In children with CP, however, persistent fetal antetorsion is a causative factor in the development of hip instability. This is discussed in greater detail later in the chapter.

Atypical pressures, such as those seen in children with obesity or spasticity, can deform the femur and component parts of the hip. Children with obesity are at increased risk of developing a flattened femoral head and a slipped capital epiphysis because of the excessive weight on the developing femoral head.[30] Children with spasticity are at risk for subluxation or dislocation from the asymmetrical pull of spastic muscles around the hip.[179] Buckley and colleagues[19] examined 33 unstable hips in children with these disabilities and found that all had significantly shallower acetabula compared with those of a control group; the hip was most shallow in children with CP.

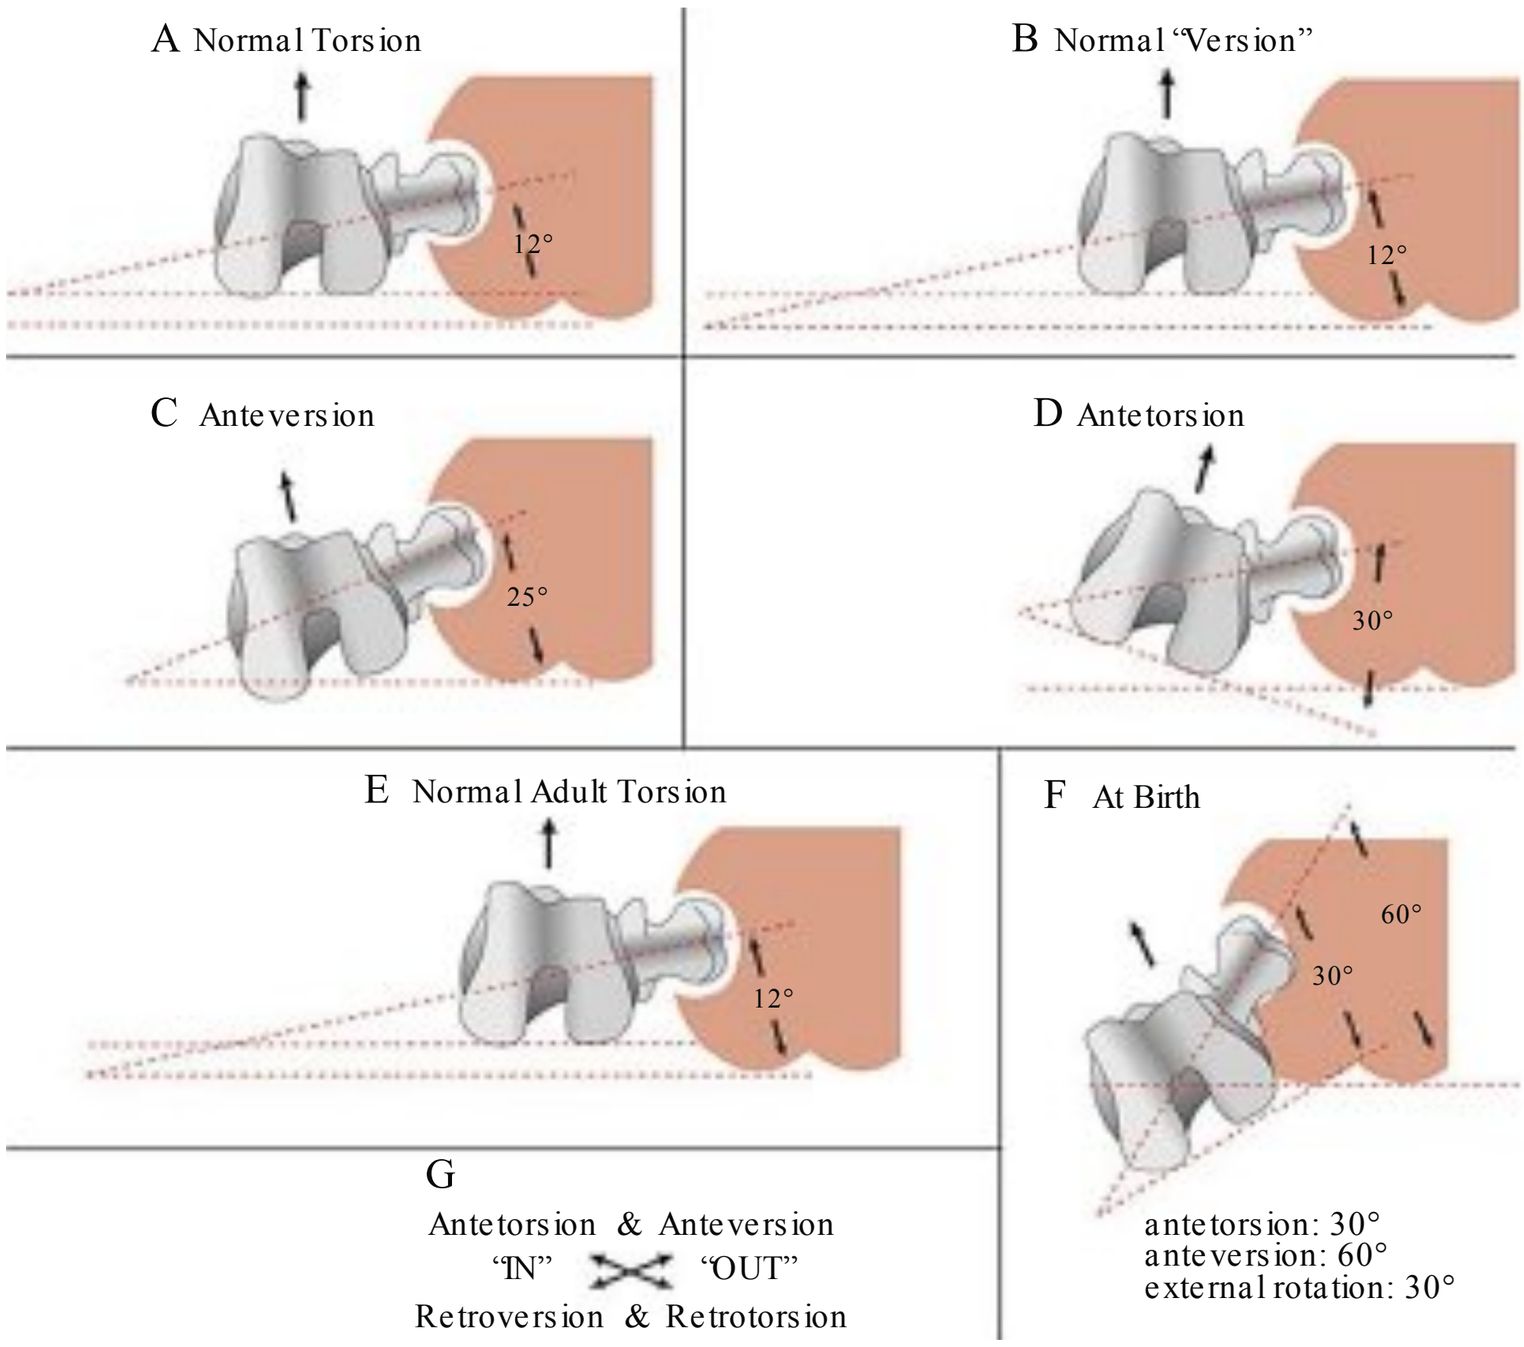

FIG. 5.7 Schematic drawing illustrating femoral version and torsion. (From Effgen, SK: Meeting the physical therapy needs of children, ed 2, Philadelphia, 2013, FA Davis Company.)

Five-year outcome of a surveillance program of children and adolescents with cerebral palsy revealed that the incidence of marked hip displacement (migration percentage > 30%) was directly related to gross motor function, classified according to the gross motor function classification system (GMFCS), with distribution of GMFCS I = 10 (3%), II = 40 (13%), III = 53 (43%), IV = 96 (59%), and V = 115 (64%).[79] Ambulation abilities provide the necessary forces to help the hip joint develop properly.

Disuse adversely affects bone by delaying secondary ossification centers and causing the bone to reabsorb. Children with a reduced activity level due to conditions such as CP, myelodysplasia, or arthrogryposis multiplex congenita are at greater risk for fracture because of disuse atrophy of the bones. The diagnosis of CP alone does not increase a child's risk for fractures. In children level GMFCS levels I to III, the risk is similar to that in typically developing children.[68,157] Children classified as GMFCS level IV or V had a twofold increase in the risk of fracture than healthy peers. Researchers have attempted to predict which children with CP are most likely to sustain a fracture.[157] The risk of fractures for those in GMFCS levels IV and V on antiepileptic drug therapy was a twofold increase ($P = 0.004$). The risk for fractures without trauma in children small for their age and those who did not use standing devices was significantly increased: adjusted incidence rate ratio (AIRR) 4.16 ($P = 0.011$) and 3.66 ($P = 0.010$), respectively. The use of a gastrostomy feeding tube produced conflicting results. A reduced risk of fractures with trauma was reported, but an increased risk of fractures without trauma was also noted (AIRR 0.10, $P = 0.003$, and 4.36, $P = 0.012$, respectively).[45,157]

The increased risk of fracture is assumed to be due to disuse demineralization. Disuse demineralization can occur quickly. One study found a 34% decrease in bone mineralization after non–weight-bearing immobilization following a fracture or surgery in only 4 to 6 weeks.[152]

Decreased bone mineralization is also seen in chronic conditions such as hemophilia,[6] HIV,[25] leukemia,[168] symptomatic epilepsy,[134,135] long-term use of glucocorticoids,[100] growth hormone deficiency, myelomeningocele,[86] and idiopathic scoliosis.[67] Likewise, bone density deficiencies accompany digestive system conditions such as celiac disease,[21] Crohn's disease,[58] and irritable bowel disorder.[132]

Although the literature is inconsistent at times, methods to promote healthy bone mineralization have been documented.[66] A comprehensive review of dietary requirements for bone health is outside the scope of this chapter. The reader is strongly encouraged to review current literature before making any recommendations on supplements.[119] Weight bearing improves bone thickness and density as evidenced by comparing athletes with nonathletes or in individuals who increase their physical activity.[64] An increase in bone density was observed in typically developing children with a consistent program of impact exercise, whereas children who participated in a non–weight-bearing exercise such as swimming did not see an increase in bone density.[34,64]

Parents may be able to help infants with myelomeningocele improve bone mineralization.[86] Parents were asked to help their

babies' practice being upright and stepping 10 continuous minutes per day, 5 days per week on an in-home treadmill for 12 months. The results were not statistically significant but were encouraging enough to warrant future research.[86]

There is also evidence that weight-bearing programs improve bone mineral density and promote hip modeling in children with CP.[45,92,170] We do know that mobile children with CP have greater bone mineral density when compared with their less mobile peers.[175,176] In a population-based study, the use of a standing frame was associated with a much lower risk of fracture in children with CP classified as GMFCS levels IV and V.[157] In a review article by Paleg et al.,[114] the authors concluded that standing programs 5 days per week positively affect bone mineral density (60 to 90 min/d); hip stability (60 min/d in 30° to 60° of total bilateral hip abduction); and range of motion of the hip, knee, and ankle (45 to 60 min/d).

Intermittent weight bearing with movement was most beneficial to hip joint modeling.[35,147] Intermittent weight bearing with movement can be accomplished by partial–weight-bearing ambulation with the use of a treadmill or gait trainer. Choosing an appropriate standing frame is also very important. Kecskemethy and colleagues[76] measured the percentage of a child's body weight that was being directed down to the stander and found that it ranged from 37% to 100%. If the goal is to provide weight bearing, then it would be logical to obtain as much weight as the child can tolerate during standing. The authors suggested that the Rifton (Rifton Equipment; PO Box 260, Rifton, New York, 12471-0260) supine stander positioned at an angle of 70° was an appropriate choice.[9] Weight bearing is an important part of physical therapy intervention for young children with neuromuscular diseases that delay the development of stance. The formation, growth, and integrity of articular cartilage are stimulated by compressive forces and movement between bone surfaces. Intermittent joint loading leads to healthy, thick cartilage.

Age and diet also affect bone mass and strength. Children are most at risk for distal forearm fractures during their pubertal growth spurt.[5,125] The rate of increase in the child's height and weight is greater than the rate of increase in the strength of the cortical bone at the radial metaphysis, which puts the bone at a mechanical disadvantage when an adolescent falls onto an outstretched arm.[125] Children who are obese have a higher bone mass density than children of appropriate weight, but not to the extent necessary to support their size. Therefore obese children have a high incidence of upper extremity fractures compared with their lighter-weight peers.[40,169] The overall incidence of forearm fractures in childhood has been increasing; this is postulated to result from the combination of vulnerable bone tissue with changes in diet (i.e., higher soft drink consumption and lower calcium intake) and increases in higher-risk physical activity, such as skate or hover boarding.[31,80]

Changes in the muscular or skeletal system have interactive effects. Understanding the influences of these two systems on the development and final outcome of each system and recognizing the period when these systems are most mutable assist the therapist in designing effective treatment programs, as well as in knowing when to discontinue treatment procedures.

Long-Term Effects of Atypical Musculoskeletal Development

In many neurologic or genetic diseases associated with developmental delay, the initial condition is considered nonprogressive, but the musculoskeletal impairments that frequently accompany these conditions typically worsen as the child grows. Adults with CP frequently develop a wide range of musculoskeletal issues such as scoliosis, hip dislocation, cervical neck dislocation, contracture, arthritis, patella alta, overuse syndrome, nerve entrapment, and fracture.[151] Discussed here are examples of common developmental musculoskeletal pathologies. More information on specific conditions mentioned can be found in subsequent chapters in this volume.

You have learned that the hip is unstable at birth but undergoes a great deal of normal developmental change, which increases stability. These normal developmental changes result from a combination of muscle pull and weight bearing. Children with CP typically have delayed walking, ROM limitations, and atypical muscular pull/spasticity. Hip subluxation and dislocation therefore are common problems in children with spastic CP. The risk increases dramatically as the level of severity of the cerebral palsy increases. In a surveillance report, the incidence of a migration percentage of greater than 30% was minimal for GMFCS level I and rose to over 80% for level IV (level II = 15%, level III = 40%, level IV = 70%).[178] Adequate ROM allows the hip to move into a stable, well-covered position in the acetabulum. Children with CP tend to lose abduction range and to develop hip flexion contractures, both of which are detrimental to hip stability. Critical ROM values for hip stability include maintaining at least 30° of abduction and avoiding a hip flexion contracture of 20° to 25° or more.[104]

A variety of idiopathic conditions are characterized by a disorder of endochondral ossification. The incidence of many of these conditions is increasing, and the increased obesity rate in children in most often suggested as a cause.[27] See Chapter 14 for a detailed discussion of these orthopedic conditions. Legg-Calvé-Perthes (LCP) disease is a hip disorder that involves repeated episodes of transient synovitis of the hip, usually occurring in boys between the ages of 3 and 12.[62] The synovitis causes an increased joint pressure, which interrupts blood flow in the vessels ascending the femoral neck. This typically results in pain, decreased hip abduction and internal rotation, and an atypical gait pattern, in which patients have a limp and a positive Trendelenburg sign. Roughly 50% of the boys diagnosed with LCP will develop hip arthritis in adulthood.[62]

Slipped capital femoral epiphysis (SCFE) occurs in adolescents between the ages of 12 and 15 when the growth plate of the proximal femoral physis is weak. The subjects in the obese children studies had decreased femoral anteversion. This positioning, along with increased body weight, may account for increased mechanical shear forces acting across the immature hip joint.[27] Patients with SCFE usually have an antalgic gait pattern and pain in the groin. Treatment for SCFE involves keeping the displacement to a minimum, maintaining ROM, and preventing degenerative arthritis. SCFE and Legg-Calvé-Perthes disease are childhood conditions that present a risk factor for the development of osteoarthritis and disability later in life.

Lower extremity rotational and angular problems are common lower extremity abnormalities in children. Rotational problems include in-toeing and out-toeing. In-toeing is caused by metatarsus adductus, increased femoral anteversion, internal tibial torsion, or any combination of the three. Consequently, out-toeing is caused by the opposite factors for in-toeing. Internal tibial torsion is a normal finding in the newborn, but it may pose a problem at walking age if not corrected. Casting can correct metatarsus adductus, but conservative treatments

for femoral anteversion and tibial torsion have not been shown to be effective. Angular problems such as genu varus and genu valgum are also common lower extremity abnormalities. Genu varus may lead to Blount's disease, which is a progressive deformity manifested by varus deformity and internal rotation of the tibia in the proximal metaphyseal region immediately below the knee. Blount's disease leads to irreversible pathologic changes at the medial portion of the proximal tibial epiphysis caused by growth disturbances of the subjacent physis.[27,175]

Patella alta is a condition in which the patella is positioned higher than expected on the femur. It frequently presents in early adolescence as anterior knee pain and progresses with age. It is common in individuals who walk with flexed knees, such as adults with CP, or who have overactive quadriceps muscles.[77] Maintaining adequate quadriceps and rectus femoris muscle length may help prevent patella alta. With patella alta, quadriceps strength is compromised and terminal knee extension is difficult. Pain and weakness can result in functional losses during activities such as walking, climbing stairs, or getting out of a chair.

Further study into the causes and prevention of secondary conditions is greatly needed to help guide the treatment of children with developmental disabilities. Pediatric therapists are appropriate professionals to educate parents and children about the lifelong attention that will need to be given to musculoskeletal problems, such as decreased strength and ROM. When appropriate, adolescents should be taught to be responsible for their physical and cardiopulmonary needs. Another role for pediatric therapists is educating their fellow orthopedic physical therapists who treat adults about the musculoskeletal problems in the neglected populations of adults with CP, myelodysplasia, and other developmental disabilities.

Measurement and Effects of Intervention

Fundamental goals of therapeutic intervention for physical disabilities include enhancing participation in daily activities and life roles by preventing or correcting the body structures and function that result from the underlying pathologic condition or from the normal physiologic adaptations superimposed on the pathologic condition. One assumption is that activity and participation will be enhanced if impairments are prevented or corrected. One study found that a moderate correlation existed between rectus femoris size; strength of knee extensors and ankle extensors with the activity; and participation components of the International Classification of Functioning, Disability and Health–Child and Youth.[82] Additional research, however, is needed to establish causation. Achieving functional levels of ROM and strength is a fundamental goal of therapeutic intervention. Accurate assessments of ROM and strength are therefore important components of the physical therapy examination process.

Range-of-Motion Examination

A wide range of methods and instruments have been reported for examining the ROM about a joint or multiple joints, including simple visual estimation, use of various protractors and goniometers, measurements made from still photographs, complex methods using computerized motion analysis systems, and smart phone applications. For most physical therapists, however, the universal goniometer (i.e., full-circle manual goniometer) remains the most versatile and widely used instrument in clinical practice.

Technology is playing a larger role in various aspects of physical therapy including measuring range of motion. When using a smart phone or tablet application to measure ROM, it is important to keep in mind the reliability and validity of the application, which must be redetermined by the developer with each software upgrade. To date, most applications have not been validated for children or for use in dynamic situations such as using a frame of video to measure joint angles during gait.[103]

The reliability of goniometry is based on the reproducibility or stability of ROM measurements in relation to (1) the time intervals between comparable measurements or (2) the use of more than one rater. Many factors influence the reliability and validity of goniometric measurements. These factors include consistency of applied procedures, differences among joint actions and among the structure and function of body regions, passive versus active measurements, intrarater measurements (multiple measurements by one examiner) versus interrater measurements (multiple measurements by two or more examiners), normal day-to-day variations in ROM, and day-to-day variations in different pathologic conditions.[53]

Pandya and colleagues[115] studied seven upper and lower extremity joint limitations in 150 children with DMD and reported that intrarater reliability was high (intraclass correlation coefficient [ICC] range, .81 to .91), but interrater reliability was lower, with wide variation from joint to joint (ICC range, .25 to .91). Reported goniometric reliability in children with CP varies widely. Researchers agree that careful standardized procedures are necessary to ensure reliability and that variances of ±10° in ROM over time could be due to measurement error.[60,81,99]

The hip is a particularly difficult joint for which to obtain reliable ROM measures. Bartlett and colleagues[7] compared four methods of measuring hip extension (by prone extension, Thomas test, Mundale method, and pelvic-femoral angle) in 15 children with spastic diplegia, 15 with meningomyelocele, and 15 with no known pathologic condition. They reported that the Thomas test was particularly difficult to apply to patients with spastic diplegia and the least reliable. In the meningomyelocele group the Mundale technique had the lowest reliability. They also reported that the pelvic-femoral angle method is more time consuming and no more accurate than other methods. Considering the ease of measurement and reliability, they recommend the prone hip extension test for patients with cerebral palsy and meningomyelocele and recommend the Thomas test as an alternative for nonspastic patients.

To perform the prone hip extension test, the child is in the prone position on a table with the opposite leg hanging over the edge of the table. In this position, the lumbar spine is flattened. The examiner holds the pelvis down at the level of the posterior superior iliac spines and pulls the leg that is being examined into hip extension until the pelvis begins to move anteriorly. At that point, the angle between the femur and the surface is measured and reflects the degree of hip flexion contracture. One limitation of this test is that it can be difficult to perform with large children because the therapist needs to hold the leg being tested while simultaneously holding the goniometer and measuring the angle.

Physical therapists work to improve a child's range-of-motion limitations, but further research is needed to establish minimum requirements for improved function. In a study by Lowes et al.,[90] strength and to a lesser extent ROM were shown to be

accurate predictors of balance and functional skills. Follow-up studies are needed to determine if daily skills require critical ROM values. In other words, can improved ROM guarantee an improved activity level?

Strength Examination

Accurate measurement of strength is important for identifying strength deficits and for documenting changes in strength that result from interventions. See Chapter 2 for additional information on strength testing. Numerous methods of measuring strength are available, including the traditional procedures of manual muscle testing and the use of various handheld force dynamometers[16] and computerized isokinetic testing systems.[78,128] Although manual muscle testing is probably the most versatile and widely used method, evidence indicates that handheld dynamometers may yield more precise measurements and are more sensitive to small changes in strength.[15] Isokinetic systems are effective for quantifying strength in adults, but it can be difficult to adjust the various components to fit children. Another concern is normalizing force measurements to account for differences in size and age.

A therapist must also consider the reliability of methods of strength testing in different patient populations. The reliability of the strength measurements may also vary with the time of day, particularly for patients who are fatigued by the end of the day, and with the level of the child's enthusiasm; with the testing environment; and with the testing clinician's rapport with the child. Children must be able to understand the instructions and follow commands to produce accurate and reliable strength measurements. Some, but not all, children as young as 2 years old with typical development have produced consistent force with a handheld dynamometer.[52] In another sample of children with intellectual difficulties, intrarater and interrater reliability coefficients were all greater than 0.90.[149] Despite these encouraging results, the therapist should be cognizant of the abilities of individual patients. As with goniometry, standardized testing procedures are necessary for optimal reliability of strength measurements. Standardized testing positions for handheld dynamometry are listed in Table 5.2. Taking the average of two measurements rather than a maximum value also improves reliability in children with suspected myopathy and children with CP.[163]

Several authors have reported good consistency when testing the strength of children with DMD using manual muscle testing,[47] isokinetic dynamometers,[141] a handheld dynamometer,[146] and an electronic strain gauge.[44] When strength was measured with a handheld dynamometer, children with meningomyelocele (9–17 years)[94] or with Down syndrome (7–15 years)[101] yielded highly reliable results. The reliability of the measurement of strength in children with CP can be more variable than in some other patient populations, but a review article by Damian and colleagues[36] determines it is still a useful clinical tool. Both handheld dynamometry and isokinetic testing at slower speeds can produce consistent results.[3,10,33,36,90,149,155,163]

In addition to the possibility of objectively measuring the voluntary force produced in spastic muscles, a combination of technologies may now permit objective assessments of the degree of underlying hypertonicity.

Effects of Intervention on the Musculoskeletal System

Objective evidence of the effects of strengthening exercises for particular pediatric conditions is increasing. The recommendation of exercise in children with DMD and other degenerative muscle disorders has changed. A report from a roundtable discussion of experts in the field of DMD suggests that animal models support the idea that submaximal concentric exercise has no negative effect and may be of limited value in increasing strength in DMD.[95] (See Chapter 12 for a more detailed discussion of DMD.) Eccentric contractions should be avoided, as they appear to have the most damaging effect on muscle. The No Use Is Disuse cycling protocol suggests that submaximal stationary bicycle or arm ergometer exercise is safe and may be beneficial in slowing the rate of disease.[69] There are still many unanswered questions regarding the appropriate type, intensity, and duration of exercise that is safe and if it is effective in changing the natural history of the disease.

Two review articles on interventions in CP have suggested that although the data for strength training are incomplete, they appear to be useful not only for improving basic strength but for showing carryover into function and improved gait.[36,42,112,116,122] Additionally resistive strength training regimens have not been shown to adversely affect the level of spasticity.[36] The literature suggests that strength training should be an integral part of an intervention program for children with strength deficits, and we encourage clinicians to continue to document the relationship of strength changes to changes in the activity and participation levels of children.

Botulinum toxin (BoNT-A) injections are often considered to decrease the level of spasticity and increase range of motion. A review article by Strobl et al. suggested that the main decision for the use of BoNT-A is to distinguish whether high muscle tone impedes or improves function.[145] Stiffness may be caused by posturing due to weakened muscles or by simultaneous activity of a group of muscles with high muscle tone. The authors suggest that the decision to administer BoNT-A should be based less on the assessment of individual muscles and more on the general functional impairment. Impairment based assessments such as the Ashworth Scale, Modified Tardieu Scale, or Range of Motion is less important in the use of BoNT than the general functional and developmental assessment and outcome. For this reason, it is essential to define the rehabilitative goal of treatment and to appraise the result with an appropriate assessment rather than evaluating the effect on the injected local muscles only. The author suggests that spastic muscles should only be injected in developing children if the spastic muscle is limiting achievement of the next developmental milestone or putting the child at risk for joint contractures. Controlling spasticity in the very young child may be a method of promoting more normal muscle development, which, in turn, may allow more efficient expenditure of energy and better participation in daily activities. The implication of multiple injections, however, must also be considered. In study of 10 subjects with CP who received multiple BoNT-A injections, neurogenic atrophy in the medial gastrocnemius was seen in 6 participants between 4 months to 3 years post BoNT-A.[161] Type I fiber loss with type II fiber predominance was significantly related to the number of injections.[161]

Limited range of motion is a frequent concern in the children treated by pediatric physical therapists. We have discussed a number of structural changes in spastic muscles that may contribute to loss of motion. The international consensus statement titled *Botulinum toxin assessment, intervention and after-care for lower limb spasticity in children with cerebral palsy* concludes that there is insufficient evidence to determine

TABLE 5.2 Standardized Testing Positions for Handheld Dynamometry

Muscle Group Patient Position	Limb Positions	Manually Stabilized Body Part	Dynamometer Placement
Wrist flexors Supine	Arm beside trunk, elbow flexed 90°, forearm in neutral supination, wrist in neutral flexion	Arm and forearm	Just proximal to metacarpophalangeal joints on extensor surface of hand
Wrist extensors Supine	As wrist flexors	As wrist flexors	Just proximal to metacarpophalangeal joints on flexor surface of hand
Elbow flexors Supine	As wrist flexors	Arm	Just proximal to wrist joint on radial surface of forearm
Elbow extensors Supine	As wrist flexors	Arm	Just proximal to wrist joint on ulnar surface of forearm
Shoulder internal rotators Supine	As wrist flexors	Arm	Just proximal to wrist joint on flexor surface of forearm
Shoulder external rotators Supine	As wrist flexors	Arm	Just proximal to wrist joint on extensor surface of forearm
Shoulder extensors Supine	Shoulder flexed 90°, shoulder in neutral horizontal adduction	Shoulder	Just proximal to elbow on extensor surface of arm
Shoulder flexors Supine	As shoulder extensors	Shoulder	Just proximal to elbow on flexor surface of arm
Shoulder adductors Supine	Elbow extended, shoulder abducted 45°	Trunk	Just proximal to elbow on medial surface of arm
Shoulder abductors Supine	As shoulder adductors	Trunk	Just proximal to elbow on lateral surface of arm
Ankle plantar flexors Supine	Hip and knee extended	Lower limb proximal ankle	Just proximal to metatarsophalangeal joints on plantar surface of foot
Ankle dorsiflexors Supine	As ankle plantar flexors	As ankle plantar flexors	Just proximal to metatarsophalangeal joints on dorsal surface of foot
Knee flexors Sitting	Knee and hip flexed to 90°	Thigh	Just proximal to ankle on posterior surface of leg
Knee extensors Sitting	Knee and hip flexed to 90°	Thigh	Just proximal to ankle on anterior surface of leg
Hip flexors Supine	Hip flexed to 90°, knee relaxed	Trunk	Just proximal to knee on extensor surface of thigh
Hip extensors Supine	As hip flexors	Trunk	Just proximal to knee on flexor surface of thigh
Hip abductors Supine	Knee extended, hip in neutral abduction	Contralateral lower extremity	Just proximal to knee on lateral surface of thigh
Hip adductors Supine	Knee extended, hip in neutral abduction	Contralateral lower extremity	Just proximal to knee on medial surface of thigh

Adapted from Bohannon R: Test-retest reliability of hand-held dynamometry during a single session of strength assessment, Phys Ther 66:206-209, 1986.

whether the use of BoNT-A in conjunction with serial casting improves outcomes.[89] Two class II studies showed improvements in the Gross Motor Function Measure walking domain, spasticity, stride length, ankle kinematics, passive ROM, and dorsiflexion strength when BoNT-A was used in conjunction with casting.[1,18] In contrast, a study by Kay[75] revealed that the concurrent addition of BoNT-A to a serial casting regimen led to earlier recurrence of spasticity, contracture, and equinus in gait by 6 months. An explanation of the results was that we as therapists need to strengthen the opposite muscle group to allow for balance. When BoNT-A is combined with serial casting, strengthening cannot occur.

Passive and active slow static stretching exercises are also used routinely to address range-of-motion limitations. De Deyne[38] suggested that muscle adaptation to stretch in healthy, non-neurologically compromised muscles comes from a combination of biomechanical, neurologic, and molecular mechanisms. Short-term improvements in range of motion following short duration stretch, frequently reported as less than 30 seconds, is likely due to the viscoelastic properties of muscle.

The evidence for stretching neurologically compromised muscles is less clear. Despite the widespread use of stretching with children with CP, little is known about its efficacy or effect on activities and participation. Reviews of published literature report that there is insufficient evidence to support/refute manual stretching for lengthening muscles, reducing spasticity, or improving gait.[74,118,171] Limitations that are present in the evidence for stretching spastic muscles include small gains in ROM,[49,74] poor reliability in measuring ROM in spastic muscles discussed earlier in this chapter, and limited carryover to Activities and Participation components of the ICF.[74,118,171]

A classic study by Tardieu,[154] however, supports the use of prolonged stretching. The study found that no progressive contracture was observed after stretching for 6 hours per day, but contractures continued to worsen if stretching was performed for less than 2 hours per day. This would suggest that sustained stretching through the use of night or resting splints is necessary to maintain range of motion.

Serial casting is another way to obtain prolonged stretch on a muscle. A review of the literature completed in 2014[162]

concluded that serial casting non-neurologically compromised idiopathic toe walkers did have preliminary evidence of beneficial effects on passive ankle dorsiflexion and gait kinematics. The sustainability of these positive effects after conservative treatment, including casting and physical therapy, was short, up to 1 year.

There is insufficient evidence to support the use of serial casting in children with CP.[11] Some small studies suggest that it can improve range of motion and gait, but there are also concerns about accompanying weakness. BoNT-A injections did not improve the results of casting a neurologically intact muscle system. A review of serial casting, both with and without BoNT-A injections, on individuals with neurologic impairments showed that serial casting with and without BoNT-A had a greater effect on improving range of motion than injections alone,[56] though the effects of BoNT-A when combined with serial casting remain inconclusive. Serial casting a neurologically impaired muscle may improve weight bearing for transfers, relieve pain, and enhance the ability to wear and tolerate orthotics.

The shape and size of the skeletal system are most susceptible to alteration during periods of rapid growth; hence undesirable forces, as well as appropriate corrective forces, are most influential during childhood. Many deformities that occur during the fetal or early postnatal period are more easily corrected in the infant than in the older child. For example, developmentally dislocated hips often readily respond to treatment with a Pavlik harness during the first year of life.[23,144,167] If, however, the dislocated hip is not diagnosed until after 12 months, surgery is often necessary. Similarly, serial casting for wrist deformities in children with distal arthrogryposis was very effective when applied during infancy.[143]

Many parents seek a physical therapist's opinion about what to do if their child has flat feet. Flexible flatfoot is a condition in which the medial longitudinal arch of the foot collapses during weight bearing and restores but is present when the body weight is removed (see Chapter 14 for more detailed information). Most infants are born with flexible flatfoot. Arch development begins between 2 and 6 years of age and becomes structurally mature by 12 or 13 years of age. Prevalence of flexible flatfoot in children 2 to 6 years of age has been reported at between 21% and 57%. Roughly 85% of those with flat feet improve with age, whereas about 15% of the population maintains a flat arch.[136] If flexible flat feet in a typically developing child are producing pain or gait abnormalities, it may be due to heel cord tightness.[59] The presence of risk factors, including ligamentous laxity, obesity, rotational deformities, tibial influence, pathologic tibia varum, equinus, presence of an os tibiale externum, and tarsal coalition, would require further foot evaluation. Treatment of flexible flat feet such as the use of orthotics is controversial and not well researched.[93] Prior to recommending long-term orthotics for flat feet, it is important to remember that cartilage needs movement to survive and repair itself, and joints that are stabilized too long frequently become rigid.

This leads to the question of what to do with asymptomatic flexible flat feet in children with hypotonia. Martin[96] studied 14 children with Down syndrome between the ages of 3.5 and 8 years. Significant improvements on the Gross Motor Function Measure and the Bruininks-Oseretsky Test of Motor Proficiency that could not be attributed solely to maturation were seen with supramalleolar orthoses. During kinematic gait analysis, children with Down syndrome who also had flat feet showed an altered ankle moment and decreased power generation at push-off.[55] This suggests that the child has a less efficient gait pattern.

Submalleolar (below ankle) bracing provided the children with Down syndrome a more neutral foot alignment, decreased toe-out position during walking, and a more controlled walking pattern. Speed, however, did not change.[133]

In general, the decision to brace in the pediatric population is supported in five main areas of documented value: (1) preventing deformity, (2) correcting deformity, (3) promoting a stable base of support, (4) facilitating the development of skills, and (5) improving the efficiency of gait. More evidence is required to determine at what age or developmental functional level bracing is most effective. Orthoses, however, can lead to the development of secondary deformities and disuse atrophy. Lusskin[91] reported two case studies of children with lower extremity paralysis resulting from poliomyelitis. Both children had marked tibial-fibular torsion and were braced in knee-ankle-foot orthoses with the knees and feet facing forward. As a result, a rotational force was placed at the ankle and foot, and these children developed severe metatarsus adductus and heel varus.

Circumferential compressive forces and restriction in active movement can interfere with normal musculoskeletal growth. Pediatric physical therapists have an important responsibility to understand, document, and frequently reevaluate the effects of external devices on the growing child. While trying to solve one problem, intervention may inadvertently create another.

Movement allows compressive forces to be spread throughout the joint surface rather than stay confined to a small area. Combining weight-bearing activities with movement would create more desirable forces for joint formation. Because remodeling of the bone and associated joints takes place most readily during the first few years of life, and because the acetabular shape, for example, is fairly well defined by the age of 3 years,[120] early intervention with weight-bearing activities may have a substantial influence on the shape and function of the joint. To help shape the joint, chronologic age and not developmental age may be more important when determining when to begin weight-bearing activities.

To improve hip stability, Paleg and associates[114] suggested that children with a gross motor delay greater than 25% should begin a supported standing program at around 9 to 10 months of corrected age, as typical children begin pulling to stand at this age. The shape of the acetabulum may not be appropriate for walking, but the hip may be more stable. Over time, this early standing may help prevent or decrease the severity of a dislocated hip. For children with milder delays, less stationary standing time and more weight bearing with movement may help to develop a more normally shaped hip socket. This may contribute to improved gait and a decreased risk of osteoarthritis in adulthood. Careful evaluation of the child's postural alignment when in equipment should be paramount.

Treadmill training has become increasingly popular as an intervention for providing movement and weight-bearing opportunities for children with Down syndrome, spinal cord injury, and CP. Accelerated acquisition of walking was demonstrated in children with Down syndrome when a parent supported the infant on a treadmill for 8 minutes 5 days per week.[158,159] In a randomized, controlled study, 30 children

received regular physical therapy, but half of them also received the in-home treadmill training program. The experimental group demonstrated the ability to pull to a standing position 60 days earlier than the control group, walked with help 73 days earlier than the control group, and walked independently 101 days earlier than the control group. Despite the documented efficacy of treadmill training in children with Down syndrome, the functional benefit of walking at 20 months versus 24 months is sometimes debated.

A review of the literature completed in 2011[160] found that because of the paucity of large, well-designed clinical trials to support the efficacy of treadmill training for children with CP, evidence for effective programs is inconclusive. This inconsistency might be due to the design of the intervention. Treatment intensity, frequency, and duration are critical to the success of a treadmill program. Traditional exercise training guidelines are explicit in the suggestion that, for fitness to improve, training must occur at a minimum of three times a week and must be sustained for 8 weeks or longer. Several small studies have reported improvements in gait, strength, and function.[26,29,109] Treadmill training can occur in a partial-weight-bearing (PWB) environment in which a therapist uses equipment that includes a harness, overhead support, and a motorized treadmill stimulus. The purpose of the PWB environment is to control body weight, posture, and balance while allowing the child the opportunity for prolonged periods of walking. This allows for strengthening and endurance improvements. Richards et al.[126] performed a 17-week multiple case feasibility study on four children with CP, ranging in age from 1.7 to 2.3 years who were not independent ambulators. They spent 20% to 30% of the time on the PWB treadmill during a 45-minute treatment session four times per week. Support ranged from 40%, 20%, and 0% of body weight with speed ranging from 0.07 m/s to 0.70 m/s. As support decreased throughout the study, the treadmill speed was increased. At the conclusion of the training, two of the children walked independently and one walked with an assistive device. Despite the articles suggesting the potential benefits of PWB therapy for CP, more research is needed to determine the best protocols for frequency, duration, and patient selection.

SUMMARY

This chapter reviewed the normal growth and development of the musculoskeletal system, with emphasis on the adaptations of muscle and bone associated with pathologic conditions encountered by pediatric physical therapists. The microscopic and macroscopic structure and function of the normal MTU and the force and length adaptations to imposed physical changes, such as immobilization and denervation, have been well documented in nonhuman studies using invasive methods of investigation. The results of human studies using noninvasive methods of investigation indicate that the human MTU undergoes adaptations similar to those reported for animals. Clinical evidence for the musculoskeletal adaptations supports these research findings.

In the developing child, atypical changes in the MTU can exert forces on the skeletal system, resulting in bony deformities. Pediatric physical therapists routinely measure physical impairments and develop therapeutic interventions designed to promote musculoskeletal adaptations. To document therapeutic efficacy in relation to specific pediatric disorders, therapists are encouraged to use objective measures of ROM and strength during specific interventions for correlating changes in musculoskeletal impairment with levels of activity and participation. Additional research is needed to examine the efficacy of therapeutic strengthening and stretching programs and their interrelation with other approaches, such as surgical procedures, casting, and pharmacologic interventions. The application of new research technologies, such as isokinetic dynamometry and EMG, now permits objective measurement of the impairments associated with neuromuscular disorders and the effects of interventions designed to influence these disorders. Additional controlled studies will enhance the scientific basis for using physical therapy to promote participation in life activities.

Physical Fitness During Childhood and Adolescence

Jean Stout

The International Classification of Functioning, Disability and Health (ICF) emphasizes components of health as important factors related to participation in society.[280] According to its press release, the World Health Organization estimates that as many as 500 million healthy life years are lost each year because of disability associated with health conditions. This statistic includes children. Ensuring physical fitness is one aspect of primary prevention and health promotion upon which the practice of physical therapy is based,[5] and it is a construct that fits appropriately within the ICF model. The scope of pediatric physical therapy in health promotion and physical fitness has explicitly been described.[207] As clinicians who design exercise programs and treat children with disabilities, we have a unique responsibility to understand and promote physical fitness as an aspect of those programs. It is a unique responsibility because we can have a great impact on the exercise lifestyle that children develop and carry with them throughout their lives. We also care for a group of children who might otherwise be physically inactive. Physical fitness is coming to the forefront of pediatric physical therapy practice as focus is directed toward prevention.[207] The research summit devoted to the topic of physical fitness and prevention of secondary conditions for children with cerebral palsy (CP), the defined scope of practice, and the importance of physical activity and fitness for adults with CP underscores the attention and importance that the profession of physical therapy as a whole is placing on this topic.[95,242] It is now well established that promotion of lifelong habits of physical activity in childhood will have direct and indirect effects on health and the prevention of disease in adulthood.[36,79,112] Meanwhile studies based on fitness standards find fewer children are achieving the minimum criterion for activity.[36]

What defines *physical fitness* for typically developing children? Are the criteria for physical fitness different in children with disabilities? How do we help children with physical disabilities incorporate physical fitness into the limitations of their disability? This chapter is designed to answer those questions and to provide an understanding of (1) physical fitness and the cardiopulmonary response to exercise in children of different ages who do not have disabling conditions; (2) the components of physical fitness (cardiorespiratory endurance, muscular strength and endurance, flexibility, and body composition) (Table 6.1); (3) the standards of fitness components consistent with good health; (4) the effects of training and conditioning on overall physical fitness; (5) the components of fitness in various special populations; and (6) guides for program planning. The chapter also includes a review of current physical fitness tests.

HEALTH, PHYSICAL ACTIVITY, AND PHYSICAL FITNESS

Physical fitness is difficult to define because it cannot be measured directly. Physical fitness is generally viewed as having two facets: health-related fitness and the more traditional motor fitness. Motor fitness generally includes physical abilities that relate to athletic performance, agility, and coordination, whereas health-related fitness includes abilities related to daily function and health maintenance. Physical activity is thought to be the path both to physical fitness and to good health and therefore is tightly coupled to fitness, but these are not synonymous terms. *Physical activity* refers to the amount of exercise in which an individual engages. Physical activity does not describe any "level" of physiologic function important to maintain health. Studies suggest that in adults, a positive correlation exists among regular physical activity, cardiovascular fitness, and reduced risk of mortality.[176] Just as in adults, physical inactivity is increasingly being implicated in the escalating "epidemic" of obesity and as a major risk factor for morbidity in children and adolescents.[45,145,157] The current consensus is that physical activity and physical fitness are reciprocally related and each exerts independent effects on health. Physical activity may improve physical fitness and health at the same time, but the improvement in health may be caused by biologic changes different from those responsible for improvement in physical fitness.[36] They are related but distinctly different contributors to health.[62,273] Some of the benefits from physical activity that are important to health and achievement have no relationship to what is defined as *physical fitness* per se.[108,166] One example is the importance of regular exercise to bone health and a reduced risk of osteoporosis; osteoporosis is related to health but not to the components of physical fitness.

Limited information is available regarding how much physical activity is necessary for health and fitness in children. The work of Strong and colleagues outlines the effects of physical activity on health and behavioral outcomes in school-aged youth and offers guidelines for the amount of exercise necessary.[233] The US Department of Health and Human Services published a first-ever Physical Activity Guidelines for Americans, which includes a chapter on children and youth.[193,250] New programs such as the National Football League–sponsored NFL PLAY 60 FITNESSGRAM Partnership project are devoted to promoting physical activity and physical fitness in youth.[12]

TABLE 6.1 Health-Related Fitness Components and the Rationale for Importance to Health Promotion and Disease Prevention

Component	Rationale
Cardiorespiratory endurance	Improved physical working capacity
	Reduced fatigue
	Reduced risk of coronary heart disease
	Optimal growth and development
Muscular strength and endurance	Improved functional capacity for lifting and carrying
	Reduced risk of lower back pain
	Optimal posture
	Optimal growth and development
Flexibility	Enhanced functional capacity for bending and twisting
	Reduced risk of lower back pain
	Optimal growth and development
Body composition	Reduced risk of hypertension
	Reduced risk of coronary heart disease
	Reduced risk of diabetes
	Optimal growth and development

Adapted from Pate PR, Shephard RJ: Characteristics of physical fitness in youth. In Gisolfi CV, Lamb DR, editors: Perspectives in exercise science and sports medicine: youth, exercise, and sport, vol 2, Indianapolis, IN, 1989, Benchmark Press.[187]

How much physical activity is enough? This question is not easily answered because it depends on many factors. Assessing and understanding physical activity in preschool children relative to child development presents even more challenges.[77] Studies under way, such as the longitudinal Lifestyle Of Our Kids (LOOK) project in Australia, which is investigating how early physical activity contributes to health and development, may also help to answer that question.[240]

The premise that physical activity is the path to both physical fitness and good health has become a primary focus in programs instituted by the US Department of Health and Human Services. As early as 1985, the Centers for Disease Control put forth a specific activity plan for youth through old age to attain specific health fitness goals and achieve optimal health benefits. Developing lifelong physical activity patterns was one of the specific goals for children.[112] In 1990, Healthy Children 2000, a major federal planning document for health promotion and disease prevention for children, was introduced.[246] Originally, eight objectives were outlined to increase the physical activity and fitness levels of youth, with a target date of attainment by the year 2000. Every 10 years, through the Healthy People initiative, the Department of Health and Human Services develops the next iteration of the national objectives for promoting health and preventing disease, which includes physical fitness. Final objectives for Healthy People 2020 retained physical fitness as part of the goal of physical activity but dropped the reference to fitness in the title of the objective[249] (http://www.healthypeople.gov/2020/topics-objectives/topic/physical-activity/objectives).

Progress to targets has been slow. Many of the year 2000 targets were retained in the 2010 objectives, and most of the 2010 objectives remain in the 2020 objectives. Targets directed toward elementary-age and junior high–age children dropped from the 2010 objectives have been reinstated. Eleven objectives for physical activity and fitness are included in Healthy People 2020 (Box 6.1). Plans for 2030 targets have not yet begun.

Physical activity as the path to physical fitness is no less surprising than the relationship of physical activity to improved health and disease prevention. The content of the current nationwide objectives has been guided in part by the concept of health-related fitness. What is different may be the intensity of physical activity required to be physically fit compared with what is necessary to receive benefits to health. Regardless of intensity, both physical fitness and improved health begin with physical activity. The amount and intensity of physical activity were found to be the best predictors of vascular health and function in a group of 10- and 11-year-old children.[114] Evidence of the impact of physical activity and fitness in childhood on fitness, health, and prevention of disease in adulthood is mixed,[36,79,92,123,133,154] but any direct or indirect benefits for the development of lifelong habits of physical activity and fitness in terms of health and disease prevention for typically developing children should be no less true for children with physical disabilities. The concept of physical fitness becomes more important because as individuals become less active in adulthood, the decrease in activity level is more likely to result in loss of function, injury, or both.

Definition of Physical Fitness

As defined previously, *health-related fitness* is a state characterized by (1) an ability to perform daily activities with vigor and (2) traits and capacities that are associated with low risk of premature development of hypokinetic disease (i.e., physical inactivity).[186] Physical fitness is multidimensional. A combination of traits and capacities contributes to physical fitness, and the interaction among them creates true fitness. Each facet is a unique, independent characteristic or ability that is not highly correlated with other components. As the concept of health-related fitness has gained acceptance, four basic components have been identified: cardiorespiratory endurance, muscular strength and endurance, flexibility, and body composition. The rationale for the importance of these parameters in day-to-day functional capacity, health promotion, and disease prevention, and therefore physical fitness, is presented in Table 6.1. The relative independence of the components from one another has been verified by low correlations between components. Of 60 possible correlation coefficients among test items for these components, only 6 were greater than 0.35.[204,206] The conceptual framework developed by the Institute of Medicine Committee on Fitness Measures and Health Outcomes in Youth also highlights the interplay of fitness components, modifying factors, and health markers in the following areas: cardiovascular/respiratory health, metabolic health and obesity, mental and cognitive health, musculoskeletal health, and adverse events.[185]

Cardiopulmonary Response to Exercise

As in adults, the response of a child to exercise (a single event or repeated exercise) includes physiologic changes in the cardiovascular and pulmonary systems, as well as metabolic effects. In children, however, differences in physiologic changes are seen as growth and development occur. Physiologic capacities depend on growth of the myocardium, skeleton, and skeletal muscle. Maturation and improved efficiency of the cardiovascular, pulmonary, metabolic, and musculoskeletal systems are also important. The physical work capacity of children increases approximately eightfold in absolute terms between the ages of

BOX 6.1 Healthy People 2020: Objectives: Physical Activity (PA)

Goal: Improve health, fitness, and quality of life through daily physical activity.

Objectives for Children and Adolescents

PA-3 (retained but modified from Healthy People 2010). Increase the proportion of adolescents who meet current physical activity guides for aerobic activity and muscle-strengthening activity.
- Target: 31.6%; baseline: 28.7% adolescents who meet aerobic activity guidelines
- No target for adolescents who muscle-strengthening activity guidelines

PA-4 (retained from Healthy People 2010). Increase the proportion of the nation's public and private schools that require daily physical education for all students.
- Target: 4.2%; baseline: 3.8% elementary schools
- Target: 8.6%; baseline: 7.8% middle and junior high school
- Target: 2.3%; baseline: 2.1% senior high schools

PA-5 (retained from Healthy People 2010). Increase the proportion of adolescents who participate in daily school physical education.
- Target: 36.6%; baseline: 33.3%

PA-6 (new to Healthy People 2020). Increase regularly scheduled elementary school recess in the United States.
- Target: 17 states; baseline: 7 states
- Target: 62.8% school districts; baseline: 57.1%

PA-7 (retained from Healthy People 2010). Increase the proportion of school districts that require or recommend elementary school recess for an appropriate period of time.
- Target: 67.7%; baseline: 61.5%

PA-8 (retained but modified from Healthy People 2010). Increase the proportion of children and adolescents who meet guidelines for screen time.
- 8.1 Increase the proportion of children age 0 to 2 years who view no television or videos on an average weekday.
- Target: 44.7%; baseline: 40.6%
- 8.2 Increase the proportion of children and adolescents aged 2 years through 12th grade who view television or videos or play video games for no more than 2 hours a day.
- Target: 83.2%; baseline: 75.6% children aged 2 to 5 years
- Target: 86.8%; baseline: 78.9% children aged 6 to 14 years
- Target: 73.9%; baseline: 67.2% adolescents in grades 9 through 12
- 8.3 Increase the proportion of children and adolescents age 2 years to 12th grade who use a computer or play computer games outside of school (for nonschool work) for no more than 2 hours a day.
- No target; baseline: 97.4% children aged 2 to 5 years
- Target: 100%; baseline: 93.3% children aged 6 to 14 years
- Target: 82.6%; baseline: 75.1% adolescents in grades 9 through 12

PA-9 (new for Healthy People 2020). Increase the number of states with licensing regulations for physical activity provided in child care.
- Target: 35 states; baseline: 25 states require activity programs in child care providing large muscle or gross motor activity, development, and/or equipment
- Target: 13 states; baseline 3 states require children in child care to engage in vigorous or moderate physical activity
- Target: 11 states; baseline 1 state to require physical activity in child care for a number of minutes per day or by length of time in care

PA-10 (retained from Healthy People 2010). Increase the proportion of the nation's public and private schools that provide access to their physical activity spaces and facilities for all persons outside of normal school hours (that is, before and after the school day, on weekends, and during summer and other vacations).
- Target: 31.7%; baseline 28.8%

PA-11 (new for Healthy People 2020). Increase the proportion of physician office visits that include counseling or education related to physical activity.
- Target: 8.7%; baseline 7.9%

PA-13.2 (retained but modified from Healthy People 2010). Increase the proportion of trips to school of 1 mile or less made by walking in children and adolescents age 5 to 15 years.

PA-14.2 (retained but modified from Healthy People 2010). Increase the proportion of trips to school of 2 miles or less made by bicycling in children and adolescents age 5 to 15 years.

PA-15 (new for Healthy People 2020). Increase legislative policies for the built environment that enhance access to and availability of physical activity opportunities.

From U.S. Department of Health and Human Services, Public Health Services, http://www.healthypeople.gov/2020/topics-objectives/topic/physical-activity/objectives#5078. Retrieved November 15, 2015.

6 and 12 years, partially as a result of growth and maturation.[1] The absolute exercise capacity of children may be less than that of adults, but relative exercise capacity is similar.

Any exercise, in a child or an adult, increases the energy expenditure of the body. The energy for muscle contraction and exercise depends on splitting of adenosine triphosphate (ATP) at the cellular level. ATP is available in small quantities in resting muscle, but once contraction starts, additional sources are required if contraction is to be maintained. Three sources of ATP are available: (1) creatine phosphate (CPh), (2) glycolysis, and (3) the tricarboxylic acid or Krebs cycle. It is beyond the scope of this chapter to describe these mechanisms in detail. The reader is referred to a standard textbook on exercise physiology.[40]

CPh and glycolysis as sources of ATP are referred to as anaerobic pathways because they do not require the presence of oxygen. CPh is found in the sarcoplasm of the muscle cell. During breakdown, it releases a high-energy phosphate bond that can be combined with adenosine diphosphate (ADP) to create ATP:

$$\text{CPh C} + \text{Pi} + \text{Energy} \quad [1]$$

$$\text{ADP} + \text{Pi} + \text{Energy ATP} \quad [2]$$

CPh breakdown together with ATP production will provide enough energy for 10 to 15 seconds of exercise. Glycolysis, the other anaerobic pathway, breaks down glucose to produce pyruvic acid or lactic acid and ATP. This reaction takes place in the sarcoplasm of the cell. Together, glycolysis and CPh breakdown are methods of anaerobic energy production that can sustain energy for muscle contraction for 40 to 50 seconds.

Energy production by the tricarboxylic acid cycle is called an *aerobic pathway* because it requires oxygen. A supply of oxygen is required for sustained exercise and depends on the aerobic pathway. Most, if not all, activities use both aerobic and anaerobic pathways for the supply of ATP, but often tasks are more highly dependent on one type of pathway than the other.

Because aerobic pathways must be used to sustain exercise, an index of maximal aerobic power is used to reflect the highest metabolic rate made available by aerobic energy. The most common index is maximal oxygen uptake (VO_{2max}), or the highest volume of oxygen that can be consumed per unit time. Oxygen supply to muscle is described by the Fick equation: oxygen uptake (VO_2) is equal to cardiac output (CO) times the difference in oxygen content between arterial (Cao_2) and mixed venous (Cvo_2) blood, or

$$VO_2 = CO\,(Cao_2 - Cvo_2)$$

Because CO is the product of heart rate and stroke volume, the following relationship is also true:

$$VO_2 = \text{Heart rate} \times \text{Stroke volume} \times \text{Arteriovenous} \times O_2 \text{ difference}$$

For VO_2 to increase, one or more of these factors must increase. During exercise, CO is elevated by increases in both heart rate and stroke volume. Elevated blood flow to the muscles increases the difference in oxygen content between arterial and venous blood.

VO_{2max} traditionally implies a plateau in oxygen uptake has been reached despite further exercise. Not all children display a plateau in oxygen uptake during a maximal exercise test to exhaustion. Pediatric exercise science now defines maximal oxygen uptake as VO_{2peak} to indicate that a maximal oxygen uptake may not have reached a plateau.[7,8] Because older literature typically refers to maximal oxygen uptake as VO_{2max} regardless of whether a plateau was reached, this convention will be used to avoid confusion.

VO_{2max} increases throughout childhood from approximately 1 L/min at age 5 years to 3 to 4 L/min at puberty.[8] These changes occur as a result of maturation of the cardiovascular, pulmonary, metabolic, and musculoskeletal systems. As a child grows, the cardiopulmonary and musculoskeletal systems are integrated so that oxygen flow during exercise optimally meets the energy demands of the muscle cells, regardless of body size.[52]

Cardiac Output

CO in children, as in adults, rises at the beginning of exercise or on transition from a lower to a higher level of exercise. CO can increase by an increase in either stroke volume or heart rate. CO in children is similar to that in adults despite the fact that stroke volume in a 5-year-old is about 25% of the stroke volume in an adult.[102] Stroke volume increases parallel to left ventricular size.[208] At all levels of exercise, stroke volume in boys is somewhat higher than in girls.[17] CO levels in children are similar to those in adults because of an increased heart rate throughout childhood. Maximal heart rates in children vary between 195 and 215 beats per minute (bpm) and decrease by 0.7 to 0.8 bpm per year after maturity.[39]

Arteriovenous Difference and Hemoglobin Concentration

At rest, the difference between arterial and mixed venous blood oxygen content is the same in children as in adults.[8,230] Research suggests, however, that children have a higher blood flow to muscles after exercise than do young adults, resulting in a higher arteriovenous oxygen difference.[129] Greater muscle blood flow facilitates increased oxygen transport to exercising muscles and thus a decrease in the oxygen content of the mixed venous blood.

Hemoglobin concentration is lower in children than in the average adult, and this affects the oxygen transport capacity of the blood in children. Studies suggest that children have greater ability to dissociate oxygen from hemoglobin at the tissue level and use a larger percentage of their oxygen-carrying capacity than adults, which partially compensates for the lower hemoglobin concentration.[8]

Arterial Blood Pressure

Lower exercise blood pressure is seen in children than in adults—a finding consistent with lower CO and stroke volume. Blood pressure may also be reduced because of lower peripheral vascular resistance secondary to shorter blood vessels.[17]

Ventilation

Ventilation is the rate of exchange of air between the lungs and ambient air, measured in liters per minute. In absolute terms, ventilation increases with age. Ventilation normalized by body weight is the same for children and adults at maximal activity.[17] At submaximal exercise levels, ventilation is higher in children and decreases with age, suggesting that children have a lower ventilatory reserve than do adults. Studies suggest that children have less efficient ventilation than do adults (i.e., more air is needed to supply 1 L of oxygen in a child than in an adult).[17] Minute ventilation is dependent on a number of factors including neural signals, and it is protocol dependent. Ventilation does not limit the VO_{2max} of healthy children and adolescents.[8]

Vital Capacity

Vital capacity in a 5-year-old child is about 20% of that in an adult and increases with age. It is highly correlated with body size, particularly height,[102] and generally has not been found to be a limiting factor in exercise performance.

Respiratory Rate

Children have a higher respiratory rate than do adults during both maximal and submaximal exercise. A high rate of respiration compensates for decreased lung volume; respiratory rate decreases as lung volume increases.[17]

Blood Lactate

Blood and muscle lactate levels are lower in children than in adults. It has been suggested but not confirmed that lactate production is related to testosterone production and therefore to sexual maturity in boys. Low lactate production in children could limit glycolytic capacity and thus contribute to reduced anaerobic capacity.[8,9,73]

Table 6.2 summarizes comparisons between children and adults for various cardiopulmonary variables. Growth and maturation play a vital part in determining the values of these variables. Despite size differences between adults and children (which might lead one to believe that oxygen transport in children is less efficient because they are smaller), optimal oxygen transport is maintained by highly integrated functions between the cardiopulmonary and musculoskeletal systems.

Review of Tests of Physical Fitness

It has now been longer than 50 years since the first US national youth fitness battery was published.[4] Once emphasizing motor fitness and the readiness of youth for military service, the transition of fitness testing to health-related fitness with a public health emphasis began in the 1970s. The National Children and Youth Fitness Study Tests I and II[203-206] represented the only effort to measure national youth fitness levels for three decades. The prevalence of national physical fitness testing in US schools at the turn of the 21st century was approximately 65% across all school levels.[122,173] Comparison of nationally and regionally used health-related fitness and systematic review of field tests and fitness batteries used worldwide can be found elsewhere.[28,97,185] The FITNESSGRAM/ACTIVITYGRAM[53,169] is now the only national youth fitness test used throughout the United States. The Presidential Youth Fitness Program,[198] which replaced the President's Challenge Youth Fitness Test, has adopted the FITNESSGRAM as its fitness assessment. Together, the FITNESSGRAM and President's Challenge Fitness Test were the basis for the majority of

TABLE 6.2 Cardiopulmonary Function Variables and Response to Exercise in Children

Function	Child Versus Adult Response	Sex Differences
Heart rate (max, submax)	Higher	M = F (max); F > M (submax)

scientific decisions over the past half century.[174] A third program, Physical Best,[103] developed concurrently with the others, has since discontinued its assessment component.[173,174] Each test emphasizes health-related fitness components. Most tests provide some information regarding interrater reliability. The validity of health-related fitness components has previously been reviewed.[116,185]

Physical Best Program

This program, originally designed to be both a physical fitness measure and an educational program to promote health and prevent disease, was developed by the American Alliance for Health, Physical Education, Recreation, and Dance (AAHPERD). AAHPERD changed its name to the Society of Health and Physical Educators in 2014, doing business as SHAPE America. The Physical Best Program remains active as a comprehensive health-related fitness education program for physical educators (http://www.shapeamerica.org/prodev/workshops/physicalbest).

FITNESSGRAM Program

This test is a battery that uses criterion-referenced standards that reflect the levels of fitness important for good health. The program was developed by the Cooper Institute for Aerobics Research (https://www.cooperinstitute.org/youth/FITNESSGRAM). Since its initial development, it has been revised three times, most recently in 2010.[53,169] Extensive information on the reliability and validity of the specific standards for all fitness components can be found in the test manual and has been published separately. Development of the standards and the scientific method used to revise the standards is also described. Revised standards for aerobic fitness and body composition using receiver operator characteristic (ROC) curves were completed and published in 2011 as a supplement issue of *American Journal of Preventive Medicine*.[172]

Standards compatible with the FITNESSGRAM for individuals with disabilities have been developed in the Brockport Physical Fitness Test.[276]

National Children, Youth, and Fitness Study I and II

These tests were used in national studies undertaken to assess current levels of physical fitness of children and youth in the United States.[203-206] Until the National Health and Nutrition Examination Survey (NHANES) National Youth Fitness Survey conducted in 2012,[37] these tests represented the only effort to assess youth fitness levels and they remain the basis of most current fitness tests. Initiated by the US Office of Disease Prevention and Health Promotion, the results have been used to set appropriate targets for improved health and fitness. The National Children, Youth, and Fitness Study I (NCYFS I) produced normative data by sex and age and by sex and grade for children and youth age 10 to 18 years, and NCYFS II provided the same information for children age 6 to 9 years. Training procedures were developed for test administrators, and Pearson correlation interrater reliability estimates were found to be .99 for body composition measurements. Concurrent validity of the distance run and VO_{2max} for children of elementary school age had already been established.[117]

Presidential Youth Fitness Program (Replacement for President's Challenge Youth Fitness Test)

The Presidential Youth Fitness Program (PYFP) replaced the President's Challenge Youth Fitness Test (https://www.presidentschallenge.org/challenge/pyfp.shtml) in 2013.[198] A partnership that included the President's Council on Fitness, Sports, and Nutrition, the Amateur Athletic Union, American Alliance for Health, Physical Education, Recreation, and Dance (now SHAPE America), Cooper Institute, and the Centers for Disease Control and Prevention initiated a new focus promoting health among youth versus measuring performance. Fitness within PYFP is assessed using the FITNESSGRAM. The PYFP is a comprehensive program model promoting fitness, physical activity, and education, and its goal is to lead youth to be active throughout life. The President's Challenge Youth Fitness Test has been the most commonly used fitness test among states in the United States that require fitness testing.[173] The change in focus, therefore, has potential for an immediate large-scale impact nationwide. Research on the historical evolution of both the President's Challenge and FITNESSGRAM fitness batteries has been previously published.[185,196]

Brockport Physical Fitness Test

This health-related criterion-referenced test for youth with disabilities was revised in 2014.[276] It offers options for test administrators to individualize testing based on health-related needs and desired fitness profile. The test builds on the framework of the FITNESSGRAM, including the concept of Healthy Fitness Zone, a registered trademark of the Cooper Institute.[169] Target populations for the test include those with visual impairment, intellectual disability, cerebral palsy, spinal cord injury, and amputation, among others. The validity and reliability of the test have been reported separately.[277] The Brockport Physical Fitness Test (BPFT) has been adopted by the Presidential Youth Fitness Program as its assessment program for youth with special needs.[198]

Comparison of Tests

All tests measure similar components of health-related fitness. Each includes items for testing cardiorespiratory endurance, muscular strength and endurance (now sometimes referred to as musculoskeletal fitness), body composition, and flexibility. The tests differ in the reference standard used. Tests are either norm referenced (performance is compared with that of a national US sample of children taking the same test) or criterion referenced (performance is compared with a preset standard consistent with fitness). Criterion-referenced standards are independent of the performance of other children on the same items. The FITNESSGRAM is the only criterion-referenced test. Guidelines for the interpretation of findings with respect to norm-referenced and criterion-referenced evaluations are available.[185]

COMPONENTS OF PHYSICAL FITNESS

The components of health-related fitness, as mentioned earlier, are cardiorespiratory endurance, muscular strength and endurance, flexibility, and body composition. The following information will be reviewed for each component:

- The criterion measure of the component
- Laboratory measurement
- Developmental aspects of the component and standards by age
- Field measurement of the component and its validity in relation to the criterion measure
- Standards by age as determined by the FITNESSGRAM program, a computer-scored fitness test with a health-related focus
- Physical activities with high correlation to the particular fitness component
- Response to training
- Assessment of the component in children with disabilities

Cardiorespiratory Endurance

Criterion Measure

The most widely used criterion measure for cardiorespiratory endurance is directly measured maximal oxygen uptake (VO_{2max} [with a plateau or without a plateau]). This component measures the capabilities of the cardiovascular and pulmonary systems and is significant because oxygen supply to the tissues depends on the efficiency and capacity of these systems. VO_{2max} is the highest rate of oxygen consumed by the body in a given time period during exercise of a significant portion of body muscle mass.[130] It defines the limits of oxygen utilization by exercising muscle and serves as the fundamental marker of physiologic aerobic fitness.[208] Cardiorespiratory endurance is so important to overall fitness that many people view physical fitness as being synonymous with cardiorespiratory endurance.

Laboratory Measurement

Laboratory measurement techniques include measurement of VO_{2max} with the use of an ergometer during progressive exercise to the point of exhaustion. This method is referred to as *direct determination* of VO_{2max}. *Indirect determination* methods predict VO_{2max} from submaximal exercise. A systematic review of reference values of both direct and indirect methods of cardiopulmonary exercise testing in children has been published.[29]

Direct determination. An ergometer is a device that measures the amount of work performed under controlled conditions. The two devices commonly available are a cycle ergometer and a treadmill. The cycle ergometer has the advantage of being relatively inexpensive and portable, but compared with the treadmill it exercises a smaller total muscle mass. With the cycle ergometer, local fatigue develops (primarily in knee extensors), resulting in premature termination of the testing. Depending on the source, values of VO_{2max} are reported to be 5% to 30% lower on a cycle ergometer than on a treadmill.[17,39,130] For children, the coordination and rhythm, or cadence, required on a cycle ergometer are sometimes difficult to achieve. Both the treadmill and the cycle ergometer present problems when used to test populations with disabilities, in particular those with impairments of balance or coordination.

A variety of protocols for direct determination can be used with children. The most common protocol is one in which resistance, inclination, speed, or height is increased every 1 to 3 minutes without interruption until the child can no longer maintain the activity. In interrupted protocols, which are sometimes used, there is an interruption between each successive increment of exercise. Examples of some common direct determination protocols are given in Table 6.3. The main criterion for indicating that VO_{2max} has been achieved during a progressive protocol is that an increase in power load is not accompanied by an increased VO_2 (usually 2 mL/kg/min or higher).[130] Astrand,[9] however, reported that 5% of all children tested failed to reach a plateau in VO_2, even though evidence from secondary criteria suggested that exhaustion had been reached. This finding in subsequent studies as well has prompted the field to adopt the term VO_{2peak} in children.[7,8]

Despite the difficulty of determining attainment of maximal oxygen uptake, studies suggest that the reliability of direct determination testing with children is high. Coefficients of variation of 3%, 5%, and 8% for VO_{2max} determined by treadmill walk-jogging, running, and walking, respectively, have been reported.[188] A mean variation of 4.5% was reported for children exercising to exhaustion on a cycle ergometer.[272]

Indirect determination. Indirect determination methods use submaximal exercise to indirectly predict VO_{2max}. The child is not taken to his or her self-imposed maximum. Heart rate during one or more stages is the variable most commonly used to derive the index of VO_{2max}. Step tests for children are usually submaximal tests, with recovery heart rate used to predict VO_{2max}. Evidence suggests that height-specific step tests can be reliable predictors of VO_{2max}.[96] Important limitations exist, however, in predicting VO_{2max} from submaximal exercise data, and these should always be kept in mind.[282] Examples of test protocols are presented in Table 6.4.

The W_{170} is an index used to predict mechanical power in a submaximal test. Two or more measurements of heart rate are obtained at different powers or workloads, and heart rate is then extrapolated to 170 bpm. The corresponding power is W_{170}. This index, originally described by Wahlund,[263] is based on the assumption that heart rate is linearly related to power at 170 bpm or less. To minimize error, more than two heart rate measurements are taken, one of which is as close as possible to 170 bpm.

More recently, maximal power (as measured during a maximal exercise test on a cycle ergometer) has been advocated, used, and validated as a surrogate for direct measurement of VO_{2max}. This method has been used in children with and without obesity.[66]

Developmental Aspects of Cardiorespiratory Endurance

Maximal oxygen uptake (VO_{2max} or VO_{2peak}) has been extensively studied and documented. Many reviews have combined both cycle ergometer and treadmill data, which has clouded understanding.[8] Maximal oxygen uptake increases with age throughout childhood and is slightly higher in boys than in girls.[8,130,209,221] Initial differences between boys and girls during early childhood are approximately 10%, increasing to 25% by age 14 years, and exceeding 50% by age 16.[8,130] The development of a greater muscle mass in boys and increasing differences in the amount of time spent in vigorous physical exercise are the most commonly given explanations. Overall, the physical working capacity of children increases approximately eightfold between the ages of 6 and 12 years. Few data are available on VO_{2max} for children younger than age 6.[1,208]

Relative to body weight, only a 1% change in VO_{2max} is noted between the ages of 6 and 16 years for boys (52.8 mL/kg/min at age 6; 53.5 mL/kg/min at age 16), whereas girls display a 12% reduction between the same ages (52 mL/kg/min at age 6; 40.5 mL/kg/min at age 16).[8,130,221] VO_{2max} is highly correlated with lean body mass. The decline in VO_{2max} in girls begins around age 10, when changes in body composition occur as girls develop a relatively increased amount of subcutaneous fat. When VO_{2max} is measured with reference to lean body mass, the difference in values between the sexes disappears.[39] Despite the fact that conventional normalization of VO_{2max} or VO_{2peak} is relative to body mass, the ratios remain size dependent, confounding interpretation.[7,271]

Although the increases in body dimensions of the heart, lungs, and exercising muscle are primarily responsible for the rise in VO_{2max} during the course of childhood, evidence indicates that other factors also contribute. When same-sex adolescents of different ages with identical body weight or body height are compared, the positive relationship with age remains.[231] Functional changes in cardiovascular, pulmonary, hematologic, and musculoskeletal systems resulting in improved efficiency with maturity may play a role. Cooper and colleagues,[52] however, suggested that the functional components of body systems are integrated so that aerobic capacity is optimized throughout the growth process. When cardiovascular responses to exercise are assessed relative to body surface area, they are not substantially different from those measured in adults.[262]

Measurement in the Field

The most common measure of cardiorespiratory fitness in the field is a long-distance run of various structures or lengths. All the physical fitness batteries reviewed previously have a distance run test, commonly a 1-mile run. Test-retest reliability of VO_{2max} during field testing has been shown to be between .60 and .95.[54,212] Construct and concurrent validity with VO_{2max} of 9- and 12-minute run tests in elementary children have also been established.[117,211] Estimation of peak oxygen consumption based on 1-mile run/walk performance is commonly used,[55] but a study has shown that this equation systematically underestimates peak oxygen consumption in endurance-trained children and adolescents with high peak oxygen consumption. This suggests than an alternate method should be applied to children in this category.[48] Prediction models that are independent of body mass index have also shown promise with good criterion-referenced agreement with measured peak VO_2.[43]

The Progressive Aerobic Cardiovascular Endurance Run (PACER) (Fig. 6.1) is an alternative to the 1-mile walk/run test used in the FITNESSGRAM battery. Aerobic performance is estimated on a series of seven 20-meter runs of incrementally increased exercise intensity. Criterion-referenced reliability and equivalency of the PACER were found to be similar to the 1-mile walk/run test in a group of high school students.[24] New minimum Healthy Fit Zones are now available based on the revision of the aerobic capacity standards.[169,268] When examined sequentially by repeated measures, aerobic performance using

FIG. 6.1 High school students participate in the 20-meter PACER (Progressive Aerobic Cardiovascular Endurance Run). (Photo taken by Sgt. Brian Ragin.)

the PACER is noted to fluctuate over a 12-month period, likely the result of changing patterns of intensity and type of physical activity.[44] Cross-validation of the PACER with the 1-mile run distances to estimate aerobic capacity is now complete.[33]

Standards by Age

Standards of performance are determined by ranking a child's performance in relation to the performance of a group of children tested on the same test (norm-referenced standard) or against an established criterion found to be consistent with good health (criterion-referenced standard). Criterion-referenced standards are independent of the proportion of the population that meets the standards. A ranking by a norm-referenced standard does not necessarily represent a desirable level of fitness or performance. The limitation of criterion-referenced standards, however, is that they are somewhat arbitrary and the criteria used in the current physical fitness tests differ from one another.[56] Criterion-referenced standards are most accepted today.

FITNESSGRAM has revised criterion-standards for aerobic fitness.[269] The design of new standards is based on receiver operating characteristic curves, an established procedure for establishing clinical thresholds.[270] This is consistent with the current-day emphasis on linking fitness to functional health outcomes. The process of developing new standards also included validation of field tests, as well as classification of students with both old and new standards.[268] A comparison of walk/run standards by age is provided in Table 6.5.

Physical Activities

Activities that are highly correlated with the development of cardiorespiratory endurance are boxing, running, rowing, swimming, cross-country skiing, and bicycling. The common component among these activities is a prolonged, sustained demand on the cardiorespiratory system that requires general stamina.

Response to Training

Debate exists over whether maximal aerobic power of prepubescence is a component that can be affected by training. Research results are equivocal. Studies that report improvement in aerobic power with training suggest that the principles of training of children before puberty (i.e., frequency, intensity, and duration) are similar to those for adults. The functional results of conditioning on the cardiorespiratory system include decreased heart rate, increased stroke volume, improved respiratory muscular endurance, and decreased respiration rate.[17,261] A more specific focus on conditioning and training will be found later in this chapter.

Assessment of Cardiorespiratory Endurance in Children With Disabilities

Children with disabilities often exhibit decreased or limited exercise capacity relative to their nondisabled peers. This can result from limited participation in exercise, which leads to

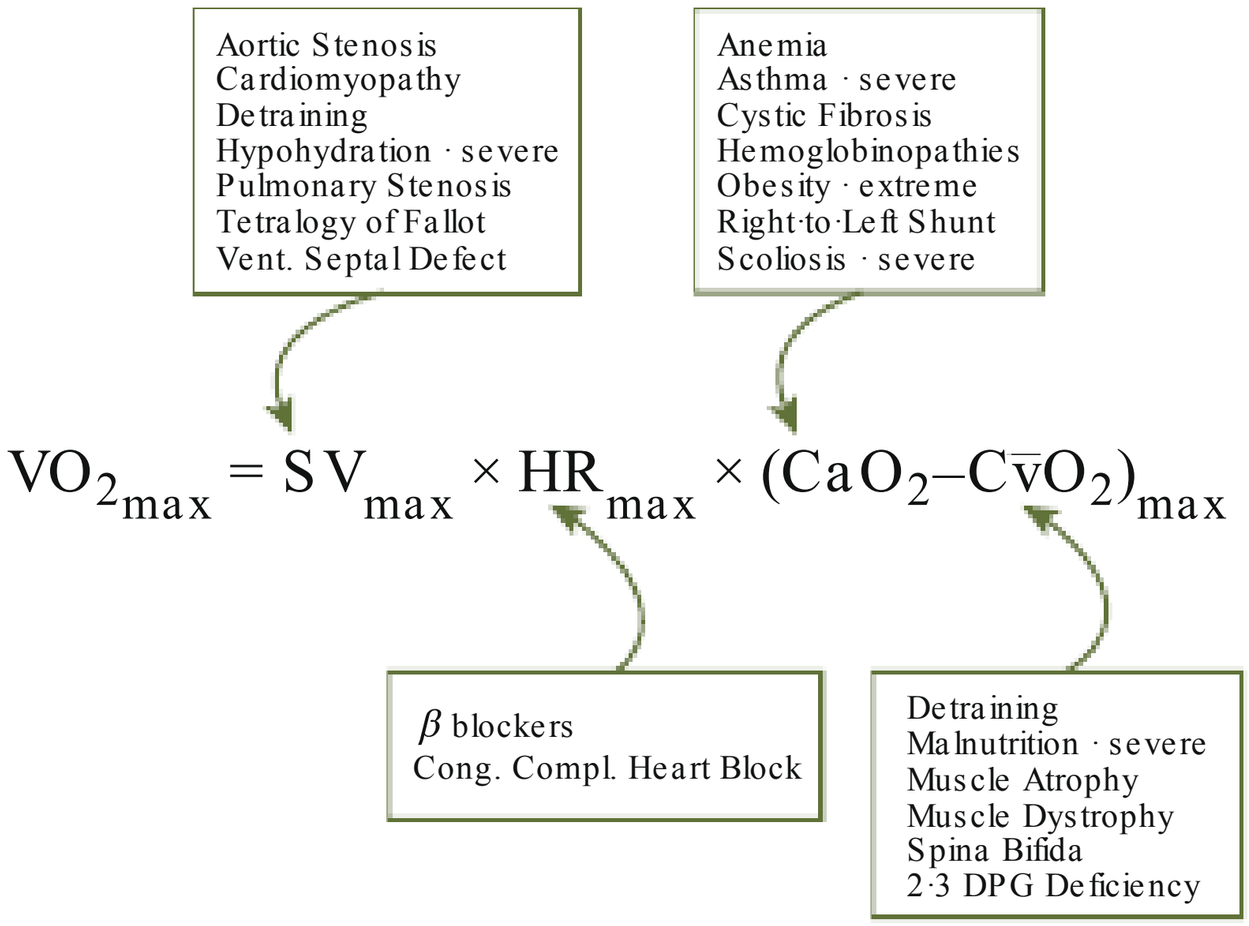

FIG. 6.2 Maximal aerobic power (VO_{2max}) and pathology. The Fick equation and specific pathologic conditions that affect its variables and reduce VO_{2max} are shown. (From Bar-Or O, editor: Pediatric sports medicine for the practitioner, New York, 1983, Springer-Verlag.)

deconditioning, or the specific pathologic factors of their disability that limit exercise-related functions. Regardless of the cause, children with disabilities often enter a cycle of decreased activity that precipitates loss of fitness and further decreases in activity levels.

Pathophysiologic factors that may limit cardiorespiratory endurance can sometimes be separated by the specific component of the Fick equation that they affect. This provides a convenient way to categorize conditions or diseases by the fitness components they affect most[19,21] (Fig. 6.2). Studies suggest that maximal aerobic uptake is limited not only by central mechanisms of the cardiopulmonary system but also by peripheral mechanisms controlling blood flow, excitation processes in the muscle fiber, local fatigue, and enzyme availability.[214,234] When limitations or reductions in VO_{2max} in children with disabilities are considered, both central and peripheral limitations must be taken into account.

Cerebral palsy. The directly measured maximal aerobic capacity of children and adolescents with cerebral palsy (CP) is 10% to 30% less than that of control subjects. The measurements have been shown to be reliable.[14,139,253] It seems that peripheral mechanisms related to the neuromuscular disorder itself are more likely to contribute to decreased capacity than are central cardiopulmonary mechanisms, although this has not been studied.

When indirectly assessed from submaximal heart rate, the aerobic capacity of adolescents was found to be reduced by 50%.[150] Low mechanical efficiency, however, creates disproportionately high submaximal heart rates in individuals with CP, making submaximal heart rate a poor predictor of maximal aerobic power.[18] Submaximal exercise tests, in general, underestimate aerobic capacity in poorly trained individuals.[9] Numerous studies suggest that heart rate is a good predictor or an appropriate substitute clinical measure of oxygen uptake because of its linear relationship to heart rate.[201,202] It is not a measure of maximal aerobic capacity, however, and therefore it is not an alternative measure of cardiorespiratory fitness.

An increase in blood flow to exercising muscles after conditioning is a response observed in children with CP but not seen in typically developing children without disabilities.[151] Spastic muscles of individuals with adult-onset brain damage exhibit subnormal blood flow during exercise.[134] Whether the rate of blood flow changes after conditioning in individuals with adult-onset brain injury is not known. One hypothesis to explain the increase in blood flow in conditioned individuals with CP is that it results from a decrease in spasticity. More rapid deterioration of maximal aerobic uptake is seen after discontinuation of training in children with CP than in typically developing children.[18]

Functional assessments that relate to the cardiorespiratory fitness of children with various disabilities are becoming more commonplace. The Pediatric Orthopedic Society of North America developed a functional outcomes questionnaire directed toward assessment of pediatric musculoskeletal conditions.[58] Within this questionnaire are queries regarding a child's ability to complete a 1-mile and a 3-mile walk. As more professionals caring for children with disabilities incorporate this assessment and others like it in daily practice, insight will be gained that may assist in determining cardiorespiratory fitness. The 6-minute walk test has been used in children with CP as a submaximal test of capacity.[241] Standards for field testing aerobic capacity in individuals with CP using a long-distance run have been previously published for children age 10 to 17 years.[278]

The Brockport Physical Fitness Test recommends the target aerobic movement test (TAMT) to measure aerobic behavior in children with CP.[276] It measures the aerobic behavior of youngsters and their ability to exercise at or above a recommended target heart rate for 15 minutes. Appropriate activity for the test may include swimming, dancing, running, arm-ergometry, or other aerobic exercise. This test can be used across functional levels for children with CP. The PACER and 1-mile run are also used. See Chapter 19 for more information on CP.

Juvenile idiopathic arthritis. Maximal aerobic capacity measured by cycle ergometry in children with juvenile rheumatoid arthritis has been reported to be 25% to 30% lower when compared to typically developing subjects.[251] No correlation was found between severity of articular disease and aerobic capacity, but it is related to disease duration.[192,237] A randomized controlled trial has demonstrated that exercise programs are safe without and can be performed without disease exacerbation.[223] Physical activity recommendations include radiographic screening for C1-C2 instability before participation in collision/contact sports.[192] Children will have a shorter duration of exercise before exhaustion, which occurs at a lower than normal work rate with a lower peak heart rate. Deficient oxygen extraction from exercising muscles or low blood flow to exercising muscles has been postulated to occur in this population as a result of decreased activity levels.[18,21] See Chapter 7 for more information on juvenile idiopathic arthritis.

Scoliosis. Chest deformity, decreased lung size, and decreased physical activity are believed to contribute to the lower maximal aerobic capacity of children with advanced scoliosis. Peak oxygen uptake during cardiopulmonary exercise testing has been shown to be reduced if compared to healthy individuals at a similar level of peak ventilation.[71] Chronic deconditioning also plays a role in the functional exercise limitations.[229] See Chapter 8 for more information on scoliosis.

Intellectual disabilities. Most studies indicate that individuals with intellectual disabilities display lower VO_{2max} scores than do their peers without disabilities; however, significant variability has been reported among individuals with the same level of disability. Technical problems associated with testing individuals with intellectual disabilities are encountered that create difficulties in establishing reliable and valid information. Treadmill testing appears to be the most reliable form of testing. Despite lower VO_{2max} scores, individuals with intellectual disabilities without Down syndrome have been shown to exhibit similar age-related trends and changes as individuals without disabilities (i.e., decline with age).[23] Field test standards and alternative test items for aerobic capacity in individuals with intellectual and other disabilities are available.[276] See Chapter 18 for more information on children with intellectual disabilities.

Children with obesity. The prevalence of obesity in children age 2 to 19 years designated as overweight by the National Health and Nutrition Examination Survey (2011-2012) was estimated at 16.9%, and 31.8% were estimated to be overweight or obese.[180] Although obesity is not considered a category of "disability" in traditional terms, public health concerns for this group of young people make it worthy of special attention. Field tests of cardiorespiratory endurance in obese youth using the 1-mile walk/run test demonstrate that they perform below typical standards for nonobese peers.[160] Only 34% of obese boys and 38% of obese girls tested fell within the Healthy Fitness Zone of the FITNESSGRAM 1-mile walk/run standards as compared with 73% and 61% of their nonobese counterparts, respectively. Estimation of peak oxygen uptake from the same 1-mile walk/run performance suggested similar results for VO_{2max}.[160] Evidence, however, suggests that VO_{2max} values from prediction equations or submaximal exercise tests overestimate actual VO_{2max} when measured on a maximal exercise test.[10] This suggests that the percentage of obese youth that fall within a zone of healthy fitness may actually be less. Racial differences in obese adolescents have also been reported. Black adolescents had significantly lower VO_{2max} and lower hemoglobin than did white adolescents with no differences in maximal heart rate or respiratory exchange ratio.[6]

Muscular Strength and Endurance

The second component of physical fitness is muscular strength and endurance. Strength is required for movement and has a direct impact on effective performance. Strength is also important for optimal posture and reduced risk of lower back pain, which is the criterion health condition to which this component of physical fitness is linked. Similar to cardiorespiratory endurance, positive relationships between musculoskeletal fitness and health status in adults have been demonstrated.[89,121] The theoretical link between fatigue-resistant trunk muscles (abdominal flexors and trunk extensors) and healthy low back function, however, is stronger than the research evidence between muscular strength and flexibility and the onset or recurrence of low back pain.[194] A growing body of evidence is emerging for children as well as adults that enhanced musculoskeletal fitness is associated with an overall improvement in health status.[195,264,273] No critical level of strength or muscular endurance for good health has been identified.

Muscular strength, muscular endurance, and *muscular power* are not synonymous terms. Muscular strength refers to maximal contractile force. Muscular endurance is the ability of muscles to perform work and assumes some component of muscular strength. Muscular power refers to the ability to release maximal muscular force within a specified time. As velocity increases or time decreases (for maximal muscular force to be obtained), power increases. Because muscular endurance and muscular power have their basis in muscular strength, strength is the primary focus of this discussion.

Laboratory Measurement

The laboratory standard for muscular strength is measurement by dynamometry. Tests include isometric dynamometry, isokinetic dynamometry, and single-repetition maximal isotonic dynamometry. Most measurements are made on specific, selected muscles, then results are extrapolated to give "whole body" strength. The validity of the extrapolation method has been questioned.[195] The deficits not only in reliable, valid laboratory and field standards for musculoskeletal fitness but also the need for scientific links between musculoskeletal fitness and health risk factors/markers have been highlighted.[195] Unfortunately, a limitation for setting standards for strength is that force measurements depend on the type of dynamometer used.[30] The most commonly selected measures are hand grip, elbow flexion and extension, knee flexion and extension, and plantar flexion strength.

Isokinetic strength testing during childhood and adolescence is a relatively new area of study. The reliability of isokinetic testing in children presents unique issues because of the variability of muscle coordination and neuromuscular maturation. Coefficients of variation from 5% to 11% have been reported.[30] Children demonstrate the capacity to perform consistent maximal voluntary contraction under controlled conditions by age 6 to 7 years. Comparative muscle performance data (upper and lower body power and velocity) for children ages 3 to 7 years are now available.[98] The limited amount of research and the lack of available data do not allow definite conclusions on the effects of age and gender differences on isokinetic strength development. Body weight and muscle cross-sectional area, however, appear

to correlate positively with isokinetic strength. Gender differences are minimal between ages 3 and 11. After age 13, boys tend to have greater isokinetic strength for the muscles tested than do girls.[15,239]

Developmental aspects and standards by age

Grip strength. Grip strength is the most commonly reported upper extremity strength measure in children. Absolute strength scores, however, are highly sensitive to the type of dynamometer used and to its positioning, making the results of studies difficult to compare. In general, single-hand grip strength increases from an average of approximately 5 kg for children at age 3 years to 45 kg for boys at age 17 and 30 kg for girls at age 17. Bilateral grip strength has been measured at a mean of 25 kg for children at age 7 years, increasing to an average of 95 kg for boys and 50 kg for girls by age 17 years.[30,156] The rate of increase in strength for boys rises dramatically at puberty. This finding is confirmed in the Longitudinal Experimental Growth Study, where a marked acceleration of strength or a strength spurt was noted around the age of peak height velocity. The maximal increase in static strength occurs approximately 1 year later.[239] Absolute values of the developmental range of strength throughout childhood were measured to be slightly larger. Pearson correlations to static strength in adulthood were reported to be fair to high, depending on whether individuals were noted to be early, average, or late maturing.

Elbow flexion and extension. Isometric elbow flexion strength is greater than isometric elbow extension strength throughout childhood and adolescence, and the difference between them increases with increasing age.[279] A 3-year longitudinal study demonstrated that the extension/flexion strength ratio for boys is approximately 0.85 at the age of 13 years and decreases to 0.75 by the age of 15 years. The ratio for girls is less, starting at 0.75 at age 13 years and decreasing to 0.66 by age 15 years.

Knee flexion and extension. Isokinetic knee flexion strength and knee extension strength also increase throughout childhood. Rather than examining each in isolation, studies advocate evaluating reciprocal muscle group ratios to better understand knee function.[63] Eccentric/concentric ratios provide information on knee function, injury risk, and knee stability. Available data for children indicate that during fast velocity movements, prepubescent children have a lower capacity for generating eccentric to concentric torque. Irrespective of age, girls appear to have a reduced capacity for concentric actions, which may make them more susceptible to injury.[64]

Trunk and neck flexion and extension. Few data are available for laboratory dynamometry standards for trunk strength in children. Values for isokinetic trunk flexion and extension strength at varying speeds are available for a group of prepubescent children with and without back pain (mean age 11.9 years).[168] Similar to findings in adults, both extensor and flexor peak torque decreased with increasing speed. Flexor and extensor peak torque were higher in males than females.

Pediatric data are also available for isometric neck strength in children, adolescents, and young adults.[138] Maturation of neck strength increases with age and is modeled as a second-order polynomial. The mismatch between head circumference and muscle strength may implicate susceptibility to injury in prepubertal children. For example, an 8-year-old has an average head circumference that is 91% that of an adult, but strength is only 50%.

Evoked responses.

A second method for muscular function assessment in the laboratory is by evoked responses from electrical stimulation. Muscle contractile characteristics, including force production, are studied with this method. Few data are available for children.[30,32]

Developmental Aspects of Muscular Strength and Endurance

A description of the development of the musculoskeletal system is found in Chapter 5. The development of strength depends on the maturation of force production and is influenced by numerous factors, such as the muscle's cross-sectional area.[239] Muscular strength in absolute terms increases linearly with chronologic age from early childhood in both sexes to approximately age 13 to 14 years. Increases in strength are closely related to increases in muscle mass during growth. Boys have greater strength than do girls at all ages (seen as early as age 3 years) and have larger absolute and relative amounts of muscle (kilogram of muscle per kilogram of body weight).[30,239] The sex difference in relative strength (per kilogram of body mass) before puberty is caused at least in part by a higher proportion of body fat in girls from mid-childhood onward—a difference similar to the trend in cardiorespiratory endurance.[91,180] Rarick and Thompson[200] suggested that boys are 11% to 13% stronger than girls during childhood. This value reaches 20% by adulthood for strength per cross-sectional area of muscle.[161] Correlates and determinants of strength are thought to include age, body size, muscle size, muscle fiber type and size, muscle contractile properties, and biomechanical influences.

During adolescence, a marked acceleration in development of strength occurs, particularly in boys. Boys between the ages of 10 and 16 years who were followed longitudinally showed a 23% increase in strength per year. Peak growth in muscle mass occurred during and after peak weight gain, but maximal strength development occurred after peak velocity of growth in height and weight, suggesting that muscle tissue increases first in mass and then in strength.[153,239] Girls generally show peak strength development before peak weight gain.[88] Overall muscle mass increases more than 5 times in males from childhood to adulthood; the increase in females is 3.5 times.

Differentiation in strength between the sexes at puberty is caused, at least in part, by differences in hormonal concentrations, particularly testosterone. Hormones other than the male sex steroids also make an important contribution.[90] Unfortunately, no pediatric studies to date have correlated age-associated changes in endocrinologic function with muscle size and muscular strength.

Measurement in the Field

Strength is considered an important part of physical fitness; however, the standards to meet minimal fitness requirements and the link between musculoskeletal fitness and health are the least clear. Some suggest that the single most pressing research need in this area is to understand which musculoskeletal fitness test items can be unequivocally linked to health risk factors.[194] Field measurements of muscular strength usually entail movement of part or all of the body mass against gravity. The common tests for muscular strength are the flexed arm hang or 90° push-up and the curl-up. The curl-up has replaced the sit-up as the common field test item. The FITNESSGRAM also includes a trunk

lift test for back strength (Fig. 6.3). The correlation between abdominal strength and endurance and shoulder girdle strength as measures of absolute strength for physical fitness is not well established. Available data for the reliability and validity of the curl-up and sit-up, tests of trunk extension, and upper arm and shoulder assessments are well outlined by Plowman. Results are variable. In some cases, such as for trunk extension, data on children are lacking.[194]

Curl-ups/sit-ups. The exact relationship between curl-up performance (Fig. 6.4) and abdominal strength and endurance is unclear. How abdominal strength is related to a given number of curl-ups is unknown. Test-retest reliability estimates for curl-ups is well outlined in the FITNESSGRAM reference manual.[194] The most recent study in the series for youth was conducted in 2001 and indicated reliability of between .75 and .89.[190]

Chin-ups/*fl*exed arm hang/90° push-ups. The recommended test for upper body strength and endurance within the FITNESSGRAM is the 90° push-up at a cadence of one repetition every 3 seconds.[194] The flexed arm hang (Fig. 6.5) or chin-up are optional items. The three items are not anatomically interchangeable. Correlations among the field tests exhibit a range from low to high. Concurrent validity has not been established for these tests as definitive measures of strength or muscle endurance. Limited research is available for children.

FIG. 6.3 FITNESSGRAM trunk lift test. (From the Cooper Institute, Dallas Texas. Reprinted with permission.)

Standards by Age

The standards of performance by age for the FITNESSGRAM Program are listed in Table 6.6.

Sex differences typically begin at puberty, but each item has slightly different timing when the standards diverge. Modified pull-up standards are the first to diverge between ages 8 and 9 years, followed by 90° push-up standards between age 10 and 11 years, flexed arm hang between standards between 11 and 12 years, and last to diverge are standards for the curl-up, which diverge between age 12 and 13 years. In each case, the standard for boys is higher than it is for girls. The only test item that displays no differentiation by sex is the trunk lift.[169]

Physical Activities

Activities that have a high correlation with muscular strength are gymnastics, jumping, sprinting, weight lifting, and wrestling. Local muscular endurance is affected by cycling, figure skating, and middle-distance running.

Response to Training

Training-induced increases in strength can be influenced by numerous factors, including enhancement of motivation, improvement in coordination, increase in number of contractile proteins per cross-sectional area of muscle, and hypertrophy of muscle.[105] Children can achieve gains in strength and muscle mass with training before or after puberty. Strength improvements in prepubescent children have typically been attributed to neurologic adaptations to training and improved motor unit activation rather than to increased cross-sectional area of muscle,[87,105] but both play a role. Research has demonstrated that a 12-week resistance training program in prepubertal boys was effective in improving both strength and force per unit muscle volume.[72] Direct evidence for the role of neurologic adaptation during strength training has been documented by increases in integrated electromyographic amplitudes and maximal isokinetic strength following an 8-week

FIG. 6.4 FITNESSGRAM curl-up. (From the Cooper Institute, Dallas Texas. Reprinted with permission.)

strength program.[184] Because the magnitude of change in neuromuscular activation is generally smaller than the observed increase in strength, it has been postulated that improved movement coordination is a contributor to strength gains, particularly in complex multijoint exercises.[25] Neuromuscular maturation in the prepubescent child is therefore an important contributor to strength and should not be underestimated.

FIG. 6.5 FITNESSGRAM flexed arm-hang test. (From the Cooper Institute, Dallas Texas. Reprinted with permission.)

Controversy has existed for a number of years regarding the safety and efficacy of strength training programs for children and adolescents. The American Academy of Pediatrics Council on Sports Medicine and Fitness guidelines[3] and an international consensus statement from the United Kingdom Strength and Conditioning Association[144] are available for review. The international consensus statement has been endorsed by the American Academy of Pediatrics.

Assessment of Muscular Strength and Endurance in Children With Disabilities

Muscular strength and endurance are crucial fitness components for walking, lifting, and performing most daily functions. Deficits of muscular strength in children with disabilities are a primary focus for the clinician in an attempt to improve (or maintain) maximum function. It is important to keep in mind, however, that strength as measured clinically is not simply the ability of a muscle to generate force. Strength measured clinically is the effectiveness of the muscle force to produce movement of the joint. This encompasses both the ability of the muscle to generate force and appropriate skeletal alignment. In children with disabilities, strength deficits result from the muscles' inability to generate force, malalignment of the skeleton, or a combination of both.

Muscular dystrophy. Strength measurements by dynamometry in children with Duchenne muscular dystrophy (DMD) exhibit progressive deterioration as compared with healthy children.[141] Failure of muscular strength to increase with growth is seen. The result is that the absolute strength in a child with DMD at the age of 16 years is similar to that of a typical 5-year-old.

The use of quantitative muscle testing (QMT) has shown better reliability than manual muscle testing in this population.[162] Longitudinal data have shown increases in QMT in boys up to age 7½ years, followed by substantial decreases. The average 1-year changes were significantly different from those of healthy controls.[141]

TABLE 6.6 Field Standards for Strength

Age, yr	FITNESSGRAM Curl-Ups, Number Completed		FITNESSGRAM Modified Pull-Ups, Number Completed		FITNESSGRAM Flexed Arm Hang, Seconds		FITNESSGRAM 90° Push-Ups, Number Completed		FITNESSGRAM Trunk Lift, Inches

Data adapted from the Cooper Institute: FITNESSGRAM®/ACTIVITYGRAM test administration manual, updated ed 4, Champaign IL, 2010, Human Kinetics.

Muscular endurance (the ability to sustain static or rhythmic contraction for long periods) is also affected in children with DMD. Ninety-two percent of the children tested by Hosking and colleagues scored below the 5th percentile for strength in holding the head 45° off the ground. Measurement on the Wingate anaerobic cycling test indicates that both peak muscular power and mean muscular power output are significantly less than is typical.[21] The test-retest reliability of this test for various neuromuscular and muscular disease conditions has been established.[243] See Chapter 12 for more information on DMD and other types of muscle diseases.

Cerebral palsy. Strength deficits in children with CP are common, and strength profiles for lower extremity muscle groups in children with spastic CP are available.[274] Children with spastic diplegia demonstrated strength values ranging from 16% to 71% of same-age peers depending on the muscle tested. The gluteus maximus and soleus muscles showed the greatest strength deficits. The involved side of children with hemiplegia exhibited values from 22% to 79% of strength values of same-age peers. The gluteus maximus and the anterior tibialis were the weakest muscles. Strength in children with CP is an active area of research. A randomized controlled trial of the efficacy of a 12-week combined functional anaerobic and strength training program on walking ability and gross motor functional capacity is under way.[101]

Inadequate joint moment and power production as measured by computerized gait analysis are seen in children with CP.[100,183] These measures provide indirect evidence in a functional context of decreased strength because strength is a prerequisite for moment and power production. Power production by the ankle plantar flexor muscles in terminal stance phase provides a key source of power for forward motion during the typical walking cycle. Power production in terminal stance phase is often reduced in children with CP. Occasionally, inappropriately timed power production results in excessive, but nonproductive, energy expenditure during gait[99] (Fig. 6.6).

Muscular endurance is also decreased in children with CP. Performance on the Wingate anaerobic test in a group of children with CP resulted in averages that were 30% to 60% lower than typically developing peers.[14,21] The test exhibits moderate reliability in this population.[13]

Modifications for lower and upper extremity strength field test items in children with CP are available within the Brockport Physical Fitness Test manual.[276] Modifications are suggested based on the classification system used by the Cerebral Palsy International Sports and Recreation Association.[49]

Children with obesity. Performance on field tests of abdominal and upper body muscle strength (curl-up and modified pull-up or flexed arm hang) is poorer for children identified as overweight (≥ 95% body mass index). Children who were overweight were 3 times less likely to pass the upper body strength test and 1.5 times less likely to pass the abdominal strength test than children who were not overweight.[126] The negative influences of biomechanical factors related to (1) increased body size such as the need to move fat tissue, which acts as an inert load; (2) weakened force production caused by increased mechanical work and moment of inertia due to a higher trunk mass; and (3) the fact that gravity itself may pull the trunk down; in certain tests, all factors likely contribute to impaired muscle strength and endurance performance.[91] The inverse relationship of obesity to fitness measures of strength is seen across cultures.[38,91,115] An increased incidence of musculoskeletal problems has been reported.[67,131,238]

Flexibility

Inconsistency and controversy exist in how flexibility is classified and its importance as a component of health-related fitness. The Institute of Medicine report maintains fitness as a separate component, consistent with the original categories, but FITNESSGRAM includes flexibility under the umbrella of musculoskeletal fitness along with muscle strength and

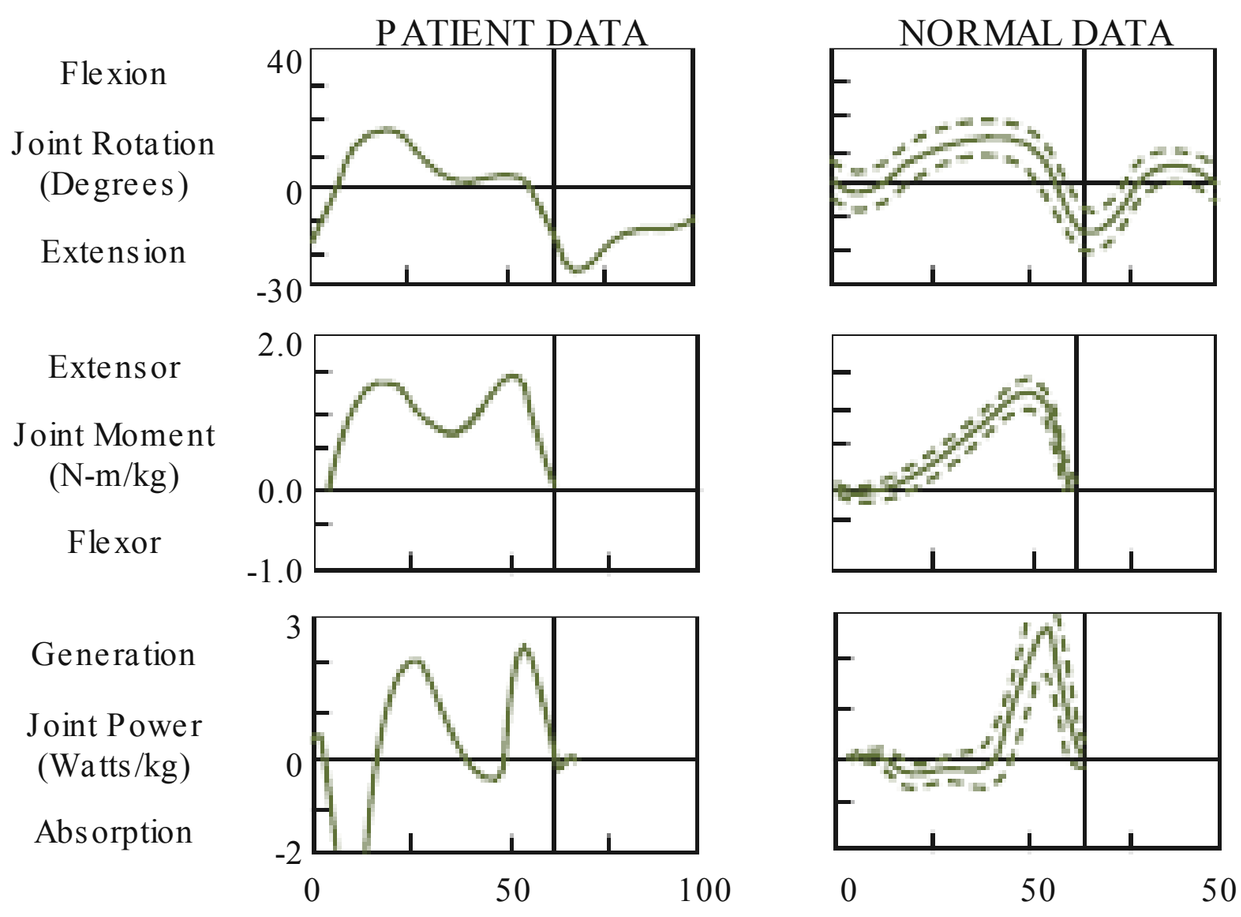

FIG. 6.6 Sagittal plane joint rotation (kinematic), joint moment, and power (kinetics) of a child with cerebral palsy versus a normal child. The child's joint moment is biphasic, and the power graph indicates two distinct bursts of power generation instead of one. The first burst is abnormal and functions to drive the center of gravity upward, not forward, which is nonproductive energy expenditure. (From Gage JR: Gait analysis in cerebral palsy, London, 1991, MacKeith Press.)

endurance.[185,194] Evidence supports flexibility as a unique construct of fitness.[76] The definition of flexibility according to the Institute of Medicine report is "the intrinsic property of body tissues including muscle and connective tissues that determines the range of motion achievable without injury at a joint or group of joints."[185] The association to health outcomes has been difficult to clearly demonstrate, but the historical importance of flexibility as a component of health-related fitness is related to the prevention of musculoskeletal impairments later in life, especially lower back pain and posture.[249] The associations have been studied in adults, but the association with flexibility in youth has not been established. As a result, the Institute of Medicine committee did not recommend a flexibility test for a national youth fitness survey. Plowman identified the question of whether flexibility should be part of a health-related fitness assessment as one of the top 10 pressing questions relevant to musculoskeletal fitness testing.[195]

Historically, it is felt that flexible muscles permit proper pelvic rotation, decrease disc compression, and avoid excessive stretch of musculature. Flexibility of the lower back, legs, and shoulders contributes to the prevention of injury. Limitations in spinal mobility can interfere with activities of daily living, such as dressing, turning, and driving. Restrictions in back mobility can also contribute to abnormalities in walking.

Criterion Measure

Joint range of motion (ROM) is the criterion used for standards of flexibility. Although ROM measures for adults are well established and can be found in various textbooks,[178] ROM information for the pediatric population correlated with changes in stature is limited. Upper extremity ROM data for children are not well documented. The typical measurement tool is the universal goniometer. A review of the reliability of goniometry is found in Chapter 5.

Laboratory Measurement and Developmental Aspects of Flexibility

Extremity range of motion. Lower extremity passive ROM measurements have been described in the newborn, infant, and toddler.[75,191,267] Newborns exhibit hypoextensibility of both hip and knee flexor muscles and increased popliteal angles consistent with the flexed posture in utero. Range of motion increases in the first months of life. Ranges of hip abduction and rotation also differ from adult values. See Chapter 5 for information on ROM values for newborns.

Little to no information has been reported for ROM during childhood. Unpublished data from my laboratory on lower extremity ROM measurements in 140 children between the ages of 2 and 18 years suggest variation in some joints throughout childhood and relative stability in others[191] (Table 6.7). Test-retest reliability using Pearson correlations was .95, and interrater reliability was .90. Results suggested age and sex differences, with females exhibiting a trend toward greater flexibility at all ages. Greater flexibility of the hamstring muscles in females is especially apparent during the teenage years in straight leg raising and popliteal angle measurements.

Posture and spinal mobility. Spinal mobility has been measured in both young children and adolescents.[109,170] The technique of measurement of back mobility uses tape measure distance changes in bony landmark relationships before and after a standardized spinal movement. The concurrent validity of this measurement technique with anterior spinal flexion measured radiographically has been established.[152,170] Anterior spinal flexion appears to remain relatively stable throughout childhood and adolescence, but lateral flexion increases linearly with age through adolescence and into early adulthood. Girls were significantly more flexible than boys in both anterior flexion and lateral flexion in the 5- to 9-year-old age group.[109]

The relationship of posture to physical fitness is not often addressed in today's emphasis on health-related fitness. Previous research discussing the relationship of posture to fitness included the importance of posture to trunk strength and the potential for imbalance, back pain, headache, foot pain, and orthopedic deformities.[51,124] Each aspect of posture may be important to mobility in children but becomes of greater importance in adulthood, when impairment can lead to further deformity and loss of function.

Measurement in the Field

The field tests for measurement of flexibility in tests of physical fitness are the sit and reach test or, more recently, the modified sit and reach test—a measure of hamstring muscle and lower back flexibility. This test measures the distance a child can reach forward (shoulders flexed to 90° and elbows extended) from a long-sit position. Starting position is with the back straight, hips at 90°. No field test is available for the assessment of low back flexibility. The back-saver sit and reach test (Fig. 6.7) used in the FITNESSGRAM is similar to the traditional sit and reach test except that the measurement is performed on one side at a time (opposite leg is flexed with opposite foot flat on the floor). The intraclass correlation for test-retest reliability of the sit and reach test was found to be high; coefficients between 0.94 and 0.99 have been reported.[110,118,152] Jackson and Baker[118] assessed

TABLE 6.7 Selected Range-of-Motion Measurements During Childhood

Mean Range of Motion (Degrees)	2–5 Years		6–12 Years		13–19 Years	
	M	F	M	F	M	F

the criterion-related validity of the sit and reach test both for hamstring flexibility and for lower, upper, and total back flexibility. A moderate correlation with measurement of straight leg raising using a flexometer was found for hamstring flexibility (0.64). On the other hand, a low correlation with lower back flexibility (0.28) was found with this protocol developed by Macrae and Wright,[152] using tape measure distance changes in bony landmark relationships before and after a standardized spinal movement as the criterion measure (intraclass correlations). Upper back flexibility and total back flexibility were not correlated with the sit and reach scores. The criterion-related validity of the sit and reach test and the modified sit and reach test have been questioned.[47,50,110] Although both tests were found to be related to hamstring flexibility, both hip and low-back flexibility also contribute to the performance of the task.[50] Girls typically show better flexibility than boys at all ages.

Standards by Age

The criterion standard of performance on the FITNESSGRAM Program for the back-saver sit and reach test is 8 inches from the ages of 5 to 17 years in boys. The criterion standard for girls is 9 inches (ages 5-10 years), 10 inches (ages 11-14 years), and 11.5 inches (ages 15-18 years).[169]

Physical Activities

Activities that require a high degree of flexibility include figure skating, gymnastics, jumping (track and field), and judo. Stretching is an important part of any exercise program for general warm-up before vigorous activity and to reduce the potential for injury. Possible physiologic mechanisms for the benefits of stretching include increased blood flow to muscles, increased mechanical efficiency of muscle and tendon, and reduction of viscosity within the muscle.[17] Decreased resistance to extension of connective tissue leads to increased efficiency and power output by muscles. Much of this research is on the adult population, but the same principles are believed to apply to children.[19,132,283]

Assessment of Flexibility in Children with Disabilities

For clinicians involved in the rehabilitation (or habilitation) of children with musculoskeletal disorders, maintenance of flexibility or joint ROM is often a primary concern. Almost any musculoskeletal or neuromuscular disorder for which physical therapy is recommended includes treatment for loss of flexibility. Conditions such as CP, juvenile rheumatoid arthritis, muscular dystrophy (MD), or long bone fracture are common examples.

In Chapter 5, both measurement of and the effects of intervention on improving joint ROM in children were addressed. The challenges of goniometric reliability of joint ROM measurements in children and adults with spasticity are well documented.[35,81,125,164] Similar results have been found in adults.[35,81] Because maintenance of flexibility is an important component of most physical therapy programs for children with disabilities, methods for more reliable assessment of joint ROM are needed.

Field test standards for the back-saver sit and reach test and suggested modifications for test administration have been published for children with visual impairment, mental retardation, and Down syndrome.[276]

Children with obesity. Performance on field tests of flexibility (back-saver sit and reach test) is similar for children identified as overweight (≥ 95% body mass index) compared with typical weight or underweight peers.[126] This finding is supported for adolescents as well.[91]

Body Composition

The term *body composition* is understood to mean total body content of water, protein, fat, and minerals or the components that make up body weight.[65,104] The major contributors are muscle, bone, and fat content, along with organs, skin, and nerve tissue. The importance of body composition to health-related fitness has two components: (1) skeletal muscle, bones, and fluid, the major components of fat-free body mass, are critical to the performance of functional activities, and (2) excessive fat mass (i.e., obesity) is associated with clustering of a number of health risks including coronary artery disease, hypertension, and diabetes mellitus, among others. The relevance of obesity to a child's present and future health cannot be overemphasized. The prevalence of childhood and youth obesity is increasing worldwide. In the United States alone, the prevalence of children classified as overweight increased from 10% in 1988-1994 to 14.4% by 1999-2000 and 16.5% by 2002.[261] Examination of the extent to which children exceed the overweight threshold indicates that the prevalence of overweight children becoming heavier is increasing faster than the prevalence of children becoming overweight.[120] Attainment of appropriate body weight for overweight individuals was an explicit objective of Healthy Children 2000 that has actually moved away from its target.[246,247] Healthy People 2020 has maintained objectives related to the nutritional health of adolescents and youth as one of its focus areas.[248] Large discrepancies continue to exist between current nutrition practices and projected targets.[177]

Laboratory Measurement

The purpose of body composition measurements, whether in the laboratory or in the field, is to obtain a measure of fat-free or lean body mass. Chemical analysis is the only direct method to measure body composition.[128] Because this is expensive and impractical, even laboratory standards of measurement are from indirect assessment. Most standards rely on formulas

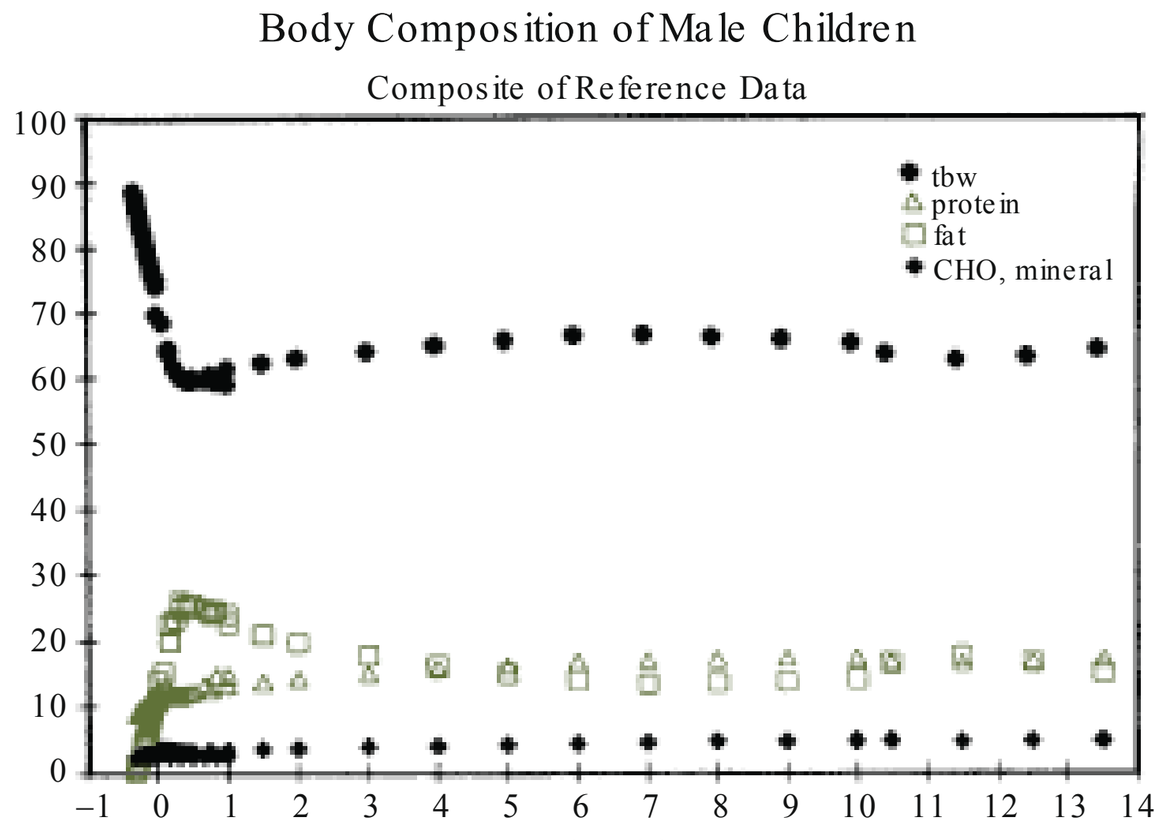

FIG. 6.8 The normal body composition of male children as it changes with age. Derived from data found in descriptions of the reference fetus, infant, male child at 9 years, children from birth to 10 years, and adolescent male. CHO, carbohydrate; tbw, total body water. (From Spady DW: Normal body composition of infants and children, 98th Ross Laboratories Conference on Pediatric Research, 98:67-73, 1989. Used with permission of Ross Products Division, Abbott Laboratories, Columbus, OH. ©1989 Ross Products Division, Abbott Laboratories.)

and models of composition, which assume that fat and lean body mass are constant. Because infants and children exhibit variable, not constant, body composition throughout childhood,[34,111,147,227] numerous problems in determining body composition in children are encountered. Use of adult standards leads to overestimation or underestimation of body fatness, depending on the technique.[34] All methods presented have some limitations for use with children, but all have been used. There is no one gold standard for children.

Densitometry. More commonly referred to as underwater or hydrostatic weighing, densitometry determines the density of an individual by dividing actual body weight by the decrease in weight when the person is completely submerged in water. The densities of fat and lean body mass are assumed to be constant and can be calculated for an individual when the density of the whole body is known. Although it is considered the gold standard for measurement of body composition in adults, it has limited applicability to young children because of the requirement for submersion underwater.

Total body water. The measurement of total body water is used as a means of estimating the nonfat portion of the body because neutral fat does not bind water. Stable isotopes of hydrogen or oxygen are administered orally and then measured to determine the amount of dilution in a body fluid.

Bioelectric impedance analysis. This method is based on the principle that impedance to electrical flow varies in proportion to the amount of lean tissue present. A weak electric current is passed through the body, and its impedance is measured. Portable devices are now available that make this method more accessible for clinical and field use.

Dual-energy x-ray absorptiometry. Using dual-energy x-ray absorptiometry (DXA), the body's differential absorption of two low-dose x-rays at different energy levels is measured. The ratios are used to predict total body mass, lean body mass, and bone mineral density. It has fast become a reference standard for measurement of body composition. Despite its wide use, because of variability of software calculations and instrumentation, the continuous change in body composition of children as they grow suggests that DXA has not yet achieved sufficient reproducibility to be considered the gold standard in pediatric studies.[140,222] Cross-validation between DXA and bioelectric impedance analysis in children and adolescents suggests that the methods are not interchangeable but provide useful and complementary assessments of the percentage of body fat. Less reproducibility is found when younger children are assessed.[78,142]

Developmental Aspects of Body Composition

The influence of rapid growth in fetal and early infancy on fat mass percentage and body composition at 6 months of age has been investigated to gain a better understanding of predictions of obesity later in life. Findings suggest that factors and growth patterns as early as the third trimester of life in utero influence a higher fat mass percentage and body composition at 6 months of age.[11] From prenatal development through adolescence, body composition is constantly changing. Part of this change is caused by chemical maturation as a result of increasing mineral mass and hydration of adipose tissue.[227] Chemical maturation occurs after adolescence, when the constants relating one component of body composition to another stabilize until the last decades of life.[34,147]

The four major components of body composition are water, protein, mineral, and fat. Reference models describe the body composition of these components in the child at various ages.[93,94,111,285] A composite of these reference models and changes with growth in males appears in Fig. 6.8.

- Water content: Water content of the body is approximately 89% of body weight at 24 weeks of gestation and drops to 75% at 40 weeks.[227] By 4 months of age, water content stabilizes at approximately 60% to 65% and remains at that level until puberty.
- Protein content: Protein content as a proportion of body weight increases from approximately 13% at birth to 15% to 17% at age 10 years.
- Mineral content: Mineral content of the body rises from 3% at birth to 5% at age 18 years.
- Fat content: Fat is the most variable component of body composition during infancy and childhood. Increases begin in utero when fat content changes from 2.5% at 1 kg of body weight to 12% at term gestation.[227] The proportion of body fat rises from 12% to an average of 25% from birth to 6 months of age. Fat content as a proportion of body weight decreases during early childhood as muscle mass increases. Sex differences are noted early in childhood; girls exhibit a greater percentage of fat content than do boys. At 6 to 8 years of age, the average fat content for boys is 13% to 15%, and for girls it is 16% to 18%.[148] During adolescence, fat content increases in girls so that between the ages of 14 and 16 years the mean percentage of fat content is 21% to 23%.

Differences between the sexes exist in each major component of body composition throughout childhood and are magnified at adolescence. Major changes during adolescence in both sexes consist of a decrease in the percentage of water and an increase in the percentage of osseous minerals.[111,149] These distinct age- and gender-associated variations in body composition have been reaffirmed with the development body fat percentile curves.[135]

Measurement in the Field

Examination of body composition in the field is typically done by measuring skinfold thickness. The validity of this measure is suspect, just as the validity of laboratory methods is in question. The major problem is that skinfold measurement is based on the assumption that body surface measures and body density relationships are stable throughout childhood.[146] Two other threats to the validity of this measurement are (1) that use of skinfold thickness implies that the subcutaneous fat layer reflects the total amount of fat in the body and (2) that selected measurement sites reflect average thickness. These assumptions may not be true.[128] Other researchers have not found large deviations in skinfold thickness distribution across sites.[149,225]

Despite this controversy, measurement of body composition is an important part of almost all health-related fitness tests. Concurrent validity has been demonstrated consistently with moderately high correlations of 0.70 to 0.85 between measurements of skinfolds and densitometry or potassium spectrometry.[103]

Typical sites for measurement of skinfold thickness are the triceps brachii, subscapular area, and calf. Usually these areas are measured in some combination. The method for estimating the percentage of body fatness from skinfold measurement involves estimating density from skinfold measurements and then converting density to the percentage of body fatness. The reader is referred to other sources for more detailed information.[146,147,180] A 3% to 5% error is reported for adults when body fatness is estimated from skinfold measurements.[146]

FITNESSGRAM revised criterion standards for body composition.[269] The design of new standards, like the new standards for aerobic fitness previously described, is based on receiver operating characteristic curves, an established procedure for determining clinical thresholds.[137] This is consistent with the current emphasis on linking fitness to functional health outcomes. The process of developing new standards also included validation of field tests, as well as classification of students with both old and new standards.

Although skinfold measurement and bioelectric impedance remain the preferred methods of assessing body composition, use of body mass index (BMI) has become more prevalent. A major limitation of BMI is the lack of differentiation between fat and lean mass.[197] Classification accuracy using BMI ranges from 87% to 89% when placing subjects into risk categories based on the percentage of body fat.[136]

Standards by Age

The criterion values for ranges of body fatness within the FITNESSGRAM healthy fit zone vary by age and sex.[169] Values for boys range from 8% to 19% at age 5 years to 6% to 22% above age 17 years. Ranges for girls are 9% to 20% at age 5 years to 16% to 30% above age 17 years. Values higher than 25% in boys and 35% in girls are considered to place the child at risk for associated morbidities.

Response to Training

Conditioning and training programs alone may or may not affect body composition. If changes are to occur, the type of exercise must entail high-energy expenditure of intense effort. Appropriate activities include swimming, running, and weight training. Evidence of program effects on body composition is inconclusive in adults. Little information is available on children, but what is available indicates that the percentage of body fatness can be reduced during training for specific sports but rises again when programs are discontinued. Significant changes in body composition with structured physical activity programs are less likely than changes in bone mineral density in both obese and nonobese children.[108,167]

Assessment of Body Composition in Children with Disabilities

Premature infants.

Clinicians treat many children with disabilities who were born prematurely. Premature birth has been shown to affect body composition.[228] Compared with a "reference" fetus of similar weight, the infant who was born prematurely has a higher total fat content and a lower total body water content. These differences in composition are probably the result of living outside the womb and being faced with the necessity of increasing body fat for temperature regulation. The implications of this altered body composition during growth have not been studied, nor has body composition been studied in premature infants who experience neonatal complications. There may or may not be effects of premature birth on composition throughout childhood and into adulthood. The previously described pattern of growth changes noted to influence fat mass percentage at 6 months of age may particularly influence children born prematurely, but again this has not been studied.[11]

Cerebral palsy.

The importance of body composition measurement has come to the forefront for individuals with CP.[107,179,255] An increased percentage of body fat has been noted.[255] It is postulated that children with CP may have proportionately more subcutaneous fat in the lower extremity skinfold sites because of disuse. More recent work advocates

the use of CP-specific equations for clinical assessment.[107,179] Correlations between methods (including DXA) were found to be excellent for determining fat-free body mass and moderate for determining fat mass and percentage of body fat.[143,179] Subject numbers across all studies were relatively small and included children with various types of CP and functional levels. Both type of CP and functional level are likely to be important variables affecting body composition.[179]

Myelomeningocele. The risk of obesity in children with all forms of spina bifida has been a concern of clinicians for decades.[113] Children with myelomeningocele, on average, exhibit decreased stature, reduced fat-free mass, and an increased percentage of body fat compared with typically developing peers.[16,175] The increased total body fat percentage is primarily related to the excess adiposity in the lower extremities. This may reduce the negative health impact.

The percentage of adolescents classified as obese ranged between 29% and 35% as measured by skinfold thickness and BMI.[41,42,252] Nonambulatory individuals had a higher percentage of body fat than those who were ambulatory. However, BMI did not demonstrate a significant correlation with physical activity.

Muscular dystrophy. Regional and whole body composition has been assessed in children with Duchenne muscular dystrophy (DMD) in comparison with typically developing children using DXA.[224] As noted in earlier studies, a decrease in lean tissue mass was observed. Body fat percentage was higher in children with DMD as well. In both cases, regional differences were noted. Trunk and lower leg lean tissue mass differences were not statistically different from those without DMD. Lean tissue mass was found to correlate well with the corresponding regional peak isometric strength for control subjects, but poor correlations were noted for individuals with DMD.[163,224]

CONDITIONING AND TRAINING

Whether physical fitness components can be affected by training programs is an important question, especially to clinicians who are designing programs for children with disabilities. Bar-Or[19] differentiated between the terms *conditioning* and *training,* which are often used interchangeably. *Physical conditioning* is defined as the process by which exercise, repeated over a specified duration, induces morphologic and functional changes in body systems and tissues. The tissues and systems can include skeletal muscles, the myocardium, adipose tissue, bones, tendons, ligaments, the central nervous system, and the endocrine system. Bar-Or considered conditioning to consist of general exercise for overall physical fitness. *Training,* by contrast, is specific exercise designed to promote changes in performance of a particular type of activity. In the context of this chapter, training is discussed in relation to specific fitness components, but overall conditioning is discussed in reference to children with disabilities.

Fitness Components and Training in Children

Many of the physiologic changes that result from training and conditioning in adults also take place during the process of growth and maturation in childhood. These naturally occurring changes make it difficult to study the specific effects of conditioning and training. The primary components of physical fitness of interest to trainers are cardiorespiratory endurance and physical strength.

Cardiorespiratory Endurance

Controversy exists over whether maximal aerobic power or VO_{2max} can be increased by cardiorespiratory training in children.[19,130] Besides the improvements that occur naturally during growth and maturation, other problems in assessing the effects of training include seasonal differences in activity, difficulty in ensuring that a true VO_{2max} has been reached during the testing process, and the already high level of physical activity in young children.

Krahenbuhl and colleagues[130] as early as 1985 concluded that maximal aerobic power can be significantly increased after regular intensive training in children 8 to 14 years of age. A review of the influence of school-based programs continues to demonstrate the positive effects previously noted, especially in adolescence.[68] The long-term impact of such programs is unknown, and only one study reviewed used a direct measurement of VO_{2max}.[46] Endurance exercise appeared more effective than intermittent exercise. General physical education programs alone were not effective in improving VO_{2max}. Effective activities included running, cycle ergometry, and swimming. Increases of 8% to 10% were measured in effective programs. Some studies reported little or no change in VO_{2max} despite improved long-distance running performance after training programs lasting 1 to 9 weeks.[19]

Less controversy exists over whether training improves cardiorespiratory endurance in adolescence. The effects of training in adolescents appear to be similar to those in adults. The functional and morphologic changes of the cardiovascular and pulmonary systems that take place as a result of training are listed in Table 6.8. Training effects usually include increases in myocardial mass, stroke volume, ventilation, and respiratory muscular endurance.

Muscular Strength and Endurance

Muscular strength is a component of fitness that can be affected by training, especially in children at or after puberty. *Resistance strength training (RST)* refers to training for improved muscular strength by repeatedly overcoming heavy resistance. The practice of resistance strength training is problematic in preadolescent

TABLE 6.8 Cardiorespiratory Function Variables and Response to Training in Children

Function Variable	Change With Training
Heart volume	Increase
Blood volume	Increase
Total hemoglobin	Slight increase
Stroke volume (max, submax)	Increase
Cardiac output (max, submax)	Increase, no change, or decrease
Arteriovenous difference (submax)	No change
Blood flow to active muscle	No change
Ventilation/kg body wt (max)	Increase
Ventilation/kg body wt (submax)	Decrease
Respiratory rate (submax)	Decrease
Tidal volume (max)	Increase
Respiratory muscle endurance	Increase

max, maximal exercise; submax, submaximal exercise.
Adapted from Bar-Or O: Physiologic responses to exercise in healthy children. In Bar-Or O, editor: Pediatric sports medicine for the practitioner, New York, 1983, Springer-Verlag.

children because controversy exists regarding (1) whether children can gain strength and muscle mass, (2) whether gains improve athletic performance, and, particularly, (3) whether children are more susceptible to injury when participating in such training. Despite the controversy, RST has been shown to increase voluntary force production at all ages, may reduce the risk of injury during athletic participation, and may have beneficial effects on important health-related indices such as cardiovascular fitness, body composition, and bone mineral density among others.[32,82,87]

Additionally, it has been reported that the risk of musculoskeletal injury in RST is no greater than for many other sports and recreational activities in which children and adolescents participate.[87] Just as in any exercise program, risks are minimized by appropriate program design, sensible progression, and careful selection of program equipment. Recommendations are available from the American Academy of Pediatrics Council on Sports Medicine and Fitness[3] (http://pediatrics.aappublications.org/cgi/content/abstract/121/4/835), the National Strength and Conditioning Association (http://www.nsca-lift.org/publications/posstatements.shtml)[87] and other sources.[155]

As previously described, the strength increases associated with growth are closely related to increases in muscle mass, including an increase in the numbers of sarcomeres and fibrils per muscle fiber.[153,156] The enhancement of muscular strength caused by growth is estimated to be approximately 1.5 kg per year from age 6 to 14 years. In conjunction with muscular adaptations, neural adaptations associated with improved coordination and motor learning may play a role. For example, the increases in voluntary strength noted with training in prepubescent children have been found to be independent of increased muscle mass or hypertrophy such as that seen in postpubescent children or adults.[31,155,213] Improved motor unit activation and neural adaptations (including more appropriate co-contraction of synergist muscles and inhibition of antagonist muscles, as well as improvements in motor unit recruitment order and firing frequency within the prime movers) are believed to play a role in producing training effects in both adults and children.[155,171,184,199] It has been suggested that during the early stages of training, neural adaptation predominates in altering performance. Muscular adaptation contributes in the later stages of training[31,213] (Fig. 6.9).

A compelling body of scientific evidence indicates that children and adolescents can significantly increase their strength above and beyond growth and maturation, provided the RST is of sufficient intensity, volume, and duration.[84-87,244] Children show a greater increase in strength than do adults when training-induced strength improvements are expressed as a percentage of change. During maximal voluntary contraction, children can develop the same force per unit of muscle cross-sectional area as adults despite differences in absolute strength and muscle size. Programs that incorporate resistance training with skill-related components of fitness over an 8-week period have also been shown to improve cardiorespiratory endurance.[83] Resistance training programs have been shown to influence tendon properties that may minimize risk of injury.[266]

Principles of Training

The principles of an effective training program include specificity, as well as guidelines for intensity, frequency, and duration of exercise. Rules for children are essentially the same as those for adults.

Specificity

The changes that take place in the body as a result of training are specific to the type of exercise performed and to the tissue involved. Myocardial tissue, for example, is affected by long-distance running but not by RST. The type of contraction (concentric, eccentric, or isometric), the number of repetitions performed, the velocity of muscle contraction, and the particular muscles exercised all influence the results of a strength training program. Different sports develop different components of fitness.

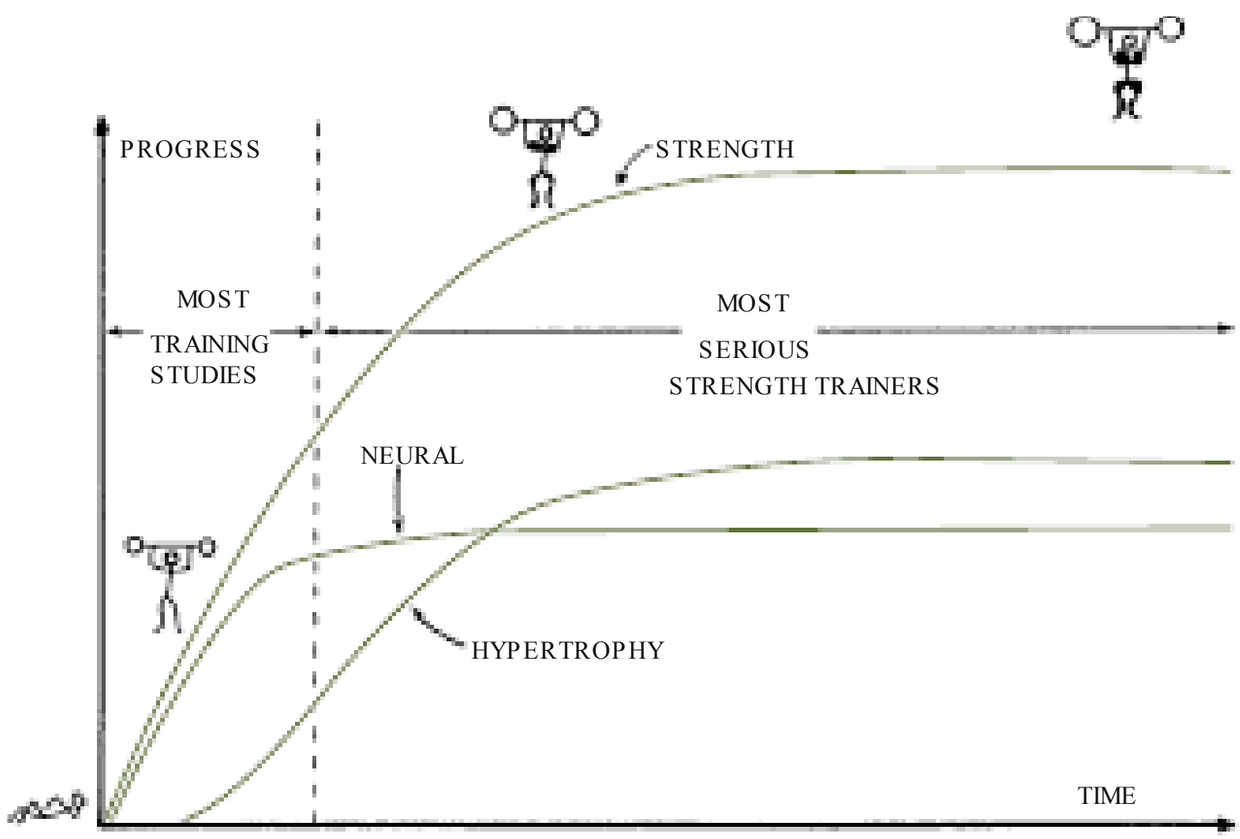

FIG. 6.9 Relative roles of neural and muscular adaptation in strength training. Neural adaptation plays the biggest role in the early phase of training, which can last up to several weeks. Muscular adaptation predominates later and is limited by the extent to which muscles can hypertrophy. (From Sale DG: Strength training in children. In Gisolfi CV, Lamb DR, editors: Perspectives in exercise science and sports medicine: youth, exercise, and sport, vol 2, Indianapolis, 1989, Benchmark Press.)

Intensity

Activity at a certain intensity is required to achieve conditioning or training effects. Intensity should be determined as a percentage of the individual's maximum, because the same amount of activity can represent two entirely different levels of intensity for two different individuals. For example, a child with CP who walks at the same velocity as a typically developing child may consume twice as much oxygen, so walking as a form of exercise for the child with CP is more intense. An average 6- to 12-year-old walking at an average velocity consumes about 25% of VO_{2max}; for a child with CP, oxygen uptake can be as high as 75% to 90% of VO_{2max}.[57]

Intensity threshold refers to the intensity of exercise below which few or no training or conditioning effects are observed.[17] The intensity threshold of maximal aerobic power in adults required to produce a training effect is 60% to 70% of VO_{2max}. The threshold for strength is approximately 60% to 65% of maximal voluntary contraction. The principle of overload in strength training is in part related to the intensity threshold of exercise. *Overload* refers to a task that requires considerable voluntary effort to complete. No specific data are available for intensity thresholds in children, but they are thought to be at least equal to those of adults. Whether intensity thresholds for children with various disabilities are the same as those for children without disabilities is also unknown.

Frequency

The optimal frequency of training depends on the type of program, and frequency is interrelated with intensity and duration. Two or three times per week on nonconsecutive days is a general rule of thumb.[3,19,87]

Duration

Any program, whether a therapeutic program or a fitness program, requires a minimum implementation time before benefits are seen. Most effective conditioning programs last at least 6 to 8 weeks. The optimal duration of an exercise session depends on the type of program. In general, the session should consist of a warm-up phase of 10 minutes, an exercise phase above the exercise threshold for 15 to 30 minutes, and a 5- to 7-minute cool-down period. The warm-up phase has been shown to be important for increasing performance of both aerobic and anaerobic tasks in children.[3,19,87] The warm-up period should include (1) activities to raise core body temperature, (2) stretching exercises, and (3) activities specific to the exercise task. The American Academy of Pediatrics[5] recommends that strength training regimens for children include activities to provide strength training for all parts of the body to ensure balanced development.[3]

The duration of the exercise phase in strength training is sometimes associated with the goal of achieving maximal overload. This is usually done in one of two ways: by repeating brief maximal contractions or by repeating submaximal contractions to the point of fatigue.

Progression

A conditioning or training program must be progressive in its demands for continued improvement. The intensity threshold, the duration of exercise sessions, the number of repetitions performed during a session, or the frequency of exercise sessions may need to be increased. All contribute individually and collectively to the progression of the exercise program.

Conditioning in Children with Disabilities

Cerebral Palsy

As children with CP approach and move through adolescence, an important aspect of function is the ability to maintain ambulation. Oxygen uptake during ambulation in preadolescent children with CP (ages 6 to 12 years) is more than twice that of typically developing children walking at the same velocity.[232] If body weight and adiposity increase in adolescence without an increase in muscular strength, maximal aerobic capacity decreases, and the task of walking becomes more and more difficult. Growth in mass is a cubic function (volume), and growth in strength is a function of the square (cross-sectional muscle area). As previously mentioned, muscles increase first in mass, then in strength.[153] During the adolescent growth spurt, mass increases at a faster rate than does strength. For typically developing children, this process occurs without a noticeable deficit or loss of function, but for children with CP, loss of function sometimes occurs because the rate of increase in strength is inadequate to support the rate of increase in muscle mass. A major goal of physical therapy for adolescents with CP is maintenance of the ability to ambulate throughout the growth spurt. If a child has maximal strength and aerobic capacity on entering the growth spurt, function is also likely to be at maximal capacity. Conditioning in a child with CP could play a vital role in the process of maximizing the potential not only of the adolescent but of the preadolescent and school-aged child as well.

The ultimate goal of conditioning programs for children with CP is similar to the goal for all children—to promote life habits and physical health benefits. In addition, children with CP are often faced with deterioration of capacity during adolescence and adulthood. Children who lack the requisite fitness capacity may not be able to achieve their own maximum potential in gross motor activities. Daily physical activity has been found to correlate inversely with the energy cost of walking.[158] Verschuren and colleagues used field tests of physical fitness to assess gross motor capacity and found that performance-related fitness items and functional muscle strength exhibited higher correlations to gross motor capacity than aerobic capacity.[259] This finding supports previous research suggesting that short-term muscle power or anaerobic capacity is a better measure of gross motor capacity than aerobic capacity in children with CP.

The intensity of physical activity is an important aspect of cardiorespiratory fitness in children with CP similar to typically developing children. Children who spend more time in vigorous physically activity (> 3410 counts/min as measured by an accelerometer) have been shown to exhibit greater cardiorespiratory fitness than those who engage in moderate or light physical activity.[210] Current guidelines recommend that children accumulate 60 minutes of moderate to vigorous activity daily. The only guideline for vigorous activity is that "vigorous-intensity activities should be incorporated … at least 3x/week."[281] Children with CP may meet the physical activity guideline with moderate physical activity and may still exhibit low cardiorespiratory fitness. A clinical trial of a high-intensity training program for children with CP and other disabilities is under way.[286] The implications for exercise prescription for programs to increase or improve fitness is clear—to improve outside of cardiorespiratory fitness, vigorous activity must be included. Clinical programs implementing fitness exercise prescription for children with disability including CP are becoming more common with a goal not only to promote wellness but also to reduce/prevent future health risks and prepare for elective surgical procedures.

Along with programs to increase and improve cardiorespiratory fitness, attention is also given to the benefits of strengthening in both children and adolescents with CP. The work of Damiano and colleagues has been instrumental to developing the awareness and benefits of resistance training programs. Functional improvements in both gait and Gross Motor Function Measure scores were noted, as was decreased spasticity.[59–61] A systematic review evaluated 20 studies related to exercise programs for children with cerebral palsy.[260] Of the 20 evaluated, only 5 were randomized controlled trials, which provide the optimal design to test treatment (in this case, training) effects.[69,70,189,245,254] On the basis of the strength training programs reviewed, evidence exists supporting the view that progressive resistance exercise can increase the ability to generate force in children with CP.[260] Functional exercises combining aerobic capacity, anaerobic capacity, and muscle strength have demonstrated a 22% increase in strength in previous studies.[258] Unfortunately, the benefits gained during training often are only partially maintained at follow-up.[254,258] More recent studies of progressive resistive exercise training programs have demonstrated improvements in strength but not improvements in walking ability.[216,217] Context-specific strength training for gait or other functional activities is likely an important factor to consider.

Evidence suggests that neither regular physical education classes nor habitual activities are sufficient to induce conditioning changes in children with CP.[27,74] The program must increase in intensity beyond habitual exercise levels. The duration of the overall program should be longer than 6 weeks; results of 6-week training programs are equivocal.[80] Target heart rate was typically maintained for 15 to 30 minutes in most studies. Longer-duration protocols have been reported.[216] Activities in accordance with the child's ability were used; examples are cycle ergometry, swimming, running, and jogging. Although the importance of increasing vigorous activity in conditioning regimens cannot be overemphasized, decreasing sedentary behavior is imperative as well.[257] Guidelines for activities and field tests are readily available.[14,139,259]

Cystic Fibrosis

Results of studies in children and adolescents with cystic fibrosis (CF) that emphasized aerobic conditioning for 3 to 5 months suggest that VO_{2max}, endurance of respiratory muscles, and pulmonary function all show improvement.[181,284] Jogging, cycling, swimming, weight lifting, and calisthenics of various durations and combinations were used. Statistically significant increases in strength, balance, and submaximal aerobic exercise capacity have also been reported after a 4- to 6-week inpatient rehabilitation program emphasizing sporting-type activities.[106] Based on a growing body of research, it is now well accepted that exercise and exercise training programs are effective therapy methods to improve aerobic exercise capacity and strength as attributes of physical fitness and lung function in individuals with CF.[127,182,215,219]

In addition to the positive effects of conditioning on physical fitness, clinical benefits in the management of the disease have been reported.[20,106] Increased coughing and clearance of mucus may reduce the need for chest therapy to manage secretions.[192]

The effects of exercise on children with CF and other clinical populations must be closely monitored to reduce or avoid potential detrimental effects. Particular concerns in the population with CF are dehydration (especially in high heat) and oxygen desaturation.[192] See Chapter 26 for more information on the management of CF.

Muscular Dystrophy

The role of exercise in DMD continues to be controversial largely due to a lack of evidence. Markert and colleagues summarized potential methods and outcome measures to be used in studying the effects of exercise on the underlying mechanisms.[159]

There appears to be a consensus that low to moderate resistance and aerobic training may be helpful in patients with slowly progressive myopathic disorders.[2,218,235,236,256] A training program instituted for individuals with Becker muscular dystrophy demonstrated improvement in aerobic capacity without rendering patients susceptible to structural or mechanical damage to muscle.[235] Assisted bicycle training was also found to be feasible and safe for boys in one of the first randomized controlled trials in this population.[119] The role of cardiopulmonary exercise testing may offer the potential to detect moderate to severe exercise limitations in participants with only mild functional and motor impairments.[22] Clearly, more work needs to be done in this area.

Children With Obesity

Although addressed elsewhere in this chapter, it is important to highlight known evidence regarding the influence of training and conditioning programs on children with obesity. Studies suggest that resistive training programs are safe and result in positive and significant changes in body composition, strength, and power.[26,165,220,226,265] Most studies found that an 8-week program was sufficient to achieve significant effects. Most resistive exercise programs or aerobic exercise programs did not demonstrate significant changes in peak oxygen uptake.[26,265] As in other areas, better-controlled randomized trials are needed to substantiate evidence.

SUMMARY

This chapter was designed to provide information on physical fitness and conditioning in children with typical development for promoting health and preventing disease. The components of fitness, how they are tested, and how they contribute to health were reviewed. An understanding of physical fitness, physical activity, and conditioning is valuable for appreciating the impact of disabling conditions on these variables, but health-related physical fitness is important for reducing future health risks in every child, regardless of the presence or absence of disability. Preadolescent fitness may be especially important to children with disabilities because of the effects particular disabilities may have on children as they enter puberty and adulthood. The design of exercise programs (their intensity, frequency, and duration) should encompass the minimal requirements for physical fitness, as well as incorporate therapeutic goals. Exercise programs should be designed so that the energy requirements for accomplishing day-to-day activities through the growth period are met. Meeting this goal is likely to require additional exercise beyond current therapy or physical education. One of our goals as pediatric physical therapists should be to ensure, to whatever extent possible, that our clients end their childhood at a fitness level suitable to a healthy adulthood. Research is needed to document the extent to which this goal can be met for specific populations and levels of disability.

Much research remains to be done in those without disabilities as well. Reliability and validity studies must continue on criterion-based measures now being used to determine minimal fitness levels. Research must establish reliable, valid,

and universal criteria, both in the laboratory and in the field. Continued identification of the relationship between childhood physical activity and fitness and health in adulthood is vital to our overall understanding of health-related fitness.

Research to benefit those with disabilities has barely begun. With an inadequate base of research in children without disability, developing standards of fitness for those with specific disabilities begins at a disadvantage. A question that remains to be answered is whether the fitness performance criteria for children without disabilities are valid for children with disabilities or special needs. Experience with development of testing and measurement tools for other purposes would suggest that they are not. Are children with disabilities such as CP more fit because they expend in walking an amount of energy equivalent to that of a nondisabled person walking up and down stairs all day long? Are the thresholds and target zones for fitness improvement the same for children with a variety of disabilities as for children with typical development? How are conditioning and training programs best designed for children with disabilities? Do conditioning programs initiated before the onset of puberty help maintain fitness during and after puberty? What physiologic and behavioral factors limit a child's capacity to improve fitness variables or to exercise? How much exercise is detrimental? How do presurgical strengthening programs affect the recovery of strength after surgery? Questions such as these represent only the beginning of our quest for understanding. The journey has just begun.

Juvenile Idiopathic Arthritis

Janjaap van der Net, Paul J.M. Helders, Sr., Tim Takken

Chronic arthritis in childhood can result from any one of a heterogeneous group of diseases, of which juvenile idiopathic arthritis (JIA) is the most common. The disease causes joint swelling, pain, and limited mobility and can significantly restrict a child's activities. Box 7.1 lists the common clinical manifestations of JIA. Other conditions that may cause childhood arthritis include juvenile psoriatic arthritis (JPsA), juvenile ankylosing spondylitis (JAS), and other enthesitis-related arthritides. Arthritis may also be a feature of juvenile scleroderma, systemic lupus erythematosus, and juvenile dermatomyositis.

This chapter provides an overview of the body function and structure impairments, activity limitations, and participation restrictions common to JIA and describes the role of the physical therapist as a member of the rheumatology team in the examination, evaluation, and intervention for the child with arthritis. Outcome instruments appropriate for use in JIA, issues related to school and recreational activities, surgical procedures, and adherence to therapeutic regimens are discussed. Case scenarios illustrate the therapeutic management of a child with JIA.

ROLE OF THE THERAPIST

Physical therapists (PTs) are essential members of the pediatric rheumatology team, which includes the pediatric rheumatologist, nurse, occupational therapist, pediatric ophthalmologist, pediatric orthopedist, and pediatrician. Other pediatric specialists, including dermatologists, cardiologists, orthotists, psychologists, and social workers, provide occasional consultation as needed. After a thorough history the PT conducts a comprehensive examination to identify impairments of body structures and functions relevant to physical therapy intervention and caused by the disease and determines their relationship to observed or reported activity and participation restrictions. Based on an evaluation of these findings, the PT develops a prioritized problem list and an intervention plan to reduce functional limitations, to prevent or minimize secondary problems, and to improve activity and participation levels (Table 7.1). Therapists work with parents and the child to develop a "joint health and self-management" program that includes balanced rest and exercise and to provide guidelines for choosing (extracurricular) physical activities and consult with school personnel to ensure the child's full participation in educational activities.

The role of the therapist varies based on stage and progression of the disease and the care setting; often more than one PT is involved in the child's care. Physical therapists working in a specialized pediatric rheumatology center may perform the initial assessment, set treatment goals, plan a "joint health and self-management" program, and monitor the child's functional status at routine clinic visits. Therapists within the child's home, school, or community usually provide direct services. The frequency of therapy varies widely and depends on the child's physical status, reimbursement for therapy services, and the availability of therapists. Web-based technologies are increasingly utilized, also by PTs, to compensate for limited resources or to increase health service levels such as e-consultation and e-health monitoring or e-learning programs.

BACKGROUND INFORMATION

DIAGNOSIS AND CLASSIFICATION

Three systems are used to diagnose and classify childhood arthritis: the American College of Rheumatology (ACR) criteria for juvenile rheumatoid arthritis (JRA),[8] the European League Against Rheumatism (EULAR) criteria for juvenile chronic arthritis (JCA),[19] and the International League of Associations for Rheumatology (ILAR) criteria for juvenile idiopathic arthritis (JIA).[71] The ILAR criteria are used in this chapter. All three systems are currently based on the disease phenotype; however, increasing insight in the genotype of JIA will gradually lead to new classifications.[72] Juvenile idiopathic arthritis is not a single disease but a term that encompasses all forms of arthritis that begin before the age of 16 years, persist for longer than 6 weeks, and are of unknown cause.[72] The term represents, therefore, an exclusion diagnosis. Because there are no definitive laboratory tests for JIA, the diagnosis is primarily clinical and sometimes is undecided until a clear picture of the disease evolves. Table 7.2 shows the characteristics of the different disease types: systemic arthritis (sJIA), oligoarthritis, polyarthritis (polyJIA), enthesitis-related arthritis, and psoriatic arthritis. All are defined by the clinical signs and symptoms observed during the first 6 months of the disease.

An oligoarticular onset occurs in 27% to 56% of children with JIA, mostly girls between 2 and 4 years of age.[72] Disease signs include low-grade inflammation in four or fewer joints, most often the knee, followed in frequency by the ankles and

BOX 7.1 Primary (P) and Secondary (S) Clinical Manifestations of Juvenile Idiopathic Arthritis (JIA)

Primary

Joint swelling, pain, stiffness
Morning stiffness
Muscle atrophy; weakness; poor muscle endurance
Acute or chronic iridocyclitis (most common in oligoarticular JIA)
Systemic manifestations (may be severe in systemic JIA; mild to moderate in polyarticular JIA)

Secondary

Limited joint motion; soft tissue contracture
Fatigue
Decreased aerobic capacity; reduced exercise tolerance
Growth abnormalities (local and general)
Osteopenia; osteoporosis (increased risk with long-term use of oral corticosteroids)
Difficulties with activities of daily living
Possible activity/participation restrictions

Primary and Secondary

Gait deviations

elbows (Fig. 7.1). The hip and small joints of the hand are usually spared. The joint is swollen and may be warm but is not always painful. Systemic signs such as skin rash or spiking fever are unusual, but about 30% of children develop iridocyclitis, an asymptomatic inflammation of the eye that may lead to functional blindness. These children must have their eyes examined by an ophthalmologist at diagnosis and, depending on the risk, every 3 to 4 or 6 to 12 months. Systemic or topical corticosteroids are used to control the inflammation.

Polyarticular JIA (Fig. 7.2), subdivided into a rheumatoid factor (RF)–positive and an RF factor–negative polyarthritis and defined as arthritis in five or more joints, occurs in 2% to 28% of children with JIA, mostly girls. The RF factor–positive form has an early peak at 2 to 4 years and a later peak at 6 to 12 years, and RF factor–negative polyarthritis has an onset at late childhood or adolescence.[72] Onset is often insidious, with arthritis noted in progressively more joints. Arthritis is symmetrical, affects both large and small joints, and may include the cervical spine and temporomandibular joints. Joints are swollen and warm but rarely red. Systemic symptoms are usually mild and include low-grade fever and mild to moderate hepatosplenomegaly and lymphadenopathy. About 19% develop iridocyclitis. The RF-positive group, mostly females with disease onset

TABLE 7.1 Interventions in Juvenile Idiopathic Arthritis

Outcome	Level of ICF	Intervention	Reference
Physical Function			
Morning stiffness	Function	Movements of any kind, especially in extension direction of joints and stretching biarticular muscles	None
Joint range of motion	Function	Gentle movements of any kind, especially in extension direction of joints and stretching biarticular muscles	None
Muscle strength	Function	Isometric and isokinetic muscle strength exercise	Sandstedt E, 2013
Physical fitness (health related)	Function	Aerobic exercise	Takken et al., 2003
Anaerobic fitness	Function	Anaerobic exercise	Klijn PH, (2004)
Pain behaviors	Function	Relaxation with: Mindfulness, Tai Chi, or Qigong	Stephens (2008)
Gait	Function	Insoles (soft or supinating, retrocapital support) or rocker-bottom external soles	None
Physical Activity and Participation			
Gross and fine motor performance	Activity	Sports and gym activities; play (adapted)	None
School function (writing)	Activity	Pencil thickeners, floating-ball pencils, keyboard and tablet writing	None
Walking	Activity	Nordic walking	None

TABLE 7.2 Frequency, Age at Onset, and Sex Distribution of the International League of Associations for Rheumatology (ILAR) Categories of Juvenile Idiopathic Arthritis

	Frequency[a]	Onset Age	Sex Ratio
Systemic arthritis	4%–17%	Throughout childhood	F > M
Oligoarthritis	27%–56%	Early childhood; peak at 2–4 years	F >>> M
Rheumatoid factor–positive polyarthritis	2%–7%	Late childhood or adolescence	F >> M
Rheumatoid factor–negative polyarthritis	11%–28%	Biphasic distribution; early peak at 2–4 years and later peak at 6–12 years	F >> M
Enthesitis-related arthritis	3%–11%	Late childhood or adolescence	M >> F
Psoriatic arthritis	2%–11%	Biphasic distribution; early peak at 2–4 years and later peak at 9–11 years	F > M
Undifferentiated arthritis	11%–21%	Not known	Not known

[a]Reported frequencies refer to percentage of all juvenile idiopathic arthritis.

FIG. 7.1 Oligoarticular juvenile idiopathic arthritis causing swelling and flexion contracture of the left knee in a 2-year-old girl. (From Zitelli BJ, McIntire SC, Nowalk AJ: Zitelli and Davis' atlas of pediatric physical diagnosis. 6th ed. Philadelphia, Saunders; 2012.)

in late childhood or adolescence, follows a disease course similar to that seen in adults with rheumatoid arthritis. Individuals may have rheumatoid nodules on the elbows, tibial crests, and fingers and may develop erosive synovitis early in the disease course. Nodules are less common in children with RF-negative disease, and fewer joints are affected. Persistent arthritis may occur, causing juxta-articular osteopenia, muscle atrophy, weakness, contractures, and growth disturbances.

Systemic JIA occurs in 4% to 17% of cases. The disease arises as often in boys as in girls and does not know a preferential age onset. The diagnostic marker is a spiking fever of 39°C (102.2°F) or higher that occurs once or twice daily (afternoon or evening) for at least 2 weeks, with a rapid return to normal or below between spikes. The fever is accompanied by a typical evanescent rash (discrete, erythematous macules) that is most often found on the trunk or limbs but may be seen on the face, palms, and soles of the feet (Fig. 7.3). Other systemic signs include pleuritis, pericarditis, myocarditis, hepatosplenomegaly, and lymphadenopathy. Systemic disease may precede arthritis by several months or years. Fever, rash, and pericarditis often subside after the initial disease period but may recur during periods of exacerbation of the arthritis.[12,69,72]

Incidence and Prevalence

Childhood chronic arthritis is not rare. Reported incidence and prevalence vary considerably throughout the world, and the true frequency is unknown. Based on estimations in the industrialized world in an under–18-year-old population of 225 million, the incidence figure is between 11,700–22,500 and prevalence ranges from 186,750–900,000.[11] The reported peak age at onset is still between 1 and 3 years for the total group and for girls, primarily those with oligoJIA and polyJIA.[86] Disease onset for boys showed two peaks, one at 2 years, representing mostly boys with polyJIA, and another between 8 and 10 years of age that may partially represent children with JAS. Almost twice as many females as males develop JIA. The ratio of girls to boys is 3:1 for oligoJIA (5:1 for those with iridocyclitis) and 2.8:1 for polyJIA.[11]

Origin and Pathogenesis

The cause and pathogenesis of JIA are still poorly understood but seem to include both genetic and environmental components. The prevailing theory is that it is an autoimmune inflammatory disorder, activated by an external trigger, in a genetically predisposed host. A viral or bacterial infection often precedes disease onset. The notion that an infection triggers JIA in genetically susceptible individuals is attractive but not yet fully unraveled.[72] Physical trauma may be associated with onset but may just draw attention to an already inflamed joint. The difference in onset types and disease course, the higher prevalence among girls, the narrow peak age periods of onset for all but systemic JIA, and the extensive immunologic abnormalities suggest that JIA may not be a single disease. Different etiologic vectors may be responsible for each onset type, or a single pathogen may cause distinct clinical patterns as it interacts with the host.

The role of the immune system in the pathogenesis and persistence of inflammation is evident in the altered immunity, abnormal immunoregulation, and cytokine production. The T-cell abnormalities and the pathology of the inflamed synovium suggest a cell-mediated pathogenesis. The presence of multiple autoantibodies and immune complexes and the complement activation indicate humoral abnormalities. The importance of genetic predisposition to JIA is not completely understood. Many of the suspected genetic predispositions are within the major histocompatibility complex (MHC) region of chromosome 6, but the pathogenesis may involve the interactions of multiple genes. Recent studies indicate that correlations found between human leukocyte antigen (HLA) specificities and various types of JIA may have specific risks and protective effects that are age-related for each onset type and some course subtypes.[64]

Pharmacologic Management

The goals of pharmacologic therapy in JIA are to induce remission of the disease and/or control the arthritis, thereby preventing joint erosions, and to manage extra-articular manifestations.[73] Children with severe or persistent disease often require a carefully orchestrated combination of sometimes-aggressive drug therapies, started early in the disease. A core set of six outcome variables is often used in clinical trials to determine subjects' responses to medical therapy.[24] These include physician global assessment of disease activity, parent/patient assessment of overall health status, functional ability, number of joints with active arthritis, number of joints with limited motion, and erythrocyte sedimentation rate (ESR). A positive clinical response is defined as improvement of at least 30% from baseline in at least three of the six variables, with no more than one of the other variables worsening by more than 30%.

Currently (inter-)national consensus on the prescription of medication is published yearly by the Childhood Arthritis and Rheumatology Research Alliance (CARRA). These are referred to as consensus treatment plans (CTPs) and are available on CARRA's website. Because novel therapeutic agents are entering the clinical practice with ever-increasing tempo, it is necessary to review actual consensus statements such as those provided by CARRA. Therefore only a few generic treatment principles are

FIG. 7.2 Presentations of polyarticular juvenile idiopathic arthritis. (A) Failure of development of the lower jaw some 5 years after systemic onset of disease. The neck is short and slightly flexed. (B) Polyarthritis affecting the small joints of the hands and wrists. (C) Dactylitis seen in toes of a child with psoriatic juvenile idiopathic arthritis. (D) Severe polyarticular disease. ([A] From Hochberg MC: Rheumatology. 6th ed. Philadelphia: Mosby; 2015. [B] From Denman G, Jandial S, Foster H: Diagnosing arthritis in children, Paediatr Child Health 25:541-548, 2015. [C] Image courtesy of © UMB Medica/RheumatologyNetwork.com. [D] From Kanski JJ, Bowling B: Clinical ophthalmology: a systematic approach. 7th ed. Edinburgh, Saunders; 2011.)

touched on briefly here. The references as well as the websites provide informative algorithms and guidelines for prescription.[76] Nonsteroidal anti-inflammatory drugs (NSAIDs), such naproxen, tolmetin, and ibuprofen, are still the most widely used first-line therapy. The most common adverse effect is gastrointestinal irritation, although NSAIDs that selectively inhibit the cyclo-oxygenase 2 (COX-2) enzyme may limit this problem. Methotrexate (MTX) is the most common disease-modifying antirheumatic drug (DMARD) prescribed for children with polyJIA and sJIA (Fig. 7.4).[73] The drug is usually administered orally once a week, although subcutaneous injection is given if the response is inadequate or if the child experiences adverse effects with the oral dose, including gastrointestinal upset. Although liver toxicity in children taking MTX appears to be rare, physicians check blood counts and liver enzymes periodically. Data on the health risks associated with long-term use of MTX in children are not yet available but expected to be nil.

Patients with a poor prognosis who fail to respond to MTX are treated with one of the so-called biologic medications that targets the tumor necrosis factor (TNF), a cytokine responsible for many of the effects of inflammation.[60] These drugs include etanercept, infliximab, and adalimumab, but many more enter the market these days. Systemic glucocorticoid drugs are reserved for children, mostly those with sJIA who do not respond to other therapies. Although steroids have a potent anti-inflammatory effect, they do not alter disease course or duration. Serious adverse effects of long-term oral steroids include iatrogenic Cushing's syndrome, myopathy, growth disturbance, osteoporosis and fracture, diabetes mellitus, obesity, and increased susceptibility to infection. For children with refractory disease who are steroid dependent, aggressive therapy with cyclosporin A or cyclophosphamide may provide some benefit.[76] Intra-articular injections of long-acting corticosteroids are used successfully to treat severely inflamed and swollen joints.[76] A study found that intra-articular steroid injections for lower extremity joints decreased the incidence of leg length discrepancies, a major cause of gait and postural abnormalities in children with JIA.[81]

FIG. 7.3 Typical rash of systemic-onset juvenile idiopathic arthritis in a 3-year-old boy. The rash is salmon colored, macular, and nonpruritic. Individual lesions are transient, occur in crops over the trunk and extremities, and may occur in a linear distribution (Koebner's phenomenon) after minor trauma such as a scratch. (From Petty RE, Laxer RM, Lindsley CB, et al., editors: Textbook of pediatric rheumatology. 7th ed. Philadelphia, Elsevier; 2016.)

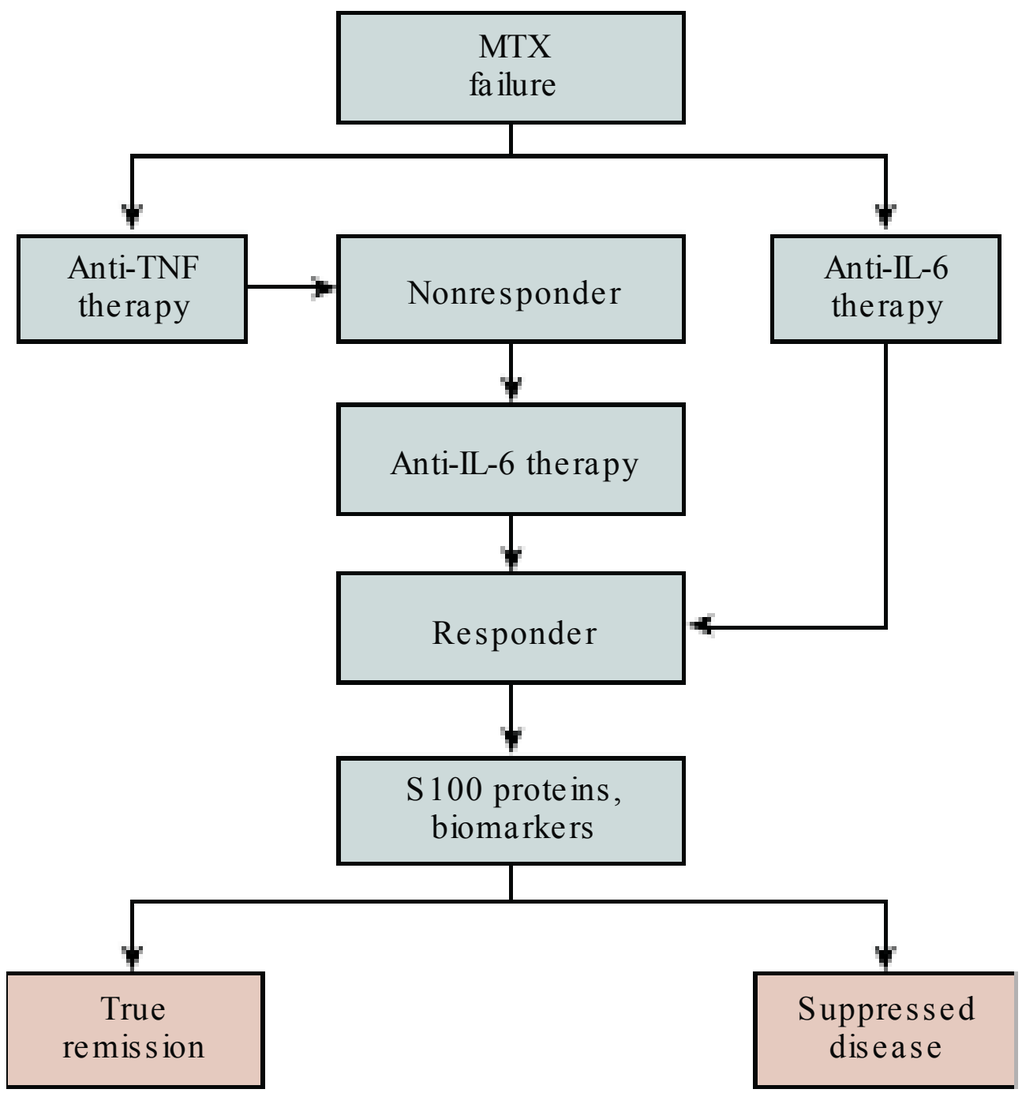

FIG. 7.4 Treatment options for patients with JIA include MTX as well as biologic agents that target TNF or the IL-6 receptor. After clinical remission is achieved, S100 proteins and other biomarkers could help to differentiate between "true" remission and suppressed disease. JIA, juvenile idiopathic arthritis; MTX, methotrexate. (From Prakken B, Martini A: Paediatric rheumatology in 2014: digging deeper for greater precision and more impact in JIA. Nat Rev Rheumatol 11:70-72, 2015.)

PROGNOSIS

Studies assessing outcomes of JIA have provided inconsistent or conflicting results. Studies over the past 10 years have shown that only 40% to 60% of patients had inactive disease or clinical remission at follow-up. Despite long-term persistence of disease activity in most patients, a pronounced improvement in functional outcome has been documented in the past decades.[28,73] Poor articular and functional outcomes in sJIA and polyJIA are linked to the presence of hip involvement and polyarthritis in the first year of disease activity.[83] Children with oligoJIA have the best prognosis for joint preservation and function but may develop contractures during active disease and later degenerative arthritis. They also remain at high risk for inflammatory eye involvement. About 5% to 10% follow an extended disease course, adding multiple joints after the first 6 months. Those who are RF+ often follow a course similar to that of children with RF+ polyJIA, with persistent disease and poor functional outcomes. In contrast, outcome is usually good in boys with disease onset at 9 years of age or older, who are positive for the *HLA-B27* gene, and have arthritis mostly in the hip and sacroiliac joints.

Reports of long-term functional outcomes in JIA vary, possibly because of differences in study methods. And these reports date back to the millennium change, which limit their importance because the treatment paradigm has changed significantly.[73]

BODY FUNCTION AND STRUCTURE

Joint Structure and Function

The cardinal signs of inflammation are swelling, end-range stress pain, stiffness, and loss of full range of joint motion. Swelling around a joint may be the result of intra-articular effusion, synovial hypertrophy, soft tissue edema, or periarticular tenosynovitis. The anatomic bony landmarks of the joint may also be enlarged as a result of bony overgrowth due to increased blood supply to the inflamed area. Swelling and protective muscle spasm contribute to pain. This muscle spasm is referred to as a contraction deformity, in contrast with the more common conception contracture, which refers to a morphologic change in the periarticular soft tissue. Inactivity stiffness most noted upon awakening (also referred to as "morning stiffness") and after periods of prolonged sitting is a common indicator of disease activity.

Chronic inflammation causes abnormalities in joint structure and function. Increased production of synovial fluid stretches and weakens the joint capsule and adjacent structures, leading to ligamentous laxity and joint instability. Massive overgrowth of the synovium, called pannus, spreads over and invades the articular cartilage, releasing inflammatory enzymes into the synovial fluid. In some patients, erosions in the articular cartilage and subchondral bone cause irregularities in the joint surface, compromising alignment, congruency, and stability.[11] Early radiographs show periarticular swelling with widening of the joint space, juxta-articular osteopenia, and periosteal new bone.[74] Radiographs of joints placed under physiologic strain (i.e., tested in function) provide a more precise indication of the quality of the periarticular soft tissue condition (e.g., laxity of wrist ligaments may be visualized in the translation of carpal bones).[33] General demineralization, thinning and loss of articular cartilage, marginal erosions, and osteophytes occur

with persistent disease.[11] Nutritional deficiencies, low body weight, and decreased physical activity may result in low bone density and risk for fracture. This will be exacerbated in case of long-term use of systemic corticosteroids.[56] Joint contractures usually result from intra-articular adhesions and fibrosis of adjacent tendons.

The therapist should be aware of possible patterns of joint restriction in JIA and their potential effects on function (Table 7.3). Arthritis may occur in any joint, but the large joints are affected most often. Hip arthritis occurs in 30% to 50% of children, mostly those with sJIA and polyJIA.[83] Early signs of hip disease may include leg length inequality, pain in the groin, buttocks, medial thigh, or knee, and a gluteus medius limp. A child may compensate for a mild hip flexion contracture with increased lumbar lordosis. Children with oligoJIA may lose hip motion secondary to knee flexion contracture and leg length discrepancy. The knee is the joint most often affected in oligoJIA, but it is also involved in other disease types. Flexion contracture may result from intra-articular swelling, joint immobility, spasm of the hamstrings, and shortening of the tensor fasciae latae. Chronic synovitis, with overgrowth of the medial femoral condyle, results in a valgus deformity that is exaggerated by tightness in the iliotibial band (ITB) (see Fig. 7.2). Ankle arthritis occurs in all disease types, but involvement of the small joints of the feet is more common in polyJIA. Problems may initially include loss of ankle dorsiflexion or of plantar flexion and metatarsalgia. In prolonged disease subluxation of the metatarsophalangeal joints, hallux valgus, hallux rigidus, hammer toes, and overlapping toes may become prominent. Arthritis of the subtalar joint may result in hindfoot valgus with forefoot pronation (Fig. 7.5), although some children develop calcaneal varus and a forefoot cavus deformity. Both result in a walking pattern with toeing in or toeing out respectively.

The cervical spine and the temporomandibular joints are frequently involved. Early signs of neck involvement include pain and stiffness in the back of the neck, with loss of extension and limitations in rotation and lateral flexion or restricted shoulder elevation. Atlantoaxial subluxation may occur early in the disease, placing the child at risk for injury from trauma or during intubation for surgery. Cervical spine ankylosis is sometimes seen and can cause similar problems during surgery.

Temporomandibular joint involvement includes difficulties in chewing food, loss of range of motion as shown by a restriction in mouth opening, and pain in the ear region. Chronic involvement of temporomandibular joints will lead to an overgrowth of the jaw or to micrognathia (undergrowth of the mandible) and difficulties in mouth closure. Even the joints of the larynx and the area of the vocal cords can be affected, leading to hoarseness of the voice.

Restrictions in shoulder rotation, flexion, and abduction may occur with arthritis in the glenohumeral joint, as well as in the acromioclavicular, sternoclavicular, and manubriosternal joints. Elbow flexion contractures occur early and may be accompanied by loss of forearm supination. Arthritis in the wrist and small joints of the hands is most common in polyJIA. The pattern and extent of involvement are related to disease type, the child's age, and maturation of the epiphyses at disease onset. Wrist malalignment associated with subluxation and undergrowth of the ulna, with ulnar deviation, occurs in children with disease onset at a young age. Those 12 years or older at onset have a pattern typical of adults, with radial deviation. The metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints are also involved, either directly by synovitis or indirectly as a result of inflammation in adjacent joints or tendon sheaths.

Muscular Structure and Function

The different stages of the disease will show a difference in muscular structures and functions.

In the acute phase of the disease, periarticular musculature of the affected joints will show spasm and hypertonus, also referred to as contraction deformity.

In subacute and chronic stages of the disease, muscle atrophy and weakness are more pronounced, especially near the affected joints. This also may occur in distant areas and can persist long after remission of the arthritis.[10,24,35] Contributing factors to an altered muscle structure and function include alterations in anabolic hormones, production of inflammatory cytokines and high resting energy metabolism,[48] abnormal protein metabolism,[34] motor unit inhibition from pain and swelling, and disuse. Also a disease onset very early in life, with long periods of active arthritis, may negatively affect muscle development.[103]

Systemic muscle flexibility, tested with a sit-and-reach test, may also be limited as a result of a decreased level of physical activity.

Growth Disturbances and Postural Abnormalities

Retardation of linear growth is associated with extended periods of active disease and is exacerbated by long-term use of systemic steroids. Accelerated growth may occur during remission if the epiphyses are still open. Puberty and the appearance of secondary sex characteristics may be delayed. Osteopenia, mainly in the appendicular skeleton, may be due to inadequate bone formation for age, low bone turnover, and depressed bone formation.[9,11] These circumstances may contribute to an increased risk of bone fracture. Increased blood supply to the inflamed joint early in the disease may cause accelerated growth of the ossification centers, resulting in bony overgrowth. Leg length discrepancies often occur as a result of unilateral knee arthritis. Growth discrepancies between ulnar and radial bones in wrist arthritis have been reported to contribute to instability and functional loss.[65] Premature closure of the growth plates may also occur. This may be widespread and symmetrical, as seen in the small hands and feet of some children with polyJIA, or isolated to a single digit.[11] Micrognathia may result from temporomandibular joint arthritis.

The therapist should observe the child's postural alignment in sitting and standing. Hip and knee flexion contractures, genu valgus, and foot deformities will affect the child's posture in standing. Children with asymmetrical cervical spine arthritis may present with torticollis. Children with leg length differences may develop a functional scoliosis. Small lifts of known thickness placed under the shorter leg with the child standing will level the pelvis and confirm or rule out idiopathic scoliosis.

Physical Fitness: Health-Related Fitness and Performance-Related Fitness

Physical fitness is known to be limited in a multitude of childhood chronic conditions, among them JIA.[96] Physical fitness can be divided into various components, namely, health-related fitness (peak oxygen uptake [VO_2peak]) and performance-related fitness (muscle strength, anaerobic capacity). The VO_2peak is most frequently assessed using progressively graded exercise

TABLE 7.3 Joint and Soft Tissue Restrictions and Clinical Adaptations in Juvenile Idiopathic Arthritis (JIA)[a] [2,4,17,46,105]

Clinical Manifestations	Restrictions/Adaptations
Cervical Spine	
In polyJIA and sJIA	Loss of EXT, rotation, side FLEX
Inflammation, narrowing, then fusion; observed first in C2-C3, but may progress to involve the entire cervical spine[b]	May develop torticollis if asymmetrical Intubation for anesthesia[b]
Dysplasia of vertebral bodies	Eye movements or turning body compensates for ↓neck ROM
Odontoid process instability (less common than in adult RA)	
Temporomandibular Joint	
Common in polyJIA; less common in oligoJIA; often associated with cervical spine disease	Restriction in opening mouth; pain on chewing; may need orthodontia
Mandibular asymmetry if unilateral involvement	Greater functional restrictions if cervical spine is involved
Undergrowth of the mandible (micrognathia); malocclusion of the teeth	EXT is restricted
Shoulder Complex	
Most common in polyJIA[b]	Loss of active GL-H ABD and IR first limitations noted; limited
Overgrowth of humeral head with irregular shape, shallow glenoid fossa	FLEX, tightening of pectorals and scapular protractors; more dysfunction when elbow and wrist involved
Subluxation may occur	
Elbow	
Involved early in disease course[b]	EXT lost early; eventual limitation in FLEX and forearm rotation
Occurs in all types; symmetrical in polyJIA and sJIA; asymmetrical in oligoJIA[b]	Shoulder ROM initially compensates for ↓supination; loss of > 45° EXT restricts ability to push off from chair
Overgrowth of radial head restricts ROM	
Proximal radioulnar joint involved[b]	Wrist involvement accentuates loss of pronation and supination
Ulnar nerve entrapment possible	
Wrist	
All types; starts early; symmetrical in polyJIA and sJIA; unilateral in oligoJIA[b]	Rapid loss of EXT; weakness of extensors; FLEX contracture and volar subluxation
Accelerated carpal maturation	Rests in flexion and ulnar deviation with spasm of wrist flexors
Undergrowth of ulna; ulnar shortening; may migrate dorsally	In older-onset or RF+ polyJIA, tendency is toward radial deviation[b]
Radiocarpal and intercarpal fusion	Distal radioulnar disease causes loss of pronation and supination
Flexor tenosynovitis; carpal tunnel syndrome is rare; may occur late in disease	
Hand	
Premature epiphyseal fusion and growth abnormalities	PIP (especially 4th) more common than DIP contractures
Flexor tenosynovitis may be dramatic	Loss of MCP FLEX (especially 2nd digit); loss of MCP hyperextension
Involvement later in polyJIA and sJIA than in oligoJIA	Marked decrease in grip strength
MCP and CMP subluxation deformities	Boutonniere < swan neck
Thoracolumbar Spine	
Unusual site in JIA	Kyphosis in association with neck and shoulder involvement
Steroid drug therapy may cause osteoporosis, wedging of vertebral bodies, small compression fractures	Lumbar lordosis 2° to hip flexion contractures; scoliosis 2° to lower limb asymmetries
	Pain with compression fractures[b]
Hip	
Femoral head overgrowth	Flexion contractures, may be masked by lumbar lordosis
Osteoporosis	May present as pain in the groin, over buttocks, medial thigh, around knee[b]
Trochanteric growth changes	IR and ABD lost early 2° to pain and spasm of FLEXs and ADDs
Shallow acetabulum, ↓femoral neck angle, especially if weight bearing limited	
Lateral subluxation of femoral head aggravated by tight adductors	May have marked pain on standing
Potential for protrusio acetabuli, avascular necrosis	Gluteus medius weakness may cause Trendelenburg gait deviation[b]
Primary cause of ↓ROM and dysfunction	Secondary deformities of the contralateral hip, knees, and lumbar spine
Occurs in polyJIA and sJIA after a few years	

Continued

TABLE 7.3 Joint and Soft Tissue Restrictions and Clinical Adaptations in Juvenile Idiopathic Arthritis (JIA)[a] [2,4,17,46,105]—cont'd

Clinical Manifestations	Restrictions/Adaptations
Potential for regeneration of articular cartilage with fibrocartilage if remission of synovitis[b]	Mobility and weight bearing improve cartilage repair[†]
KNEE	
Most common joint involved early in all types	Rapid development of flexion contracture
Overgrowth of distal femur may cause leg length discrepancy in unilateral disease	Rapid atrophy of quadriceps; loss of patellar mobility due to adhesions
Knee valgus aggravated by tight hamstrings and iliotibial band	Risk of femoral fracture associated with falling due to flexion and osteoporosis
Posterior tibial subluxation 2° to prolonged joint	Loss of flexion (often only to 90°)
Involvement or excessive correction of knee flexion contracture	Secondary hip flexion contracture
Ankle/Foot	
Altered growth causes bony changes in tarsals with potential fusion	Early loss of inversion, eversion
Hindfoot valgus/varus due to ankle joint arthritis or 2° to knee valgus	Later loss of D-FL and PL-FL, especially if ambulation is limited
MTP subluxation	Altered gait, loss of MTP hyperextension affects toe-off
Hallux valgus	Overlapping of IPs, especially with hallux valgus
IPs: growth changes due to premature epiphyseal closure	

[a]Data in this table are summarized from information published in Ansell, 1992; Atwood, 1989; Cassidy and Petty, 1990; Emery, 1993; Libby et al., 1991; Reed and Wilmot, 1991; Rhodes, 1991; White, 1990; and Cassidy JT, Petty RE: Juvenile rheumatoid arthritis. In Cassidy JT, Petty RE, editors: Textbook of pediatric rheumatology. 4th ed. Philadelphia: WB Saunders; 2001.
[b]The listing is not inclusive, but the features described are characteristic of juvenile arthritis.

tests on a cycle ergometer with respiratory gas analysis in children with JIA,[89] although some researchers have used treadmill testing in children with JIA.[42]

A large body of evidence shows that the peak oxygen uptake of children and adolescents with JIA is lower than that in healthy peers. In the most recent studies in JIA, in the age between 6.7 and 18 years, VO_2peak (L/min) and VO_2peak corrected for body mass (VO_2peak/kg in ml/kg/min) were respectively 69.8% and 74.8% in children and 83% and 80% of predicted for adolescents with JIA.[53,97] These observations confirm the results of a previous meta-analysis showing that VO_2peak per kilogram body mass was on average 21.8% lower in children with JIA compared with healthy control subjects or reference values.[89]

Giannini and Protas[25,26] also found that children with JIA had a significantly lower peak work rate (amount of watt that a subject can generate on a cycle ergometer), peak exercise heart rate (HRpeak), and exercise time than healthy control subjects matched for age, gender, and body size. Unpublished observations in 98 children with JIA (Takken et al.) showed that children with JIA had on average an HRpeak of 182 ± 14.7 beats per minute, while healthy children have on average an HRpeak of 193 ± 7 beats per minute. Some of the children with JIA stopped the exercise test because of fatigue and/or musculoskeletal complaints—not because of a cardiopulmonary limitation. In addition, HR and VO_2 values during submaximal exercise were higher in subjects with JIA, suggesting that they worked at a higher percentage of their aerobic capacity than did control subjects during routine activities.[15]

Impaired aerobic capacity does not appear to be significantly related to the severity of joint disease but may be due to hypoactivity secondary to disease symptoms, especially in children with long-standing arthritis.[25,26] Physiologic factors, including anemia, muscle atrophy, generalized weakness, and stiffness, resulting in poor mechanical efficiency may also limit the child's performance.

ACTIVITY AND PARTICIPATION RESTRICTIONS

Self-Care and Participation

The impact of JIA on a child's activities depends on the extent and duration of active disease, the child's developmental stage, resiliency, and desire to be independent, and expectations placed on the child by parents and others. Changes in motor activity could very well be the first notable sign of behavioral change

in a child. For example, the first sign of wrist involvement in a toddler could be incomplete or compensated palmar support (e.g., when on "all fours"), limiting the ability to crawl during play activities on the floor. Another sign of wrist involvement may be a compensatory pattern of palmar support in which the child does not bear weight on the full palmar part of the hand but only on the palmar part of the fingers, utilizing the ability to hyperextend the MCP joints (which may have a detrimental effect on joint function later in life). A classic example of early impact on motor activities is the change in ambulation in a toddler with arthritis in the knee, leading to a change from walking to bottom shuffling. A child with oligoJIA may demonstrate few functional limitations, but one with severe polyJIA may need assistance with activities of daily living (ADLs) long past the time when other children of the same age are independent. They may have difficulty moving between standing and sitting on the floor, getting into and out of the bed or a bathtub, negotiating steps, and walking long distances. Even children with mild disease may be dependent for some self-care tasks, particularly if parents provide assistance that may be unnecessary. Children may fail to develop gross motor proficiency if parents discourage them from typical childhood activities, such as riding a bike, climbing on playground equipment, or other active play.[63] Most parents are confused as they tend to mix up juvenile idiopathic arthritis with the adult type of rheumatoid arthritis. Research has shown that preschool-age children display greater motor proficiency delays, whereas children at early school age face more delays in activity and participation development.[99] From this cross-sectional study it is not clear if these delays are transient, but clinical observations support the notion that the resilience of children helps them to overcome physical challenges.

The child's participation will also be affected by the extent and quality of supportive services available and utilized by the child and family. Many children who report problems with some aspect of their educational program do not receive related services recommended by the rheumatology team.[57] Tardiness as a result of morning stiffness and frequent absence due to illness or medical appointments may cause the child to miss academic time and social interactions with classmates. Children may feel different and somewhat isolated because they are unable to participate in the same activities as their classmates. Daily fluctuations in disease symptoms may also affect the child's mood and ability to cope.[78] Adolescents with JIA may be unable to gain the same level of independence as their peers because of physical limitations and the need for continued medical care.

FOREGROUND INFORMATION

BODY FUNCTION AND STRUCTURE

Physical Therapy Examination

When examining a child with JIA, the physical therapist has to consider the stage of the disease. In the acute phase the child exhibits a great number of functional limitations, resulting in compensatory motor behavior that will change or disappear when the disease activity is adequately controlled. It is important to understand that physical therapy intervention will be significantly hampered in children with partially controlled or noncontrolled disease. Regular communication between (pediatric) rheumatologist and physical therapist during the acute phase is of utmost importance.

The approach to physical therapy examination in JIA must consider the child's age, motor development before disease onset, and cognitive and emotional development. By first gathering information about the child's activities and participation, the therapist is able to focus the physical examination on impairments that may contribute to the activity limitations or participation restrictions. Monitoring joint motion and integrity is of great importance because loss of range of motion may be the first sign of joint damage and may signal an increased risk for functional decline. Table 7.4 lists standardized outcome instruments that provide quantitative data to guide intervention and evaluate change. A new generation of outcome measures in childhood arthritis has been developed. These are composed of a "composite outcome measure" and a "multidimensional outcome measure"—the Juvenile Arthritis Disease Activity Score (JADAS)[9] and the Juvenile Arthritis Multidimensional Assessment Report (JAMAR),[22] respectively. The JADAS is an outcome measure that scores disease activity on multiple (four) levels. It measures "active joint count," "physician & parent global assessment," and "erythrocyte sedimentation rate" and uses these data to determine one composite score. The JAMAR is a parent- or child-reported measure. It rates the dimensions "well-being," "pain," "functional status," "health-related quality of life," "morning stiffness," "disease activity," "disease status and course," "joint disease," "extra articular symptoms," "side effects of medications," "therapeutic compliance," and "satisfaction with illness outcome" and transfers these into one overall score. The significance of these new outcome measures is that they enable quick and reliable monitoring of both disease status and disease outcome, which is also relevant for the PT.

Pain Examination

Pain is one of the causes of activity restrictions in JIA and is a predictor of the child's adjustment to the disease. Acute pain may result from inflammation and some medical procedures. The cause of chronic pain is less clear, but it may be due at least in part to abnormal joint loading during activity as a result of soft tissue restrictions and muscle imbalance. Older children, especially those with newly diagnosed JIA, report more pain than young children or those with long-standing disease, suggesting that pain perception and report are more closely related to age than to disease severity or duration.[30] Assessment of pain should be ongoing and should include a pain history, a self-report for children over the age of 4 years, a parent report, and behavioral observations. Validated pain behaviors in JIA include bracing, guarding, rubbing, rigidity, and flexing.[40] Self-report tools for young children include the Wong-Baker Faces Rating Scale[108] and the Oucher.[7] The child can also complete a body map, using different colors to represent pain intensity (Fig. 7.6). Children over the age of 7 years can use a numeric rating scale, a horizontal word graphic scale, or a visual analog scale (VAS). This Pain-VAS is also part of Childhood Health Assessment Questionnaire (CHAQ). The Varni/Thompson Pediatric Pain Questionnaire (PPQ)[94] provides a comprehensive assessment with both parent and child reports.

Joint and Muscle Examination

When examining the joints, the physical therapist has to consider the stage of the disease: acute, subacute, or chronic. Each stage of the disease has its typical joint expression. The acute or early phase of the disease is dominated by joint inflammation, joint effusion (fluid can be felt and moved around), ligamentous

laxity, and joint instability (can be felt when moving the distal joint parts along its axis). In the subacute and chronic phases, the inflammation has become prolonged (longer than 3 months), leading to joint swelling due to synovial hypertrophy (has a doughy feel) and loss of joint integrity, such as loss of normal joint physiology, erosive changes in cartilage, and loss of joint alignment. During joint examination, special attention should be paid to these typical disease expressions.

Joint counts for swelling (JC-S) and limitation of motion (JC-LOM) are recorded on a stick figure to document disease activity and joint restrictions (Fig. 7.7). Fig. 7.8 shows two methods of verifying a joint effusion by observing fluctuations of fluid from one area of the joint to another, eliciting a bulge sign. To detect an effusion in the knee, the synovial pouch medial to the patella is emptied by stroking in an upward direction and then is refilled by stroking along the lateral border in an upward or downward direction.

Active joint motion can be estimated by watching the child perform a series of movements during various childhood activities, but goniometric measurement is necessary to document limited joint motion.[31] Two standardized measures of the JC-LOM are the Articular Severity Score (ASS) and the Global Range of Motion Score (GROMS). The ASS scores global range of motion (ROM) for each joint, averaged for the right and left sides, on a 5-point scale (0 = no LOM; 1 = 25% LOM; 2 = 50% LOM; 3 = 75% LOM; and 4 = fused). In contrast, the GROMS

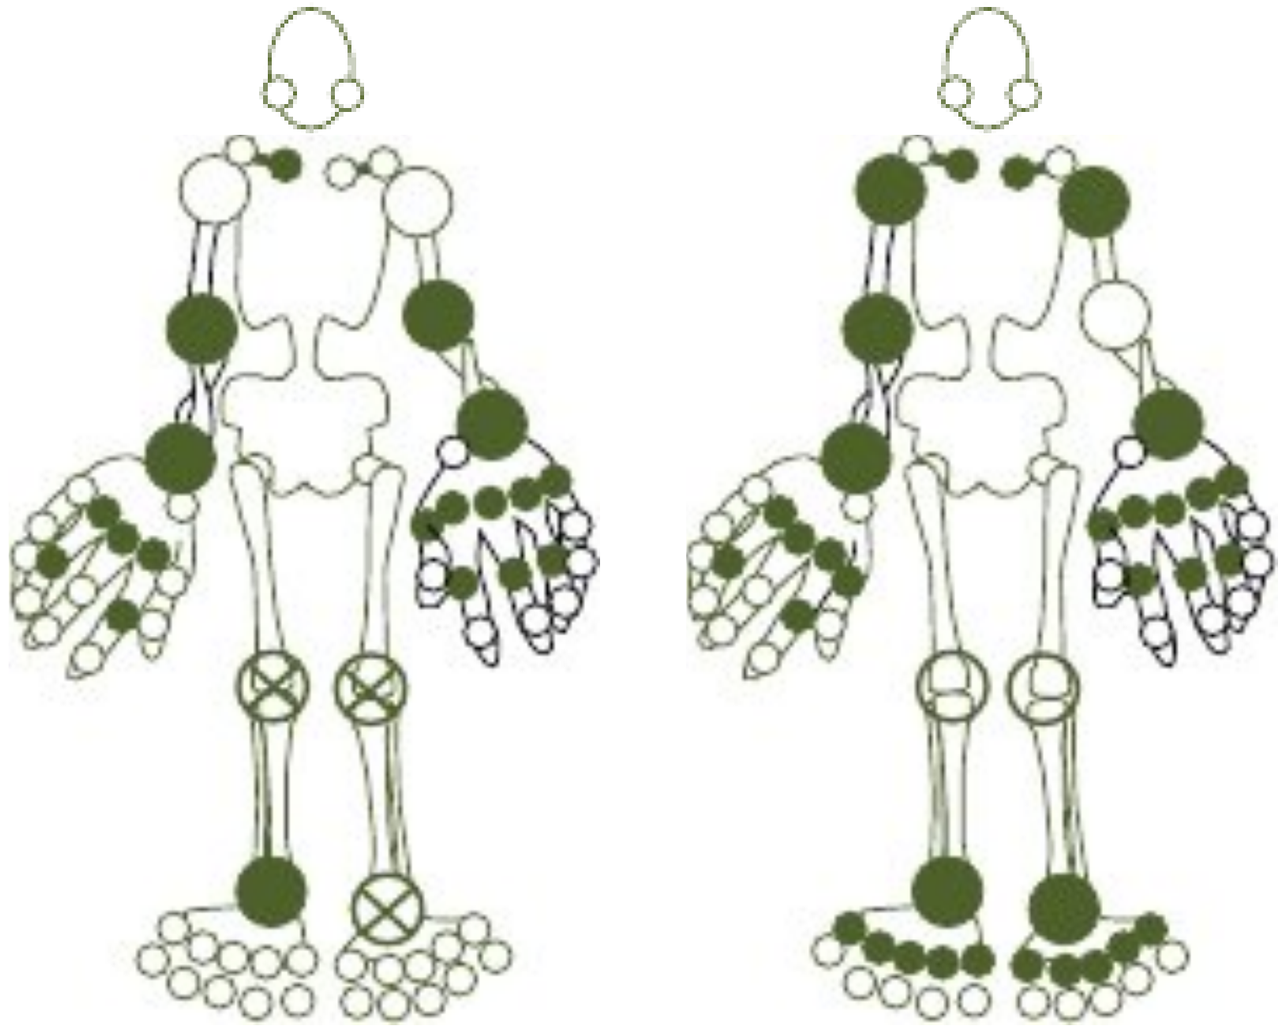

FIG. 7.6 Example of active joint count in a child with polyarticular disease. There are 38 active joints. The left figure shows 22 with effusion (•) or soft tissue swelling (X). The right figure shows joints with stress pain or tenderness (•). (From Wright FV, Smith E: Physical therapy management of the child and adolescent with juvenile rheumatoid arthritis. In Walker JM, Helewa A, editors: Physical therapy in arthritis. Philadelphia: WB Saunders; 1996. p 215.)

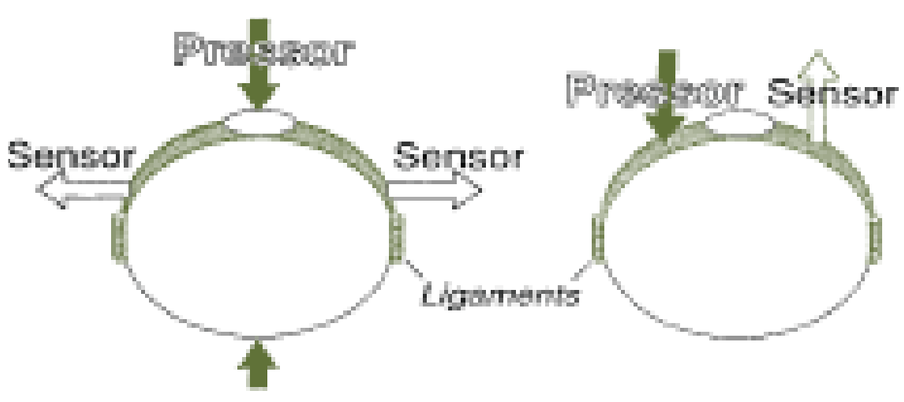

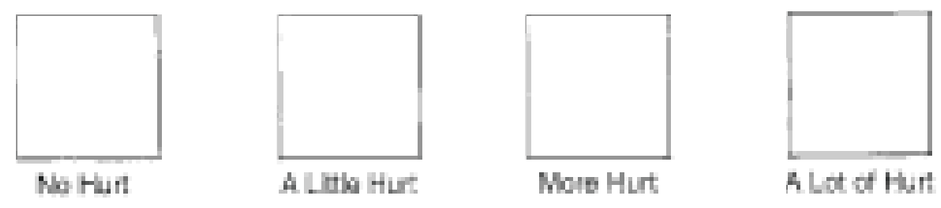

FIG. 7.7 Two ways of detecting joint effusions. Two ways of detecting joint effusions. (From Smythe HA, Helewa A: Assessment of joint disease. In Walker JM, Helewa A, editors: Physical therapy in arthritis. Philadelphia: WB Saunders; 1996. p 133.)

provides a single score for global joint function. Each joint movement is weighted from 0 (least important) to 5 (essential), based on expert opinion of its functional importance. The examiner records the mean ROM in degrees for the right and left sides. The ratio of the measured value to the normative value is calculated to obtain the joint movement score. The total GROMS is calculated as the sum for all movements multiplied by 100 and divided by the number of movements (Table 7.5).

A reduced 10-joint version of the GROMS is also available that includes only those joint motions weighted as 5 (essential) on the original GROMS. The total score is calculated using the same method as the full scale. The Pediatric Escola Paulista de Medicina ROM Scale (pEPM-ROM)[54] also includes 10 essential joint movements but uses predetermined cutoff points for scoring (0 = full motion to 3 = severe limitation). The total score (0 to 3) for each side of the body is the sum of all joint scores divided by 10. Each scale demonstrates adequate concurrent validity with other measures of disease status and function in JIA.[18]

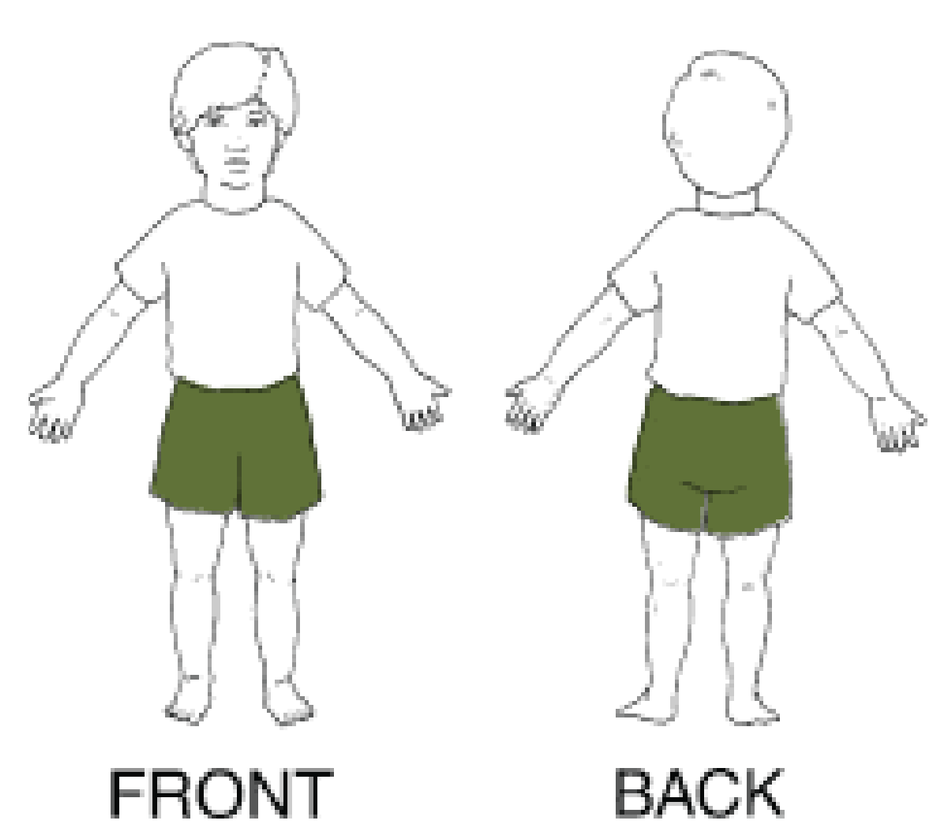

FIG. 7.8 Pain may be assessed by allowing the child to color a body map. Intensity of pain is matched with four different colors.

TABLE 7.5 Calculating a GROMS Using All Joint Movements Except the Lumbar and Thoracic Spine[a]

	A	B	C	D	E
Joint Movement	**Measured**	**Normative**	**A + B**	**Mode**	**C × D**
Cx spine extension	30	45	0.66	4	2.64

From Epps H, Hurley M, Utley M: Development and evaluation of a single value score to assess global range of motion in juvenile idiopathic arthritis. Arthritis Care Res 47:398, 2002. Reprinted by permission of Wiley-Liss Inc, a subsidiary of John Wiley & Sons, Inc.

[a]GROMS, Global Range of Motion Scale; Mode = weighted value for joint movement based upon experts' opinion of its functional importance.

Cx, cervical; ER, external rotation; IR, internal rotation; MCP, metacarpophalangeal; PIP, proximal interphalangeal; DIP, distal interphalangeal; RU, radio-ulnar.

Excellent test-retest and intertester agreement are reported for the pEPM-ROM.[54] Testing of the 10-joint GROMS continues. Although a reduced JC-LOM saves time during the examination, it may not be appropriate for patients whose arthritis is extensive or does not affect any of the 10 joints measured.

Periarticular muscles may show decreased flexibility due to contractures or "contraction deformities." This can be tested with a "sit-and-reach test" including all lower limb, dorsal trunk, and upper limb muscles in a "functional manner" or per joint. In the latter case it is important to follow the procedures for muscle length testing as described, for example, by Kendall and Kendall.

Physical Fitness Examination

Many centers do not have the equipment to perform respiratory gas analysis to measure VO_2peak. However, peak workload (Wpeak) during a graded bicycle test can be used as a surrogate measure for VO_2peak because an excellent correlation between Wpeak and VO_2peak ($r = 0.95$, $P < 0.0001$) has been observed in 92 children with JIA (Takken et al, unpublished observations). VO_2peak can be predicted from Wpeak, weight, and gender using the following equation (ref 16a):

$$VO_2\text{peak (L/min)} = 0.308 + 0.146 \times \text{sex (0 = female, 1 = male)} + 0.005 \times \text{weight (kg)} + 0.008 \times \text{W (peak) (W)}$$

Activity

Performance-Related Fitness Examination

Performance-related fitness includes components like muscle strength and anaerobic capacity. Impairments in muscle strength include weakness in hip extension and abduction, knee extension, plantar flexion, shoulder abduction and flexion, elbow flexion and extension, wrist extension, and grip. Muscle bulk, strength, and endurance should be examined at disease onset and monitored regularly. Bilateral measurements of circumference quantify asymmetries in muscle bulk. Functional muscle strength can be estimated in young children by observing their performance of age-appropriate motor tasks or ADLs. In older children, manual muscle testing can be done to measure isometric strength, especially if the child has pain while moving the limb against resistance. Instrumented measurements using a handheld or isokinetic dynamometer or a modified sphygmomanometer[104] provide consistent and reliable information in individuals with arthritis.

Muscle strength testing in children with JIA, especially handheld dynamometry using the "break" technique, might be problematic in some cases because children might give way as a result of pain instead of the limits in muscle strength.[107]

Dynamic muscle testing of functional muscle groups can be performed when there is no sign of joint inflammation or damage. The maximal weight the child can lift throughout the

available ROM for 10 to 15 repetitions (6 to 10 repetition maximum [RM]) is usually sufficient to establish a baseline level of strength and monitor change.[49] An alternative method for children who have pain on movement is to measure isometric strength at multiple angles throughout the ROM. Muscular endurance can be measured by having the child perform as many repetitions as possible at a specified percentage (60% to 80%) of the 6 to 10 RM. A warm-up period of light activity should precede strength testing.

One study suggested that muscle weakness may contribute to activity restrictions in children with arthritis. Fan and colleagues[21] found a significant relationship between 50-meter run times and lower extremity CHAQ scores in girls with JIA.

Two studies investigating anaerobic capacity in children and adolescents with JIA reported significantly lower values of anaerobic capacity in subjects with JIA.[53,97] Anaerobic capacity was reduced to the same extent as aerobic fitness (VO_2peak). Previously, it was found that reduced anaerobic capacity was significantly correlated with CHAQ scores in 18 children with juvenile arthritis, age 7 to 14 years.[93] This is not surprising in that the typical physical activity behavior of children—short bursts of intense activity separated by periods of rest—is anaerobic in nature.[6] Given the apparently similar deficits in anaerobic capacity of youth with JIA, exercise training of the anaerobic energy system (e.g., high-intensity interval training) might be equally as valuable as training of the aerobic system and therefore warranted in children with arthritis. However, this training modality has not yet been studied.

Another widely used performance-related fitness test is the 6-minute walk test (6MWT). In this test, children have to cover as much distance as they can in 6 minutes by walking (not running). This test is used in different patient groups such as JIA, spina bifida, cerebral palsy, and hemophilia.[32,79,95] Lelieveld et al. found a low correlation between walking distance and VO_2peak in children with JIA.[52] In addition, Paap et al. found that children with JIA were exercising at 80% to 85% of their HRpeak and VO_2peak during the 6MWT, indicating that it is an intensive, submaximal exercise test used to measure functional exercise capacity in children with JIA.[68] Furthermore, these data indicate that exercise intensity at the end of the 6MWT can be used for the programming of exercise intensity during aerobic exercise training in children with JIA because this intensity is sufficient to improve fitness levels.

Activity and Participation

Activity and Participation Examination

Several standardized instruments examine the child's activities. The CHAQ, a measure of physical function designed for children age 1 to 19 years, includes 30 activities organized into eight categories.[82] The respondent (parent or child 9 years or older) scores each item based on how much difficulty the child had performing the task during the past week (0 = without any difficulty; 1 = with some difficulty; 2 = with much difficulty; 3 = unable to do). An item is scored as "not applicable" if the child has difficulty because he is too young. The highest scored item in each section determines the score for that category. If the child needs an assistive device or help from another person to perform a task, the score for that category is at least 2. The Disability Index (DI), calculated as the average score for the eight categories, has a range of 0 to 3. Higher scores indicate greater disability. The CHAQ also includes a question about the presence and duration of morning stiffness and VASs to measure pain intensity and general health status. Recently, the CHAQ has been revised and extended with eight more physically demanding items to meet the challenges of a more physical active lifestyle in children with rheumatic conditions.[50]

Other questionnaires designed to measure physical function include the Juvenile Arthritis Functional Assessment Index (JASI)[110] and the Juvenile Arthritis Functional Assessment Report (JAFAR).[37] A school checklist can be used to examine school-related problems.[87] The School Function Assessment may also be useful[14] (See Chapter 2 for more detail). Two other instruments measure both physical function and quality of life (QOL) in children with JIA. These are the Juvenile Arthritis Quality of Life Questionnaire (JAQQ)[16] and the Pediatric Quality of Life Inventory (PedsQL).[101] The only instrument that measures the child's actual performance is the Juvenile Arthritis Functional Assessment Scale (JAFAS). The child is observed and timed while completing 10 tasks. The score is 0 if the time to complete the task is equal to or less than the criterion time, 1 if the time exceeds the criterion, and 2 if the child cannot perform the task. The test takes 10 minutes and requires a minimum of simple equipment.[59]

PHYSICAL THERAPY INTERVENTION

The focus of physical therapy during the acute stage of the disease is different from that during the subacute and chronic stages. While in the acute phase, efforts are focused on maintaining and preserving joint function; in the subacute and chronic stages, the focus is on restoration and compensation of function and activities.

The overall goals of physical therapy are to restore and optimize the child's activity, participation, and physical health by maintaining or improving function and providing education and support to the child and family. Box 7.2 illustrates the physical therapy intervention in JIA. Intervention is geared to each child's physical, cognitive, and social development and must also consider the family's cultural background. Physical activity and graded exercise are essential to manage the effect of the disease and to maintain optimal health. Exercise in a warm pool, where the buoyancy of the water allows easier movement, is especially recommended during the acute inflammatory stage of joint disease. Most children with mild to moderate JIA can also participate in land-based exercise.

Adherence to the therapeutic regimen is extremely important. Home exercise programs may be necessary but are often a source of conflict between the parent and the child. Giving the child some control over the exercise program—for example, choosing the time and place to exercise—may improve adherence. Older children can collaborate with the parent and therapist to set goals and plan intervention.

Body Function and Structures

Management of Joint Health

Physical measures used in the management of joint health include cold, exercise, and occasional splinting. There is no place for superficial or deep heat application in the management of arthritis. Studies have shown that intra-articular inflammation is increased when these modalities are used.[66,67] Ultrasound and short wave diathermy are not used in children. A study by Wiltink et al.[106] has suggested that these modalities may harm endochondral ossification and the proliferation of epithelial cells.

BOX 7.2 Interventions for Juvenile Idiopathic Arthritis

Coordination, Communication, and Documentation

Anticipated Goals

Care is coordinated with child, family, school, and other professionals.
Insurance payer understands needed rehabilitation services.
Need for modifications in school is determined.
Available resources are maximally utilized.
Decision making regarding child's health, wellness, and fitness needs is enhanced.

Specific Interventions

Communication with community therapist, school personnel, and community resource providers
Prescriptions and letters of medical necessity to support rehabilitation needs
Individualized education plan (IEP); accommodations under Section 504 of Rehabilitation Act

Patient-Related Instruction

Anticipated Goals

Awareness and use of community resources are increased.
Behaviors that protect joints from secondary impairments are enhanced.
Functional independence in activities of daily living (ADLs) is increased.
Patient and family knowledge of the diagnosis, prognosis, interventions, and goals and outcomes are increased.

Specific Interventions

Home exercise program
Instruction regarding joint protection principles
Information from the Arthritis Foundation regarding disease
Referrals to other community resources

Therapeutic Exercise

Anticipated Goals

Ability to perform physical tasks related to self-care, home management, community and school integration, and leisure activities is increased.
Aerobic capacity is increased.
Gait is improved.
Joint and soft tissue swelling, inflammation, or restriction is reduced.
Joint integrity and mobility are improved.
Pain is decreased.
Postural control is improved.
Strength, power, and endurance are improved.

Specific Interventions

Aerobic conditioning
Aquatic exercise
Low-impact weight-bearing exercise
Gait training
Body mechanics training
Postural training
Strengthening, power, and endurance training
Active-assistive, active, and resistive exercise
Task-specific performance training
Flexibility exercise
Muscle lengthening
Range of motion
Static progressive stretching
Balance, coordination, and agility training

Functional Training in Self-Care and Home Management

Anticipated Goals

Ability to perform physical tasks related to self-care and home management is increased.
Level of supervision required for task performance is decreased.
Risk of secondary impairment is reduced.

Specific Interventions

ADL training
Assistive and adaptive device or equipment training
Self-care or home management task adaptation
Leisure and play recommendations
Orthotic, protective, or supportive device or equipment training
Injury prevention training

Functional Training in School, Play, Community, and Leisure Integration

Anticipated Goals

School attendance is improved.
Participation in peer groups for recreation and leisure activity is improved.
Architectural barriers to access home, school, and community resources are removed.

Specific Interventions

Appropriate transportation plan to school identified on IEP
Modifications to school instruction identified on IEP
ADL training
Assistive and adaptive device or equipment training
Adaptation of equipment to allow inclusion in recreation and leisure activity
Home and school site visit to plan for accommodation of any architectural barriers

Prescription, Application, and Fabrication of Devices and Equipment

Anticipated Goals

Ability to perform physical tasks is increased.
Deformities are prevented.
Gait is improved.
Joint stability is increased.
Optimal joint alignment is achieved.
Pain is decreased.
Protection of body parts is increased.

Specific Interventions

Adaptive devices or equipment
Assistive devices or equipment (ambulation aids, wheelchairs, ADL equipment)
Splints and orthotic devices (shoe inserts, resting splints, dynamic splints, braces)
Protective devices (splints, taping, elbow or knee pads)
Supportive devices (compression garments, cervical collars)

Electrotherapeutic Modalities

Anticipated Goals

Muscle performance is increased.
Pain is decreased.

Specific Interventions

Biofeedback

Physical Agents and Mechanical Modalities

Anticipated Goals

Pain is decreased.
Soft tissue swelling, inflammation, or restriction is reduced.
Tolerance to positions and activities is increased.
Joint integrity and mobility are improved.

Specific Interventions

Cryotherapy (RICE—rest, ice, compression, elevation)
Hydrotherapy (aquatic therapy, whirlpool tanks)
Continuous passive motion devices

Modified from Scull S: Juvenile rheumatoid arthritis. In: Campbell S, Vander Linden D, Palisano R, editors: Physical therapy for children. 2nd ed. Philadelphia: WB Saunders; 2000. p 245.

Balanced rest and exercise are important in managing joint health and function in JIA. Children who participate in group aquatic or land-based exercise programs report decreased pain.[5,23,44,91] Restful sleep helps to reduce morning stiffness and pain. Sleep time fragmentation is observed to have a relationship with disease symptoms and may corrupt daytime performance.[85] Custom-made resting splints can support joints, may preserve function, and may relieve pain during the night.

When ROM exercises are indicated to preserve joint motion and soft tissue extensibility, active ROM is preferred. Several studies have shown that passive movements of inflamed joints evoke an increase in the release of the proinflammatory peptide substance P,[61] resulting in more pain and inflammation. The child can also be taught combination patterns cloaked in games that encourage motion in several joints at once.

Application of passive corrective modalities demands careful consideration of the biomechanical forces that result from the application. Precautions should be taken not to induce a subluxation or to overload joint parts.

Muscle Strength

Limited evidence suggests the effectiveness of muscle strength training for children with JIA. A recent randomized controlled trial studied muscle strength training in children with JIA within the context of an exercise program.[77] Muscle strength in hip and knee extensors increased after the 12-week program and this was maintained in knee extensors at follow-up.

Strengthening exercises target the muscles surrounding and supporting the joints with arthritis and adjacent areas. During acute joint inflammation, isometric exercise can be used to maintain muscle bulk and strength. Prolonged maximal isometric contractions should be avoided because they may increase intra-articular pressure and constrict blood flow through the muscles.[41] EMG biofeedback may be helpful in training the child to regulate the intensity of the contraction.

Dynamic exercise is added when joint inflammation subsides. Both concentric and eccentric exercises are included. External resistance can be safely added once the child is able to correctly perform light activities against gravity without pain.[62]

Clear directions and illustrations of the exercises are necessary, and training sessions should be supervised. Progression is based on periodic reassessment. Each training session should begin with light aerobic and flexibility activities and end with cool-down and stretching activities. Resistance exercises should be performed twice a week, allowing time between sessions for rest and recovery.[20]

Aerobic Capacity

A Cochrane review identified only three published randomized controlled studies investigating the effects of exercise training for children with JIA.[90] None of these studies found improvements in VO_2peak after the aerobic training program was completed. This lack of effect can be owed to a low exercise frequency (e.g., one time a week), a low exercise intensity (intensity of exercise has to be above the intensity of daily activities), or a low exercise adherence (children often skipped exercise sessions), or it may indicate that children did not perform the prescribed home exercises. However, aerobic fitness is important to improve the child's endurance for routine physical activities and play. In addition, aerobic fitness helps the recovery after intensive exercise. Based on the available literature, it is recommended that children with JIA and a deficit in aerobic fitness should train at least two times a week, with moderate to vigorous intensity (60% to 85% HRpeak), for 45 to 60 minutes per session for at least 6 to 12 weeks.[45,46,88] The specific mode of exercise appears to be less important than the intensity, duration, and frequency. However, weight-bearing exercise is necessary to maintain optimal bone growth and density. Low-impact activities to improve proprioceptive function, balance, and coordination can be incorporated into aerobic fitness training programs. However, not only strenuous activities produce improved aerobic outcome but also more gentle types of exercise such as Qigong, as was shown by Stephens et al.[84]

Anaerobic Capacity

In a study, van Brussel et al.[98] hypothesized that training of the anaerobic energy system (e.g., high-intensity interval training) might be equally valuable as training of the aerobic system and therefore warranted in children with JIA. Although this training modality has not yet been studied in children with JIA, improvements have been observed in function and fitness with anaerobic exercise training in children with other chronic conditions (e.g., cystic fibrosis, cerebral palsy).[47,102] Particularly in children with a larger reduction in anaerobic capacity compared with aerobic capacity, this training modality might be effective. In addition, children prefer this anaerobic type of exercise over the adult type of approach of continuous endurance exercise. The suggested exercise set consists of 15 high-intensity cycling sprints (15 to 30 seconds all out); each sprint is followed by 1 to 2 minutes of active rest (cycling with low resistance). A training session could consist of three of these exercise sets, with 5 minutes of active rest for recovery between the three sets of interval training.

Activity and Participation

Encouraging Active-Healthy Living

Several studies have identified a hypoactive lifestyle of children with JIA.[34,51,92] A significant association has been reported between accelerometry-measured physical activity and health-related fitness (VO_2peak) in children with JIA,[92] suggesting a cause–effect relationship. In addition, no adverse effects of regular sport activity have been observed on joint scores in children with JIA.[43] The link between physical activity levels of children and motor performance[111] suggests that the physical activity levels of children with JIA might be enhanced by improvements in reduced motor proficiency observed in children with JIA.[99] Further, given the fact that adult physical activity levels are established in youth, it is important to encourage children and families of children with JIA to participate in regular physical activity. Regular physical activity can help in the prevention of cardiovascular risk factors, obesity, and reduced bone health, as well as reduced health-related quality of life, in youth with JIA. Physical therapists should reassure parents and stimulate an active-healthy lifestyle as soon as possible.

Self-Care Activities

A primary goal for every child with a chronic condition is to achieve independence in self-care within the home, school, and community. Expectations for independence differ at each age and stage of development. It has been reported that ambulation skills in children with JIA are delayed as early as 4 years of age.[99] This is in contrast with preschool age children, who show more limitations in motor proficiency and in the development of motor milestones.[99] Intervention for an infant with JIA may

include suggestions to prevent contractures and facilitate function. A child with limited grasp may benefit from adapted toys. Functional wrist and hand splints can support the joint during hand use, and assistive devices can compensate for a weak grip and reduce hand pain and fatigue. Dressing and hygiene aids include Velcro closures on clothing and shoes, elastic shoelaces, a long-handled shoehorn, a dressing stick, a buttonhook, a zipper pull, and a long-handled bath brush. Built-up handles on grooming items, eating utensils, and writing implements may be necessary for optimal function and independence.

Some modifications within the home may be beneficial, including replacing knobs and faucets with levers, using a jar opener or an electric can opener, adding a raised toilet seat, and installing safety bars in the bathtub. More substantial modifications, including widening doorways and adding a ramp to the entrance, are needed for a child who must use a wheelchair. The therapist must consider the financial, physical, and emotional impact of these changes on the family. The device or adaptation must be affordable and must achieve the stated purpose, be easy to use, and be acceptable to the child and parent. When considering substantial modifications, it is of critical importance to be informed about the prognosis of the course of the disease. Temporary exacerbations may introduce the need for a wheelchair, but most do not need structural changes in and around home.

Functional Mobility

Weight bearing and ambulation are vital for optimal bone growth and density, joint health, and muscle development. Standing, cruising, and walking should be encouraged at the expected age, although the use of infant walkers should be avoided because they may promote an abnormal gait pattern and carry a high risk for injury. Toddlers and preschool-age children should be encouraged to walk within the home and short distances outside. Shoes should support and cushion the joints of the feet and accommodate any deformities. Sneakers with a flexible sole, good arch support, and high heel cup are good choices for most children. A wide, deep toe box may be necessary for a child with swelling in the forefoot joints or hallux valgus, hammer toes, or claw toes. A child with arthritis in the feet and toes should not wear high heels because of the excessive pressure on the MCP joints. A rockerlike addition to the sole of the shoe may provide a mechanical assist at toe-off for a child who has limited or painful toe hyperextension. Custom molded in-shoe orthoses can replace the standard insole to accommodate foot deformities and decrease pressure on those tender joints and provide relief in the majority of the cases.

Few children with JIA require an assistive device for ambulation. However, if a child begins to show problems with weight bearing or difficulty walking, the cause should be determined and addressed. Leg length differences can be accommodated by placing a lift inside the shoe or on the sole of the shoe on the shorter side. A child with unilateral lower extremity pain or weakness can use a cane or elbow crutch on the opposite side to unload the involved limb and increase stability during ambulation. A walker or crutches may be needed if problems are bilateral. Platform attachments can be added if the child has upper limb impairments.

Some children may need to use a form of wheeled mobility for long distances within the school or community environment. A wagon or stroller with a firm seat and back is appropriate for toddlers or preschool-age children. Older children can use a tricycle or a bicycle with training wheels to get around the community. A power-assisted bicycle may facilitate ambulation in the wider neighborhood and allow for peer contact. A nonpowered two-wheeled scooter allows younger children to propel themselves with their feet without weight bearing. A powered scooter or lightweight wheelchair may be necessary for efficient mobility in school. Children with upper extremity arthritis often maneuver the wheelchair with their feet. Powered wheelchairs are usually reserved for children with severe impairments but may be necessary for a college student who must negotiate a large campus. Children who use a wheelchair should spend part of every day out of the chair, standing and walking to preserve bone health, prevent contractures, and maintain walking tolerance.

Issues Related to School

Children with JIA may need occasional modifications to their school program. These might include a second set of books for home, built-up or adapted writing tools, or an easel top for the desk in the classroom. Children with significant hand arthritis may need to record class notes on a tape recorder or word processor and take tests under untimed conditions. Modifications to the school schedule may include time out of the classroom to take medication or rest for brief periods during the day, extra time to travel between classes, or permission to use an elevator if the child is unable to negotiate stairs. Some schools provide these services voluntarily. In other situations, the child may need an individualized educational plan (IEP) or accommodations specified under Section 504 of the Vocational Rehabilitation Act. Vocational counseling is often necessary to prepare adolescents for the transition to higher education and work. Although most states mandate transition planning, Lovell and colleagues[62,64] found that only 8% of children with JIA received vocational counseling. A recent review underlines the paucity of studies examining the early employment experiences of young adults with arthritis. The employment status found in the review ranged from 11% to 71%, and although not always statistically significant, young adults with arthritis were less likely to be employed when compared to their healthy peers. Greater disease severity, less educational attainment, and being female were related to not participating in paid work.[41]

Regular participation in physical education is encouraged. The instructor should be aware of the child's diagnosis and any activity restrictions or precautions. In general, the child should be allowed to monitor his or her own activity level, resting as needed. However, some activities may be strongly discouraged because of their potential for injury or joint damage. These activities include headstands and somersaults; handstands, push-ups, cartwheels, and other similar activities in a child with wrist and hand arthritis; and high-impact running or jumping in a child with spinal or lower extremity arthritis. The therapist can consult with the physical education instructor to modify activities as necessary.

Recreational Activities

Recreational activities provide physical and psychosocial benefits. The choice of activities depends on the child's preferences, physical status, motor skills, and fitness level. Participation on any given day sometimes must be modified to accommodate disease symptoms. Websites such as PRINTO provide updated evidence-based and expert-based recommendations for exercise and sports for parents.[38] Swimming, water or low-impact

weight-bearing aerobics, and bicycling provide good cardiovascular exercise. Activities that cause high-impact loading on inflamed or damaged joints should be avoided. Contact sports, including football, hockey, and boxing, and those with a high inherent potential for injury should be carefully evaluated with child and parents and may be ultimately discouraged. Competitive team sports may be physically and emotionally stressful, but each situation should be evaluated individually.

A physical conditioning program before participating in a sport prepares the child for the physical demands of the activity. Warm-up before each practice session or game and a cool-down period after the activity should be encouraged. Instruction in motor skills specific to the sport may be necessary. A sports orthosis or other adaptive equipment may improve joint alignment and stability and is therefore helpful to secure joint health.

ORTHOPEDIC SURGERY AND THE ROLE OF THE PHYSICAL THERAPIST

Orthopedic surgery in children with JIA has become rare over the last decades because more powerful immunosuppressive and immunomodulatory medication results in earlier remission, less extensive joint damage, and fewer growth disturbances in most children.

Total joint arthroplasty (TJA) is considered in the chronic stage of the disease when there is irreversible joint damage and the child has significant pain and functional limitation. The procedure is most frequently performed at the hip and knee, although prostheses are available for other joints. Several factors are considered in the decision, including the child's age, skeletal maturity, general physical status, upper extremity function, and ability to successfully complete the lengthy and intensive postoperative rehabilitation regimen. Customized computer-designed prostheses may be necessary to accommodate changes in joint anatomy, small bone size, and osteoporosis. The longevity of the prosthesis must also be considered, especially when TJA is performed in young children. Procedures are staged if the child requires extensive surgery to ensure the best functional outcome.

SUMMARY

JIA is an autoimmune inflammatory disorder and the most common rheumatic disease of childhood. Although the exact cause is unclear, three major distinct onset types are recognized: systemic, polyarticular, and oligoarticular. With advances in the recognition and diagnosis of the disease and more effective medications to treat joint inflammation, most children with JIA do well with early diagnosis and appropriate treatment. However, for many children, JIA results in both short- and long-term problems, including chronic joint swelling, pain, and limited motion, as well as muscle atrophy and weakness, poor aerobic function, and impaired exercise tolerance. General and localized growth disturbances, postural abnormalities, and gait deviations occur with persistent disease. Activity and participation restrictions that result from the arthritis and extra-articular manifestations can negatively affect the child's quality of life. The long-term prognosis depends upon the child's age at disease onset, onset geno- and phenotype, severity and duration of active inflammation, and quality and consistency of medical care and other resources available and utilized by the family. This chapter reviews the most common characteristics of JIA, standardized examination and outcome measures developed for use in children with arthritis, and current research findings regarding the effects of exercise and physical activity in individuals with chronic inflammatory arthritis. Physical therapists are vital members of the pediatric rheumatology team, providing examination, evaluation, and intervention, and monitoring joint health, physical function, and physical health in a child with JIA. Therapists also serve as an important resource to parents or caregivers and school and community personnel to adapt activities so the child with JIA can participate fully in the home, school, and community environments.

ACKNOWLEDGMENT

Susan E. Klepper, PhD, PT, for her valuable contributions of this chapter in four consecutive editions of this textbook. We have continued to build on her text.

CASE SCENARIOS

Two case scenarios with video are presented. The first case is a toddler with lower extremity involvement. Part 1 of this case illustrates the importance of careful observations during movement to structure the examinations based on the topographic distribution of impaired joints. Part 2 of this illustrates interventions specific to the examination findings with attention to the biomechanical consequences of inflamed joints.

The second case is a teenager with a more severe polyarticular presentation. Examination findings and therapy interventions across ICF domains are discussed.

Spinal Conditions

Suzanne Green, Heidi Friedman

The spine is the framework for our posture and our movement. It supports our cranium, extremities, and spinal cord; allows for trunk flexibility; acts as a shock absorber; and provides structural support for normal chest and respiratory development. Orthopedic concerns arise when spinal alignment is altered by congenital or acquired changes, producing scoliosis, kyphosis, or lordosis.

Each one or a combination of these conditions, if left untreated, may affect a child's pulmonary function, psychosocial well-being, potential for back pain, and life expectancy. We, as physical therapists, play a vital role in the detection and treatment of spinal conditions. Two to four percent of the population of school-age children (7–18 years) is at risk for adolescent idiopathic scoliosis, the most common form of scoliosis.[103,107] The prevalence of other spinal conditions varies with the condition and the underlying disease process.[131] This chapter addresses the prevalence and natural history, identification, examination, and treatment of these spinal conditions. Specific cases are presented to discuss impairments and restrictions in activity and participation of children with spinal conditions. Physical therapy intervention is emphasized, along with nonsurgical and surgical management of these spinal conditions.

BACKGROUND INFORMATION

DEVELOPMENT OF THE SPINE

Pathologic spinal conditions are discussed in this chapter, so it is necessary for the reader to have some knowledge of normal spinal development (Fig. 8.1). Therefore a discussion of development in the embryologic, fetal, and childhood stages follows.

Fetal development is divided into three stages. The first 3 weeks after fertilization is termed the preembryonic period. The embryonic period is next, lasting from week 3 to week 8 of gestation; during this stage, the organs of the body develop. The fetal period lasts from week 8 until term, and during this stage, maturation and growth of all structures and organs occur.[93]

Early development of the skeletal, muscular, and neural systems is related to the notochord. Cell proliferation occurs at approximately 3 weeks, forming a trilaminar structure with layers of ectoderm, mesoderm, and endoderm. Proliferation of the mesodermal tissue continues, forming 29 pairs of somites (a pair of blocklike segments that give rise to muscle and vertebrae, which are formed on each side of the notochord[123]) in the fourth week and the remainder (42–44 total) in the fifth week. Differentiation of the somites then occurs, producing 4 occipital, 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 8 to 10 coccygeal somites. The occipital somites form a portion of the base of the skull and the articulation between the cranium and the cervical vertebrae, while the last five to seven coccygeal somites disappear. Cervical, thoracic, lumbar, and sacral somites form the structures of the spine.[137]

Proliferation of the somites occurs, leading to the development of three distinct areas. Dorsally, the cells become dermatomes, giving rise to the skin. Medially to the dermatome, cells migrate deep to give rise to skeletal muscle. The ventral and medial cells migrate toward the notochord and the neural tube to form the sclerotome.[93,137]

The sclerotomal cells proliferate and differentiate, giving rise to rudimentary vertebral structures, including rib buds. Chondrification begins at the cervicothoracic level, extending cranially and caudally. Centers of chondrification allow for formation of the solid cartilage model of a vertebra with no line of demarcation between body, neural arch, or rib rudiments.[93]

Ossification occurs at primary and secondary centers. Ossification begins during the late fetal period and continues after birth. Primary centers of ossification extend to the spinous, transverse, and articular processes. Secondary ossification centers develop at the upper and lower portions of the vertebral body, at the tip of the spinous processes, and at each transverse process. These centers expand in late adolescence. Secondary ossification centers also develop in the ribs: one at the head of the rib and two in the tubercle. Ossification of the axis, atlas, and sacrum differs slightly from that of the other vertebrae. The atlas has two primary centers and one secondary center of ossification, and the axis has five primary and two secondary centers of ossification. Ossification of the axis begins near the end of gestation with fusion of the two odontoid centers and is completed in the second decade of life with fusion of the odontoid and centrum. Fusion of the sacrum begins in adolescence and is completed in the third decade of life.[93]

Spinal growth occurs throughout adolescence. Knowledge of spinal growth is essential in nonsurgical and surgical treatment of spinal deformities. Spinal growth studies have demonstrated that there are two periods of rapid spinal growth: the first from birth to age 5 and the second during the adolescent growth spurt. In the years between, growth occurs at a slower rate.[18]

The spinal pubertal growth spurts occur at different chronologic and Tanner ages for females and males. In females the growth spurt coincides with Tanner 2 or a chronologic age of 8 to 14 years, with maximum growth occurring at a mean of 12 years of age. The spurt lasts 2.5 to 3 years. The growth spurt occurs later in males, at Tanner 3 or chronologic age 11 to 16 years, with maximum growth at age 14 years. These values are average values based on white Anglo-Saxon populations.[31]

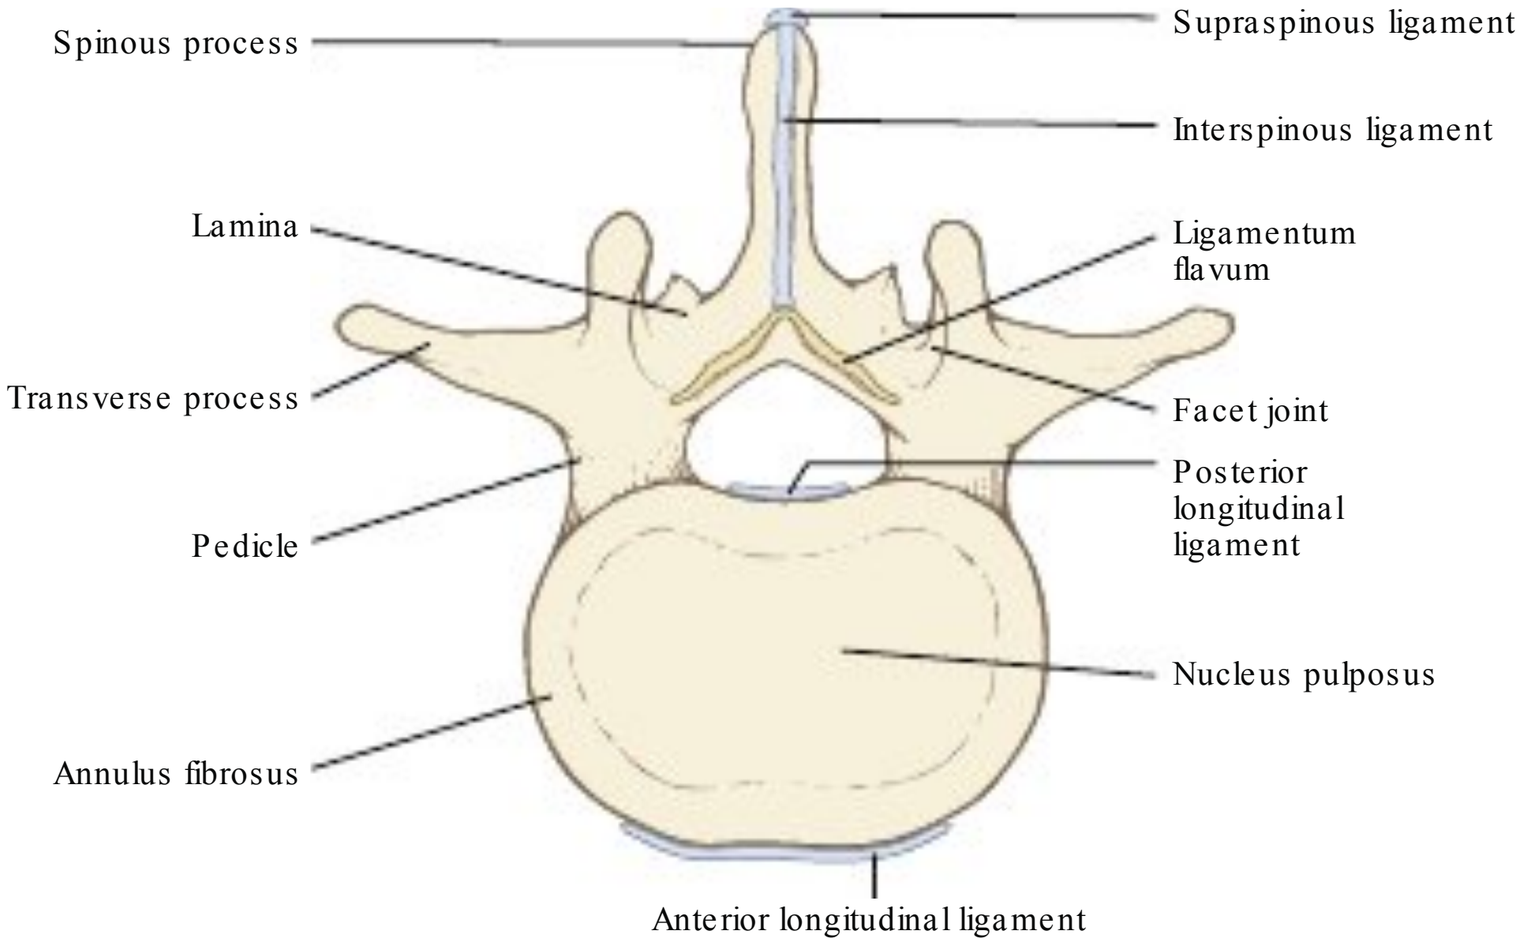

FIG. 8.1 The L2 vertebra viewed from above. (Redrawn from Covino BG, Scott DB, Lambert DH: Handbook of spinal anaesthesia and analgesia. Philadelphia, WB Saunders, 1994.)

A fused area of the spine does not grow longitudinally, as documented by Moe and colleagues.[92] The surgeon, therefore, considers the information on spinal growth potential for each individual case.

SCOLIOSIS

Background Information

Detection and Clinical Examination

Detection of scoliosis occurs primarily by identification of trunk, shoulder, or pelvic asymmetries. The American Academy of Pediatrics (AAP), American Academy of Orthopaedic Surgeons (AAOS), Scoliosis Research Society (SRS), and Pediatric Orthopaedic Society of North America (POSNA) commissioned a task force to investigate the effectiveness of scoliosis screening. They concluded that the literature does not provide sufficient evidence to merit scoliosis screening of asymptomatic adolescents. However, the societies do not support recommendations against scoliosis screening. The societies acknowledge the benefits of clinical screenings, including the potential to affect curve progression by brace treatment, as well as earlier detection of severe deformities requiring operative correction.[106] Due to gender differences in the onset of puberty and risk of curve progression, the societies recommend that if scoliosis screening is initiated, females should be screened twice, at ages 10 and 12, and males once, around age 13 or 14.[114]

Children with asymmetries should be referred to an orthopedic surgeon with an interest in and knowledge of scoliosis for a baseline evaluation. An examination begins with a complete patient history to obtain information regarding curve detection, familial conditions, general health, and physical maturity. A basic neurologic examination should also be performed on all patients with evidence of scoliosis including strength testing, deep tendon reflexes, and a check for upper motor neuron signs.[111] The physical examination may include assessment of general alignment including shoulder and pelvic symmetry, spinal alignment by forward bend test, trunk compensation using a plumb line, and leg length measurement. The magnitude of a rib hump is quantified using a scoliometer with the forward bend test.[93] The scoliometer, an inclinometer designed by Bunnell,[10] is placed over the spinous process at the apex of the curve to measure the angle of trunk rotation (ATR). The ATR correlates with the severity of the scoliosis.[107] A minimal measurement of at least 5° by the scoliometer is considered a good criterion for identifying lateral curvatures of the spine with Cobb angles of 20° or greater. Therefore, a scoliometer reading of 5° or greater warrants further evaluation[10] and is an indication for a radiograph.[118]

Standing radiographs with two initial views, lateral and anterior-posterior,[108] are used to determine location, type, and magnitude of the curve, as well as skeletal age with anterior-posterior views used at subsequent appointments. Skeletal maturity is determined using the Risser sign, which quantifies the amount of ossification of the iliac crest, using grades 0 to 5. Grade 0 represents absence of ossification. Grades 1 to 4 are excursions from 25% to 100%, starting at the anterior-superior iliac spine.[143] Grade 5 categorizes skeletal maturity. Grades 0, 1, and 2 correlate with the highest risk for curve progression,[108] grade 3 with progressing skeletal maturity, grade 4 with cessation of spinal growth, and grade 5 with cessation of increase in height (Fig. 8.2).

The spinal curvature is measured using the Cobb method. To complete the measurement, one must first identify the end vertebrae. The end vertebrae are described as the most cephalad vertebra of a curve whose upper surface maximally tilts toward the curve's concavity and the most caudal vertebra with maximal tilt toward the convexity. Lines are drawn as extensions of the end vertebrae from end plate or pedicles. The degree of curvature is measured as the angle formed by the intersection of lines perpendicular to these end vertebral lines[118] (Fig. 8.3). Magnetic resonance imaging, computed tomography, myelography, and bone scans can be used to identify subtle central nervous system abnormalities and to provide additional information as necessary to aid in diagnosis and detection of spinal conditions.

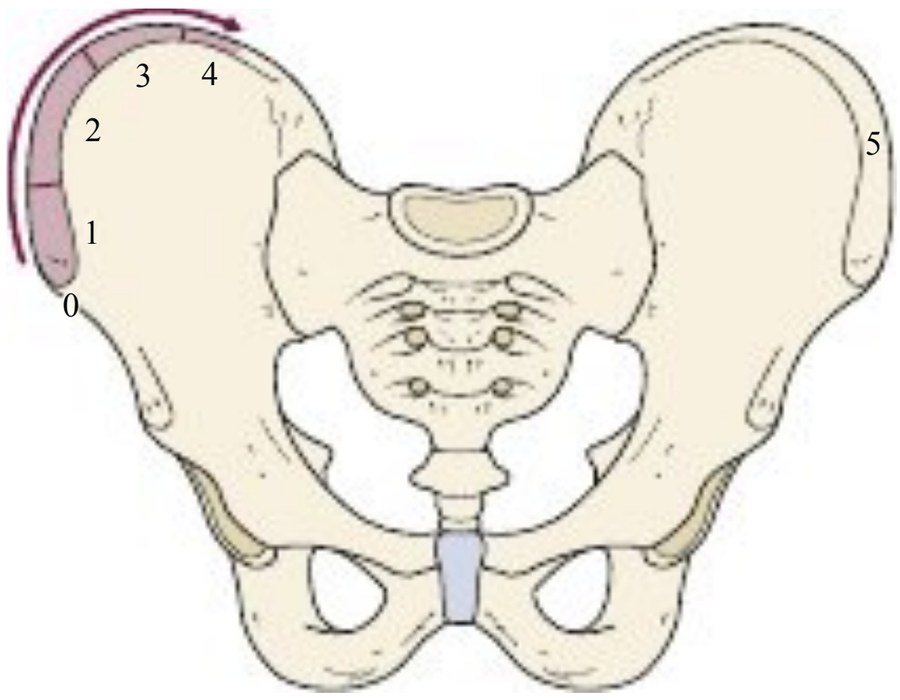

FIG. 8.2 Risser sign, grades 0 to 5. (From Adam A, Dixon AK, Gillard JH, et al, editors: Grainger & Allison's diagnostic radiology, ed 6, Edinburgh, 2015, Churchill Livingstone.)

Curr Opin Pediatr 21:55-64, 2009.)

Terminology

Scoliosis refers to a three-dimensional curvature of the spine. To be considered a scoliosis, the curvature in the coronal plane must be greater than 10° with a vertebral rotation component on the radiograph.[5,36] Spinal deformities are classified according to origin, location, magnitude, and direction. Curvatures may be idiopathic, neuromuscular, or congenital and may be further classified by the area of the spine in which the apex of the curve is located, as described in Table 8.1.

Magnitude is measured using the Cobb method as described above. Direction of the curve is designated as right or left by the side of the convexity of the deformity.[108] Right thoracic curves are most common. Left thoracic curves are not directly linked to a disease process but merit further evaluation, as they are more likely to have an underlying neurologic cause.[111]

TABLE 8.1 Classification of Spinal Curve Based on Location

Cervical curve	C1-C6
Cervicothoracic curve	C7-T1
Thoracic curve	T2-T11
Thoracolumbar curve	T12-L1
Lumbar curve	L2-L4
Lumbosacral curve	L5-S1

There are two major types of curvatures: structural and nonstructural. A nonstructural curve fully corrects clinically and radiographically on lateral bend toward the apex of the curve and lacks vertebral rotation. A nonstructural curve is usually nonprogressive and is most often caused by a shortened lower extremity on the side of the apex of the curve. It is essential, however, to monitor nonstructural curves during growth because they may occasionally develop into structural deformities.

A structural curve cannot be voluntarily, passively, or forcibly fully corrected. Rotation of the vertebrae is toward the convexity of the curve. A fixed thoracic prominence or rib hump in a child with a thoracic deformity or a lumbar paraspinal prominence in a child with a lumbar curve is evidence of rotation when observed on clinical examination.[46]

Idiopathic Scoliosis

Idiopathic scoliosis denotes a lateral curvature of the spine of unknown cause and is the most common form of scoliosis in children. Three strong factors have been identified that correlate with curve progression for idiopathic scoliosis: curve magnitude, Risser sign, and the patient's chronologic age at the time of diagnosis.[77]

Background

Origin, Incidence, and Pathophysiology

In 1954, James, et al. defined three subtypes of idiopathic scoliosis based on the age of onset: infantile, juvenile, and adolescent.[94] These categories correlate to major growth spurts with potential for maximal progression of scoliosis.[19] Infantile idiopathic scoliosis develops in children between birth and 3 years, usually manifesting shortly after birth. This form of scoliosis accounts for less than 1% of all cases in North America.[86,91] Infantile idiopathic scoliosis occurs more frequently in male infants, and most curves are left. Eighty to ninety percent of these curves spontaneously resolve, but many of the remainder of cases will progress throughout childhood resulting in severe deformity. Because infantile idiopathic scoliosis is common in England and northern Europe but rare in the United States, environmental factors have been implicated in the development of the deformity.[46,86]

Juvenile idiopathic scoliosis develops between ages 4 and 9 years.[27] The most common curve is right thoracic, occurring in males and females with equal frequency.[17] It is most often recognized at around 6 years of age. Juvenile idiopathic curves have a high rate of progression and result in severe deformity if untreated. Charles et al.[17] found that curves greater than 30° at onset of the pubertal growth spurt increased rapidly and presented a 100% prognosis for surgery. Curves 21° to 30° also presented a 75% progression risk and would benefit from careful follow-up.

Adolescent idiopathic scoliosis (AIS) categorizes curves manifesting at or around the onset of puberty and accounts for approximately 80% of all cases of idiopathic scoliosis. The prevalence of idiopathic scoliosis is 2% to 3% of children ages 10 to skeletal maturity.[111] The female-to-male ratio is 1:1 in curves of approximately 10°. With curve magnitude of 10° to 20°, the female-to-male ratio increases to 5:1. For curves greater than 30°, the ratio further increases to 10:1.[111] A greater percentage of curves will progress in the female patient: 19.3% compared with 1.2% of males. A large number of AIS curvatures are structural at the time of detection, although flexibility and the progression of these curves vary. Structural curves have a greater tendency to progress throughout adolescence at an average rate of 1° per month if untreated, whereas nonstructural curves may remain flexible enough to avoid becoming problematic.[46]

Currently in the orthopedic literature there is newer terminology categorizing scoliosis into early-onset scoliosis (EOS) and late-onset scoliosis (LOS), although therapists and families may continue to see previous verbiage in use (infantile, juvenile, and adolescent scoliosis). The Scoliosis Research Society describes EOS as occurring before 10 years of age. Use of this terminology is controversial. People who advocate its use believe that it delineates populations of patients with greater risk of developing pulmonary failure versus LOS patients, for whom that is unlikely.[109] Age of onset is an important factor because major thoracic curves seen prior to the age of 5 years old are more likely to be associated with thoracic insufficiency syndrome (to be discussed later in this chapter) and increased mortality.[94] On the other hand, supporters of the use of the terms *infantile* (0 to three years of age) and *juvenile* (4 to 10 years of age) scoliosis acknowledge that there are increased mortality rates but less so in juvenile than infantile scoliosis, thereby demonstrating the continued relevance of these terms.

Extensive research has been devoted to uncovering the cause of idiopathic scoliosis; still the mechanics and specific origin are not clearly understood. A number of theories have been proposed to attempt to explain the mechanics of vertebral column failure and decompensation of the spine, as seen in idiopathic scoliosis. It is thought that the cause of scoliosis is multifactorial. Current researchers have investigated many areas, including, but not limited to, growth timing in relationship to maturational changes; biomechanics; skeletal framework, specifically, spine slenderness; disproportionate growth of the anterior portion of the vertebrae compared with the posterior portion; melatonin; and genetics.[11] Data from studies by Wynne-Davies[140] and Cowell and colleagues[22] reflect the existence of a familial tendency. Janicki[57] also stated that a genetic component is included, noting that siblings of patients with scoliosis are diagnosed seven times more often and children of patients with scoliosis are diagnosed three times more often. Current research provides strong evidence for a genetic basis for idiopathic scoliosis; however, the specific mode or modes of heritability are still not clear. Understanding the genetic transmission of this disorder would be helpful in determining appropriate intervention approaches, particularly for those who might be at risk for severe disability.[90]

According to Wolff's law, bone remodels over time in response to the loads applied to it. In accordance with the Hueter-Volkmann principle, compressive loading will hinder bone growth, and reduced loading will hasten it.[112] Asymmetrical loading of a growing spine will lead to asymmetrical bony growth, resulting in wedge-shaped vertebrae.[120] Changes occurring on the concave side of the curvature include compression and degenerative changes of intravertebral discs and shortening of muscles and ligaments (Fig. 8.4). Changes in the thoracic spine directly affect the rib cage. The translatory shift of the spine causes an asymmetrically divided thorax, producing decreased pulmonary capacity on the convex side and increased pulmonary capacity on the concave side. Severe curves in the thoracic spine associated with increased angulation of the ribs posteriorly further reduce aeration of the lung on the convex side, potentially causing abnormal stresses on the heart and disturbed cardiac function.[26,50] The pulmonary system may also be affected. Czaprowski D et al.[23] examined the physical capacity of girls with mild and moderate AIS. They found that maximal oxygen intake was lower in the girls with moderate scoliosis (25° to 40° curvature) as compared to the control group, which is an indication of decreased cardiovascular endurance with physical activity.

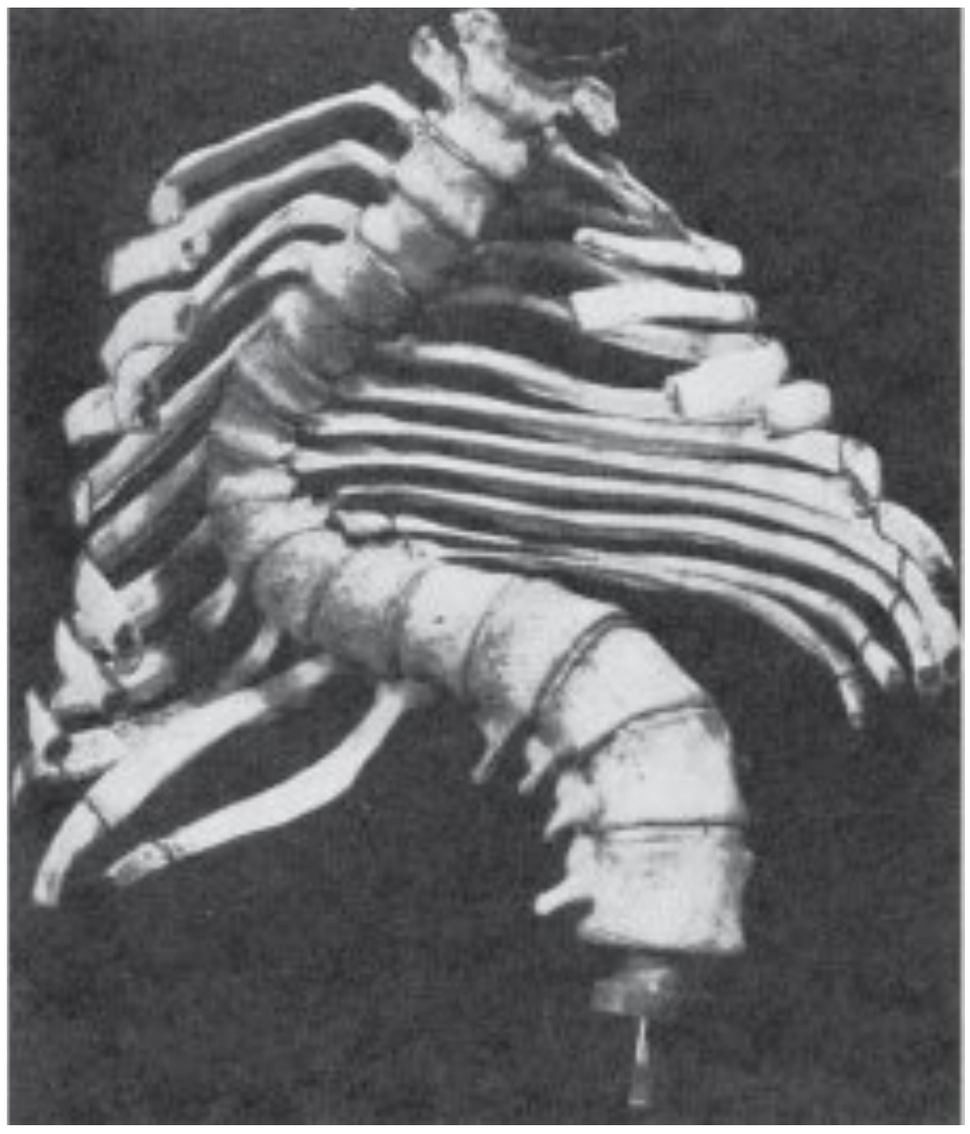

FIG. 8.4 Anatomic specimen of the spine demonstrating structural changes of right thoracic scoliosis. Note vertebral wedging on the concave side and rotation of the vertebral bodies to the convexity of the curve. (From James JIP: Scoliosis, ed 2, London, 1976, Churchill Livingstone.)

Investigators have established an association between scoliosis and vestibular dysfunction. Multiple groups have found increased body sway and diminished balance control in situations where there are proprioceptive and visional challenges in patients with scoliosis. Furthermore, cognitive integration of vestibular signals was impaired compared to patients without scoliosis. There are also studies describing anatomic differences in patients having scoliosis from their peers in their vestibular system apparatus.[43] Therefore for the treating clinician, the balance testing during the physical therapy evaluation is warranted.

Natural History

A progressive curve is defined as a sustained increase of 5° or more on two consecutive examinations occurring at 4- to 6-month intervals. An untreated progressive curve has the potential to increase in magnitude in adult life. Following are the main factors that influence the probability of progression in the skeletally immature patient[108,111,118]:

The younger the patient at diagnosis, the greater the risk of progression.

Double-curve patterns have a greater risk for progression than single-curve patterns.

The lower the Risser sign, the greater the risk of progression.

Curves that are larger at initial presentation are more likely to progress.

Risk of progression in females is approximately 10 times that in males with curves of comparable magnitude.

Greater risk of progression is present when curves develop before menarche.

Congenital Scoliosis

Origin, Incidence, and Pathophysiology

Congenital scoliosis curves are caused by anomalous vertebral development in utero. Kaplan et al.[58] suggested that congenital scoliosis has both a genetic and environmental basis and that abnormalities appear to be sporadic. The term *congenital scoliosis* should not be confused with *infantile scoliosis*. Clinical manifestations of congenital scoliosis may not be apparent at birth, but the vertebral anomaly is present. Infantile scoliosis will not demonstrate vertebral anomalies upon radiography.[132] Congenital anomalies of the vertebrae can be attributed to failure of vertebral segmentation, failure of vertebral formation, or mixed defect, which is a combination of the two. Both pathologic processes are frequently seen in the same spine and may occur at the same or at different levels. Location of the pathologic process on the vertebrae (anterior, posterior, lateral, or a combination) determines the congenital deformity. Purely lateral deformity produces congenital scoliosis, and anterolateral and posterolateral deformities produce congenital kyphoscoliosis and lordoscoliosis, respectively.[137,138] The male-to-female ratio for congenital scoliosis is 1:1.4.[75]

A defect of segmentation is seen when adjacent vertebrae do not completely separate from one another, thereby producing an unsegmented bar with no growth plate or disk between the adjacent vertebrae. A lateral, one-sided defect of segmentation produces severe progressive congenital scoliosis. Circumferential failure of segmentation produces en bloc vertebrae, an anomaly that results in loss of segmental motion and loss of longitudinal vertebral growth but no rotational or angular spinal deformity.[137]

FIG. 8.6 Computed tomography illustrating a hemivertebrae. (From Janicki JA, Alman B: Scoliosis: Review of diagnosis and treatment. Paediatr Child Health 12:771-776, 2007.)

Defects of formation may be partial or complete (Fig. 8.5 A–B).[21] Anterior failure of formation of all or part of the vertebral body produces a kyphosis. A partial unilateral defect of formation of a vertebra produces a wedge-shaped hemivertebra (Fig. 8.6) with one pedicle and only one side with growth potential. A nonsegmented hemivertebra is completely fused to the adjacent proximal and distal vertebrae. A semisegmented hemivertebra is fused to only one adjacent vertebra and is separated from the other by a normal end plate and disc. A segmented hemivertebra is separated from proximal and distal vertebrae by a normal end plate and a disc. Hemivertebrae may be unbalanced, with the defect present on one side of the spine, or balanced, with different hemivertebrae present, with defects on opposite sides of the spine compensating for any curves.[137,138]

Abnormalities involving other organ systems have been found in as many as 61% of patients with congenital scoliosis.[45] Multiple organ systems develop while the sclerotomes are

differentiating to form vertebral bodies during the embryonic period. Therefore any noxious influence affecting the formation of vertebral structures may also have an adverse effect on the concomitant development of organ systems, including the heart, kidneys, trachea, and esophagus. Cardiac anomalies have been associated with congenital scoliosis of the thoracic spine, and kidney anomalies have been associated with lumbar scoliosis.[75]

The risk of curve progression can be analyzed by examining the growth potential of the congenital anomaly. Many congenital curves become stable and do not progress. The highest risk of progression occurs when asymmetrical growth occurs, in which the convexity outgrows the concavity. This discrepancy usually occurs when the anatomy of the convex side is relatively normal and the concave side is deficient. A shortened trunk may be the main deformity if both convex and concave growth deficiencies occur over multiple levels.[138] Thoracolumbar involvement has the worst prognosis in curves greater than 50° by the age of 2.[58]

Thoracic Insufficiency Syndrome

Growth of the lungs is limited to the anatomic space provided by the boundaries of the thorax. Spinal and rib cage malformations that reduce thoracic volume early in life may have a negative impact on the size of the lungs at skeletal maturity, explaining why patients with congenital scoliosis have lower vital capacities on pulmonary testing than patients with idiopathic scoliosis with equivalent degrees of curvature.[14] The most rapid period of spinal growth is in the first 5 years of life increasing to 50% of its length[18] at a rate of 1.4 cm per year, 0.6 cm per year between the ages of 5 and 10 years old, and increasing in rate again during adolescence to 1.2 cm per year.[59] The greatest increase in alveolar number is within the first 2 years of life and is complete by age 8, although lung volumes continue to increase into adolescence. Pulmonary volumes are expected to begin to decline in the mid-30s.[18]

Thoracic insufficiency syndrome as defined by Campbell et al.[14] is "the inability of the thorax to support normal respiration or lung growth" resulting in lack of pulmonary development. This is correlated to the rib fusions and chest wall anomalies that are associated with congenital scoliosis. If the chest cannot elongate with growth, there will be inadequate space for alveolar growth. Thoracic insufficiency is a combination of two thoracic deficiencies: it must provide support for normal respiration and support normal lung size that is required as an adult. When a child has a thorax that cannot support normal breathing, the child will form compensations that may enable him to appear clinically normal with mild thoracic insufficiency syndrome, but progression of the deformities leads to progression of the syndrome, stressing lung development and function. However, when the child can no longer compensate adequately, clinical signs of respiratory insufficiency may emerge. Dyspnea may appear, with the potential need for supplemental oxygen or ventilatory support to maintain arterial oxygen levels. Recommendations for the treating therapist include monitoring the patient's tolerance to exercise. Items to monitor include facial coloring, heart rate, and respiratory rate. Mild thoracic insufficiency syndrome should be monitored by the child's physician with clinical evaluation of respiratory function, physical examination, radiographs, imaging, and pulmonary function studies. Early intervention during rapid lung growth is preferable.[14]

Congenital scoliosis likely leads to decreased vital capacity because of diminished growth potential of the malformed vertebrae and resultant spinal and chest wall deformity. Also it is known that an increased number of involved vertebrae is related to worsening pulmonary function.[59] Campbell et al.[14] found that even in cases with early spinal surgery children with thoracic spinal deformities may still have hypoplastic thoraxes. During early childhood these children demonstrate nearly typical tolerance to exercise; however, they develop respiratory insufficiency in later adolescence when their body mass increases. People with restrictive lung disease may clinically tolerate it for long periods, but after 40 years of age, some will become oxygen or ventilator dependent with a significant increase in mortality.

Interventions for Idiopathic and Congenital Scoliosis

Treatment decisions are based on the skeletal maturity of the child, as measured by the Risser sign, the growth potential of the child, and the curve magnitude. In addition to surgical intervention, nonsurgical interventions that include serial casting, orthotic treatment, and exercise may be provided.

Surgical Interventions

The major indication for spinal fusion is a documented progressive idiopathic curve with a Cobb angle that reaches 45° or greater in an immature spine. Curves greater than 40° are increasingly difficult to manage with orthotics and have significant risk of progression after skeletal maturity.[67] The main objective of spinal fusion surgery is to obtain a solid arthrodesis because the fusion mass is ultimately what prevents further progression of the deformity.[29,67] The ideal correction system should provide correction in all three planes of the scoliosis, provide rigid fixation, and attain maximal correction with minimal fusion levels.[70]

The classification system that is frequently used when working with children with AIS is the Lenke system, developed in 1983. The main goal of the Lenke system is to categorize surgical curves by analyzing curve pattern similarities to provide comparisons that will ultimately provide the best treatment when making surgical decisions regarding which levels need to be fused.[73] Lenke's system classifies curves into six types[84] with subsets including lumbar and sagittal modifiers.[74] The curve is analyzed looking at upright coronal and sagittal plane x-rays and lateral flexion in supine. The Cobb angles are measured in the proximal thoracic, main thoracic, and thoracolumbar/lumbar regions to determine the major and minor curves, and then they are identified as structural or nonstructural curves. Lenke's recommendations include the major curve and minor structural curves in the instrumentation and exclude nonstructural minor curves.[74]

A posterior surgical procedure, posterior spinal fusion (PSF) with instrumentation, is currently considered to be the gold standard used for spinal fusion.[102,139] The differences among posterior spinal fusion techniques lie with the instrumentation used to obtain correction and protect the fusion.

Spinal instrumentation has evolved since Harrington designed the first generation of posterior instrumentation for scoliosis. Harrington rods correct frontal plane deformities but do not allow for sagittal plane correction and do not address the rotatory components of scoliosis. Further, the placement of Harrington rods calls for postoperative bracing.[105]

The Cotrel-Dubousset (CD) posterior spinal instrumentation (Fig. 8.7) was introduced in the early 1980s and strove for

FIG. 8.7 Cotrel-Dubousset instrumentation system implanted on a plastic spine.

a three-dimensional correction of the spinal deformity while avoiding the need for postoperative bracing. A minimum of two parallel rods are used: one on either side of the spine and attached to the spine with hooks or screws. Selective compression or distraction forces may be applied on the rod at any level to correct the deformity.[30] Recent articles have questioned the rotational correction of scoliosis using conventional CD instrumentation.[70,97,121]

In 1999 a new model called direct vertebral rotation (DVR) was introduced. In a prospective study, Lee et al.[70] found improved curve correction as well as correction of apical vertebral rotation when patients with AIS underwent DVR as compared with simple rod derotation. The concept of DVR is to apply both a coronal and a rotational correction. Pedicle screw fixation allows a correcting force to be directed opposite the deformity. The addition of DVR provides the rotational plane correction of the deformity in idiopathic scoliosis.[70]

It is important to treat children with scoliosis while they are still growing, though PSF with instrumentation is generally postponed until the child reaches skeletal maturity in order to preserve spinal growth and ensure adequate space for pulmonary development.[14] Growth-sparing techniques have been developed to manage the scoliotic curve while allowing continued growth of the spine in an effort to delay PSF until the child reaches skeletal maturity. Growth-sparing techniques will be discussed in the next few paragraphs.

Expandable growing spinal rod technique surgery is indicated for children without bony anomaly of the vertebrae or rib cage and with curve flexibility. The mechanism of distraction yields increased growth of the spine and vertebral column. Serial lengthenings must be performed approximately every 6 months during the growing years. Matsumoto et al.[84] report that as the number of rod-lengthening procedures increases, so does the complication rate. Magnetically controlled growing rods (MCGR) have been developed to address this challenge,[84] as they allow for gradual distraction from an external device.[69] MCGR are now in clinical use and will be an area for further research.[84]

A surgery performed for patients with congenital scoliosis with fused ribs or thoracic insufficiency syndrome is insertion of vertical expandable prosthetic titanium ribs (VEPTR) with an expansion thoracotomy. In this procedure, one or more rib-to-rib or rib-to-spine configurations may be placed.[141] Campbell and Hell-Vocke[13] concluded that growth of the spine approached normal rates after the insertion of VEPTR, including those with bony bars. They believe that the distraction applied by the prosthesis unloads the concave side of the scoliosis, thereby facilitating growth by the Hueter-Volkmann principle. Smith et al.[117] found improvement in lung volume and density, suggesting consequential improved pulmonary function. This is of importance because the lungs are rapidly developing during childhood. A tenfold increase in the number of alveoli occurs by adulthood, but most form within the first 8 years of life.[54] Complications of VEPTR surgery may include brachial plexus injury and multiple outpatient subsequent lengthenings as the child grows.[141]

Vertebral stapling procedures and flexible tethering have been studied to treat AIS. Although these implants vary in flexibility, they are mechanically similar in that they restrict unilateral growth of the convex side of a curvature, accomplished by increasing stress over the growth plates of two adjacent vertebrae, then take advantage of remaining spinal growth to allow the concave side to grow and change over time.[2,20,28] Several studies have noted that various growth-sparing techniques, whether they be tethering,[2,51] growing rods,[113] or fusionless devices in general,[28] focus on coronal plane correction and do not necessarily correct sagittal or transverse plane deformities. Although this is a clear disadvantage of fusionless devices, the benefit of postponing spinal fusion until the child reaches skeletal maturity often outweighs this limitation.

Of note, hospitals are scrutinizing the frequency of readmissions within 90 days of the original surgery because they are now financially accountable for these readmissions under provisions in the Affordable Care Act.[56] This will continue to be an area of continued research going forward.

Nonsurgical Interventions

Idiopathic curves of less than 25°, curves of nonsurgical magnitude of any type in a skeletally mature patient, and nonprogressive congenital curves are evaluated by clinical examination every 4 to 6 months. Radiographs are obtained at each visit; however, unchanged results of a scoliometer examination may reduce the frequency of radiographs to every other visit, depending on individual physician and institution practice.

Serial casting. One technique addressing the treatment of EOS is serial casting. It is theorized that the rapid growth of children in this age group inside the constricted environment of the hard cast allows the Hueter-Volkmann principle to take effect, decreasing curve progression by unloading the growth plates on the concave side of the curvature, therefore fostering growth of the spinal column.[42] The primary goal of casting is to be a growth friendly modality to enhance thoracic spine growth, allowing for closer-to-normal pulmonary function.

During the casting process, children lie on a specially designed frame by the surgeon. Patients are placed under general anesthesia while the plaster or fiberglass cast and traction are applied. The casts are changed every 2 to 3 months.[33]

Serial casting has been shown to preserve thoracic vertebral height growth at the same velocity as the expected norm, having a positive impact on pulmonary function.[4] Authors have reported good results with this technique. In cases of mild to moderate idiopathic EOS with curves of 60° or less, complete resolution has been achieved if started at less than 2 years of age. For older children and for those with more severe curves, recent evidence demonstrates that serial casting may delay surgery, theoretically reducing the potential for complications with recurrent surgical procedures.[24]

Baulesh et al.[4] reported complications from serial casting affected 19% of the children and included nonfatal pulmonary complications that required a break from casting and superficial skin irritation; all complications were resolved without invasive interventions. Hassanzadeh et al.[42] state that the effect of casting on pulmonary function is an area meriting further study.

Orthotic management. The goal of orthotic management is to alter the natural history of curve progression in AIS. Correction of a frontal plane curvature involves application of force in directions opposite to the natural tendency of the curve. Forces are applied at the apex of the curvature, and opposing forces are applied both above and below it.[44]

The indication for orthotic use depends on curve type, magnitude, and location. Orthoses are typically prescribed for children with idiopathic scoliosis who are skeletally immature with a Risser sign of 0, 1, or 2 and have a curve from 25° to 45°[38,60,104] (see Fig. 8.2). A curve with a greater magnitude at the time of detection has an increased risk of progression. Similarly, the effect of an orthosis on prevention of curve progression decreases as the magnitude of the curve increases.[61]

The Milwaukee brace or cervical-thoracic-lumbar-sacral orthosis (CTLSO) remains the gold standard for idiopathic scoliosis in terms of curve correction (based on mechanics), but it is rarely used today in the United States due, in part, to psychosocial stressors associated with brace wear and limited dosage reported by patients. Additionally, the introduction of the thoracolumbosacral orthosis (TLSO) offers a low-profile option for the treatment of curves with an apex as high as T7.[54] There are a number of different TLSO types available, but the goal of the brace design remains the same. Rigid brace design can promote active correction as the patient shifts away from pressure within the brace, or passive correction, preventing curve progression using external forces of the brace on the spine.[134] Appropriate force application is a must. An orthotist molds a prefabricated brace to the patient and customizes the orthosis by adding lumbar pads and relief areas to meet the individual's specific needs. The rigid shell provides a firm support, and the foam lining allows for comfort. A Boston brace is an example of a TLSO and best treats a thoracic curve with an apex of T7 or below.[132] A Boston brace may be modified by the addition of an extension on the concave side with lateral pressure from a convex pad to achieve improved control of curves with an apex at T7 to T9.[62,132] Other TLSO types include the Wilmington and Charleston models. A Wilmington TLSO is a total-contact, custom-molded orthosis that achieves maximal spinal correction by the tight contact and fit, not by pads and relief areas.[62] A Charleston orthosis is used for idiopathic curves and is worn only at night because it is fabricated in the position of maximum side-bend correction.[101]

A recent multicenter trial of the effects of bracing with patients with AIS demonstrated that dosage was the biggest factor when it comes to orthotic management. If a patient wore the brace anywhere from 0–6 hours/day, it was comparable to findings in the observation only group. However, if the patient wore the brace at least 12.9 hours/day, it was associated with success rates of 90% to 93%.[134] The amount of brace wear was logged using thermal indicators. A relatively high success rate with a brace-wearing schedule well below the previously recommended 23 hours/day would likely contribute to improved patient adherence with the recommended dosage and have a subsequent positive impact on patient outcomes.

Margonato et al.[83] suggested that bracing appears to limit maximal exercise performance and recommended moderate physical exercise during brace wear to offset the limitations of the cardiovascular, respiratory, and musculoskeletal systems associated with the brace encompassing the rib cage. Frownfelter et al.[35] found that wearing a TLSO does restrict pulmonary function both at rest and after exercise in healthy adults and suggested adding an abdominal cut out to the TLSO to ease the work of breathing. Further research would be necessary to monitor spinal stability and ensure curve correction is maintained in patients with AIS when using a TLSO with an abdominal cutout.

Orthotic treatment continues until one of two conditions occurs: the curve is no longer controlled (usually at 45° or higher), at which time the patient may become a surgical candidate (treatment failure), or until skeletal maturity occurs, at which time weaning of the brace may begin (treatment success). An orthotic treatment is considered successful if the curve magnitude at the end of treatment is within 5° of the magnitude at the start of the treatment.

FOREGROUND INFORMATION

Physical Therapy Considerations for Postoperative Management

Activity restrictions following spinal fusion surgery are largely anecdotal, although they are often imposed as best practice in an effort to protect the fresh surgical site until the arthrodesis is formed. Activity restrictions are set at the discretion of the orthopedic surgeon and may include avoiding trunk rotation, hip or shoulder flexion greater than 90°, and/or prone activities. A physical therapist's role in the acute postoperative phase includes instruction in body mechanics for bed mobility, transfers, dressing, and ambulation. To avoid trunk rotation, the therapist must instruct the patient in log-rolling and in transitioning from a supine position to sitting without rotation. Shoes and socks are donned or removed with the legs in a "figure four" seated position with negligible forward flexion (patient positioned sitting with the ankle of one leg supported on the distal thigh of the other leg, such that neither lower extremity exceeds hip flexion greater than 90°). If applicable the therapist may also instruct the patient in donning or removing the orthosis while in bed, while from a sidelying to a supine position, or while standing with assistance (if not contraindicated by physician's orders). For the acute stage, donning or removing of the orthosis in bed is preferable. The patient is instructed in general range of motion and strengthening exercises (without resistance) for the extremities such as ankle pumps to promote circulation, isometric quadriceps contractions, supine hip abduction, heel slides, and isometric gluteal sets. Because the patient's functional activities for the first two postoperative weeks are limited

to showering and walking, the therapist's role is to encourage ambulation. Not only does this enable the patient to experience fewer side effects from bed rest, it is also beneficial for the development of a strong, healthy fusion mass or arthrodesis.

Formal guidelines to return to sport following spinal fusion are not well established in the literature. Lehman, et al.[71] surveyed experienced surgeons to better describe the variability in practice. Overall, they found that surgeons will allow earlier return to sports after surgery to correct AIS with the use of pedicle screw constructs as compared to hybrid (a combination of pedicle screws and hooks) and hook constructs. According to the survey, most patients with pedicle screw constructs are permitted to return to running by 3 months, both noncontact (e.g., PE class, swimming) and contact sports (soccer, basketball, volleyball) by 6 months, and collision sports (American football, hockey, rugby) by 12 months postoperatively. There are, however, approximately 20% of respondents who reported that they do not permit patients to return to collision sports, regardless of construct. Further research is merited to establish evidence-based guidelines for return to sport.

Exercise

Currently, research is evaluating the potential for physiotherapy scoliosis-specific exercises (PSSE) to play a role in improvement of postural awareness and subsequent spinal alignment in patients with AIS. The characteristics of PSSE include self-correction, elongation, and chest wall expansion with focus on incorporation of the corrected posture into one's daily activities of living.[52] Different PSSE approaches have emerged including, but not limited to, the Scientific Exercise Approach to Scoliosis (SEAS) in Italy and the Schroth technique from Germany. In an effort to investigate optimal treatment techniques for scoliosis that may include both operative and nonoperative treatment strategies, the SRS supports pilot research studies to critically evaluate the efficacy of PSSE in the treatment of AIS. Together with the Society on Scoliosis Orthopedic and Rehabilitative Treatment (SOSORT), the SRS is evaluating current treatment strategies for scoliosis including bracing, PSSE, and other fusionless treatments. The current stance of the SRS (2014) is that, while some evidence has shown that some PSSE programs are superior to programs with nonspecific exercises, it is too soon to comment on their general applicability.

A home exercise program designed to maintain or improve trunk and pelvic strength and flexibility is often prescribed for children with idiopathic or congenital scoliosis. Exercises include spinal stabilization, balance activities, core strengthening, and postural correction, including lateral shifts, flexibility exercises, and respiratory activities. Negrini et al.[98] investigated the SEAS protocol. In this approach the patient actively corrects his own posture with a goal of maximal curve correction and follows a specific exercise program designed to increase spinal stability, improve balance reactions, and retain physiologic sagittal spinal curvatures.

The Schroth method, introduced in the 1930s, also utilizes a personalized exercise protocol tailored to each patient to achieve maximal postural correction. The Schroth method strives to decrease curve progression, reduce pain, increase vital capacity, and improve posture and appearance.[72] The Schroth method has three major contributing concepts: postural correction, correction of breathing patterns, and correction of postural perception. The Schroth school believes that in order to affect postural control one must first change his postural perception.[135] Initially, Schroth addressed large thoracic spine curves (curves exceeding 70° to 80°),[8] but over the past several decades the program has evolved to affect small or moderate curves and to incorporate a focus on activities of daily living (ADLs) training to prevent loss of postural control throughout daily activities.[135] Originally, the program was performed over a period of at least 3 months, but recently shorter programs have been developed.[8] A 2015 study examined patients with AIS dividing them into 3 groups: a group performing Schroth exercises in a clinical setting under direct supervision of a physiotherapist, a home exercise group, and a control group who were observed. The investigators concluded that the exercise group under direct supervision was superior to a home exercise program or to no treatment at all, the latter two showing curve progression. The authors found that the home exercises may affect change in the lateral plane but without change in the rotation component.[7,127]

Borysov and Borysov investigated the effect of the Schroth method on the ATR and vital capacity in 34 children with AIS over 7 days. Both ATR and vital capacity were decreased, indicating improvement. These trials demonstrate that physical therapy may have the potential to effect positive change with idiopathic scoliosis. However, these studies and others are preliminary. Researchers have indicated that there are no mid- or long-term studies and more research is needed, which is in agreement with the statement put out by the SRS. The recommendation for the treating therapist is to incorporate exercises including spinal stabilization, balance activities, core strengthening, and postural correction, including lateral shifts, flexibility exercises, and respiratory activities into the plan of care. It is important to note that the Schroth method is copyrighted and certification is required to practice this technique (Fig. 8.8).

Outcomes for Persons with Idiopathic Scoliosis

Most people with AIS live functional and normal lives and have a mortality rate similar to that of the general population.[130,133] However, Weinstein et al.[130] found that patients with untreated scoliosis not only reported an increased incidence of both chronic and acute back pain but were found to have decreased body image as compared with people of similar age and gender without scoliosis. A Cobb angle greater than 50° at skeletal maturity was identified by Weinstein et al.[130] as a strong predictor of decreased pulmonary function. A curvature with a thoracic apex is also associated with shortness of breath.[130] Severe thoracic curves, greater than 100°, have been shown to decrease pulmonary function with dyspnea upon exertion leading to probable alveolar hypoventilation and chronic respiratory failure.[68]

Merola et al.[88] studied patients' status postsurgical correction of AIS and found statistically significant improvements in general self-image, function from back condition, and level of activity domains as compared with preoperative status but no significant correlation between magnitude of curve correction and outcome scores. Successful outcomes may be correlated with patient perception, such as elimination of the rib hump or restoration of the waistline, rather than focusing on magnitude of curve correction alone.[88]

The natural history of idiopathic scoliosis continues into adult life because curves can progress after skeletal maturity. Risk of progression depends on curve magnitude and location.[79] Curves of greater than 45° at the time of skeletal maturity have a higher risk of progressing and producing complications.

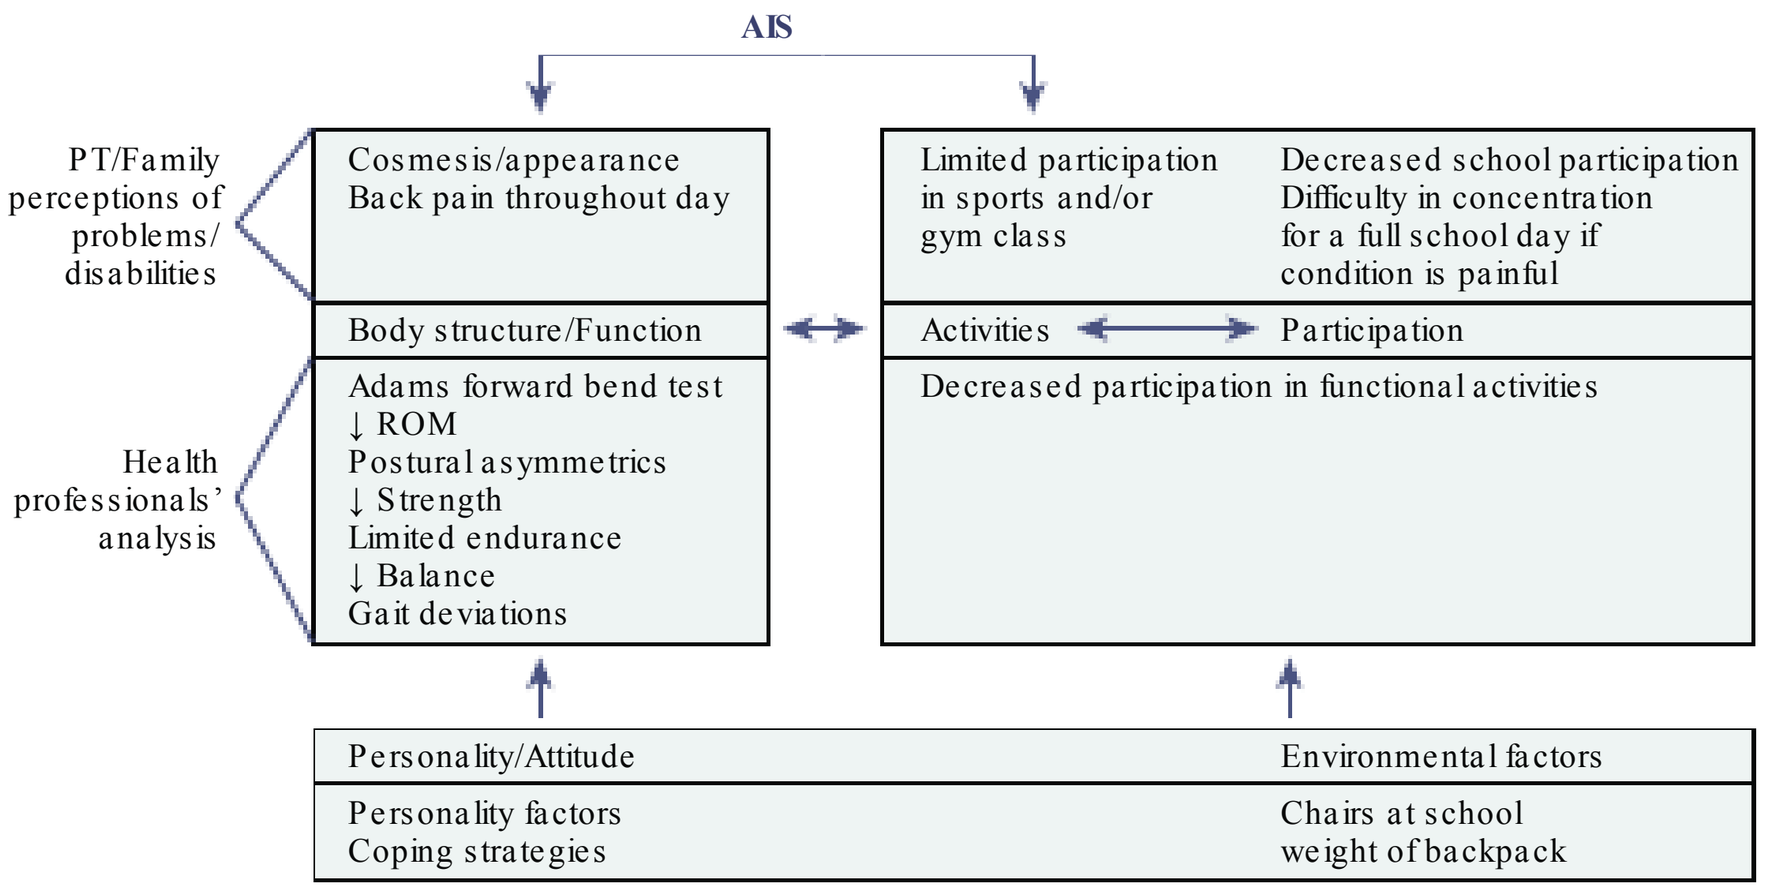

FIG. 8.8 Adolescent idiopathic scoliosis table of interventions. (Created using data from Steiner WA, Ryser L, Huber E, et al.: Use of the ICF model as a clinical problem-solving tool in physical therapy and rehabilitation medicine. Phys Ther 82:1098-1107, 2002.)

Although both thoracic and lumbar curves can progress, progression in the thoracic region may cause more significant complications because of its effects on the cardiopulmonary system. Complications of untreated scoliosis include severe cosmetic deformity and major disability, which may include pain, respiratory insufficiency, or right-sided heart failure.[46] Indications for adult treatment include back pain, compromised pulmonary function, psychosocial effects, and an increased risk for premature death. The treatment plan is consistent with that for adolescent idiopathic scoliosis.[131]

BACKGROUND INFORMATION

Neuromuscular Scoliosis

In contrast to idiopathic scoliosis, neuromuscular scoliosis is associated with systemic or chronic diseases and often has a rapid progression.[96] Neuromuscular curves tend to progress more rapidly and to have more disabling outcomes such as decreased ability to sit, diminished hand function, respiratory compromise due to intercostal muscle weakness,[132] and decreased lung capacity[53] and are highly associated with pelvic obliquity.[125] In the general population the prevalence of scoliosis is 1% to 2% while in cerebral palsy (CP) it has a large variance of 15% to 80%. The variance in those with CP is attributable to age, nature of severity of the neurologic impairment, extent of the physical impairment, and whether the child was positioned in supine versus upright when the x-ray was taken. It has been reported that a scoliosis of at least 40° at maturity is present in 30% of people with quadriplegic CP, 10% of those with diplegia, and 2% of those with hemiplegia.[66] See Chapter 19 for more detailed information on cerebral palsy.

In Duchenne muscular dystrophy (DMD) the development of scoliosis is correlated with the ability to ambulate; ambulators do not develop scoliosis. As children with DMD lose their ability to ambulate and become more dependent on their wheelchairs, a scoliotic curve begins to develop, typically in the thoracolumbar region.[95] A correlation between the ability to ambulate and the development of scoliosis has also been noted in those with CP in that the prevalence of scoliosis in nonambulators with total body involvement is also significantly higher than the prevalence in ambulators.[125] Scoliosis affects 100% of patients with spinal muscular atrophy (SMA) type II, typically beginning at about 3 years of age. On average, curves are greater than 54° by 10 years of age, typically with a low thoracic C-curve although 17% will develop an S-curve.[95] See Chapter 12 for more information on Duchenne muscular dystrophy.

The direct cause of neuromuscular scoliosis is not understood; however, Berven and Bradford[5] identified asymmetrical paraplegia, mechanical forces, intraspinal and congenital anomalies, sensory feedback, and control of spinal balance by central pathways as possible contributors in children. Disruption in any one of these areas may lead to spinal deformity. The SRS divides neuromuscular scoliosis into two categories: neuropathic (i.e., cerebral palsy [upper motor neuron] or spinal muscular dystrophy [lower motor neuron]) and myopathic (i.e., Duchenne muscular dystrophy).[132]

Important health issues are associated with neuromuscular conditions that may be influenced by scoliosis. Mullender et al.[95] reported in patients with either DMD or SMA type II, scoliosis is related to a decline in pulmonary function and that the decline in vital capacity is part of the natural history of the condition and not necessarily causally related to DMD or SMA type II. Large curves affect the ability to sit, requiring upper extremity propping and large rib prominences can be susceptible to pressure to the skin and may lead to ulceration and pain in children with cerebral palsy.[66]

An understanding of the orthopedic consequences associated with neuromuscular scoliosis is essential. Physical therapists play an important role in helping to manage and educate families about orthopedic concerns. The curve pattern commonly seen among people with neuromuscular scoliosis is a long C-curve (Fig. 8.9) beginning in the thoracic region and extending into the sacrum.[132] Relationships between the spine, pelvis, and hips have been investigated by several authors. Terjesen, Lange, and Steen[122] found that the severity of the

FIG. 8.9 Severe neuromuscular scoliosis. (From Moe JH, Winter RB, Bradford DS, et al.: Scoliosis and other spinal deformities. 2nd ed. Philadelphia: WB Saunders, 1987.)

curve correlated with the severity of the pelvic obliquity. Studies have reported there may be increased potential for hip subluxation in patients with scoliosis,[16,95] while multiple studies have described a link between the direction of a windswept deformity and the curve convexity.[66] Therapists should be aware of these potential consequences. Physical therapists should be monitoring spinal and hip range of motion for changes. They can instruct caregivers in positioning, stretches, and active or assistive-active range-of-motion exercises. Changes in seating in the patient's wheelchair may also be warranted.

Surgical Intervention

Surgical intervention for neuromuscular scoliosis differs from that for idiopathic scoliosis in several ways. In nonambulatory patients with CP the fusion with instrumentation is extended from the upper thoracic spine into the pelvis in order to obtain curve correction and reduce the risk of recurrent deformity. Improved pelvic alignment can also be achieved when the fusion is extended into the pelvis[66] for nonambulators.[125] The goals of the spinal fusion are to attain improvement of the deformity, stability of the new spinal shape, and a safe and tolerable surgery.[66]

Complications in patients undergoing spinal fusion have been shown to be high in children with CP,[66,110] occurring in 40% to 80% of patients. Major complications include blood loss, pulmonary compromise, deep wound infection, spinal cord dysfunction, and pseudoarthrosis.[66] Death occurs in 1% of patients. Pulmonary function is compromised in up to 25% of patients with neuromuscular scoliosis. It is most commonly seen when preoperative testing demonstrates a forced vital capacity of less than 40%.[66,110] Pulmonary function is at increased risk in children with neuromuscular scoliosis for respiratory problems, with pulmonary function being compromised for various reasons that may include weakness and scarring from aspiration or pneumonia. Pulmonary capacity is further compromised in scoliosis. Flexibility of the rib cage is decreased, restricting chest wall excursion when breathing. Organs contained within the thorax are compressed by shortening of the trunk. These changes result in decreased gas exchange and diffusion capacity and ventilation/perfusion imbalance.[110] It is important that the treating physical therapist keep these limiting factors in mind and adjust intervention as needed.

In children with DMD or SMA the preferred fusion levels are T2 or T3 to L5. Fixation to the sacrum has been associated with loss of function, increased surgery length, and increased blood loss. A more mobile lumbosacral joint may assist functions such as seating and transfers when fusing to L5.[95]

The recommended surgical approach in this condition is to use the Luque segmental spinal instrumentation (SSI)–Galveston procedure. The Luque SSI procedure uses L-shaped rods surgically fixed at each segment with sublaminar wires forming a more rigid fixation in comparison to the Harrington rods due to the correction at each level. The Luque procedure was later modified with the use of intrailiac (Galveston) posts that are long lever arms to reduce lateral bending and flexion-extension movement. This allows the rods to span the sacroiliac joint. Long-term studies have demonstrated that this surgery is efficient and safe in those with DMD. Due to cardiac and respiratory issues it is recommended that spinal fusion be considered earlier than curve progression to 40°. The primary goal of surgery is to stop curve progression to obtain comfortable seating.[53] Healing from the spinal fusion takes an extended period of time; the arthrodesis takes 3 to 9 months to be completely healed. Precautions including spinal rotation and hip flexion beyond 90° are not permitted.[95]

A curve may require both an anterior approach with a discectomy and posterior fusion with instrumentation, although this is no longer the typical surgical approach. The anterior component of the procedure can improve spinal flexibility, minimizing residual curve and helping to achieve a level pelvis in children with CP.[66] Studies demonstrate that there is increased blood loss and length of hospital stay, including time spent in the intensive care unit, for combined anteroposterior spinal fusion compared to posterior only procedures.[126]

The role of the physical therapist is similar to that for postoperative treatment of other curve types. The intervention may have to be modified to adjust to a patient's motor and cognitive abilities.[95] Multiple studies utilizing parent/caregiver questionnaires suggest that spinal fusion surgery is beneficial and has a positive impact on their child's quality of life for children with neuromuscular scoliosis.[87] The parents of children with CP felt that their children had improved trunk balance, sitting, ease of transfers, and personal care.[66,125,126]

Nonsurgical Intervention

Nonsurgical intervention for neuromuscular spinal curvatures includes clinical observation, radiographic examination, and orthotic management.[132] Clinical observation allows a thorough assessment of the child's present and potential function, level of comprehension, and ability to cooperate.[32] Mullender et al.[95] discuss the importance of a well-fitting and supportive seating system as an integral part of the care in this population. This is best addressed by the team approach, including a physical therapist, an occupational therapist, a physician, an equipment vendor, and an orthotist. Please refer to Chapter 33, Assistive Technology, regarding appropriate seating options for this population.

The goal of orthotic management in children with neuromuscular scoliosis is to provide support directly to the trunk and possibly aid in simplifying the required seating.[66] Studies have demonstrated that the use of a spinal orthotic for a neuromuscular scoliosis does not have an impact on curve progression.[89] In DMD, as the spine matures, curve progression is predicted to be 10° per year with the use of bracing.[53] Terjesen, Lange, and Steen[103] found that, despite this, many families and caregivers have remained pleased with the outcome following TLSO use for 2 years, with improvements in sitting stability and overall function being reported. Orthotic management might include the custom-molded, total-contact TLSO; the underarm TLSO; or the Milwaukee brace.[78]

Researchers have studied other methods to manage neuromuscular scoliosis. King et al.[65] evaluated the effects of daily corticosteroid use on orthopedic outcomes in 143 boys with DMD. They found that those treated with steroids not only demonstrated a decreased prevalence of scoliosis, but they also had decreased magnitude of curvatures as compared with the untreated group. However, 32% of the treated group suffered vertebral compression fractures, a serious adverse effect of corticosteroid therapy. Other researchers have looked at the ability to prolong walking in boys with DMD and have seen some boys walk up to the ages of 13 to 15 years old, therefore slowing the rapid development of scoliosis, but this had not been corroborated.[95] Hsu and Quinilvan[53] reported that the lordotic posture present in boys with DMD delays development of spinal collapse while ambulatory. Other researchers have studied the effects of intrathecal baclofen (ITB) on curve progression[115,116] using matched groups for age, functional impairment, and curve magnitude and concluded that ITB does not have a significant effect on curve progression. Curve progression was found to increase compared with the expected natural history after insertion of ITB pumps in nonambulatory children with quadriplegic cerebral palsy and neuromuscular scoliosis.[37]

KYPHOSIS

Background and Foreground Information

A kyphosis is an abnormal posterior convexity of the spine; normal thoracic kyphosis measures 20° to 40° between vertebral segments T5 through T12 with a lumbar lordosis and a Cobb angle typically measuring 20° to 50°.[41] A spinal kyphosis may occur as the result of trauma, congenital conditions, or neuromuscular, post-traumatic (tuberculosis), or Scheuermann disease. The most common causes of an abnormal thoracic kyphosis in children and adolescents are Scheuermann disease and poor posture.[41] The discussion in this section focuses on congenital kyphosis, postural roundback, and Scheuermann disease.

Congenital Kyphosis

Congenital kyphosis is a rare deformity that is typically progressive, consisting of anterior nonsegmentation, centrum deficiencies, and mixed deformities. The exact cause is unknown, although animal studies suggest that there may be a vascular disruption causing centrum defects. Anomalies occur later during the chrondrification and ossification stages of the embryonic period. Additionally, posterior segmentation and block vertebrae defects have been seen. The most frequent defects are multiple hemivertebrae (44%), anterior segment defect (32%), and single hemivertebrae (18%). Up to 60% of patients may have associated anomalies, including the renal and cardiac systems, or sacral agenesis. Congenital kyphosis typically requires surgical intervention and without surgery the progressive natural history will likely lead to paraplegia or cardiac dysfunction. Studies have demonstrated that orthotics are an ineffective treatment modality. Recommendations for surgery may be as young as prior to 3 years old to reduce possible neurologic sequelae. Posterior spinal arthrodesis can be safely completed in patients as young as 6 months of age. The goals of surgery are to stop deformity progression that leads to unbalanced growth and anterior decompression that places neural structures at risk. Arthrodesis with a posterior spinal fusion is recommended for deformities less than 50° to 60° and an additional anterior release and arthrodesis for larger deformities. In the immature spine, some spontaneous correction can occur after a posterior arthrodesis due to continued growth in the anterior portion of the vertebral body.[64] Basu et al.[3] studied the incidence of defects of other organ systems in patients with both congenital kyphosis and scoliosis and found it to be high, concluding that an essential part of patient evaluation is MRI and echocardiography. Zeng Y et al.[144] stated that there is an incidence of 20% to 40% of intraspinal anomaly associated with congenital spine deformity and therefore this must also be evaluated.

The spine is angled in congenital kyphosis and kyphoscoliosis compressing the rib cage forward on both sides, therefore impairing movement of the diaphragm when this compression occurs in the thoracic spine. A cross-sectional study demonstrated that with a more severe kyphosis, respiratory function became more impaired.[85]

Postural Roundback

Differential diagnosis of Scheuermann disease includes postural roundback. In this condition the thoracic kyphosis is up to 60°. It is flexible and will correct with hyperextension; it is smooth and nonprogressive. There is no disc involvement, and the vertebrae have a normal appearance.[124] The hallmark sign that distinguishes postural roundback from Scheuermann disease is a rigid spine.[41] Exercise alone as described below for Scheuermann disease is the treatment of choice. If the kyphosis progresses beyond 60°, the patient may be treated with a Milwaukee brace to prevent permanent structural changes.[93]

Scheuermann Disease

Scheuermann disease is a rigid form of postural kyphosis. It often is neglected, developing during childhood and adolescence, and usually is ascribed to poor posture[132] resulting in delayed referral to the appropriate clinician, diagnosis, and initiation of treatment.[1] Scheuermann kyphosis is the most common type of kyphosis in the adolescent population. The a rate of incidence ranges from 1% to 8% with nearly equal incidence in males and females.[80] Onset typically occurs during the prepubescent growth spurt becoming clinically apparent between the ages of 11 and 14 years of age.[41] In most cases progression is slow and stops when axial skeletal growth is completed.[34] Diagnosis is made by radiographic criteria including: (1) anterior wedging of 5° or more for at least three or more contiguous vertebrae, (2) narrowing of the intervertebral disc space,[76,80] (3) kyphosis greater than 45°[124] between vertebral segments T5 and T12 coupled with compensatory cervical and/or lumbar hyperlordosis[41] that is uncorrected on active hyperextension,[1] and (4) irregular vertebral end plates with Schmorl nodules, which are disc protrusions of the nucleus pulposus through the end plate into the vertebral body appearing as incongruent depressions.[9]

One third of patients have a mild scoliosis measuring 25° or less with minimal vertebral rotation[9,41,124] and varying degrees of spondylolysis and spondylolisthesis.[1,9,124] Back pain is an associated component typically occurring at the apex of the kyphosis, but occasionally in the low back. It is commonly aggravated with sitting, standing, and strenuous activities.[1] The pain is dull and nonradiating in nature.[124] Scheuermann disease also has thoracolumbar and lumbar variants. Gradual disc degeneration may be seen at the apex of the kyphosis[9,124] correlating the acute angulation and short segmented curves.[124]

Further research on the origin of Scheuermann kyphosis is needed. Studies demonstrate a strong genetic prevalence inherited though an autosomal dominant gene confirming a familial aggregation[142] with a less significant environmental component.[80] Relatives who were examined at age 40 or older presented with osteochondrosis (78%), spondylosis (56%), and arthrosis (33%), all of which are considered to be secondary changes.[142] Histologic studies have shown disorganized endochondral ossification, reduced amounts of collagen with thinner fibers, and increases in end plate mucopolysaccharides.[80,132] One theory based on examination of the mechanical factors suggests that some kyphosis is likely present from early in life, which leads to vertebral wedging caused by anterior pressure exerted upon the vertebrae.[132]

Clinical findings include tight pectoral, hamstring and iliopsoas muscles,[124,132] increased thoracic kyphosis with a compensatory increased lumbar lordosis, and forward head posture. Furthermore, 38% of patients with Scheuermann kyphosis had pain and worked in lighter-duty jobs than controls.[80]

Intervention

Surgical intervention is controversial because of the limited evidence on the natural history of Scheuermann disease. Surgical correction can be recommended for patients with curves greater than 70° that bracing does not control; those with disabling pain that is resistant to nonoperative measures including activity modification and exercises; those who have used antiinflamatories for at least 6 months; or those who have concerns regarding their appearance.[124] Surgical management of a less rigid curve often includes a posterior spinal fusion, although more rigid curves also require an anterior fusion.[49,124]

Orthotic treatment is used when the kyphosis is between 45° and 65°. A modified Milwaukee-type brace is used. The reported success rate is high in the skeletally immature patient; however, skeletally mature patients do not respond to this treatment.[1,49] A modified Milwaukee brace is worn full time (22 hours per day) for 18 months.[80] Once patients have reached skeletal maturity, it may be used part-time at night for maintenance. The brace works as a three-point dynamic system and promotes thoracic extension.[1,132] Posterior pads apply pressure at the apex of the kyphosis, and pelvic pads stabilize the lumbar spine, decreasing the lordosis.[132] Brace use has been shown to decrease vertebral wedging with 12–18 months of full-time wear 22 hours per day followed by part-time wear of 12 hours per day to maintain the correction. Patients allowed 2 to 4 hours out of their brace to participate in sports generally have better acceptability of use of the brace and compromise of curve improvements were not seen.[1] It has been observed that the anterior longitudinal ligament may thicken and partial reversal of vertebral wedging may occur with use of a brace.[132] Predictors of poor outcomes to bracing include: a rigid kyphosis of greater than 65°, vertebral wedging of greater than 10°, and limited or no remaining spinal growth. Whether a scoliosis is present does not impact the outcome of bracing. With appropriate patient selection, kyphosis can be improved. However, even with the most adherent patients, partial correction of an average of 30° can be expected once the brace is discontinued.[124]

Exercise plays an integral role in the treatment of patients with Scheuermann disease. The prescribed exercises are specific for active trunk extensor strengthening, general postural exercise, and hamstring stretches (Fig. 8.10). Sports that have a trunk extensor component such as volleyball or swimming and aerobic exercise are recommended. The goals of physical therapy are to improve postural alignment and to increase flexibility and extensor strength.[132] The progression of the kyphosis is not affected by physical therapy, but it is recommended for symptomatic patients as an adjunct to bracing to prevent increased stiffening of their spines. Studies have demonstrated that pain can be lessened with exercise.[124]

LORDOSIS

Background and Foreground Information

An anterior convexity (or a posterior concavity) of a segment of spine is termed a *lordosis*. Congenital lordosis is the result of bilateral posterior failure of segmentation.[137] Lordosis, both fixed and flexible, may be found in children with a variety of diagnoses. Lordosis in children with myelomeningocele usually occurs in the lumbar spine secondary to use of a tripod gait pattern. A lordosis may develop in the thoracic vertebrae to compensate for an increased lumbar kyphosis.[46] Hahn et al.[40] stated that a lumbar lordosis facilitates balanced sitting in the DMD population. In children with DMD the postural control muscles are weakened; therefore support for the vertebral column and upright control are affected. Hip flexion contractures, which are often present in individuals with DMD, mechanically pull the pelvis anteriorly, thereby leading to an increased lumbar lordosis. Kerr et al.[63] found that lordosis improved stability of the lumbar spine through locking of the articular facet joints.

Children without motor deficits may have an increased lumbar lordosis. Assessment includes testing of lower extremity ROM, spinal flexibility, trunk and lower extremity strength, posture, and gait. Interventions include abdominal strengthening (curls, crunches, and pelvic lifts), pelvic tilts in supine and standing positions, trunk extensor strengthening, and appropriate lower extremity stretching.

Spondylolysis and Spondylolisthesis

Spondylolysis is a defect of the pars interarticularis (Fig. 8.11). Herman, Pizzutillo, and Cavalier[48] suggest that upright, bipedal position, genetic predisposition, and repetitive loading of the lumbar spine are possible causative factors. Athletes involved in sports with repetitive hyperextension and rotational loading on the lumbar spine, such as gymnastics and diving, are noted to have a higher incidence of spondylolysis and spondylolisthesis than the general population.[15,47] Spondylolisthesis is the forward translatory displacement of one vertebra on another, usually occurring at the fifth lumbar vertebra (see Fig. 8.11). Multiple classification systems have been proposed for spondylolysis and spondylolisthesis; however, the Wiltse-Newman method remains the most widely utilized.[15] Five types of spondylolysis and spondylolisthesis have been classified by Wiltse and associates[136] as follows:

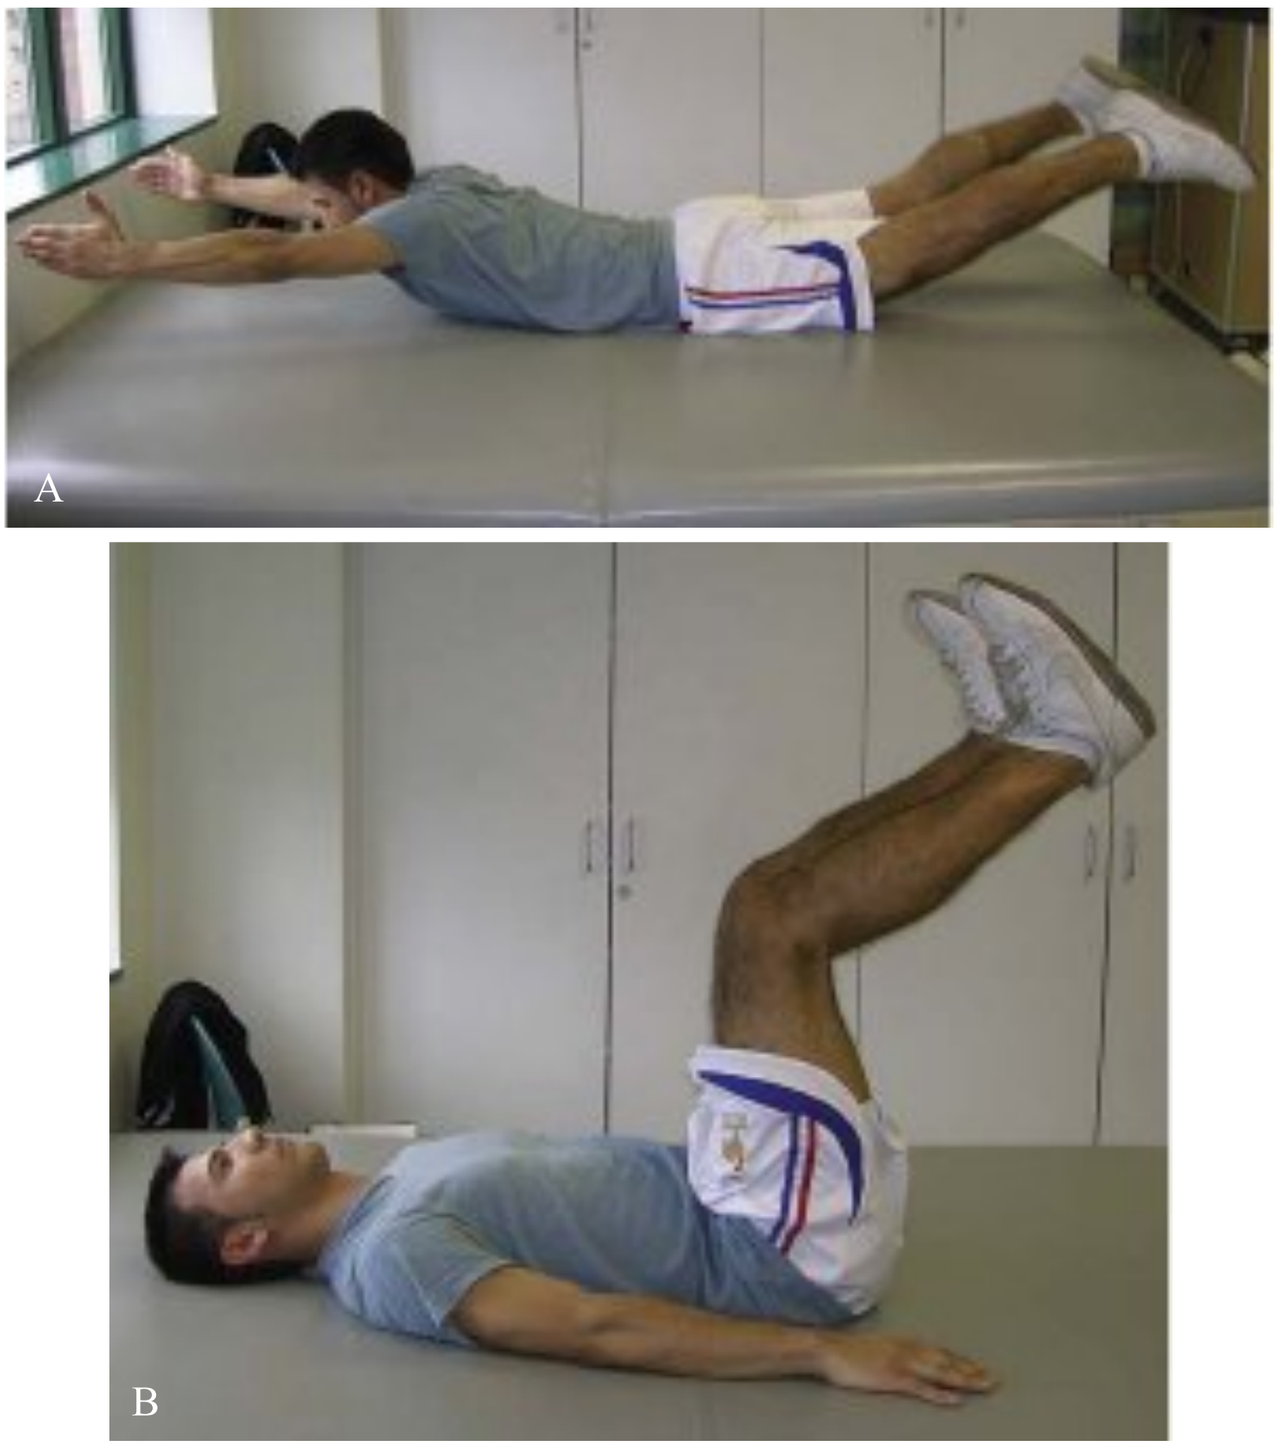

FIG. 8.10 (A) Active trunk extensor strengthening by prone lifts. (B) Lower abdominal strengthening exercises.

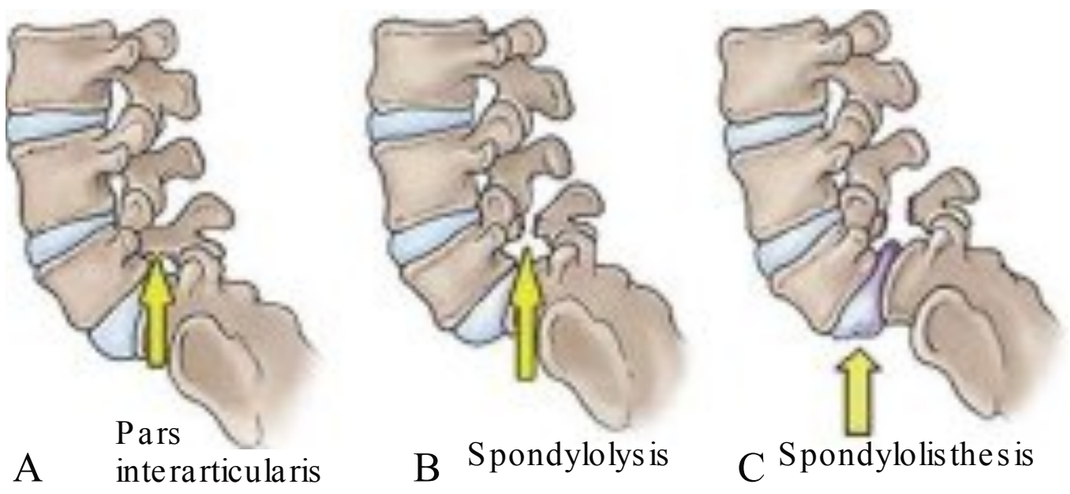

FIG. 8.11 (A) The pars interarticularis is the bony segment between the inferior and superior articular facets in the lumbar spine. (B) Spondylolysis, depicting a fracture of the pars interarticularis. (C) Depiction of spondylolisthesis, anterior slippage of one vertebra on another. (Courtesy of John Killian, MD, Birmingham, AL.)

Dysplastic malformations develop secondary to congenital malformations of the sacrum and posterior vertebral arch of L5. These malformations may include hypoplasia of the superior surface of the body of S1, hypoplasia-aplasia of the facets, elongation of the pars interarticularis, and spina bifida. The malformations decrease the efficiency of the posterior stabilizing system.[136] The degree of slippage is usually severe and may produce neurologic deficits as the laminae of L5 are pulled against the dural sac.[50]

Isthmic describes spondylolisthesis in the setting of spondylolysis. It describes the anterior slip of a vertebrae relative to the next caudal segment, often occurring at L5 over S1, related to a defect in the pars interarticularis.[47] Isthmic is divided into Type II A, lytic-fatigue fracture of the pars, Type II B, elongated but pars intact (pathogenic factors cause elongation of the pars secondary to repeated microfractures that heal with the pars in an attenuated-elongated position),[50] and Type II C, acute pars fracture.[47]

A degenerative type occurs in adults older than age 50 and is caused by the structural destruction of the capsule and ligaments of the posterior joints, producing hypermobility of the segment.

A traumatic type, more correctly defined as a fracture, is caused by a sudden fracture of the posterior arch of a vertebral segment. The fracture may occur at the pedicle, laminae, or facet, leaving the pars interarticularis intact.

Pathologic spondylolisthesis occurs most often secondary to an infectious disease that destroys the posterior arch of the vertebra.[136]

Dysplastic and isthmic spondylolisthesis types are the most common types seen in the pediatric population. Spondylolisthesis is further described by the degree of severity as characterized by percentage of slippage. According to the Meyerding classification system, grade I is the mildest slippage at less than 25%, grade II is 25% to 50% slippage, grade III is slippage of 50% to 75%, grade IV is 75% to 100% slippage,[50,136] and grade V refers to the ptosis of the cranial vertebra.[99]

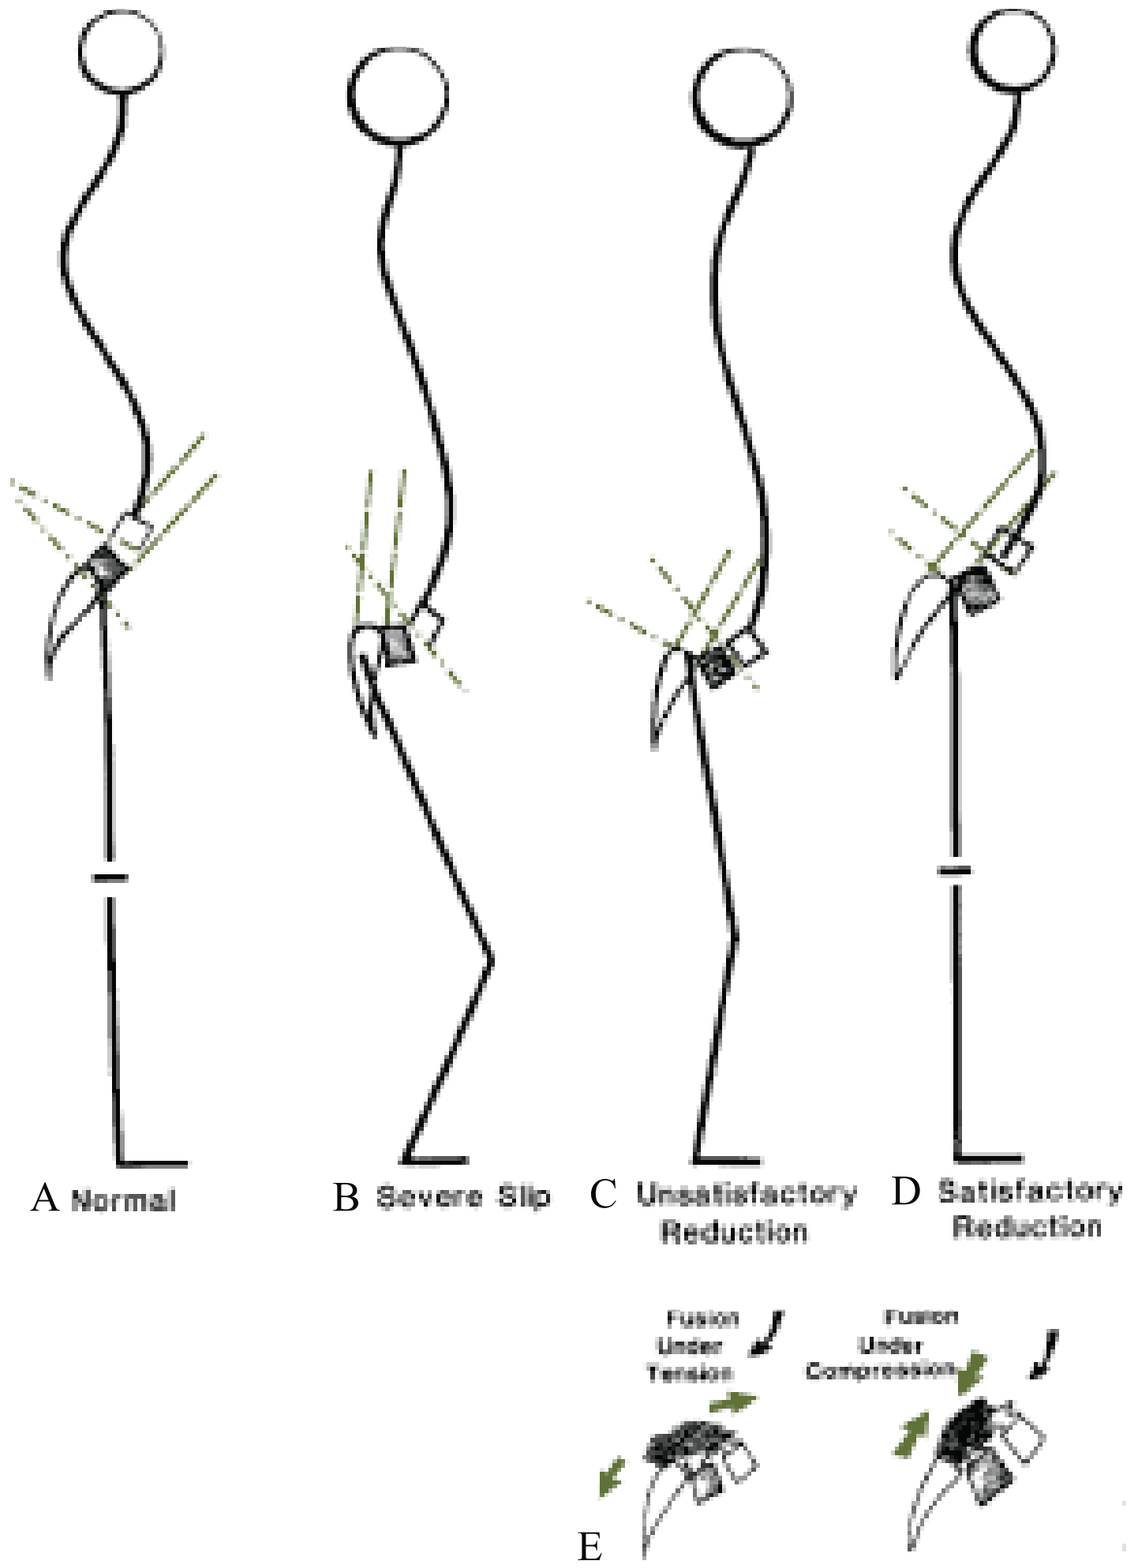

FIG. 8.12 (A) Normal sagittal plane spinal alignment. (B) Loss of alignment can be visualized after a severe L5 spondylolisthesis. The sacrum becomes vertical, and the resultant lumbosacral kyphosis "pushes" the lumbar spine forward. (C) An unsatisfactory reduction occurs when L5 has little mobility and L4 lies anterior to the "anatomic zone" and is kyphotic in relationship to the sacrum. The fusion in this case will be under tension and less likely to hold. (D) A satisfactory reduction occurs when L4 can be placed in the anatomic zone and oriented lordotic in relation to the sacrum. (E) The more L4 can be positioned over the sacrum, the more posterior compressive forces will be directed across the fusion. In this position, sagittal plane alignment and hence deformity will be corrected. (From Moe JH, Winter RB, Bradford DS, et al.: Scoliosis and other spinal deformities. 2nd ed. Philadelphia: WB Saunders, 1987.)

Clinical Symptoms

A spondylolisthesis is often an incidental finding, discovered on a radiograph taken for some other purpose. The clinical picture includes poor posture and increased lumbar lordosis in mild slippage. Higher-grade slippage may produce a flattened lumbar spine, a vertically oriented sacrum, and a visible or palpable step-off at the involved level.[47,48] (Fig. 8.12). Symptoms may include low back pain relieved by rest, sciatic-type pain, local tenderness, hamstring spasm or tightness, and, in severe cases, torso shortening.[50]

Risk of Progression

The risk of progression of spondylolysis and low-grade spondylolisthesis is low, occurring in less than 3% of skeletally immature children or adolescents.[47] Clinically, adolescents who are symptomatic are at a higher risk for increased slippage during their growth spurt. Females are at greater risk than males, as are patients with increased ligament laxity, including those with Down syndrome or Marfan syndrome. Presently, the best radiographic measure to help guide prognosis appears to be the slip angle.[81] Positive slip angles appear as kyphotic slips while negative slip angles appear as lordotic slips.[81] Radiographically, dysplastic types or patients with a 50% slippage, with a slip angle greater than 55° (kyphotic) in a skeletally immature patient (normal: −10° to 0° [lordotic] as identified by Mac-Thiong and Labelle)[82] or with bony instabilities or decreased anatomic stability of L5 and S1 are at greater risk for increased slippage.[50,93]

Surgical Intervention

Indications for surgery include persistent back pain despite conservative measures such as physical therapy, as well as gait deviations, greater than 50% slippage, marked instability of the

defect with slip progression, neurologic deficit/radiculopathy, and hamstring contracture.[47,50] Surgery is recommended for patients with high-grade spondylolisthesis (grades III–V), even for asymptomatic patients due to the high risk of neurologic compromise if left untreated.[81] The goals of surgery are to prevent further slippage, immobilize the unstable segment, prevent further neurologic deficit, relieve any nerve root irritation, and correct clinical symptoms of poor posture, gait, and decreased hamstring length.[50]

Surgical options include posterolateral arthrodesis, anterior arthrodesis, decompression, and reduction with instrumentation. The surgical procedure most often performed is a bilateral posterolateral arthrodesis in situ. The fusion usually extends from L4 to S1 and is performed with an iliac bone graft.[39] Physical therapy is indicated for bed mobility, gait training, and activities of daily living and may be initiated to regain normal hamstring flexibility.

A neurologic deficit is the most common reason to perform a decompression. A decompression consists of removal of the bony anatomy that is causing nerve root irritation. The segments are then fused posteriorly to prevent further slippage.[128,129]

A reduction of the spondylolisthesis is indicated in cases in which the sacrum is in a vertical position, causing a severe lumbosacral kyphosis that displaces the lumbar spine anteriorly (see Fig. 8.12). The result is a marked compensatory lumbar lordosis. An open reduction technique can be anterior or posterior, with or without instrumentation, or a combination of surgical approaches may be used. An anterior fibular strut graft may be used for severe slips.[55] Circumferential fusion may also be performed. This technique improves stability of the fusion and provides increased surface area for loading the joint surface.[82]

Nonsurgical Intervention

Observation is the treatment of choice with asymptomatic low-grade spondylolisthesis (less than 50% slippage). These children are routinely followed two times per year with clinical and radiographic examinations. Patients presenting with symptomatic spondylolysis or low-grade spondylolisthesis often respond well to activity restriction, physical therapy, and spinal bracing.[47] Upon referral to physical therapy, patients learn lumbar stabilization exercises, in which they are taught to maintain pain-free, neutral alignment of the pelvis and lumbar spine while they vary their positions.[100] O'Sullivan et al.[100] emphasized the importance of strength training of the transverse abdominis, lumbar multifidus, and internal oblique muscles. They recommended incorporating cocontraction of these stabilizers into functional activities to support the lumbar spine and decrease low back pain in patients with spondylolysis and spondylolisthesis. Exercises may include bridging, wall squats, abdominal strengthening, prone gluteal strengthening, and other stabilization exercises in supine as well as exercises targeting hamstring flexibility. A therapeutic exercise ball may be incorporated into the exercise session to allow patients to achieve and maintain neutral lumbar spine stabilization on a mobile surface.

Immobilization using a TLSO is indicated following a stress fracture of the pars or with a well-defined spondylytic defect, although the goals of treatment differ: namely, healing of the pars defect in the former and alleviation of symptoms in the latter. Brace wear ranges from 6 to 12 weeks, depending on the goal of treatment, and may continue for up to 6 months if radiographs reveal incomplete healing of the pars stress injury. Return-to-play guidelines for the young athlete include painless spinal mobility, resolved hamstring spasm and contracture, and return to activities without pain.[48] If symptoms persist, surgery is indicated.

SUMMARY

Scoliosis, kyphosis, and lordosis are common pediatric orthopedic conditions of the spine. We, as pediatric physical therapists, often concentrate our therapy for many types of patients on the trunk for midline activities, symmetry, and stability for movement; therefore we can play a vital role in early detection of spinal deformities. We encourage children to become active to improve their cardiorespiratory function, muscle strength, and endurance. We can provide a referral source for families, instruction in home exercises, input for selecting appropriate adaptive equipment and seating, and rehabilitative intervention following injury or surgery. We address issues concerning the spine on a daily basis and play an important role in achieving and maintaining good health by maximizing proper alignment and function.

Case Scenario on Expert Consult

The case scenario related to this chapter uses the ICF model to detail the physiology of spondylolysis and spondylolisthesis and to discuss how it impacts a 9-year-old girl's participation in her daily activities. A video is also included to illustrate the examination and intervention details that can be applied to this case.

Congenital Muscular Torticollis

Sandra L. Kaplan, Barbara Sargent, Colleen Coulter

Congenital muscular torticollis (CMT) and cranial deformation (CD) are commonly seen in infants at birth or soon after. CMT results from unilateral shortening of the sternocleidomastoid (SCM) muscle and is named for the side of the involved SCM muscle. It is characterized by a lateral head tilt toward and chin rotation away from the involved side. Fig. 9.1 illustrates a right CMT with head tilt to the right and rotation of the chin to the left secondary to a tight right SCM. Reports of incidence vary from 0.3% to 16% of newborns.[143] It is the third most common congenital musculoskeletal condition after hip dislocation and clubfoot.[17] CMT is associated with mandibular asymmetry, craniofacial asymmetry including deformational plagiocephaly,[26,165] eye and mouth displacement,[26] scoliosis,[13,21] brachial plexus injury,[10] pelvic asymmetry, congenital hip dysplasia, foot deformity,[26] muscle[109] and functional asymmetry,[13] and greater use of related services in early school years.[158] Synonyms for CMT include fibromatosis colli, wry neck, or twisted neck.[74]

CD is a distortion of the shape of the skull resulting from mechanical forces that occur pre- or postnatally.[127] It is different from craniosynostosis, defined as cranial asymmetry resulting from premature closure of one or more of the cranial sutures.[72] CD is a coexisting impairment in up to 90.1%[26] of infants with CMT and increases the risk of facial,[7] ear,[7,99] and mandibular asymmetry.[73,140] Prevalence of CD is age dependent and ranges from 6%[160] to 61%[143] at birth, 16%[61] to 46.6%[98] from 1.5 to 4 months, 6.8% at 1 year,[61] 3.3% at 2 years[61] and 2% at 12–17 years.[126] Synonyms for CD include positional deformation, deformational cranial flattening, or nonsynostotic head asymmetry.

Physical therapy intervention is highly effective in resolving CMT and CD when initiated early in infancy.[86,120] This chapter discusses the etiology and pathophysiology, screening and examination, intervention, and expected outcomes for CMT and CD.

BACKGROUND INFORMATION

ANATOMY OF THE STERNOCLEIDOMASTOID MUSCLE AND CRANIUM

The SCM illustrated in Fig. 9.2 has two major palpable bands: the medial band originates at the manubrium of the sternum and the lateral band originates from the medial third of the clavicle, with both joining to insert on the ipsilateral mastoid process and the superior nuchal line of the cranium.[102] The SCM muscle is innervated by the second and third cervical nerves for sensation; the spinal portion of the accessory nerve provides motor innervation to both the SCM and the upper trapezius muscle. Infants with CMT present with unilateral tightness of the SCM, a possible mass or nodule in the muscle and may also have ipsilateral restrictions or tightness of the upper trapezius muscle.[116] The trapezius is a synergist of the ipsilateral SCM muscle for lateral head tilt, and it elevates the scapula. The contour of the upper part of the neck is formed by the fibers of the SCM muscle, and the contour of the lower part of the neck is formed by the fibers of the trapezius muscle.

An infant's cranium is composed of bone plates (frontal, occipital, parietal, temporal) that are separated by fibrous sutures (coronal, lambdoid, metopic, sagittal, squamosal) and fontanelles (anterior, mastoid, posterior, sphenoid), which are soft membrane–covered spaces, often referred to as soft spots. Open sutures and fontanelles, illustrated in Fig. 9.3, give the infant's cranium flexibility to pass through the birth canal and to expand in response to pressure exerted by the rapidly growing infant brain. Head circumference increases considerably over the first year of life: approximately 2 cm per month in the first 3 months, 1 cm per month between 4 and 6 months, and 0.5 per month from 6 to 12 months.[57] Approximately 70% to 80% of skull growth occurs by 2 years of age, and the remaining growth occurs slowly into adulthood.[104]

ETIOLOGY AND PATHOPHYSIOLOGY OF CMT

The etiology of CMT has been attributed to prenatal, perinatal, and postnatal factors. Prenatal factors that might cause CMT include ischemic injury based on abnormal vascular patterns or head position in utero leading to compartment syndrome,[37] intrauterine crowding or persistent malpositioning,[79] rupture of the muscle, infective myositis,[158] and hereditary factors.[138,153] Perinatal factors may include birth trauma from breech presentations or assisted deliveries.[79,146] Postnatal factors associated with CMT, but not necessarily causative, include the presence of hip dysplasia,[163] positional preference,[14] and the presence of deformational plagiocephaly.[38] There are no clear correlations with pre- or perinatal factors and the severity of the CMT that an infant will develop.

Histologic tissue changes of the SCM in infants with CMT include excessive fibrosis, hyperplasia, and atrophy.[24] The degree of fibrosis evident on ultrasound may fluctuate with age but typically decreases over time.[89] In some infants a palpable nodule, illustrated in Fig. 9.4, may be present in the SCM as early as 2–3 weeks[37]; both the degree of fibrotic changes and the location of the nodule are associated with the prognosis for resolution. Nodules in the lower one third of the SCM are most likely to resolve with conservative stretching as compared to nodules that occupy the middle one third or both the lower and middle one third, and those that occupy the length of the SCM are the most recalcitrant.[27,89] Synonyms for the nodule include SCM mass, tumor,[138] or pseudotumor of infancy.[148,165]

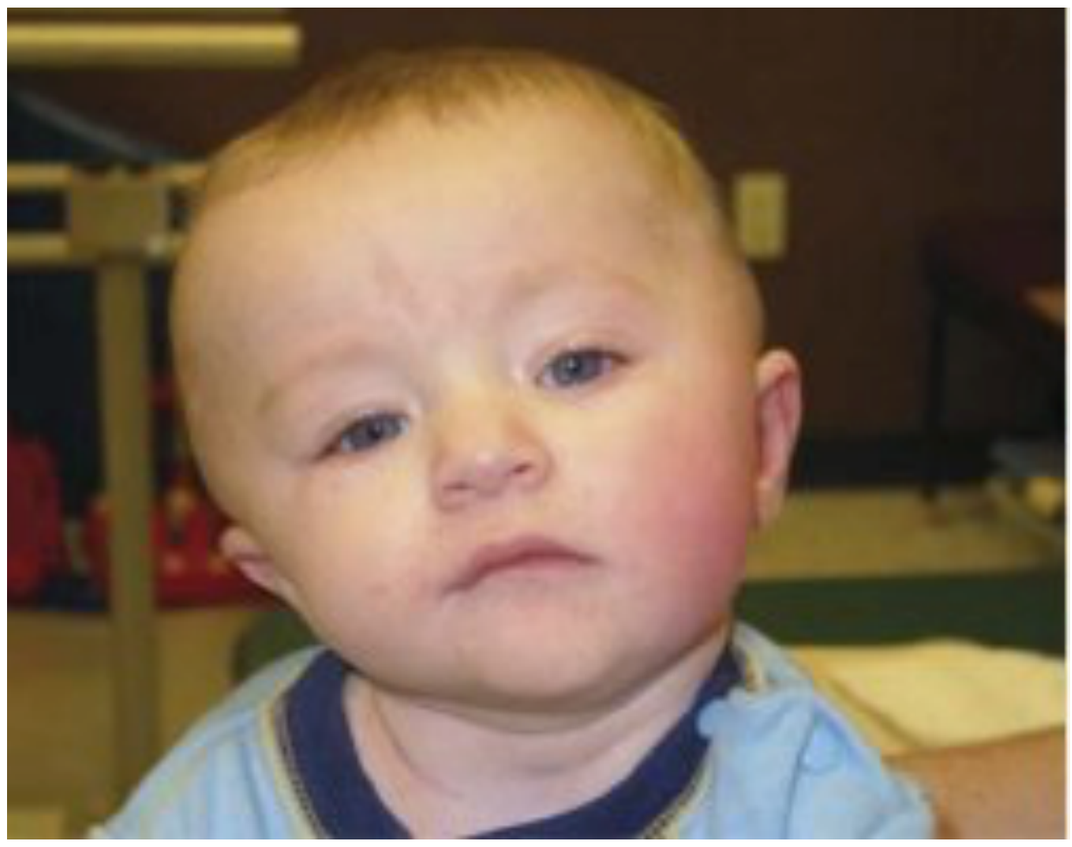

FIG. 9.1 Child with right CMT and CD, left asymmetrical brachycephaly. Note the right lateral flexion, chin turned to the left, asymmetry of the ear pinnae, eyebrows, mandible, and neck folds, wider forehead, right shoulder elevation, and trunk rotation.

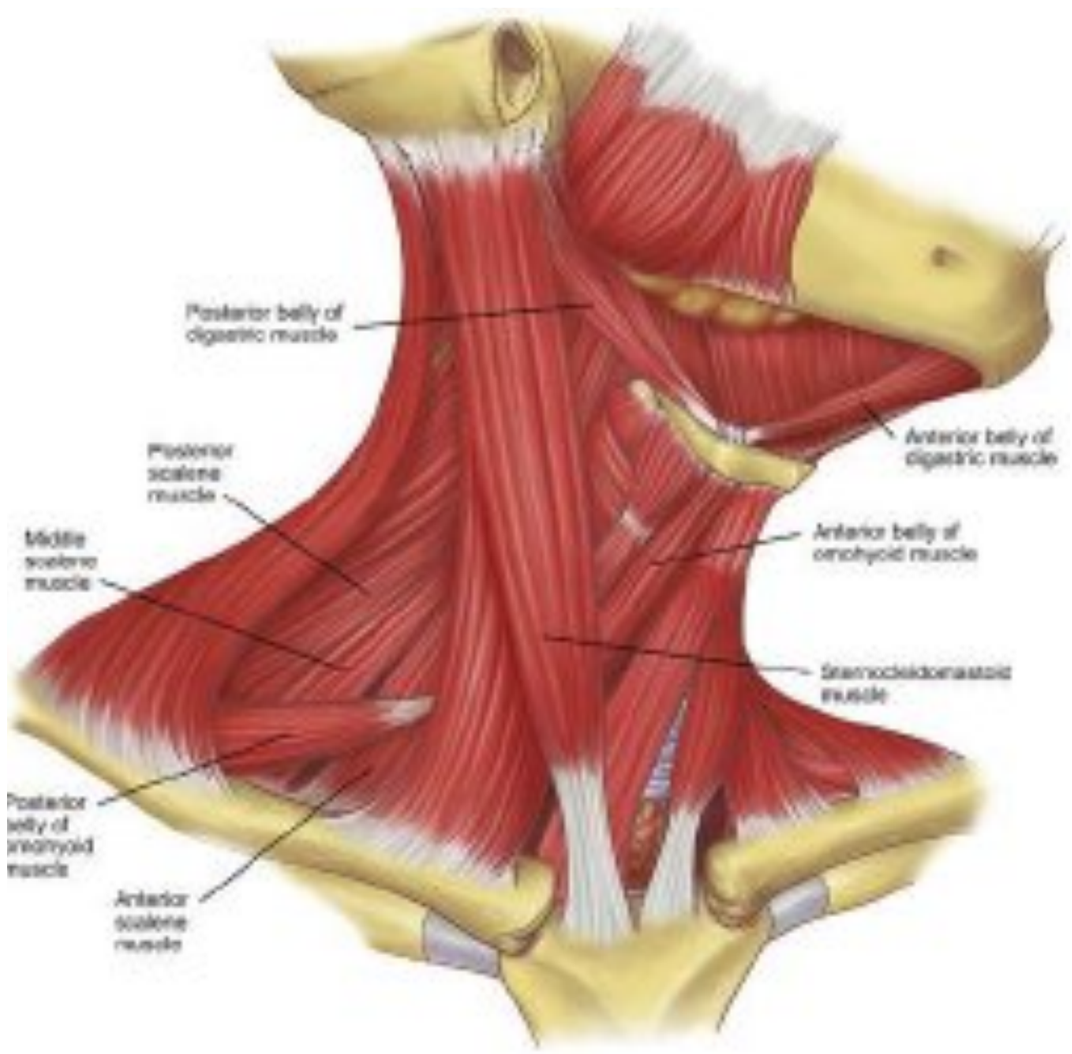

FIG. 9.2 Anatomy of the sternocleidomastoid muscle. (From Deslauriers J: Anatomy of the neck and cervicothoracic junction. Thorac Surg Clin 17:529-547, 2007.)

Potential confounding factors to full resolution of CMT are age at which an infant is referred for intervention,[20,120] the severity of the range-of-motion (ROM) limitations,[25,85] the thickness of a SCM nodule,[59] and the variability in foci and dosage of intervention.[114,152]

Postures that can mimic CMT may result from nonmuscular causes, including absence of the SCM,[60] benign paroxysmal torticollis,[155] congenital malformations, bony anomalies, brachial plexus injury, ocular disorders, and

neurologic impairments,[10,155,156] so it is important for clinicians to take a detailed history and carefully examine infants who present with asymmetrical postures to rule out causes other than CMT.

ETIOLOGY AND PATHOPHYSIOLOGY OF CD

The etiology of CD has been attributed to intrauterine deformation that worsens postnatally,[118,143] postnatal positioning,[69,160] and cervical muscular imbalance or CMT.[52]

Intrauterine deformation has been theorized to result from uterine constraint that is perpetuated and accentuated postnatally as the infant preferentially lies in supine on the flattened area of the skull.[118,143] Factors associated with increased risk for CD include: male gender, firstborn, delivered with assistance using forceps or vacuum extractor, cumulative exposure to the supine position, and neck problems.[12] Although CD may be present at birth, a relationship between CD at birth and CD after 6 weeks has not been established.[160]

Stronger support exists for the hypothesis that postnatal positioning is a causal factor in CD. An increase in referrals for CD has been noted by craniofacial clinics[16] since the 1992 "Back to Sleep" campaign.[1] The American Academy of Pediatrics recommends that infants be placed on their backs to sleep to prevent sudden infant death syndrome (SIDS).[3] Although this recommendation has resulted in more than a 40% reduction in the incidence of SIDS in the United States, an unintended consequence was the observed increase in CD.[2] Supine sleeping[61,69] is associated with CD, as well as several other postnatal positioning factors including: infrequent tummy time,[66,160] consistent bottle feeding on the same arm,[160] and consistent positioning in a crib.[66,160] Motor development is inversely associated with CD, supporting the theory that earlier achievement of motor milestones, such as head control, may provide a possible preventive effect for CD.[160] This is further supported by the observation that infants whose mothers perceive them as having lower activity levels[61,66] or developmental delays[66] have a higher risk of CD.

Cervical muscular imbalance or CMT has been proposed as a causative factor of CD.[127,129] CD at birth and limited passive cervical rotation[5] or CMT[118] are not associated; however, associations have been established between CD at 6–7 weeks of age and limited newborn passive cervical rotation,[61] positional head preference in supine sleeping during the first 4 weeks of life,[160] and positional head preference at 6 weeks.[66] Furthermore, up to 75% of infants with CD exhibit SCM imbalance or CMT.[52] Taken together, this evidence suggests that although intrauterine constraint may induce some cases of CD, positional preference from cervical muscular asymmetry and cumulative exposure to the supine position in early infancy likely interact to make a stronger contribution to the development of CD in the majority of infants.

The natural history of CD is characterized by increasing incidence until approximately 4 months of age, when infants independently maintain their head upright, then decreasing incidence until 2 years of age.[61] Controversy exists as to whether CD at 2 years of age persists[35] or further normalizes[126] during childhood and adolescence. Factors that contribute to the degree of resolution of CD are the severity of the CD,[162] age at which an infant begins intervention,[78,133] and type of intervention.[47] Fig. 9.5 illustrates how persistent positional preference to the right in supine can contribute to asymmetrical development of the infant's skull.

COMBINED CONDITIONS OF CMT AND CD

It is not clear in all children whether the CMT yields the CD or whether the CD with a positional preference might lead to CMT. Infants with CMT who spend excessive time with the head turned to one side may develop flattening of the skull on that side. Likewise, an asymmetrical skull may cause the head to persistently tip toward the flattened side when supine, causing ipsilateral adaptive shortening of the SCM. Regardless of cause, many children present with both conditions and both will need to be addressed in the plan of care.

METHODS OF CLASSIFICATION FOR CMT

Infants with CMT have been grouped in many ways, including the age at which their intervention began, severity of the ROM limitations, the presence of deformational plagiocephaly, the muscle fiber qualities based on ultrasound imaging, and the type of CMT.[74]

The three types of CMT commonly described are postural, muscular, and SCM nodule. Postural CMT is the mildest form and presents as a positional preference of the head and neck by the infant without limitations to PROM and without a nodule in the muscle.[14,138] Muscular CMT involves unilateral tightness of the SCM apparent during cervical rotation and/or lateral flexion, without a nodule in the muscle. The most severe form

presents with a palpable nodule[50] or fibrous bands[86] in the SCM and limitations in either or both cervical rotation and lateral flexion.[106]

CMT severity can also be classified with ultrasound images based on the degree of muscle fibrosis and fiber orientation.[43,86] In general, larger and thicker nodules and/or higher ultrasound ratings are correlated with more severe presentations and longer treatment durations.[149]

The clinical practice guideline on the management of CMT[74] suggests a classification method that accounts for the type of CMT, the degree of ROM limitations, and the age at which treatment begins. Seven grades of severity are provided with operational definitions that provide greater detail for comparing clinical outcomes (Table 9.1).

TABLE 9.1 Grades of CMT Severity

Grade	Definition
Grade 1: Early Mild	These infants present between 0 and 6 months of age with only postural preference or muscle tightness of less than 15° of cervical rotation.
Grade 2: Early Moderate	These infants present between 0 and 6 months of age with muscle tightness of 15° to 30° of cervical rotation.
Grade 3: Early Severe	These infants present between 0 and 6 months of age with muscle tightness of more than 30° of cervical rotation or an SCM nodule.
Grade 4: Late Mild	These infants present between 7 and 9 months of age with only postural preference or muscle tightness of less than 15° of cervical rotation.
Grade 5: Late Moderate	These infants present between 10 and 12 months of age with only postural or muscle tightness of less than 15° of cervical rotation.
Grade 6: Late Severe	These infants present between 7 and 12 months of age with muscle tightness of more than 15° of cervical rotation.
Grade 7: Late Extreme	These infants present after 7 months of age with an SCM nodule or after 12 months of age with muscle tightness of more than 30° of cervical rotation.

METHODS OF CLASSIFICATION FOR CD

CD is classified by the type and severity of the deformation.[91] The three types are plagiocephaly, brachycephaly, and dolichocephaly. Infants may also present with a combination of types.[65,99]

Deformational plagiocephaly (DP), depicted in Fig. 9.6B, is characterized by a parallelogram shape of the skull with ipsilateral occipital flattening and contralateral occipital bossing or bulging. DP is commonly associated with CMT,[26] and the flattened occiput is typically contralateral to the tight SCM; for example, left CMT with a shortened left SCM is associated with right DP. DP is also known as lateral deformational plagiocephaly, nonsynostotic occipital plagiocephaly, and positional plagiocephaly.

Deformational brachycephaly (DB), depicted in Fig. 9.6C, is characterized by central occipital flattening and is commonly associated with prolonged supine positioning.[53,54] DB is also known as posterior deformational plagiocephaly and flat head syndrome. When DB presents asymmetrically with bilateral posterior flattening greater on one side of the skull compared to the other, it is specifically called asymmetrical brachycephaly.

Deformational dolichocephaly, also known as scaphocephaly and depicted in Fig. 9.6D, is characterized by a disproportionately long and narrow skull. It is commonly associated with premature birth.[68]

The severity of CD can be classified by rating scales based on clinical observation.[7,108] Argenta's clinical classification scale[7] is the most frequently reported. It distinguishes five types of DP and three types of DB based on the severity of the asymmetry of the skull, ear position, and face. Refer to Tables 9.2 and 9.3 for definitions and diagrams of each type.

Quantitative measurement techniques for CD include using calipers,[166] digital photographic techniques,[62] or three-dimensional (3D) digital imaging.[9] These techniques are often used in research or by specialized craniofacial clinics. All three techniques measure cranial width, cranial length, and transcranial diagonals as illustrated in Fig. 9.7. DP is quantified by the transcranial diagonal difference (TDD),[141] oblique cranial length ratio (OCLR),[64] and cranial vault asymmetry index (CVAI).[103] These three measures vary in the location of their measurements, but they all measure the ratio of the longer to the shorter transcranial diagonal. Standard cutoff values have not been established but the following have been proposed: TDD of 3–10 mm is mild, 10–12 mm moderate, and > 12 mm severe.[91]

Plast Reconstr Surg 135:833-842, 2015.)

DB is quantified by the cephalic or cranial index (CI), the ratio of cranial width to cranial length. Standard cutoff values have not been established, but the following have been proposed: CI of 82% to 90% is mild, 90% to 100% moderate, and > 100% severe.[91] Deformational dolichocephaly is defined as a CI of < 76%.[88] Normative cranial values are available with age- and gender-specific cutoffs for mild, moderate, and severe DP or DB or a combination of DP and DB.[166]

CMT CHANGES IN BODY STRUCTURE AND FUNCTION, ACTIVITY, AND PARTICIPATION

Common body structure and function, activity limitations, and participation restrictions of CMT are listed in Table 9.4. CMT typically presents as a consistent head preference into ipsilateral cervical lateral flexion and contralateral cervical rotation due to unilateral shortening or fibrosis of the involved SCM. Primary impairments include the presence of a tight band or nodule in the involved SCM,[26,28] tightness of the involved SCM and ipsilateral cervical musculature, and decreased PROM into contralateral cervical lateral flexion and ipsilateral cervical rotation of the involved SCM.[26,113] Additionally, muscle imbalance and decreased strength of the cervical musculature may result in decreased active range of motion (AROM) into contralateral cervical lateral flexion and ipsilateral cervical rotation of the involved SCM.[113] Tightness of the SCM and cervical musculature can lead to red, irritated skinfolds of the ipsilateral anterior cervical region.[55] The SCM and cervical musculature tightness can cause discomfort or pain during extremes of passive stretching.[21] As the infant grows and if a positional preference is maintained, the cervical tightness and muscle imbalance can lead to asymmetrical movement of the face, spine, rib cage, and extremities that may lead to secondary tightness, muscle imbalance, and deformities of the cranium and face,[168] or spine and extremities,[55,143] some of which are illustrated in Fig. 9.8. Deformities associated with CMT include facial asymmetry,[168] mandibular hypoplasia,[168] C1-C2 subluxation,[136] mild scoliosis,[13,55] and hip asymmetry.[70]

Consistent positional preference by the infant may lead to activity limitations and participation restrictions resulting from difficulty actively rotating the head toward the side ipsilateral to the involved SCM. Clinical reports describe decreased visual tracking toward the ipsilateral side,[55,82,119] altered midline perceptual motor coordination,[152] decreased tolerance of the prone

TABLE 9.4 Potential Body Structure and Function, Activity, and Participation Limitations of CMT and CD

Medical Condition	Body Structure and Function Limitations	Activity Limitations	Participation Restrictions
CMT	Presence of tight band or nodule in SCM[27]	Restricted neck motion[152]	
	SCM, cervical, or upper trapezius ROM tightness[26]	Positional preference[158] and decreased tolerance to prone positioning[94]	Prefers bottle feeding to one side or difficulty breastfeeding equally on both sides[14]
		Asymmetrical propping on upper extremities[67]	Reduced tolerance of prone positions for play[111]
	SCM, cervical, or upper trapezius weakness[109]		Reduced tolerance to prone positions for play[111]
	Asymmetrical postures in all positions[159]	Asymmetrical movements and transitions: rolling, sitting, quadruped, kneel, one-half kneel, and standing[67]	Possible delays in development[111,130]
	Possible hip dysplasia[163]		
	Red, irritated skinfolds[55]		Difficulty cleaning infant's neck
	Pain during stretches[21]	Resistance to stretching that increases with head control	
	Cervical and thoracic scoliosis[21]	Asymmetrical sitting, standing postures	
CD	Lateral or bilateral occipital flattening[7]	Visual tracking in supine	
	Widening of the posterior skull or cranial base[7]		Teasing by peers due to craniofacial asymmetry[134,142]
	Frontal bossing and/or temporal bulging[7]		
	Abnormal vertical growth of the posterior skull[7]		
	Facial and ear asymmetry[7,168]	Difficulty fitting eyeglasses[124]	
	Mandible asymmetry[140 73]		Difficulty bottle or breastfeeding equally on both sides[164]

position,[111] asymmetry in head turning in all developmental positions,[55] delayed rolling,[55] and asymmetrical or delayed protective and righting reactions of the head, neck, and trunk.[67] Participation restrictions include a preference for side-of-bottle feeding[81,161,160] and nursing,[164] preference to look toward one side during play, and preference to look toward one side while sleeping.[101,121] In addition, CMT is associated with delays in gross motor development at 2 and 6 months of age.[111,130,131] For most children, the delays resolve by 10 months,[111] but for others, delays may persist into early childhood.[130]

CD CHANGES IN BODY STRUCTURE AND FUNCTION, ACTIVITY, AND PARTICIPATION

Common body structure and function, activity limitations, and participation restrictions of CD are listed in Table 9.4. Craniofacial asymmetries observed in infants with CD are specific to the type of deformation. DP is characterized by asymmetry of the posterior cranium with lateral occipital flattening.[7,16] As the severity of the deformity increases, the following may be observed: cranial base deformation[7]; ear asymmetry with the ear ipsilateral to the posterior flattening displaced anteriorly, inferiorly, or both[7]; protrusion of the frontal bone ipsilateral to the posterior flattening (frontal bossing)[7]; facial asymmetry[7]; and temporal bulging or abnormal vertical growth of the posterior skull.[7] Fig. 9.9A–D illustrates cranial asymmetry consistent with DP. Activity limitations and participation restrictions associated with DP include difficulty with visual tracking to the contralateral side of the posterior flattening, particularly when supine or in equipment that supports the head in a reclined sitting position, e.g. car seats and infant swings. If ear asymmetry is present, DP may also result in difficulty fitting glasses.[124] Peer teasing about head shape has been reported by 5% to 10% of elementary school children with CD.[134,142]

DB is characterized by central occipital flattening.[7] As the severity of the deformity increases, the following may be observed: widening of the posterior half of the skull and temporal bulging or abnormal vertical growth of the posterior skull.[7,90] DB has not been reported in the literature to be associated with specific secondary impairments, activity limitations, and participation restrictions; however, clinical presentations may include excessive use of supine-supported positioning devices,[90] bilateral shoulder hiking and decreased active and passive cervical ROM in rotation and lateral flexion, and reduced cervical flexion due to upper trapezius muscle tightness. Reflux may contribute to the severity of DB if infants require prolonged upright positioning after feeding; reflux discomfort may cause trunk and neck arching[87] with increased pressure against the supporting surface. Infants with DB may have decreased tolerance to prone positions for play if they have not had supervised prone positioning from early infancy (see Fig. 9.6C).[54,101]

Deformational dolichocephaly is characterized by a disproportionately long and narrow skull.[68] It may result in activity limitations and participation restrictions associated with difficulty maintaining the head in midline when supine or in equipment that supports the head in a reclined sitting position (see Fig. 9.6D).

CD has traditionally been regarded as a cosmetic condition with benign neurodevelopmental sequelae.[124] However, recent evidence demonstrates an increased prevalence of gross motor delay in infants with CD,[63,117] lower developmental scores in preschool children with CD,[30] and an increased use of special education and therapy services in school-aged children with a history of CD.[100] Although it cannot be ruled out that CD is the

FIG. 9.8 Anterior and posterior views of characteristic asymmetric postural deformities shown in a 3-month-old infant (A–B), an 8-month-old infant (C–D), and an untreated 8-year-old child (E–F). All have left congenital muscular torticollis (CMT) and deformational plagiocephaly (DP). (A) 3-month-old in supine with incurvation of the entire vertebral column. (B) Same 3-month-old infant in prone. Note little change in the postural alignment. (C) 8-month-old in sitting exhibiting postural asymmetry. (D) 8-month-old in sitting exhibiting ipsilateral shortening of the posterior cervical muscles, shoulder elevation, and rotation of the thorax. (E–F) Untreated 8-year-old in standing with long-term functional consequences of CMT and DP, including postural asymmetries.

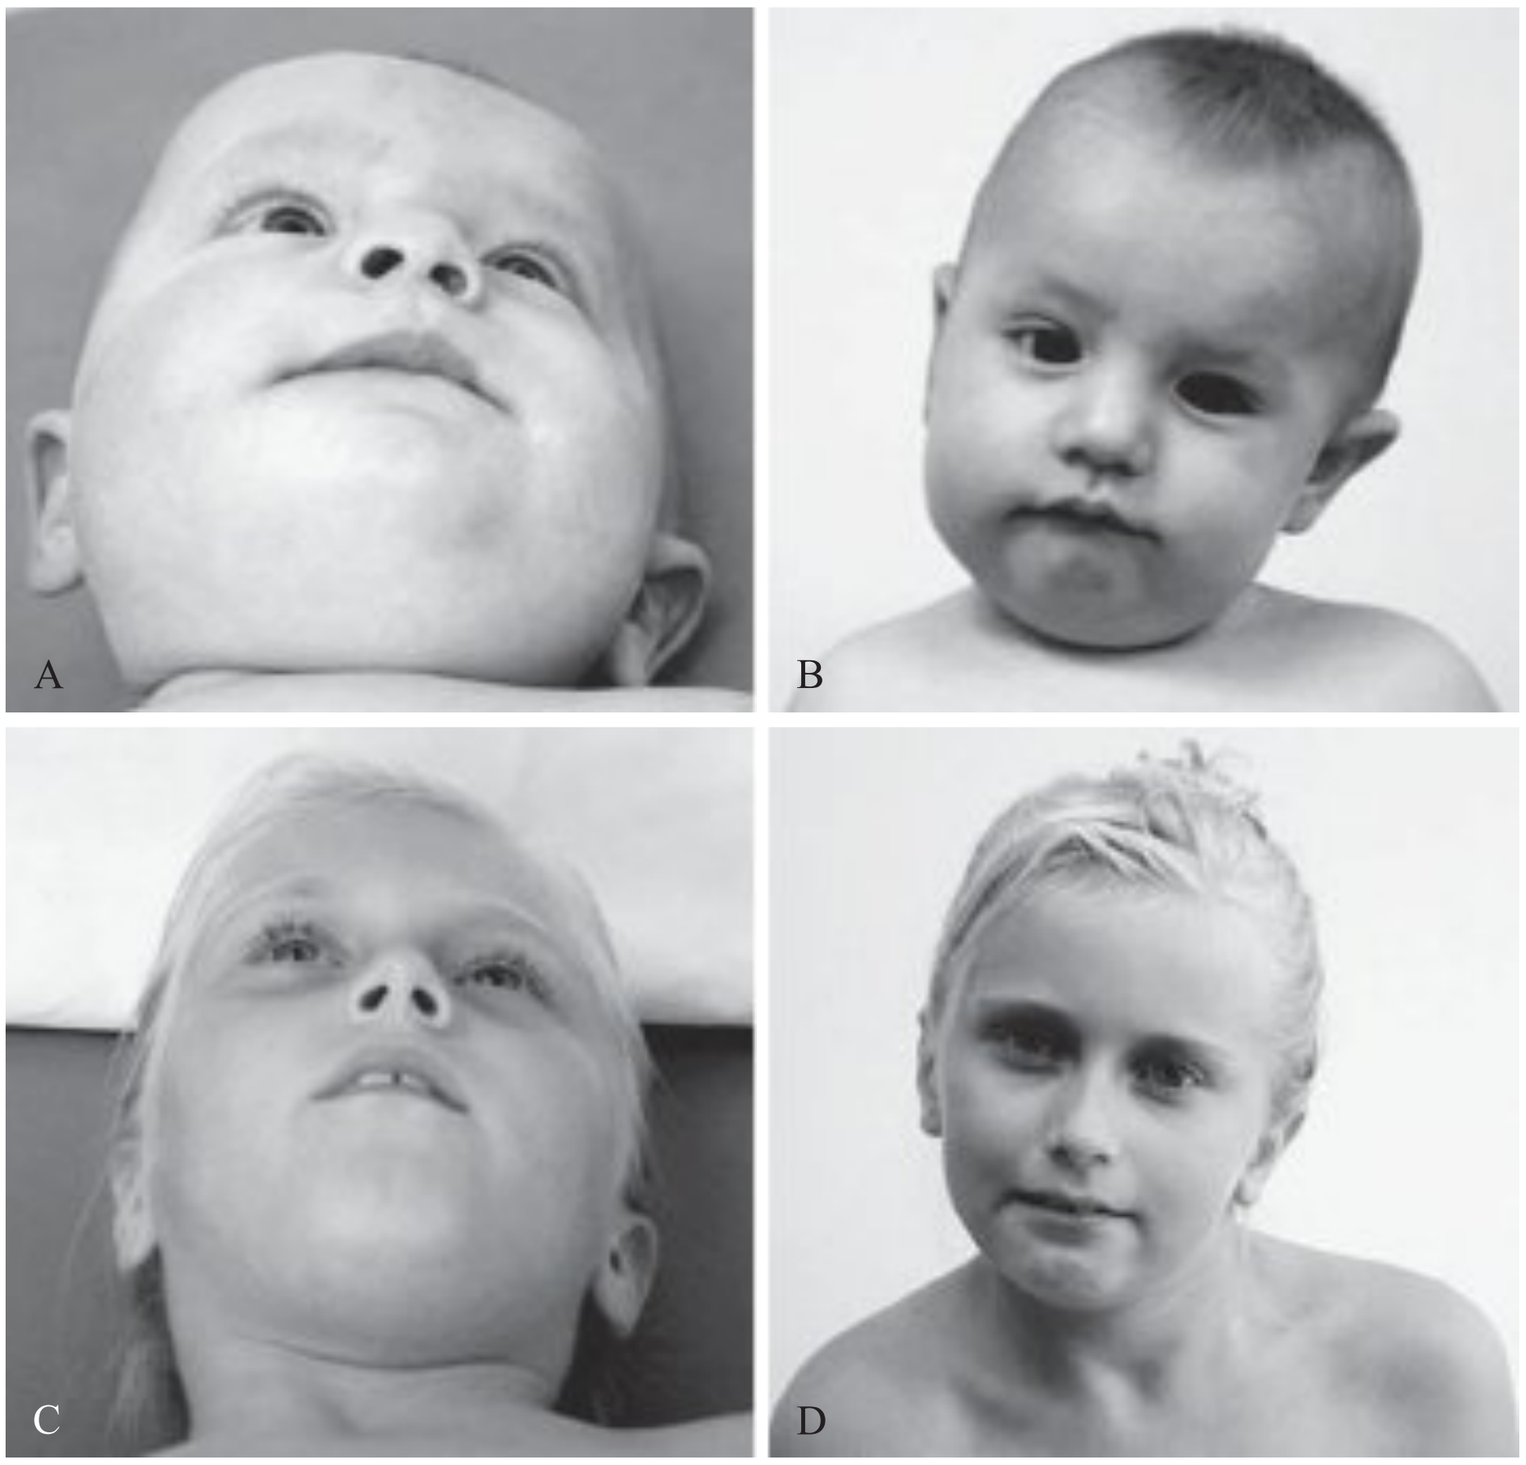

FIG. 9.9 Craniofacial asymmetries. (A) Submental view of an 8-month-old infant with left congenital muscular torticollis (CMT) and deformational plagiocephaly (DP). Note recession of the frontal bone, eyebrow, and zygoma on the ipsilateral side and inferiorly and posteriorly positioned ipsilateral ear. (B) En face view shows hemihypoplasia of the face, decreased vertical facial height on the left, asymmetry of the eyes with the ipsilateral eye smaller, inferior orbital dystopia, canting of the mandible, and deviation of chin and nasal tip. (C) Submental view of an 8-year-old with untreated left CMT and DP demonstrating the same facial asymmetries as the 8-month-old infant. (D) En face view of same 8-year-old demonstrates similar cranial facial asymmetries and shortening of the left sternocleidomastoid muscle.

cause of the delays, it may be that infants with early neurodevelopmental concerns are at increased risk for developing CD[30,125] due to abnormal muscle tone[49] and decreased activity levels.[61]

FOREGROUND INFORMATION

PHYSICAL THERAPY MANAGEMENT OF CMT AND CD

The overall management of CMT and CD begins with prevention of limitations and deformities by repositioning to facilitate symmetrical movement and head shaping; clinicians can provide prevention education to caregivers, professional staff, and the community. Physical therapy intervention is highly effective in resolving CMT and CD when initiated early in infancy[86,120]; therefore, it is imperative that infants receive a physical therapy evaluation and therapeutic intervention as soon as asymmetries are identified. Management follows the American Physical Therapy Association (APTA) patient management model,[6] beginning with screening to rule out potential causes of asymmetry that are not CMT; conducting a full examination; diagnosing the limitations in body structure and function, activities, and participation; providing a prognosis based on the severity of the conditions; providing intervention to correct the conditions; and all the while, reexamining to determine if progress is adequate, if discharge criteria are met, or whether referrals to other specialists are needed. The following examination and intervention descriptions follow the 2013 CMT clinical practice guideline (CMT CPG),[74] augmented by the literature on CD.

Screening and Differential Diagnosis for Confounding Conditions

The purpose of screening is to rule out conditions that mimic CMT postures, to determine if the asymmetrical posture is congenital or acquired, and to determine the risk for or the presence of CD. Infants with suspected CMT require a thorough history and screening for neurologic, musculoskeletal, visual, gastrointestinal, integumentary, and cardiopulmonary integrity. This is necessary to identify possible conditions other than CMT that could cause asymmetrical posturing and for which

consultation with the child's pediatrician and/or appropriate specialists may be necessary.

The typical history of CMT begins with the parent reporting or pediatrician noticing a persistent positional preference of tilting or turning to one side, or resistance to passive cervical rotation. Parents report challenges with cleaning under their infant's chin, breastfeeding on one side more than the other, or positioning the infant symmetrically in car seats, or they notice the infant's asymmetrical posture in pictures. Action Statement 3 of the CMT CPG[74] specifies nine health history factors to document, in addition to standard intake information. Standard intake information includes date of birth, date of examination, gender, birth order, birth weight, birth length, reason for referral or parental concerns, general health of the infant, and other health care providers who are seeing the infant. The nine health history factors include items that are known to be associated with CMT and/or are typically included in a physical therapy history. They are:

1. Age at initial visit[20,93] because this assists with assigning a severity grade and determining a prognosis for the episode of care.
2. Age of onset of symptoms[26,44] because this assists with distinguishing between acquired torticollis and CMT and with determining a prognosis for the episode of care.
3. Pregnancy history, including maternal sense of whether the infant was "stuck" in one position during the final 6 weeks of pregnancy[144] because this assists with identifying factors associated with CMT and CD.
4. Delivery history including birth presentation (cephalic or breech)[26] or multiple births[79] because this assists with understanding possible causes of CMT and CD.
5. Use of assistance during delivery such as forceps or vacuum suction[143,150] because these methods may be a cause of CMT if the SCM was strained during delivery.
6. Head posture/preference[14,160] and changes in the head/face[25,143] because these asymmetries are classic presentations of CMT and possible CD.
7. Family history of torticollis or any other congenital or developmental conditions[138,153] because there may be a genetic component to the condition.
8. Other known or suspected medical conditions[10] because they may be a cause of asymmetries.
9. Developmental milestones appropriate for age because delays may signal other contributing factors to asymmetries or may be a consequence of CMT.[130,152]

Following the history, the clinician continues a systems-based screen for neurologic, musculoskeletal, visual, gastrointestinal, integumentary, and cardiopulmonary integrity. Up to 18% of children presenting with a torticollis posture may have a nonmuscular etiology.[10] Thus the differential diagnostic process requires screening for possible conditions that may cause posturing that mimics CMT and taking an accurate history of the onset of asymmetrical posturing to rule out an acquired torticollis.

Neurologic causes of asymmetrical posturing include brachial plexus injuries, central nervous system (CNS) lesions, astrocytomas, brain stem or cerebellar gliomas, agenesis of CNS structures,[10,106] and hearing deficits.[83] CMT is not typically associated with pain or discomfort at rest or during PROM within the bounds of muscle tightness; thus the presence of pain may indicate an acute condition needing medical referral.[10,155] The clinician will need to distinguish between infant crying due to pain and stranger or setting anxiety. Screen for the following red flags: abnormal or asymmetrical tone, retention of primitive reflexes, resistance to movement, cranial nerve integrity, brachial plexus injury, and pain signals during movement; a neurologic consult may be appropriate.

Musculoskeletal conditions that mimic CMT include Klippel-Feil syndrome (fusion of cervical vertebrae), clavicle fracture, congenital scoliosis, or C1-C2 rotary subluxation.[10] Screen for the following: asymmetry of the face, neck, spine, and hips, asymmetrical passive neck rotation, the presence of masses in the SCM. Red flags include: atypical positions, such as right cervical rotation with a right lateral flexion, asymmetrical cervical vertebrae on palpation, acute pain responses on cervical movement, tissue masses outside of the SCM or in other areas of the body, children with Down syndrome, C1-C2 cervical spine instability, and late onset of a head tilt with known symmetry for the first few months of life; an orthopedic consult may be appropriate.

Visual conditions may cause asymmetrical posturing as the infant attempts to stabilize his or her focus and include ocular apraxia, strabismus, ocular muscle imbalances, and nystagmus.[10,106] Screen for the following: asymmetrical and discoordinated visual tracking in any direction or clinician inability to distinguish between limitations due to ocular control versus neck rotation; an ophthalmologic consult may be appropriate.

Gastrointestinal conditions include Sandifer syndrome, a hiatal hernia with gastroesophageal reflux[105] that typically causes trunk arching and neck flexion to the right following eating,[42] a history of reflux or constipation,[155] and easier or preferred feeding to one side.[14] Through parental report and observing the infant's behavior before, during, and after feeding, screen for the following red flag: curvature or arching of the trunk and head turning as a means of extending away from the esophagus, usually accompanied by crying; a gastrointestinal consult may be appropriate.

Integumentary conditions include redness or irritation in the folds of the neck, asymmetry of the skinfolds about the neck, asymmetry of the skinfolds of the hips as a sign of hip dysplasia,[107] and color of the skin that might suggest trauma as a cause of asymmetry.[107] Screen for the following red flags by inspecting the skin and ROM with clothing removed: asymmetrical skinfolds, bruising, raw skin breakdown, or purulent exudate; a medical consult is appropriate.

Cardiopulmonary conditions include asymmetric expansion and appearance of the rib cage and respiratory distress.[107,155] Screen by observation of the chest wall during breathing at rest and when active or crying. Red flags include: stridor, wheezing, shortness of breath, cyanotic lips; a consult with the child's pediatrician or a cardiologist is appropriate.

Acquired torticollis, in contrast to congenital torticollis, may occur in older babies and children and be caused by ocular lesions, benign paroxysmal torticollis, dystonic syndromes, infections, Arnold-Chiari malformation, syringomyelia,[33] posterior fossa tumors,[157] and trauma.[107,138] The natural history of these conditions includes a more acute onset, a red flag that should be discussed with the child's pediatrician and that may require immediate medical attention.

Cranial deformation screening identifies cranial asymmetries and differentiates them from pathologic craniosynostosis, or premature closure of one or more cranial sutures. Craniosynostosis results in characteristic head shape asymmetries due to restriction of growth perpendicular to the fused suture. Although craniosynostosis is rare (approximately 0.04%

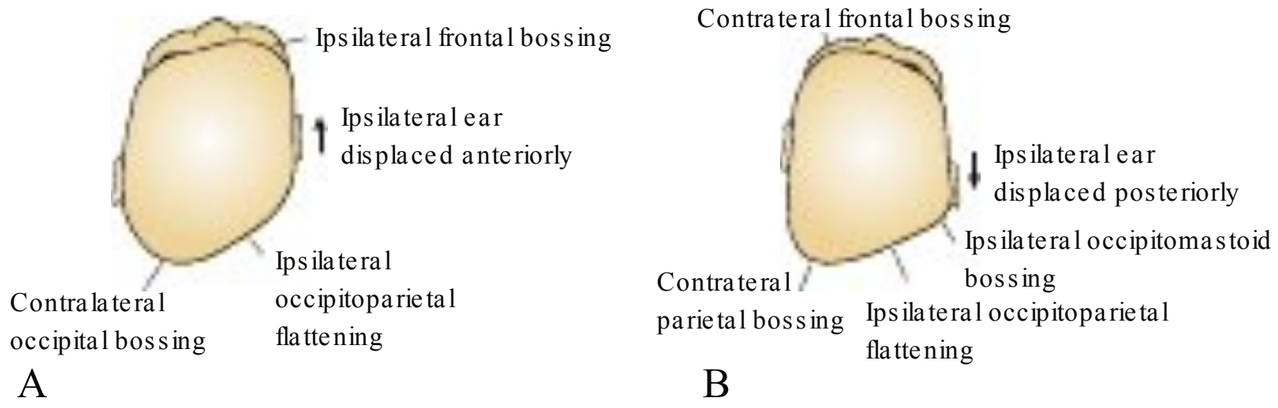

FIG. 9.10 Comparison of typical skull changes for deformational plagiocephaly (A) and unilambdoid synostosis (B). (From Kabbani H, Raghuveer TS: Craniosynostosis, American Family Physician 69(12):2863-2870, 2004.)

of births[15]), early identification is critical because craniosynostosis may restrict brain growth and increase intracranial pressure necessitating surgical intervention to prevent neurologic complications.[34,46] Screen for head shape asymmetries not consistent with DP, DB, or deformational dolichocephaly by observing the symmetry of the skull from the front, top, and sides, noting symmetry of the ears and eyes and midline alignment of the chin and nose relative to the perimeter of the face. Premature closure of one lambdoid suture results in the plagiocephalic head shape commonly associated with CMT. Fig. 9.10 illustrates a way to differentiate between DP and unilambdoid synostosis: posterior displacement of the ear ipsilateral to occipital flattening is indicative of unilambdoid synostosis, whereas anterior ear displacement is more consistent with DP. If craniosynostosis is suspected, prompt referral to a craniofacial specialist is recommended.[34,46] See e-fig. 9-1 for greater detail on characteristics of craniosynostosis.

Consistent with the CMT CPG,[74] the physical therapist should request copies of x-ray, ultrasound, computerized tomography (CAT), or magnetic resonance imaging (MRI) images or image reports from the child's parents or guardians that may have been performed prior to the physical therapy screening. These will provide additional details about the infant's physical status and, in the case of ultrasound images or reports, may help the clinician to visualize the location and extent of any existing nodule(s).

If no unusual signs or symptoms are identified through screening, the clinician may proceed with a more detailed examination. If there are red flags that the asymmetrical posture may not be caused by CMT or CD, the clinician will need to determine whether to refer the infant back to his or her primary physician for immediate care, for further consultation, or whether to consult with the physician but also proceed with conservative intervention.

Physical Therapy Examination

The detailed physical therapy examination should evaluate and document across the three International Classification of Functioning, Disability and Health (ICF) domains of body structure and function, activities, and participation (Tables 9.5 and 9.6). The exam is typically organized to maximize the infant's ability to cooperate throughout the full exam, although documentation may reflect a different order of information. (See e-fig. 9-2 for a sample CMT/CD initial evaluation form.[58]) This means engaging the infant in play to assess participation and functional mobility before conducting measures of impairments, when greater handling and movement restrictions are required.

Participation

Participation for young infants includes their ability to pose for pictures, symmetrically explore their immediate surroundings both visually and physically, alternate sides easily during breast or bottle feeding, and tolerate playing while prone for increasingly longer periods of time. Time spent in supported supine-positioning devices, such as car seats, strollers, bouncers or infant swings, should allow for symmetrical positioning. Examination of participation is through parent interview and observation of the infant during these activities.

Parents may first suspect a problem when trying to pose their infant for photographs, when positioning him or her in car seats, or when observing him or her during diaper changes. Perusing photos on a parent's smartphone of the infant's earliest days may help to pinpoint when the asymmetry first appeared. Preference for or more efficient feeding to one side may be a subtle accommodation to limited neck rotation or an asymmetrical mandible.[164] Purposive positioning of the young infant is a critical intervention for correcting CMT, preventing CD if it is not present, and correcting CD if it is present.[161] Questions should be asked about sleep position, head rotation or turning preference when sleeping, sleeping surface, and tolerance to prone positioning. Understanding the amount of time the infant spends in passive positioning devices versus time in prone play is important for parental education and for designing an intervention approach.

E-FIG. 9.1 Craniosynostoses: sagittal synostosis, metopic synostosis, and right coronal synostosis. (A) Typical skull contour with a characteristic anterior fontanelle. (B) Sagittal synostosis: elongated skull shape associated with a narrow biparietal diameter and relative frontal prominence. This image also illustrates the blunted anterior fontanelle that may be palpated in some affected children. (C) Metopic synostosis: triangular forehead shape, decreased bifrontal diameter, and supraorbital rims visible from the bird's eye view. The anterior fontanelle is often posteriorly displaced. (D) Right coronal synostosis: asymmetry of the forehead with flattening of the right frontal bone, relative prominence of the right eye, slight ipsilateral occipital flattening, and the consistent finding of twisting of the nasal tip away from the affected suture. The anterior fontanelle is also blunted at the intersection with the right coronal suture and deviated to the left. (From Cunningham ML, Heike CL: Evaluation of the infant with an abnormal skull shape, Curr Opin Pediatr 19:645–651, 2007.)

Activities

Infant activities focus on acquisition of developmental milestones and symmetrical exploration of their own movements and their immediate environment. Full and active range of the neck, spine, and extremities is critical for exploring surfaces, visually tracking activity around them, and moving through space. Activity limitations and developmental milestones should be documented at each visit, including changing tolerances to positions, acquisition of or delays in milestones, presence, absence, or asymmetry in reflex postures or protective reaction patterns, and asymmetry of volitional movements and positions. Development should be assessed with an age-appropriate, standardized valid and reliable tool. Examples of such tests that can assist with early identification of delays during the age range when CMT is often evident include the Test of Infant Motor Performance (http://thetimp.com/) for infants who are 34 weeks postconception to 4 months postterm, the Harris Infant Neuromotor Test (HINT, http://thetimp.com/) for infants 2.5–12.5 months old, and the Alberta Infant Motor Scale (AIMS, http://www.albertainfantmotorscale.com/) for infants who are 0–18 months old. More information on these tests can be found in Chapter 2.

Body Function and Body Structures

The CMT CPG[74] describes seven key body function and body structure items to examine. They are presented in order from the most active to most passive in terms of an infant's ability to cooperate. Infant posture in supine, prone, sitting, and standing, with or without support as appropriate for age, is assessed for symmetry and tolerance for the position. Parents can assist in this portion of the examination by placing their infant in these positions to mitigate stranger anxiety and to allow for a therapeutic trust to build among the infant, the parent/caretaker, and the clinician. In supine and prone, document the side of CMT and any asymmetries of the shoulders, spine, hips, or legs. In prone, document the infant's tolerance to the position as an indicator as to whether prone play is a natural part of the infant's experiences. In sitting and standing, whether supported or independent, document the child's ability to maintain the position and any postural asymmetries. If feasible and permitted by the clinic, digital images in these positions can provide accurate measures of the observed asymmetries.[123] Specifically, the following impairments should be documented at the initial examination and routinely until discharge.

Bilateral active cervical rotation, lateral flexion, and diagonal movements. Rotation should be measured in supine for infants under 3 months; for infants > 3 months, it should be measured while sitting on the parent's lap using the rotating stool test,[82] by enticing the infant to follow toys or sounds in all directions. Lateral flexion should be measured with the Muscle Function Scale[113,115] by holding the infant vertically in front of a mirror and tipping her horizontally 90° to each side, observing for the amount of active neck righting from the horizontal line. The Muscle Function Scale is reliably scored with a picture scale (ICC ≥ 0.94)[115] as 0 = with the head below horizontal, 1 = with the head on the horizontal line, 2 = with the head slightly over the horizontal line, 3 = with the head high over the horizontal line, and 4 = with the head very high over the line approaching vertical.[113] Active neck extension and rotation should be assessed in prone to determine whether the infant has enough AROM to clear the airway and face; this is critical for safety during prone play.

Passive and AROM of the upper and lower extremities, including screening for hip dysplasia. Passively move the upper and lower extremities through full range to examine for brachial plexus injuries, clavicle fractures, abnormal tone, neurologic impairments, or CNS lesions.[107] Assess for tightness of the upper trapezius, scalene, and posterior neck muscles of the ipsilateral side. Use the Ortolani and Barlow maneuvers in infants < 3 months old to screen for hip dysplasia.[145] For infants > 3 months, the Galeazzi sign, asymmetrical posturing, or hip abduction limitations may be stronger indicators of hip dysplasia.[32] Observe active movement of the extremities for symmetrical and reciprocal use, particularly bilateral hand exploration and upper extremity (UE) midline play to assess for hemi-neglect. More information on the Ortolani and Barlow maneuvers is located in Chapter 14.

Bilateral passive cervical rotation and lateral flexion should be measured with an arthrodial protractor. Reference values for typically developing infants are 110 ± 6.2° for cervical rotation and 70 ± 2.4° for lateral flexion.[113] Cervical neutral should be maintained in all measures.[48]

For cervical rotation, infants and young toddlers should be measured in supine; children older than 2 years can be measured in sitting if they are able to cooperate.[77] Measuring with a clear arthrodial protractor requires a minimum of two adults with a mounted protractor, one to stabilize the infant (usually the parent) and one to rotate the head while maintaining cervical neutral and to read the measures. If the protractor is not securely positioned on a wall, plinth, or in a frame, an additional adult may be needed to hold the protractor above the infant, as depicted in Fig. 9.11A. Testing in supine may require elevating the infant's torso on a blanket or 2-in mat, or extending the infant's head beyond the edge of the mat table, to allow for clearance of the rotating occiput and to ensure a cervical neutral position. Visually assess for symmetry of the nose, chin, and ear placement to ensure that the head is in neutral and the nose is aligned to 90° as the starting reference point.

Lateral flexion is measured in supine with the arthrodial protractor laid in the same plane as the infant, as depicted in Fig. 9.11B. A parent/caregiver can stabilize the infant's torso while the clinician supports the head laterally over each ear or under the occiput while moving into the end ranges. Again, care should be taken to test in cervical neutral; raising the trunk with a blanket or 2-inch mat may be required.

Whatever measurement approach is chosen, measurement procedures should be consistent within each child and across children within a practice setting.

Pain or discomfort at rest and during passive or active ROM, using the Faces, Legs, Activity, Cry, Consolability (FLACC) scale.[96] Pain is not a typical sign or symptom of CMT. It can be associated with skinfold irritation or acute or acquired asymmetries, for which immediate medical attention is appropriate. Pain, exhibited as facial grimacing or crying, may be observed during stretching or positioning out of the infant's preferred postures. The revised FLACC tool rates facial expressions, movement, and behavior states on a 3-point scale of 0 for no expression or a quiet state, 1 for occasional expressions or movements, and 2 for frequent grimacing or large movements. Discriminating whether crying is a sign of pain, versus stranger or clinic anxiety, is most easily accomplished by handing the infant to the parent and observing the speed with which the infant stops crying.

Integumentary evaluation of the infant's cervical skin and hip folds. This includes assessment of skin integrity; symmetry of skinfolds; the presence and location of a SCM nodule or

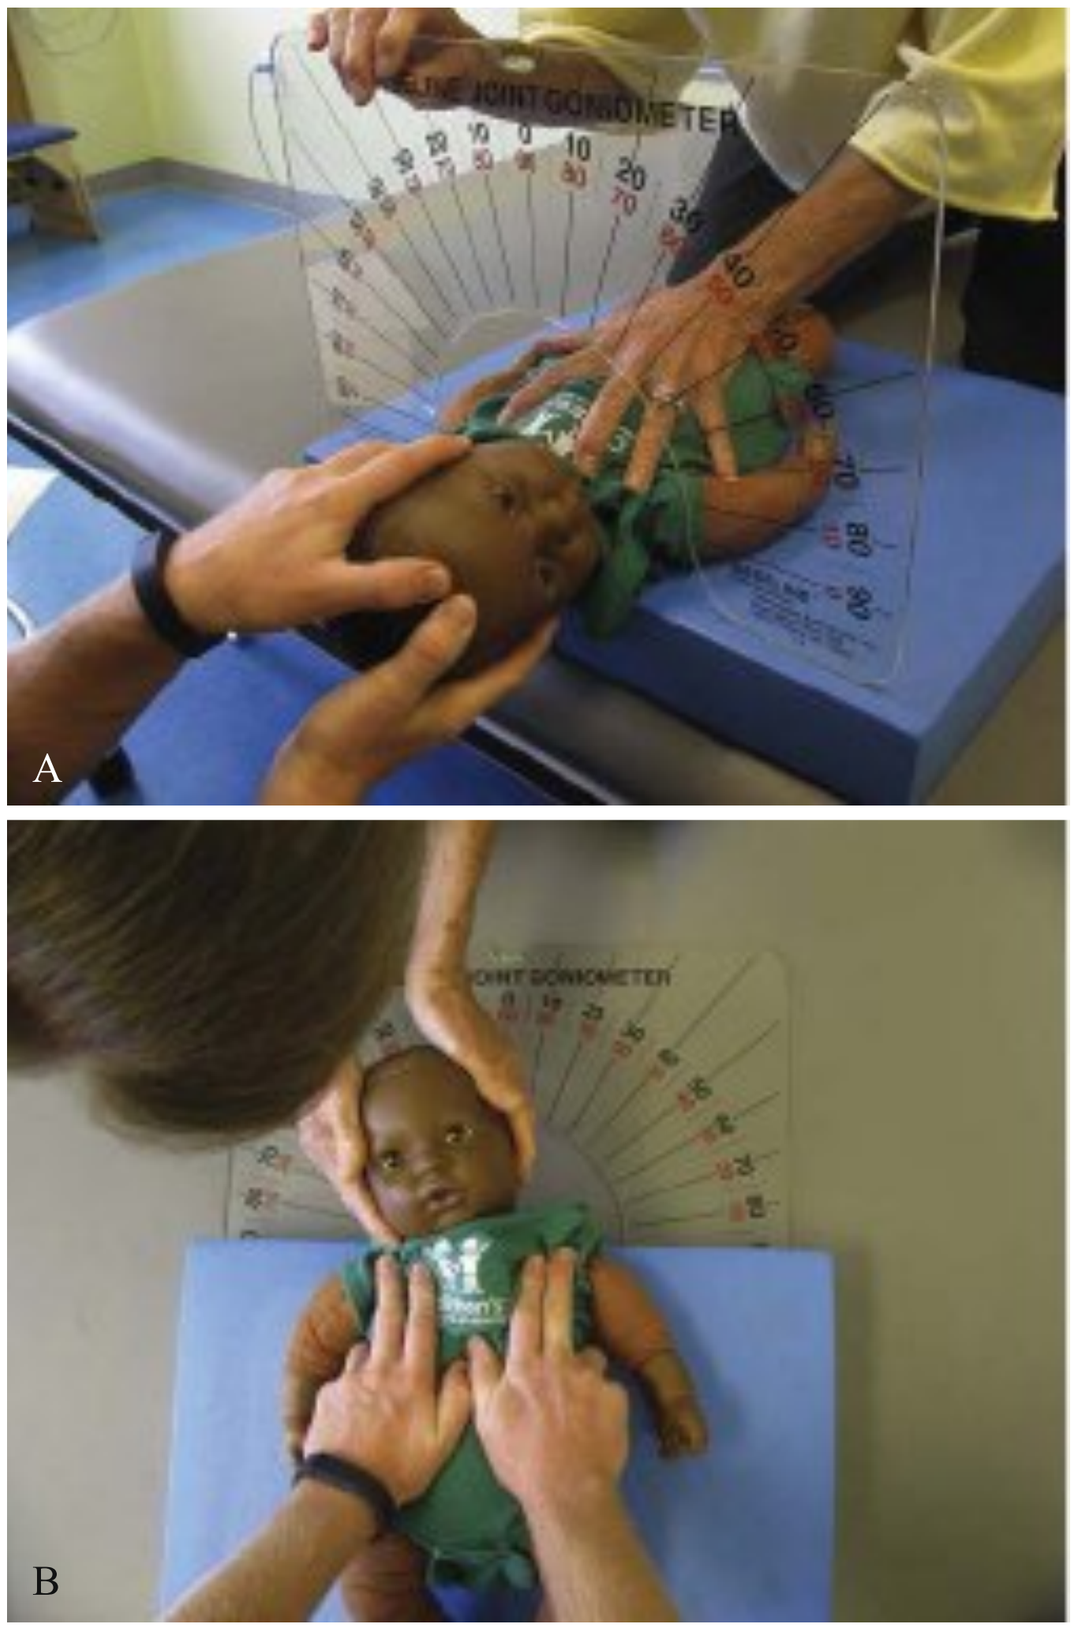

FIG. 9.11 Measuring with an arthrodial protractor. (A) Position of the arthrodial protractor for measuring neck rotation. (B) Placement of the protractor for measuring lateral neck flexion.

fibrous band; and size, shape, and elasticity of the SCM capital and trapezius muscles. Evaluate skin integrity by noting areas of discoloration, reddening, skin breakdown, irritation, or rashes. Observe for symmetry of the skinfolds about the neck for consistency with CMT and the hip joints or inguinal folds for potential hip dysplasia. Palpate the SCM to determine the quality of tightness and pliability of the muscle and to identify the presence, size, and location within the SCM of any nodule. Nodules that are higher up or less than one third of the muscle length tend to resolve more quickly than those that extend through a greater proportion of the muscle or are located in the lower one third.[27,28] Redness and deeper skinfolds along the anterior lateral side of the neck are characteristic of SCM tightness. Redness and deeper posterior neck skinfolds are an indication of tightness in the upper trapezius muscle.

Craniofacial assessment for asymmetries. This includes palpation of the anterior and posterior fontanelles for size, shape, position, and fullness; palpation of cranial sutures to assess for ridging over each suture; and visual assessment of craniofacial symmetry with photo documentation.[34,91] The assessment of craniofacial symmetry is done in six views, depicted in Fig. 9.12A–F: an anterior view to assess symmetry of the cheek, eyes, ears, and nose (Fig. 9.12A); a vertex (top down) view to assess symmetry of the frontal bones and occiput, width of the biparietal diameter, skull length, shape of the forehead, and relative anteroposterior position of the ears (placing one index finger in each of the infant's ears and viewing from above can aid in detecting anterior or posterior displacement of one ear [Fig. 9.12B]); a posterior view to assess whether the skull base is level and to identify the presence of a temporal bulge and/or vertical displacement of an ear (Fig. 9.12C); two lateral views to evaluate the presence of a high sloping forehead or abnormal vertical growth of the posterior skull (Fig. 9.12D–E); and an inferior or submental view to evaluate symmetry of the forehead, ears, eyes, and cheek (Fig. 9.12F).

Physical Therapy Classification and Prognosis for Clinical Management

Based on the results of the examination, the clinician should classify each condition's severity. Classification supports more accurate prognoses of the expected outcomes and episode of care and more appropriate alignment of interventions to achieve the expected outcomes. For both CMT and CD the key factors that impact classification and prognosis are the age at which the infant presents for intervention and the severity of the impairments.

The prognosis for infants with CMT, with or without CD, should address the potential for resolution of CMT and/or CD relative to the grade of severity and the options for intervention, the estimated episode of care to reach resolution relative to different intervention approaches, and the potential benefits, harms, and/or costs of implementing each approach.[74] This should be communicated clearly to the parents/caregivers to facilitate shared decision making about the frequency of clinical visits, the dosage of home exercise programs, the use of cranial remolding therapy, the potential for more invasive interventions if conservative management is ineffective, and concerns about the social, functional, and developmental implications of watchful waiting.

CMT Classification and Prognosis

Table 9.1 describes the seven grades of CMT severity recommended by the CMT CPG[74]; they account for the age at which the infant is initially evaluated, the limits of cervical rotation, and the presence or absence of an SCM nodule. Assigning a grade of severity can assist with estimating the length of the episode of care; lower grades are associated with faster impairment resolution.[120] Assigning grades can also assist with measuring service outcomes because infants can be compared to others with the same severity grades rather than being grouped together.

The prognosis for full resolution of CMT is 100% for infants < 3 months of age, if they are referred early and caregivers are adherent with conservative intervention. The prognosis for full resolution drops to 75% for infants referred between 3 to 6 months of age, and 30% for toddlers between 6 to 18 months of age.[41] Because the potential for full resolution reduces with increasing age of treatment initiation, the potential for surgical release increases with later ages of referral.[41,120]

CD Classification and Prognosis

Tables 9.2 and 9.3 describe the Argenta Clinical Classification Scales for DP and DB[7] recommended by the CMT CPG[74] for documenting the severity of CD in clinical settings. These scales are clinically practical, easily understood by families, do

FIG. 9.12 Six craniofacial views to assess for asymmetries (3-month-old infant without CD). (A) Anterior. (B) Vertex. (C) Posterior. (D) Left lateral. (E) Right lateral. (F) Inferior or mental. (Copyright © 2016 Cranial Technologies, Inc.)

not require time-intensive measurements or use specialized equipment,[7] and demonstrate moderate interrater (weighted kappa = 0.51–0.66) and intrarater (weighted kappa = 0.6–0.85) reliability.[139]

The prognosis for full resolution of CD is 77% after parent education in repositioning and 94% to 96% after cranial remolding therapy, whether or not it is preceded by parent education in repositioning.[141] Risk factors for moderate to severe CD after parent education in repositioning with or without physical therapy include poor adherence, initiating intervention after 3 months of age, persistence of CMT beyond 6 months of age, developmental delay, and severity of initial CD.[141] Risk factors for moderate to severe CD after cranial remolding therapy include poor adherence with wearing the helmet and initiating intervention after 9 months of age.[141] Surgical management of CD is considered in only very severe cases because outcomes are inconsistent and high rates of complications have been reported.[36,97]

Conservative Interventions for CMT and CD

Currently, most authors advocate conservative, nonoperative interventions for CMT and CD, and those interventions can be divided into first-choice interventions with strong and consistent evidence for effectiveness and supplemental interventions with weaker or less consistent evidence of effectiveness (Tables 9.7 and 9.8).

First-Choice Interventions

The conservative first-choice interventions for CMT consist of five components: parent/caregiver education, environmental adaptations, passive neck ROM exercises, neck and trunk AROM, and facilitation of symmetrical movement activities.[74] The conservative interventions for CD include parent/caregiver instruction in repositioning and environmental adaptations for CD under 6 months of age and cranial remolding therapy for severe CD after 4 months of age.[47,125]

TABLE 9.7 Key Interventions for CMT

Limitation	PT Intervention
Decreased cervical rotation	Manual stretching of tight musculature, active cervical rotation toward nonpreferred side, strengthening of cervical musculature, passive positioning to stretch tight tissues
Head tilt	Manual stretching of tight musculature, active cervical lateral flexion away from head tilt, strengthening of cervical musculature, passive positioning to stretch tight tissues
Positional preference and/or trunk asymmetry	Active movement and strengthening opposite of the preferred side or asymmetry
Prone position intolerance	Increase use of prone positioning to strengthen capital muscles and facilitate symmetrical trunk and head alignment
Asymmetrical postures	Active movement and strengthening opposite of the asymmetry
Developmental delay	Facilitate equal use of all extremities and head turning to both directions during daily activities and play

TABLE 9.8 Key Interventions for CD

Limitation	PT Intervention
Brachycephaly	Increase prone positioning to relieve pressure on occiput to allow for reshaping. Refer severe cases for cranial orthotic assessment at 4 months of age and moderate cases for cranial orthotic assessment at 6 months of age.
Plagiocephaly	Head turning and positioning opposite of preferred position, increased time in prone, facilitation of development to encourage overall movement away from the flattened side. Refer severe cases for cranial orthotic assessment at 4 months of age and moderate cases for cranial orthotic assessment at 6 months of age.

Parent/caregiver education. Parent/caregiver daily adherence to the home program is critical to the success for remediating CMT and CD; it must be stressed to the caregivers that they are the primary interventionists for these conditions and that the role of the clinician is to help guide and advance the home program.

Prevention of CMT and CD through early parental education and active infant repositioning, including the use of prone positioning and unfettered movement, can effectively reduce the incidence of either or both CMT from positional preference and postnatal CD.[22,159] The American Academy of Pediatrics recommends counseling of all parents during the newborn period (by 2 to 4 weeks of age) in active infant repositioning and environmental adaptations to prevent CD,[82] and increasing evidence supports that parent guidance before discharge from the maternity ward may reduce the prevalence and severity of CD in early infancy.[4,22] Reinforcing or improving neck ROM, strength, and postural control can be accomplished in any number of ways throughout the day. In infants without CMT or CD, caregivers should be aware to change the infant's position throughout the day and present voice and objects of interest equally to the right and left sides. Midline development should be stressed.

In infants with CMT and/or CD, caregivers should be taught to purposefully carry, hold, and position the infant in ways that create a prolonged stretch of the tight muscles and promote midline development and symmetry of movements.[13,152] Toys should be presented to the nonpreferred side to facilitate head turning and reaching in all planes.[13] Caregivers should also be taught to approach and feed the infant to promote looking toward the nonpreferred side[160] or by alternating sides for feedings.[92] Home exercise programs should include eliciting balance reactions for strength development of the neck and trunk muscles, specifically cervical lateral flexion away from the preferred head tilt. Once an adequate amount of neck muscle strength is obtained, the exercises should be task specific to encourage the infant to use that strength to lift the head against gravity during pull to sit, in prone play, and for visual tracking in all directions.[152] Strengthening neck and trunk rotator muscles promotes development of transitional movements such as rolling and coming to sit from prone and supine.

Caregivers providing ROM exercises should be instructed to observe for changes in the infant's behavioral and physiologic states and to discontinue exercises if the following occur: changes in face color, breathing rate, or heart rate; increased hand and foot movement; plantar or palmar sweating; eye squeezing; perspiration; nasal flaring or brow bulging; mouth gaping; and crying.[11] Passive movement should be done slowly, and stretching should not be done against an infant actively resisting the stretch.

Parent education to prevent and minimize CD includes repositioning to decrease pressure on the flattened area of the skull when sleeping in supine and during bottle and breastfeeding and supervised prone positioning for play[4,47] with a goal of at least 30–60 min a day.[82]

Environmental adaptations for CMT and CD. Adaptations to the infant's environment can support the home exercise program and facilitate goal attainment. Attention should be paid to the type of positioning devices used by the family and the amount of time an infant spends in those devices.[82,119] Parents should be aware that car seats, infant swings, and bouncy seats that rely on semireclined supine positioning need to be used with correct postural alignment to prevent reinforcement of CMT and that time in those devices should be minimized in favor of supervised prone play.[82] Environmental adaptations to correct CMT, or to prevent and minimize CD, include limiting time in supported supine positions such as car safety seats, infant swings, and infant carriers and environmental modifications to encourage the infant to rotate the head toward the nonpreferred side, including changing toy positions and the position of the infant's crib relative to the door and reversing the head-to-toe position of the infant in the crib and on the changing table.[4,47]

PROM of the neck. The origin, insertion, and biomechanics of the SCM muscle, and the location of any nodules or fibrous bands, dictate the angles of stretching necessary to elongate the muscle to correct CMT. The elongated position can be attained with ipsilateral rotation, contralateral lateral flexion, and contralateral asymmetric extension from a starting point of neutral cervical spine alignment. In younger infants stretching can be accomplished in most positions, including when carried prone on the caregiver's forearm, up against the chest wall, in supine, or supervised prone lying, as illustrated in Figs. 9.13 for cervical rotation and Figs. 9.14A–C for lateral flexion. To maximize stretching routines in the older infant, placing the infant supine on the parent's lap or in a reclined sitting position may be more comfortable and acceptable to the infant. Regardless of the chosen position, the clinician should consider the following factors:

- Starting position: Place the infant in a comfortable position, either supine or reclined sitting on the caregiver's lap, with the head and neck in midline, aligned as possible with the trunk and pelvis. Use the infant's nose and umbilicus as landmarks for midline alignment.
- Identify the tight muscles and their line of pull to maximize stretching biomechanics.
- Stabilize the shoulders. Stretching should be isolated to the tight muscles. Differentiate between cervical and shoulder tightness in order to determine the correct stretch.
- Check for skin irritation and redness. These may be indicators of muscle tightness.
- Do not force the stretch. PROM should not be painful. Low-intensity, sustained holding at the end of range will avoid microtrauma of the muscle[159]; positioning and handling to facilitate passive elongation are also effective.[110,151] PROM through passive positioning or manual stretching while walking around or rocking the infant provides multiple sensory stimuli to the infant and may distract him or her from resisting the stretch sensation.
- Contraindications for passive neck ROM include Klippel-Feil syndrome, bony abnormalities, fractures (particularly of

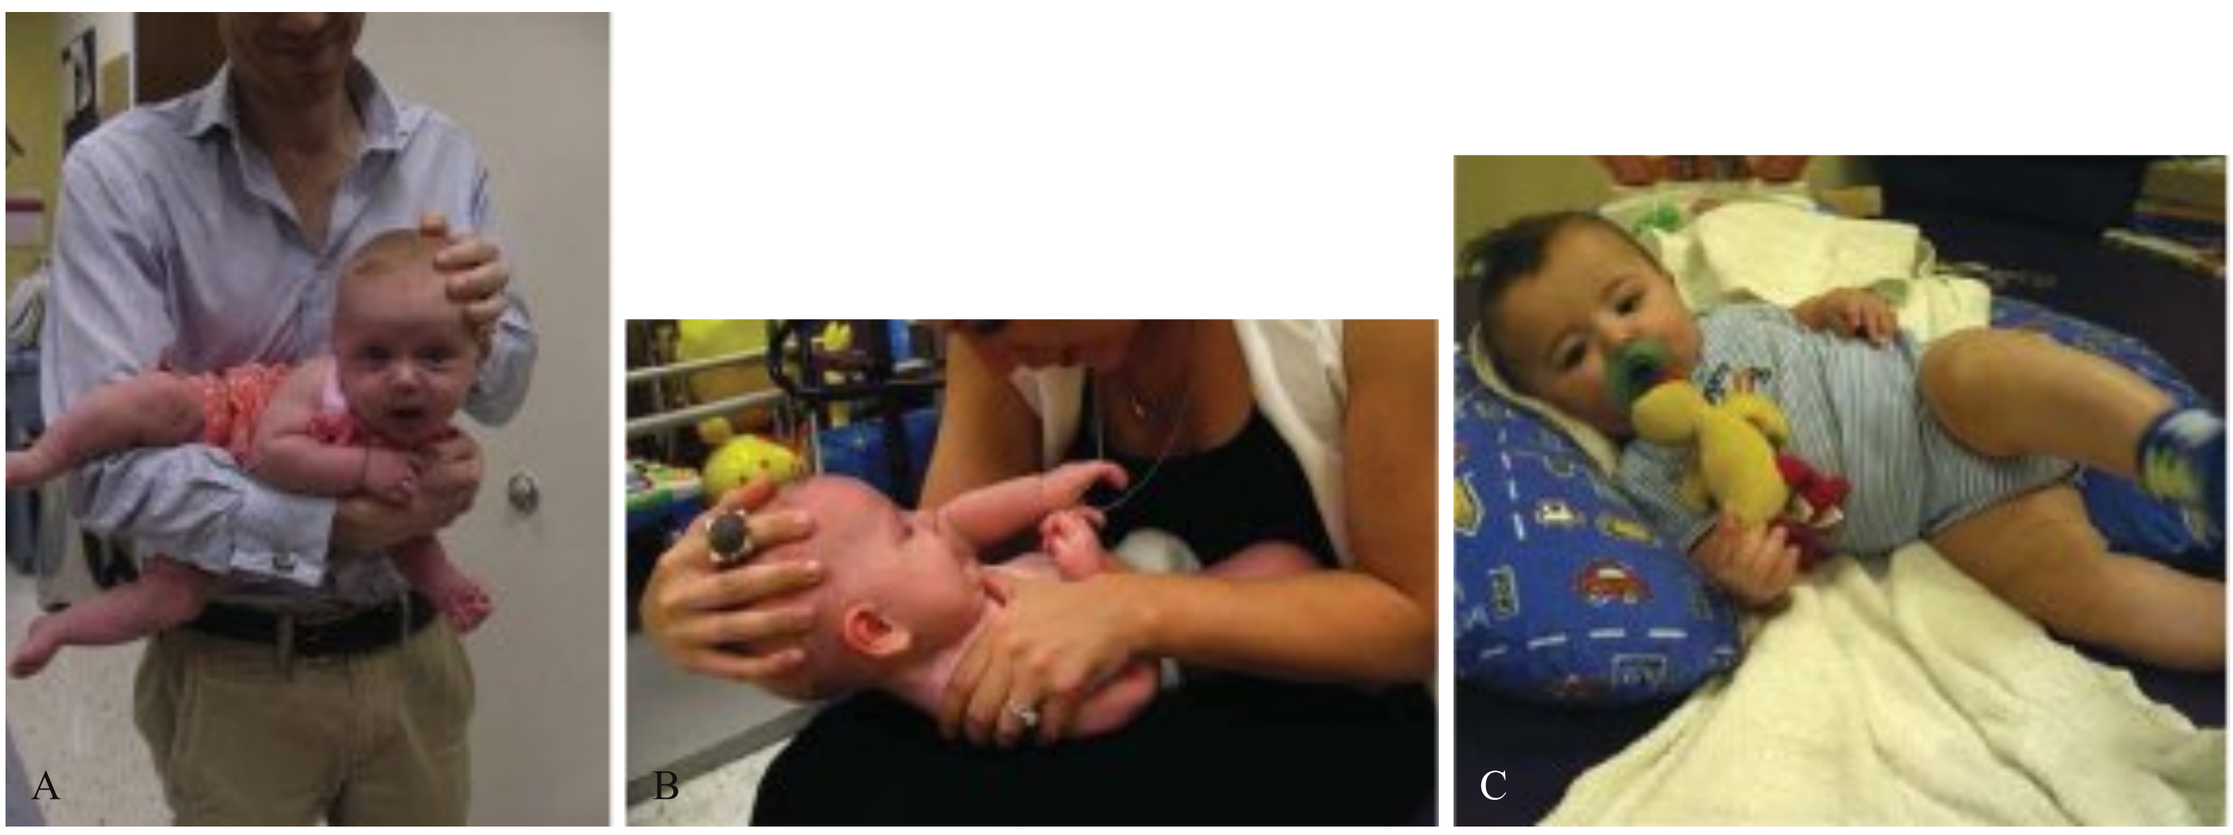

FIG. 9.14 Positions to encourage cervical lateral flexion. (A) PROM into right lateral flexion to stretch the left in a modified football carry. (B) PROM into left lateral flexion and right cervical rotation in supported supine, with gentle stretch to right upper trapezius. (C) PROM during supported sidelying to stretch the right lateral cervical and trunk flexors.

the clavicle), C1-C2 subluxation, odontoid abnormalities, CNS or bone tumors, or brain stem malformations (e.g., Arnold-Chiari malformation).[106,137] Caregivers providing ROM exercises should be instructed to observe for changes in physical appearances such as worried facial expressions, chin quivering, nasal flaring, and increased body tone and physiologic signs such as changes in color, breathing, or heart rate[8] and to consult with the clinician on how to continue a safe home program.

AROM of the neck and trunk. The focus of AROM is to strengthen weak neck and trunk muscles. This can be achieved through positioning, handling, and carrying during care and play,[110] offering food from the nonpreferred side to encourage active cervical rotation,[155] and using righting reactions to activate weaker muscles[110,155] as depicted in Fig. 9.15A–C. Active play in prone may need to be modeled for the parent/caregiver who is wary of placing the infant prone or who is not sure how to modify the prone position so that the infant can tolerate it. Prone play is critical for elongating the neck flexors and strengthening capital muscles.[45,95]

Symmetrical motor development. In addition to remediating impairments about the neck, the clinician should facilitate development of age-appropriate function, inclusive of rolling, creeping, crawling, sitting, and standing, as well as active and symmetrical play within each of those positions. There are several studies supporting a possible association between CMT and delayed development,[111,130,131] and any postural preference to one side may bias an infant for associated rotation along the spine, resulting in asymmetrical postures.[152,158]

Intervention dosage. The duration of physical therapy intervention and outcomes of intervention depend on the cause of the torticollis, the initial deficit of passive cervical rotation, and the age of the infant when intervention is initiated. Published intervention protocols for CMT vary considerably and are often standardized to fit research protocols. They range from cervical stretching done 2 to 3 times daily, repeating each

FIG. 9.15 Positions for AROM, strengthening, and midline orientation. (A) Sitting on parent's lap using weight shifting on right to encourage active left cervical and trunk lateral flexion via righting reactions. (B) Sitting on parent's lap to encourage active right cervical rotation to interact with toys. Notice the parent stabilizing the trunk. (C) Facilitated sidelying play with intermittent manual assist to encourage prolonged antigravity activation of right cervical lateral flexors.

stretch 5 to 15 times with 1- to 10-second holds,[28,44] to two-person passive neck stretching exercises carried out 4 to 8 times daily with at least 30 to 40 repetitions in each set.[23,41] The exact intervention dosage for clinical use will depend on the level of severity, the ability of the family to adhere to the recommended stretching protocols, and the age of the infant and his or her ability to tolerate intervention. Younger infants tolerate stretching better because they have less neck strength; infants 3 to 4 months or older are developing sufficient neck strength and willpower to resist passive stretching if they are not comfortable with the sensation or if they are intent on looking at something on the preferred side. The overall consensus across studies is that stretching should be done frequently across the day and should be tied to routines of infant carrying, playtime, diaper changes, feedings, bath times, and position changes.

Supplemental Physical Therapy Interventions with Evidence for CMT

CMT and mild CD in most infants will respond to the first-choice interventions, but for infants with slower resolution or more severe presentations, there are other approaches described in the literature but for which the body of evidence is smaller, the study designs are less rigorous, or there may be conflicting evidence. Nevertheless, these approaches may provide useful additions to the first-choice interventions to support CMT or CD resolution. The choice of a supplemental intervention should be based on discussions with the family, the child's current rate of improvement, the family's ability to adhere to additional or different protocols, the family's perceived acceptance of the approach, the clinician's skill or training to provide the approach, potential additional costs, and the likelihood of the child's improvement.

Clinicians who use these approaches should be vigilant to document objective measures to determine their effectiveness on the degree and speed of resolution because they may add to the cost of care. Clinicians who choose to use approaches that have no peer-reviewed publications that describe foundational principles and provide evidence of effectiveness should be conscientious about receiving the informed consent of the caregivers and documenting objective measures at baseline and throughout care. All clinicians are encouraged to publish cases that are emblematic of new approaches or unusual outcomes.

Microcurrent for CMT

Low-intensity alternating current (200 μA) is applied superficially over the involved SCM such that the infant does not perceive the current; stretching follows the treatment. Two small randomized controlled trials (RCTs)[76,80] have demonstrated similar outcomes of increased ROM in significantly less time than with passive stretching alone or stretching combined with ultrasound diathermy. The overall episodes of care averaged 2.6 months for infants receiving microcurrent and 6.3 for those who received only stretching.[80] Infants receiving microcurrent cried less during treatment than infants who did not receive it,[76] and ultrasound imaging of the SCM posttreatment demonstrated significantly less tissue thickness of the involved SCM.[80] Replication of this approach with larger sample sizes is appropriate, but microcurrent appears to be a promising approach with strong evidence for shortening the episode of care without adverse reactions. Clinicians will need to be comfortable with administering microcurrent and have the proper type and size of equipment to provide this intervention.

Myokinetic Stretching for CMT

This technique consists of applying mild overpressure with 1 or 2 fingers on the SCM while it is in its lengthened position.[29] PTs provided 60 repetitions over 30-minute treatment sessions, 5 times week on infants less than 50 days old; parents additionally performed home stretching, massage, and positioning. Given the young age of the subjects and the confounding factor of a home program, it is not clear if this particular technique is significantly different from any other strategy of SCM intervention; however, if other approaches are not tolerated, this study provides moderate evidence for an alternative stretching technique. Clinicians will need postgraduate training to provide this approach.

Kinesiologic Taping for CMT

Stretchable tape is applied to supporting muscles to provide sensory feedback. A retrospective study provides weak but promising evidence that when kinesiologic tape is applied for the purpose of relaxing the affected side, immediate Muscle Function Scale gains were significantly greater[112]; long-term benefits have not been reported. The approach requires postgraduate training, and some infants may have skin sensitivity to the tape.

Tscharnuter Akademie for Motor Organization (TAMO) Approach for CMT

A single case study describes this approach as using light touch and the infant's responses to gravity and support surfaces to facilitate movement exploration.[122] The approach was mixed with AROM, home programming, carrying techniques for passive positioning, and head righting, so it is not clear how much the TAMO approach contributed to the resolution of CMT, but there was a notable absence of PROM as an intervention. Clinicians will need postgraduate training to provide this approach.

Cervical Collars for CMT

Several versions of neck orthoses are described in case reports but have not been rigorously assessed as to their comparative benefits over conservative management alone. All are intended to facilitate active movement within a corrected range and are not meant to be passive supports for the neck. As with other supplemental approaches, cervical orthoses may be an appropriate adjunct to conservative care if changes are occurring slowly, but they require careful application, supervision, and monitoring by the caregiver. As with all cervical collars, remove the collars immediately if there are any concerns about fit, skin irritation, or development of pressure areas. Clinicians may need postgraduate and/or supervised training to properly fit and apply selected collars.

The Tubular Orthosis for Torticollis (TOT collar)[44] is a cervical orthosis designed to decrease head tilt posture, assist in midline head control, and stimulate movement away from the tilted head position[55] in infants with adequate head control and who demonstrate more than 5° of head tilt. The TOT collar is worn during waking hours when the infant is moving, playing, and even feeding. The clinician must be knowledgeable of the indications for, fitting of, and modifications

to the TOT collar before fitting it to an infant. For example see eFig. 9-3.

Soft cervical foam collars may be used for immediate post-operative management following SCM release,[138] post-SCM release with physical therapy,[83,84] and after Botox injections[71] to protect the surgical site and facilitate movements away from the side of released SCM. The use of soft felt cervical collars was described by Binder et al.[13] in infants with a persistent head tilt and restrictions in active cervical rotation.

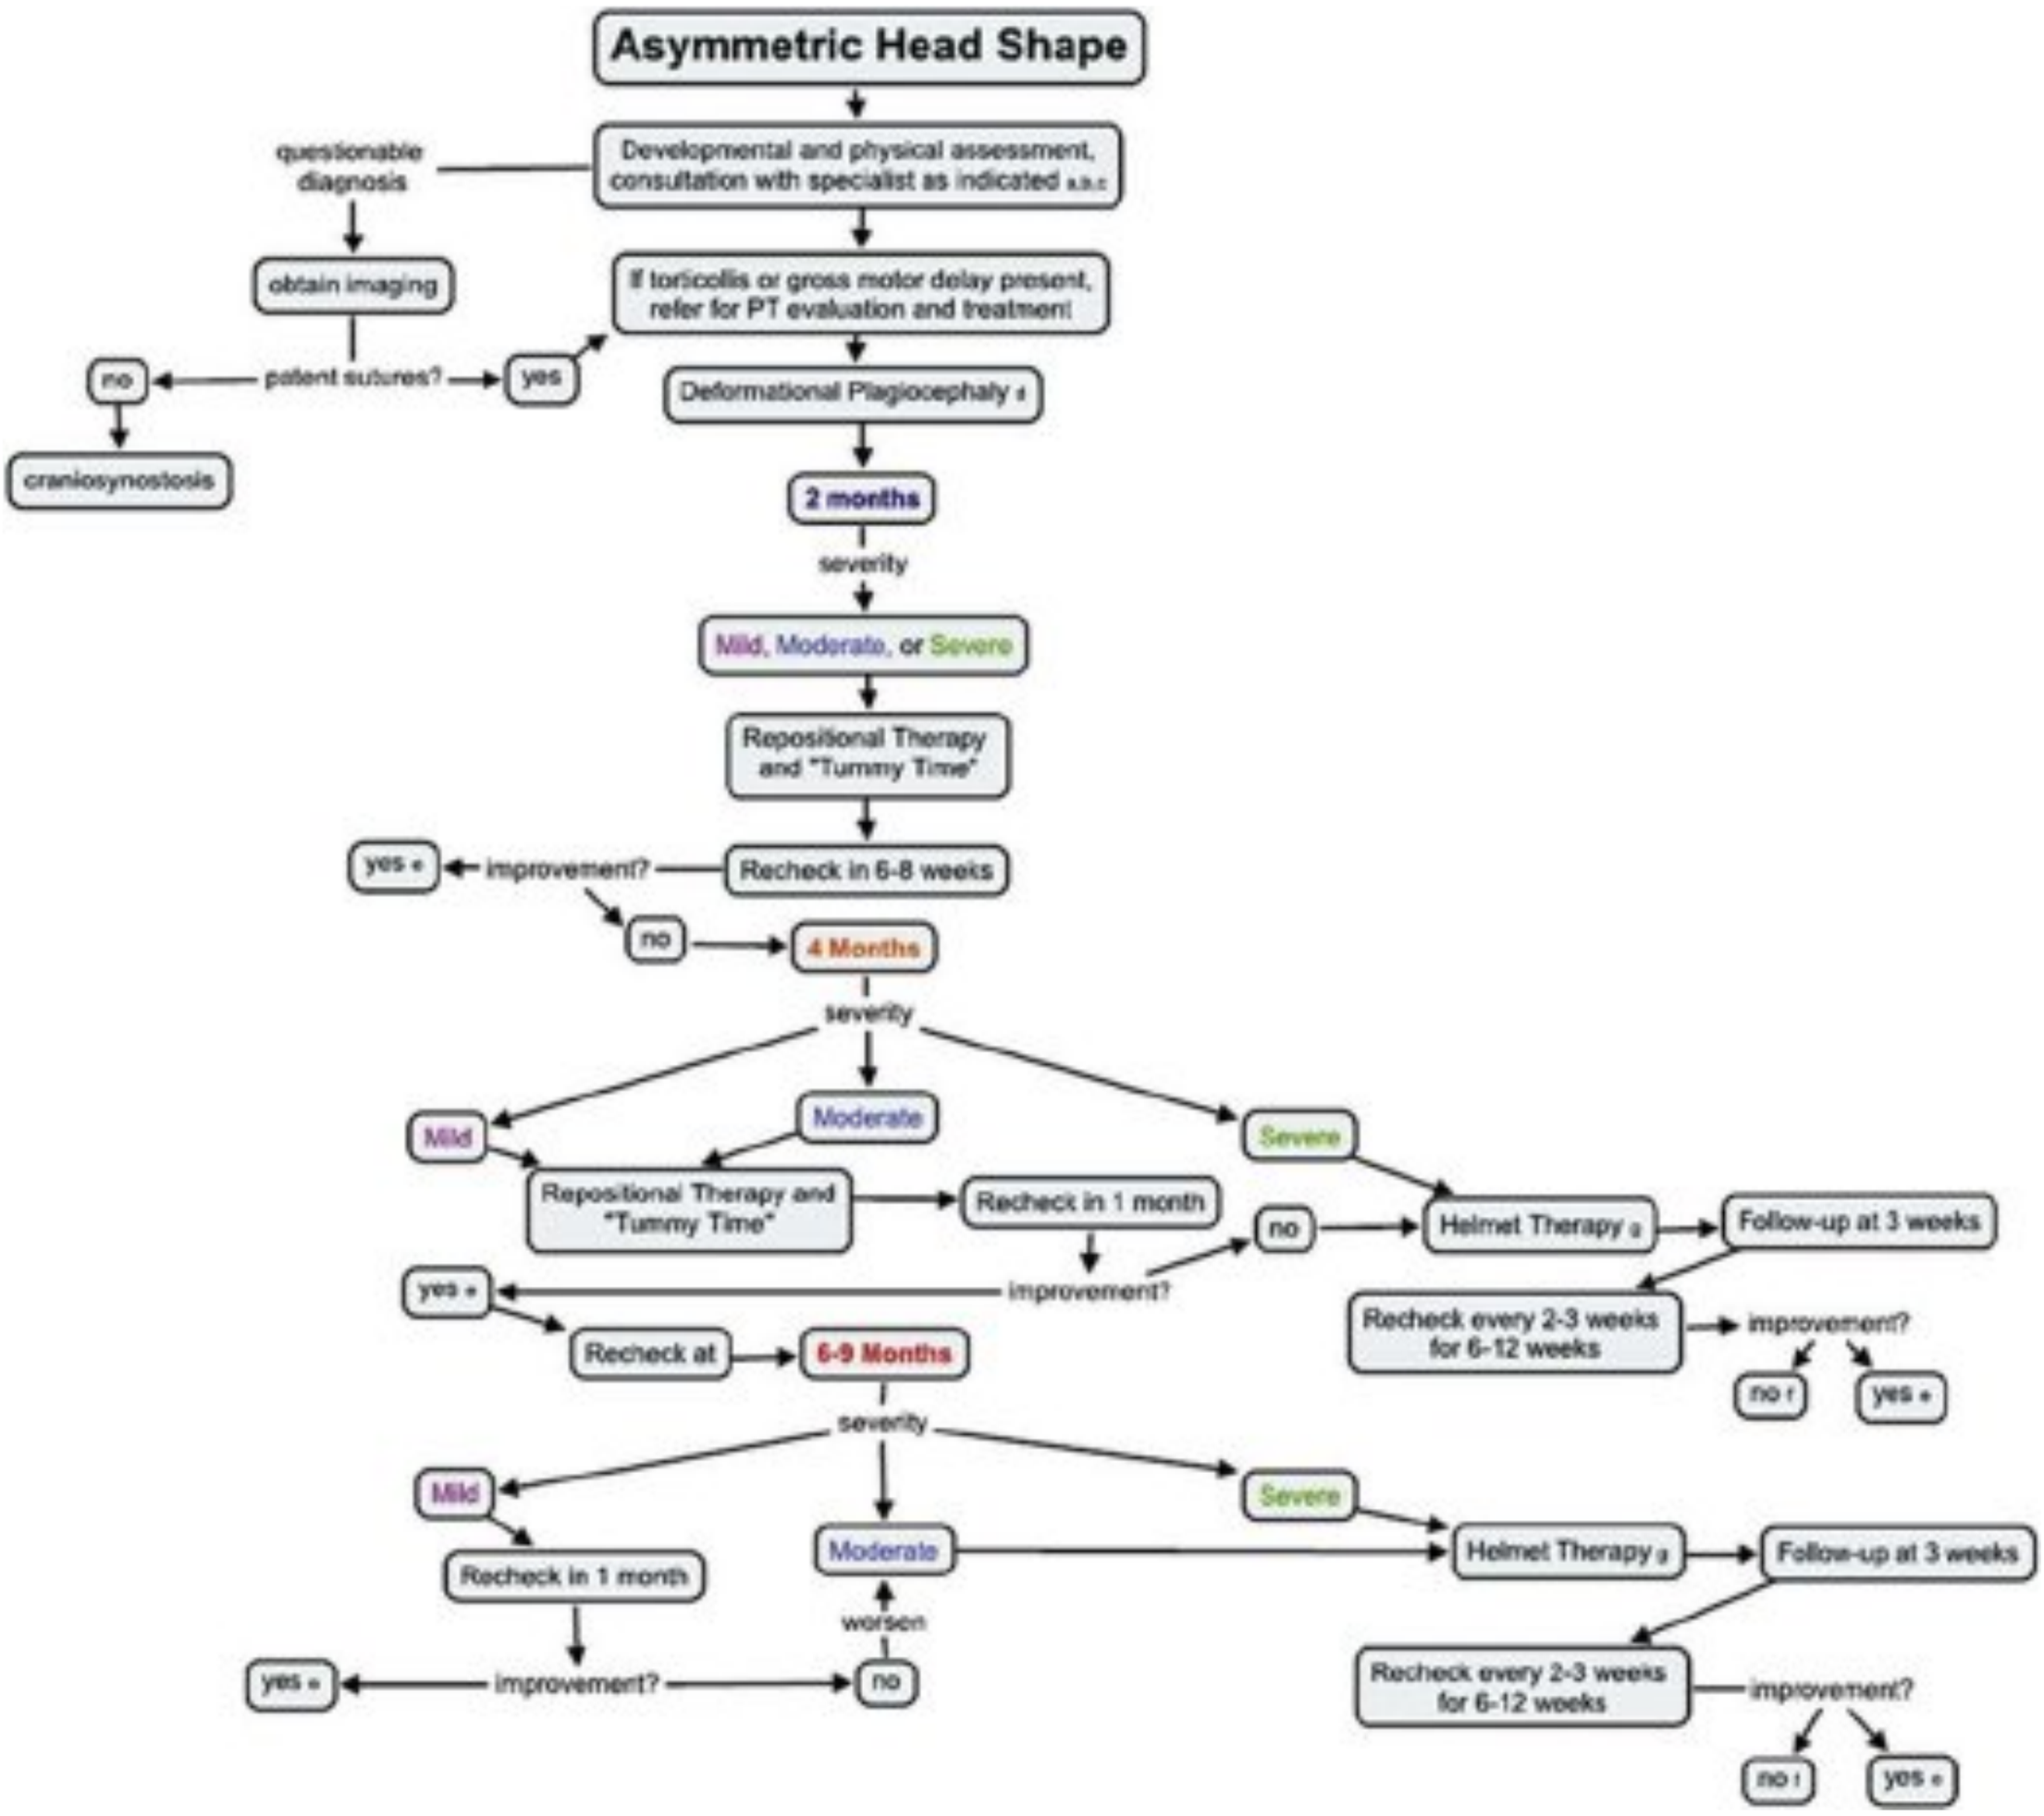
Cranial Remolding Therapy and Positioning Devices for CD

Cranial Remolding Therapy for CD

Cranial remolding therapy uses cranial orthoses, helmets, or bands. Cranial orthoses are constructed from high-temperature thermoplastic materials, and most are lined with high-density, hypoallergenic medical grade foam.[39] Cranial orthoses do not restrict cranial growth but rather redirect subsequent cranial growth into voided areas facilitating a symmetrical shape,[75] as illustrated in Fig. 9.16A–B. Most cranial orthoses are custom fabricated, but soft shell helmets in generic sizes with custom foam padding are commercially available.[154]

Cranial orthoses are initiated from 4 to 6 months of age and worn 20 to 23.5 hours a day for 2 to 7 months for optimal outcomes.[47,51] Duration of cranial remolding therapy varies based on the age of the child and severity of the CD because the rate of correction decreases logarithmically with increasing age.[133] At 5 months of age, the rate of cranial asymmetry improvement is 0.93 mm per week, whereas at 8 to 11 months of age the rate of improvement stabilizes at 0.41 to 0.42 mm per week.[133] Cranial remolding therapy results in more complete correction and shorter treatment duration when initiated before 6 months of age,[78] but correction can occur up to 15 to 18 months of age although the correction will likely be incomplete and require a substantially longer treatment duration.[75,133] After 12 months of age the rate of correction decreases due to reduced rate of skull growth and adherence issues as older infants may adamantly refuse the cranial orthotic and independently remove it.[82,133] Adverse effects associated with cranial orthoses are low but include occasional malodorous perspiration, minor skin irritations and fungal infections, poor helmet fit with severe DB, nonreimbursable cost, social stigma of cranial orthotic use, and unsatisfactory cosmetic results.[56] Daily cleaning of the cranial orthotic is critical to avoid skin irritations and fungal infections.

Assessment for cranial remolding therapy is indicated based on the age of the child and the severity of the CD.[47] It is not indicated for infants under the age of 4 months or infants at any age with mild CD that is limited to the posterior skull (Argenta DP Type I, Argenta DB Type I).[47,82] Cranial orthotic assessment is indicated for infants over 4 months with severe CD that includes facial asymmetry (Argenta DP Type IV) and temporal bulging and abnormal vertical growth of the skull (Argenta DP Type V, Argenta DB Type III).[82] Cranial orthotic assessment is also indicated for infants over 6 months with moderate CD that includes ear displacement (Argenta DP Type II), frontal bone protrusion (Argenta DP Type III), or widening of the posterior skull (Argenta DB Type II).[47,82] At the cranial orthotic assessment, quantitative measures of CD are taken and a decision is made as to whether cranial remolding therapy is warranted. Some practitioners recommend an objective assessment of the infant with moderate CD at 4 months and again at 6 months to document whether 2 months of repositioning was effective in reshaping the skull; this will assist with the determination of whether cranial remolding therapy is warranted at 6 months. Refer to eFig. 9-4 for a clinical decision tree for managing CD.[47]



Consistent and strong evidence supports that cranial remolding therapy is effective in reducing cranial asymmetry in infants with moderate to severe CD when implemented by 6 months of age and parents/caregivers diligently follow the prescribed wearing schedule.[47,51] However, it is unknown whether cranial remolding therapy, as compared to parent education in repositioning, results in a clinically significant difference in cranial shape that affects long-term satisfaction and quality of life.[47,51] The only RCT to compare cranial remolding therapy with parent education in repositioning in 5- to 6-month-old infants with moderate to severe CD did not find a statistically significant difference in cranial asymmetry between the two interventions when children were 2 years of age.[162] However, only 23% to 26%

FIG. 9.16 Examples of custom cranial orthoses. (A) En face view of a 4-month-old infant with right congenital muscular torticollis and deformational plagiocephaly wearing a cranial band (B) 8-month-old infant with DP wearing a cranial helmet. ([A] Courtesy iStock.com. [B] From STARband Orthomerica, Orlando FL.)

E-FIG. 9.3 Five-month-old infant with left congenital muscular torticollis concordant deformational plagiocephaly fitted with a tubular orthosis for torticollis (TOT Symmetric Designs Ltd., 125 Knott Place, Salt Spring Island, BC, Canada, V8K2M4). A, The anterior strut is shorter than the posterior strut and spans vertically from the anterior angle of the mandible to the midclavicle. B, The posterior strut is longer than the anterior strut and spans vertically from the occiput at the inferior nuchal line to the superior medial angle of the scapula where the levator scapulae muscle attaches.

E-FIG. 9.4 Clinical decision making tool for management of deformational plagiocephaly. (From Flannery ABK, Looman WS, Kemper K: Evidence-based care of the child with deformational plagiocephaly. Part II: management, J Pediatr Health Care 26:320–321, 2012.)

of children in both groups obtained complete correction at 2 years of age, a much smaller percentage than in previous studies, perhaps because the study's criteria for complete correction was more stringent than previous studies.[162] Further high-quality evidence is needed to determine the efficacy of cranial remolding therapy as compared to parent education in repositioning.

Positioning Devices

Positioning devices that alter the shape of the surface an infant lies on have been investigated as a means to prevent or minimize CD. These devices rest the infant's head into a depression to redistribute contact pressure between the surface and the cranium. Although some devices have shown favorable results, such as bedding pillows,[167] passive orthotic mattresses,[135] cranial cups,[40,128] and Plagio Cradle orthotics (Boston Brace, Avon, MA),[132] others such as the Safe T Sleep Sleepwrap positioning wrap (safetsleep.com)[64] have not. Although the evidence is weak and does not support that these devices are more effective than repositioning alone for most infants, these devices may be promising for infants with severe CD who are younger than 4 months or whose development is compromised. Additional studies are needed to determine their effectiveness as compared to conscientious repositioning, as well as the cost-effectiveness of available devices.

Nonconservative Interventions for CMT

Nonconservative interventions for CMT should be considered for infants who are not progressing after 6 months of conservative intervention or for children initially referred after 1 year of age and who have Grade 7 severity.[74] These options include surgery or botulinum toxin type A (Botox) for CMT. The clinician should collaborate with the infant's primary or referring physician for follow-up care if these approaches are being considered. This form eliminates any misinterpretation that the PT is doing these interventions.

Surgery

Surgical options range from tendon lengthening to unipolar or bipolar release of the SCM. Indications for surgery include persistent residual tightness of > 15°[18] or progressing ROM limitations.[159] The goals of surgery are to normalize neck ROM and to improve or prevent additional craniofacial asymmetry resulting from persistent asymmetrical posturing. Concerns with surgical interventions include potential damage to the facial, greater auricular, or spinal accessory nerves, visible scars, recurrent muscle band formation, loss of neck contour, and the recurrence of SCM contracture.[18,19] Endoscopic surgery by an experienced surgeon avoids many of these complications by improving the operative field view with magnification, ensuring precise muscle fiber transection, and preserving the neurovascular structures.[18] Children who have releases before 1 year of age have the best chance of reversing their facial and skull deformities[19]; however, older children and untreated adults can benefit from the procedure as well.[147]

Botox

This neurotoxin is injected into the SCM and is presumed to either relax the tight muscle by inhibiting acetylcholine release or by causing muscle atrophy that allows for easier stretching.[116] The use of Botox is considered off label for infants; however, there is a growing body of support for its use with recalcitrant CMT to reduce the need for surgical correction.[31,71,116]

ANTICIPATED OUTCOMES AND DISCHARGE CRITERIA

If left untreated, CMT is a condition that will persist and possibly progress. As the infant grows older, growth of the surrounding musculoskeletal structures can be impacted by the SCM tightness causing further restriction of range or CD.[137] Infants who are discharged from physical therapy for CMT should be monitored throughout their early childhood to observe for return of tightness as they go through growth spurts; achieve antigravity milestones such as crawling or walking; during higher-stress activities such as climbing, pulling, or other resisted sporting activities; or when ill or teething.[79] Parents should be alerted that temporary asymmetrical presentations will most likely resolve when the challenging factor is resolved but that a physical therapy examination may be indicated if the postural preference persists. A longer treatment duration of cranial remolding therapy may be indicated if the infant's CD has resolved but the CMT has not; repositioning and use of a cranial orthotic during sleep may be continued until the CMT is resolved to prevent reoccurrence of cranial asymmetry.

The anticipated outcomes and criteria for discharge from physical therapy intervention are:

1. Full PROM of neck, trunk, and extremities to within 5° of the nonaffected side
2. Symmetrical movement patterns throughout the passive range
3. Age-appropriate gross motor development including symmetrical movement patterns between the left and right sides during static, dynamic, and reflexive movements
4. Improved skull symmetry to Argenta Type I or referred for further management of CD
5. No visible head tilt
6. Parents/caregivers understand what to monitor as the child grows

SUMMARY

This chapter discussed the management of CMT and CD. They are often comorbidities, and physical therapy is highly effective in resolving both CMT and CD when initiated early in infancy. A fibrotic and shortened SCM muscle is the most typical finding in CMT, resulting in rotation away from and a lateral head tilt toward the involved SCM muscle. The "back-to-sleep" campaign is thought to have spurred a growing incidence of CMT and CD. Differential diagnosis is critical to rule out other causes of asymmetrical posturing, such as neurologic, visual, or orthopedic conditions. Most infants with CMT can be successfully managed with first-choice conservative treatments including parent/caregiver education, environmental adaptations, passive neck ROM exercises, neck and trunk AROM, and facilitation of symmetrical movement activities. The CMT severity grade assists with prognosis for the episode of care to achieve resolution. CD is typically responsive to repositioning during the early months, but cranial remolding interventions may be necessary to correct moderate to severe CD in infants older than 4 to 6 months. Physical therapy for both CMT and CD should address all aspects of the ICF framework. Evidence-based objective measures should be documented at baseline and on subsequent visits to monitor the effectiveness of home programming. Collaboration with

the family and caregivers is critical for successful outcomes; referrals for specialist consults when an infant is not progressing or when red flags are identified should be coordinated with the infant's primary physician.

Case Scenario on Expert Consult

The case scenario for this chapter describes "Riley," an infant with a classical presentation of CMT combined with CD. Data are provided for the initial evaluation and subsequent measures at 4–6 weeks, 16 weeks, and 24 weeks in the hopes of portraying typical resolution of both conditions. Shared decision making throughout the episode of care strongly influences the choice of interventions and the manner of their delivery, beginning with the immediate family and eventually extending to Riley's day care providers.

Arthrogryposis Multiplex Congenita

Maureen Donohoe

Arthrogryposis multiplex congenita (AMC) is a nonprogressive neuromuscular syndrome that is present at birth. AMC is characterized by severe joint contractures, muscle weakness, and fibrosis. Although the child's condition does not deteriorate as a result of the primary diagnosis, the long-term sequelae of AMC can be very disabling. Activity limitations in mobility and self-care skills can lead to varying degrees of participation restriction.

Working with children with AMC presents the physical therapist with a variety of challenges. Many children who have AMC are bright and motivated. Physical therapists must use their knowledge of biomechanics and normal development to maximize functional skills. Proper timing for therapeutic and medical interventions helps maximize the child's opportunities for independence. Creativity is needed to adapt equipment and the environment to allow the child with AMC to be able to participate in life roles to the fullest extent possible.

In this chapter, we address the pathophysiology of AMC, its management from a medical and surgical perspective, physical therapy examination and evaluation, and specific physical therapy and team interventions used for children with AMC from infancy to adulthood.

BACKGROUND INFORMATION

INCIDENCE AND ETIOLOGY

Arthrogryposis, which is defined by the presence of contractures in two or more body areas, is diagnosed in 1 of every 3000 to 5000 live births.[4,28,56] Many times the cause of AMC is unknown; however, the insult is believed to occur during the first trimester of pregnancy.[16,26,72] It is believed insults occurring early in the first trimester have the potential for creating greater involvement of the child than those occurring late in the first trimester. The basic pathophysiologic mechanism for multiple joint contractures appears to be fetal akinesia.[19,27,66] More than 150 different contracture syndromes have been mapped to specific genes. Over 400 specific conditions have been identified that relate to gene mutations and chromosomal abnormalities.[21,27]

Various forms of arthrogryposis are known; amyoplasia is the most commonly recognized. Newborns with congenital contractures fall evenly into three groups: one consists of amyoplasia, the second is related to the central nervous system and is lethal, and the third is a heterogeneous group. The heterogeneous group includes neuromuscular syndromes, congenital anomalies, chromosomal abnormalities, contracture syndromes, and skeletal dysplasia. Distal arthrogryposis, which affects primarily the hands and feet and is highly responsive to treatment, has a genetic basis and is inherited as an autosomal dominant trait.[21,22] Gene mapping has been helpful in identifying those with arthrogryposis. Neuropathic arthrogryposis is found on chromosome 5 and can have survival motor neuron gene deletion.[12,58] Distal arthrogryposis type I maps to chromosome 9.[3,5]

AMC is associated with neurogenic and myopathic disorders in which motor weakness immobilizes the fetal joints, leading to joint contractures. It is not known whether all those with the neuropathic form of AMC have degeneration of the anterior horn cell, but of those studied postmortem, this is a consistent finding. A neurogenic disorder of the anterior horn cell is believed to cause muscle weakness with subsequent periarticular soft tissue fibrosis.[20,25,70,72] Because of failure of the muscle to function, the joints in the developing fetus lack movement, which probably explains the stiffness and deformities of the newborn's joints. The fetus may have an imbalance in strength of oppositional muscle groups, creating the tendency toward a certain posture. For example, the fetus with good strength in the hamstrings and triceps brachii but weakness in the quadriceps and biceps brachii will have a flexed knee and extended elbow posture in utero. Decreased amniotic fluid throughout the pregnancy, but especially during the last trimester when the fetus is largest, may further inhibit freedom of movement in utero.

Although the cause of AMC remains unknown, several factors have been implicated. Hyperthermia of the fetus is caused by a maternal fever greater than 37.8°C (100°F). Some mothers of children with AMC report having an illness with a fever for 1 to 2 days during the first trimester. Prenatal viral infection, vascular compromise of the blood supply between mother and fetus, uterine fibroid tumors, and a septum in the uterus have all been proposed as causes of AMC.[26,27,28,57,72]

PROGRESS IN PRIMARY PREVENTION

Arthrogryposis has been documented in artwork as early as the 1700s, although medical literature did not begin to address it until nearly the 1950s. Eight major categories of problems can occur during a pregnancy that could precipitate the lack of movement associated with congenital contractures; these include maternal illness or exposures, fetal crowding, neurologic deficits, vascular compromise, metabolic disturbances, neuromuscular end plate abnormalities, connective tissue abnormalities/skeletal defects, and muscle defects.[28] Given its nonspecific origin, little progress has been made in prevention of this rare disorder. However, significant improvements have been made in the management of children with AMC.

DIAGNOSIS

No definitive laboratory studies can diagnose AMC prenatally, unless a familial trait is documented. Some forms of arthrogryposis have been mapped to chromosomes 5, 9, or 11.[5,47,58] Most AMC cases occur sporadically with no known familial trait; therefore prenatal testing beyond ultrasound studies is inconsequential. Over 70% of cases of amyoplasia were missed on prenatal testing.[22] If a parent or physician suspects that something is amiss, a detailed ultrasound evaluation can be helpful in identifying anomalies and decreased fetal movements. Real-time ultrasound studies lasting up to 45 minutes, repeated several times during the pregnancy, are most useful. Having an ultrasound track movement over a longer period of time helps to identify if there are limitations in movement or movement biases due to position of the fetus. Repeating this test several times helps to identify if the same movement issues are persisting throughout the pregnancy. Clues that are looked for include nuchal edema; thin, undercalcified bones; small lungs; decreased movement time after 11 weeks of gestation; limitations in the diaphragm; and structural or space limitations.[21,22,27] If arthrogryposis is diagnosed during pregnancy, the mother can do some things to help exercise the baby as long as she is cleared by her physician from a health standpoint.[28] These activities include deep breathing, light exercise, and daily caffeine intake to help stimulate the baby.

Blood tests including a genetic microarray can be helpful in finding genetic alterations associated with arthrogryposis.[4] Muscle biopsy in AMC varies with the muscle under study. Histologic analysis reveals that relatively strong muscles appear virtually normal, and very weak muscles reveal fibrofatty changes but may have normal muscle spindles. Embryologically, the muscles are formed normally, but they are replaced by fibrous and fatty tissue during fetal development.[24, 26] With electromyographic testing, neuropathic and myopathic changes can be seen in different muscles in the same patient.[53,58] Muscle biopsies along with blood tests and clinical findings rule out progressive and fatal disorders, while providing evidence to support the diagnosis of AMC.

CLINICAL MANIFESTATIONS

Clinical manifestations of AMC demonstrate great variability but generally include severe joint contractures and lack of muscle development or amyoplasia. The typical severely affected body parts in the AMC population include, in decreasing order of prevalence, the foot (78%–95%), the hip (55%–90%), the wrist (43%–81%), the knee (38%–90%), the elbow (35%–92%), and the shoulder (20%–92%).[41,48,64]

Two commonly seen variations of AMC have been noted. In one type the child has flexed and dislocated hips, extended knees, clubfeet (equinovarus), internally rotated shoulders, flexed elbows, and flexed and ulnarly deviated wrists (Fig. 10.1). In another type the child has abducted and externally rotated hips, flexed knees, clubfeet, internally rotated shoulders, extended elbows, and flexed and ulnarly deviated wrists (Fig. 10.2). Parents often describe the legs in the first type as jackknifed, and in the second type as froglike. Because of the stiffness of the joints, extremity movements are described as wooden or marionette-like. The position of the upper extremities in the second type is described as the "waiter's tip" position owing to the internally rotated shoulder, extended elbow, pronated forearm, and flexed wrist. Common to both types are clubfeet, flexed and ulnarly deviated wrists, and internally rotated shoulders. Other associated characteristics may include scoliosis, dimpling of skin over joints, hemangiomas, absent or decreased finger creases, congenital heart disease, facial abnormalities, respiratory problems, and abdominal hernias. Intelligence and speech are usually normal. Many arthrogrypotic syndromes occur that have the main characteristics of AMC but may also involve abnormal muscle tone, webbing at contracted joints, changes in cognition, seizure activity, feeding issues not related to muscle strength or jaw opening, and limited visual skills.[54,70]

MEDICAL MANAGEMENT

The main component of medical treatment includes well-timed surgical management.[25,51] Orthopedic treatment should be timed so that the child benefits optimally from the procedure. For example, clubfoot management with minimally invasive surgical techniques such as the Ponseti method should start approximately 1 month after the child is born. This allows the child to naturally stretch out and the family to become accustomed to the therapy routine before embarking on months of serial casting and positioning devices, allowing for plantigrade feet in time for developmentally appropriate upright activity.[8,38,46,69] Ponseti method is frequently being used to address relapsing clubfeet through serial casting and minimally invasive soft tissue lengthening.[50]

Although becoming less common, some continue to have open surgical techniques such as the posteromediolateral release (PMLR) for clubfoot. The entire hindfoot is opened during surgery so as to shorten the lateral column, lengthen the medial column, and lengthen the tendo Achillis.[49,63] Occasionally, wires are used to realign the talus and the calcaneus. If the clubfoot recurs and does not respond to serial casting, a second PMLR involves shortening the cuboid bone to help improve forefoot alignment. If the foot is tight just in the hindfoot and no forefoot adductus is noted, a distal tibial wedge osteotomy is done to realign the foot in reference to the floor. Later in life, when the child is near the end of growth, a triple arthrodesis can be performed to prevent future inversion of the foot. This involves fusing the calcaneus to the cuboid, the talus to the navicular, and the talus to the calcaneus. Use of an external fixator such as an Ilizarov procedure to address recurrent clubfoot problems has had some promising results, although no data from long-term outcome studies are presently available.[11,14] Historically, in severe cases of equinovarus and in cases in which the Ilizarov procedure fails, a talectomy may be performed.[13,43] Salvage procedures to correct recurrent problems are difficult, however, when a talectomy has been previously performed.[42,49,63] Research supports that invasive surgical correction of feet results in stiff painful feet in adulthood.[35,42]

Children with AMC often have subluxed or dislocated hips. Dislocation is as frequently bilateral as unilateral. One dislocated hip is usually relocated to prevent secondary pelvic obliquity and scoliosis, unless the hip is extremely stiff.[55,62] Given that these hips tend to have poor acetabular development, if both hips are dislocated, they are not always surgically reduced because of the risk of continued unilateral dislocation even after open reduction. Careful evaluation of dislocated hips is necessary before surgical intervention is undertaken because if the hips are very tight into extension, limiting sitting ability, they will be even tighter after surgery. If the hips are dislocated high

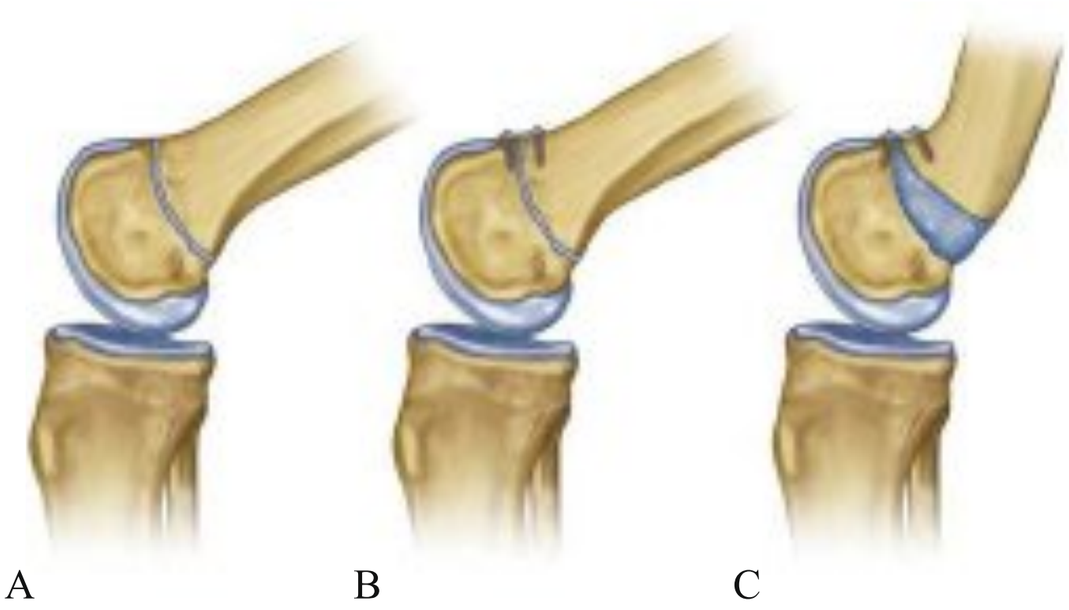
and posterior, with poor bony elements for the acetabulum, satisfactory surgical reduction may not be possible. Those who surgically reduce arthrogrypotic dislocated hips most commonly perform the surgery during the first year of life and use an anterolateral approach.[44,55,62,64,65] Szoke and colleagues[65] advocate early open reduction with a medial approach because resultant hip stiffness was greater for those who were older at the initial surgery. Yau and colleagues[73] found that open reduction was necessary to have success in treating dislocated hips because closed reduction in children with AMC was never successful. It may be more important to have mobile, painless, yet dislocated hips than to have very stiff but located ones. Prolonged immobilization following open or closed techniques can lead to the serious sequelae of fused or stiff hips.[1]

Moderate to severe contractures of the knee joint can be addressed surgically, but through the conservative approach, one waits until the child is ambulating comfortably before performing surgical correction. Knee flexion contractures are most commonly associated with capsular changes within the joint. Medial and lateral hamstring lengthening or sectioning (if the muscle is fibrosed), along with a posterior capsulotomy of the knee joint, may be performed.[48,66] These contractures respond inconsistently to hamstring lengthening and posterior capsulotomy because subsequent loss of muscle strength and risk of scar tissue lead to further joint stiffness and recurrence of the contracture. A distal femoral osteotomy is more frequently successful in realigning the joint and changes the arc of motion without risk of increased scar tissue and loss of strength[17] (Fig. 10.3). Growing children with moderate knee flexion contractures do well with distal femoral anterior epiphysiodesis. This procedure is done when the child is large enough to accept the surgical hardware but small enough to have adequate growth available, usually after the child is 5 years old but before 11 years of age. It allows the posterior aspect of the femur to continue to grow while the anterior aspect remains unchanged (Fig. 10.4). The angle of the femur results in apparent knee straightening.[37,40,52] Severe knee flexion contractures are often addressed through the use of external fixators to distract the joint and slowly elongate the tissues.[11,34,68]



Knee extension contractures frequently have associated patellar subluxation.[10] Patellar realignment is done before the fifth birthday to allow the femoral groove to develop with growth.[10] Later in life, extension contractures are addressed by quadriceps lengthening if at least 25° of range of motion (ROM) is observed in the knee. Intra-articular procedures such as a capsulotomy may be necessary if the knee is stiff.[33] Some evidence suggests that surgery to address knee extension contractures results in better outcomes than surgery to address knee flexion contractures.[61] An important consideration before surgical intervention is determination of whether the limitation in ROM is creating problems with sitting or walking and, if so, if surgical intervention will likely improve the child's function. For example, if the legs extend straight out when sitting, this position may interfere with activities such as sitting at school desks or riding in a car and as a result may decrease participation at school and in the community. The child should participate in decisions regarding surgical interventions as appropriate for his or her age.

Restrictions in shoulder movement are rarely addressed through surgical interventions such as capsular or soft tissue release because the musculature is usually inappropriate for transfer. If adequate muscle strength and control are present,

surgery may be indicated to place wrists and elbows in positions of optimal function. One scenario involves a child with symmetrical weakness or severe contractures of the upper extremities. In this case a dominant arm can be identified for feeding (postured in flexion) and the other arm for hygiene care (postured in extension).[71] If both arms were postured in extension, surgery would be necessary to position one arm in a functional flexion position. Such surgical considerations would include a pectoralis or triceps brachii transfer to give a child active elbow flexion with a posterior capsulotomy to allow for elbow flexion.[2,66] The muscle under consideration for transfer would need to be strong before transfer with adequate passive elbow flexion could present. A consistent passive ROM and stretching program from birth is essential to maintain elbow motion for this type of surgery to be successful.

Wrists can be fused in positions for function if conservative splinting and stretching management have been unsuccessful. Wrists are fused in dissimilar positions. Before a surgical wrist fusion, casting of the wrist for 1 week in the position of the potential fusion is suggested. During this time, the child's functional ADL (activity of daily living) skills are assessed while the child is wearing the cast to ascertain the appropriateness of this potential surgery. Surgical management through carpectomies or dorsal wedge osteotomies of the carpal bones should be considered only if finger function will be enhanced.[2]

Scoliosis is frequently managed conservatively with bracing. In about one fifth of children and adolescents with AMC, a long C-shaped thoracolumbar scoliosis develops.[66] If the curve continues to progress, surgical fusion should be considered. Those with a progressive congenital scoliosis have done well with the use of the vertical expandable prosthetic titanium rib implant for correcting scoliosis while allowing a significant amount of growth.[31] Most commonly, a posterior spinal fusion is performed when the child is close to puberty. On large stiff curves, an anterior release of structures limiting spinal mobility may be necessary before posterior spinal fusion to obtain satisfactory results.[74] The type of fixation used is based on the preference of the orthopedic surgeon (see Chapter 8).

FOREGROUND INFORMATION

BODY STRUCTURES AND FUNCTIONS

Diagnosis and Problem Identification

The primary impairments in the child with AMC are limitations of joint movement and decreased muscle strength and bulk. Joint contractures are evident at birth, although a formal diagnosis of AMC may not be given at that time. In AMC, limitation of movement typically is seen in two or more joints in different body areas.[27] In the amyoplasia form of arthrogryposis, 85% have symmetrical presentation of contractures.[27,28]

Contractures can develop from an imbalance in muscle pull of agonist and antagonist muscles but also occur when symmetrical weakness is present on all sides of the joint, thus hindering movement. Theoretically, this may be indicative of the point in fetal development at which the insult occurs. For example, because flexors develop before extensors in the upper extremity, a child may develop elbow flexion contractures but does not develop the usual strength in either the biceps or the triceps brachii subsequent to the time of insult.

Decreased muscle bulk is evidence of muscle weakness secondary to decreased functioning motor units in a muscle. Histologic analysis of muscles reveals nonspecific changes in the muscle such as fibrofatty scar tissue. Weakened muscles often have a fat layer around the muscle with dimpling of the skin. A muscle with a contracture but of normal strength through its available ROM may not have normal muscle bulk secondary to its inability to be active throughout the entire ROM.

Problem Identification by the Team

The team evaluation establishes a baseline from which to set realistic and functional goals. In addition to physical therapists, the primary intervention team consists of patients and their families and such medical professionals as orthopedists and geneticists, occupational therapists, and orthotists. Occasionally, speech pathologists, dentists or oral surgeons, neurologists, neurosurgeons, and ophthalmologists are consulted as well. One of the goals of the primary team is to educate the family about AMC. Families are taught that arthrogryposis is a nonprogressive disorder but that without positioning, stretching, and strengthening, or possible surgery, the child's

TABLE 10.1 International Classification of Functioning, Health, and Disability for Children With Arthrogryposis Multiplex Congenita

Changes in Body Structure	Changes in Body Functions	Activity	Participation
Prenatal damage to the anterior horn cells, resulting in neurogenic and myopathic disorder	Multiple joint contractures Fibrotic joint capsule	Limited functional mobility skills, including rolling, creeping, and feeding, transitional movements, and high-level mobility skills	Limited opportunity for play with young peers Inability to live independently Limited access to educational and work opportunities Need to learn how to adapt for new alignment once allowed to mobilize Limited access to a wide range of environments Health insurance may not pay for adaptive equipment necessary for least restrictive mobility device. Limited participation in physical activities because of endurance and safety issues Social isolation
Decreased number of motor units within a muscle	Strength limitations, frequently imbalance of oppositional muscles with stronger muscles often shortened	Limited ability to transfer Dependence for transfers for ADL including toileting Limited independence in self-care skills, including dressing Limited ambulation Inability to manage uneven terrain	
Scar tissue and fibrotic tissue do not grow and stretch to the same extent as healthy muscles.	Joint contractures can be progressive with growth.	Immobilization during periods of orthopedic management Increased limitations in mobility while immobilized Limited independence in wheelchair mobility without costly adaptations Decreased endurance	

impairments could lead to further activity limitations and participation restrictions in later life (Table 10.1).

During the initial examination by the team, photographs and videos are taken of the child, illustrating the child's position of comfort and specific contractures such as clubfeet. This is an objective way to document changes that occur during growth and throughout splinting procedures and should be repeated every 4 months for the first 2 years.

In physical therapy, baseline goniometry is performed, documenting passive ROM and the resting position of each joint. ROM can be measured with a standard goniometer cut down to pediatric size. Active ROM is measured at the hips, knees, shoulders, elbows, and wrists. If possible, the same therapist consistently measures ROM for the child. Intratester and intertester reliability is determined for all therapists who evaluate children with AMC and should be checked annually. Functional active ROM is also assessed to assist with visualizing the whole composite of motions and evaluating functional abilities. For example, functional active ranges include assessment of hand to mouth, ear, forehead, top of head, and back of neck.

A formal manual muscle test is performed when appropriate. Muscle grades for infants and very young children are ascertained by using palpation, observing the ability of extremities to move against gravity, and evaluating gross motor function. The strength of the extensor muscles of the lower extremities is especially important in determining the appropriate level of bracing. Less than fair (grade 3/5) muscle strength in hip extensors will require bracing above the hip. Less than fair (grade 3/5) strength in knee extensors will require bracing above the knee. Corrected clubfeet require molded braces during growth to minimize problems of recurrent clubfeet. Children with poor upper extremity function and weak lower extremities may not be functional community ambulators as a result of decreased motor control and protective responses. Power mobility may be the most appropriate means of community locomotion.

Gross motor skills and functional levels of mobility and ADL are assessed. No current developmental tests have been designed specifically for children with AMC, but these children usually score lower than average on formal gross motor tests secondary to inadequate strength and ROM in their extremities. Certain gross motor skills may never be attained owing to physical limitations. For example, some developmental milestones such as creeping may not be attained, even though the child is able to stand and is beginning to walk. Cognitively, children with AMC tend to score average to above average in formal developmental tests.[55,60]

The physical therapist assesses the child for current and potential modes of functional mobility. This may include ambulation with assistive devices or the use of a manual or power wheelchair or mobility devices. The therapist evaluates movement patterns and muscle substitutions used to accomplish each motor task or ADL skill. Therapists should address a child with AMC from a biomechanical approach because having limb segments aligned for mechanical advantage maximizes function and ultimately participation.

Following the examination, short-term and long-term goals are developed by the team related to splinting, stretching, developmental stimulation, orthopedic management including a surgical plan, and bracing. Incorporating the family early on as part of the team is important to maximize the child's independence in ADL and mobility.

PHYSICAL THERAPY IN INFANCY

Babies born with contracture syndromes have most significant involvement in the newborn period because they have had limited mobility in utero, so benefit from early opportunities to stretch out and remold. It is important to be aware that a large population of newborns have early feeding issues caused by structural abnormalities at the jaw and tongue.[54]

Great variability can be seen in the presentation of contractures; however, two more common body types have been noted. One body type involves clubfeet, hip flexion contractures, knee extension contractures, shoulder tightness (especially internal rotation), and elbow and wrist flexion contractures. At birth, these children are commonly breech presentations. Another

body type often associated with the amyoplasia type of AMC exhibits posturing of hips widely abducted, flexed, and externally rotated, flexed knees, clubfeet, internally rotated shoulders, extended and pronated elbows, and flexed wrists. Asymmetrical posturing of the extremities, which is especially problematic at the hip when dislocation of only one hip is present, occurs. The resulting asymmetry makes surgical correction the treatment of choice to relocate the hip and secondarily prevent pelvic obliquity and scoliosis. Children who are born with rocker-bottom feet and multiple contractures often have a syndrome with associated arthrogryposis and benefit from further genetic workup to possibly identify the specific contracture syndrome.

Examination

Formal assessment of an infant with arthrogryposis begins as soon as possible after birth. The assessment consists of goniometry of passive ROM with reevaluation of ROM done on a monthly basis during this period. The therapist also documents the presence and strength of muscles based on observation of the child's movements and palpation of muscle contractions. Muscles of the trunk and upper and lower extremities are evaluated. Formal developmental assessment tools are used occasionally but reflect poorly on a child with contractures because strength and ROM limitations preclude the achievement of many motor milestones. Delayed motor milestones may result in activity limitations and participation restrictions when children with AMC are compared with healthy peers on standardized developmental tests.

Motor milestones in these children are often delayed or skipped. For example, good trunk control and balance, coupled with weak upper extremities in compromised positions, results in development of the ability to sit-scoot rather than creep for early floor mobility. Functional mobility and the mechanism used in attaining this mobility are more important to evaluate than is assignment of a developmental level or score. The therapist assesses activities such as rolling, prone tolerance, sitting control, scooting, creeping, crawling, transitional movements, and standing tolerance and upright mobility. Occupational therapy (OT) plays a key role in assessing feeding, ADL skills, and manipulation of objects. Physical therapists also assess the fit of any supportive or assistive devices that may be used. Another key role of therapists dealing with young children who have arthrogryposis is to track clubfoot alignment. Early recognition and aggressive treatment of clubfoot relapse may limit immobilization time.

Although it is not imperative to use formal scales in assessing motor development and documenting activity restrictions, some useful tests include the Alberta Infant Motor Scale, the Bayley Scales of Infant Development, and the Peabody Developmental Motor Scales. The Pediatric Evaluation of Disability Inventory (PEDI), Patient Reported Outcomes Measurement Information System (PROMIS), and the WeeFIM (Functional Independence Measure for Children) may be used to measure activity and participation (see Chapter 2 for more information on these measurement tools). Use of such tools helps to identify baseline skills and areas of need for treatment planning. Use of standardized testing helps not only for baseline but allows for tracking change over time, qualifying a child for support services, and identifying if therapeutic intervention is making a measureable change in functional skills. See Chapter 2 for more specific information on these and other tests and measures.

Physical therapy goals for very young children include maximizing strength, improving ROM, and enhancing general sensorimotor development. Education of the family emphasizes instruction in proper positioning, stretching techniques, and the avoidance of potentially harmful activities that feed into deformity.

Intervention Strategies

Intervention strategies focus on improving alignment to maximize the biomechanical advantage for strengthening and reducing the joint contracture through stretching, serial casting, foot abduction braces, thermoplastic serial splinting, and positioning activities. Interventions address developmental skills and teaching compensatory strategies) especially in ADL and alternative modes of mobility) to maximize participation in age-appropriate activities.

Development, Strength, and Mobility

Infants with the first type of AMC described earlier begin life with limited positioning options as a result of hip flexion contractures. Consequently, stretching hip flexors and prone positioning are encouraged within the first 3 months of life. Developmentally, these infants learn to roll or scoot on their bottoms as their primary means of floor mobility because it is nearly impossible to comfortably assume the quadruped position without reinforcing a flexed posture of the upper extremities. Although delayed in their ability to attain sitting independently, they are often able to do so by 15 months of age using trunk flexion and rotation. These children typically are able to stand when placed well before they initiate pulling to stand. If the child has dislocated hips that have been surgically reduced in the first year, the child may have significant stiffness initially, limiting willingness to change position from sitting to standing. Usually, the child begins to walk with assistance, an assistive device, and lower extremity orthotics around 18 months of age; most are independent ambulators by the middle of their second year of life.

Initially, infants with the amyoplasia type of AMC have more positioning options due to their hip and knee flexion contractures. Some have difficulty with prone positioning because of elbow extension contractures that limit their ability to comfortably prop. A towel roll or wedge under the infant's chest assists with increasing tolerance for this position. Positioning the hips in neutral rotation and neutral abduction is encouraged. Towel rolls can be placed along the lateral aspect of the thighs when the infant is sitting, and a wide Velcro band can be strapped around the thigh when the child is lying supine to keep the legs in more neutral alignment (Fig. 10.5).

Developmentally, these children tend to be a little slower in attaining rolling but faster in attaining sitting and scooting than children with the first type of posturing. Although assuming the quadruped position and creeping are often feasible for this type of child, sitting and scooting are more energy efficient. Depending on muscle strength and the amount of bracing needed for standing, these children may never perform transitional movements from sitting on the floor to standing independently. They begin ambulating by the middle of their second year but require a significant amount of bracing for success. Independence with ambulation may take years and sometimes is not fully accomplished. Therapy focuses on addressing some key functional motor skills, such as rolling,

FIG. 10.5 This child with arthrogryposis multiplex congenita is wearing a wide Velcro band strapped around the thigh to keep the legs in more neutral alignment.

FIG. 10.6 Child who has arthrogryposis multiplex congenita in a standing frame.

sitting, sit-scooting, standing, and strengthening those muscles that assist in maintaining posture. The goal is to maximize mobility to enhance participation in age-appropriate activities but with an eye toward skills necessary for lifelong independence.

Strengthening during the first 2 to 3 years is most frequently addressed through developmental facilitation and play. Dynamic strengthening of the trunk can be achieved by having the child reach for, swipe at, or roll toys in the positions of sitting and static standing or while straddling the therapist's leg so that the child must rotate the trunk. These maneuvers incorporate stretching and strengthening into the therapeutic play activity. Aquatic therapy is often helpful for strengthening and developing functional mobility skills. If working on upright control in the pool, knee splints, specifically for use in the water, are helpful when bracing is needed on land, too. One way to determine whether functional training is having a strengthening effect is to ascertain the child's improved ability to perform the task.

Self-care skills, feeding, and manipulation of objects are dependent on hand function and elbow flexibility. Children with limited upper extremity strength may have decreased ability to manipulate objects. Fortunately, these children tend to be resourceful in using other body parts, such as their feet or mouth, to manipulate objects when hands have inadequate strength and ROM. These skills are quite useful early in life but not as useful in an older child. If the child has adequate ROM but inadequate strength, the child learns to support the arm on a leg or a table to assist in bringing hand to mouth. If the child is unable to get hand to mouth, adaptive equipment may make it possible to do some self-feeding. For example, if shoulder strength is absent, overhead arm slings are fashioned out of polyvinyl chloride piping and added to the high chair to permit finger feeding. If the upper extremities are postured in elbow extension, a typical and effective method of grasping an object is with a hand crossover maneuver, which affords some control and strength in holding or lifting an object. Electronic toys can be adapted so that the child can operate them via switches that can be activated by movement of the head, hand, or foot. These compensatory intervention strategies help to enhance skills needed for independence in ADL.

Standing is an important component of physical therapy during the first and second years. Families are encouraged to begin standing the child at approximately 6 months of age, as is normally done with children without physical limitations. If a child is in casts with knees flexed, upright positioning continues to be an important component of therapy because it helps to strengthen the trunk for standing once casts are removed. Standing is best completely upright rather than angled toward supine or prone because it helps develop skill in the biomechanical alignment necessary to stand without external support. During standing, splints can be used to maintain the lower extremities in adequate alignment. Shoes can be wedged to accommodate plantar flexion deformities and to allow the child to bear weight throughout the plantar surface of the foot.

Standing is initiated in a standing frame and progresses to independent static standing in the frame (Fig. 10.6). A therapist may need to be creative to work on standing with a child who is wearing a foot abduction brace, but use of the brace should not limit work on standing skills. By 1 year of age, a child should be able to tolerate a total of 2 hours a day in the standing frame. This standing helps the child begin self-stretching of the feet and encourages emerging independent standing and walking skills. Use of a prone stander is usually avoided because this type of stander does not encourage dynamic trunk control, and therefore the child is less likely to be working on the skills needed to stand outside the stander. Dynamic standing is encouraged through ball games such as kicking a soccer ball or batting a ball off a tee. Floor-to-stand activities usually do not begin to emerge until the child is ambulating securely, and sit-to-stand

activities from a low chair usually begin to emerge when ambulation begins. Limitations in lower extremity strength and ROM can be addressed through splinting and bracing while the child is standing. Knee extension splints may be worn to compensate for weakness of knee extensors and mediolateral instability of the knees.

Stretching and Splinting

Stretching programs for joint contractures are imperative and should be taught to parents and caregivers from the time of the initial examination. This intervention strategy addresses one of the primary impairments of AMC. A stretching program is divided into 3 to 5 sets a day with three to five repetitions during each set. Each stretch is held for 20 to 30 seconds. With the realization that this is a significant time commitment, families are taught to incorporate stretching into times when the child would normally have one-on-one time with the caregiver, such as performing lower extremity stretches during diaper changes and upper extremity stretches during feeding. Dressing and bath times also provide good opportunities for stretching, especially once the child is self-feeding and out of diapers. Stretching must be a daily lifelong commitment for a person with arthrogryposis, but consistent stretching is most critical during the growing years and especially within the first 2 years of life.[63]

To maintain the prolonged effect of the stretch, the extremity is maintained in a comfortable position of stretch with thermoplastic splints. Attempting to maintain the maximum stretch, rather than a comfortable position, over prolonged periods will cause skin breakdown and intolerance to splints. Splints are adjusted for growth and improvements in ROM, usually every 4 to 6 weeks during infancy. When ankle-foot orthoses (AFOs) are fabricated for clubfeet, the calcaneus must be aligned in a neutral position because this will affect the position of the entire foot. If the calcaneus is allowed to move medially with respect to the talus, the forefoot will fall into an undesirable varus position. When the hindfoot and the forefoot are in a neutral position between varus and valgus, splinting can address insufficient dorsiflexion of the hindfoot rather than forefoot. This will prevent the potential problem of a midfoot break resulting in a rocker-bottom foot. To be maximally effective, AFOs are worn 22 hours per day.

Knee contractures are addressed early using splinting and stretching. For the first 3 to 4 months, anterior thermoplastic knee flexion splints for extension contractures or posterior knee extension splints for knee flexion contractures are worn up to 20 hours per day. For an older infant with knee extension contractures, it is advised that children not wear a knee flexion splint at greater than 50° of flexion for sleeping because this may encourage hip flexion contractures. Older babies with knee extension contractures should use the knee flexion splints for activities that require flexion, such as sitting in the car seat or the high chair, or when positioned in prone, utilizing knee flexion and the splint to enhance the quadruped position. Knee extension splints, which control knee flexion contractures or medial-lateral instability, are initially worn up to 18 hours a day, especially during sleep. Once the child is older than 6 months of age, the knee extension splints can be used for standing activities because they encourage optimal lower extremity alignment during upright activity. Splints to control knee flexion contractures should be off 6 hours a day to allow floor mobility in a child with emerging skills.

Newborns are provided with cock-up wrist splints, but splints for hands are generally provided only after 3 months of age. This allows the child to integrate the normal physiologic flexion before placing a stimulus across the palm. Two sets of hand splints are fabricated. For day use the child wears dorsal cock-up splints with a palmar arch in a position of neutral deviation and a slight stretch into extension as tolerated. This allows the child to have fingers available to manipulate toys. For night wear, the splint is a dorsal cock-up splint with a pan to allow finger stretching when the child is sleeping.

When considering elbow splinting, note that function and independence in ADL are improved when one elbow is able to flex adequately to reach the mouth and one elbow is in adequate extension to reach the perineum. Other factors to consider include available muscle strength and ROM, response to stretching, and potential future surgical procedures. Elbow extension splints are best worn while sleeping, but elbow flexion splints and elbow flexion-assist splints tend to be most functional when worn during the day. This allows the child to experiment with the hand in a more functional position for most play activities.[39]

Young children respond most readily to conservative treatment using serial splinting, frequent stretching, and proper positioning. In Fig. 10.7A, the infant's posture is shown without leg splints. In Fig. 10.7B, the infant's lower leg is held out of the deforming postures through molded thermoplastic knee and AFO splints. The key to successful intervention for contractures is family education. Family education begins during the initial evaluation as caretakers not only are given general information about arthrogryposis but also receive information regarding their child's specific needs. Appropriate stretching exercises for involved joints are given with sketches or photographs to supplement the verbal instructions. Subsequent visits to the physical therapist allow work on splint fabrication and modification and positioning. Developmental play ideas are incorporated into the exercises to help the child progress developmentally. Physical therapists also work with the family to adapt age-appropriate toys to stimulate the child both physically and cognitively.

PHYSICAL THERAPY IN THE PRESCHOOL PERIOD

During the preschool period, the child's functional abilities and age-appropriate participation vary according to the degree of involvement. Poor upper extremity function from the contractures and lack of muscle strength may limit the child's independence in feeding, dressing, and playing, at a time when typical peers are relishing their independence. This may be particularly distressing for the parents, who become more aware of the magnitude of their child's limitations when the child is no longer an infant in whom dependency is expected.

Structural limitations impeding participation in age-appropriate activities during this stage are similar to those found in the younger child. Restriction in joint ROM continues to be a problem secondary to rapid growth changes. Independent ambulation is often limited by poor protective responses of the upper extremities.

Examination

Passive and active ROM continues to be closely monitored by the physical therapist and caregivers. Proper fit of orthotics and splints is imperative in providing adequate stretch and positioning to impede the development of further deformities.

FIG. 10.7 (A) A child who has arthrogryposis multiplex congenita without leg splints. (B) The same child's lower extremity is held out of the deforming positions through the use of molded thermoplastic knee splints and ankle-foot orthoses.

Functional muscle strength is an important component in the preschooler because it determines to a great degree the extent of bracing necessary and the level of independence in self-care skills. Formal manual muscle testing[32,36] becomes more appropriate during this period because the child can comprehend verbal instructions. When testing strength, it is important to grade the resistance throughout the arc of motion because the child with AMC will frequently be strong in the midrange but unable to move the extremity to the shortened end range. This finding is significant because the end range is where the child needs to work the muscle to maintain stretch of the antagonist muscles.

Examination of gait function should include distance, use of assistive devices (including braces and shoe adaptations, as well as upper extremity support), speed, symmetry of step length, gait deviations, and muscle activity. Increased lateral trunk sway is not uncommon with arthrogryposis.[9] Some children ambulate as their primary means of locomotion; others rely on a stroller for community mobility. Despite research that supports powered mobility for the very young,[56,67] mobility with wheelchairs is not usually addressed until school age, when slow speed of ambulation, endurance, and safety concerns may preclude the child from interacting with peers. These children are bright and will often forgo ambulation for power mobility if it is presented too early. Forgoing ambulation early may limit standing for functional activities later in life.

Goals

Ability rather than disability must be stressed, with a strong emphasis on assisting the child through problem solving rather than through physical assistance. The ultimate goals for this age are to reduce the disability and enhance independent ambulation and mobility with minimum bracing and use of assistive devices. Physical and environmental structural barriers may limit achievement of some fine and gross motor skills, but social skill attainment is paramount. Another goal is for the team to work together to improve the child's function in basic ADL skills.

Intervention Strategies

The team will work together during the preschool period to solve basic ADL challenges, such as independent feeding and toileting. For example, the use of a lightweight reacher may assist with dressing skills. Preschoolers usually can self-feed with adaptive equipment.[30] These children are often toilet trained but lack the ability to perform the task independently. At times, orthopedic surgical intervention will be used to help gain better biomechanical alignment of joints. These surgeries initially may change the focus of the therapeutic intervention, but ultimately, the focus and the goal remain the same because surgical intervention is done to enhance position and function.

Stretching

The need for stretching at this age continues to be addressed despite the preschooler's decreased tolerance to passive stretching three to five times a day. Two times a day for the stretching program is more realistic and appears to maintain ROM adequately in most cases. Families report that the best time for this is during dressing and bathing, which incorporates the program into an automatic part of the daily routine. Children can be taught how to assist with stretching through positioning. The child is also encouraged to verbally participate in the program,

for example, by counting the number of repetitions. AFOs and positional splints continue to be worn to maintain the achieved positions.

Independent mobility in a safe and efficient manner is important for the preschooler to achieve and enhance social skills, as well as allow functional mobility. Independent ambulation with supportive bracing and with as few assistive devices as possible is stressed. Children with adequate strength and ROM who do not require bracing to walk generally need an AFO to prevent recurring clubfoot deformities. Older preschoolers with AMC are generally at the level of bracing that will be continued throughout school age.

Orthotics

Most orthotics are fabricated from lightweight polypropylene although those with less foot deformity may use carbon fiber braces. Children with knee extension contractures tend to require less bracing than those with knee flexion contractures. If there is any question about the child's ability to maintain an upright position without hip support, the child's first set of long leg braces, a hip-knee-ankle-foot orthosis, will include a pelvic band. This type of orthosis is used for several reasons. The family may perceive that the child is regressing if initially unsuccessful ambulating occurs without the pelvic band, and later a band is added for ambulation success. The pelvic band encourages neutral rotation and abduction of the lower extremities. The pelvic band can also facilitate full available hip extension, and the hips can be locked in that position for prolonged standing. Use of a pelvic band allows a pivot point for the trunk to move into extension to help with posterior weight shift on the stance side during gait. Once the child is ambulating with both hips unlocked, without jackknifing at the hips during stance, the pelvic band can be removed.

Maintaining hip strength, especially when the pelvic band is removed, continues to be important. One activity is to have the child begin static and dynamic standing on the tilt board. The child also begins taking steps forward, backward, and sideways. Strengthening, as with progressive resistive exercises, may be appropriate at this time. Clinical experience suggests that muscles may increase in strength by one half to a full muscle grade with exercise.

Ideally, the least amount of bracing is optimal, but if decreasing the bracing requires the child to use an assistive device that was previously unnecessary, increased bracing may be more appropriate. A child with strong extensors such as the gluteus maximus and quadriceps is more functional than a child who requires bracing as a functional substitute for the extensors. The child with a good deal of bracing has difficulty donning and removing braces and usually is dependent for locking and unlocking hip and knee joints for standing and sitting.

Those children who learn to walk may be limited in their independence if they do not have adequate strength and ROM to manipulate the assistive device, such as a walker, that is required to ambulate. Walkers are often heavy and cumbersome for the child, who may have inadequate protective responses in standing and upper extremity limitations. Thermoplastic material can be molded to the walker for forearm support when hand function is limited, affording the child added support and control (Fig. 10.8). Many children prefer to walk with someone rather than use a walker while they are gaining confidence in ambulatory skills. When learning to stand and walk, it is of utmost importance that the child learn how to use the head and trunk to stand and balance and then to weight shift for limb advancement. If a child uses a gait trainer and leans on the device to move it, without regaining balance, he or she may not be training in the skills necessary to stand and balance for functional transfers for a lifetime. Use of a gait trainer that enhances the opportunity to stand upright and weight shift (Fig. 10.9) while relying on the support as a "safety net," rather than leaning into it, may produce better long-term functional outcomes in upright for transfers and ADL. Careful evaluation

FIG. 10.8 Thermoplastic forearm supports can be customized to the walker.

FIG. 10.9 Child with arthrogryposis multiplex congenita wearing polypropylene hip-knee-ankle orthosis and using a gait trainer that allows dynamic weight shift.

of ambulation potential is needed when one is deciding on an assistive device for ambulation. Some walkers will give independence in exercise walking but will not translate into greater independence outside the walker.

Children with weak quadriceps and knee flexion contractures tend to ambulate with locked knee and ankle-foot orthoses. These braces can be fabricated with dial knee locks so that the knee position can be adjusted to coincide with the changing state of the knee flexion contracture. This will afford the ongoing opportunity to stretch out the contracture. Shoes may need external wedges to compensate for hip and knee flexion contractures that interfere with static standing.[7] If the brace cannot stand in the wedged shoe, the child cannot be expected to balance in the brace with the shoes. The child should be able to comfortably balance with the feet plantigrade without upper extremity support.

Families may require assistance in identifying and removing environmental barriers that impede the child's independence both in the home and in the preschool environment.

Children in this age group are encouraged to participate in activities with children the same age in preschool, day care, and swimming classes and in other peer group activities. They are encouraged to develop relationships with children who do not have disabilities, as well as with those who do. These early relationships help to enhance lifelong participation in integrated activities with peers. During the preschool period, many states mandate therapy services for children with special needs. Preschool services, as well as additional therapy services, are imperative for maximizing these children's skills for the demands they will encounter during school.

PHYSICAL THERAPY DURING THE SCHOOL-AGE AND ADOLESCENT PERIODS

The focus of physical therapy moves from the outpatient clinic into the classroom at this stage. Most children are enrolled in regular classrooms in their neighborhood schools, although they may have adaptive physical education, physical therapy, occupational therapy, and speech services to enhance the educational process.

Participation in school and classroom activities may be impeded by limitations in mobility. At school, children have increased demands to travel longer distances and move in groups under limited time frames. Alternative means of mobility such as a motorized wheelchair or a scooter may be needed to enhance independence while managing materials (such as books and personal effects) with minimal outside assistance. Efficient and independent dressing, feeding, and toileting abilities take on a more compelling nature. Joint contractures continue to be problematic, especially through the last few growth spurts. This is a time when the adolescent is becoming more independent in self-care, and adult monitoring of contractures tends to decrease.

Examination

The school therapist acts as a team member, addressing goals of the child and family with regard to enhancing the child's educational experience. The physical therapy examination determines what types of training and adaptive equipment are needed to achieve educational objectives. Functional ADL skills are assessed to ascertain how efficiency and independence can be improved. The School Function Assessment (SFA)[15,45] is a tool that is helpful in identifying functional skill levels in the school environment and in identifying activities for individualized educational plan (IEP) goals so that physical therapy interventions can ultimately allow for greater participation of the child at school. The Activity Scale for Kids (ASK) is a self-report tool that may be helpful in defining where a child is having greatest limitations in functional skills at home and in the community.[75] See Chapter 2 for more information on these examination tools.

Goals

During this period the child with AMC must be responsible for self-care and for an exercise program to be performed to the best of the child's ability. If the child is physically unable to do these tasks, it is still important to be able to orchestrate care through verbal instructions to a caregiver. The family must also become more responsible for expecting and allowing the child to be more independent. The goal of independence in mobility and keeping up with friends is important in the development of peer relationships. Early school-based goals should include ability to independently participate in one to three playground activities during recess.

ROM is not an educational goal, but it continues to be a focus to maximize long-term function. The child with AMC will lose motion if he or she does not continue to stretch throughout the growing years. As sitting requirements for education increase, hip and knee flexion contractures also can increase if positioning options to enhance extension are not addressed. Final growth spurts, coupled with increased sitting requirements for education, can result in a significant loss of extension at the knees and the hips. If the school-age child is not conscientious about night splint use and positioning for stretch, the ability to walk may be lost during the teen years. Surgical intervention to regain ambulation skill during the second decade of life is not always an option.

Intervention Strategies

Dressing, toileting, and feeding may require adaptive equipment or setup for the child to be independent. Children with AMC require some selective pieces of adaptive equipment for achieving independence, but most are adaptable and innovative in using compensatory strategies rather than relying on assistive devices to achieve their goals. Frequently, classroom chairs and tables must be at custom-made heights to accommodate rising from a chair without manipulating brace knee locks. The desktop may need to be adjusted so that the child, by using a mouth stick or a wrist aid to hold writing implements, can maneuver items on the desk or write (Fig. 10.10). Assistive technology is quite helpful for those with limited hand function to perform school work on a computer, although management of the computer may be challenging for a child who changes classes. Implementation of ideas such as these limits disability by providing the child with successful compensatory strategies (Table 10.2).

Continued adherence with the customized splinting and stretching program is expected. Children at this age may lose a few degrees of motion during growth, but further regression may result in loss of skills that previously were not a problem when more motion was available. Surgical intervention is sometimes helpful for improving joint position. A self-stretching program, utilizing assistive straps, braces, and positioning, can be incorporated into the child's routine to promote independence in attaining goals. The adolescent must be permitted to

FIG. 10.10 Child who has arthrogryposis multiplex congenita using a wrist aid to hold a crayon.

help plan his or her schedule, or adherence can be expected to be poor. Adaptive physical education in school, as well as adaptive sports programs outside school, can be adjunctive to physical therapy for promoting strength, endurance, and mobility.[23] During adolescence and through adulthood, the importance of maintaining a healthy weight is imperative because weight gain can significantly limit one's mobility and ultimately one's independence. Vocational rehabilitation may be a helpful adjunct in assisting those with physical limitations to access future employment opportunities.

Speed and safety in independent mobility are important in the development of peer relationships. Families may be advised during this time to consider powered mobility devices as an adjunct to manual mobility devices. Cumbersome bracing, inefficient gait, and poor upper extremity function can limit a child's ability to participate in playground or social activities.[18] Alternative modes of mobility may allow the child to participate safely. Use of alternative modes need not preclude ambulation but rather provides supplemental mobility for safety and energy conservation. Most children can achieve functional household ambulation but may require a wheelchair for efficient community mobility. The importance of standing and walking skills for maximal independence in the bathroom cannot be overstressed.

TABLE 10.2 Recommended Measures for Children with Arthrogryposis

	Test Information	Considerations for Arthrogryposis	Reference
Body Structures and Function			
Range of motion	Goniometer can be used to identify range of motion as well as resting posture of the limbs.	May need to cut down a goniometer to allow reliable use with a small child.	Clarkson HM: Musculoskeletal assessment: joint motion and muscle testing. 3rd ed. Baltimore, Lippincott, Williams & Wilkins, 2012.
Strength	Observation, palpation, and hand pressure are used to determine muscle strength.	In the young child, one must identify bony landmarks when testing because rotational differences influence the biomechanics of the muscles.	Hislop HJ, Montgomery J, editors: Daniels & Worthingham's muscle testing: techniques of manual examination. 8th ed. Philadelphia, Elsevier Science, 2007.
Activity: Single Task			
Timed standing balance	Documentation of amount of time the individual can stand statically.	No norms for this population. Tracks change over time for the individual. Able to compare with and without orthotic support as well as with and without heel wedges. Translates to functional skills such as transfers and self-care.	
Gait speed	Documentation of speed traveling a specific distance. Document for bracing and assistive device during testing.	No norms for this population. Can track change over time for the individual.	Lythgo N, Wilson C, Galea M: Basic gait and symmetry measures for primary school-aged children and young adults. II: Walking at slow, free and fast speed. Gait Posture 33:29-35, 2011.
6-minute walk test	The individual walks as far as possible in a 6-minute period.	No norms for this population including level of bracing necessary and assistive device. Can track change over time for the individual.	Please refer to Chapter 2 for more information.
Timed up and go	Individual rises from a standardized chair height, walks 3 meters, turns around, and returns to sitting in the chair.	No norms for this population. Child may be too small to safely get in and out of the standardized chair height. Tracks change over time for the individual. Record chair height for the individual if not using the standardized chair height and replicate height during future testing.	Please refer to Chapter 2 for more information.

TABLE 10.2 **Recommended Measures for Children with Arthrogryposis—cont'd**

	Test Information	Considerations for Arthrogryposis	Reference
Activity: Multiple Items			
Peabody Developmental Motor Scale	Fine and gross motor assessments compare skills to those of typically developing peers aged birth to 72 months.	Due to limited motion and strength, some children may never attain some of the skills on this test.	Please refer to Chapter 2 for more information.
Patient Reported Outcomes Measurement Information System (PROMIS)	Parent and/or child report. Multiple dimensions to help tease out perceived strengths and needs. Helpful in therapy goal establishment.	Short and long forms available. Can be reported on paper or via computer access. PROMIS has pediatric and adult versions.	Please refer to Chapter 2 for more information.
School Function Assessment	Educational staff report on child's abilities. Helpful in identifying needs within the educational environment.	Some children will need assistance with skills but should learn to how to orchestrate care.	Please refer to Chapter 2 for more information.
Pediatric Evaluation of Disability Inventory (PEDI and PEDI-CAT)	Self or caregiver report tool designed to identify functional delay in areas of daily activities, mobility, social/cognitive, and responsibility.	The PEDI takes 1 hour to administer while the PEDI-CAT is a shorter, more intuitive computerized version.	Please refer to Chapter 2 for more information.

TRANSITION TO ADULTHOOD

Little has been published about the transition from childhood to adulthood for the person who has arthrogryposis. Several authors[29,59] have published surveys focused on issues related to aging. Results indicated that activity limitations during adulthood were related to continued problems with ROM and strength that consequently limited independence in ADL, ambulation, and mobility. Those who required assistance with ADL during their school-age years continued to require assistance throughout their lifetime but were able to achieve a degree of independence with feeding, dressing, and grooming using selected assistive ADL devices. Those with severe joint involvement had long-term dependency on others for ADLs.[18,29,60]

Pain appears to be a significant issue that occurs with aging. Most survey respondents reported difficulty with back and neck pain and increased discomfort in other joints as well.[59] Those who have had surgical intervention for clubfeet can expect pain and stiffness to develop during the adult years.[35] Some specific problems that occur in adults include arthritic changes in weight-bearing joints and overuse syndromes in muscles and joints that are used for compensation or unique postures. Osteoarthritis, carpal tunnel problems, and neuropathies may develop as a result of prolonged joint constrictions and deformities. Increasing muscle weakness with increasing age has been found to occur, starting in early adulthood.[59] Mobility problems emerging later in life may stem from secondary degenerative changes and muscle overuse syndromes.[25,53] Manual or power wheelchairs may be used more commonly by adults than by adolescents and teenagers. Adults with AMC often use a wheelchair as their primary mode of mobility for long distances.

Advanced education is of utmost importance so that the adult with AMC becomes trained in a specialized skill or field. The type of work chosen will depend on the degree of activity limitations, education, and marketable skills. Computer-related work and occupations that do not rely on manual labor should be considered as employment options. Advancements in technology allow those with arthrogryposis to have opportunities that enhance their freedom of mobility and their career options. Assistive technology, including computers and voice-activated equipment, can be of value in helping the individual safely and efficiently achieve work and leisure goals. Many people who have arthrogryposis who are artistically talented use their skills in painting and drawing for vocation and avocation.

Many of the barriers that the adult with AMC will meet are physical barriers. Although the Americans with Disabilities Act has helped, transportation continues to limit access to vocational and avocational activities. Those who live near strong public transportation systems or who have access to an automobile with proper adaptations have better opportunities for participation in activities outside the home. Personnel at adult rehabilitation facilities are probably unfamiliar with AMC owing to the small number of adults who consistently seek care during adulthood. These facilities can provide services regarding assistive technology, seating systems, and orthotics, as well as help in funding for supportive equipment and services.

Intervention Strategies

Once skeletal growth has stopped, stretching is not as imperative, but maintaining flexibility and proper positioning is encouraged to impede the further development of deformities. Those with AMC who used orthoses during the school-age years typically continue to do so throughout adulthood. Those who used only AFOs for clubfoot control tend not to need these orthoses once growth is complete. Dressing and, most important, donning of shoes are often the last skills achieved because abandoning bracing allows for easier dressing of the lower body.

Information about the long-term sequelae of AMC in relation to degenerative changes, mobility levels, and use of adaptive ADL devices is critical to providing the most effective therapy to persons with AMC. Joint conservation and addressing the secondary impairments resulting from degenerative changes that occur in adulthood are necessary to maximize long-term independence.

Research regarding the extent of independence of children, adolescents, and adults who have AMC is lacking in the areas of ADL, use of manual or power wheelchairs, and ambulation ability. This lack of data may be a result of the fact that children are followed early on within a medical model that addresses their primary orthopedic concerns, but when they transfer to the educational setting and require less medical intervention, they are lost to follow-up. To meet the objective of providing the most appropriate intervention to this population, a

nationwide database on functional outcomes, mobility, and associated long-term problems should be established. Those who do enter the physical therapy system are often referred because of pain management issues. Pain is most likely due to overuse injuries, as well as to inefficient strategies for ADL. The emphasis of therapy should be placed on energy conservation, assistive devices to enhance efficiency, and the primary issue leading to the referral. As adults who have contracture syndromes age, they have secondary complications of being sedentary; therefore education on lifelong fitness opportunities needs to be investigated to help with cardiovascular fitness and weight management (Table 10.3).

TABLE 10.3 Interventions Based on International Classification of Functioning, Health, and Disability for Individuals With Arthrogryposis

	Activities Across the Life Span	Early Intervention through School Age	School Age Through Adulthood	Adolescence Through Adulthood	Other
Body Structure	Joint contracture bias will continue throughout lifetime if left untreated.	Treatments focus on putting limbs in a position of biomechanical advantage for function.	Muscle transfer surgery will give power to joints that were not previously strong.		Due to limited number of motor units supplying the strength to the muscle, with aging, fatigue of motor units is noted similar to post-polio syndrome.
Body Functions	Bracing is important to assist with upright mobility and standing. Shoe wedges help to balance the individual when full extension or dorsiflexion is not available when braced.	Emphasis on range of motion for upright mobility. Serial casting and management of clubfeet, bracing to get end range alignment for antigravity extension of hip and knee. Focus on standing balance with progression to ambulation.	Surgical management to align joints in alignment for lifetime independence in motor skills, coupled with therapeutic exercise to maximize surgical outcome. Bracing to support muscles not strong enough to maintain upright alignment against gravity with weight shift. Biomechanically, addressing alignment with shoe wedges to bring heel to the floor while allowing end range hip extension.	This is an age when bracing is often not as readily accepted. In this situation, strategies for independence using bias of contractures is important. Once in adulthood, progression of contractures is not as big an issue, but ability to use alignment will be important.	Weight management is important. Obesity negatively impacts on transfers and independent mobility.
Activity	Identify equipment needs to enhance independence.	Joint contractures and limitations in muscle strength may limit ability to achieve all motor milestones. Emphasis on rolling, scooting, standing balance, and ambulation. Use of an assistive device for endurance but short distance ambulation without an assistive device will translate to better independence for ADLs in the future including toilet transfers and dressing.	Emphasis on independent mobility both from a wheelchair level and from a functional mobility standpoint. Emphasis on reaching for highest level of functional mobility with independence.	Work toward mobility in the community. Identify self-care limitations and work toward highest level of independence.	Adapt environment as necessary to help with independence. Some with joint contractures and muscle weakness in all extremities will need external support for ADLs throughout the life span.
Participation	At each age group, focus needs to be on age-appropriate peer participation.	Playground and gym-related play is imperative in preschool and school age, working to find activities that allow independent participation as well as fitness opportunities.	Identify physical activities allowing for lifelong exercise and recreation participation and peer groups.	Work on strategies to enhance community participation with focus on activities addressing positive quality of life including but not limited to employment and recreation.	Teach self-advocacy. Those who cannot do for themselves need to be able to orchestrate their own care.

SUMMARY

Arthrogryposis poses a variety of challenges for the health care team throughout the patient's lifetime. Although AMC is nonprogressive, its sequelae can limit participation in even basic ADLs. Variability in clinical manifestations has been noted, but severe joint contractures and lack of muscle development are hallmarks of the disease. Each stage of development requires special attention for maximizing the child's function. An early goal of the team is to educate the family about AMC and to create the understanding that, without intervention, the child's body structure and functional skills could lead to further limitation in activity throughout a lifetime. Early medical and therapeutic management includes vigorous stretching, splinting, positioning, and strengthening, all of which will allow the child to develop optimal positions for functional ADL and will enhance motor skill development. Timing of surgical procedures is critical to minimize intervention while maximizing benefit.

Each age has challenges on which physical therapy can have a positive impact. During infancy, motor milestones are often delayed or skipped, and determining functional mobility is more important than ascribing a developmental level. Intervention strategies focus on maximizing postural alignment through serial splinting and strengthening and on facilitating developmental activities. Ambulation is a preliminary primary goal, but once the child reaches school age, the focus shifts toward more independent, functional, and safe mobility. During the school-age years, the child must become more responsible for stretching exercises because stretching is an integral part of the program throughout the growing years. The team emphasizes assisting the child with problem solving and working toward independent mobility. Adaptive equipment is often necessary to allow the child with AMC to be independent in mobility and self-care. A comprehensive and integrated team approach is critical in developing strategies to meet these challenges. Ultimately, the goal is to have the child who has arthrogryposis grow to be an adult who is as independent as possible and an active participant in the community.

Case Scenarios on Expert Consult

The case scenarios related to this chapter address two case scenarios. Both focus on management over time, emphasizing mobility and function. They also highlight episodic care and educationally based services. Will's case begins as an infant and progresses to age 18 and Joseph, with video as a younger child, is followed from early intervention through early school age.

ACKNOWLEDGMENT

Special thanks to Dr. Robert Wellmon for insight, support, and a view on the diagnosis that is forever helpful.

Osteogenesis Imperfecta

Maureen Donohoe

Osteogenesis imperfecta (OI) is an inherited disorder of connective tissue. Other terms in the literature used to describe OI include *fragilitas ossium* and *brittle bones*. OI has an incidence of 1 in 10,000–20,000 births.[57,75] This disorder comprises a number of distinct syndromes and has great variability in its manifestations. The salient impairments of OI are lax joints, weak muscles, and diffuse osteoporosis, which result in multiple recurrent fractures. These recurring fractures, which can be sustained from even minimal trauma, when coupled with weak muscles and lax joints, result in major deformity. Additional impairments in OI with variable presentation include blue sclerae, dentinogenesis imperfecta, deafness, hernias, easy bruising, and excessive sweating. Dentinogenesis imperfecta is a defect in the dentin and the dentinoenamel junction of the tooth. Often the enamel is normal, but teeth initially look gray, bluish, or brown because of the dentin defect. These teeth have a higher incidence of cracking, wear, and decay as the enamel cracks away from the dentin. Primary teeth are often more affected than adult teeth.[62]

Without early and adequate intervention, these problems in children with OI may lead to irreversible deformities and disability. Physical therapy can have a positive impact on these children and their families. Therapists can accomplish this through strengthening exercises, conditioning activities, adapting the environment, educating caregivers, and encouraging activity participation across a lifetime. Early physical therapy and medical interventions help prevent deformities and long-term functional limitations.

Children and adolescents with OI are often overprotected as a result of recurring fractures, which can contribute to social isolation. Some have difficulty interacting in peer play, adjusting to regular school, and achieving an independence level necessary to accomplish vocational goals. Most children with OI have average or above-average intelligence and greatly benefit from a stimulating educational environment. These children become adults who are usually productive members of society.[79] Management of their disabilities should be directed toward obtaining optimal independence, social integration, and educational achievement. The overall prognosis of OI and its long-term sequelae depend on the severity of the disease, which ranges from very mild to severe. Likewise, disability ranges from relatively mild with no deformities to extremely severe, with death occurring at birth or shortly thereafter.

In this chapter, we address the classification and pathophysiology of OI, medical and surgical interventions, physical therapy examination, evaluation, and interventions from infancy through adulthood. A case scenario of a child with OI is presented on Expert Consult.

BACKGROUND INFORMATION

CLASSIFICATION

OI is a heterogeneous collection of impairments with varying severity, marked by fragility of bone. Clinically, many types of OI present similarly. Despite this, OI is not a single genetic disorder but rather an array of different disorders based on a complement of information, including clinical presentation, genetic testing, and histologic analysis.

Prior to gene mapping, classification was based on clinical presentations and historically divided into three classifications, OI congenita (OIC) and OI tarda type I (OIT type I) and OI tarda type II (OIT type II), with OIC being the most severe and disabling form.[26,43,64,68] It is characterized by numerous fractures at birth, dwarfism, bowing or deformities of the long bones, blue sclerae (80% of cases), and dentinogenesis imperfecta (80% of cases). Infants with OIC have a poor prognosis, with a high mortality rate resulting from intracranial hemorrhage at birth or recurring respiratory tract infections during infancy.[74]

OIT is considered the milder form of OI, in which fractures occur after birth. It has been subclassified on the basis of the degree of bowing of the extremities or the number of fractures.[74] Clinical characteristics of OIT type I include dentinogenesis imperfecta, short stature, and bowing of only the lower extremities. Most with OIT type I can ambulate but may need external support such as orthotics. Surgery is often indicated for correction of the long bone deformity. OIT type II is the least disabling form of OI, where fractures are not associated with bowing of the bones. Most of these children approach average height and have an excellent prognosis for ambulation.

In 1978, Sillence and Danks delineated four distinct genetic types of OI. This numeric classification system is based on clinical presentation, radiologic criteria, and mode of inheritance and is generally well accepted by clinicians, as well as basic scientists.[69] The Sillence Classification uses a numeric system that correlates with morphologic and biochemical studies of OI.[68] With the onset of gene mapping and better databases for tracking the OI population, Glorieux expanded the classification to 11 distinct categories that help with medical management of the individual with OI.[6,32,75.]

Most of the first four types of OI are considered autosomal dominant in inheritance.[68–70] The first four types of OI are caused by a defect in type I collagen structure that can be tracked back to a mutation in the genes *COL1A1* and *COL1A2* located on chromosomes 7 and 17. These genes are responsible for encoding the two alpha chains that make up type I collagen genes.[29,60] The other classifications of OI, types V through VIII,

do not have a type I collagen defect but do have significant bone fragility and present clinically similar to types with the collagen defect.[31,33,35,61] Physical therapists are most likely to see types I, III, IV, V, VI, XI, mild versions of VII, as well as possibly the severe forms of type VIII, IX, and X. Types II, VII, VIII, IX, and X have lethal versions where some therapists may meet the baby briefly in the NICU.

OI Type I

OI type I makes up 50% of the total OI population.[31] It is characterized by markedly blue sclerae throughout life, generalized osteoporosis with bone fragility, joint hyperlaxity, and presenile conductive hearing loss. Patients are generally short but are not as short as those with other forms of OI. At birth, weight and length are normal; short stature occurs postnatally. Dentinogenesis imperfecta is variably present. Those with OI type IA have normal teeth, and those with OI type IB have dentinogenesis imperfecta. Fractures may be present at birth (10%) or may appear at any time during infancy and childhood.[68] The frequency and development of skeletal deformity are also variable.

OI Type II

Based on the Sillence Classification, OI type II is not compatible with life, and infants may be stillborn or may die within a few weeks. Extreme bone fragility occurs with minimal calvarial mineralization. Marked delay of ossification of the skull and facial bones is noted, and the long bones are crumbled.[74] Infants are small for their gestational age and have characteristic short, curved, and deformed limbs.

OI Type III

According to the Sillence Classification, OI type III usually is autosomal dominant, but on the rare occasion it is recessive. This form is severe, with progressive deformity of the long bones, skull, and spine, resulting in very short stature. Abnormal growth plate lines give the long bones a popcorn-like appearance.[53] Usually, severe bone fragility, moderate bone deformity at birth, multiple fractures, and severe growth retardation are noted. OI type III appears similar to OI type II, except that the lack of skull ossification is not as marked, and birth weight and length are within normal range. Sclerae in OI type III have a variable hue, tending to be bluish at birth and becoming less so with age. Dentinogenesis imperfecta occurs in 45% of patients with OI type III, and hearing loss is common. As a result of the complications of severe kyphoscoliosis and resulting respiratory compromise, death may occur in childhood.

OI Type IV

OI type IV is characterized by mild to moderate deformity and postnatal short stature. Bone fragility and deformities of the long bones of variable severity are noted. Dentinogenesis imperfecta is common in type IV while hearing loss is variable. The prognosis for ambulation in this population is excellent.[12]

OI Type V

In 2000, Glorieux first described the autosomal dominant OI type V. It is characterized by hypertrophic calcification of fractures and surgical osteotomies. Many patients have calcification of the interosseous membrane of the radius and ulna, ultimately limiting supination/pronation of the forearm. OI type V represents 5% of the moderate-to-severe cases of OI.[31-33,61]

OI Type VI

OI type VI is autosomal recessive and extremely rare and presents with moderate-to-severe deformity, similar to OI type IV, but with normal teeth and sclera. No abnormality of calcium, phosphate, parathyroid hormone, vitamin D metabolism, or growth plate mineralization is noted.[31,33,61]

OI Type VII

OI type VII is presumed autosomal recessive and is associated with a gene defect mapped to chromosome 3p22-24.1. This mutation affects the translation of the collagen with mutations in the cartilage-associated protein gene *(CRTAP)* and the prolyl 3-hydroxylase-1 gene *(LEPRE1)*.[6,31,77] No type I collagen defect is noted in this form of OI, rather the defect involves how the collagen is translated to create bone.

With this gene defect, there is moderate-to-severe bone fragility and shortening of the humerus and femur.[40] Those with partial expression of *CRTAP* have moderate bone dysplasia similar to OI type IV; all cases with absence of *CRTAP* have been lethal.[31]

OI Type VIII

OI type VIII is presumed autosomal recessive and caused by mutations of genes that affect the translation of the collagen with mutations in the *CRTAP* and the *LEPRE1*.[6,46] No type I collagen defect is noted in this form of OI, rather the defect involves how the collagen is translated to create bone.

The absence or severe deficiency of prolyl-3-hydroxylase activity due to the *LEPRE1* gene results in lethal to severe osteochondrodystrophy. Osteochondrodystrophy is a disorder of skeletal growth due to a bone and cartilage malformation resulting in severe growth deficiency and bone fragility in those who survive into the teen years. Those affected have flattened, long bones, slender ribs without beading, and small-to-normal head circumference.[45,53] OI type VIII is clinically similar to OI types II and III.

OI Type IX

OI type IX is clinically similar to Sillence Classification, OI type II, or a severe type III with extreme bone fragility. The gene mutation is on chromosome 15q22.31. This *PPIB* mutation is responsible for how protein folds when it creates collagen resulting in severe skeletal dysplasia.[29,75]

OI Type X

OI type X is clinically similar to Sillence Classification, OI type II or a severe type III with extreme bone fragility. The gene mutation is on chromosome 11q12.5. This *SERPINH1* mutation is responsible for matching up with another protein and "chaperoning" it to encode with another collagen binding protein to create collagen. The defect in the gene results in severe skeletal dysplasia due to lack of collagen type 1 formation.[29,75]

OI Type XI

OI type XI is clinically similar to Sillence Classification, OI type III with extreme bone fragility. The gene mutation is on chromosome 17q21. The *FKBP10* gene causes delayed collagen secretion, resulting in progressive deformity including joint contractures as well as bone fragility. Histologically, the bone looks similar to type VI with a fish scale–like appearance on the bone lamellae.

With the rapid rate of gene mapping and the dedication of the Osteogenesis Imperfecta Foundation to maintaining a patient database, it is expected that new information on classification of OI will continue to grow. Many of the classifications defined beyond Sillence's initial four types resemble the first four types clinically, but molecularly, the bone fragility is vastly different (Table 11.1).[29,31,81] Knowing how the bone disease presents genetically helps in planning treatments because some disorders do not respond to the bisphosphonates. With the expansion of the classification via genetic testing, the need for grouping based on clinical presentation has again become important from a rehabilitation and functional skill level.

PATHOPHYSIOLOGY

In the first four types of OI a defect in collagen synthesis results from an abnormality in processing procollagen to type I collagen, apparently causing the bones to be brittle. This defect affects the formation of both enchondral and intramembranous bone. Collagen fibers fail to mature beyond the reticular fiber stage. Studies show that osteoblasts have normal or increased activity but fail to produce and organize the collagen.[59] Although similar bone fragility is found with OI types VI, VII, and VIII, the defect lies in how the normally developed type I collagen is translated into bone.[32] Histological variability is evident among the different types of OI. With OI type I, morphologic findings include an increased amount of glycogen in osteoblasts, mild hypercellularity of bone,[1] and no abnormality in collagen fiber diameter.[18] Those with OI type II have abnormally thin corneal and skin collagen fibers.[11] Bone histology reveals decreased trabeculae and cortical bone thickness.[61] In types III and IV, morphologic findings include an increased amount of woven bone, increased cellularity, an increased number of resorption surfaces, and wide osteoid seams.[25] Histologically, OI type V has lamellar organization in an irregular meshlike pattern.[61] OI types VI and XI have a unique fish scale–like appearance of the lamellae. The appearance of a mineralization defect similar to osteomalacia is apparent with osteoid accumulation histologically, although no defects are associated with calcium, phosphate, parathyroid hormone, or vitamin D metabolism.[29,61]

OI type VII is histologically similar to OI type I, and it is not until analysis of the collagen and the genes is done that it can be differentiated. Both have decreased cortical width and trabecular number with increased bone turnover.[76] The lethal forms of OI types VIII, IX, and X are similar to OI type II because bone histology has decreased trabeculae and cortical bone thickness.[61]

Persons who have inherited OI tend to have the same type of mutation through the family, although clinical manifestations within that type may be variable. First-generation OI tends to be caused by a novel mutation of the gene. This specific gene mutation can then be passed to offspring. Genetic counseling when OI is found gives parents an accurate estimate of the risk of recurrence and an understanding of clinical variability in the family.[55,80]

MEDICAL MANAGEMENT

No cure for OI is known. Historically, no consistently effective medications were available to strengthen skeletal structures and prevent fractures until the bisphosphonate class of drugs was introduced to this population in the late 1990s.[3,4,41] Since then the direction of OI management has dramatically changed, especially for individuals with moderate to severe bone fragility.[2]

Bisphosphonates are having promising effects. Positive results such as reducing fractures and improving bone density have been reported from such pharmacologic agents as bisphosphonates,[41] including pamidronate and alendronate.[24,48,56] Bisphosphonates work by reducing normal bone turnover. They inhibit osteoclast activity; therefore the osteoblasts are not destroyed as rapidly by the osteoclasts.

Despite significant improvements that have resulted from the use of bisphosphonates, great debate continues over long-term use and implications of use around the time of orthopedic surgery.[45,50,51,60,78]

Another aspect of care with OI is ensuring adequate vitamin D level. Vitamin D allows the body to absorb calcium. Inadequate vitamin D limits the body's ability to form the hormone calcitriol, leading to insufficient calcium absorption from the diet; therefore the body must take calcium from the skeleton.[42] If vitamin D deficiency is established, vitamin supplementation, as well as calcium supplementation, is recommended.

Bone marrow transplant and stem cell therapy have been used sparingly. Transplantation of normal mesenchymal stem cells with the potential to differentiate into mature osteoblasts may result in significant improvement in bone collagen and mineral content. The therapeutic effect is possibly due to the selective growth advantage of normal cells over diseased host cells. Some research is being directed toward transplanting bone marrow cells with osteogenic potential with the collagen gene.[13,36,52,58]

The use of whole body vibration (WBV) is being researched as a minimally invasive technique to improve bone density and strength in children and adolescents with significant motor impairment. The child is on a vibrating platform on a tilt table. Increased bone density and improved function, based on the Brief Assessment of Motor Function and the Gross Motor Function Measurement, occurred in children who participated in vibration studies. Those who have telescoping rods and/or a history of joint subluxation are not good candidates for this treatment.[37,65–67] There is some concern that the vibration may be too stressful across instable joints and may create movement in the hardware of the telescoping rods.

Once a fracture occurs, the bone is more susceptible to refracture. The already weakened structure predisposes the child to limb deformities from bowing of the long bones. Immobilization to assist in setting the bone in proper alignment can cause disuse osteoporosis, causing greater risk of future fractures. A vicious circle is created: osteoporosis leads to fracture, and then immobilization for the fracture creates disuse osteoporosis, putting one at risk for further fracture. The goal is to limit immobilization of the extremities as much as possible to reduce osteopenia and risk of additional fractures.

Fractures in patients with OI generally heal within the normal healing time, although the resultant callus may be large but of poor quality. These fractures must be immobilized for pain relief and to promote healing in the correct alignment. Pseudarthrosis may occur when the fracture is not immobilized. Immobilization may occur in the form of splinting with thermoplastic materials, orthoses, hip spica posterior shells, or

casting. With malunion of fractures, angulation and bowing of the long bones occur, frequently accompanied by joint contractures. The physis may be disrupted, resulting in asymmetrical growth and deformity. When angulation occurs, mechanical forces tend to increase the deformity, aggravating the overall problem.[1] The cartilaginous ends of the long bones are disproportionately large and have irregular articular surfaces. Fortunately, in nearly all patients with OI the fracture rate diminishes near or after puberty.

The most successful means of fracture stabilization in long bones in OI is internal fixation with intramedullary rods.[38] Consensus indicates that intramedullary rods are advantageous, although significant debate continues over the type of internal fixation to be used in terms of material (steel versus titanium) and fixation (static rod versus telescoping rod). Although use of the intramedullary rod is not without complications, it can be helpful in preventing long bones from bowing after fracture. The rod provides internal support to prevent additional fractures. Indications for stabilization with rods include multiple recurring fractures and increasing long bone deformity that is interfering with orthotic fit and impairing function.[38] The age of the patient and the size of the bone determine the type and timing of surgery. Intramedullary rod fixation of the femur is best done after 4 or 5 years of age, when the thigh is not so short as to complicate surgery by compounding the technical difficulty. Surgical insertion of the rod in thin bones is also technically difficult.

The type of rod used depends on the type and severity of fracture. When a solid rod is used, bone growth may occur beyond the ends of the rods, necessitating subsequent surgery later for placement of a longer rod. Because children with severe OI are at greater than normal anesthetic risk from potential respiratory compromise, the number of operative procedures is best kept to a minimum. Special instrumentation has been designed that "elongates" with the child's growth, eliminating the need for multiple surgical revisions as the bone grows (Fig. 11.1).[29]

FIG. 11.1 Extensible intramedullary fixation rods that elongate as the bone grows in a child with osteogenesis imperfecta.

Telescoping rods are most frequently used in the femur but also may be used in the humerus, tibia, and forearm. Problems with intramedullary rods involve the control of rotation and migration when extensible rods are used; thus postoperative casting may be necessary.[38] Orthoses may be needed after insertion of the rod for further external support. Early weight bearing with orthotic support is initiated as soon as possible. With internal fixation a risk of osteopenia around the rod is present, especially with telescoping rods.

Spinal deformities, including scoliosis and kyphosis, occur in 50% of patients with OI as a result of osteoporosis and vertebral compression fractures. Progressive spinal deformities such as scoliosis and pathologic kyphosis are more likely to occur in children with types III and IV OI than in those with type I OI.[20] Kyphoscoliosis can be disabling and may be present in 20% to 40% of patients.[74] Unlike in the typical population, kyphoscoliosis in those with OI can be progressive over a lifetime, which further compounds the patient's short stature. The most common curve is that of thoracic scoliosis. Scoliotic and kyphotic curves in patients with OI are not usually amenable to conservative bracing. The incidence of a scoliosis developing in adolescents and adults with severe OI is 80% to 90%. Surgical stabilization is often advocated for the management of these deformities because the greater the curve, the greater the difficulty involved in meeting motor milestones.[22]

IMPAIRMENT

Diagnosis and Problem Identification

In the most severe forms of OI, the infant is born with multiple fractures sustained in utero or during the birth process. The prognosis of OI depends on its type. In its most severe forms, including types II, VII, VIII, IX, and X, multiple fractures noted prenatally and developed during delivery are associated with a high mortality rate. Prognostic indicators concerning survival and ambulation include the time of the initial fracture and the radiologic appearance of long bones and ribs at the time of the initial fracture. Spranger and associates[71] devised a scoring system for providing an accurate prognosis for newborns with OI. This system coded the degree of skeletal changes based on clinical and radiographic findings in 47 cases. These investigators found that newborns who had marked bowing of their lower extremities but less severe changes in the skull, ribs, vertebrae, and arms and normal sclera survived and had fewer fractures as they grew older. For the moderate and mild types, although the prognosis varies, a gradual tendency toward improvement has been noted when fracture incidence decreases after puberty.

If a family is known to be at risk of having a child with OI and the collagen defect or if the genetic mutation has been identified in the parent, human chorionic villous biopsy can be done prenatally at 10 weeks of gestation to determine whether the child has the same defect. A prenatal ultrasound examination in the second trimester of pregnancy can be helpful in identifying skeletal dysplasia and associated fractures.[39]

The infant is usually of normal size at birth, but postnatal growth is impaired. Although no conclusive causative factors for this impaired growth are known, possible factors include the deformities themselves or abnormalities in the epiphyseal growth plates. The radiologic appearance of long bones

associated with the most severe cases indicates bones with a thin radiolucent appearance. The malformed ribs affect respiratory function, which may lead to respiratory tract infection and reduced functional potential of the child.

Children with moderate OI are often identified after several fractures have resulted from seemingly slight trauma. An example is a fractured humerus caused by the child holding on to a car seat while the caretaker is trying to get the child out of the car. Those children who begin to have fractures of unknown origin at a young age can have collagen and biochemical studies done, usually from a skin biopsy. These tests can also be helpful in ruling out other disorders, such as idiopathic juvenile osteoporosis, leukemia, and congenital hypophosphatasia. Genetic testing can be done to identify if the child has one of the identified forms of OI, although not all forms of bone fragility have been specifically mapped at this time. Infants with large heads and short limbs may be initially misdiagnosed because OI and achondroplasia are often confused. Radiographic reports, however, easily distinguish between the two.

Dual-energy x-ray absorptiometry (DEXA) is a helpful evaluation tool in the detection of low bone density. It is most useful in those children with milder forms of OI because it can detect changes more specifically than traditional radiographs.[49] DEXA scans are also helpful in tracking drug efficacy in gaining bone density.

Collagen and biochemical studies can assist in differentiating a battered infant from an infant with OI. Radiographic studies are helpful because fractures at the epiphysis are rare in OI but common in child abuse in which soft tissue trauma is also evident. Bruising is common to both the infant with OI and the battered infant, but the bruising will disappear when the battered infant is in a safe environment. Three of the most helpful radiographic views in diagnosing OI are those of the skull (wormian bones), the lateral view of the spine (biconcave vertebrae or platyspondyly), and the pelvis (the beginnings of protrusio acetabuli).[83]

In moderate-to-severe forms of OI, early childhood fractures lead to multiple recurring fractures caused by the already weakened structure. The child develops limb deformities from bowing, which leads to impairment of mobility and of other functional skills. In the least severe forms of OI, because the first pathologic fractures occur later in childhood, recurring fractures with associated long bone deformities are less likely, and the overall prognosis is improved.

Engelbert and colleagues,[23] in a cross-sectional study of 54 children with OI, analyzed range of motion (ROM) and muscle strength for different types of OI. In OI type I, generalized hypermobility of the joints occurred without a decrease in ROM. In OI type III, extremities, especially the lower extremities, were severely malaligned. In OI type IV, upper and lower extremities were equally malaligned. Muscle strength in OI type I was normal except in periarticular muscles at the hip joint. In OI type III, however, muscle strength was severely decreased, especially around the hip joint. In OI type IV, the proximal muscles of both upper and lower extremities were weak.

Team members other than physical therapists who have an important role in the management of OI include orthopedists, orthotists, occupational therapists, audiologists, dentists, and geneticists. Little progress has been made in the primary prevention of this disorder, but much improvement in medical management is evident in recent years.

FOREGROUND INFORMATION

EXAMINATION, EVALUATION, AND INTERVENTION TABLES 11.2 TO 11.4

Infancy

Typical participation restrictions for an infant with OI depend on the severity of the case. In severe cases the most serious impairments are those of rib and skull fractures, which may compromise pulmonary status and neural status, respectively. Because of possible cardiopulmonary compromise, time may be spent in the neonatal intensive care unit; this could lead to decreased parental interaction and bonding. If OI is moderate to severe, parents have increased anxiety about holding the infant for fear of fracturing the infant's bones. This may result in minimal contact and may decrease the mutually nurturing interaction vital to both parent and child. Children with severe OI who have reduced mobility from skeletal deformities may be unable to achieve age-appropriate activities of daily living (ADLs) or to play in the normal peer environment.

Infants with OI are at a very delicate stage of life. They have special needs regarding handling, positioning, and playing. During this stage, the role of caregivers is paramount in minimizing fractures, thereby limiting further muscle weakness and joint laxity. This is accomplished primarily through a physical therapy home program and caregiver education involving proper positioning and handling, which begin as soon as the child has been recognized as an infant with fragile bones.

At birth the infant may be of normal size, but postnatal growth is almost always stunted. Typical deformities of the infant include a relatively large head with a soft and membranous skull and bowed limbs, which usually are short in the more severe forms of OI. Other features include a broad forehead and faciocranial disproportion, which give the face a triangular shape. Radiographically, fractures present at birth may be at varying stages of healing. The bones of infants with severe OI are short and wide with thin cortices, and the diaphyses are as wide as the metaphyses. Crepitation can be palpated at fracture sites.

The physical therapist should be aware of the infant's medical history of past and present fractures and should know the types of immobilizations employed before beginning the examination. Assessing pain is important when working with this population because it can establish baseline comfort and anticipated changes with intervention. The FLACC (face, legs, activity, cry, and consolability) Scale is an observational scale that is used to quantitatively assess pain behaviors in preverbal patients.[44,47]

Assessment of the caregiver's handling and positioning techniques during dressing, diapering, and bathing is necessary. Therapists can be helpful in identifying and modifying techniques that put the child at fracture risk. If the baby is hospitalized, it is imperative that all caregivers be educated in proper handling techniques.

Therapy assesses active, but not passive, ROM in the young child with OI because passive stretching is contraindicated in most cases. A standard goniometer can be used for measuring active ROM but may need to be cut down to a size suitable for the infant. This active ROM can be translated to functional ROM, useful in visualizing the whole composite of motions needed in functional abilities. For example, functional active ranges include the extent to which the child can bring the hand

TABLE. 11.2 International Classification of Functioning, Health, and Disability for Children With Osteogenesis Imperfecta

Changes in Body Structure	Changes in Body Functions	Activity	Participation
Connective tissue disorder secondary to defect in collagen synthesis	Diffuse osteoporosis resulting in multiple recurrent fractures	Limited functional mobility skills, including rolling, creeping, transitional movements, and higher-level mobility skills	Limited participation in physical activities caused by endurance limitations and safety concerns
Brittle bones	Weak muscles	Limited ability to transfer	Limited peer play
	Joint laxity	Limited ambulation	Infantilization
	Bowing of long bones	Decreased endurance	Limited access to educational and work opportunities
	Scoliosis	Limited independence in self-care skills, including dressing and feeding	Limited access to wide range of environments
	Kyphosis	Limited ability for ambulation on uneven terrain	Limited independent living
		Limited independence in wheelchair mobility	Social isolation

TABLE. 11.3 Recommended for Children With Osteogenesis Imperfecta

	Test Information	Considerations for Osteogenesis Imperfecta	Reference
Body Structures and Function			
Range of motion	Goniometer can be used to identify range of motion as well as resting posture of the limbs.	May need to cut down a goniometer to allow reliable use with a small child.	Clarkson HM: Musculoskeletal assessment: joint motion and muscle testing. 3rd ed. Baltimore, Lippincott, Williams & Wilkins, 2012.
Strength	Observation, palpation, and hand pressure are used to determine muscle strength.	Extreme caution is necessary when testing across long bones. Manual muscle testing is more a guideline of strength above or below antigravity strength.	Hislop HJ, Montgomery J, editors: Daniels & Worthingham's muscle testing: techniques of manual examination. 8th ed. Philadelphia, Elsevier Science, 2007.
Activity: Single Task			
Timed standing balance	Documentation of amount of time the individual can stand statically.	No norms for this population. Can track change over time for the individual. Can look at stand on one foot and compare symmetry.	
Gait speed	Documentation of speed traveling a specific distance. Document for bracing and assistive device during testing.	No norms for this population. Can track change over time for the individual. Can also be used to monitor manual wheelchair speed.	Lythgo N, Wilson C, Galea M: Basic gait and symmetry measures for primary school-aged children and young adults. II: Walking at slow, free and fast speed, Gait Posture 33:29-35, 2011.
6-minute walk test	The individual walks as far as possible in a 6-minute period.	No norms for this population including assistive device. Useful to track change over time for the individual.	Please refer to Chapter 2 for more information.
Timed up and go	Individual rises from a standardized chair height, walks 3 meters, turns around, and returns to sitting in the chair.	No norms for this population. Child may be too small to safely get in and out of the standardized chair height. Tracks change over time for the individual. Record chair height for the individual if not using the standardized chair height and replicate height during future testing.	Please refer to Chapter 2 for more information.
Activity: Multiple Items			
Peabody Developmental Motor Scale	Fine and gross motor assessments compare skills to typically developing peers aged birth to 72 months.	Higher-level locomotor skills and object manipulation skills should be approached with caution because these activities could put a child at risk for fracture.	Please refer to Chapter 2 for more information.
Brief Assessment of Motor Function (BAMF)	Test specifically designed for OI population. Predictive of ambulation potential.		Cintas HL, Siegel KL, Furst GP, Gerber LH: Brief assessment of motor function: reliability and concurrent validity of the Gross Motor Scale, Am J Phys Med Rehabil 82:33-41, 2003.

	Test Information	Considerations for Osteogenesis Imperfecta	Reference
Patient Reported Outcomes Measurement Information System (PROMIS)	Parent and/or child report. Multiple dimensions to help tease out perceived strengths and needs to help with goal establishment.	Short and long forms available. Can be reported on paper or via computer access. PROMIS has pediatric and adult versions.	Please refer to Chapter 2 for more information.
School Function Assessment	Educational staff report on child's abilities. Helpful in identifying needs within the educational environment	Some children will need assistance with skills but should learn to how to orchestrate care.	Please refer to Chapter 2 for more information.
Pediatric Evaluation of Disability Inventory (PEDI and PEDI-CAT)	Self-report or caregiver report tool designed to identify functional delay in areas of daily activities, mobility, social/cognitive, and responsibility.	The PEDI takes 1 hour to administer while the PEDI-CAT is a shorter, more intuitive computerized version.	Please refer to Chapter 2 for more information.

TABLE. 11.4 Interventions Based on International Classification of Functioning, Health, and Disability for Individuals With Osteogenesis Imperfecta

	Activities Across the Life Span	Early Intervention Through School Age	School Age Through Adulthood	Adolescence Through Adulthood	Other
Body Structure	Postfracture management for strength and motion.				Have a fracture plan in place for home/school/community/work.
Body Function	When working on rehabilitation from fracture or surgery, providing intervention in an aquatic medium is often helpful to address strength and mobility prior to achieving the same skills on land.	Encourage child to avoid rotational and deforming forces across joints when learning postural transitions. Position with neutral alignment of hips when possible.	Equalize leg length for those who are standing and/or walking. Work on trunk strength and overhead reaching to help limit the progression of scoliosis.	Lifetime participation in some type of cardiovascular fitness is important.	Weight management is important. Obesity negatively impacts on transfers and independent mobility.
Activity	Identify equipment needs to enhance independence.	Work developmental sequence to help enhance transfers and potential for ambulation.	Emphasis on independent mobility both from a wheelchair level and from a functional mobility standpoint. Emphasis on reaching for highest level of functional mobility with independence.	Work toward mobility in the community. Identify self-care limitations and work toward highest level of independence.	Adapt environment as necessary to help with independence.
Participation	At each age group, focus needs to be on age-appropriate peer participation.	Playground and gym-related play is imperative in preschool and school age, working to find activities that allow independent participation as well as fitness opportunities.	Identify physical activities that allow for lifelong participation and peer groups.	Work on strategies to enhance community participation with focus on activities to address improvement in quality of life including but not limited to employment and recreation.	Teach self-advocacy, especially during emergency situations. School and work need to have an action plan in place prior to an emergency. This may include whom to call, splinting of fractures, and triage prior to calling an ambulance to send the individual to the emergency room.

to the mouth, reach hands to midline, and reach toward the top of the head. If possible, the same therapist measures ROM during reevaluations. Intrarater and interrater reliability of goniometry should be determined for therapists and should be checked annually if more than one therapist examines the child.

Muscle strength is assessed through observation of the infant's movements and palpation of contracting muscles, rather than with the use of formal muscle tests.

A gross motor developmental evaluation should also be performed because these children often have delayed development of gross motor skills secondary to fractures and muscular weakness. Delayed gross motor skills are manifested as activity limitations involving impaired achievement of motor milestones. Sitting by the age of 10 months is a good predictor of future walking ability.[16] Formal tests used include the Peabody Developmental Motor Scales, 2nd edition[28]; the Pediatric Evaluation of Disability Inventory[34]; the Bayley Scales of Infant Development II[9]; and the Brief Assessment of Motor Function, which can be used to obtain a quick description of gross, fine, and oral motor performance.[15,54] See Chapter 2 for more information on examination tools. Finally, it is important to assess the appropriateness of equipment used for seating, transporting, and encouraging independent mobility of the infant.

Physical therapy includes early parent education on proper handling and positioning techniques. Safe bathing, dressing, and carrying of an infant with OI are critical to reduce the risk of fracture.[8] When handling the infant, it is important that forces not be put across the long bones; instead the head and trunk should be supported with the arms and legs gently draped across the supporting arm. Some parents feel most comfortable supporting the infant on a standard-sized bed pillow for carrying at home. It is important to have a repertoire of carrying positions for the infant, so the baby can develop strength by accommodating to postural changes. Holding and carrying positions that safely challenge head control are important in that head control is a hallmark of function over time. Loose clothing and front snaps, side snaps, or Velcro closures can facilitate dressing and undressing. Overdressing should be avoided to reduce excessive sweating. Proper diapering includes a technique of rolling the infant off the diaper and supporting the buttocks with one hand with the infant's legs supported on the caregiver's forearm, while the other hand positions the diaper. The infant should never be lifted by the ankles. Bathing is done in a padded, preferably plastic, basin. Infant carriers that are designed to safely support the head, trunk, and extremities are frequently used for household transporting. For the very fragile infant, the carrier can be customized, as with a one-piece molded thoracolumbosacral orthosis, which incorporates the legs so they will not dangle and sustain injury. This carrier minimizes stresses to the fragile bones while it aids in positioning and transporting the infant. Physical therapy can play a role in educating families on the proper car seat, even before the child is initially discharged from the hospital. Early on, an infant may need a car bed (Fig. 11.2) if a rear-facing infant seat is too large or if the risk of fracture while getting into and out of the seat is too great during the first few months. Extra padding may have to be added between the child and the transportation device, allowing a snug fit without putting undue stress on the fragile child through the strap systems. Families need to be trained on how to rearrange padding in the seat to accommodate the various devices the child may be placed in for immobilization of

FIG. 11.2 Example of a young infant in a car bed.

FIG. 11.3 Infant positioned lying on side using rolls. Emphasis is on maintaining trunk alignment while allowing for active and spontaneous but safe movement.

fracture sites. Given the low bone density and the high risk for fracture, the child should use a rear-facing car seat for as long as possible to maximize safety in the car.

Proper positioning is a critical component of the home program and management of the infant with OI. One position that offers good support is sidelying with towel rolls along the spine and extremities, so they are aligned and protected while allowing the child to be active (Fig. 11.3).

Prone positioning should start with the baby on the caregiver, where the child is well supported and most comfortable when being challenged. As the child gains skill in prone, the baby can be positioned over a towel roll or with a soft wedge under the chest as an alternative. Prone positioning is helpful for improving head control, strengthening back extensors, and molding the anterior chest wall. When supine, the infant needs support for the arms, and the hips should be in neutral rotation with the knees over a roll (Fig. 11.4). Positions should be changed frequently and should not restrict active spontaneous movement because spontaneous movement enhances muscle strengthening and bone mineralization.[8] Positioning is useful not only for the purpose of protecting from fracture but also for minimizing joint malalignment and deformities. Fig. 11.5 shows an infant's legs being poorly positioned in an infant carrier. The

FIG. 11.4 Infant positioned supine with hips in neutral rotation and knees flexed and supported through the trunk.

FIG. 11.5 Child positioned poorly in an infant seat.

same seat is modified with lateral leg pads to keep the infant's hips and legs in neutral alignment, along with lower leg molded plastic splints (Fig. 11.6). Varying the position of the infant promotes the development of age-appropriate developmental skills.

Promotion of sensorimotor developmental skills is an ongoing component in the management of the infant and child. Identification of appropriate and safe toys for a child and of comfortable play positions that promote development is often addressed jointly by the occupational therapist and the physical therapist. For example, lying prone on a soft roll or over a parent's leg allows weight-bearing use of the arms with cocontraction of the shoulder musculature, which promotes active neck and back extensor muscle control (Fig. 11.7). Increasing muscle strength and support around the joint in activities such as this is

FIG. 11.6 Child with improved positioning in an infant seat.

FIG. 11.7 Infant positioned prone over a bolster encourages weight bearing, extremity and trunk alignment, and strengthening of extensor musculature during developmental play.

especially important because the joint ligaments are lax. Prone positioning may be most comfortable over an elevated surface such as a wedge, a sofa cushion, or a roll, but just as important is lower extremity positioning with hips in neutral rotation and maximal hip extension.

Developmental activities such as rolling and supported sitting should be encouraged as tolerated by the child. When rolling is encouraged, the infant's arm is placed alongside his or her head, and then he or she attempts to roll over. Supported sitting is accomplished with seat inserts or corner chairs. Upright unsupported sitting can begin on the parent's lap with a pillow. When the child exhibits appropriate head control, short-sit and straddle activities can be done over the caregiver's leg or a roll but with avoidance of rotation across the lower extremity. These activities promote the development of protective and equilibrium responses and the beginning of protected weight bearing of the lower extremities. Many children with OI spend much time scooting on their buttocks before crawling is accomplished. Many children develop sitting skill and mobility in

sitting long before they develop consistent ability to move from horizontal prone or supine to sitting. This is due to short arms in relation to body length and can be adapted for by giving a child a raised surface to push off of, such as a pillow, as the child is learning to move into a sitting position.

Proper handling while encouraging developmental skills is of key importance. For instance, a pull-to-sit maneuver is contraindicated when a distraction pull on the hands is used. Rather, this maneuver should be modified and facilitated by supporting the child around the shoulders while the child attempts to sit up. In working on trunk control over a ball, the therapist's hands are positioned on the pelvis and trunk rather than supporting or facilitating movement from the legs. Parents should be cautioned against using devices that support a baby upright in standing such as baby walkers or jumping seats. These devices put unnecessary stress on the legs where the child fits through the sling, and if the baby has difficulty controlling the device, devastating torque to the bone may result. These devices do not foster proper positioning and weight bearing for these fragile children. Such upright activities can give parents a false sense that the infant is protected. Active, spontaneous activity and exercise are encouraged in sidelying and supine positions and in supported sitting, with the child reaching for, swiping at, rolling, and lifting lightweight toys of different textures. Pool exercises may begin as early as 6 months of age with the goals of promoting active exercise and weight bearing.[8] Extremity movement may occur unobstructed in the water as the child is supported in a flotation device accompanied by a parent or the therapist.

At this stage, goals include teaching safe handling and positioning techniques to caregivers and providing opportunities for development of age-appropriate skills. The intensity of treatment varies with the individual needs of the infant and family, but providing a home program and regular home visits by a physical therapist at least weekly is essential to ensuring that the environment is suitable for sensorimotor and cognitive development. The therapist can act as a resource and support for the caregivers as together they develop strategies to meet the challenges of safe caregiver handling, mobility, and developmental facilitation. Another important role for early intervention therapists in the home is to help families develop a repertoire of positioning and activity options for the child. This is most important when the child recovers from fractures.

When fractures do occur, they may require splinting with materials such as thermoplastic materials or fiberglass. Ace wraps have been used to support and protect a limb in mild cases and in young infants. Fractures may heal within 2 weeks in the newborn and generally within the same time frame as other fractures in infancy (usually 6 weeks).

Preschool Period

Bone fragility, joint laxity, and reduced muscle strength continue to be present in the preschool period but are now accompanied by secondary impairments of disuse atrophy and osteoporosis from fracture immobilization (Fig. 11.8). At this point, if a child has had issues with recurrent fractures, treatment with bisphosphonates has begun to help decrease the fracture cycle. Structural changes and secondary impairments from fractures may limit mobility and subsequently restrict participation in play and socialization for the child with OI. This may affect the child's adjustment to regular school and may hinder academic progress. The temperament of the child with OI may play a role in his ability to adjust to his activity limitations and participation restrictions. Cintas and colleagues[15] demonstrated that the temperament of children with OI was comparable with that of children without disability except for having lower activity scores. Temperament was significantly and positively related to motor performance in terms of persistence, approach, and activity.

FIG. 11.8 Child with osteogenesis imperfecta showing joint laxity and bony deformities: femoral anterolateral bowing and tibial anterior bowing.

At this stage, muscles are usually weakened and developmental motor skills are lagging as a result of frequent immobilization and relative disuse. Despite this, cognitive skills should be appropriate for the child's age. When a fracture is sustained, children with OI typically complain little of pain and usually have minimal soft tissue trauma.[84]

If the child begins to walk without adequate support, further bending of the long bones occurs as a result of abnormal stress on the weakened structure. Bowing occurs in the anterolateral direction in the femur and anteriorly in the tibia. In those children who do not walk, lack of normal weight-bearing stress leads to a honeycomb pattern of osteoporosis in the long bones.

Emphasis at this stage is on protected weight bearing and self-mobility for enhanced independence. Although proper positioning, handling, and transferring are still important, the focus shifts to the child's active participation in his or her care. During this period the child with OI should have adequate upright control to begin bearing weight and, at the very least, should be held in a standing position because early weight bearing appears to have some beneficial effect.[30] When radiographs of children with OI from the time of birth and several years later are compared, the changing levels of bone density suggest that progressive osteoporosis has been superimposed on the basic bone defect.[10] Upper extremity bones were frequently denser than those of the lower limbs and were less likely to fracture. This finding may be related to the use and stress placed on upper extremity bones during self-care and play activities.

FIG. 11.9 Straddle roll activity of supported sit-to-stand for lower extremity strengthening and weight bearing.

For the preschool child an evaluation of modes of mobility and adapted equipment is essential to promote supported sitting functional mobility and independence. Equipment requires constant updating because of changing positional needs related to mobilization-immobilization status. Splinting needs and adaptive ADL equipment are assessed for fit and function to allow optimal levels of independence.

Developmental assessment tools that are appropriate include the Peabody Developmental Motor Scales II, the Brief Assessment of Motor Function, and the Pediatric Evaluation of Disability Inventory to assess gross motor function and activity limitations in children with OI. Pain should continue to be assessed in the preschool-age child. Appropriate pain assessments include the FLACC Behavioral Scale and the self-report Numeric or Wong-Baker Faces Scale.[44,82] Active exercise continues to be emphasized to increase muscle strength of weakened muscles, most typically, hip extensor and abductor muscles. Active exercise can be achieved primarily through developmental play. One developmental activity to increase weight bearing and maintain or increase strength in the quadriceps and hip extensor musculature involves having the child straddle a roll and come to stand, with the therapist supporting the child's pelvis (Fig. 11.9). The therapist begins with the child sitting on a high roll that requires a small excursion of movement to go from sitting to standing and then gradually changes to using a lower roll. An active-resistive program graded for the patient's tolerance should be cautiously established. Use of light weights may be incrementally increased, but they should be attached close to large joints so as to avoid a long lever arm, which increases the potential for fracture.

Early gym-related activities that can be introduced at this age may include scooter board activities, riding tricycles, and playground games such as Simon Says, Red Light Green Light, and Follow the Leader. Activities that encourage overhead reaching are helpful in maximizing trunk extension. These activities can include modified basketball activities when the ball is light and the child uses low-speed passing. Racket sports using a tethered tennis ball help to build upper body strength. A responsible adult to ensure safety should closely monitor all activities. If the child is attending preschool, all members of the team should have a basic emergency plan if fractures occur at school. This plan would include but is not limited to notification of family and splinting of involved extremities while awaiting supportive medical intervention.

An aquatic exercise program is excellent for the child with OI. It can be started at an early age and continue for a lifetime. Aquatic therapy benefits include the opportunity to socialize with peers in a safe environment, a safe method of strengthening muscles through resistance and assistance of the water, and the opportunity to improve cardiovascular fitness and bear weight in a protected environment. The therapist can finely grade the progression of exercises in the pool by first using the buoyancy effect of the water to assist weak movements, then supporting the movements, and finally, using water to resist active movements. Exercises can be modified with floats by changing the length of the lever arm of the moving body part through the use of turbulence and by altering the speed and direction of the movement.[19]

Pool exercises can enhance deep breathing to facilitate chest expansion and enhance overall respiratory function, which are especially important because chest deformities that compromise breathing capacity are common. Certain precautions should be taken when pool therapy is considered for the child with OI. The heat of the water creates a rise in body temperature and increases metabolism, which is frequently already elevated in these children. It is suggested, therefore, that time in the water, water temperature, and activity level be closely monitored for each child. Initially, pool sessions are generally limited to 20 to 30 minutes.[14]

Pool exercise therapy may interrupt the cycle of further disuse and secondary complications from immobilization. Not only is aquatic therapy an ideal therapeutic modality for the child with OI, it also can be a therapeutic, lifelong avocational activity that can ameliorate the effects of the disabling process.

One key goal and big challenge for the preschool child who has frequent fractures is safe, independent mobility. The aim is to prevent an activity limitation of reduced mobility resulting from the initial impairment. Research has linked limited mobility opportunities in the first few years with later life problem-solving skill difficulties.[72] Opportunities for multiple safe modes of mobility should be explored to expand the child's repertoire of environmental experiences. A scooter for sitting propelled with legs or hands may be useful (Fig. 11.10). Families should be encouraged to investigate ride-on toys that can be purchased at a toy store. It is often a challenge to get a device that accommodates the child's shortened femurs and shortened arms yet gives enough weight-bearing surface to enhance trunk control. Sometimes handlebars need to be adapted to allow the child to steer effectively. A ride-on toy may give the child safe mobility without the rotational components of sit-scooting.

The degree of ambulation attainable varies for preschool children with OI. Those children with limited ambulatory skills may need formal gait training as well as the instruction of family members. Interest in standing often occurs in the child's second year of life. Factors affecting the ability to stand and ambulate include the degree of bowing in the extremities and the muscle strength of the limbs. Ambulation is often introduced in the

FIG. 11.10 Scooter used for mobility that can be propelled by a child's legs or arms.

pool, for protected weight bearing. Because the buoyancy of water provides support for the body, weight bearing on weakened extremities and unstable joints can be gradually introduced without fear of causing trauma.

Weight relief depends on the proportion of the body that is below the water level. For maximum weight relief for ambulation, the child begins standing in the pool where the water level is at the child's neck. Over time, the child gradually progresses to bearing more weight in shallow water. If the child with OI is recovering from a fracture, it is recommended that thermoplastic splints be used to further protect the extremity while in the pool during early weight bearing. General guidelines for walking reeducation in water according to Duffield[19] suggest that a patient start in parallel bars or a walking frame, with the therapist initially supporting the pelvis from the front. The patient practices weight shifts from side to side, forward, and backward and progresses to walking forward. The therapist cues the patient to lean slightly forward to counteract the upthrust of buoyancy, which tends to cause the child to overbalance backward. In this manner, protected walking for a child with OI can start much earlier than on a solid surface. Unsupported standing on solid ground is not recommended because it leads to rapid bowing of the long bones. When severe bowing of the extremities occurs, the child usually undergoes orthopedic surgery in the form of osteotomies. Age-appropriate lower extremity weight bearing is encouraged, although the child with moderate to severe OI needs external devices such as splints or braces to protect fragile long bones.

In moderate-to-severe OI, braces and splints are usually required to begin standing activities on solid surfaces. Use of orthotics provides the protected weight bearing needed to reduce the impact of stress on osteoporotic bony deformities. Braces or splints may be used first in conjunction with a standing frame if the child has significant lower extremity bowing and does not have standing skill.

The child who does not naturally embark on a standing program can use a standing device for support. An air splint can be used to prevent fractures and to temporarily manage fractures. Use of such a device may be a nice stepping stone between using a stander for weight bearing and standing freely without support.[63] Many children begin early ambulation with sit-to-stand activities and cruising along furniture. Air splints can be helpful to institute graded weight bearing and gait training in a child with OI. Drawbacks of air splints are that they may be bulky and hot, so the child may not always tolerate them well.

Once a child graduates from a stander, ambulation may be protected through the use of parallel bars or a walker. A walker that supports the majority of body weight through the trunk and pelvis is often used to assist in weight bearing during initial overland ambulation. This walker supports weight by means of a trunk support cuff and a padded pommel that is positioned between the child's legs. Rear-wheeled and four-point walkers followed by canes or crutches (depending on the type and severity of OI) also may be used. Forearm attachments to walkers or crutches afford a degree of weight bearing distributed throughout the forearm to reduce stress on the arm and wrist, as well as to relieve some weight bearing on the lower extremities. Older preschoolers who use a walker may benefit from a walker with a seat, so they can easily rest between walking activities and can fully participate in preschool-related play. Most children ambulate without braces when the fracture rate decreases. Although bracing of the lower extremity is not as prevalent as it had been before the use of bisphosphonates, many benefit from orthotics in the shoe to support the longitudinal arch that often collapses as the result of ligamentous laxity.

Families often will invest in a lightweight wheelchair the child can self-propel during times of fracture recovery. For those who have significant bone fragility, a motorized wheelchair is a consideration at this age. With training, the child could safely handle a mobility device allowing age-appropriate peer-related play. These alternative mobility modes do not preclude ambulation but are useful additional mobility options. Regardless of the mode of mobility used, it is imperative to provide the child with a degree of functional independence in the home and in the preschool environment that will promote participation in social activities.

Physical therapists are often consulted on seating issues with children who have OI. Given that most states mandate child safety seats in cars for children younger than 8 years of age, it is important to assist families in proper seating choices once the child has outgrown the infant car seat. Children with the most severe forms of OI are safest in rear-facing seating devices for as long as possible. A five-point harness rather than a seat belt helps to distribute pressure from accidents more evenly. Booster seats should be used until the child meets the size restrictions for the seating; the age restrictions of the law should not be the only focus in these decisions.

School Age and Adolescence

Due to reduced mobility and limited independence in ADLs, school-age children and adolescents often have limited ability to participate in peer-related activities (Table 11.2). Social skill development also may be hampered if the school-age child has been overprotected by caregivers because of overwhelming fear and anxiety regarding fractures. This may have an impact on the school-age child's scholastic endeavors and future vocational achievements. Studies have shown that children with OI tend to have similar temperament to typically developing peers.[73] The child who has negative behavior, including negative moods and high intensity of expression, influences the parent's perception

of the difficulty related to dealing with the care of and individual with bone fragility. The severity of the child's disease does not have as big an impact on parental coping as does the child's temperament.[73] Parents and educators should encourage a positive attitude and excellence in school performance to prepare the child for a productive future.

At this age the spine may exhibit varying degrees of deformity. Usually, scoliosis, kyphosis, or both are present, resulting from compression fractures of the vertebrae, osteoporosis, and ligamentous laxity. The child with moderate-to-severe OI typically has marked bowing of the long bones from multiple fractures and growth arrest at the epiphyseal plates. In the femur the neck-shaft angle may be decreased with a coxa vara deformity and acetabular protrusion. The tibia is anteriorly angulated, which, in combination with the angulation of the femur, results in an apparent knee flexion contracture. The patellofemoral joint frequently dislocates, predisposing the patient to falls and fractures. Pes valgus frequently occurs at the ankle. In the upper extremities the humerus is angulated laterally or anterolaterally and the forearms are limited in supination and pronation. The elbows often exhibit cubitus varus deformities, and elbow flexion contractures may be present.

The frequency of fracture tends to decrease markedly after puberty. Possible causes include hormonal changes, increased awareness of how to prevent fractures, improvement in coordination, and increasing bone strength.[31] Paradoxically, the adolescent who senses his or her increased stability and emerging independence may maximize involvement in activities, which increases the risk of more severe types of fractures. In an effort not to discourage these activities and independence, ongoing use of safe methods of mobility, caution, and responsible behavior should be stressed in patient instruction throughout childhood.

Physical therapy management at this stage involves other team members, including professionals in orthopedics, orthotics, occupational therapy, and rehabilitation engineering, to maximize the child's independence in ADLs, mobility, endurance, problem solving, and adjustment to the school environment.

Children and adolescents should be encouraged to be active family members. They should have a share in home-related chores and responsibilities within their functional capacity. This is important because it helps the child learn a level of independence for a lifetime, allows the child to feel valued, and may lessen sibling rivalry.

In this period, physical therapy may be helpful in returning the child to premorbid mobility status after a series of immobilizations from prepubertal fractures. Weight management and physical activity are important at this age.

Management of scoliosis and kyphosis is usually addressed by a spinal fusion, but the long-term results in maintaining alignment are questionable. Back braces have been shown to be ineffective in controlling scoliosis and kyphosis.[7]

Along with occupational therapy, physical therapy can help to maximize the child's independence by identifying safe, energy-efficient positions in which the child can work. Adaptive equipment is imperative for those with severe involvement. Occupational therapists, physical therapists, and rehabilitation engineers work together to adapt wheelchairs and seating and mobility devices to accommodate skeletal deformity, scoliosis, and kyphosis. A variety of lightweight and easily maneuverable manual wheelchairs can be adapted with seating inserts for trunk control and proper positioning. Vinyl upholstery is usually unsatisfactory for the child with OI because of the propensity for excessive perspiration. Proper wheelchair positioning is critical for prevention of further disabling deformity and for protection of exposed extremities from trauma. Those who do rely on power mobility may benefit from a seat elevator and a motorized transfer arm to allow independence in transfers and ability to access all work surfaces in the home and at school (Fig. 11.11).

FIG. 11.11 Adolescent using power mobility with a seat elevator and a motorized transfer arm.

The adolescent continues physical therapy to work on ambulation, endurance, and strength. Household ambulation is usually achieved with assistive devices if adequate upper extremity strength is present. Walkers with progression to canes or crutches may be used.

Many children with OI who have primarily used the wheelchair for mobility are now able to ambulate about the house without any special change in their program. It is important to emphasize the maintenance of adequate skeletal alignment and maximal muscular strength throughout childhood to prepare for this improved function as an adolescent and adult. Community ambulation, however, is not practical given the patient's short stature, the energy expenditure required, and the reduced muscle power. Most school-age and older children with OI use wheelchairs for community ambulation.[10] Independence in mobility is paramount because it has been shown to correlate with the degree of adaptation to the community environment. Bachman[5] found that independence in travel away from home was the most important factor in an adolescent's ability to participate successfully outside the school environment.

Strengthening and endurance programs can be most successful when the child participates in developing a program that suits his or her interests and schedule. Of key importance at this age for those who are not ambulatory population is core

strength and the ability to sit-scoot. Adequate trunk strength will positively affect the child's ability to assist with transfer and self-care skills throughout adulthood. Programs can consist of progressive resistive exercises using incremental weights, aquatic activity, adaptive sport activities, or computer-assisted physical activity. Enjoyable avocational activities that incorporate functional strengthening and mobility also must be stressed at this age. Although contact sports, such as football, soccer, and baseball, must be avoided, customized athletic and fitness programs are vital for youngsters with OI. These adaptive physical education activities can assist in improving physical health, finding a competitive outlet, helping to discover one's potential, and providing an opportunity to make friends.[17] Sports and recreation activities should be encouraged as an adjunct to therapy. These activities will assist children to develop lifelong fitness interests. Adaptive sports that are available to the child who is interested include swimming, challenger baseball, cycling, boating, non-contact martial arts, adaptive dance, billiards, golf, wheelchair sports, racket sports, and even sled hockey. It is important to keep an open mind when helping a child develop fitness interests. Weigh the benefits against the risks when helping a child make choices. The physical therapist's role is to set appropriate parameters for participation, to provide precautions, and to upgrade the level of activity progressively. Volunteer jobs and social opportunities, such as Boy Scouts and Girl Scouts, encourage emotional growth and develop leadership skills. Experience in a volunteer capacity can be helpful to the adolescent when applying for employment in the future.[27]

Transition to Adulthood

In the transition to adulthood, emphasis needs to be placed on the skills necessary for independent living. Identifying personal goals for education and employment is important for the physical therapist to help to establish a plan of care. Once personal goals are established, the therapist can assist the young adult in problem-solving aspects of the activity to allow participation. The mildly involved person with OI tends not to seek assistance; more involved individuals may need support to address specific goals such as transfers for toileting in public or gaining the skills necessary to run a household without outside assistance. Strategies need to be established to maximize independence with and without the presence of fractures. In the transition to adulthood, appropriate career placement is important, while taking into consideration the patient's intellectual capacity and physical constraints. Because most patients with OI become productive members of society, optimal academic, social, and physical development will enhance their opportunities to succeed in a competitive job market.[10]

In addition to functional independence, those who have OI need to participate in behaviors to enhance lifelong health. These involve regular exercise, weight management, a healthy calcium-rich diet, limited caffeine consumption, and avoidance of smoking tobacco. Therapists need to review how each aspect influences overall health and, more important, the management of osteoporosis.

Some encounter problems with deafness in adult life. Scoliotic curves may be severe and may continue to progress. The incidence of scoliosis approaches 80% to 90% in teenagers and adults.[1] Patients who have OI are especially susceptible to postmenopausal osteoporosis or the osteoporosis of immobilization,[68] when more fractures may occur.[55] Adults with OI also report problems with arthritic changes and back pain.

By the time these children reach adulthood, most moderately involved persons use either manual or power wheelchairs for community mobility. Ambulation consists of household walking with an assistive device.

Case Scenario on Expert Consult

The case scenario related to this chapter illustrates issues related to the many episodes of care children with OI will have secondary to frequent fractures. "Jenna's" needs for mobility are the focus of this case, in which she is followed from early childhood to middle school.

Muscular Dystrophies and Spinal Muscular Atrophy

Allan M. Glanzman, Amanda Kusler, Wayne A. Stuberg

Neuromuscular diseases include disorders of the motor neuron (anterior horn cells and peripheral nerves), neuromuscular junction, and muscle. Duchenne muscular dystrophy (DMD) and spinal muscular atrophy (SMA) are two prevalent, progressive neuromuscular diseases that require physical therapy. Progressive weakness, muscle atrophy, contracture, deformity, and progressive disability characterize both diseases. No cure is available for either disease. Incurable, however, is not synonymous with untreatable, and the physical therapist can be influential in prevention of complications, preservation of function, and maximizing quality of life.

The objective of this chapter is to present an overview of childhood neuromuscular disorders and to discuss the role of the physical therapist as a member of the management team. The clinical presentation of these diseases is reviewed and examination procedures are presented to assist the clinician in identifying impairments and limitations in activity and participation associated with diseases of the muscle and nerve. Guidelines for physical therapy management are outlined and reflect our clinical experience and review of related literature. Background and foreground information are presented throughout, in each of the following condition-specific sections.

ROLE OF THE PHYSICAL THERAPIST

As a member of the management team in the educational or medical setting, the physical therapist assists in identification and amelioration of impairments, as well as in promotion of activity and participation for persons with neuromuscular disorders. The team often includes physician(s) (neurologist, orthopedist, or physiatrist), physical therapist, occupational therapist, nutritionist, speech therapist, educator, social worker, genetic counselor, psychologist, and orthotist. Because therapists typically maintain a higher frequency of contact with families, referral to and ongoing communication with other team members becomes an important part of maintaining continuity of care.

The team approach should be family centered with a focus on collaborative goal setting among affected individuals, family members, and professionals to ensure optimal care.[277] When care is provided using a family-centered philosophy, the pivotal role of the family is recognized and respected in the lives of people with special health care needs.

Prevention is an important role of the physical therapist. Stress on the child/individual and family can be reduced and coping facilitated through accurate prognostic information and recognition of signs that portend changing status and a resultant increase in disability. Examples of status change are seen in the period before the loss of walking, before the need for architectural modifications to accommodate adaptive equipment for mobility, during transition from the educational to the vocational/avocational environment, and during the terminal stages of the disease, when the decision to use mechanical ventilation becomes a major issue.

Providing information to the patient, family, and team regarding physical limitations and expected participation restrictions is an important role of the physical therapist. Many resource materials are available online through the national Muscular Dystrophy Association (MDA) or through Parent Project Muscular Dystrophy for DMD and Cure SMA.

PHYSICAL THERAPY EXAMINATION AND EVALUATION

The progression of the more common neuromuscular disorders is relatively well known, but many of those that are less common can be quite variable and the natural history is often less known. A full understanding of the expected clinical progression is critical to providing quality patient care and being able to anticipate and address the evolution of impairments and their expected functional impacts. The clinician must carefully monitor the child for changes that require intervention and modifications in the context of the expected natural history. As stated by Thomas McCrae (1870–1935), "More is missed by not looking than by not knowing,"[241] but clearly both are important. Ongoing dialogue with families is invaluable in identifying family-centered goals and the need for program modification.

The physical therapy examination is the initial step in management of the child with neuromuscular disorders and should include those components identified in the *Guide to Physical Therapist Practice*.[4] The following domains should be carefully considered and used as appropriate. Please see Chapter 2 for more details on selected measures in these domains.

1. History with family concerns
2. Aerobic capacity and endurance
3. Assistive and adaptive devices
4. Community and work (job/school/play) integration
5. Environmental, home, and job/school/play barriers
6. Gait, locomotion, and balance
7. Integumentary status (when using orthoses, adaptive equipment, or wheelchair)
8. Muscle performance and strength
9. Neuromotor development
10. Orthotic, protective, and supportive devices
11. Posture
12. Range of motion
13. Self-care and home management
14. Ventilation/respiration

Systematic documentation of disease progression is essential for timing interventions during transitions from one functional status to another or during times of increased family need.

DISEASES OF THE MUSCLE

The most prevalent types of muscle disease that typically exhibit initial clinical signs in infancy, childhood, or adolescence are listed in Table 12.1. Emery-Dreifuss muscular dystrophy (humeroperoneal) is very rare and will be discussed only briefly. Limb-girdle muscular dystrophy may exhibit signs late in the first decade or in the second decade of life, and at times the onset of symptoms can occur in early adulthood; therefore along with the adult-onset forms of MD, it is not discussed in this chapter.

Most diseases of the muscle are the result of single gene defects and often have either recessive or dominant inheritance patterns. Here DMD and Becker muscular dystrophy (BMD) will be used as examples of dystrophic muscle disease. The diagnosis of the specific muscle disease is confirmed by genetic testing that identifies a causative gene mutation or by muscle biopsy where an absence of or decrease in the specific protein is noted. The process of diagnosis may include a history, clinical examination, electromyography, muscle ultrasound, blood levels of the muscle enzyme creatine phosphokinase, muscle biopsy, and DNA analysis.[126] Criteria for classification of the various forms of muscular dystrophy (MD) have changed over the years, and various classification systems have been suggested. When the first forms of muscular dystrophy were identified in the 1800s, phenotypic classification was the standard with distribution of weakness, age of onset, and mode of inheritance driving classification. With the growth of light microscopy, various microscopically descriptive diagnostic categorizations invaded the lexicon. In the age of genetics and identified protein products, identifying diagnosis based on the defective protein has become more prevalent.

The primary impairment in all forms of muscular dystrophy is insidious weakness. In congenital forms of muscular dystrophy, the weakness is pronounced at birth and is easily recognizable. In DMD, the weakness becomes evident between age 3 and 5 years. In most diseases of the muscle cognitive function is preserved; however, there are a few exceptions to this. The incidence of intellectual disability is highest in congenital myotonic dystrophy with impairment correlating with physical symptomatology.[26] Cognitive delay is also noted in DMD but it is less frequent.

Secondary impairments in all forms of MD include the development of contractures and postural malalignment. Postural malalignment is seen in antigravity positions of sitting and standing and often includes development of scoliosis. Other secondary impairments include decreased respiratory capacity, cardiac dysfunction, easy fatigability, and, occasionally, obesity, oral motor dysfunction, and impaired GI motility. Although significant intellectual impairment is not usual in DMD, IQ commonly averages 85; 30% of boys with DMD have an IQ below 70.[3] This finding is related to a loss of dystrophin in the brain and is more common with mutations in the region of exons 45–52.[6,52] Learning difficulties are reported in more than 40% and ADHD in almost a third of boys with DMD while cognitive impairment is found in both DMD and BMD although those with BMD appear less impaired.[21,45,285]

With the progression of muscle weakness, increasing caregiver assistance is required for people with DMD to carry out activities of daily living (ADLs). Progressive disability is a hallmark of DMD and requires multidisciplinary team management to maximize participation through the use of adaptive equipment and environmental adaptations.

Physical management is a key intervention in the treatment of DMD because no therapy has been found to be curative.[115,175,191,258] Physical therapy has been used to prolong the child's independence, slow the progression of complications, and improve quality of life.

DYSTROPHIN-ASSOCIATED PROTEINS AND MUSCULAR DYSTROPHY

Over the past 10 years, significant advances have been made in the molecular genetics and pathophysiology of the muscular dystrophies. These advances have followed identification of the genetic defect behind DMD and the missing protein dystrophin. The pathology underlying these diseases results from a fragility in muscle membrane stability during muscle contraction and relative muscle hypoxia as a result of an aberrant vascular response to exercise. This combination results in a progressive loss of muscle contractility caused by the destruction of myofibrils and replacement with fat and connective tissue that can be seen on muscle biopsy as characteristic dystrophic changes.

Dystrophin is present within the muscle cell and has functional attachments to both actin and the transmembrane proteins alpha and beta dystroglycan that allow the transmission of force to the extracellular matrix. These transmembrane proteins along with the sarcoglycans are termed *dystrophin-associated proteins (DAPs)*.[27] The DAPs form a complex of extracellular, transmembrane, and intracellular proteins, which are represented in Fig. 12.1.[54,118]

TABLE 12.1 Muscle Disease Characteristics

Type	Typical Onset	Inheritance	Course
Duchenne muscular dystrophy	1–5 years	X-linked	Rapidly progressive; loss of walking typically by 9 to 10 years; death in late teens
Becker muscular dystrophy	5–10 years	X-linked	Slowly progressive; maintain walking past 16; life span into third decade or beyond
Congenital muscular dystrophy	Birth	Recessive	Course dependent on specific genetics variable severity; shortened life span
Congenital myotonic dystrophy	Birth	Dominant	Typically slow with significant intellectual impairment
Childhood-onset facioscapulohumeral	First decade	Dominant/ Recessive	Slowly progressive loss of walking in later life; variable life expectancy
Emery-Dreifuss muscular dystrophy	Childhood to early teens	X-linked	Slowly progressive with cardiac abnormality and normal life span

Dystrophin and the DAP complex as a whole act as an anchor in the intracellular lattice to enhance and transmit tensile strength. The other proteins are thought to act as a physical pathway where various transmembrane signaling molecules anchor.[118] This includes alpha1 syntrophin, which is required for nitric oxide synthase regulation of muscle-specific adrenergic vasoconstriction allowing for appropriate adjustments in blood flow in the face of the metabolic demands experienced during exercise and daily activity. In addition, nitric oxide synthase, which impacts blood flow regulation, also binds with dystrophin. Alpha1 syntrophin also plays a role in regulation of sodium channels, which initiates calcium release and excitation-contraction coupling.[54]

Absence of dystrophin or any of the transmembrane proteins results in suboptimal integration of the complex as a whole and faulty mechanics of the cell membrane and intolerance of the mechanical forces that are experienced during muscle contraction.

DUCHENNE MUSCULAR DYSTROPHY

Background Information

The muscular dystrophies as a group have a prevalence of between 19.8 and 25.1 per 100,000.[259] DMD is the most common X-linked disorder known, with an incidence of about 1 in 3500 live male births.[187] The prevalence of DMD in the general population is reportedly between 1.7 and 4.2 cases per 100,000.[68,187,259] Initial diagnosis in families without a genetic history typically occurs around 5 years of age, although symptoms are often seen earlier and may be attributed to developmental delay.[51] Longevity is variable, from the late teens to the end of the third or into the fourth decade, depending on the rate of disease progression, the presence of complications, and the aggressiveness of cardiopulmonary care, including the use of assisted ventilation.[78]

In the late 1980s Kunkel and associates[141] identified the gene on the X chromosome (Xp21) that, when mutated, causes DMD and BMD; Hoffman and associates[116] then identified the protein (dystrophin). Cloning of the dystrophin gene was the next major accomplishment. These seminal accomplishments provided a mechanism for prenatal or postnatal diagnosis and the differentiation of DMD and BMD from other phenotypically similar limb girdle syndromes.[137]

Muscle cell destruction in DMD and BMD is caused by abnormal or missing dystrophin and its effect at the muscle cell membrane and associated proteins. Mechanical weakening of the sarcolemma, inappropriate calcium influx, aberrant signaling, increased oxidative stress, and recurrent muscle ischemia all combine as mechanisms associated with myofibril damage.[210]

The focus of research for the treatment of DMD is on exploring genetic or molecular, cellular, and pharmacologic therapies that either promote the production of dystrophin or diminish the secondary pathophysiologic consequences including hypoxia and fibrosis.[44,75,191] These interventions include gene- and cell-based replacement therapy, attempts to increase production of other dystrophin-related sarcolemmal proteins such as utrophin, and use of drugs such as steroids. All therapies are in the experimental stage, and the only one that is shown to modify the natural history of the disease is steroid therapy.

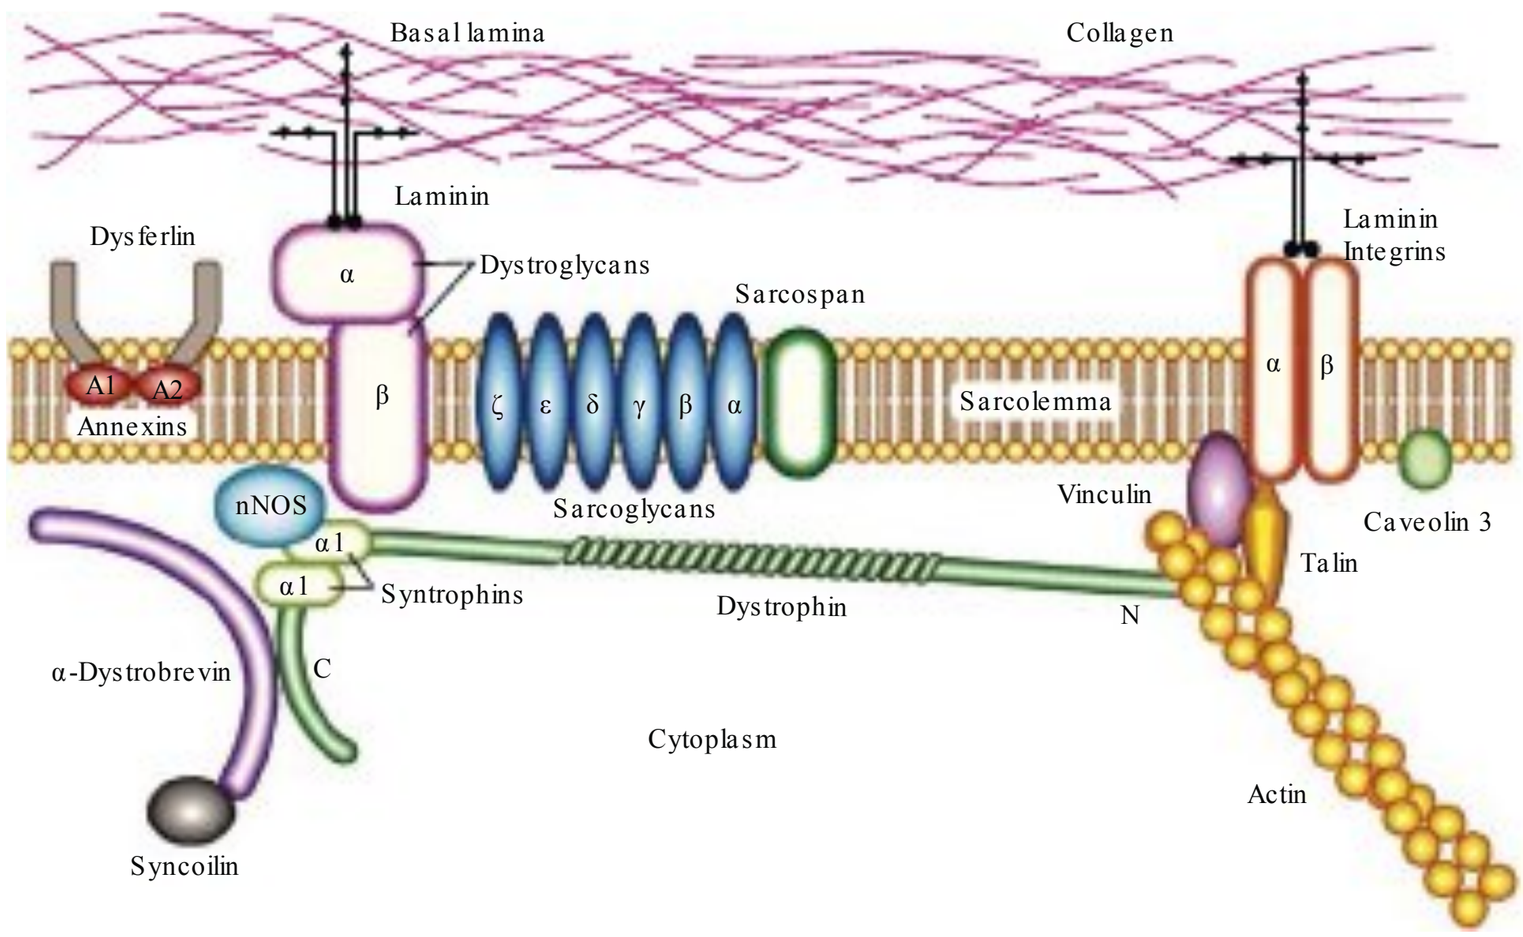

FIG. 12.1 Connections between the muscle cytoskeleton and the extracellular matrix. Actin is linked through integrins to the matrix, as in many cell types. Dystrophin forms an extra link through the dystroglycan-sarcoglycan complex of glycosylated proteins. The helical section of dystrophin is homologous to spectrin and may form homodimers or oligomers. Dystrophin links two intricate systems: the sarcolemma and the basal lamina. The COOH-terminus of dystrophin is associated with the sarcoglycans, dystroglycans, dystrobrevin, syncoilin, nNos, and the syntrophins. The NH 3-terminus links actin, vinculin, and the integrins with laminin and the basil lamina. These two adhesion systems provide a supportive substructure to maintain the integrity of the sarcolemma. The annexins and dysferlin have a role in muscle regeneration. (From Firestein GS, Budd RC, Gabriel SE, et al., editors: Kelley's textbook of rheumatology. 9th ed. Philadelphia, Saunders, 2013.)

Genetic therapy research involves exon skipping and stop codon readthrough. Exon skipping involves the use of medication that removes entire exons from the RNA that is used to make the final protein and medication for stop codon readthrough acts to make the ribosome ignore premature stop codon signals during reading of the RNA. Exon skipping with antisense oligonucleotides can cause the damaged exon to be excluded during the splicing process, removing the damaged exon and reestablishing the reading frame. When the abnormal exon is removed, the reading frame of the ribosome is reestablished and a partially functional protein is produced.[172] In the case of mutations that cause a stop codon, medications that promote the ribosome to continue reading despite the premature stop codon facilitate the production of dystrophin.

Another strategy for genetic therapy is the introduction of a custom-made mini dystrophin gene that is delivered in a viral vector. The gene must be modified because of dystrophins' large size so it fits in the vector. It is also important that it is modified to retain the functional binding domains of dystrophin but is small enough to be packaged in a virus. Pharmacologic approaches can focus on protein upregulation as a replacement for dystrophin; primarily these have focused on utrophin. Utrophin is a muscle protein that has molecular similarity to dystrophin. Utrophin levels in the muscle are high in the fetus and newborn but gradually diminish. Utrophin is found primarily at the neuromuscular or musculotendinous junction in adults and in children with DMD. Utrophin levels have been shown to increase in the mouse model of DMD through upregulation.[56,260] It is hypothesized that utrophin might act as a substitute for abnormal or missing dystrophin.[209] Upregulation of other compensatory proteins such as integrin and sarcospan has been reported in animal models, but human clinical trials have not yet begun.[158,191]

Pharmacologic approaches can also focus on ameliorating the downstream mechanisms that are at the heart of the impairment in individuals with DMD. This includes muscle fiber necrosis, fibrosis, and calcification in addition to muscle inflammation and hypoxia.[139] Currently there is preliminary support for the roll of tadalafil in alleviating muscle hypoxia in boys with DMD, and clinical trials are ongoing to evaluate the impact of this on function.[190] The use of creatine in boys with DMD has demonstrated improved muscle strength and endurance and a reduction in joint stiffness.[20,73,136,148] Louis and colleagues also reported improved bone mineral density in boys who were wheelchair users, suggesting that the negative effects of steroids on bone mineral density might be offset by the use of creatine. However, the impact is small: on the order of less than 9% in terms of muscle. Other downstream mechanistic targets are in various stages of evaluation and many show promise but have yet to reach clinical trials.

Long-term steroid use (prednisone and deflazacort) has been shown to improve outcomes, including prolonged walking by up to 3 years, improved isometric muscle strength by 60% in the arms and 85% in the legs when compared with untreated control subjects, and improved pulmonary function and possibly even cognitive skills.[22,24,28,115,175,229,284] Reported side effects, however, include weight gain (particularly with prednisone), growth suppression, cataracts, and osteoporosis. Strict dietary controls to offset the side effects are recommended.[284] Deflazacort is available outside of the United States, although it has not been approved by the FDA.

Although it is commonly agreed that the prevention of contractures and the preservation of independent mobility are primary goals of a physical management program,[266] the prolongation of ambulation through surgery remains controversial. Some authors promote the use of surgery and lightweight knee-ankle-foot orthoses (KAFO)[13,18,111,120,178,256]; others express skepticism about prolonging the inevitable in a progressive disease, when the financial and emotional costs to the family may be very high.[88] Evidence is available that the use of steroids and supported walking and standing with KAFOs are associated with reduced risk of scoliosis development and later onset of scoliosis.[134] A decreasing trend in the use of KAFOs from 69% of the MDA clinics surveyed in 1989 to 27% in 2000 has been reported[12] and would suggest a trend of less aggressive orthotic management in this population. Consistent recommendations regarding the use of KAFOs for prolonged walking or standing are important, and a recognition of and discussion of the characteristics of ambulation with KAFOs are often helpful in guiding the parents in this choice. Ambulation with KAFOs is always exercise ambulation and not functional because assistance will be needed transferring to and from standing.

Surgical management has focused on control of lower extremity contractures, use of orthoses in conjunction with surgery to prolong ambulation, and spinal stabilization for control of scoliosis. Achilles tendon lengthening and fasciotomy of the tensor fasciae latae and iliotibial bands are two procedures commonly reported to be used either in conjunction with KAFOs and physical therapy to prolong ambulation or maintain standing[13,81,105,120,155] or early in the course of the disease to correct initial onset of contracture. The latter approach has been accompanied by occasional loss of ambulation if the musculotendinous unit is overlengthened and ground reaction forces are diminished. Posterior tibialis transfer into the third cuneiform to reverse equinovarus deformity has also been reported.[120]

Surgical management of scoliosis typically includes the use of spinal instrumentation with segmental fixation.[157] With the increased prevalence of steroid treatment, the incidence of scoliosis has declined[142]; however, boys with DMD still have an increased risk of developing severe scoliosis.[217] Orthotic management has not been shown to stop the progression of the curve,[112] but fusion to avoid development of a significant curve may allow some functional benefit related to sitting balance and comfort.[134,252] For many boys, spinal fusion is also met with some functional challenges that the physical therapist needs to be aware of and address proactively. All boys have a lack of spinal motion as a result of the fusion, and often when they rely on spinal (and neck) flexion to bring their mouth to their hand when feeding this can be a challenge following surgery and use of a ball bearing feeder, of which there are many kinds. Some feeders have elastic properties that drive a 4-bar linkage to unweight the arm, like the Wilmington Robotic ExoSkeleton, and to assist with antigravity movement while others are of a more basic design.[74,110] Ball bearing feeders are helpful following surgery and should be in place prior to spine surgery so that the individual can become accustomed to use of the device.

Impairments, Activity Limitations, and Participation Restrictions

Examination of the 4- to 5-year-old child demonstrates the onset of classical clinical features of DMD and primary impairment of muscle weakness. The posterior calf is usually enlarged as a result of fatty and connective tissue infiltration, which is the origin of the term *pseudohypertrophic muscular*

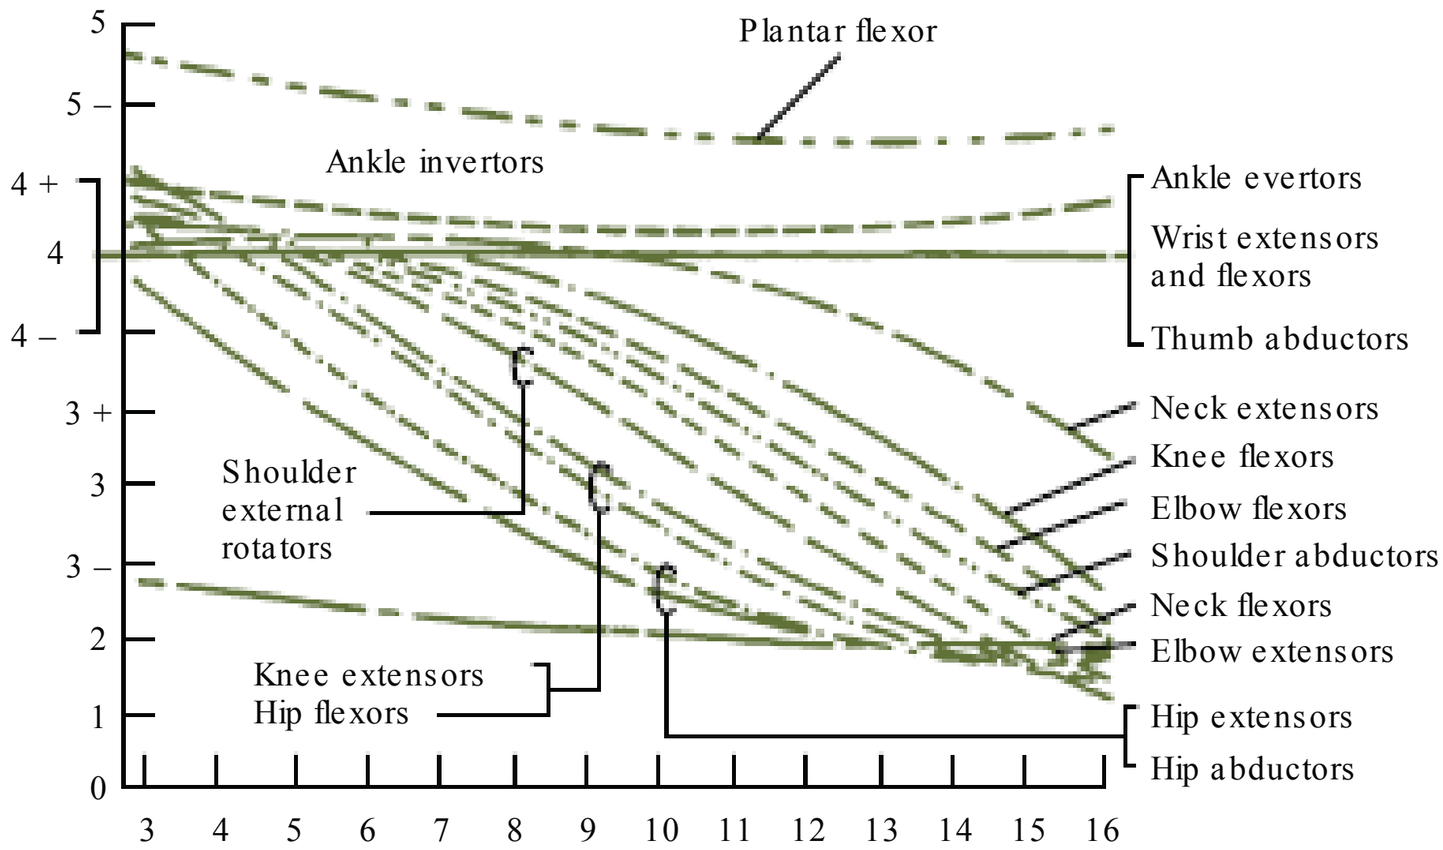

FIG. 12.2 Muscle strength 50th percentile lines plotted against age of 150 children with Duchenne muscular dystrophy (Redrawn from Brooke, MH: A clinician's view of neuromuscular diseases. 2nd ed. Baltimore, Williams & Wilkins, 1986.)

dystrophy. Pseudohypertrophy occasionally can be seen to affect the deltoid, quadriceps, or forearm extensor muscle groups. Initial weakness of the neck flexor, abdominal, interscapular, and hip extensor musculature can be noted, with a more generalized distribution with progression of the disease. Fig. 12.2 demonstrates the trends of muscle strength decline up to age 16 years from a study by Brooke.[34] These data were obtained in a multiclinic study of 150 children with DMD over a follow-up period of 3 to 4 years. The data represent approximately 15 data points per boy, as recorded during follow-up visits. Similar findings on anthropometric data, range of motion, spinal deformity, pulmonary function, and functional skills were reported by McDonald and colleagues[167] in a cohort of 162 boys with DMD followed over a 3-year period and for the 6-minute walk test and dynamometry in over 400 boys.[96,166]

Muscle strength can be documented using manual muscle testing (MMT), which has been reported to have acceptable intrarater reliability,[80] although it is not as sensitive as using specialized devices such as a dynamometer. Instruments such as a handheld dynamometer[248] or strain gauge devices[37] can be used to obtain objective strength recordings in the older child to assist in monitoring the progression of the disease process. Timed functional activities have also been shown to be closely correlated to muscle strength and are predictive of loss of ambulation. Ten-meter walk/run time more than 9 seconds and inability to rise from the floor predict loss of ambulation within 2 years, and a 10-meter time of more than 12 seconds predicts loss of ambulation loss within 1 year.[164]

No limitations in range of motion (ROM) are typically noted before 5 years of age in DMD. Mild tightness of the gastrocnemius-soleus and tensor fasciae latae muscles usually occurs first. The normal lordotic standing posture is increased, and mild winging of the scapulae is then seen as compensation to keep the center of mass behind the hip joint to promote standing stability (Fig. 12.3). Scoliosis typically develops just before or during adolescence.

FIG. 12.3 A patient with typical Duchenne dystrophy; notice prominent lordosis and winging of the scapulae and mild calf muscle enlargement. (From Bertorini TE: Neuromuscular case studies. Philadelphia, Butterworth-Heineman/Elsevier, 2008.)

Foreground Information

Management Considerations

An international collaboration recently published a consensus document on the management and outcome measurement for patients with DMD.[39,40] More specific information related to

BOX 12.1 Evidence-Based Tests and Measures

Duchenne Muscular Dystrophy

Body Functions and Body Structures
Goniometry
Handheld myometry
Manual muscle testing
Quantitative muscle testing (for DMD)
Pulmonary function testing

Activity: Single Task
6-minute walk test
Timed testing (10-m walk/run, time up 4 steps, timed Gowers', timed sit-to-stand)
9-hole peg test

Activity: Multiple Items
Northstar ambulatory assessment
The Performance of Upper Limb for Duchenne
Motor function measure

Pediatric Evaluation of Disability Index
PEDS QL
Egen Klassifikation Scale

physical therapy management by age and progression follows. See Box 12.1 for key tests and measures.

Infancy to Preschool-Age Period. Impairments, activity limitations, and participation restrictions typically seen in the infant or toddler with DMD are related to delayed development. Gardner-Medwin[89] reported that half of the children fail to walk until 18 months of age. Delay in walking, however, rarely leads to the diagnosis of DMD. Symptoms of obvious weakness are seldom noted before age 3 to 5 years unless the family history is positive and caregivers are looking for early signs. The mean age at diagnosis is usually reported to be around 5 years.[178]

Although no significant disability occurs in early childhood, many disability-related issues must be addressed. The family will have questions regarding peer interaction, routine activity level for the child, and the prognosis. The therapist must be aware of each family's coping response, goals, and needed supports, to provide family-centered care. This is the appropriate time to discuss with the family the social aspects of the disability and to answer questions without portraying a future without hope. Given the established natural history related to contracture of the ankle anticipatory guidance related to early night splinting and range of motion can be considered at this time.

Early School-Age Period. Initial limitations in activity in DMD typically become more apparent by age 5 years and include clumsiness, falling, and inability to keep up with peers while playing. The young child's gait pattern is only slightly atypical, with an increased lateral trunk sway (compensated Trendelenburg). Attempts at running, however, accentuate the waddling pattern, and running is marked by a high step pattern with limited push off. Gowers' sign (through plantar grade using the arms to push on the thighs to attain standing) is usually present when the child transitions from the floor to assuming a standing position (Fig. 12.4).

Stair climbing and arising to standing from the floor become progressively more difficult and signal the first significant functional limitation by age 6 to 8 years. Progressive changes in the gait pattern include deviations of an increased base of support, pronounced lateral trunk sway (compensated Trendelenburg), toe-walking, and lordosis with retraction of the shoulders with lack of reciprocal arm swing. Toe-walking initially may be a compensation for weakness of the abdominal and hip extensor muscles or may be related to limited ankle range of motion and the inability to attain a comfortable plantar grade posture. A restrictive pattern of pulmonary impairment and progressive decline in maximal vital capacity also becomes increasingly evident.[87]

Physical therapy management typically begins when the child is initially diagnosed at age 3 to 5 years. Goals of the program are to provide family support and education, obtain baseline data on muscle strength and ROM, monitor for the progression of muscle weakness that will lead to limitations in activity and participation, and, most importantly, maintain flexibility. Initial therapeutic input should not be burdensome to the child or family and is typically limited to ankle stretches and night splinting because the child is usually independent in all ADLs before the age of 5 years.

Information should be provided to the family pertaining to the therapist's role as a member of the management team. An appropriate activity level to avoid fatigue should be discussed with the family and school staff. Information on services available through the local MDA office should be provided, including identification of support groups or contact families.

Strength and exercise. Muscle weakness is apparent in the school-age child by age 6 to 8 years and should be objectively documented using a handheld dynamometer,[248] electrodynamometer,[228] isokinetic dynamometer,[180,231] or other device. Use of a dynamometer in conjunction with manual muscle testing has been shown to provide reliable information on the progression of weakness in key muscle groups.[37,83,248] Contracture development should be documented using goniometry and a standardized protocol. Intrarater reliability of measurements has been shown to be acceptable in

FIG. 12.4 Gowers' sign in a boy with hip girdle weakness due to Duchenne muscular dystrophy. When asked to rise from a prone position (A), the patient uses his hands to walk up his legs to compensate for proximal lower extremity weakness (C–D). (From Kliegman RM, Stanton B, St. Geme J, et al., editors: Nelson textbook of pediatrics. 20th ed. Philadelphia, Elsevier, 2016.)

providing objective information for program planning when a standardized measurement protocol is used.[199]

The role of exercise in the treatment of DMD is controversial.[7,8,82,104,266] It is widely accepted that both eccentric strenthening[48,121,125,269] and immobilization[269] are detrimental. The use of graded resistive exercise has been reported to have a range of results from good[268] to limited[59] to adverse.[7] Resistive exercise theoretically would be indicated with the disproportionate loss of type II (fast-twitch) muscle fibers in DMD.[67] However, the use of resistive exercise in the young school-age child with DMD should not be universally prescribed. An early submaximal endurance exercise program has been shown to have beneficial effects.[84,97] However, the optimal characteristics of exercise and intensity are not well understood and such an approach should be offered only to families who have a specific desire to include it in the child's program.[123] Consideration should be given to the fact that significant muscle weakness is not seen in the early stage of the disease, and the use of an exercise program may be burdensome to the child and family.

If exercise is initiated early, the key muscle groups to be included are the abdominal, hip extensor and abductor, and knee extensor groups. Cycling and swimming are excellent activities for overall conditioning and are often preferred over formal exercise programs.[3,8,89,124,266] Standing or walking for a minimum of 2 to 3 hours daily has also been recommended.[240,286] High-resistance and eccentric exercise should be avoided; however, the characteristics required to optimize exercise are clearly still controversial.[7,8,9,43]

Range of motion. One of the primary considerations in the early management program of the young school-age child is to slow the development of contractures. Contractures have not been shown to be preventable, but their progression can be slowed with positioning and a ROM program.[122,232,234,283] The initial ROM program should include stretching the gastrocnemius-soleus and, later, the hamstrings and tensor fasciae latae. Progressive contracture of the gastrocnemius-soleus and tensor fasciae latae corresponds to gait deviations of toe-walking and increased base of support. Stretching for the gastrocnemius-soleus for older children can be done using a standing runner's stretch. The child stands on a supportive surface, places one leg back at a time with the knee straight, and leans forward. The position also assists with maintenance of hip flexor flexibility; however, specific stretching for the hip flexors should be included when any limitation is noted. Having the child lie supine with one thigh off the edge of a mat or bed and the other held to the chest (Thomas test position) can be used to stretch the hip flexors initially. An alternative method is discussed later for use as progression of hip extensor weakness evolves. A standing stretch for the tensor is accomplished by having the child stand with one side toward the supportive surface with the feet away from the wall and with the knee kept straight while leaning sideways toward the supportive surface.

A home ROM program should be emphasized for the young child, and the family should be instructed in the stretching activities because self-stretch in young children is often not effective. Agreement is lacking as to the frequency and duration of the stretching program. Suggested frequency of the program varies from once daily[89,178,232] to twice daily,[269,286] and duration from 1 repetition up to 10; however, total end range time is likely an important factor as well.[269] Other authors have suggested a time frame of 10[283] to 20[89] minutes to complete the stretching exercises. As a general recommendation, each movement should be repeated for five repetitions with a 30- to 60-second hold in the stretched position. The stretch should be done slowly and should not be painful. A good rule is to use the child's tolerance to guide the program because stretching needs to be a continuous process over the life span. Developing a good relationship with the child and allowing him or her a degree of control over what can be at times uncomfortable are important factors in successful implementation. Reassessment of the contracture progression should be used as the final guide to stretching frequency and duration.

The ROM program can often be part of the physical education program at school. Instruction should be provided to the physical education teacher to develop an adapted program, particularly if the teacher does not have an adapted physical education endorsement. General physical education activities will require modification for the child's participation and should not be exhaustive. Physical fitness test activities such as push-ups, sit-ups, or timed running for long time periods should be modified or excluded to avoid fatigue or overwork weakness.

Night splints are helpful for slowing the progression of ankle contractures and should allow positioning at comfortable end range. Scott and associates[232] studied the efficacy of night splints and a home ROM program in a group of 59 boys diagnosed with MD and ranging in age from 4 to 12 years. Subjects were categorized into three groups on the basis of adherence with splint wear and use of stretching. The group that followed through on the daily passive stretching program and the use of below-knee splints over the 2 years of the study demonstrated significantly less progression of Achilles tendon contractures and less deterioration in functional skills, leading to a longer period of independent walking. Boys in the group who did not follow through on the stretching or splint program lost independent walking at a younger age. In a randomized study comparing the effects of ROM exercise versus ROM and night splints, the combined intervention was found to be 23% more effective than ROM alone in slowing the progression of posterior calf contracture.[122] Similar findings were reported in a study by Seeger and colleagues,[234] which compared the use of night splints, stretching, and surgery. For those who are unable to adhere to night splinting and stretching regimens, serial casting is an option to improve range of motion. However, one must be cognizant of the fact that the gain in range of motion in this population is slower and the risk of tendonitis and falls is greater than other populations that use serial casting. Therefore it should be reserved for individuals who are relatively more functional and can rise from the floor without assistance.[92,153]

The use of prone positioning at night to slow the progression of hip and knee flexion contractures may be possible if tolerated by the child. The recommendation to have the child sleep prone with the ankles off the edge of the bed has not been shown to affect the progression of knee flexion contractures but is theoretically beneficial. Additionally, the progression of knee flexion contractures is slow prior to loss of ambulation and therefore generally does not impact function until the child is using a wheelchair full time.

Respiratory function and spinal alignment. A clinical estimate of respiratory function can be obtained through measurement of respiratory rate and chest wall excursion (using a tape measure) and by noting the child's ability to cough and clear secretions. A portable spirometer is recommended to obtain a more direct and objective reading of expiratory capacity before formal pulmonary function testing is needed. Breathing exercises have been shown to slow the loss of vital capacity and forced expiratory flow rate.[138,160,222] Game activities such as inflating balloons or using blow-bottles to maintain pulmonary function can easily be included in a home program and will decrease the severity of symptoms during episodes of colds or other pulmonary infections. Inspiratory muscle training has also been investigated in patients with DMD and has good support in the literature with short-term follow-up.[261]

Scoliosis is not common when the child is ambulatory, but the spine should be checked routinely.[134] Kinali and associates[134] report an incidence of scoliosis ranging from 68% to 90% in boys with DMD who are not on steroids. Onset is typically seen after cessation of standing at around 12 years; however, this has become significantly more variable with the increased use of steroids in this population and many boys don't develop scoliosis. Postural analysis using the forward bend test is recommended to monitor spinal alignment for scoliosis. The presence of a rib hump with the forward bend test verifies a structural versus functional curve of the spine. Amendt and colleagues[1] demonstrated that a rib hump measuring at least 5° of inclination with a scoliometer is a reliable method and can be correlated with radiographic assessment. Although the study by Amendt and colleagues[1] was not inclusive of children with DMD, it demonstrates an objective method of performing noninvasive screening for scoliosis. Orthopedic referral is indicated if a rib hump is documented. Surgical intervention for scoliosis is ideally completed while the curve is still flexible and pulmonary function relatively intact and may not be possible for individuals when vital capacity values fall below 30% of age norm values.[156]

Functional mobility, equipment, and participation. An examination to document limitations in activity and participation is essential. Various formats have been reported[245,270] that are variations of the guidelines initially published by Swinyard and associates.[255] A classification system published by Vignos and colleagues[269] is outlined in Box 12.2. A more detailed examination format for DMD published by Brooke and associates[35] includes pulmonary function and timed performance of activities, the latter of which along with the 6-minute walk test (6MWT) (see Chapter 2) has become a standard measurement tool in patients with DMD.[201] Normative data for DMD have been published using the clinical protocol of Brooke and associates.[34] A similar assessment called the North Star Ambulatory Assessment (NSAA) has been devised and reliability established for use in multicenter clinical trials.[60,163] The assessment tool chosen will depend on the diagnosis because tools vary in their responsiveness depending on the rate of progression and pattern of progression of the various types of muscular dystrophy.[39,149] Other functional assessment tools, such as the Performance of Upper Limb (PUL) for DMD, Pediatric Evaluation of Disability Inventory (PEDI)[107,200] (see Chapter 2), the School Function Assessment (SFA)[55] (see Chapter 2), the Egen Klassifikation (EK) Scale,[245] or the Barthel Index,[189] should also be considered to obtain more specific information on the child's functional skills. The EK Scale, which was recently validated for DMD and SMA, includes ordinal scoring of 10 categories, including items on mobility, transfers, ability to cough/speak, and physical well-being and reflects the untreated natural history of the disease. The PEDI, the SFA, or

BOX 12.2 Vignos Functional Rating Scale for Duchenne Muscular Dystrophy

1. Walks and climbs stairs without assistance
2. Walks and climbs stairs with aid of railing
3. Walks and climbs stairs slowly with aid of railing (over 25 seconds for eight standard steps)
4. Walks, but cannot climb stairs
5. Walks assisted, but cannot climb stairs or get out of chair
6. Walks only with assistance or with braces
7. In wheelchair: Sits erect and can roll chair and perform bed and wheelchair ADLs
8. In wheelchair: Sits erect and is unable to perform bed and wheelchair ADLs without assistance
9. In wheelchair: Sits erect only with support and is able to do only minimal ADLs
10. In bed: Can do no ADLs without assistance

the Vignos (Brooke) functional testing format can be used for diagnosis of other types of MD or SMA.

Falls and complaints of fatigue while walking become increasingly more frequent as the child reaches age 8 to 10 years. Guarding during stair climbing or during general walking should be considered to ensure safety as balance becomes tenuous. As weakness progresses it is important to maintain an open dialogue with the family regarding the risk of falls and potentially fractures. This discussion should also focus on the risks of restricting mobility to prevent falls, recognizing the disuse atrophy that can accompany restriction beyond what is necessary for safety. Each parent will balance the risks and benefits of end-stage ambulation differently and needs to be supported through this process. A manual wheelchair, stroller, or scooter with appropriate fit and accessories will allow for limited mobility as walking becomes more difficult. As progression of weakness in the trunk and hip girdle begins to make walking difficult, a similar amount of weakness of the shoulder girdle musculature is also present, making propulsion of a manual wheelchair difficult, except on level and smooth surfaces such as linoleum. A motorized scooter should be considered to provide the child with independence provided that access is available in the home and school (Fig. 12.5). Ideally a scooter (or stroller) is obtained well in advance of loss of ambulation, when there are many years of walking ahead. It is often used for long community trips and should be considered when the family begins to select options for entertainment based on what activities the child has the endurance to participate in. When this is the case, a mobility device can help the child regain access to those marginal activities, which is emotionally positive for the child and family because loss of ambulation is not a risk at that stage.

Information should be made available to families concerning recreational activities provided through the local chapter of the MDA or other groups. Summer MDA camp is a wonderful experience for most children, and a support group is often developed for the child or family through participation in MDA and other group activities that provide both physical and emotional support (Boxes 12.3 and 12.4).

Adolescent Period. Adolescence marks a time of significant progression of physical symptomatology that results from the combined impact of muscle weakness and contractures. Walking is typically lost as a means of mobility, and increasing difficulty in mobility and transfers is seen. Use of powered mobility becomes necessary during adolescence. When powered mobility is used, assistance with finances for the purchase of equipment or home modifications for access is typically needed, with coordination through a social worker or an MDA patient services coordinator. Many MDA offices have equipment pools that allow families to borrow equipment, including power chairs, at no cost. Changes in physical capacity such as muscle strength and pulmonary function using the EK Scale have been reported among adolescents by Steffensen and colleagues.[244] Muscle weakness leads to increasing difficulty with ADLs, including dressing, transfers, bathing, grooming, and feeding. Physical and occupational therapists can help during this time by providing adaptive equipment or alternate strategies. Surgical intervention may be considered for the management of scoliosis[47] or contractures or to prolong exercise ambulation with the use of orthoses if this is the family's choice.[18]

Exercise and range of motion. With the cessation of walking in late childhood or early adolescence, the emphasis

BOX 12.4 Evidence-Based Interventions for Children With DMD

Body Functions and Body Structures

Stretching
Night splinting at end range
Concentric endurance exercise (pool, bike, non–weight bearing)
Inspiratory muscle training
Cough assist/BiPAP with respiratory insufficiency (per pulmonary)
Percussion and postural drainage (with upper respiratory infection)

Activity

Standing program prior to or at cessation of ambulation
Mobile arm support with feeding difficulty or prior to spinal fusion

Participation

Power mobility
Environmental modification
Ramps
Bathroom adaptation or equipment
Van with lift/tie down
Assistive tech for computer access (onscreen keyboard dictation programs etc.)
Adapted gym/sport activity

of an endurance exercise program should shift from the lower extremities to the upper extremities. More important, however, active endurance exercise should be encouraged by having the adolescent assist as much as possible in ADLs such as grooming, upper body dressing, and feeding through consultation with an occupational therapist and by either a pool or upper extremity ergometry program.[3] Key muscle groups for maintenance of strength for transfers include the shoulder depressors and triceps. The shoulder flexor and abductor and elbow flexor muscle groups are key areas for exercises to maintain routine ADLs such as self-feeding and hygiene. Weakness of the upper arm musculature by 16 years of age makes ADLs extremely difficult, and consideration of mobile arm support is important when these activities are effortful in advance of a complete inability to participate in feeding and grooming.

The ROM program will require further modification as the adolescent becomes nonambulatory. Gentle stretching of the ankle, hamstrings, hip flexors, and iliotibial band that were initiated in the school-age child should be continued to maintain flexibility. Additionally, stretching of the long finger flexors, shoulder, and elbow should be included as indicated. Limitations in shoulder flexion and abduction, elbow extension, forearm supination, and wrist extension are most common.

Once ambulation is lost, the focus of manual stretching often needs to shift. Contracture of the ankle and knee that typically accompanies the loss of ambulation can be diminished with the use of a standing program, and splinting can be used either in the daytime or night depending on preference. Contractures should continue to be monitored to ensure that they do not become an obstacle to routine ADLs, and the focus of the range of motion and splinting programs needs to be shifted to maintaining upper extremity flexibility and functional skills. Typical upper extremity contractures that begin to develop at this stage include the forearm pronators, elbow flexors, and long finger flexors. Later in the course of the disease the thumb adductors also become affected. The shoulder musculature is also at risk for contracture but is much less functionally relevant due to the severe proximal weakness that is present. However, maintenance of shoulder ROM might be important in the context of any shoulder pain that might develop later in the course of the disease.

Respiratory function and spinal alignment. Maintaining the spine in a neutral or slightly extended position is essential to slow the formation of a scoliosis. The spine should be in slight extension to increase weight bearing through the facet joints, minimize truncal rotation and lateral flexion, and slow the progression of scoliosis formation.[90] The lordotic posture in the ambulant child is suggested to delay development of spinal collapse, and prolonging ambulation can slow the development of scoliosis.[119] Spinal orthoses have not been shown to prevent development of a significant scoliotic curve.[41,53] Custom-molded seating inserts, corsets, and modular seating inserts are options to provide trunk support in an attempt to slow the progression of the scoliosis. However, studies comparing the three methods of spinal control in DMD have concluded that the progression of the curvature was not significantly changed by any of them.[53,235]

With the use of corticosteroids the risk of developing scoliosis that requires surgical intervention has been reduced from 90% to only 15% to 20% of patients.[119,142] When necessary, early surgical intervention is recommended for the control of scoliosis through the use of segmental spinal instrumentation with Luque rods or similar techniques.[157,177,237] Miller and associates[177] have reported improved quality of life, attainment of a balanced sitting posture, and more normal alignment following surgical intervention for scoliosis.[119,142,143] Suk and colleagues[252] have reported reduced rates of pulmonary function decline following spinal fusion as compared to no surgical intervention. Pulmonary complications are reported as minimal if forced vital capacity is at least 30% of normal age-predicted values.[5]

Continuation of standing or walking. As muscle weakness becomes more pronounced in the trunk and hip musculature and as contractures of the hip flexors, tensor fasciae latae, and gastrocnemius-soleus progress, walking becomes increasingly difficult until cessation of independent walking occurs, usually by age 10 to 12. If orthoses or a stander is used to maintain a standing or walking program, it should be initiated before the child reaches the stage of being nonambulatory. If a stander is the choice, one might consider ordering one when the 10-meter walk time falls below about 9 seconds so that the child can begin a standing program prior to the loss of ambulation.

The use of orthoses for a standing program or continuation of supported walking is not appropriate for all individuals; in fact, this should be considered a personal rather than a therapeutic decision. Although a standing program may be useful to slow the progression of contractures, a braced walking program has little long-term functional or practical application aside from contracture prevention. The child will eventually use a wheelchair, so it is often easier for the child to accept this transition rather than hold on to ambulation when it is no longer functional. Continuation of standing through use of a standing frame, knee immobilizers, or KAFOs is a goal at our facility to address the issue of decreased bone mineral density[168] and subsequent increased risk of contracture and fracture.[23] Because surgery is often required in addition to orthotics for prolonged ambulation, there are additional risks associated with this option. The parents and the adolescent must agree to balance these risks with a realistic informed view of the characteristics and functionality

of ambulation that will be gained. Prolongation of ambulation through surgery and orthotics is not a common goal. More typically, power mobility, adaptive equipment, and environmental adaptations provide for a more functional experience and tend to optimize quality of life.

Prognostic factors for success that should be considered in making the decision to use orthoses to prolong walking include residual muscle strength (approximately 50%)[266]; absence of severe contractures; timely application of braces[13]; residual walking ability[267]; and motivation of the child and family.[32] The degree of cognitive impairment and obesity should also be considered. The timely use of orthoses has been shown to prolong walking.[13,32,111]

If the decision to use orthoses to prolong standing or walking is made, KAFOs should be prescribed (Fig. 12.6).[18,32] The characteristics of ambulation with KAFOs should be reviewed with the patient and family including the need for assistance with transferring from sitting to standing so that an informed choice can be made before pursuing these devices. Ankle-foot orthoses (AFOs) are appropriate for positioning but do not provide the knee stability required to avoid falls while walking. Although the use of AFOs to control equinus is common for other diagnoses such as cerebral palsy, with DMD the orthoses often interfere with walking speed and step length.[263] Assistive devices such as standard walkers, crutches, or canes are seldom functional because of the degree of proximal shoulder girdle and upper extremity muscle weakness that is present. Standby assistance should be provided when KAFOs are used owing to the risk of injury from falls. Closer guarding and increased assistance will be needed as the weakness progresses. Transfers to and from standing are dependent because the knee joints of the KAFO must be locked to provide stability. KAFOs or standers that can accommodate ankle, knee, and hip contractures and allow for a lateral transfer in sitting and a transition to standing in the device can be used for continuation of a standing program even after walking is no longer possible.

FIG. 12.6 Polypropylene knee-ankle-foot orthosis on two brothers (ages 12 yr and 9 yr) with Duchenne muscular dystrophy. They had continued ambulation in orthoses 2 years and 6 months, respectively, after provision of orthoses. (From Dubowitz V: Deformities in Duchenne dystrophy. Neuromuscul Disord 20[4]:282, 2010.)

The patient may prefer surgical intervention and braced ambulation. Indications for surgery include ankle plantar flexion contractures greater than 10°, iliotibial band contractures greater than 20°, or knee-hip flexion contractures greater than 20° but less than 45°.[32] Subcutaneous tenotomy of the Achilles tendon or more commonly gastrocnemius facia lengthening and fasciotomy of the iliotibial bands are the most commonly reported surgical procedures.[13,32,120,266] Transfer of the posterior tibialis tendon is occasionally used for correction of equinovarus foot posture.[120,230]

An intensive postoperative management program is essential to minimize the effects of immobilization.[241] Standing in the plaster casts can be done on the first or second postoperative day. Gait training is begun as tolerated, and general conditioning exercises for the hips, trunk, and upper extremities are recommended. Breathing exercises and aggressive pulmonary management should also be stressed with any surgical procedure to minimize the chance of postoperative atelectasis and pneumonia.[179] A smooth transition to bracing is ensured by having the child fitted for the KAFOs before hospitalization for surgery.

Functional mobility and equipment. Various methods to predict the termination of walking have been reported, including 50% reduction in leg strength,[231,267] manual muscle test grade below grade 3 for hip extensors or below grade 4 for ankle dorsiflexors,[167] or inability to climb steps. Brooke and colleagues[34] reported the cessation of unassisted walking within 2.4 years (range, 1.2–4.1 years) when 5 to 12 seconds was required to climb four standard steps, or within 1.5 years (range, 0.6–2.2 years) when longer than 12 seconds was required. Monitoring and management of contractures become a key element in maintaining walking when the older child spends more time in a sitting position. Because the hip extensor musculature is significantly weak in the early stage of the disease and weakness of the quadriceps muscles becomes pronounced by age 8 to 10 years, inability to maintain the center of gravity behind the hip joint or in front of the knee joint during stance will lead to loss of the ability to stand.

Standing pivot transfers eventually will be replaced by one- or two-person lifts or use of a patient lift because of the development of knee and hip flexion contractures and the pronounced weakness of the lower extremities. Transfers to and from the wheelchair, toilet, tub, car, and furniture usually become dependent shortly after the loss of ambulation. A sliding board typically is not functional due to the significant upper extremity weakness, and hydraulic lift can help during transfers. Parents typically prefer manual lifting with either a one-person or two-person lift for as long as one of them is able. Despite this, having an hydraulic lift in place so both parents can participate in transfers or in case one parent becomes injured is important to consider. Proper instruction for transfers is also needed because the degree of trunk muscle weakness makes sitting balance more and more tenuous as the child ages. If the

caregiver is using manual lifting for transfers, he or she should be observed for and instructed in proper body mechanics and safety. A hydraulic lift can be used for transfers to and from the wheelchair, particularly when the adolescent is large or obese or when the caregiver cannot safely perform a manual lift. A U-style divided leg sling with headrest extension should be used with the lift to provide adequate head and trunk support during transfers and to allow the sling to be removed from under the child after the transfer.

Hydraulic lifts cannot be used for transfer to the tub or shower. If the parents are unable to lift the child to a bath bench, either a dedicated tub lift or sliding-style shower commode that can roll over the toilet and then attach to a base in the shower or tub and slide onto the secondary base for bathing can provide a solution for limited bathroom transfers. Some families will have the resources to construct a barrier-free shower for bathing for which they will need a wheeled rehabilitation shower commode. Depending on bathroom accessibility and the amount of renovation that is done, a review of the bathroom size and layout is necessary to ensure that the chosen equipment will fit in the existing space. Many bathrooms are small, and sliding-style shower commodes do not fit, so alternative systems may need to be considered.

A power scooter like the one shown in Fig. 12.5 should be considered as an initial power wheelchair prescription for the child who is having difficulty for longer distances in the community. This transition is often easier when ambulation is still secure and limitations are related to endurance. The power scooter can be presented as an opportunity to access social and community activities that the child no longer chooses to participate in because ambulation has become limited either from a stability or endurance point of view. Because the child no longer chooses to participate in the activities, he or she will be less concerned with substituting power mobility for ambulation and more accepting of now having access to an activity that he or she has since abandoned. The scooter is also often more easily accepted by the child and may be used as an initial step in the transition to a standard power wheelchair because it can fold and stow in the trunk of a car. One needs to be aware that the scooter will not be able to be used for transport on a bus to and from school, and the child will need to be able to transfer out of the scooter to a standard bus or car seat or obtain a wheelchair that is crash tested for transit. If a power scooter is used initially, transition to a power wheelchair will be necessary when the adolescent is seen propping on the arm rests for trunk control or is no longer able to maintain contact with the tiller to drive. Asymmetric sitting postures should be aggressively managed owing to the correlation of increased sitting time and asymmetric sitting posture with the onset of scoliosis.

A manual wheelchair or stroller can be considered as a backup to the primary power mobility device if resources allow and can be used for nonaccessible areas in the usual environment. Architectural barriers in the home or inability to transport a power wheelchair may also necessitate the use of a manual wheelchair, manual wheelchair with power assist, or a scooter, all of which can be stowed in the trunk of a car. However, ramps or lifts for the home are the best long-term solution to accessibility barriers because they allow full use of the power wheelchair. Additionally, if an adapted van is not available, an alternative device as a backup should be considered and is often available through insurance or as a loaner from some parent organizations such as the MDA.

Fit of the wheelchair must be closely monitored to provide adequate support. The reader should refer to Chapter 33: Assistive Technology for information on wheelchairs and postural support systems. Special attention should be given to alignment of the spine and alignment and pressure relief for the pelvis. Accessories to be considered for the manual or power wheelchair prescription should include a solid back and seat, lateral trunk support on the side of the joystick, adductor pads, seat belt, and chest strap. The angle adjustable footrests should be modified to support the ankle in a neutral position. Additional items that may be appropriate include a tray, head support, or coated push rims, if the child has the strength to propel the wheelchair. A reclining back will allow a position change for toileting or changing while sitting in the wheelchair and will help deter flexion contracture formation at the hip, and a tilt-in-space option can be considered to allow for pressure relief. Midline placement of the control stick on a power wheelchair may be considered to assist in symmetrical trunk alignment if the child chooses to have a tray in place most of the time. However, many children will prefer to have a joystick with a quad link mount that they can push out of the way, allowing them to roll up to a table.

The seating evaluation should start with the base of support and evaluation of the pelvis. It is important to note where the weight line falls within the base of support and how this impacts pressure distribution. The patient's weight line must be assessed both in the frontal and sagittal plane; this becomes more critical the weaker the boy and the more tenuous the head control becomes. The younger patient who has relatively good sitting balance will do well with a cushion with a foam base and flow lite pressure-relieving gel. For individuals in the later stage of disease or those with more rigid pelvic obliquity, often the high side of the pelvis will need to be supported either with a foam obliquity insert in the cushion or with an air-filled cushion that allows the four quadrants of the cushion's pressure to be adjusted. This will provide for accommodation of the fixed pelvic deformity, as might be the case following spinal fusion. In the sagittal plane, most boys will sit forward with an anterior pelvic tilt that allows them to rely on the contracted posterior neck ligaments to aid in head control. This forward posture also aids in allowing the patient to shift his weight because there is no friction with the wheelchair back and the patient's center of gravity is directly over the base of support. Some boys will prefer a chest strap to lean on while others will need this only for stability around corners in a vehicle. It is important to recognize this is not a crash-tested restraint and that the wheelchair and child need to be secured in the vehicle with an appropriate crash-tested restraint.

Management of lower extremity positioning in the wheelchair needs to account for the tendency for patients to assume a hip-abducted, ankle planovarus posture. The use of hip adductors mounted on the wheelchair to maintain alignment is important, and footrests that allow plantarflexion adjustment are also helpful. The headrest is less critical and typically is used only when the tilt function of the wheelchair is accessed unless the patient sits back in the chair.

The family will need to consider additional equipment or home modifications as the child reaches adolescence. A van with a lift or ramp will be needed to transport a power wheelchair. Modification of the bathroom can significantly assist the family when a wheeled commode chair is used for toileting and bathing with a handheld shower. A slider-style

bath system is a second option for bathing. Both systems will allow the child to use a mechanical lift in the bedroom, roll over the toilet, and then either roll into an adapted shower or slide over the tub or into a stall shower without necessitating an additional transfer. A urinal should be available at home and at school to decrease the frequency of transfers to the toilet, and some are specifically molded for use in a wheelchair. Modifications of the bed are also frequently required because the adolescent is unable to change position. An airflow mattress, egg-crate or memory foam cushion, and hospital bed are all possibilities to be considered. A positioning program to include position changes at night is necessary for adolescents who are thin in order to provide comfort and prevent skin breakdown. Customized foam wedges fabricated by the therapist or moldable pillows may also be helpful in positioning at night.

Transition to Adulthood. The transition to adulthood marks a time of continued progression of disability with greater reliance on assistive technology for environmental access and increased need for assistance to carry out routine ADLs.[247] Mobility using a power wheelchair is necessary because upper extremity and truncal weakness typically will not allow use of a motorized scooter once weakness progresses. Assistance with ADLs, including dressing, transfers, and bathing, is now required. Hygiene about the face and feeding become increasingly difficult but usually remain manageable for a period of time. Many social issues also arise with the completion of educational programming and transition to a prevocational, vocational, or home environment on a more full-time basis. Another major issue that requires thoughtful consideration by the family, individual, and management team is the utilization of assisted ventilation with progressive respiratory involvement at the terminal stage of the disease.

Although it may be assumed by care providers that the quality of life and therefore satisfaction are significantly reduced for severely disabled individuals with DMD, this notion may be incorrect. In a survey of 82 ventilator-assisted individuals with DMD, Bach and colleagues[15] concluded that a vast majority of individuals had a positive outlook and were satisfied with life despite the physical dependence. Furthermore, it was found in a survey of 273 physically intact health care professionals that they significantly underestimated patient life satisfaction scores, and therefore they may make patient management recommendations based on their attitudes rather than on the patient's wishes. Bach and colleagues[15] strongly recommended that we as professionals need to objectively assess family and individual needs when interacting to provide therapeutic programs and the inclusion of social work and psychosocial support in this process may be helpful. With the early use of steroids and intervention with ventilator assistance, longevity has been reported to increase into the third or fourth decade.[188]

The physical therapist should be aware of the stages of disease progression and especially the preterminal signs to avoid making inappropriate comments concerning prognosis. Often little needs to be said, but rather a good listening ear is needed to help the family work through the crisis that is ever pending. The person with DMD and his family members may indicate the need for additional support, and if issues are not being resolved adequately by the support that is available, consideration for involvement by a social worker, psychologist, counselor, clergy member, MDA support group, or other trained professional is indicated. Literature is available through the MDA to comfort family members, and texts are available if the family is interested.[46,188,220]

Respiratory function. Progressive muscular weakness results in decreased ventilatory volumes caused by restriction of chest wall excursion both as a result of weakness and contracture. Forced vital capacity and peak expiratory flow typically improve in absolute value until the age of 10, and after the age of 18 typically both FVC and PEF show a decline over time.[161] Coordination of care with the respiratory therapist is essential when clinical findings of respiratory muscle weakness, inability to cough, or chest wall restrictions are observed. Close monitoring of respiratory function should become routine with increasing age because respiratory failure or pulmonary infection is the major contributing factor to death in children with DMD.[91] Longevity in DMD can be significantly prolonged by assisted ventilation.[16,65] A 1997 survey of MDA-sponsored clinics reported that 88% of clinic directors offered noninvasive ventilatory aid for acute respiratory failure.[12] Bach and Chaudhry[12] stressed the need for health care professionals to explore attitudes toward mechanical ventilation because our perceived impression of patient desires may often be incorrect. The use of daytime intermittent positive-pressure ventilation via mask or nasal cannula, nocturnal bilevel positive airway pressure (BiPAP), negative-pressure ventilators, and suctioning should be considered for the chronic hypoventilation related to weakness of respiratory musculature.[12]

Breathing exercises, postural drainage, or intermittent pressure breathing treatments should be included in the management program based on results of pulmonary evaluation and sleep studies that should be considered in the second decade of life.[222] Specific tests of pulmonary function that document respiratory status include forced vital capacity (FVC = amount of air expired following a maximal inspiration) and peak expiratory flow rate (highest flow rate sustained for 10 ms during maximal expiration). BiPAP is recommended for nighttime use when indicated by sleep study.[150,244] Assisted ventilation with tracheostomy or by mask or sip is recommended when respiratory insufficiency is present with abnormal blood gas levels during the day or night.[244,271] In addition to breathing exercises and assisted coughing, the family and caregivers should be instructed in the technique of postural drainage. For additional details, the reader should refer to the American Thoracic Society consensus statement on the care of individuals with DMD or the report from the DMD working group.[5,40,65]

Functional mobility and equipment. By late adolescence assistance is required for transfers. The use of a hydraulic or other mechanical lift should be considered depending on the patient's weight and the parent's comfort. A divided leg sling with headrest extension, to allow it to be removed after the transfer, is indicated because head and trunk control are minimal at this stage of the disease.

A power recline and tilt feature on the power wheelchair may be desirable, depending on accessibility and family choice, if funding is available. If not, a regular schedule for pressure relief through lateral weight shifting with assistance is needed. A properly fitted and well-tolerated cushion to avoid skin breakdown becomes an important area of intervention with loss of the ability to weight shift in the wheelchair. Skin breakdown is not a typical problem in DMD, but a cushion should be considered. A Jay Medical cushion (Jay Medical, Boulder, CO) is often well tolerated and provides a firm base of support to control pelvic obliquity, yet the gel inserts can be adjusted to

allow for adequate pressure distribution. A customized insert will be needed if deformity becomes severe (e.g., severe scoliosis without surgical stabilization). If the firmer cushion is not tolerated well, then use of a Roho quatro cushion (The Roho Group, Belleville, IL) is recommended because it will allow for greater pressure relief.

A ball bearing feeder may be considered to assist arm movement when progression of upper extremity weakness makes independent feeding difficult.[50] The device can also be used to assist with general use of the arms in conjunction with activities at a table, such as when using a computer, or to maintain the ability to self-feed. Trial use of a mobile arm support is recommended, and a mobile arm support with elastic assist like the WREX (Wilmington Robotic Exoskeleton) could be considered. Coordination of planning with an occupational therapist to address feeding and dressing issues is needed to identify solutions to increased dependence in the areas of feeding, dressing, and hygiene.

A power-controlled bed to allow elevation of the head for respiratory management should be considered. Use of a bed with elevating capability also allows for greater ease in transfers, and height adjustment promotes use of proper body mechanics by family members for activities that require assistance such as dressing; however, some insurance companies will view this as a convenience for the family and will not cover the cost. Mattress selection should also be reviewed with the family because an airflow mattress or memory foam mattress may be needed when increasing dependence for bed mobility is encountered. Use of a mattress with deep pressure relief may decrease the frequency of need for turning and repositioning at night. If sitting in a wheelchair is no longer tolerated in the later stages of the disease, which may occur if severe scoliosis and back pain are present, elevation of the head of the bed becomes beneficial for reading or watching television. An easel will be required for reading.

To maintain independence in environmental access, consideration should be given to using environmental control devices. An environmental control unit included on the power wheelchair can be used to independently access lights, telephone, television, motors on doors, or a computer, to name just a few applications. Computer access for vocational applications such as word processing or avocational activities such as games is available.

BECKER MUSCULAR DYSTROPHY

Background Information

Becker muscular dystrophy (BMD), a more slowly progressive variant of DMD, has an incidence of about 1 in 20,000 births and a prevalence of 2 to 3 cases per 100,000 population.[68] The impairments and participation restrictions of BMD closely resemble those of DMD; however, the progression is slower, with a longevity into the forties.[70,91] The genetic defect for BMD is located on the same gene as that for DMD. Dystrophin is present in reduced amounts or inconsistently integrated into the muscle cell structure rather than completely absent as in DMD, which may explain the slower progression of clinical symptoms.[146]

Initial clinical symptoms typically are not identified in boys with BMD before late childhood or early adolescence except for families with a history of the disease. Emery and Skinner[70] found the mean age at onset of symptoms to be 11 years, inability to walk at 27 years, and death at 42 years although this has changed with the increased use of steroids for muscle strength and medication for the associated cardiac comorbidities. The authors pointed out that the range of walking cessation is very wide, but by definition to be classified as having BMD one needs to continue independent bracefree ambulation beyond the 16th birthday.

The impairments of BMD are the same as in DMD, although less severe, and initial clinical signs include gastrocsoleus contracture and proximal weakness in the mid to late teens. The exception is the increased presence of cardiac involvement in BMD that is not necessarily correlated with the degree of weakness. Dilated cardiac myopathy is more prevalent with BMD because of the longer life span, and routine cardiac screening is recommended.[129] The pattern of weakness is the same as in DMD, and pseudohypertrophy of the calves may be present. The incidence of contracture, scoliosis, and other skeletal deformities is lower in BMD. Although not as severe as in DMD, hip, knee, and ankle plantar flexor muscle contractures can be present when walking is no longer possible. The use of night splints to maintain ankle dorsiflexion ROM is often indicated, along with a home program of posterior calf stretching. Significant disability may develop by the mid-20s in most individuals, although this is variable. As weakness progresses, the use of power mobility may be required. KAFOs can also be used to prolong walking; however, braced ambulation will not be functional for community access but rather as a means of exercise.

Foreground Information

The general goals and management procedures for BMD are the same for as those for DMD, including the progression from walking to use of power mobility, although the predictive guidelines may differ because the rate of progression in BMD is slower. Although the precautions against eccentric exercise, excessive fatigue, and delayed-onset muscle soreness should be followed with BMD as with DMD, because of the milder phenotype of individuals with BMD, endurance training has been found to be beneficial.[253] Sveen and colleagues reported on a cohort of 11 individuals with BMD who participated in a cycling program of 50 30-minute sessions at 65% of their maximal oxygen uptake level over 12 weeks. The group demonstrated 47% improvement in maximum oxygen uptake and an 80% increase in maximal workload with no evidence of increased serum creatine phosphokinase levels and no presence of necrotic or increased numbers of central nuclei on muscle biopsy. The exercise group also demonstrated a significant increase in strength in select lower extremity muscles. Sveen and colleagues also reported that endurance training may be beneficial for increasing strength in these individuals without leading to increased muscle damage; however, more research is needed to determine the most appropriate intensity of training.[254]

Transition planning following completion of school and assistance with living arrangements to accommodate the progressive nature of the disability into adulthood become major issues in this population. Longevity is commonly reported into the mid-40s, with complications from dilated cardiac myopathy being the limiting factor on longevity.[58] Vocational or avocational choices should be made with the disease progression and disability level in mind. Vocational rehabilitation services should be initiated before completion of high

school to allow adequate time for evaluation and transition plan development. Governmental support through Medicaid, Social Security, or other sources may be needed to offset expenses to allow for independent living and access to post-secondary education. Typically, both adaptive equipment and an attendant will be needed in addition to an environmental evaluation and modification. No data are available regarding the number of individuals who go to college or become employed following high school, but with the assistive technology available to promote independence, either option can be explored.

CONGENITAL MUSCULAR DYSTROPHY

Background Information

Congenital MD is a heterogeneous group of muscle disorders with onset in utero or during the first year of life that are characterized by delayed motor development and early onset of weakness.[214] The mode of inheritance in congenital MD is reported as autosomal recessive.[69,187] Although all forms are rare, the range of severity and disability varies significantly among types. Recent advances have led to the identification of several new genes associated with forms of congenital MD. A new classification system reports forms based on genetic, clinical, and pathologic characteristics along the spectrum of the disease. Reported forms of congenital MD include (1) defects of dystroglycan associated with central nervous system (CNS) disease (Fukuyama syndrome, Walker-Warburg disease, and muscle-eye-brain disease); (2) defects of structural proteins, including merosin-deficient congenital MD and collagenopathies (Ullrich MD Bethlem myopathy); (3) defects of the endoplasmic reticulum and nucleu (rigid spine syndrome); and (4) defects of the mitochondria merosin-deficient, Ullrich, and Fukuyama forms.[169,174,242] The reader should refer to the review chapter by Sparks and Escolar for additional information.[242] Other valuable resources for information are the Online Mendelian Inheritance of Man (OMIM) website of the National Center for Biotechnology (www.ncbi.nlm.nih.gov/omim) and GeneReviews (www.genereviews.org).

Congenital MD with complete merosin deficiency (MDC1A) is the most common form, affecting approximately 30% to 40% of the children in European countries but is less reported in North America.[242] Onset is at birth, and children never attain the ability to walk unsupported in contrast to children with partial merosin deficiency, for which onset is during the first decade and children typically are able to walk by the age of 2 to 3 years. Children with congenital MD typically have decreased respiratory function observed by the end of the first decade and often require overnight ventilator support. Feeding difficulties are also frequently reported.

In children with merosin-absent or partial merosin-deficient MD, abnormalities on brain imaging are reported, but with infrequent reduction in IQ. Thirty percent are reported to develop epilepsy.[113] Contractures and scoliosis are common, along with early breathing difficulties that may require assisted ventilation. Children with the merosin-deficient form of MD are reported to have cardiac involvement. In congenital MD with partial merosin deficiency, a delay in walking, with acquisition of walking ranging from 13 months to 6 years, is reported.[193]

Progressive contractures may be present, and in most cases of merosin-deficient congenital MD the child never attains the ability to walk independently. Twenty-five percent of children are reported to be able to walk with support. Longevity ranges from 15 to 30 years. Pegorago and associates[208] reported on a cohort of 22 children with merosin-deficient congenital MD. All children demonstrated severe floppiness at birth, normal intelligence, and delay in achievement of motor milestones. Merosin-deficient congenital MD is due to a defect in the *LAMA2* gene at chromosome 6q22.

Muscle weakness and contractures are the primary impairment in merosin-deficient congenital MD, with scoliosis common in merosin-absent MD. Brain malformations can include cobblestone type II lissencephaly or polymicrogyria as pathologic features of the CNS portion of the disease. Weakness is more pronounced in proximal muscles. Feeding delays are common with lesser involvement of the bulbar muscular than is generally observed with weakness of the trunk and axial musculature, requiring a feeding program that should be coordinated with occupational therapy. Contractures must be managed aggressively with a home ROM program that includes manual stretching, positioning, and splinting. Although children with partial merosin-deficient MD can develop walking, ankle plantar flexion contractures that cannot be managed conservatively may require orthopedic intervention.

Another more prevalent form of congenital MD is Ullrich MD, due to a collagen VI defect. It is characterized by hypotonia and weakness with distal joint hyperlaxity. Proximal joint contractures and skeletal abnormalities may also be observed. Hip dysplasia is seen in about 50% of cases. Delayed milestones can be the first symptom leading to diagnosis, and usually this clinically manifests around 12 months of age. Most patients achieve independent walking; however, this skill is often lost by the teen years. Children also develop respiratory insufficiency, often requiring the use of noninvasive ventilator support overnight. Characteristic facial features include rounded face, drooping of lower eyelids, and prominent ears. Intelligence is normal in these children, and longevity has been described well into adulthood. Early management of these children includes mobilization and maintenance of ROM. Gait is marked by crouch and progressive knee flexion contracture and/or ankle contractures. Standing frames, orthotics, and ambulatory aides may be prescribed. As contractures progress over time, surgical intervention may also be indicated. A milder phenotype is Bethlem myopathy. Mild weakness and laxity may be observed in childhood with contracture development at the end of the first decade. Weakness becomes more pronounced in the third and fourth decades and many require assistance to walk around the age of 60 years.[30]

In congenital MD with associated CNS disease (Fukuyama type), intellectual disabilities and seizures are common, along with moderate to severe weakness at birth and the presence of contractures.[86] Magnetic resonance imaging reveals cerebral malformations and occasionally cobblestone type II lissencephaly as pathologic features of the CNS disease. Contractures typically involve the lower extremities (hips, knees, and ankles) and elbows. Other commonly reported dysmorphic features include torticollis, congenital dislocation of the hips, pectus excavatum, pes cavus, and kyphoscoliosis. Facial weakness and ptosis are common, and weakness of the extraocular muscles, optic atrophy, and nystagmus has also been reported.[214] Children with this type of MD rarely attain the ability to walk; however, milder

phenotypes have been identified and present as a limb girdle phenotype.[69,98] The genetic defect is at chromosome 9q31-q33 with the missing protein fukutin.

Foreground Information

The early management program in children with congenital MD with central nervous system disease should focus on family instruction, developmental activities to address delays in gross motor skill development, and aggressive management of contractures. Attention to positioning is necessary to guard against secondary deformity resulting from gravitational effects on the trunk with the presence of moderate to severe weakness. Early intervention by an occupational or speech therapist to address feeding and oral motor control issues is commonly coordinated with physical therapy to help with positioning the upper trunk and neck and adjusting the body position with respect to gravity to aid in oral motor control and optimize the chances of success. Impaired respiratory function and pulmonary complications are hallmark features of congenital MD. The family should be instructed in airway clearance techniques including percussion and postural drainage, and consultation with a respiratory therapist and pulmonologist may be needed on an ongoing basis.

Because many children with congenital MD and associated nervous system disease do not attain walking, maximizing functional skills in sitting becomes a primary goal of the physical therapy management program as the child ages. Therapeutic exercise to improve head and trunk control should be aggressively addressed with use of adaptive equipment to slow the progression of spinal deformity and contractures and to maximize access to the environment. Because intellectual disabilities are common, power mobility may not be an option. Additional management issues for children with significant weakness are discussed later in the chapter in the section on acute SMA.

Activity limitations, such as delayed acquisition of gross motor skills, should be managed with an understanding of the natural progression of the diagnosis because a slower rate of skill progression is expected. Because these children vary in their rate of motor skill development, information can be provided to the family concerning probable rates of motor skill acquisition, but unrealistic therapeutic expectations should be avoided. Because children with congenital MD have a wide range of functional deficits, care must be taken in predicting functional gross motor outcomes or level of participation at home and school.

CHILDHOOD-ONSET FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY

Background

Facioscapulohumeral MD is rare, with an incidence of 1 in 10,000 to 21,000, and typically demonstrates onset in adulthood.[198] The disorder is inherited as autosomal dominant disorder that is unique in that it results from a contraction of a triple repeat found in the gene.[227] In addition, there is a high rate of new mutation. The genetic defect is on chromosome 4q35 in the case of *FSHD1,* which accounts for 95% of cases with the remaining cases classified as *FSHD2*. The disorder affects males and females equally. Childhood-onset facioscapulohumeral MD typically results in the onset of clinical signs within the first 2 years but without significant impairment or disability until later in the first decade. Contractures are seldom a problem for mobility.

Foreground

Infancy and Preschool-Age Period

The impairment of muscle weakness about the face and shoulder girdle is typically the only prominent feature of the disease during the infant and preschool-age period. Parents report that the child may sleep with the eyes partially open, and on physical examination weakness of the facial musculature is predominant although from a functional mobility point of view the weakness of the trunk muscles, plantarflexors, and sometimes quadriceps can be the most impairing.[10,218,219] Children frequently are unable to whistle, and drinking with a straw may be difficult due to the facial weakness. When asked to purse the lips together and puff the cheeks out, the child is unable to maintain the cheeks out when even the slightest pressure is applied. The child's smile may also be masked because of the weakness, thereby hindering communication as a result of inconsistency between what is spoken and the affect displayed.

Children with childhood-onset facioscapulohumeral MD typically develop independence in walking without significant delay. An excessive lordotic posture during walking is a classic clinical feature with progression of weakness, and the plantarflexor and quadriceps weakness often lead to hyperextension of the knee to maintain stability in stance. The scapulae are widely abducted and outwardly rotated, giving evidence of the degree of interscapular muscle weakness and winging that can be elicited by a number of maneuvers.[132]

School-Age Period

Progressive activity limitations occur during the school-age period, with weakness becoming more generalized throughout the trunk, shoulder, and pelvic girdle musculature. Progression of childhood-onset facioscapulohumeral MD is more insidious than in the adult form, and independent walking may be lost by the end of the first decade.[89]

Severe winging of the scapula, a hallmark feature of the adult form of the disease, becomes more prominent with age in activities such as reaching overhead. Management should focus on instruction to the child and family on activities to avoid that may cause fatigue, and endurance training should be considered for this population.[36,125,196,272]

As weakness of the hip and knee extensors progresses, the use of lightweight carbon fiber AFOs that resist dorsiflexion and stabilize the knee with a ground reaction force can be considered, and eventually KAFOs for assisted walking and transfers may be beneficial. When walking becomes increasingly difficult, power mobility using a scooter or power wheelchair should be considered because the degree of upper extremity weakness will not allow independence in propulsion of a manual wheelchair.

Transition to Adulthood

No specific prognostic information on the longevity of individuals with childhood-onset facioscapulohumeral MD is available; therefore transition planning from the educational environment should be a goal of the therapy program, and standard of care documents and the available natural history experience should be considered to guide management.[249,257] If severe weakness is present and significant assistance from the family is needed, individuals may not desire to plan for living outside the family home. If independent living is desired, coordination of planning with vocational rehabilitation services and an attendant may be necessary and accessibility issues will need to be evaluated. The wide variability of severity and pattern

of weakness in this population even between family members needs to be considered in terms of the expected prognosis when planning for the future; however, progression over time in each individual is often uniform and slow with long periods of stability and most patients remain ambulatory.[249] The reader is referred to an excellent review by Shree Pandya for an overview of the phenotypic presentation and functional considerations one must be aware of in this population.[198]

MYOTONIC DYSTROPHY

Background

Myotonic dystrophy is the most common adult-onset neuromuscular disease, with an incidence of 1 in 8000 births.[109] Congenital myotonic dystrophy is rare and demonstrates severe clinical features of the adult-onset diagnosis (see OMIM, myotonic dystrophy type 1). Inheritance is reported as autosomal dominant with a genetic defect of chromosome 19q13.3 affecting males and females equally. A second form of myotonic dystrophy (myotonic dystrophy type 2) (proximal myotonic myopathy, or PROMM) has been reported and linked to chromosome 3q21.[216]

Children with congenital myotonic dystrophy are almost exclusively born to mothers with myotonic dystrophy who have the chromosome 19 defect. Approximately 25% of children born to mothers with myotonic dystrophy will have congenital myotonic dystrophy.[26,109] Most children demonstrate severe weakness at birth; however, a few children have no significant motor impairments as infants and first show signs of intellectual disability only by age 5 years as the cognitive demands increase at school age. Because the children who initially have only intellectual impairment follow a progression of motor impairment similar to that of adult-onset myotonic dystrophy, the infant-onset form is the primary focus of discussion in this section of the chapter.

Intellectual disability in congenital myotonic dystrophy is common, affecting 50% to 60% of the children. An average IQ of 74 is typically reported for children with cognitive impairment with verbal IQ higher than performance; however, like the motor phenotype there is wide variability among the population.[62,223,243] No evidence of progressive deterioration of cognitive function has been found. A study by Rutherford and coworkers[226] of 14 children provided prognostic information regarding survival and its relationship to mechanical ventilation at birth.

In children with congenital myotonic dystrophy survival beyond the early weeks of life indicates a prognosis of steady improvement in motor function over the first decade, with most children developing independent walking after age 2.[66,111,128,223] A follow-up study by O'Brien and Harper[194] of 46 children reported only 4 children who died outside the neonatal period at ages 4, 18, 19, and 22 years. Four additional children demonstrated significant disability associated with a poor prognosis, and none was older than age 30 years. In a study of 115 children with congenital myotonic dystrophy, Reardon and colleagues[213] reported that 25% of the children lived to age 18 months, and of those who survived infancy, 50% lived into their mid-30s. The use of noninvasive ventilation has improved this number significantly, but there may still be a 25% mortality rate in the first year.[42]

Severe weakness and partial paralysis of the diaphragm at birth are clinical features that often suggest the diagnosis of congenital myotonic dystrophy. Myotonia (delay in relaxation after muscular contraction) is a hallmark feature of myotonic dystrophy. Myotonia in congenital myotonic dystrophy typically is not considered to be a significant impairment or a cause of functional limitations in comparison with the degree of weakness that is present. The symptoms of myotonia, however, are increased with fatigue, cold, or stress. Typical facial features include a tented V-shaped upper lip. Facial movements are limited with a typical pattern of a myopathic face. Severe respiratory impairment is prominent in the newborn period, requiring resuscitation and assisted ventilation in the most severe cases. Cardiac involvement is common, and there have been reports of arrhythmias in up to 90% of patients with some requiring the insertion of pacemakers.[26] It is recommended that cardiac consults be obtained for young adults who are engaging in sports activities.[66] Talipes equinovarus contractures are reported in more than 50% of children, and a general arthrogrypotic pattern with contracture of more than one joint at birth occurring in less than 5%.[109]

Foreground

Infancy

Talipes equinovarus contractures should be aggressively managed in infancy with Ponseti casting and stretching exercise but may ultimately require surgical orthopedic intervention to facilitate optimal weight-bearing foot position for walking.[213] Ankle-foot orthoses and/or night splints are indicated on the basis of individual needs to maintain correction. In addition to home instruction for ROM activities to manage contractures, the family should be provided with a general program of activities to promote gross motor skill development.

Consultation with a respiratory therapist on pulmonary care will be needed until the infant is weaned from assisted ventilation. Feeding may require the use of a nasogastric tube during the newborn period or early infancy, and initiation of a feeding program should be coordinated with an occupational or speech therapist. A swallowing study may be indicated when the feeding program is initiated to evaluate potential for aspiration. If the newborn survives early respiratory difficulties, progressive improvement in pulmonary function is usually seen without the need for ongoing intervention.

School-Age Period

Progressive improvement in gross motor skills can be expected if the child survives the newborn period. The degree of intellectual impairment becomes a major factor in the progression of milestone acquisition as the child ages.

Children typically develop walking, but further activity limitations follow the clinical progression of adult-onset disease. In some cases, progressive weakness may occur in the second decade, leading to a loss of ambulation. However, it is most frequently reported that activity limitations remain steady and slight throughout childhood and later progress in the third or fourth decades of life.[66] Patients present with the typical impairments of ligamentous laxity, generalized weakness, and a drop foot during the swing phase of gait that often will benefit from a lightweight AFO.[109]

Consultation for development of adaptive physical education participation will be needed during the school-age period. Other physical therapy–related activities will depend on the use of orthoses and the progression of gross motor skill development. Specific therapeutic exercise programs for

ROM and strengthening have not been reported but may be indicated.

Transition to Adulthood

The natural progression of myotonic dystrophy is insidious weakness of the distal upper and lower extremity musculature and myotonia, leading to activity limitations and participation restrictions; however, in the moderately affected group the cognitive findings are often the most impactful as adolescents transition to adulthood. Children with congenital myotonic dystrophy will demonstrate progression in the disease as described for adults, but typically at an earlier stage. The severity of disease represents the full spectrum from adults with very mild impairments to infants with very severe disability.[66] The reader should refer to references on adult myotonic dystrophy for further information on clinical course and management.[109]

EMERY-DREIFUSS MUSCULAR DYSTROPHY

Background

The most common form of Emery-Dreifuss muscular dystrophy (EMD), known as XL-EMD or EDMD1, is inherited as an X-linked recessive disorder at gene locus Xq28 resulting in the absence of the protein emerin. Another identified form of EMD can also be inherited, but as either an autosomal dominant (AD-EMD) or recessive (AR-EMD) disorder with a defect on chromosome 1q21.2 and a defect of the protein lamin.[29] The dominant form is more common, with the recessive form only reported in one case of a family with a severe phenotype.

The clinical features of Emery-Dreifuss vary widely but consist of a pattern of contractures, slowly progressing muscle weakness, and cardiac disease.[239] The clinical pictures of XL-EMD and AD-EMD are similar but have some differences. Typically, in XL-EMD joint contractures precede signs of weakness, whereas in AD-EMD there is pronounced muscle weakness prior to the development of contractures. Loss of ambulation can occur in AD-EMD but is not common in XL-EMD. The risk of cardiac involvement is also higher in XL-EMD. A very characteristic pattern of contractures includes contracture of the posterior neck and spinal extensors, elbow flexors, pectoral muscles, and ankle plantar flexors. A prominence of contracture over weakness in the presentation of the phenotype is common. A humeroperoneal pattern of muscle weakness is observed with usual onset in the teen years but ranges from neonatal to the third decade. Progression of weakness to the legs with a peroneal weakness pattern is reported with a drop foot in the swing phase of gait.

Cardiac evaluation with Holter monitoring is advised to identify cardiac abnormalities, and pacemakers are often needed to control rhythm. Sudden death has been reported in persons ranging in age from 25 to 56 years[211] in a large family cohort with bradyarrhythmias; all patients should be screened by Holter monitoring at diagnosis.

Foreground

Physical therapy management is often focused on maintaining flexibility during the childhood period because contracture is the most common impairment. Independent walking is typically maintained into adulthood. A ROM program for contracture prevention is advised, and serial casting and orthopedic intervention are common to correct the posterior calf contractures.[159]

BACKGROUND INFORMATION

SPINAL MUSCULAR ATROPHY

Classification of SMA into four groups is based on clinical presentation and progression (Table 12.2). Historically the four groups have been referred to in various ways. Type I can also be referred to as Werdnig-Hoffmann disease, type II as chronic SMA, type III as Kugelberg-Welander disease, and type IV as adult-onset SMA. This latter group frequently has a different genetic basis and overlaps with motor neuronopathies. These are also often classified with Charcot-Marie-Tooth disease and present with different phenotypic patterns and genetic causes and will not be discussed here.

Standards of care have been developed, and as part of that effort we have included the most up-to-date rehabilitation literature available.[182] The standard of care document that has been in place is currently in the process of being revised in light of advances that have occurred in the intervening years.[173] Information regarding the functional status of children with SMA and the overall disease progression is now more readily available as the result of international collaborations that have allowed the collection of large data sets for this relatively rare disease.[49,79,130,131] There is currently no cure, but various compounds have been evaluated in clinical trials with some limited success.[135,203]

Diagnosis and Pathophysiology

SMA represents the second most common group of fatal recessive diseases after cystic fibrosis.[157] The primary pathologic feature of SMA is loss of the anterior horn cells in the spinal cord. The diagnosis of SMA is often suspected based on clinical examination and laboratory procedures, including electromyography, muscle ultrasound, and muscle biopsy, and is ultimately confirmed by genetic testing.[151] Electromyographic findings include decreased combined motor unit action potentials and spinal H reflexes, positive sharp waves, fibrillation potentials,

TABLE 12.2 Classification of Spinal Muscle Atrophy

Type	Typical Onset	Inheritance	Course
SMA type I, Werdnig-Hoffmann, acute	0–4 mo	Recessive	Rapidly progressive; severe weakness; mortality dependent on aggressiveness or respiratory support, typically 1–10 years
SMA type II, childhood-onset	6–12 mo	Recessive	Initial progression that becomes slowly progressive over years; moderate to severe weakness
SMA type III, Kugelberg-Welander, juvenile-onset	1–10 yr	Recessive	Slowly progressive; mild impairment

and a decrease in the number of motor units by EMG estimation. Sensory and motor nerve conduction velocities are both normal. Muscle biopsy demonstrates changes that are typical of a disease involving denervation (i.e., large groups of atrophic fibers dispersed among groups of normal or hypertrophic fibers).

SMA is typically inherited as autosomal recessive with the genetic defect on chromosome 5q11.2-13.[144,170,171,236] The gene for SMA, termed survival motor neuron *(SMN1),* is found on chromosome 5q13. An almost identical copy of *SMN1,* thought to be a paralog, is found just proximal to *SMN1*. This almost identical copy is termed *SMN2*. These two genes are responsible for the production of a protein bearing the same name.[212,225] The SMN protein is involved in a number of basic cellular functions, including axonal transport and most notably the splicing of pre-mRNA into mRNA. Ultimately, as the result of defective splicing of a number of lower motor neuron–specific genes, the anterior horn cell and the spinal reflex arc are impacted leading to apoptosis (programmed cell death).[76] The primary modifying gene in SMA is *SMN2*. *SMN2* produces a smaller amount of SMN and acts to modify the phenotype with more full-length protein being produced the more copies of *SMN2* that are present. In addition to the *SMN2* gene, there are other modifiers of the phenotype including plastin 3[281] and another gene in a near locus that that codes for neuronal apoptosis inhibitory protein (NAIP), which is thought to play a role in SMA.[59,221,264]

The incidence of SMA as a whole is between 1 in 6000 and 1 in 10,000 live births.[236] The majority of cases are children with SMA type I (60%) with type II accounting for about 27% of cases and SMA type III representing the smallest group.[195,251] Classification of SMA is based on the highest level of functional ability achieved.[63] Despite the classification into various types, SMA is now viewed more as a continuum of involvement. Here we will use this rubric because it helps to clarify management goals and guide intervention. Patients with genetically confirmed SMA can be classified into three categories based on the maximal motor skill achieved. Those with SMA type III have been able to ambulate without assistance or bracing at some point in their lives, patients with SMA type II have been able to sit independently at some point, and those with SMA type I have never been able to sit independently. SMA (type I) was first reported by Werdnig and Hoffmann in the late 1800s.[117,278] A more slowly progressive form of SMA (type III) with onset usually between the ages of 2 and 9 years was reported by Kugelberg and Welander[140] and also by Wohlfart and colleagues.[282] Werdnig-Hoffmann disease and Kugelberg-Welander disease have therefore become the eponyms for infantile-onset and juvenile-onset SMA; however, most authors prefer to use the numeric classification system as outlined in Table 12.2.

No cure is available for SMA, but physical therapy is commonly advocated.[159,276] Poor prognosticators for long-term survival include early age at onset, which is often noted as weak fetal movement or onset of weakness in the first months of life. More recent evidence has shown that children with SMA type I and severe onset of symptoms may survive up to their fifth birthday and beyond with proactive pulmonary management and noninvasive ventilation with two thirds surviving to 4 years of age and half to 10 years of age in some series; however, this is accompanied by severe physical impairment.[31,197] The cranial nerves are occasionally involved in SMA type II. Contractures may be a presenting feature in the most severe forms of SMA that present at birth or in utero, with reports of talipes equinovarus or other intrauterine deformities secondary to limited fetal movement. Some authors will term this SMA type 0 referring the prenatal onset of symptoms.[212,225]

SPINAL MUSCULAR ATROPHY (TYPE I)

Background

Impairments, Activity Limitations, and Participation Restrictions

The primary impairment in all forms of SMA is muscle weakness secondary to progressive loss of anterior horn cells in the spinal cord. Weakness is particularly pronounced in the acute and chronic childhood forms (types I and II). Muscle fasciculations, including fasciculations of the tongue, are most commonly reported in children with SMA type I.[159] Unlike the faces of children with myotonic dystrophy or facioscapulohumeral MD, children with SMA type I appear alert and responsive. Respiratory distress presents after limb weakness but is present early, and significant effort to augment breathing by the infant is typical with a paradoxical pattern characteristic of a reliance on the diaphragm and associated collapse of the thoracic cavity and expansion of the abdomen with each breath.

Secondary impairments in SMA type I include the development of scoliosis and contractures. It is widely reported in the literature that all children with SMA develop scoliosis, and surgical intervention is an option depending on the aggressiveness that families choose for treatment.[103,147] Other secondary impairments include decreased respiratory capacity and increased fatigability of muscle. Treatment should begin early with a focus on feeding, ROM, positioning, respiratory care, and selected developmental activities (Boxes 12.5 and 12.6).

Range of motion should be monitored by goniometry, and muscle strength can be measured in the context of functional

Health Utilities Index Questionnaire

antigravity extremity movement and head control in various postures. The Children's Hospital of Philadelphia Infant Test of Neuromuscular Disorders (CHOP INTEND) can be used to monitor motor activity over time.[93,94]

Foreground

Infancy

In SMA type I, weak or absent fetal movement during the last months of pregnancy can be reported by the mother with some authors classifying this as SMA type 0. Significant weakness typically develops within the first 2 weeks to 4 months; this manifests as inability to perform antigravity movements with the pelvic more than shoulder girdle musculature and typical posturing in a gravity-dependent position (Fig. 12.7).

Respiratory care is one focus of the therapy program in acute childhood SMA. The aggressiveness of supportive care in this population is an individual choice. The medical team needs to discuss the options with the family related to the child's therapy program as well as medical care and maintain an open dialogue about their expectations and choices regarding the aggressiveness of care in the context of a disease with a limited life expectancy.[224] Children frequently require intubation in the context of intercurrent illness and then, when they are well, often can be weaned. However, for more chronic respiratory distress some will consider use of a tracheostomy, although use of noninvasive ventilatory support is frequently advocated to allow for the development of language skills.[11,17] The use of ventilatory support with either tracheostomy or noninvasive mechanical ventilation has been shown to prolong survival in children with SMA type I.[17] Coordination with nurses and respiratory therapists on a program that includes suctioning, mechanical cough assist, and percussion and postural drainage is necessary. The use of supported sitting should be closely monitored for spinal alignment and respiratory response because, as the children become weaker, sitting may be accompanied by respiratory decompensation.

The proximal musculature of the neck, trunk, and pelvic and shoulder girdles demonstrates the greatest weakness. Limited antigravity movement of upper and lower extremity musculature is present, and a positioning program is necessary in the newborn period or at the onset of symptoms. Use of wedges should be considered to avoid supine positioning in the presence of reflux; however, respiratory distress can be an issue in the more advanced stages, and upright posture will be less well tolerated due to the effects of gravity on the diaphragm. If the supine position is used, rolled towels or bolsters are needed to keep the upper extremities positioned in midline and to prevent lower extremity abduction and external rotation. The sidelying position allows midline head and hand use for play without having to work against gravity. Prone positioning even on wedges

TABLE 12.3 Handheld Dynamometry Scores Recorded With a Standardized Protocol With Isometric Contraction

		Right, lb		Left, lb	
Measurement	**Position**	**7 yr–2 mo**	**8 yr–4 mo**	**8 yr–4 mo**	**7 yr–2 mo**
Hip flexion	Supine, 90°	9	15	7	13
Hip extension	Supine, 90°	28	26	29	28
Hip abduction	Supine, 0°	9	17	8	16
Knee flexion	Sitting, 90°	13	16	11	16
Knee extension	Sitting, 90°	20	23	19	23
Ankle dorsiflexion	Supine, 90°	10	9	9	12
Ankle plantar flexion	Supine, 90°	52	54	50	56

should be limited or not used, owing to the effort required for head righting to interact with the environment and due to the inhibition of abdominal expansion and diaphragmatic depression thus limiting respiratory function.

Head control fails to develop or is significantly impaired in those with SMA type I. Early developmental postures such as prone on elbows are not attained. The use of developmental exercise in type I SMA should be considered if the child tolerates and enjoys the activities. ROM exercises with proper positioning should be carried out to ensure maintenance of flexibility and comfort. Flexion contractures of the hips, knees, and elbows, hip abductors, ankle plantar flexors, and positional torticollis are deformities that can be minimized with a comprehensive ROM and positioning program.[25] The exercise program should also include limited activities to encourage active movement and for strengthening, such as lightweight toys or rattles with Velcro straps around the wrists or mobiles positioned close to the hands for easy access. The use of slings and springs has also been advocated to counteract the impact of gravity and provide the child with the opportunity for movement with only slight movements of the body.[71,72] Developmental activities such as the use of supported sitting for the development of head control should be of short duration to avoid fatigue.

In conjunction with an occupational or speech therapist, a feeding program that is safe and not excessively exhausting should be implemented, but the risk of aspiration needs to be closely monitored due to the rapidly changing status of these patients. The medical team should discuss the parents' expectations regarding the aggressiveness of care. Once symptoms related to feeding are noted, more frequent feedings are necessary, and referral to a GI physician is often considered for a G-tube and Nissan fundoplication should the parents want this type of treatment. Breastfeeding may be difficult in this population due to the strength needed to develop sufficient suction.[72] Special care with feeding is necessary to avoid aspiration and secondary respiratory problems.

Death secondary to pneumonia or other respiratory complications is common in the absence of medical supportive care within a few months to few years of diagnosis in SMA type I owing to the degree of weakness and apnea.[72] The mean age of death is widely variable depending on the aggressiveness of care but many children with aggressive care can live well into the first decade of life albeit with significant functional impairment.[176,197] Counseling related to end-of-life issues and treatment choices as well as support for the parents and family is an extremely important component in the management of this condition, and often a hospice team will be involved in counseling the family alongside the neuromuscular team.

SPINAL MUSCULAR ATROPHY (TYPE II)

Background

Impairments, Activity Limitations, and Participation Restrictions

The onset of weakness in SMA type II usually appears within the first year, with the course of the disease somewhat variable. Muscle strength testing in children and adults with SMA type II has been evaluated using handheld dynamometry (Table 12.3),[77] manual muscle testing,[279] and qualitative muscle testing with a tensiometer.[215] Forced vital capacity[279] data are also available. Progressive loss of strength and pulmonary function have been consistently reported.[274] However, the overall course of the disease can be stable over long periods of time with progression detectable over periods upwards of a year.[131] The Hammersmith Functional Motor Scale for Children with SMA has also been developed by Marion Main at the Hammersmith in London as a specific functional skills rating tool for children with SMA type II. It has been expanded to allow evaluation of patients with SMA type III and is part of the SMA Functional Composite score, which includes evaluation of gross motor function, upper extremity function, and ambulatory ability.[95,154,184] The functional composite could be used to monitor upper extremity and gross motor function or ambulation and muscle fatigue in response to a strength-based treatment approach or to monitor recovery following a hospitalization or surgery to determine when return to full baseline status is achieved.

Contractures are frequently an impairment in SMA type II and often develop within the first decade of life. They frequently limit the ability to stand either in a stander or in KAFOs if the contracture becomes severe. The distribution of weakness is similar to SMA types I and III with primary proximal involvement. Weakness is usually greatest in the hip, knee extensors, and elbow extensors with the hamstrings, biceps, and hip adductors being relatively preserved. Involvement of the distal musculature appears later in the course of the disease and is less severe than the proximal involvement. Involvement of the cranial nerves has been reported but is not considered to be a typical feature of SMA. Fasciculations of the tongue

have been reported in approximately one half of the children and can be seen by muscle ultrasound almost uniformly. Minimyoclonus (a fine tremor) of the hands is also often noted. Fatigue is a significant impairment for these patients, and endurance training has been shown to have an impact on oxidative capacity but with an increase in fatigue related to the training that can limit the application of an endurance exercise program.[152]

Foreground

Infancy

Because the clinical presentation and progression of SMA type II are somewhat variable, the management program must address the major impairments, activity limitations, and participation restrictions as they are manifested. Typically, presentation is during the second half of the first year of life with some of the children with mild SMA type II presenting after a year with delay in ambulation onset. Some children may develop the ability to stand but lose this ability quickly after the onset of weakness; a few are able to ambulate with KAFOs.

Sitting posture is an area of primary concern in the management program for children who demonstrate significant weakness, and external head and trunk support in antigravity positions are sometimes required. A thoracolumbosacral orthosis (TLSO, or "body jacket") for support in sitting can be used; however, this is not universally recommended due to the increased work of breathing required. It is important to make sure there is a generous abdominal cutout to allow abdominal expansion if one is prescribed. Developmental activities provided on an ongoing basis are indicated to develop gross motor skills. Therapy sessions should be monitored, and an awareness of fatigue and function following exercise is important. An ergometer can be considered, and swimming has been reported to be beneficial in maintaining muscle strength and functional skills.[57] Instruction to the family in the use of adaptive equipment for proper positioning is crucial in slowing the deforming effects of gravity on the spine when the child is sitting or standing.

Standing by the age of 12 to 18 months should be initiated prior to the onset of contractures. The adaptive equipment necessary for standing should be considered.[100,197] Merlini favored the use of KAFOs with the proximal rim fitted in a similar way to a quadrilateral socket with ischial weight bearing. It should be aligned in enough dorsiflexion (or posted at the heel) to allow the weight line to fall toward the anterior portion of the base of support and posterior to the hip. With this type of bracing patients with a milder presentation of SMA type II will be able to take some steps while those with a more severe presentation will require either parapodiums or A-frame standers. The rate of fracture incidence in SMA has been reported to be increased and falls within a wide range. Weight bearing is an important modality to maintain bone stock in those who are not able to ambulate.[19,85,238] A supine stander is recommended for children without adequate head control, and vertical standers or KAFOs as described above are appropriate for patients with better head and trunk control. Orthopedic consultation for a corset or TLSO (with abdominal cutout) should be considered for use in standing to maintain trunk alignment if the adaptive equipment does not provide adequate control.

Preschool-Age and School-Age Period

In the toddler, orthotics for standing might also be considered (lightweight KAFOs); however, the progression of weakness and contracture may make walking an unrealistic goal. In a report of promotion of walking in 12 children with intermediate SMA or SMA type II (ages 13 months to 3 years), Granata and associates[101] described success in attaining assisted ambulation, with 58% of the children using KAFOs. This has not been the experience of all investigators, but standing is nonetheless an important goal. Although only a small number of children were studied, these investigators also reported less severe scoliotic curves in the children who used the orthoses in comparison with a control group of children with SMA.

If a walking program is initiated and successful, training in the parallel bars followed by use of a walker or other device to allow greater independence is desired. Close monitoring of safety with supported walking is necessary owing to the degree of weakness present and the potential for injury from a fall. The incidence of hip dislocation and contractures has also been reported as less when a supported walking program is used.[102]

Independence with mobility other than walking is a primary goal for the child with SMA type II who typically will not develop independence in walking.[127] Because most power scooters do not provide adequate trunk support, use of a power wheelchair is indicated. Many children with SMA type II will become independent in a power wheelchair between 1 and 2 years of age and some of the stronger patients will be able to push a lightweight manual wheelchair (Fig. 12.8A) for short distances on tile floors. This is often not functional over the long term, however, and typically, a power wheelchair is needed also for longer distances (Fig. 12.8B). If a TLSO is not used to support the trunk, close attention to fit is needed with use of lateral trunk supports. Severe contractures as a result of prolonged sitting and progression of scoliosis are experienced in all children, necessitating implementation of a consistent ROM program.[85] Surgical intervention for spinal stabilization is indicated if the curve progresses.[2] A variety of internal fixation methods are available that will allow the thoracic cavity and trunk to grow yet stabilize the progression of the curve. Orthosis have not been shown to change the progression of the curve but have been helpful with sitting balance and comfort in sitting.[212]

Exercise in patients with SMA type II appears to be safe and from a practical point of view possible. There is some suggestion that endurance training can impact endurance capacity, but there is a risk of fatigue that might limit the acceptability of this to the patient, and there is limited data to suggest functional gains can be expected.[106,145,152,181]

Transition to Adulthood

Survival into adulthood is typical in SMA type II and depends on aggressive respiratory management and the progression of muscle weakness and secondary deformities.[99] Because of the significant degree of muscle weakness, assistance is typically required for transfers and ADLs. An attendant or family member is needed to provide assistance for general ADLs. Intelligence is rarely affected; therefore vocational goals in areas of interest should be explored through vocational rehabilitation services.

An aggressive program of pulmonary care is required, including breathing exercises and percussion and postural

FIG. 12.8 Child with SMA type II shown in a lightweight manual wheelchair (A) and a power wheelchair (B).

drainage with illness. Forced vital capacity has been shown to decrease by about 1.1% per year, but mechanical ventilation is seldom needed.[244] The ROM and bracing program should also be continued to control progression of the contractures with the goal of maintaining a pattern of stability over time with growth.

SPINAL MUSCULAR ATROPHY (TYPE III)

Background

SMA type III (Kugelberg-Welander disease) typically demonstrates symptoms of weakness shortly after the onset of ambulation. Barry Russman and others have divided this group into two categories: type IIIA (onset of weakness prior to 2 years of age) and type IIIB (onset of weakness after 2 years of age).[225] Of the patients in the SMA type IIIA group, 50% retained the ability to walk past the age of 12; in the type IIIB group, 50% retained the ability to walk passed the 44th birthday. Fasciculations, most easily observed in the tongue, are noted in about half of the individuals, and minimyoclonus (a fine tremor) may be a primary impairment noted on examination, but it rarely interferes with function.[61]

Impairments, Activity Limitations, and Participation Restrictions

In a study by Dorscher and colleagues[61] reviewing the status of 31 patients with Kugelberg-Welander disease, or SMA type III, proximal lower extremity weakness was the most common impairment reported, but for these patients fatigue is also a significant functional impairment.[181,182,185] Secondary impairments included postural compensations resulting from muscle weakness and contractures; in about half of patients, scoliosis develops later in the first or early in the second decade.[250] An increased lumbar lordosis and compensated Trendelenburg gait pattern are common postural compensations for proximal muscle weakness of the lower extremities. Ankle plantar flexion contractures are occasionally reported but not with the frequency seen in DMD. In adolescents with type III SMA, the incidence of scoliosis and its severity are related to the degree of weakness and functional status.[85] Individuals who maintain independent walking have a lower incidence of scoliosis and less severe curves if scoliosis develops.

Foreground

School-Age Period

The initial disability in SMA type III usually becomes apparent within the first decade and includes difficulty in arising from the floor, climbing stairs, and keeping up with peers during play. A compensated Trendelenburg or waddling gait, which becomes more pronounced with attempts at running, will also be observed. Upper extremity function is usually less prominent, and proximal upper extremity strength can be somewhat preserved.[184] Walking can in some cases be maintained lifelong as the primary means of mobility. In those cases when weakness is noted before 2 years of age, however, a manual wheelchair or scooter may ultimately be required for mobility over long distances during the school-age period as their gait becomes more inconsistent and unsteady and falls increase.[181,182,183,185,186] A significant percentage of these children will also lose ambulation through puberty.

Management for the adolescent with SMA type III is consistent with the concepts previously presented in this chapter. ROM exercises should be prescribed as appropriate, and selected strengthening and or endurance exercises may be indicated to maintain functional skills. Adaptive equipment for mobility is indicated based on functional demands, and a power scooter for long-distance mobility or manual wheelchair may be needed in certain cases. If performance of ADLs becomes a problem, collaboration with an occupational therapist to address concerns may be needed.

Transition to Adulthood

Difficulty in ADLs that require overhead lifting can be expected, and vocational activities that involve manual labor or long periods of standing are not recommended. Because the life span is not significantly shortened, vocational planning is needed. Adaptive equipment and environmental access requirements are dependent on functional needs that, unlike DMD, are more slowly progressive, leaving more time for appropriate planning. In milder cases these may not be required until later in adulthood.

SUMMARY

Muscle weakness and contracture are hallmark features of the childhood neuromuscular disorders. Background knowledge of therapeutic exercise, functional use of orthoses and adaptive equipment, and strategies to minimize disabilities secondary to the primary impairments in strength, endurance, muscle length, and cardiopulmonary function allow the physical therapist to bring unique information and skills to the management team.

Many of the disorders significantly reduce longevity. Therefore the patient's quality of life and attention to how the family copes with the stress should be included in the team's intervention program. Providing the children and families with anticipatory guidance and support as well as realistic expectations is an important goal. Connection with support groups or contact with other families that have had a similar experience should be arranged with the help of social work and can often help the family work through crisis periods, particularly when extended family support is not available.

Through the combined perspectives and innovative solutions of team members, a comprehensive program can be provided that takes into consideration the multifaceted demands of each individual and family. A philosophy of using a family-centered approach to care will help ensure that needs are met to the best of the team's ability.

Case Scenarios on Expert Consult

The case scenarios related to this chapter look at two patients. The first is "Donald," and video examples of the issues demonstrated by Donald's case are also included. The case presents Donald's issues as the disease progresses over time from diagnosis to death. The case illustrates the role of the physical therapist as addressed in the chapter. The second case, "Derek," is a child with a dystrophinopathy and focuses on management during early childhood.

ACKNOWLEDGMENTS

Our personal thanks goes to the children and their families who contributed to our knowledge of MD and SMA. Special thanks to Donald and Derek and their families for sharing their stories. Support from the SMA Foundation to AG is acknowledged.

Limb Deficiencies and Amputations

Meg Stanger, Colleen Coulter, Brian Giavedoni

The child with an amputation is defined as a person with an amputation who is skeletally immature because the epiphyses of the long bones are still open.[1] Amputations can be classified as congenital or acquired. Many different factors must be considered in the management of children with a limb deficiency or amputation. These factors differ from those involved in the management of adults with a limb deficiency or amputation because as children grow their musculoskeletal systems continue to develop. Children also are emotionally immature and variably dependent on adults for care and decision making regarding surgical and prosthetic issues.

In this chapter the causes of limb deficiencies and amputations in children, surgical management, physical therapy intervention relative to a child's age and developmental function, and pediatric prosthetic options are discussed. Emphasis is on the aspects of management that differ from those encountered by adults with amputations. The role of the physical therapist includes education of parents of infants and children with limb deficiencies, development and progression of postoperative exercise programs, training in mobility and self-care skills, and providing input to both parents and the child or adolescent regarding prosthetic options. Studies have shown that children with limb deficiencies who participated in extensive rehabilitation programs have vocational skills with high employment potential.[92]

BACKGROUND INFORMATION

CONGENITAL LIMB DEFICIENCIES

Classification

Various classification systems of congenital limb deficiencies have been developed. Greek terminology has been used to describe various deficiencies but is often inaccurate and ambiguous.[17] Frantz and O'Rahilly[25] developed a classification system based on embryologic considerations and the absent skeletal portions. Swanson and colleagues[91] modified that system with a classification system of seven categories based on embryologic failure: (1) Failure of formation of parts (arrest of development), (2) failure of differentiation (separation of parts), (3) duplication, (4) overgrowth, (5) undergrowth (hypoplasia), (6) congenital constriction band syndrome, and (7) generalized skeletal deformities. The International Society for Prosthetics and Orthotics (ISPO) and the International Federation of Societies on Surgeries of the Hand (IFSSH) made additional modifications to this classification system in 1973 and 1989. The classification developed by the ISPO and IFSSH has been published as an international standard, International Standards Organization (ISO) 8548-1:1989, "Method of Describing Limb Deficiencies Present at Birth."[17]

The ISO classification of congenital limb deficiency is restricted to skeletal deficiencies described on anatomic and radiologic bases only; Greek terminology, such as *hemimelia* and *phocomelia* is avoided because of its lack of precision and difficulty of translation into languages that are not related to Greek.[17] Deficiencies are described as transverse or longitudinal. In transverse deficiencies the limb has developed normally to a particular level beyond which no skeletal elements exist, although digital buds may be present. A transverse deficiency is described by naming the segment in which the limb terminates and then describing the level within the segment beyond which no skeletal elements exist[17] (Fig. 13.1).

In longitudinal deficiencies reduction or absence of an element or elements occurs within the long axis of a limb. Normal skeletal elements may be present, distal to the affected bones. A longitudinal deficiency is described by naming the bones affected in a proximal-to-distal sequence and stating whether each affected bone is totally or partially absent[17] (Fig. 13.2).

One of the purposes of an international classification system is to provide a common language for accuracy when reporting statistics and research. However, because the ISO system does not specifically characterize common clinical manifestations of limb deficiencies, other terminology persists, such as proximal femoral focal deficiency or fibular deficiency. Additional classifications have been proposed to further define this broad spectrum of limb deficiencies. The additional classifications may be etiologically, radiologically, anatomically, or functionally based and are often developed to guide medical interventions and decision making. Basic knowledge of the various classification systems is important because much of the literature published prior to 1989 will often use the older classification systems.

Origin

To fully understand the causes of congenital limb deficiencies, a basic knowledge of embryonic skeletal development is necessary. Limb buds first appear at the end of the fourth week of embryonic development, arising from mesenchymal tissue. During the next 3 weeks the limb buds grow and differentiate into identifiable limb segments. Development of limb buds occurs in a proximodistal sequence, with upper limb development preceding lower limb development by several days. The mesenchymal tissue undergoes chondrification to become cartilaginous models of individual bones. By the end of the seventh week, a recognizable embryonic skeleton is present. The entire process of limb development is very complex and involves precise timing of events as well as the interaction of genetics and molecular control from signaling centers in the developing limb.[82,84]

Causative factors for congenital limb deficiencies include genetic, vascular, teratogenic, and amniotic bands, but for

many children, the exact cause is unknown. A genetic link may be associated with a few limb anomalies, but most limb deficiencies are the result of sporadic genetic mutation.[46] Limb deficiencies, especially of the upper extremity, may be associated with other congenital anomalies such as Holt-Oram, Fanconi, Poland, thrombocytopenia-absent radius, and VATER syndromes. Several teratogenic factors (e.g., medications such as thalidomide and misoprostol, irradiation) have been indicated as possible causative factors for congenital limb deficiencies but account for only 4% of cases in a study conducted by McGuirk.[60] McGuirk[60] reported that the cause of congenital limb deficiencies was vascular disruption in 34% of cases and unknown in 32% of cases. A study by Robitaille et al. found that low maternal intake of riboflavin was associated with transverse limb deficiencies.[80] Teratogenic and vascular disruption factors must be present at some time between the third and seventh weeks of embryonic development to produce a limb deficiency.

Levels of Limb Deficiency

The incidence of congenital limb deficiencies ranges from 2 to 7 per 10,000 live births and has been relatively unchanged over time.[21] The US Centers for Disease Control reports an incidence of 6 in 10,000 live births per year with limb deficiencies of the upper extremity occurring twice as frequently as those involving the lower extremity.[14] The clinical presentation of a child with a congenital limb deficiency depends on the type, level, and number of deficiencies. Almost any combination or variety of limb deficiency is possible. However, some are more common, and these are discussed in this chapter in detail. Approximately 20% of children present with limb deficiencies affecting more than one limb[18] (Fig. 13.3). Longitudinal deficiencies occur more frequently than transverse deficiencies with no strong difference between left- and right-sided prevalence.[7,35] Many

transverse deficiencies proximal to the wrist and ankle are unilateral and frequently include rudimentary vestiges called nubbins (Fig. 13.4).

A complex lower extremity longitudinal limb deficiency has been termed *proximal femoral focal deficiency (PFFD)*. Aitken[2] first described this deficiency, which includes absence or hypoplasia of the proximal femur with varying degrees of involvement of the acetabulum, femoral head, patella, tibia, and fibula. The deficiency may be unilateral or bilateral. If the deficiency is unilateral, the contralateral limb often exhibits subtle deficiencies such as hypoplasia of the femur that may not be initially recognized. Aitken described four classes of severity—A through D—with class A exhibiting the least involvement based on radiographic findings (Fig. 13.5). Gillespie[32] has developed a classification system for PFFD based on the complexity of medical intervention. Children classified into group A may require only limb lengthening, and those in groups B and C may require some level of amputation or surgical revision and prosthetic fitting.

The clinical manifestations of a child with PFFD are relatively consistent. They include a shortened thigh that is held in flexion, abduction, and external rotation; hip and knee flexion contracture; and severe leg length discrepancy, with the foot often at the level of the opposite knee. These children also have instability of the knee joint secondary to absent or deficient cruciate ligaments and a 70% to 80% incidence of total longitudinal deficiency of the fibula. Fifteen percent of children with PFFD have bilateral involvement.[62] The incidence of PFFD is reported to be 1 per 50,000 live births and it is usually of unknown origin.[62]

ACQUIRED AMPUTATIONS

Acquired amputations most frequently occur as the result of trauma or disease, with trauma being twice as common as disease-related factors.[55] Disease-related factors are most frequently tumors but also include infections and vascular malformations. Ninety percent of acquired amputations involve only one limb, and the lower extremity is involved in 60% of cases.[19]

Traumatic Amputations

Males, especially in the adolescent age ranges, account for a larger percentage of traumatic amputations in children.[48,56]

Accidents involving farm machinery and household power tools are the leading cause of acquired amputations in the pediatric population, followed closely by vehicular accidents, gunshot wounds, and railroad accidents.[56] Incidences vary according to age and geographic location. When amputations of the digits are included in the data, the highest incidence of amputations is seen in the fingers of children younger than 2 years of age secondary to closing a door on the child's finger.[48] Vehicular accidents, farm machinery, gunshot wounds, and trains are more common causes of traumatic amputations in the older child.[56] Loder documented a seasonal trend with childhood amputations that could influence community prevention and education programs. It is no surprise that most traumatic amputations occur in the summer, with lawn mower injuries peaking in June, motor vehicle accidents in July, and farm machinery accidents in September.[56]

Disease-Related Amputations

Sarcoma of Bone

Primary bone tumors are rare in children, accounting for only 6% of cancers in children younger than 20 years of age. Osteosarcoma and Ewing's sarcoma are the most common of the primary bone tumors, with an annual incidence in the United States of 8.7 per million children younger than 20 years of age.[13]

Osteosarcoma

Osteosarcoma is a primary malignant tumor of bone derived from bone-forming mesenchyme in which the malignant proliferating spindle cell stroma produces osteoid tissue or immature bone. The peak incidence of osteosarcoma coincides with the pubertal growth spurt, and it occurs most frequently at the metaphyseal portion of the most rapidly growing bones in adolescence. As a result, the distal femur, proximal tibia, and proximal humerus are the most common sites for osteosarcoma. This finding supports the theory that these rapidly growing cells are susceptible to oncogenic agents or mitotic errors and that osteosarcoma is the result of an aberration of the normal process of bone growth and bone turnover.[37]

Ewing's Sarcoma Family of Tumors

The Ewing's sarcoma family of tumors (ESFT) includes a spectrum of neuroepithelial tumors ranging from the undifferentiated round cell tumor of Ewing's sarcoma of bone (ES) to the neural differentiated peripheral primitive neuroectodermal tumor (PNET). Ewing's tumors often involve both bone and soft tissue by the time of diagnosis, including infiltration into the medullary cavity and bone marrow. The most common primary sites are the flat bones of the pelvis and chest and the long bones of the lower extremities. Ewing's sarcoma is also seen during times of peak growth rates with the highest number seen in the second decade of life. [43]

Diagnosis

The initial complaint for both osteosarcoma and Ewing's sarcoma is pain at the site of the tumor with or without a palpable mass. Localized swelling or the complaint of a palpable mass is seen with both osteosarcoma and Ewing's sarcoma. Systemic

Type		Femoral Head	Acetabulum	Femoral Segment	Relationship Among Components of Femur and Acetabulum at Skeletal Maturity
A		Present	Normal	Short	Bony connection between components of femur Femoral head in acetabulum Subtrochanteric varus angulation, often with pseudarthrosis
B		Present	Adequate or moderately dysplastic	Short, usually proximal bony tuft	No osseous connection between head and shaft Femoral head in acetabulum
C		Absent or represented by ossicle	Severely dysplastic	Short, usually proximally tapered	May be osseous connection between shaft and proximal ossicle No articular relation between femur and acetabulum
D		Absent	Absent Obturator foramen enlarged Pelvis squared in bilateral cases	Short, deformed	None

symptoms are rare in osteosarcoma unless widespread metastatic disease is present. On the other hand, systemic symptoms, most commonly fever and weight loss, are complaints with large Ewing's tumors.[44] Because the initial complaint for both osteosarcoma and Ewing's sarcoma is pain at the site of the tumor, diagnosis is often delayed. Children presenting to a physical therapist with a complaint of pain that is often chronic, a negative history of injury, and no evidence of musculoskeletal abnormalities should be referred for further medical workup to rule out a malignant bone tumor.

The key to diagnosis of a bone tumor is radiologic evaluation. Plain-view radiographs will reveal evidence of a mass and bony destruction; however, a definitive diagnosis is made through biopsy and histologic examination. The extent of the tumor is more precisely defined through magnetic resonance imaging. To complete the workup, a radionuclide bone scan and chest computed tomography are performed to determine the extent of metastasis.[41]

Medical Management of Malignancies

Medical intervention for children with sarcomas typically includes a multimodality approach with chemotherapy to eradicate systemic disease and surgery and/or radiation therapy to control local disease. Medical management of bony tumors and neoplasms is based on the following goals: (1) complete and permanent control of the primary tumor, (2) control and prevention of microstatic and metastatic disease, and (3) preservation of function to the greatest degree possible. Local control of the primary tumor is most often achieved through surgery and radiation therapy. Surgical options include amputation, limb-sparing procedures, and rotationplasty. Control of microstatic and metastatic disease is achieved through radiation therapy and chemotherapy. Surgical options and use of radiation therapy are based on the type of tumor, location and extent of the tumor, age of the child, and child and family beliefs and their activities. See Chapter 16 for more information.

Radiation Therapy

Osteosarcoma is generally unresponsive to radiation therapy and is typically used only if adequate surgical margins were unable to be achieved. Ewing's sarcoma is highly responsive to radiation therapy; consequently, it has been utilized for local control of the tumor. However, improvement with surgical techniques and recognition of the long-term effects of radiation therapy has decreased the use of radiation therapy in pediatrics. As with osteosarcoma, radiation therapy is utilized for Ewing's sarcoma when full resection of the tumor is not a reasonable option.[41]

The side effects of radiation therapy are related to tumor location, dose rate and duration, age of the patient, and use of chemotherapy. Acute side effects are seen in rapidly dividing tissues such as the skin, bone marrow, and gut. Common side effects are red and tender skin, mouth sores from irradiation to mucous membranes, and nausea and vomiting from irradiation to the abdomen.[53] Children receiving radiation therapy may exhibit a decreased activity level secondary to nausea and vomiting, poor appetite secondary to mouth sores, and generalized malaise. Their physical therapy sessions may need to be altered on a daily basis to accommodate their changing energy levels. Children wearing prostheses must be monitored closely for skin irritation and breakdown.

Late side effects of radiation include fibrosis of soft tissues, bony changes ranging from osteoporosis to fractures, and growth disturbances, including damage to the epiphyseal plate and bowing of the metaphysis. Butler and colleagues[12] reported that 77% of patients with Ewing's sarcoma who received radiation therapy developed a leg length discrepancy; in 58% of these patients, the leg length discrepancy was significant enough to require treatment. Advances in surgical options have minimized the need for radiation therapy at the site of the primary tumor. If radiation therapy is indicated, attempts are made to shield the epiphyseal plate at the opposite end of the involved bone to minimize radiation-linked growth retardation and still allow for some growth of the extremity. For some young children an amputation may produce a more functional extremity than an extremity that is significantly shortened as a result of radiation therapy.

Chemotherapy

Chemotherapy is administered according to several principles, including the use of multiple drug combinations, administration of chemotherapy agents at maximally tolerated doses, and administration before the development of detectable micrometastatic disease (adjuvant chemotherapy). Most chemotherapy agents interfere with the function of DNA and RNA. However, these agents are nonselective and cause damage to both malignant and normal cells, resulting in undesirable and at times toxic side effects.[86] Physical therapists working with children receiving chemotherapy should know the specific agents being used with the child and the side effects. Typical side effects of chemotherapy can include nausea and vomiting, hair loss, diarrhea, and constipation. Other potential side effects consist of blood-related concerns such as anemia, neutropenia, and thrombocytopenia or neurologic issues such as peripheral neuropathies. The physical therapy interventions may need to be altered or limited depending on the child's status and development of potentially serious side effects.

The introduction of adjuvant chemotherapy, given preoperatively and postsurgically, in the 1970s and early 1980s increased the survival rates for both osteosarcoma and Ewing's sarcoma. Survival rates are dependent upon age, location of the tumor, and the presence and location of metastatic disease at the time of diagnosis. Three-year event-free survival (EFS) rates for children with Ewing's sarcoma treated with a combination of radiation therapy, chemotherapy, and surgery have improved to 65% to 70% for patients with nonmetastatic disease.[39] Overall 5-year event-free survival rates for children with osteosarcoma treated with a combination of surgery and chemotherapy also drastically improved from 20% in the 1970s to 65% to 70%. Children with nonmetastatic osteosarcoma of the extremity are more likely to have a favorable outcome than children with more proximal tumors and the presence of metastatic disease.[36] However, the survival rates for both Ewing's sarcoma and osteosarcoma are relatively unchanged since the mid-1980s.[28]

SURGICAL OPTIONS IN THE MANAGEMENT OF ACQUIRED AND CONGENITAL LIMB DEFICIENCIES

The goal of any surgical intervention is to improve the function of the child and, in the case of bone sarcoma, to not alter the child's chance of survival. Traditionally, amputation has been the typical approach for children with bone sarcoma. It has also been used to modify the lower extremities of children with congenital limb deficiencies for improved prosthetic fit and function. However, with improved survival rates of children with bone tumors, the long-term function and comfort of the child must also be considered. Limb-sparing procedures, including rotationplasty, are viable options for many children with congenital limb deficiencies and for those previously considered to be candidates for amputation secondary to a bone tumor. Each of these procedures offers advantages and disadvantages, and functional outcome, psychological impact, and long-term survival all must be considered in the surgical decision. This section discusses the surgical options of amputation, rotationplasty, and various limb-sparing procedures for children with congenital limb deficiencies, as well as those with a diagnosis of bone sarcoma.

Amputation as a General Surgical Option

Although most of the basic premises related to management of adults with amputations also apply to children, important differences may be noted. First, skeletal immaturity and future growth are important factors when surgical alternatives are considered. Physes should be preserved whenever possible to ensure continued growth of the limb. For the upper extremity, most growth occurs in physes around the shoulder and wrist, whereas in the lower extremity the physes around the knee account for most of the growth.[45] If an amputation will result in a significantly short residual limb, a limb-sparing procedure may offer better function and improved cosmesis for the child.

Second, the fact that amputation through long bones may result in terminal overgrowth is an important point that should not be overlooked. Terminal or bony overgrowth is a painful, spikelike prominence of new growth on the transected end of the residual limb. Significant pain can interfere with weight bearing and wearing of the prosthesis. The spikelike growth is not well understood but is seen more frequently in children under the age of 12 years.[85] Terminal overgrowth can occur in any long bone but is most frequently in the tibia. Bone capping consists of excision of the overgrowth spike and fixation of a graft on

the end of the residual limb in an attempt to prevent future terminal overgrowth. Multiple surgical revisions to remove an overgrowth spike may result in a shorter residual limb. Surgical options include revisions and bone capping. Surgical revision and bone capping with biologic materials result in frequent complications including high recurrence rates for revision and infection with biologic capping materials. More recently, surgeons have been utilizing autologous caps, specifically the proximal fibula, with promising results of decreased rates of infection and recurrence of the bony overgrowth.[23] An amputation through a joint such as a knee disarticulation eliminates the possibility of bony overgrowth. As in adults, length of the lever arm, function of the extremity, and prosthetic fit remain important considerations when deciding on the level of amputation. Saving the child's life is, of course, the most important consideration, whether the amputation is the result of a malignancy or trauma.

Finally, wound healing in children is rarely a concern as it may be in adults with peripheral vascular disease. Skin grafts therefore may be used to close the amputation site in preference to performing a higher-level amputation for a child with a traumatic injury.

Amputation to Revise Congenital Limb Deficiencies to Improve Function

Amputation and surgical reconstruction are rarely necessary with upper extremity limb deficiencies but may be indicated for some children with lower extremity limb deficiencies. Children with bilateral PFFD and equal leg lengths, however, may be more functional without any surgery. They will be of short stature but will walk quite well.[62] For cosmesis or to equalize leg lengths and stability in standing and walking, an extension prosthesis may be an option for some children with bilateral PFFD.

The surgical treatment of a child with unilateral PFFD is case-specific. If the child has a stable hip and foot and a significant portion of normal femur is present, one of the limb-lengthening procedures may be appropriate. Most surgeons agree that 60% of predicted femoral length must be present for a lengthening procedure to be a viable alternative.[31,46] If limb lengthening is not an option, surgical options for PFFD include femoral osteotomy, a knee arthrodesis, and foot amputation or a rotationplasty. Usually the Syme or Boyd amputation of the foot is recommended. A Syme amputation involves complete removal of the foot, including the calcaneus, but the Boyd amputation preserves the calcaneus. The Boyd procedure requires an arthrodesis of the calcaneus and the tibia, which adds length to the limb.[62] The knee is usually fused to form one long bone for fitting of an above-knee prosthesis[46,62] (Fig. 13.6).

Amputation may also be an option for a child with a longitudinal tibial or fibular total deficiency in which a significant limb length difference exists along with deformity of the foot. Frequently, the foot is positioned in equinovarus with a tibial deficiency or equinovalgus with a fibular deficiency, and both may include absent rays. If the tibia is completely absent, a knee disarticulation and fitting with a prosthesis will provide a very functional lower extremity for the child. If the leg length difference is too significant for limb-lengthening techniques or epiphysiodesis of the uninvolved leg, or if the ankle is significantly unstable, a Syme or Boyd amputation may lead to a more functional lower extremity with the addition of a prosthesis for a child with partial absence of the fibula. When an amputation is being considered for a child, it is important that alternatives are discussed with the family and child and that the ultimate lifestyle goals are known.

Amputation in the Management of Traumatic Injuries and Malignant Tumors

Amputations secondary to trauma may result in a short residual limb if the child has significant growth remaining. This is especially true of an above-knee amputation in which the distal physes around the knee have been resected. It may be possible to increase the length of a residual limb in older children by using one of the limb-lengthening techniques (see Chapter 14).

FIG. 13.6 (A) Child with unilateral proximal femoral focal deficiency (PFFD) without any surgical modifications to her leg. (B) Same child wearing a prosthesis to equalize limb lengths for weight bearing. Initial surgery has not yet occurred.

Lengthening of a short residual limb may increase the efficiency of gait and promote a better prosthetic fit.

The traditional approach for malignant bone tumors had been amputation of the limb in which the tumor is found. A wide surgical margin for an amputation is utilized to achieve local control of the tumor. Amputation for tumors of the pelvis or proximal femur results in complete loss of the limb or a very short residual limb, which makes functional ambulation with a prosthesis difficult. Limb-sparing procedures may result in a more functional extremity than a proximal amputation without decreasing the expected rate of survival for the child. Due to the short length of the residual limb and advances in chemotherapy since the 1970s, limb-sparing procedures have become the preferred surgical approach for both Ewing's sarcoma and osteosarcoma in the pediatric population.[43] The decision regarding an amputation is based on expectations regarding control of the primary tumor, survival of the child, and functional use of the extremity.

Rotationplasty

Rotationplasty (also called the Van Nes procedure) is an option for children with congenital limb deficiencies, specifically PFFD, as well as for those with bony tumors of the proximal tibia or distal femur. For PFFD this procedure involves excision of the distal femur and proximal tibia; 180° rotation of the residual lower limb, including the distal femur and proximal tibia, ankle joint, foot, and neurovascular supply; and reattachment to the proximal femur (Fig. 13.7). The ankle then functions as a knee joint, with ankle plantar flexion used to extend the "knee" and ankle dorsiflexion to flex the "knee"[52] (Fig. 13.8). Rotationplasty requires a functioning hip joint and ankle joint. For children with PFFD the residual foot must be adequately aligned anatomically for active plantar flexion and dorsiflexion to power the prosthetic knee. If the fibula is absent, alignment of the foot will not be adequate for a successful rotationplasty.

In the case of malignant tumors, the site of rotation is dependent on the location of the tumor. Rotation at the level of the femur proximally may have a greater effect on the function and power of the hip muscles. Rotation at the level of the distal femur or proximal tibia may have a greater effect on the muscles and function of the foot and ankle complex required to power the prosthetic knee.[40] Rotationplasty is possible only if the tumor has not invaded the surrounding soft tissue, especially the neurovascular supply.

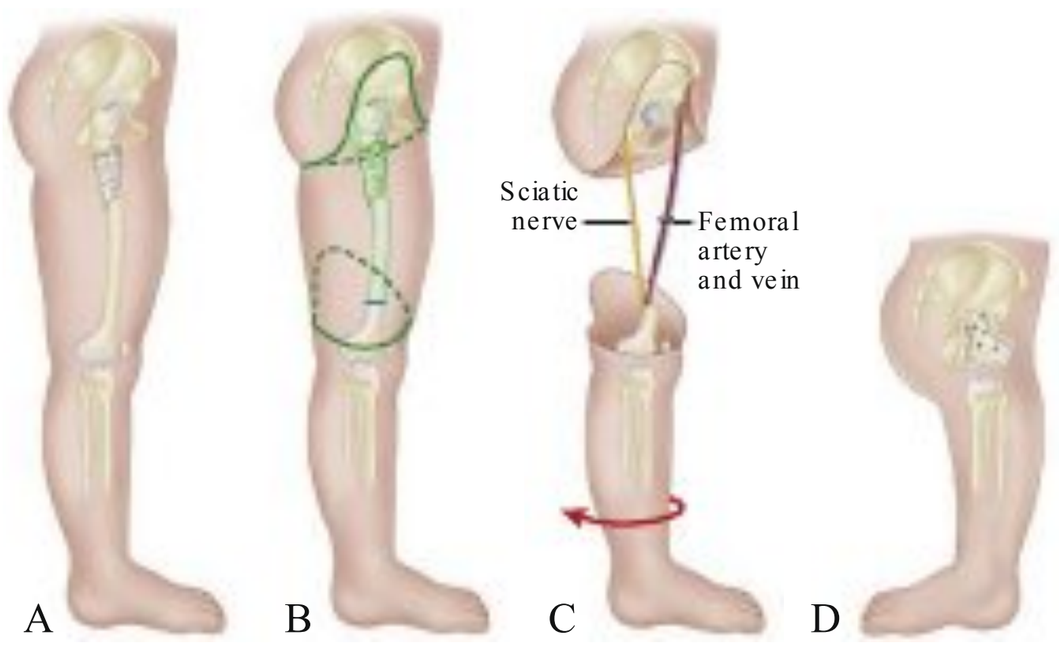

FIG. 13.7 Technique of type BI rotationplasty. (From Toy PC, Heck RK: General principles of tumors. In Canale ST, Beaty JH, editors: Campbell's operative orthopaedics, 12th ed. Philadelphia: Mosby; 2013. Redrawn from Winkelmann WW: Hip rotationplasty for malignant tumors of the proximal part of the femur, J Bone Joint Surg 68A:362, 1986.)

The advantages of a rotationplasty include increased limb length, improved prosthetic function with the ankle serving as a knee joint, improved weight-bearing capacity, and elimination of the problems of terminal overgrowth and pain from neuromas or phantom limb sensations.[51] Weight is borne through the heel, which is more suitable for weight bearing than the end of a residual limb. Rotationplasty also allows for some growth of the leg. With an appropriate prosthesis, children who have had a rotationplasty procedure can functionally participate in running, jumping, and playing with their peers and can participate in high-impact sports and activities.

Disadvantages of rotationplasty are cosmesis and derotation of the limb. Critics cite poor cosmesis and psychological issues as a deterrent to the procedure. In our experience with children who underwent a rotationplasty for a tumor or for congenital PFFD, cosmesis was not a complaint from the child or the child's parents. Krajbich and Bochmann[51] cite their experience of 27 children with osteosarcoma who underwent a rotationplasty. Twenty-two of these children are alive with no evidence of metastatic disease. No long-term complications related to cosmesis and psychological decompensation were reported; in fact, virtually all of the children with a rotationplasty now actively participate in sports and other activities with their peers. When a rotationplasty is being considered as a surgical option, it may be helpful for parents and the child to meet another child who has had the rotationplasty performed. Certainly, the cosmetic disadvantages must be discussed. Additional studies have shown that children with PFFD who underwent a rotationplasty demonstrated a higher walking speed with less oxygen consumption and fewer compensatory gait deviations than children who underwent a foot amputation and foot and knee arthrodesis.[24,68]

When the procedure is performed on young children, derotation of the limb may occur, requiring rerotation of the limb. The limb may derotate secondary to the spiral pull of the muscles proximal and distal to the osteotomy.[46] Both Krajbich[52] and Gillespie[31] discussed surgical options to limit derotation of the limb after a rotationplasty. Derotation is more common in children younger than 10 years of age and is most frequently seen in children when a rotationplasty is performed at 3 or 4 years of age.[31] Concern has also been raised about the long-term consequences of the altered weight bearing on the ankle joint. A study by Akahane[4] assessed 21 patients at a mean follow-up of 13.5 years post rotationplasty and found no evidence at that point of joint arthrodesis or degenerative joint changes.

Limb-Sparing Procedures

With the use of chemotherapy, improvements in diagnostic imaging to determine tumor margins, and new techniques of reconstruction, amputation is not always the treatment of choice for children with bony malignancies. Limb-sparing procedures may be an alternative to amputation for many children with malignant bone tumors. Limb-sparing procedures involve resection of the tumor and reconstruction of the limb to preserve function without amputation of the limb. Reconstruction of the limb may include excision of bone without replacement of the excised area or replacement with an allograft or endoprosthetic implant.

FIG. 13.8 An 11-year-old boy who underwent a rotationplasty procedure. (A) Ankle dorsiflexion. (B) Ankle dorsiflexion produces prosthetic knee flexion. (C) Ankle plantar flexion. (D) Ankle plantar flexion produces prosthetic knee extension.

Appropriate selection of children for limb-sparing surgery is critical. The goal of saving the limb should never compromise the goal of removing all gross and microscopic tumor. Limb-sparing surgery is contraindicated if the tumor has invaded the surrounding soft tissue to a large extent, if it involves the neurovascular supply, or if the tumor has invaded the intramedullary cavity.[43] In addition, limb-sparing surgery for the lower extremity of a young child may not be beneficial when the child is skeletally immature and may be left with a severe leg length discrepancy and a nonfunctional lower extremity. In these cases, amputation may be a better choice than limb-sparing surgery.

Autologous grafts are rarely appropriate because long segments of bone usually must be excised. Replacement of the excised bone with a near-equal length of noninvolved bone from another portion of the body often is not possible. Cadaver structural allografts, intercalary or osteoarticular, are another option. They involve resection of the tumor and surrounding bone and implantation of a section of cadaver bone. Osteoarticular allografts can preserve some growth plates, especially those of the distal femur and proximal tibia, if the tumor resection involves the proximal femur. The grafts are stabilized with plates or intramedullary rods until osteosynthesis has occurred. Once osteosynthesis has occurred and the child's bone has formed a latticework within the implanted bone, the graft is very stable and may last a lifetime. Complications of allografts include infection, nonunion, and fracture, all of which may compromise the long-term integrity of the implant. Infections and nonunions are early-onset complications that are seen with greater frequency in children receiving chemotherapy.[37] As is true with most limb-sparing procedures, high-intensity activities such as athletic participation are limited for the child with an osteoarticular allograft.

At times a tumor may be excised without replacing the excised bone. The proximal fibula may be resected if the soft tissue involvement is minimal and the peroneal nerve is not included in the soft tissue involvement. The biceps femoris tendon and the fibular collateral ligament are reattached to the lateral condyle of the tibia.[45] After healing, full knee motion and a normal gait pattern can be expected. Endoprosthetic devices are ultimately an extension of joint arthroplasty procedures. These manufactured devices consist of modular components that are implanted in the area of the excised bone such as the proximal humerus, elbow, proximal and distal femur, and proximal tibia. These modular components may be periodically replaced surgically to compensate for the child's growth. This surgical exchange of components involves multiple surgical procedures for the skeletally immature child, and each procedure predisposes the child to complications of infection, pain, and vigorous postoperative physical therapy to restore function and mobility.[64] Endoprosthetic designs often incorporate a telescoping unit that can be expanded to accommodate growth. Expansion of the prosthesis typically involves a surgical procedure at periodic intervals. Complications of expansion include loosening of the prosthesis, infection after lengthening procedures, mechanical failure, and fracture. The need for repeat surgical procedures to expand or grow the device is costly and inconvenient for the child, and the risk for infection is increased with each procedure. A review by Eckardt and colleagues[20] of 32 patients with expandable prostheses included patients ranging from 3 to 15 years of age. Fourteen of the 32 patients had no complications; 18 patients had 27 complications, including infection, loosening of the device, mechanical failure, fracture, knee flexion contracture, and prosthetic shoulder joint subluxation; and 1 patient died of a pulmonary embolism. The authors stressed the need for strong family participation during rehabilitation to avoid knee flexion contractures in skeletally immature patients. Effective growth of the child's limb of 7 to 9 cm with the use of an endoprosthetic device has been reported.[20]

To avoid the multiple surgical procedures involved with the modular devices and the early telescoping units, an endoprosthesis that can be expanded with the use of an external electromagnetic field was developed. Exposure of the limb to the electromagnetic field unlocks an energy-stored spring and allows for controlled lengthening without a surgical procedure.[94] Early studies showed decreased rates of infection and more frequent but smaller adjustments in length that were less disruptive to gait and possible range of motion (ROM) complications.[8,65] Ness and colleagues found that similar functional results were achieved with the noninvasive expandable endoprosthetic device compared with a modular device requiring periodic surgical procedures.[67]

Limb-sparing surgery yields similar recurrence rates as amputation when adjuvant chemotherapy is used and when particular attention is given to patient selection, surgical margins, and surgical techniques.[81] A limb-sparing procedure involving the distal femur and/or proximal tibia may result in a significant leg length difference in a child 10 years of age or younger because growth will be lost with excision of the growth plates around the knee. Futani and colleagues[26] retrospectively assessed 40 children younger than 11 years who underwent a limb-sparing procedure secondary to a bone sarcoma. They determined that a limb-sparing procedure could provide good functional outcomes in this younger population. The authors did caution that the functional outcome often was the result of multiple procedures and revisions, including limb lengthenings for expandable prostheses.[26] A long-term complication of lower extremity limb-sparing procedures is reduced ROM, especially at the knee.[10] The ROM deficits, specifically at the hip and knee, that are frequently seen after a limb-sparing procedure are correlated with deficits in mobility.[58] Children with knee flexion ROM deficits exhibited greater difficulty with timed up and down stairs, timed up and go, and a 9-minute run-walk distance.

Lifestyle of the child is another important presurgical consideration because many limb-sparing procedures such as osteoarticular allografts and endoprosthetic implants may limit participation in competitive physical activities. Recent studies have shown that young adults who underwent a limb-sparing procedure for a bone tumor participate in fitness and sports activities regularly. Participation is influenced by presurgical activity level as well as type and level of surgical procedure and long-term complications such as peripheral nerve damage.[47,54] Limb-sparing procedures such as rotationplasty and limb lengthening are increasingly used with children with congenital limb deficiencies to avoid an amputation and often result in excellent function for the child.

Comparison of Surgical Options

With improved survival rates of children with bone sarcomas since the 1970s and the increased use of limb-sparing procedures, it is important to assess the functional outcomes of the various surgical options and to understand the role of physical therapy in successful rehabilitation of these children. Limb-sparing procedures were developed to provide alternatives that spare the child's limb and minimize the functional limitations associated with high-level amputations. However, most of the outcome studies have not demonstrated the marked advantage of limb-sparing procedures that was expected because of some of the complications associated with these procedures.

To compare outcomes, it is best to differentiate between below- and above-knee amputations, as well as between femur and tibia limb-sparing procedures. Ginsberg et al.[34] compared functional outcomes and quality of life among children who had an amputation, limb-sparing, or rotationplasty procedure. They utilized a newer assessment tool, the Functional

Mobility Assessment (FMA), which measures pain, timed up and down stairs, timed up and go, use of ambulation supports, satisfaction of walking quality, participation in work and sports, and endurance.[57] Adolescents and young adults who underwent a femur limb-sparing surgery scored significantly higher on the FMA than those who had an above-knee amputation. However, those who underwent a below-knee amputation scored higher on quality of life measures than those patients who had a limb-sparing procedure of the tibia. Pardasaney[70] and colleagues found that individuals who had undergone an above-knee amputation used an assistive device and walked with a limp more frequently and had higher anxiety levels than those had a femur limb-sparing procedure. However, employment status and ability to participate in sports were not significantly different between the two groups. Researchers also reported that no significant physical functioning or psychological differences were noted between individuals who had a below-knee amputation and those who had a tibia limb-sparing procedure.

Limb Replantation

For children with traumatic amputations, limb replantation may be a surgical option. As with other surgical options, the goal of replantation is directed not only at preserving the amputated limb but also at restoring pain-free function to the extremity that is superior to the function obtained with a prosthesis. For an upper extremity replantation to be considered successful, function of the elbow and hand and distal sensation must be restored. Replantation of a lower extremity must provide a painless, sensate extremity capable of bearing weight during normal daily activities.[9]

Distal replantations of an upper extremity usually result in a more favorable outcome than proximal replantations and are performed more frequently. Digit replantation occurs in approximately 40% of pediatric finger amputations.[87] Proximal replantations are often associated with a violent mechanism of injury that results in damage to the nerves, blood vessels, and muscles. A proximal replantation also necessitates a longer distance for the nerves to regenerate for functional use of the hand. Physical therapy is indicated for these children for wound care, control of edema, joint ROM, strengthening, gait training, and self-care activities. Rehabilitation will include close communication with the physician regarding precautions and progression of activities and family instruction while the child is in the hospital and is treated as an outpatient.

Osseointegration

Osseointegration is the direct attachment of a prosthesis to the end of the bone of the residual limb. The prosthesis attaches to an abutment that has been surgically attached to the bone and protrudes through the skin. The concept of directly attaching a prosthesis to the bone is not new, but the technology to enable the interface of a foreign material with the bone and yet protrude through the skin has expanded the clinical application of this technique. Osseointegration is a long process that requires multiple surgical procedures. The first surgical stage involves the implant of a threaded cylinder directly into the end of the residual bone. At least 6 months later a metal abutment is threaded onto the existing cylinder at the second surgical stage. The metal abutment protrudes through the skin at the distal end of the residual limb and will eventually receive the prosthesis. During the last but lengthy stage, weight-bearing loads on the abutment are gradually increased through the use of a temporary and then a permanent prosthesis. To allow for secure integration of the abutment with the skeleton, this last stage of gradually increasing weight-bearing loads can take well over a year.[71,79]

The purported advantages of osseointegration are the elimination of a socket and the inherent problems associated with poorly fitting sockets and suspension methods. Because the prosthesis is directly attached to the bone through the abutment, some sensation is preserved such as the ability to perceive stepping on a stone or an uneven surface.[71] This procedure is still in its early stages and is not indicated at this time for children or adolescents who are skeletally immature.

Phantom Limb Sensations

Phantom limb sensations are an occurrence in many adults with amputations, but fewer reports are available concerning children with phantom limb sensations. Some persons may believe that if young children do not complain of phantom limb pain, they therefore must not have any pain. Melzack and colleagues[61] reported that 20% of individuals with a congenital limb deficiency and 50% of those with an acquired amputation before 6 years of age experienced phantom limb sensations. However, most of the individuals reporting phantom limb sensations reported not pain but rather the perceived ability to voluntarily move the phantom limb.[61] A study from St Jude Children's Research Hospital found that 70% of children and young adults experienced phantom limb pain at some point during their first year after a cancer-related amputation.[11]

The phantom limb sensations and pain of adolescents can become intense. If left untreated, phantom limb sensations can become debilitating and interfere with prosthetic wear and daily activities. Some teenagers are able to control the sensations through rubbing or massaging the uninvolved limb at similar points to those in which they are experiencing the phantom limb sensations of the amputated limb. Others feel more in control by keeping a daily log of their sensations and reporting the pain intensity on one of a variety of pain scales. Mirror therapy has been proposed as an effective intervention to reduce phantom limb pain through the facilitation of an illusion of an unaffected limb. Mirror therapy theorizes that this illusion of two unaffected limbs fosters reorganization of the somatosensory cortex of the brain to reduce phantom limb pain.[77] For some adolescents the use of analgesics may be beneficial. If available, a referral to a pain management team should be instituted for children undergoing amputations.

OVERVIEW OF PROSTHETICS

Upper Extremity Prosthetics

Upper extremity prosthetic systems may be body powered or externally powered. Externally powered prosthetic devices are typically referred to as myoelectric devices. Body-powered components include a terminal device, a wrist unit, possibly an elbow unit, and a socket and are operated by a harness and cable system. With a myoelectric system a muscle contraction activates electrodes placed in the direction of the muscle fibers in the socket on designated muscles, which act to control the terminal device, wrist, or elbow. Children may also utilize a prosthesis that is a combination of body-powered and externally powered components. For example, the child may operate

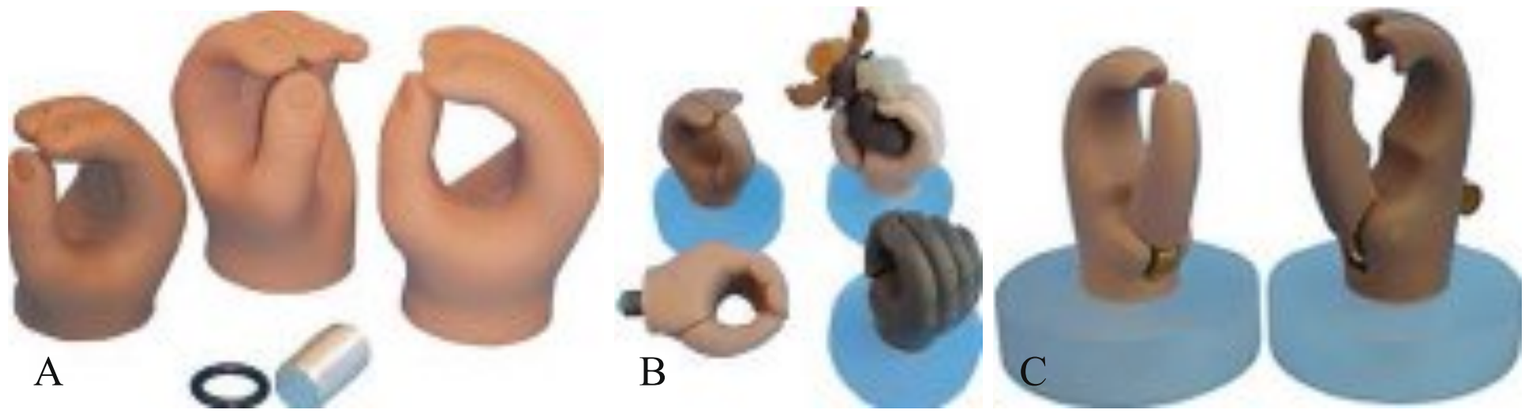

FIG. 13.9 Terminal device options: (A) Passive Infant Alpha Hand. (B) L'IL E-Z Hand promotes grasping when the thumb is moved. (C) ADEPT voluntary closing hand. (Courtesy TRS, Boulder, CO.)

FIG. 13.10 Prosthetic feet options: (A) Little Feet. (B) Flex-Foot Junior. (C) Truper Foot. ([A] Courtesy TRS, Boulder, CO. [B] Courtesy Össur Americas, Foothill Ranch, CA. [C] College Park Industries, Warren MI.)

the elbow using a body-powered cable system and operate the hand with a myoelectric system.[22]

Terminal devices range from the passive hand or fist to a myoelectric hand. Terminal devices often used in pediatrics include the passive fist or hand, the CAPP (Child Amputee Prosthetics Project [Hosmer Dorrance, Campbell, CA]), various hooks, including the Dorrance and ADEPT (Anatomically Designed-Engineered Polymer Technology [Therapeutic Recreation Systems, Boulder, CO]) models, and myoelectric hands such as the Ottobock Electrohand (Ottobock Orthopedic, Plymouth, MN) and the New York Mechanical Hand (Hosmer Dorrance) (Fig. 13.9). The child's age and size, as well as the parents' and child's desires and functional goals, determine the appropriate terminal device. The wrist unit allows forearm pronation and supination and accommodates the terminal device.

As a child's activities change, different terminal devices may be needed. Various recreational terminal devices are available to allow participation in a variety of sports activities.[16,22] Teenagers may desire a cosmetic hand for social activities and a functional terminal device for daily activities.

Suspension systems generally fall into two categories. The first is a harnessed system that is used to suspend a prosthesis or to control a terminal device. Both above-elbow and below-elbow amputation levels can use this type of suspension. The figure 8 and the chest strap are two harness configurations that can be used to suspend and/or control a terminal device.

The figure 8 harness and chest strap fit over the shoulder of the involved limb and around the chest to secure the prosthesis without limiting shoulder movement. The figure 8 harness securely anchors the prosthesis, so the child may activate the cable system of an above-elbow prosthesis. Self-suspending sockets are available for young children. A simple self-suspending socket may be all that is necessary to suspend a below-elbow prosthesis of an infant or toddler. If additional suspension is required, a small silicone sleeve can be rolled over the prosthesis and onto the humeral area. This affords added suspension without any additional restriction of movement. When the cable for the terminal device is added to the prosthesis, a triceps pad or cuff to secure the cable can be incorporated. A shoulder disarticulation prosthesis is secured with a chest strap. A prosthesis at this level is often very difficult to fit and now is most commonly restricted to myoelectric or hybrid control.

With recent developments in upper extremity research, an increasing number of options are becoming available to the child amputee. Electrodes embedded into silicone liners allow the prosthesis to be both self-suspending and myoelectrically controlled. Recent technological enhancements to electrodes now allow the fitting of children with heavy scarring or weak signal strength so they can benefit from a myocontrolled prosthesis.

Lower Extremity Prosthetics

The fact that children are growing and may be facing several surgical interventions makes fitting a child with a prosthesis very different from fitting an adult with a prosthesis. In addition, angular deformities associated with various congenital deficiencies result in gait and alignment challenges not generally seen in the adult traumatic population. Consequently, many prosthetists will fit a child with a prosthesis that accommodates some growth, stage the introduction of components, and utilize components that can be replaced as the child grows. The variety of components available to the pediatric population continues to expand but does not yet compare with the wide variety available for the adolescent or adult population.

The SACH (Solid Ankle Cushion Heel) (Ottobock) foot has long been the mainstay for pediatric prosthetic feet and continues, in various forms, to be used for young toddlers. The L'IL foot (TRS Industries, Fargo, ND) is a variation of the SACH foot. The entire foot is made of a more flexible plastic that allows a better response during kneeling and pulling to stand. However, young children can now be fitted with dynamic-response or energy-storing feet (Fig. 13.10). In two separate

FIG. 13.11 Total Knee Junior is a polycentric knee that provides stability and aids in the initiation of a smooth gait pattern. (Courtesy Össur Americas, Foothill Ranch, CA.)

FIG. 13.12 Example of a lower extremity prosthetic system, including socket; 3R60 is a polycentric knee joint and 1C30 Trias is a prosthetic foot. (Courtesy Ottobock HealthCare LP, Austin, TX.)

retrospective analyses, Anderson found that parents and children preferred the cosmetic appearance of dynamic response feet and stated that these feet improved their child's endurance and possibly stability.[3]

The shank of a lower extremity prosthesis has either an exoskeletal or an endoskeletal design. Exoskeletal shanks are fabricated of a rigid polyurethane foam and are laminated to form a hard outer covering. Endoskeletal shanks consist of a pylon made of ultralight material, such as graphite or titanium, and covered with foam. Teenagers often prefer endoskeletal shanks because of their cosmesis and decreased weight. The durability of exoskeletal shanks is often more appropriate for the younger child. Exoskeletal shanks can then be finished with various patterns or designs that are appropriate for the younger amputee.

A wider variety of prosthetic knees are now available for the pediatric population, including toddlers just beginning to pull to stand. A single-axis constant-friction knee is set to function at a certain walking speed. If the speed of walking increases, the prosthesis lags behind because the shank cannot swing through as quickly as the uninvolved limb. In addition, this type of knee is not very stable and buckles quickly if the ground reaction force is not anterior to the knee joint. When the young toddler who is only beginning to stand is fitted, the socket is aligned anterior to the knee center to increase stability. Another type of knee joint available for the pediatric population is a polycentric knee with a four-bar linkage mechanism (Fig. 13.11). A polycentric knee mimics the anatomic knee joint to increase stability. The axis of motion is posterior during stance to provide added stability and anterior during swing to shorten the shank and assist with clearance. A lower extremity prosthesis with a polycentric knee is shown in Fig. 13.12. Polycentric knees are now available for use with toddlers, leading some centers to incorporate a prosthetic knee into a child's first prosthesis.

A larger variety of knee units are available for teenagers, including hydraulic, pneumatic, and microprocessor-controlled knees. Hydraulic and pneumatic knee units are variable-friction units that allow variable walking and running speeds. Variable-friction units are equipped with a swing control mechanism that sets the drag of the shank through swing phase and a stance control unit that permits knee flexion during stance without collapse of the leg. Swing and stance control mechanisms are excellent options for active teenagers, especially those engaged in physical activities. Drawbacks of hydraulic and pneumatic knees are the added weight to the prosthesis, cost, and the intricacy of adjustments. Recent advances in technology have reduced the size and weight of hydraulic systems, resulting in a more functional option for the child amputee.

Like adult sockets, pediatric socket design has changed over the past 15 years. Children with a transfemoral amputation can be fitted with a narrowed medial-lateral ischial containment socket or an anatomically correct socket design. The narrowed medial-lateral socket with ischial containment more evenly distributes weight-bearing pressures and allows less lateral movement of the distal femur, thereby providing greater stability during stance. Adolescents with a below-knee or transtibial amputation may be fitted with the standard patellar tendon–bearing socket or total surface-bearing design. However, younger children may require a supracondylar socket that offers greater suspension. Because most congenital deficiencies result in disarticulations, the Syme prosthesis is the most common lower extremity socket design in the pediatric population. The bulbous end present in most Syme revisions allows for a suspension point just proximal to the distal end. The bladder or segmented socket design is then used to increase independence and eliminate additional suspension systems. These designs are often referred to as self-suspending.

Infants and toddlers will require some type of suspension to secure their prosthesis. A Silesian belt or total elastic suspension (TES) belt works well for younger children with an above-knee amputation or PFFD, and preschoolers can become independent in their use (Fig. 13.13). Neoprene sleeves and silicone liners with a locking mechanism are additional suspension methods commonly used with young children. The silicone liner is rolled on the residual limb, and the pin on the end of

FIG. 13.13 Toddler with a right proximal femoral focal deficiency fitted with a prosthesis before any surgical procedures were performed to modify her leg. A neoprene total elastic suspension belt is used as the suspension method to secure the prosthesis.

FIG. 13.14 Suspension systems may utilize a silicone liner that is rolled onto the residual limb and attached to the distal end of the socket with a pin-locking mechanism. (Courtesy Össur Americas, Foothill Ranch, CA.)

the sleeve is threaded into the prosthesis and locked in place. To remove the prosthesis, the pin is released by pushing a button on the distal end of the socket[16] (Fig. 13.14).

Suction sockets are appropriate for the older child who is not growing rapidly or is undergoing weight fluctuations secondary to chemotherapy treatment. Suction sockets utilize negative pressure as air is expelled through a distal valve and surface tension between the skin and socket to maintain the suspension.[16] Advances in silicone liners allow a suction fit over the liner with various design elements that may include a ring seal. A ring seal and other design elements aim to improve the suction and mechanical suspension of the socket as well as to reduce rotation and pistoning of the socket.

FIG. 13.15 Catcher is an adolescent with a left below-knee amputation.

FIG. 13.16 Tossing a tennis ball using a prosthesis with a passive hand.

Children with a rotationplasty use a prosthesis that incorporates the plantarflexed foot in the socket. The socket is essentially a below-knee socket with a thigh cuff attachment and external hinges for the knee joint. A Silesian or TES belt may be needed for suspension.

Children of all ages with a limb deficiency or amputation should be encouraged to participate in activities with their peers. Many children may want to participate in sports at a recreational or a competitive level (Fig. 13.15). Many prosthetic options are available that promote participation in various sports. Recreational prosthetics options are too numerous to mention for this discussion, and the reader is referred to other resources.[76] Ultimately, any prosthesis for a child should allow the opportunity for age-appropriate function and be cosmetically appealing to the child and family (Fig. 13.16). Decision

making for infants' and toddlers' prosthetic needs should include the parents, orthopedist, prosthetist, and physical therapist. The older child should be included in the decision-making process.

Appropriate prosthetic components are costly, and a full prosthesis must be replaced at least every 12 to 18 months for growing children and adolescents. If an adolescent chooses to participate in sports or swimming activities, an additional prosthesis or components may be required. Third-party payers are reluctant to pay for multiple prostheses or myoelectric devices. Currently, some health maintenance organizations will pay for only one prosthesis in a lifetime.

Studies are beginning to examine the cost-effectiveness of surgical procedures and various prosthetic options. Grimer and colleagues[38] compared long-term costs of limb-sparing procedures versus amputation with a prosthesis. Limb-sparing procedures are more costly initially, but amputations for children or adolescents are very costly over time because of the need for multiple and sophisticated prostheses.

FOREGROUND INFORMATION

PHYSICAL THERAPY INTERVENTION FOR THE CHILD WITH A LIMB DEFICIENCY OR AN ACQUIRED AMPUTATION

The parents are an integral part of the rehabilitation team for a child with an amputation or a limb deficiency. The rehabilitation team should also include an orthopedist, a prosthetist, and a physical therapist who are experienced in the management of children with amputations. This may often mean traveling to a major medical center for periodic assessments and prosthetic adjustments. Physical therapy can be delivered in the local community if available, but the therapist must be in communication with the managing rehabilitation team.

The overall goals of physical therapy are to facilitate as normal a sequence of development as possible for the child and to prevent or minimize the development of impairments, activity limitations, and participation restrictions. Impairments can include joint contractures and weakness with resultant activity limitations of reduced mobility and a lack of independence in self-care skills. Physical therapy goals are directed toward preventing joint contractures, minimizing muscle strength imbalances, preventing skin breakdown, and developing independence with mobility and self-care skills. Ideally these goals are accomplished through physical therapy intervention for the child, child or parent instruction, and follow-up of a child's progress and functional outcomes. The child's age, type of limb deficiency, or level of amputation, as well as other medical factors, will influence the intensity of physical therapy needed.

The physical therapy examination should follow the components listed in the *Guide to Physical Therapist Practice*.[5] A thorough examination of joint integrity and mobility and range of motion is important for the child with a limb deficiency. Some children with a congenital limb deficiency may have other associated musculoskeletal impairments, as well as other syndromes that affect the integrity of the musculoskeletal system. Integumentary integrity will be important postsurgery and for the child with a prosthesis. Examination of gait and balance, neuromotor development, aerobic capacity and endurance, community and work integration, and self-care will begin to highlight the child's functional abilities (Box 13.1).

BOX 13.1 Recommended Measures for Children With Limb Deficiencies or Amputations

Body Functions and Structures
Pain
Skin integrity
Anthropometric measures
Range of motion
Strength

Activity – Single Task
6-minute walk test
Timed up and down steps

Activity – Multiple Items
Peabody Developmental Motor Scales
Pediatric Balance Scale
Functional Mobility Assessment (FMA)
Child Amputee Prosthetics Project – Functional Status Inventory (CAPP-FSI)

Participation
Pediatric Quality of Life Inventory (PedsQL)
Pediatric Evaluation of Disability Index (PEDI)

Functional outcomes can be assessed using current assessment tools. However, these assessment tools may not be able to determine the functional effectiveness of various prosthetic options. Third-party payers and state-funded programs will opt for the prosthetic options that are less costly if outcomes are not present to justify the more expensive options. Pruitt and colleagues (1996) developed and tested an outcome measure for children with limb deficiencies. The Child Amputee Prosthetics Project—Functional Status Inventory (CAPP-FSI) assesses 40 activities on two scales to determine whether the child performs the activity with or without a prosthesis. The child is also rated for the severity of his or her limb loss. Internal reliability for the two scales that compose the CAPP-FSI was 0.96.[73] The CAPP-FSIP and the CAPP-FSIT were developed to assess the functional outcomes of preschoolers age 4 to 7 years and toddlers age 1 to 4 years, respectively.[74,75] The FMA is a more recently developed functional outcome measure that has been validated for children and young adults with bone sarcomas. The FMA comprises six categories: (1) pain, (2) function as measured by the timed up and down stairs (TUDS) and the timed up and go (TUG), (3) use of supports or assistive devices, (4) satisfaction with quality of walking, (5) participation in work, school, and sports, and (6) endurance as measured by a 9-minute walk/run test.[57]

Infancy and Toddler Period

An infant with a limb deficiency should be referred for an initial examination by a pediatric orthopedist and a physical therapist shortly after birth. Monitoring by the physical therapist with suggestions to parents regarding positioning and ROM exercises may be all that is needed initially. The motor development of children with multiple limb deficiencies or upper extremity deficiencies may become delayed or impaired owing to their inability to use their arms for such activities as pushing up to sit, crawling, and pulling to stand. Physical therapy is necessary to monitor the infant's developmental progress, ROM, and strength needed for later prosthetic use. The physical therapist should also teach the parent or caregiver how to incorporate physical therapy goals into the child's daily activities. This can

be accomplished through periodic physical therapy examinations and evaluations, optimally at 1-month intervals, with updated parent instruction provided.

Generally, infants with limb deficiencies do not develop contractures after birth, but ROM should be carefully monitored according to individual needs. The parents of a child with a PFFD may benefit from instruction to decrease the hip flexion and abduction contractures that are typically noted at birth and will later interfere with prosthetic fit. Most children with upper extremity limb deficiencies will maintain ROM and strength through their developmental activities.

Careful monitoring of the developing infant is necessary to evaluate ROM, functional strength, weight-bearing capabilities, and posture while prone, sitting, and standing. Often a child with a limb deficiency will tend to bear weight asymmetrically in prone and during sitting activities. Some children will take increased weight on their limb-deficient side to free their uninvolved side for reaching and movement. Other children may take more weight through their uninvolved side because of weight-shifting and balance difficulties. Suggestions may be given to the parents and therapy provided to encourage weight-shifting activities to improve symmetry. For the child with an upper limb deficiency, this will encourage cocontraction of the shoulder musculature as needed later for prosthetic use. For the child with a lower limb deficiency, this encourages assumption of an erect trunk with normal balance reactions. Shifting weight to the limb-deficient side is also important for the preprosthetic training needed for standing and ambulation activities.

If an infant is not progressing developmentally, physical therapy intervention may be warranted to provide alternative methods of achieving the normal developmental sequence. For example, a child with bilateral upper extremity limb deficiencies may need assistance to learn to stand from sitting or to safely learn to balance in standing.

A child is usually fitted with a prosthesis at a developmentally appropriate age. A child with a lower extremity deficiency will be fitted for a prosthesis when weight bearing is appropriate and the child is beginning to pull to stand (between 8 and 10 months of age depending on the child's developmental progress). A child with a unilateral PFFD may initially be fit with an extension prosthesis to equalize limb lengths as soon as transitioning into and out of standing while biding time to allow for skeletal development that will determine the surgical options.[62] A child with an upper extremity limb deficiency may be fitted with a prosthesis to assist with early playing skills in sitting or even as early as 3 months to assist with weight-bearing skills while prone. Children are typically fitted with an upper extremity prosthesis between 5 and 7 months, when they are able to sit independently.[83]

When a child first receives a prosthesis, the fit and alignment as well as the overall function of the prosthesis are assessed. The initial session is spent on instructing the parents in properly donning the prosthesis, checking the skin, and developing a wear schedule. The initial goal is to have the infant or toddler wear the prosthesis comfortably for as many hours a day as possible and for the parents to be comfortable in donning and removing the prosthesis. The prosthesis may be removed for naps and should be removed when the child sleeps at night.

A child with an upper extremity prosthesis may initially ignore it. The focus of therapy should be on having the child wear the prosthesis while playing and to begin to use it for bimanual play such as manipulating and holding large toys and during gross motor activities such as pushing up to sitting or quadruped, protective reactions, and propping in sitting.

FIG. 13.17 Toddler holding a toy in the passive hand of her prosthesis.

The child's first upper extremity prosthesis may have one of several terminal device options (see Fig. 13.9). A young infant may have a nonarticulating hand that is cosmetically appealing but has limited movement (Fig. 13.17). As the child begins to engage in bimanual play, reaching, and propping activities, the decision to use a body-powered or an externally powered myoelectric device is made. Body-powered devices may be a simple split hook terminal device or a CAPP voluntary opening device. The split hook is similar to that used with adult prosthetics, except it is smaller. The CAPP was designed specifically for children, is cosmetically more appealing than a hook terminal device, is safer than a hook for a young child, and provides an efficient grip without requiring great operating force. The goal for the young child at this time is to adjust to the weight of a prosthesis, to begin to use it to manipulate larger toys, and to shake or remove toys placed in the terminal device by an adult.

Children are not expected to begin to operate the terminal device until 18 months of age or later, when they understand simple commands and cause and effect.[83] Training to operate the terminal device is dependent on the child's developmental level. Generally, children are taught to open the terminal device, place objects in it, and then release them, in that order. This corresponds with the normal developmental sequence of learning to grasp before learning to release objects.[72] The therapist must be familiar with the mechanism that controls the terminal device because this can differ from child to child, depending on the design of the device. The CAPP and Hosmer Dorrance hook are voluntary-opening terminal devices; forward reaching of the arm pulls the cable tight and activates opening of the terminal device. Children with a transverse deficiency of the upper arm will need to use scapular abduction to activate opening of the terminal device with the elbow locked; control of the prosthetic elbow comes at a later age. The ADEPT hook is a voluntary-closing terminal device designed to mimic forward reaching to grasp or close on an object (Fig. 13.18).

FIG. 13.18 Child engaging in bimanual play wearing a forearm prosthesis with an ADEPT voluntary closing hook. (Courtesy TRS, Boulder, CO.)

FIG. 13.19 Young girl using her myoelectric single-site prosthesis to complete a bimanual activity.

If the decision is made to fit the child with an externally powered prosthesis, the New York Hand (Hosmer Dorrance) or the Ottobock Electrohand is commonly used with young children. Children typically are fitted initially with a myoelectric hand with only one electrode. When this electrode is activated through muscle contraction, the hand opens. When the child relaxes the muscle, the hand closes. Typically, by 3 to 4 years of age the child's myoelectric device can be converted to two electrodes, two sites, so that opening and closing the hand are controlled by the child[16] (Fig. 13.19).

Recent evidence indicates that children younger than 2 years with a lower limb deficiency or above-knee amputation can be fit with a prosthesis that incorporates a prosthetic knee. Infants and toddlers demonstrated the ability to transition into and out of positions, crawl, squat, and play in kneeling and tall kneeling incorporating the prosthetic knee[29,30] (Fig. 13.20). The principle for fitting a young child with a knee component is that knee flexion during gait simulates a more normal gait pattern and may therefore eliminate some of the gait deviations, such as vaulting on the uninvolved limb and circumduction of the prosthetic limb that may develop and become ingrained after ambulating with a prosthesis without a knee.[15] When toddlers are fitted with a lower extremity prosthesis, normal stance and gait patterns for their developmental age should be kept in mind. Children 1 year of age stand and walk with a wide base of support and exhibit increased hip external rotation during the swing phase.[90] For this reason, a toddler's prosthesis may need to be aligned with greater hip abduction than is provided to an older child.

Because a goal of physical therapy is symmetry of posture and movement during developmental activities, proper alignment and controlled weight-shifting and balance activities are emphasized for children with a lower limb prosthesis. Many children with a lower limb prosthesis do not require an assistive device for ambulation; however, initial gait training with an assistive device promotes a reciprocal gait pattern and an

FIG. 13.20 Toddler with his first bilateral transfemoral prosthesis with knee joint to promote age-appropriate ambulation skills and play activities on the floor.

erect trunk. As the child develops balance and is able to control weight shifting, he or she will naturally discard the assistive device when comfortable with independent ambulation.

Preschool- and School-Age Period

When a child attends a preschool or kindergarten class for the first time, many anxieties may resurface for the parents of a child with a limb deficiency. Parents will worry that their child may not fit in or will look different from his or her peers. This is also an age by which typical children have

achieved independence with ADL skills such as eating and dressing, and their social relationships with peers increase. The preschool years should emphasize development of independence in self-care skills and mobility and acquisition of school skills such as coloring, cutting, and writing. If these skills are achieved during the preschool years, the child will enter school with minimal or no activity limitations or participation restrictions.

The child with an upper limb deficiency should be able to activate the terminal device of the prosthesis by this age. Children using above-elbow prostheses can begin to learn to control the elbow by 3 or 4 years of age. Most above-elbow body-powered prostheses have a dual cable system that allows the child to control elbow flexion and extension and forearm pronation and supination. With control of the elbow and forearm, the terminal device of the prosthesis becomes more functional in a variety of positions.

Emphasis should always be on assisting the child to learn skills that are appropriate for his or her age. Play skills involving manipulation of smaller objects, using the prosthesis to hold and turn paper for coloring and cutting activities, holding the handlebars of a tricycle, and self-dressing and feeding skills are important. A child with a unilateral upper limb prosthesis will always use it as a helper hand and not as the dominant hand.

For those children with bilateral upper limb deficiencies, the use of a prosthesis should be carefully monitored. These children should always be allowed to use their feet or mouth for play and self-care activities. A prosthesis may aid these children for only some periods of the day and may actually limit their function during some activities. Children with lower limb deficiencies requiring the use of prostheses, including those children with unilateral PFFD, should be functional ambulators at this age. During the preschool years, some surgery is usually necessary for the child with a unilateral PFFD. Femoral osteotomy, arthrodesis of the knee joint, and foot ablation are usually performed between 2.5 and 4 years of age. These procedures increase the lever arm of the thigh and eliminate any knee instability.[31,62] Femoral or tibial epiphysiodesis may be performed at the time of knee arthrodesis. The ultimate goal is for limb length on the prosthetic side to be 5 cm shorter than on the contralateral femur. This enables the prosthetic knee joint to be at approximately the same level as the contralateral knee joint at maturity. Placement of the prosthetic knee joint at the same level as the contralateral knee joint allows for improved cosmesis and improved gait.

For the child with an acquired lower extremity amputation, an immediate postoperative fit prosthesis (IPOP) or preparatory prosthesis is typically prescribed. This may not be the case if significant trauma to the surrounding tissue was present or if skin grafting was necessary after the injury. The physical therapy examination and evaluation focuses on sensitivity of the residual limb, active movement, strength, bed mobility, transfers for toileting and getting out of bed, and ambulation. The goals of postoperative physical therapy are similar to those for an adult with an amputation.

Children are more likely than an adult to move about after an amputation, so contractures are less likely to occur. However, some children undergoing chemotherapy are extremely ill and weak and may tend to lie in bed with their residual limb propped on pillows. They must be monitored for developing contractures, and parents and nursing staff must be instructed in ROM exercises and positioning of the residual limb.

Gait training should begin as soon as cleared by the physician. Young children can safely learn to ambulate with their preparatory prosthesis using a walker or crutches. If a child has been hospitalized for a period of time, strengthening exercises for the uninvolved leg and the residual limb may be necessary.

After removal of the preparatory prosthesis, the child is fitted with a definitive prosthesis. The exception to this would be a child who is undergoing chemotherapy. Weight gain and weight fluctuations are common, and these children tend to remain in their preparatory prosthesis for a longer period of time to allow their limb size to stabilize before moving on to their definitive prosthesis. Children with above-knee amputations should be fitted with a prosthesis with a knee joint. Most children with an above-knee amputation will require a suspension method to help hold the prosthesis in place. Instruction must be given to both the parents and the child in donning and removing the prosthesis, care of the prosthesis, skin checks, and wear schedule.

For the child who undergoes a rotationplasty, gentle active and active-assisted hip, ankle, and foot exercises should be initiated per the surgeon's or team protocol. For ambulation and sitting, 0° to 20° of ankle dorsiflexion is more than adequate. Some children will be able to achieve 30° of ankle dorsiflexion, which will allow for some squatting activities and facilitate bike riding. Maximal plantar flexion will allow for greater extension of the leg in stance. Optimal plantar flexion ROM is at least 45° to 50°; the prosthetist can align the prosthesis to achieve an additional few degrees of plantar flexion for stance. Exercises should begin gently and progress to active and resistive exercises.

The child who undergoes a rotationplasty is fitted with a custom-made prosthesis that incorporates the foot in a position of maximum plantar flexion and allows it to act as a knee joint. An external knee hinge joint with an attached thigh cuff may be used for suspension, or the prosthesis may incorporate a laminar thigh socket and utilize a TES or Silesian belt for suspension. A child who has had a limb-sparing procedure will also require physical therapy after surgery. Lower extremity procedures usually require a period of non–weight bearing. Rehabilitation for children with a limb-sparing procedure to the upper or lower extremity includes exercise through active movement with progression to strengthening exercises. The progression of the intervention is dictated by the procedure that was performed, the surgeon's protocols, and the amount of bone replaced. Children who have had a limb-sparing procedure involving the femur will also frequently require physical therapy after a lengthening procedure of the endoprosthetic implant. ROM of the knee often becomes restricted, similar to what is seen with children who undergo limb-lengthening techniques (see Chapter 14).

Gait training for all children at this age will focus on symmetry and the normal characteristics of gait, such as stride length, step length, and velocity, as well as all skills that the child needs to participate in play and games with other children. When initially learning to ambulate or after a surgical procedure, most children will use an assistive device. As balance and ambulation speed improve and postsurgical limitations are lifted, many children will begin to discard the assistive device. The assistive device should be discarded, however, only if the child's ambulation is safe and speed is functional to keep pace with the child's peers.

During the school-age years the physical therapist should instruct the child in running techniques so that he or she may

participate in play and games with her or his peers. This is the age at which the child may also show an interest in participating in various sports or recreational programs designed for persons with amputations.

When attending school for the first time, the child will be questioned about the prosthesis and assistive devices. This is especially true of a child with an upper limb deficiency. A meeting before the beginning of school with the child and his or her parents, the child's teacher, and perhaps the child's physical therapist may be helpful to allay any concerns and to answer or develop a way to answer the questions of the child's peers. The child with a unilateral limb deficiency or amputation should succeed in school with minimal adaptations.

The child with bilateral upper limb deficiencies may need to use voice-activated technology or a computer to assist with writing skills. In school a child with bilateral upper limb deficiencies may be able to carry papers or books in the classroom between the chin and shoulder. The child may use the mouth for manipulating and holding objects such as pencils. Whether the child uses his or her feet in school for manipulation or grasping is something that should be clearly discussed with the child, parents, and teacher before school entrance. Many children opt not to use their feet for grasping objects in public as they get older; however, this can limit their independence, especially with toileting and feeding. If a child is adept with the use of his or her feet and is independent and chooses to use the feet, this should not be discouraged. If the teacher displays a supportive attitude toward the child's use of the feet, the child's classroom peers will soon view this as usual procedure in their classroom. The ultimate outcome is for the child to be functional in our society as an adult; this may mean use of the feet or a combination of use of the feet and prostheses.

Adolescence and Transition to Adulthood

Adolescence, with its hallmark concerns of appearance and acceptance by peers, relationships with the opposite sex, career decisions, and the struggle for independence, can be a trying time for anyone. Restrictions on participation for the child with a limb deficiency may become more apparent during adolescence. Most teenagers with a congenital limb deficiency have been adjusting both functionally and emotionally from birth. At this point in their lives, they are part of a social network of friends, realize the support of their families, and have attempted and succeeded at various activities in school and the community. They will be dealing with these adolescent issues right alongside their peers, although increased fears concerning dating and social acceptance can be typical at this time, and participation in school athletic activities may be limited. A higher percentage of children and adolescents with congenital limb deficiencies exhibit greater behavioral and emotional problems and lower social competence than their peers without a disability.[93]

Amputation of a limb during the adolescent years adds quite an emotional burden to a teenager, who must deal with the loss of a body part and the grieving process and may be facing the possibility of death. Added to the physical appearance difficulties are possible side effects such as hair loss from chemotherapy. A teenager who is facing a possible amputation as the result of cancer should be included, if he or she desires, in discussions of treatment options, including surgical options. Obviously, this is not possible if the amputation is the result of sudden trauma.

The immediate postoperative concerns and physical therapy interventions for adolescents undergoing an amputation or a limb-sparing procedure are similar to those described for school-age children. If an immediate-fit prosthesis is not used, teenagers are more likely to develop edema of their residual limb following surgery. In this case, wrapping of the residual limb or fitting with a shrinker sock should be instituted.

Teenagers who sustain a lower extremity amputation are fitted with a prosthesis when the residual limb has stabilized. They should be involved in the fitting of the prosthesis and in deciding on the design of the socket and the type of knee joint and foot to be used. For most teenagers, a large variety of prosthetic options are available. These should be fully discussed with the teenager and parents, and the choice should complement the lifestyle of the user. Both the teenager and his or her family should be cautioned that the prosthesis will not function and will not look exactly like the contralateral limb.

Many teenagers with a high above-knee amputation will attempt to ambulate with a prosthesis but may opt for no prosthesis and crutches because ambulation with crutches is faster and more energy efficient. The decision to use or not to use a prosthesis should be the child's and should not be based on society's idea of the most appropriate physical appearance. Some teenagers use a prosthesis for certain activities and not for others. Advances in microprocessor knee and ankle technology can optimize function in adolescents with complex and higher levels of limb loss. The ultimate outcome is for them to be comfortable with their peers and to interact socially with their peers at school and in the community.

The use of prosthetics varies for teenagers with upper limb deficiencies. Those who have become adept with a prosthesis since early childhood probably will continue to use their prosthesis. The teenager who has an upper limb amputation may learn to operate a body-powered above- or below-elbow prosthesis. Microprocessor partial hand and digit prostheses are being developed that offer adolescents grasp and manipulation functions. Examples of these are the i-limb and i-digits (Touch Bionics, Mansfield, MA) and Michelangelo prosthetic hand (Ottobock, Austin, TX). To become functional with the prosthesis requires much practice, and the teenager may opt not to use one. An outcome study assessed the function and quality of life of 489 children with a transverse below-elbow limb deficiency, comparing 321 children who wore a prosthesis and 168 who did not wear a prosthesis. Researchers found small differences between the two groups, but they were not significant enough to meet the definition of a clinically important difference in the Pediatric Quality of Life Inventory.[50]

One major milestone for teenagers is the acquisition of a driver's license. Nearly all teenagers with a limb deficiency or amputation can learn to drive. Hand controls can be used for the teenager with bilateral PFFD or with bilateral lower extremity amputation as the result of trauma. For the teenager with a unilateral upper limb deficiency or amputation, minimal adjustments will be necessary. Driving can be done by using the sound hand, or a driving ring can be attached to the steering wheel. The prosthetic terminal device, preferably a hook, slips into the ring to assist with controlling the steering wheel and easily slips out of the ring in emergencies. Driving becomes more difficult for the teenager with bilateral upper limb deficiencies or amputations. A driving ring may be used by the dominant limb. Controls such as light switches or turn signals may need to be

moved to the dominant side and within reach of the limb or can be operated by the driver's knee. Unless specifically trained in the area of driver education, physical therapists should assist the teenager and his or her parents to seek information and driver training from a local rehabilitation center.

Career and college decisions are also made during adolescence. Some teenagers may work at a part-time job during high school. Most teenagers with limb deficiencies or amputations eventually seek employment. At times, adjustments must be made to a prosthesis, such as a specific terminal device, to assist the young adult in his or her particular career area. Going to college is a true test of independence with self-care skills. Some individuals with bilateral upper limb deficiencies or multiple limb deficiencies will always require some degree of assistance with self-care activities. Toileting, especially wiping after defecation, and dressing, specifically managing underpants and bras, are self-care activities for which it is difficult for anyone with bilateral upper limb deficiencies or short above-elbow amputations to achieve total independence. This does not preclude attending college or independent living, but an aide or other arrangements may be needed. Creativity, experimentation, and talking with other teenagers or adults with limb deficiencies can often produce strategies for accomplishing difficult tasks. Quality of life outcomes for young adults who have survived a childhood bone sarcoma with either an amputation or limb-sparing procedure are very diverse. Some studies report high employment rates, active lifestyles, and marriage for adults who underwent an amputation as a child or adolescent.[63,92] However, survivors of childhood bone tumors are more likely to have a physical limitation than those from other groups of childhood cancer, and those survivors with physical limitations are less likely to be employed, married, and/or earning an annual income greater than $20,000.[66] The data are conflicting on quality of life outcomes comparing adults who underwent a childhood amputation with those who had a limb-sparing procedure for a childhood bone sarcoma.[59] With the improvements in prosthetic design that are available as well as the limb-sparing procedures, further research is needed to follow the functional and overall satisfaction of these individuals as adults in society (Box 13.2).

BOX 13.2 Interventions: Child and Caregiver Communication and Education Across All Three Domains

Body Functions and Structures

Desensitization techniques
Massage
Strengthening

Activity

Developmental activities training
Transfer and gait training
Training with prosthetic device for ADLs

Participation

Training with prosthetic device for IADLs (school, play, driving, sports, work)
Education regarding environmental and prosthetic adaptations for activities and sports

SUMMARY

The origin and classification of congenital limb deficiencies and the causes of acquired amputations were reviewed in this chapter. An overview of the medical and surgical management of congenital limb deficiencies and amputations was presented. Treatment of a child with a congenital limb deficiency or amputation is complex and must involve a team of professionals who recognize the impact of various treatment options on the child's functioning in both home and school environments and ultimately as an independent adult. Careful planning and thoughtful discussions with the family regarding expected outcomes, goals of physical therapy, surgical options, and prosthetic options are necessary. Each child must be assessed as an individual, with consideration given to the child's age and musculoskeletal development and immediate and long-term functional abilities, the family's and child's activity level and lifestyle choices, and prosthetic and physical therapy interventions needed to meet the child's goals.

The continued proliferation of prosthetic designs, along with advances in microprocessor technology and materials available to the pediatric population, has opened up many options for recreation and sports, vocation, and self-care, as well as early fitting of infants and toddlers with prostheses.

Case Scenarios on Expert Consult

The case scenarios related to this chapter address three patients:

"Becca": Child With PFFD (Proximal Focal Femoral Deficiency)

This case reviews the prosthetic prescription for an infant with a congenital limb deficiency and the physical therapy interventions to facilitate her developmental skills and provision of initial caregiver education. The case study follows her for several years, including a surgical revision for her involved leg and the subsequent prosthetic and physical therapy needs.

"Andrew": Child With Cancer, Osteosarcoma Right Distal Femur

The focus of this case is on the surgical options available for a very young, skeletally immature child with a bony tumor. The rationale for choosing a rotationplasty is discussed as well as the focus of his physical therapy postoperatively. Andrew is followed for several years after his initial diagnosis and surgery to demonstrate the impact of the surgical procedure on his ultimate function and participation in activities with his peers.

"Anthony": Child With Traumatic Amputation

This case scenario focuses on the acute physical therapy intervention of an adolescent with a traumatic amputation and follows his rehabilitation through the fitting of his first prosthesis.

Two video cases are also presented. The first describes a teenager who sustained a traumatic mutilating lower extremity injury, and the second shows a preschool aged child with a congenital longitudinal tibial deficiency.

Orthopedic Conditions

Mary Wills Jesse

Physical therapists working with the pediatric population may not frequently intervene with patients with primary orthopedic diagnosis; however, general knowledge of orthopedics is important throughout the intervention process. This becomes even more challenging in the pediatric population as the musculoskeletal system grows and changes with age. What may be considered "typical" at one age may be significantly atypical at another.

Additionally, as physical therapist practice becomes more autonomous, we are challenged to identify problems that may be outside the scope of our practice and make appropriate referrals for care. We have a responsibility as therapists to have the knowledge base to determine these conditions in children.

Space in this chapter will not allow an exhaustive review of all the orthopedic conditions that affect children. Many references are provided throughout the text for further study, however. This chapter presents information on conditions commonly seen; specific areas of concern to the physical therapist will be highlighted to provide a basic framework for the practicing clinician. Background and foreground information will be presented together in each of the following condition-specific sections.

TORSIONAL CONDITIONS (IN-TOEING AND OUT-TOEING)

In-toeing and out-toeing are visible conditions in children that often raise much concern for parents and family members. They are also a common reason for elective referral of a child to an orthopedist. Even though these rotational conditions usually do not require any intervention, concern often escalates with comments from neighbors, teachers, and strangers on the street: "Why does your child walk funny?" This group of children has been described by Dr. Mercer Rang as "the worried well," a phrase that indicates the strong concern of the family and others involved with the child over alignment conditions that are often part of the spectrum of normal musculoskeletal development.

Differing opinions exist on how to define torsional conditions, how to measure them, and especially how to intervene for correction, or if they should receive intervention at all. An understanding of the normal growth and development of the lower extremity is imperative in evaluating a child's rotational alignment as normal changes occur during the growth process. Further description of the normal process may be found in Chapter 5. Interventions, such as orthotic shoes, casting, and bracing, have previously been used in early childhood without success and in many of these cases, unnecessarily because the child's positioning would have corrected spontaneously over time. Often, rotational deformities are seen in typically developing children and rarely persist into adolescence. Knowledge of normal growth and development will assist therapists in making better clinical judgments as well as educating parents and family members of whether there is a need for concern. Education should also be given to the caregivers about the normal changes in alignment to help them monitor the child for changes that are occurring abnormally. As always, neuromuscular dysfunctions or other serious conditions should be ruled out.

In-toeing and out-toeing are both clinical symptoms and do not define the etiology or provide a diagnosis of the underlying problem. By definition, in-toeing is a rotational variation of the lower extremity alignment where the feet or toes point toward the midline during gait. Out-toeing is a rotational variation of the lower extremity alignment where the feet or toes point away from the midline during gait. Through clinical history and physical evaluation, the cause of the rotation can be determined.

Clinical History

A specific history provides a wealth of information regarding possible causative factors and indications for possible intervention. Specific information obtained may also direct the examiner to expand the examination to rule out other, more severe conditions that may initially produce a chief complaint of in-toeing or out-toeing. Relevant information to be elicited from the parents includes the following:

1. Birth history. Was the infant full-term or premature? Was it a vaginal or cesarean delivery? Was oligohydramnios (deficiency of amniotic fluid) present? How many times has the mother been pregnant? What is the birth order of the parent? Many of the torsional problems seen in infants are "packaging" defects (i.e., caused by a restricted intrauterine environment). It is easy to imagine that an infant's lower limbs may "grow" into a particular position as one visualizes a full-term 9-pound fetus in the womb of a gravida 1, para 1 mother.
2. Age. At what age was the in-toeing or out-toeing noted? Has it improved or worsened since first noted? Was any previous intervention provided? For the walking child, at what age did the child start to walk independently? In the differential diagnosis the index of suspicion should be increased when a child has a history or prematurity, difficult birth, or delayed motor milestones or has significant in-toeing or out-toeing that is worsening with time or is very asymmetrical. Children with mild spastic diplegia may have in-toeing, and children with Duchenne muscular dystrophy may have out-toeing and flat feet. Conditions such as these must be ruled out.

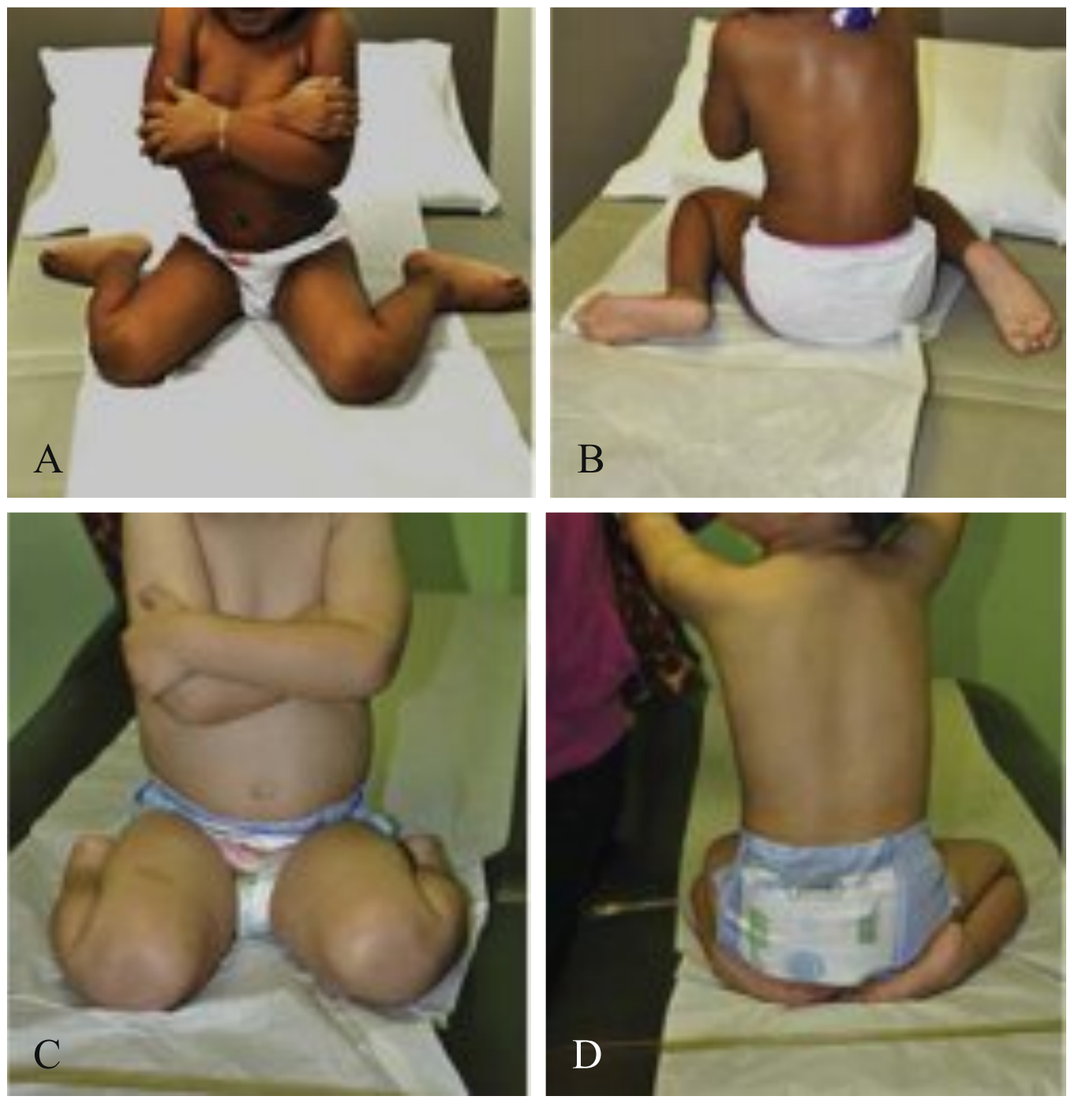

FIG. 14.1 (A–B) The W-sitting or television-sitting position with the legs externally rotated. (C–D) A similar position with the feet tucked under the buttocks accentuating the internal tibial torsion as well as metatarsus adductus. (From Harris E: The intoeing child: etiology, prognosis, and current treatment options. Clin Podiatr Med Surg 30:531-65, 2013.)

3. Family history. In many cases, a positive family history for in-toeing or out-toeing is reported, and this should be noted, especially if intervention was undertaken for other family member(s).
4. Sleeping and sitting positions. The natural positions that a child lies and sits also provide information. Sleeping prone and sitting on feet encourages internal tibial torsion.[186] Sitting in a W-sit position may encourage the persistence of femoral anteversion (Fig. 14.1).

Torsional Profile

The torsional profile is a composite of measurements of the lower extremities.[202] It differentiates thigh, leg, and foot variations as the anatomic basis of torsional deformity. It also documents the severity of the abnormality. Each segment needs to be evaluated to determine the cause of the abnormality so that intervention can be appropriately prescribed. Rotational alignment of the lower extremity is determined by the alignment of the foot, the rotation of the tibia in relation to the transcondylar axis of the femur (tibial torsion), and the rotation of the neck of the femur in relation to the transcondylar axis of the femur (femoral version). The examination usually begins with clinical observation of the child's gait pattern and progresses to evaluation from proximal to distal body segments.[42] The torsional profile generally consists of six measurements with normative data available for the first five variables. These are: foot progression angle (FPA), lateral hip rotation (LHR), medial hip rotation (MHR), thigh-foot angle (TFA), transmalleolar axis (TMA), and forefoot alignment. Also added to this description are trochanteric prominence angle test as an alternate way to examine femoral version and flexibility of forefoot to determine the rigidity of the position. Table 14.1 gives a description of these components and the method of measuring each.

Foot Progression Angle

The FPA, or "the angle of gait," is defined as the angular difference between the axis of the foot and the line of progression during gait.[201] The child is observed while walking, and a value is assigned to the angle of both the right and the left foot. This is a subjective determination and represents an average of the angle noted on multiple steps. Various footprint techniques can be used to measure FPA, but these are time consuming and may not be practical in the clinical situation. In-toeing is expressed as a negative value, and out-toeing is expressed as a positive value. This angle gives an overall view of the degree of in-toeing of out-toeing in the walking child. The FPA can also be examined in supported stance for the child who is not yet walking independently. FPA is variable during infancy. During childhood and adult life, it shows little change, with a mean of +10° and a normal range of −3° to +20°.[202] In-toeing of −5° to −10° is considered mild, −10° to −15° is considered moderate, and more than −15° is considered severe.[201] When a child toes in or toes out, the condition is usually bilateral, but occasionally one sees "windswept" lower extremities, with one limb toeing in and the other limb toeing out. Normative values can be found in Fig. 14.2.

Although this gives a composite view of the lower extremity, measurement of each segment is recommended because compensations may occur that affect the FPA. For example, significant femoral anteversion at the hip may be balanced by external tibial torsion with a straight foot (no metatarsus adductus or calcaneovalgus). The foot progression angle would be 0°/0° (right/left) with the feet pointing straight ahead even though abnormalities are present.

Hip Rotation

In order to correctly explain clinical findings at the hip, terminology in the literature should be understood. Version describes the position of the femoral head in the frontal plane. If the head lies anterior to the plane, it is anteverted, with the average angle being 14° to 20°.[34] A head that is positioned posterior to this normal average angle is retroverted.[34] Torsion describes the osseous position of the bone in its longitudinal axis, or "twist." It is measured by the angle formed at the intersection of the axis of the head and neck and the axis of the femoral condyles.[34] The difference could also be explained by femoral torsion being the osseous "twist" between the upper femur and lower femur and femoral version being the momentary position of the femur in the acetabulum or the relative position of the acetabulum on the pelvis.[77] The measurement of hip internal and external rotation will include both torsion between the femoral head and femur and also the inclination of the femoral head to the acetabulum (version).[113] Fig. 14.3 demonstrates these differences.

Hip rotation range of motion (ROM) is measured most accurately in the prone position, with the hip in a position of neutral flexion/extension and knee flexed to 90°. Femoral anteversion will be indicated by an increase in internal rotation compared to external rotation. If the differences between internal and external rotation measurements are 45° or more, this indicates an abnormally high anteversion angle at the hip.[73] Femoral retroversion is indicated by increased external rotation compared to very little internal rotation. An

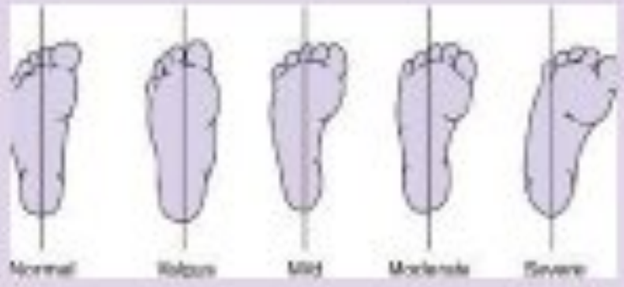

TABLE 14.1 Measurements for Torsional Profile

Measurement	Technique	Documentation	Visual
Foot progression angle	Child is observed while walking with subjective determination of in-toeing and out-toeing Footprint technique can be used to measure	In-toeing is expressed as negative value and out-toeing is expressed as positive value	
Femoral Version			
Hip rotation ROM	Child in prone position with the hip in a position of neutral flexion/extension and knee flexed to 90°	Femoral anteversion indicated by an increase in internal rotation compared to external rotation	
Trochanteric prominence angle test	Child lies prone with knees flexed to 90° Examiner stands on the contralateral side and uses the left hand to palpate the greater trochanter while the right hand internally rotates the hip At point of maximum trochanter prominence, the femoral neck is horizontal	If the tibia is externally rotated, this corresponds to an antetorsion value If the tibia is internally rotated, it corresponds to a retrotorsion value	
Tibial Torsion			
Thigh-foot angle	Child prone with knees flexed to 90° Measure the angle of the long axis of the foot against the axis of the thigh	If line of the heel points toward the midline relative to the thigh, an internal torsion is present and is given a negative value If line of the heel points away from the midline relative to the thigh, external torsion is present and is given a positive value	
Transmalleolar angle: prone	Child prone with knees flexed to 90° Measure the angle of the line that bisects the malleoli against the axis of the thigh	Measurement is the angular difference between a line projected toward the heel at right angles to the transmalleolar axis and the axis of the thigh Positive value is external torsion

abnormally low anteversion angle would be indicated by the external rotation being at least 50° higher than the internal rotation measurement.[73] This is not an accurate test in children below 3 years of age because of the limitation in internal rotation by factors extrinsic to the hip joint.[73] Normative values can be found in Figs. 14.4 to 14.6.

Another way to clinically examine femoral neck anteversion is the trochanteric prominence angle test (TPAT).[180] This test is also known as the Ryder test or the Craig test. A child lies prone. The examiner stands on the contralateral side and uses the left hand to palpate the greater trochanter while the right hand internally rotates the hip, with the patient's knee flexed to 90°. At the point of maximum trochanter prominence, the femoral neck is assumed to be horizontal. If the tibia is externally rotated, this corresponds to an antetorsion value; if it is internally rotated, it corresponds to a retrotorsion value. Reliability of this method has been questioned.[135,234]

When the hip is in anteversion (or "anteverted") because of the femoral head being positioned on the frontal plane, the

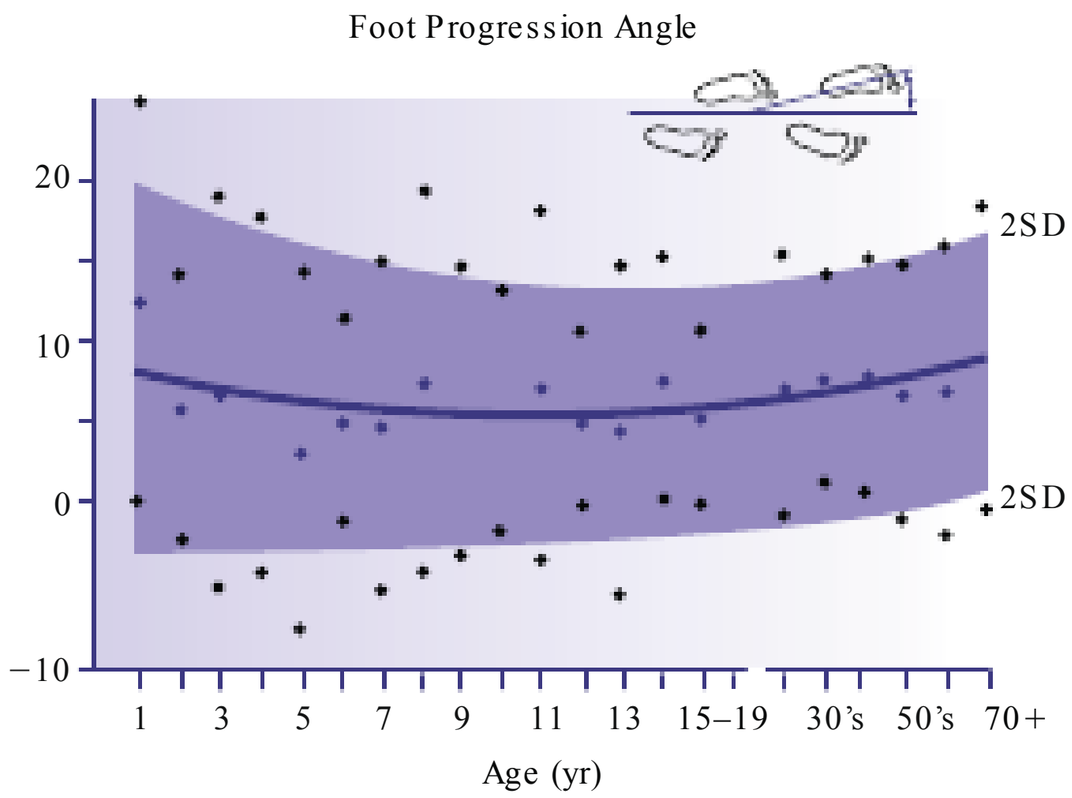

FIG. 14.2 Foot progression angle. Mean values, plus or minus two standard deviations for each of the 22 age groups. The solid lines show the mean changes with age; the shaded areas, the normal ranges; the solid blue circles, the mean measurements for the different age groups; and the solid black circles, plus or minus two standard deviations for the same mean measurements. (Redrawn from Staheli LT, Corbett M, Wyss C, et al.: Lower-extremity rotational problems in children. Normal values to guide management. J Bone Joint Surg Am 67:39-47, 1985.)

patient will usually have more hip medial rotation than lateral rotation ROM, assuming no soft tissue tightness. If hip medial rotation is measured at 70° and lateral rotation is 25°, for example, the child is said to have femoral anteversion (FA) and may in-toe when walking (Fig. 14.7). In retroversion the femoral head is positioned posterior to the frontal plane when the knee is aligned straight ahead, and the patient will have greater lateral rotation range. These describe positions in the child who matures without neurologic disorders such as cerebral palsy. The neonatal biomechanics and typical skeletal maturational changes in the child are presented in greater detail in Chapter 5.

Thigh-Foot Angle

The TFA, transmalleolar angle, and FPA are methods used to measure tibial torsion. The TFA is evaluated by placing the child prone, flexing the knee to 90°, and then measuring the angle of the long axis of the foot against the axis of the thigh.[113,201] If the line of the heel points toward the midline relative to the thigh, an internal torsion is present and is given a negative value. If the line of the heel points away from the midline relative to the thigh, external torsion is present and is given a positive value.[201] Changes in these values occur normally with development; from the middle of childhood on, the mean angle remains approximately 10°.[202] Normative values are shown in Fig. 14.8.

Transmalleolar Axis

The transmalleolar angle may be preferred over the thigh-foot angle because hindfoot varus or valgus and foot adduction or abduction will not affect results.[101] The TMA-thigh angle can be measured in the same position as the thigh-foot angle. Measurement is made between the angle of the line bisecting the thigh and the line that bisects the malleoli on the plantar surface of the foot. Normative values are in Fig. 14.9.

Another method for the TMA has the patient seated with knee flexed and leg hanging from the edge of the table with the thigh directly in front of the hip joint and heels against a flat vertical surface.[203] With the foot held in neutral position, the medial malleolus is held between the thumb and index finger and the center point is marked. The lateral malleolus is marked in a similar manner. With the heel resting comfortably against the back wall of the platform, measurements are made of the distance between the marks over the medial malleolus and the back wall (A) and the distance between the marks over the lateral malleolus and the back wall (B). The difference between these two measurements is then calculated (A−B). The intermalleolar distance is measured (width of the ankle between malleoli). Using the grid established by Staheli and Engel, the TMA can be established.[203] This method demonstrates that the TMA angle averages about 5° of external rotation during the first year, 10° during midchildhood and 14° in older children and adults.[203] Normative data and a conversion grid can be found in Figs. 14.10 and 14.11.

Others have measured the TMA by the footprint method. In this test the patient sits with his hip and knee at 90° of flexion with the hip in neutral rotation and the tibial tubercle facing forward. The foot is set on a piece of lined paper so that the lines are parallel to the knee axis. The footprint is traced, and two marks are made vertically below the centers of the malleoli. A line drawn between this line and any line on the paper will provide the TMA.[80]

Foot Alignment

Foot alignment is best documented using the Bleck heel bisector method.[38] The heel bisector line is measured with the child prone with the knee flexed and ankle dorsiflexed so that the plantar surface of the foot is parallel to the ceiling. A line is visualized parallel to the heel and extended distally to the toes. A normal heel bisector line goes through the second toe. The line passes more laterally in those with metatarsus adductus (medial deviation of the forefoot). Also, flexibility of the foot position should be determined by applying lateral force to the great toe and attempting to reduce the heel bisector line back to the second toe. The degree of metatarsus adductus can be graded as (I) flexible with the ability to correct beyond midline, (II) moderately flexible with the ability to correct to midline, or (III) severe with the inability to achieve midline.[18]

Radiographs may be used to evaluate the position of the foot but are not considered imperative and, in some cases, are difficult to reproduce.[95] The age and flexibility of the deformity are considered better predictors of outcome although the radiologic examination may help determine the presence of complex deformities or the presence of rearfoot compensation.[95]

In-Toeing

Although in-toeing is a common problem that causes parents to seek medical care, very few require medical intervention. A study of 202 children who were referred to a pediatric orthopedic clinic found that none of these children (median age of 4 years) had significant pathology.[17] Another study of 720 children below the age of 8 years referred for in-toeing found only one required an osteotomy.[110] The components that may contribute to in-toeing are femoral anteversion, internal tibial torsion, and metatarsus adductus (Table 14.2).

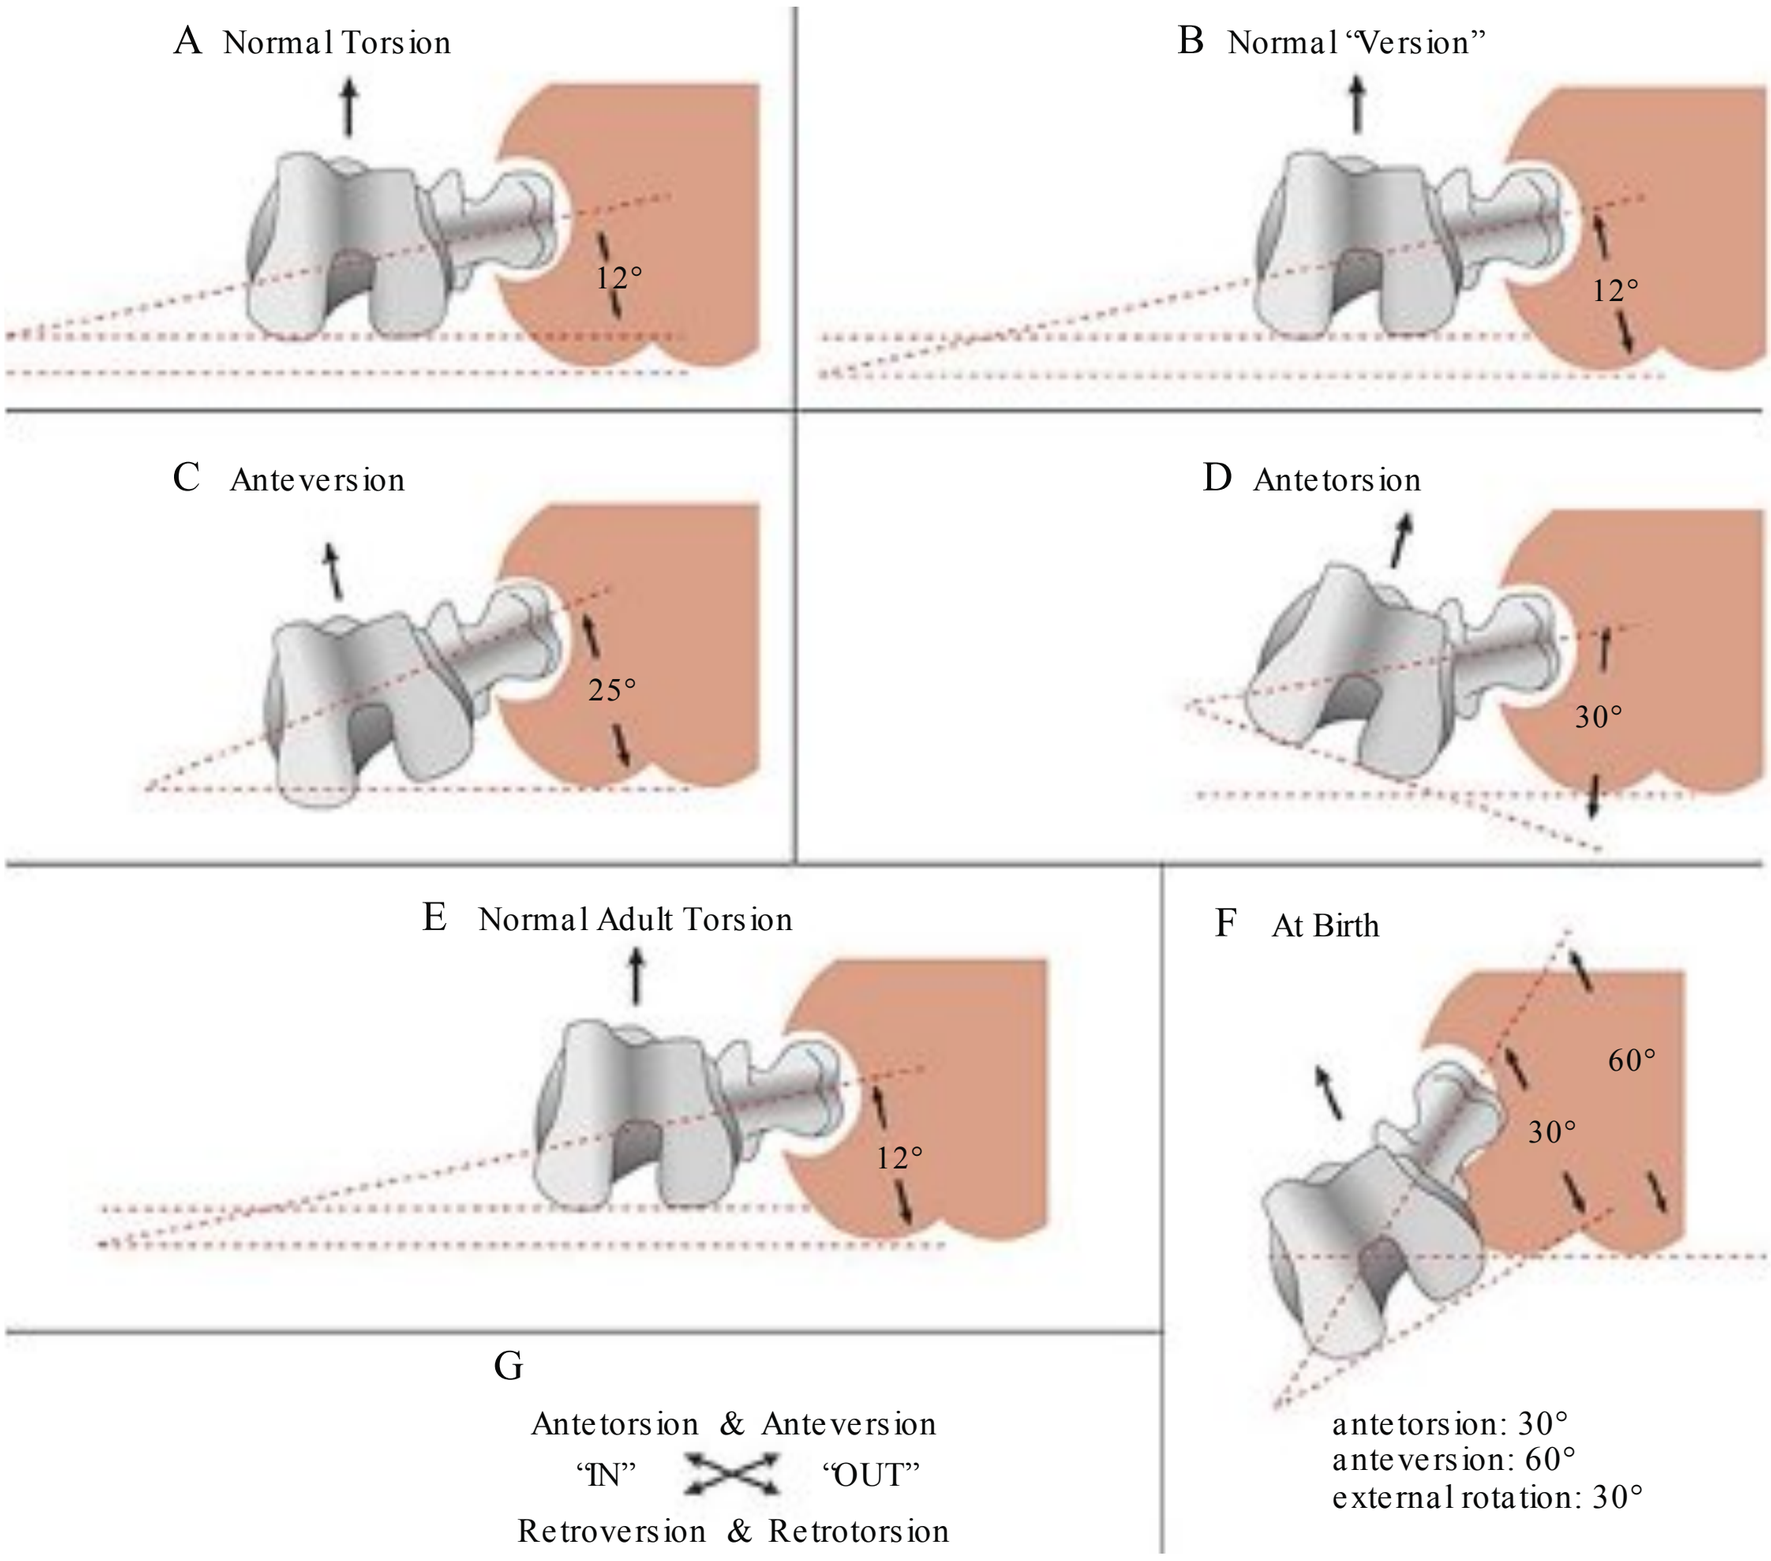

FIG. 14.3 Femoral version and torsion. (From Effgen SK, editor: Meeting the physical therapy needs of children. Philadelphia, FA Davis, 2005.)

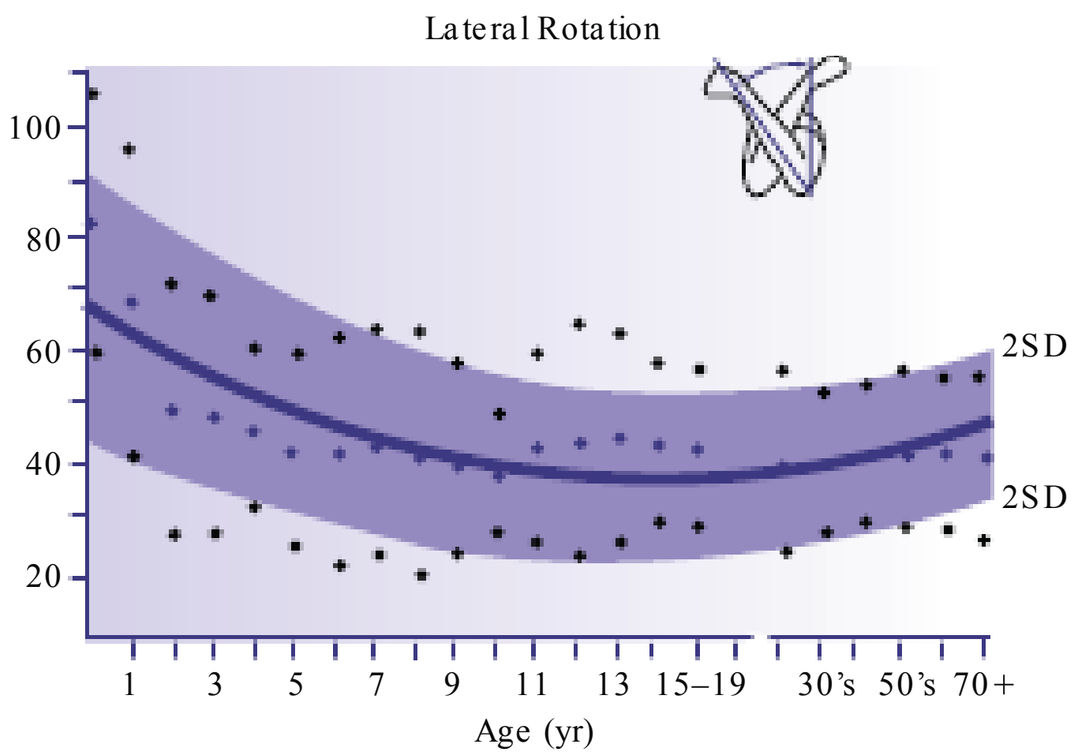

FIG. 14.4 Lateral rotation of the hip in male and female subjects combined. Mean values, plus or minus two standard deviations for each of the 22 age groups. The solid lines show the mean changes with age; the shaded areas, the normal ranges; the solid blue circles, the mean measurements for the different age groups; and the solid black circles, plus or minus two standard deviations for the same mean measurements. (Redrawn from Staheli LT, Corbett M, Wyss C, et al.: Lower-extremity rotational problems in children. Normal values to guide management. J Bone Joint Surg Am 67:39-47, 1985.)

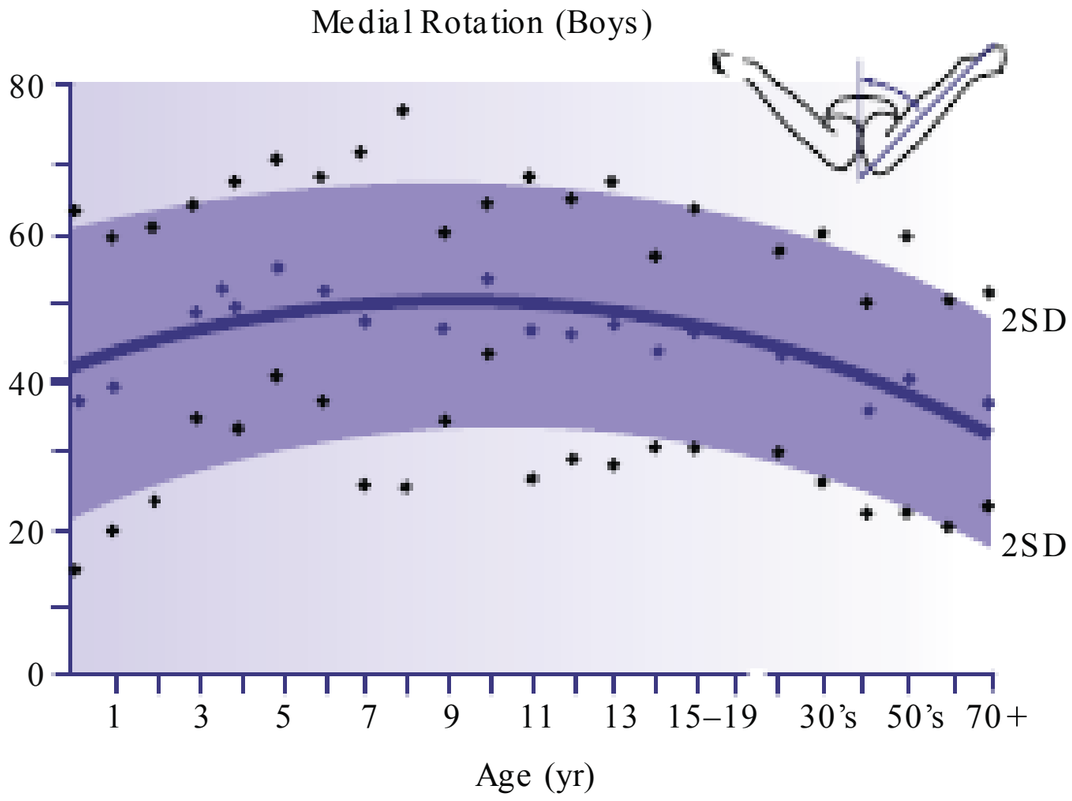

FIG. 14.6 Medial rotation of the hip in male subjects. Mean values, plus or minus two standard deviations for each of the 22 age groups. The solid lines show the mean changes with age; the shaded areas, the normal ranges; the solid blue circles, the mean measurements for the different age groups; and the solid black circles, plus or minus two standard deviations for the same mean measurements. (Redrawn from Staheli LT, Corbett M, Wyss C, et al.: Lower-extremity rotational problems in children. Normal values to guide management. J Bone Joint Surg Am 67:39-47, 1985.)

Femoral Antetorsion and Anteversion

One specific cause of in-toeing is FA. Although most of these cases will normalize spontaneously by age 8 years,[70] some cases require medical attention. Neurologically typical children are likely to spontaneously correct while those with neurologic abnormalities have a lower incidence of spontaneous correction.[77] Abnormal antetorsion is more frequently seen in females and also has been found to possibly have a genetic component because it seems to run in some families.[77]

The history of the onset is generally an observation of the child's gait being normal until age 2 years. At that time the family notices the in-toeing. This observation would go along with the changes occurring in the child's gait; hip rotation in extension is changing from relative external rotation to internal rotation, which allows the abnormal FA to be noticed.[77] The child also favors the W-sitting position as seen in Fig. 14.1.

Measurement of the abnormality will be achieved through completion of the torsional profile. Internal rotation measuring between 70° and 90° is evidence of femoral torsion.[174] In an infant, tightness in the hip external rotation muscles and capsular ligaments results in a laterally rotated position, masking the femoral anteversion. The tightness of the hip soft tissues gradually stretches out, and the true anteversion of the femur becomes apparent. This process is often described incorrectly as "femoral anteversion increases"; the amount of femoral version is actually decreasing but is more easily visualized because the muscle tightness of the external rotators is decreasing. The FA becomes increasingly more apparent clinically as the child approaches 5 to 6 years of age, with this decrease in soft tissue tightness. Studies have shown a gradual decrease in FA with age: 40° at birth to between 15° and 20° by 8 to 10 years of age.[222] Femoral antetorsion is mild if internal hip rotation is 70° to 80°, moderate if 80° to 90°, and severe if 90° plus in childhood.[201] By midchildhood, the femoral head and neck have

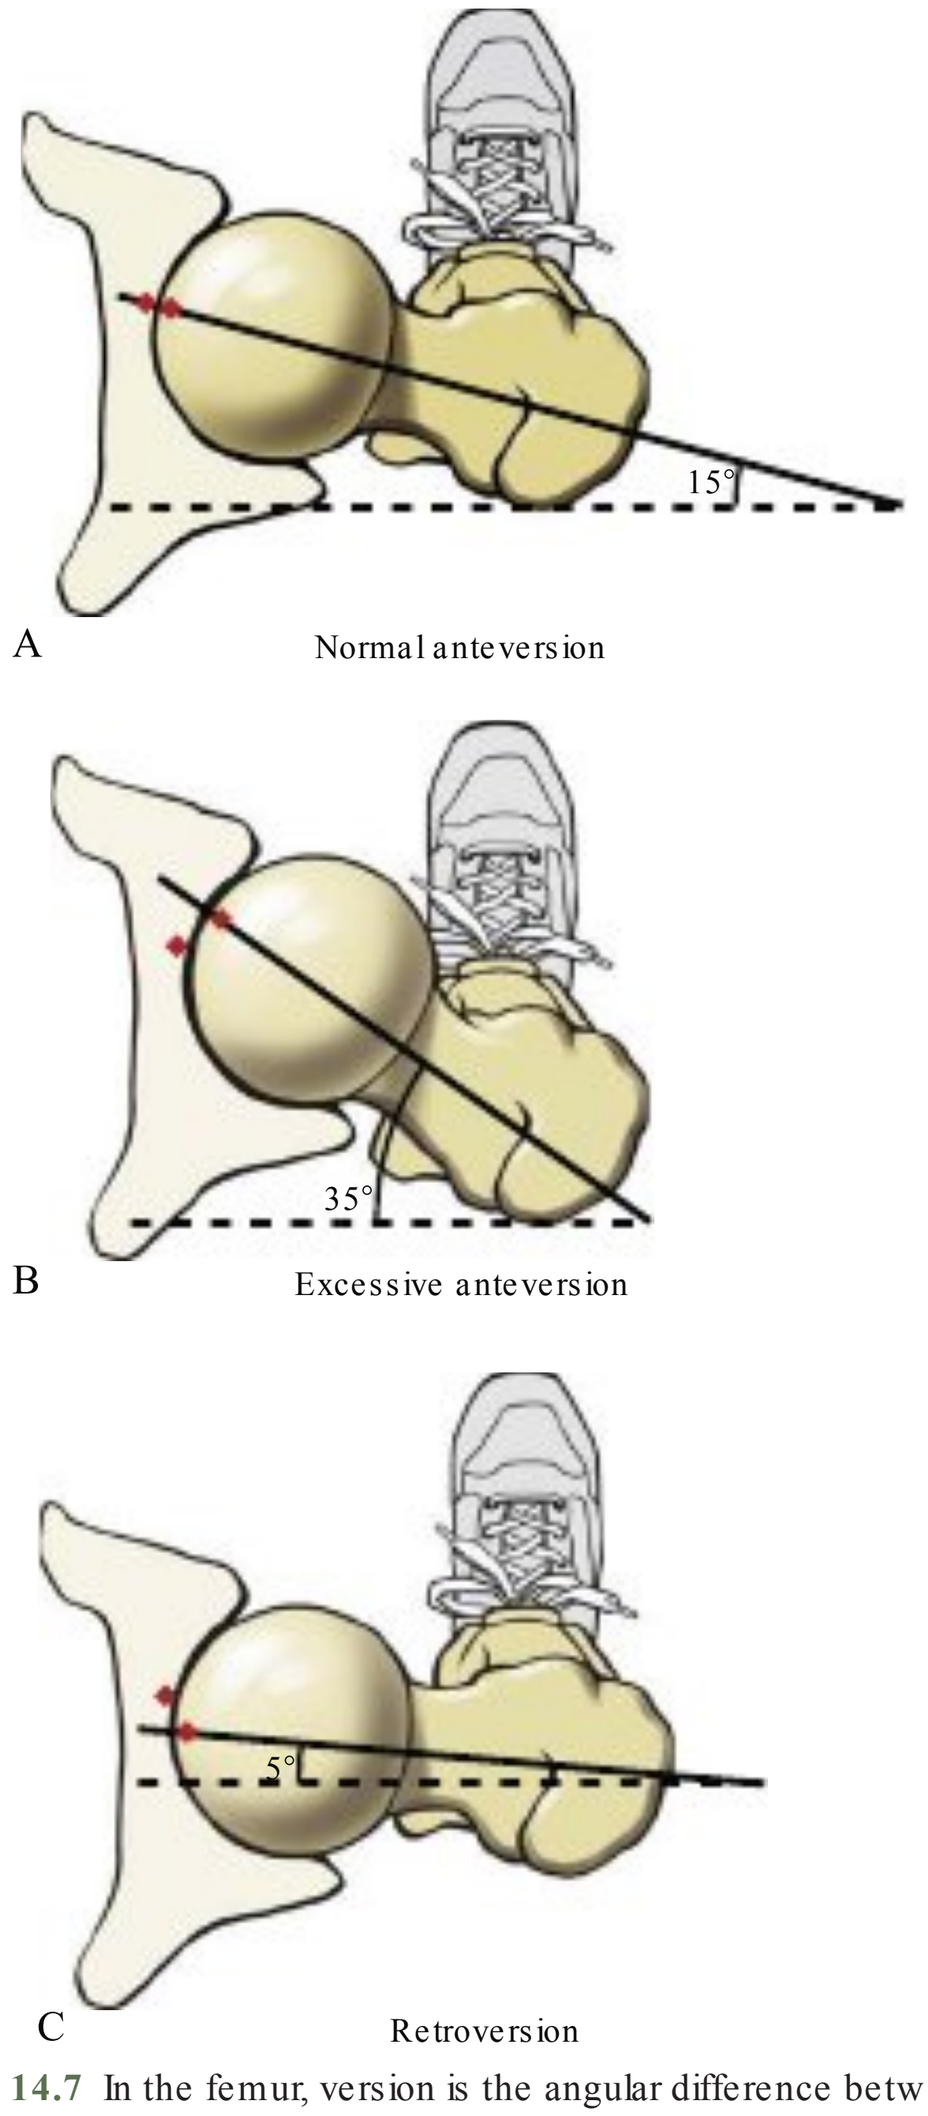

FIG. 14.7 In the femur, version is the angular difference between the transcondylar axis of the knee (the horizontal line in this drawing) and the axis of the femoral neck. These two lines form an angle and document whether the femur is in anteversion or retroversion. (A) Normal anteversion: with this small amount of anteversion, the individual can walk comfortably with the foot pointed straight ahead (i.e., a neutral angle of foot progression). (B) Excessive anteversion with in-toeing: when a large amount of anteversion is present, the individual must internally rotate the femur to seat the femoral head in the acetabulum and achieve improved joint congruity. This results in a negative foot progression angle, and the foot is pointed in during gait (in-toeing). (C) Retroversion: in this drawing, significant reduction can be seen in the angle formed between the two axes, depicting retroversion. If this were excessive, the individual would need to externally rotate the femur to seat the femoral head in the acetabulum and would have a positive angle of foot progression (out-toeing). (From Neumann DA: Kinesiology of the musculoskeletal system: foundations in rehabilitation. 2nd ed. St. Louis, Mosby; 2010.)

usually assumed a relatively more neutral position in relationship to the femoral shaft, and children typically have approximately equal amounts of hip medial and lateral rotation. Clinical measurement of rotation underestimates the true value of the medial twist of the femur that would be measured by computed tomography (CT) scan by 10° to 15°.[208] Therefore radiographic measurement may need to be pursued in cases that do not resolve spontaneously. Femoral and tibial torsions are generally measured on axial CT images. In consideration of dosages of radiation, low-dose simultaneous perpendicular biplanar radiography scanners and magnetic resonance imaging are options that are now being used.[118,179]

Many types of interventions have been tried to correct FA, including braces, twister cables, shoe modifications, or orthotic devices. These have not been proven to be effective.[218] Anecdotal findings may note the efficacy of these conservative methods, although spontaneous improvement occurs naturally in most cases. One reasonable recommendation is to have the child avoid W-sitting (reverse tailor sitting) and to encourage tailor sitting in maximum hip lateral rotation. If significant FA is still present at age 10 to 14 years and is resulting in cosmetically unappealing in-toeing, surgical correction in the form of femoral derotation osteotomies may be considered, although the possible risks of the operation may outweigh the benefits of realignment. In the adult, FA does not cause degenerative arthritis and rarely causes any disability.[201] Surgical intervention may be warranted and has proven successful in children with severe symptomatic torsional malalignment with excessive FA or external tibial torsion (ETT) associated with patellofemoral pathology when conservative intervention has failed.[204]

Internal Tibial Torsion

Internal tibial torsion (ITT) in infancy often is not apparent to the parents or the casual examiner because the hips have external rotation muscle contractures and the infant's legs tend to assume abducted and externally rotated position. The ITT may become noticeable only as the hip contractures stretch out, resulting in a more neutral position of the hip, especially when the child begins to walk independently. One interesting note is the effect of in-toeing with sprinting. Fuchs and Staheli[62] studied high school students (50 sprinters and 50 control subjects) and found that the sprinters tended to have low normal thigh-foot angles and in-toed when sprinting.

Controversy exists regarding appropriate intervention of ITT as it does in FA. Many orthopedists believe that it should not receive intervention at all because the natural history of the condition is gradual improvement. The very small percentage of children who do not improve and who have a significant functional deficit as a result of ITT can receive surgical intervention at a later date with external rotational osteotomy of the tibia and fibula. A different school of thought relies on natural improvement up to about 18 months of age and at that age advocates intervention for persistent ITT with a Friedman counter splint (Universal Shoe Splint Assembly, United States), a flexible leather strap, or a Denis Browne bar, a metal bar, for night wear, usually for about 6 months. These devices attach to shoes and hold the feet in an externally rotated position. The Denis Browne bar is an uncomfortable intervention that, because of adherence difficulties, is sometimes limited. Also, with the knees extended, the torque applied by the bar may be directed to the hips because the knees are extended. The Wheaton brace with an upper component has also been developed to isolate the correction to the tibia, not to apply torque to the hip. With this device, the knee is flexed to 90°, and improved comfort with this device may improve adherence. Another option is the Tibia Counter Rotator with toe-out gait plate (Biomechanics Technology Co Ltd, Goyang, Korea).

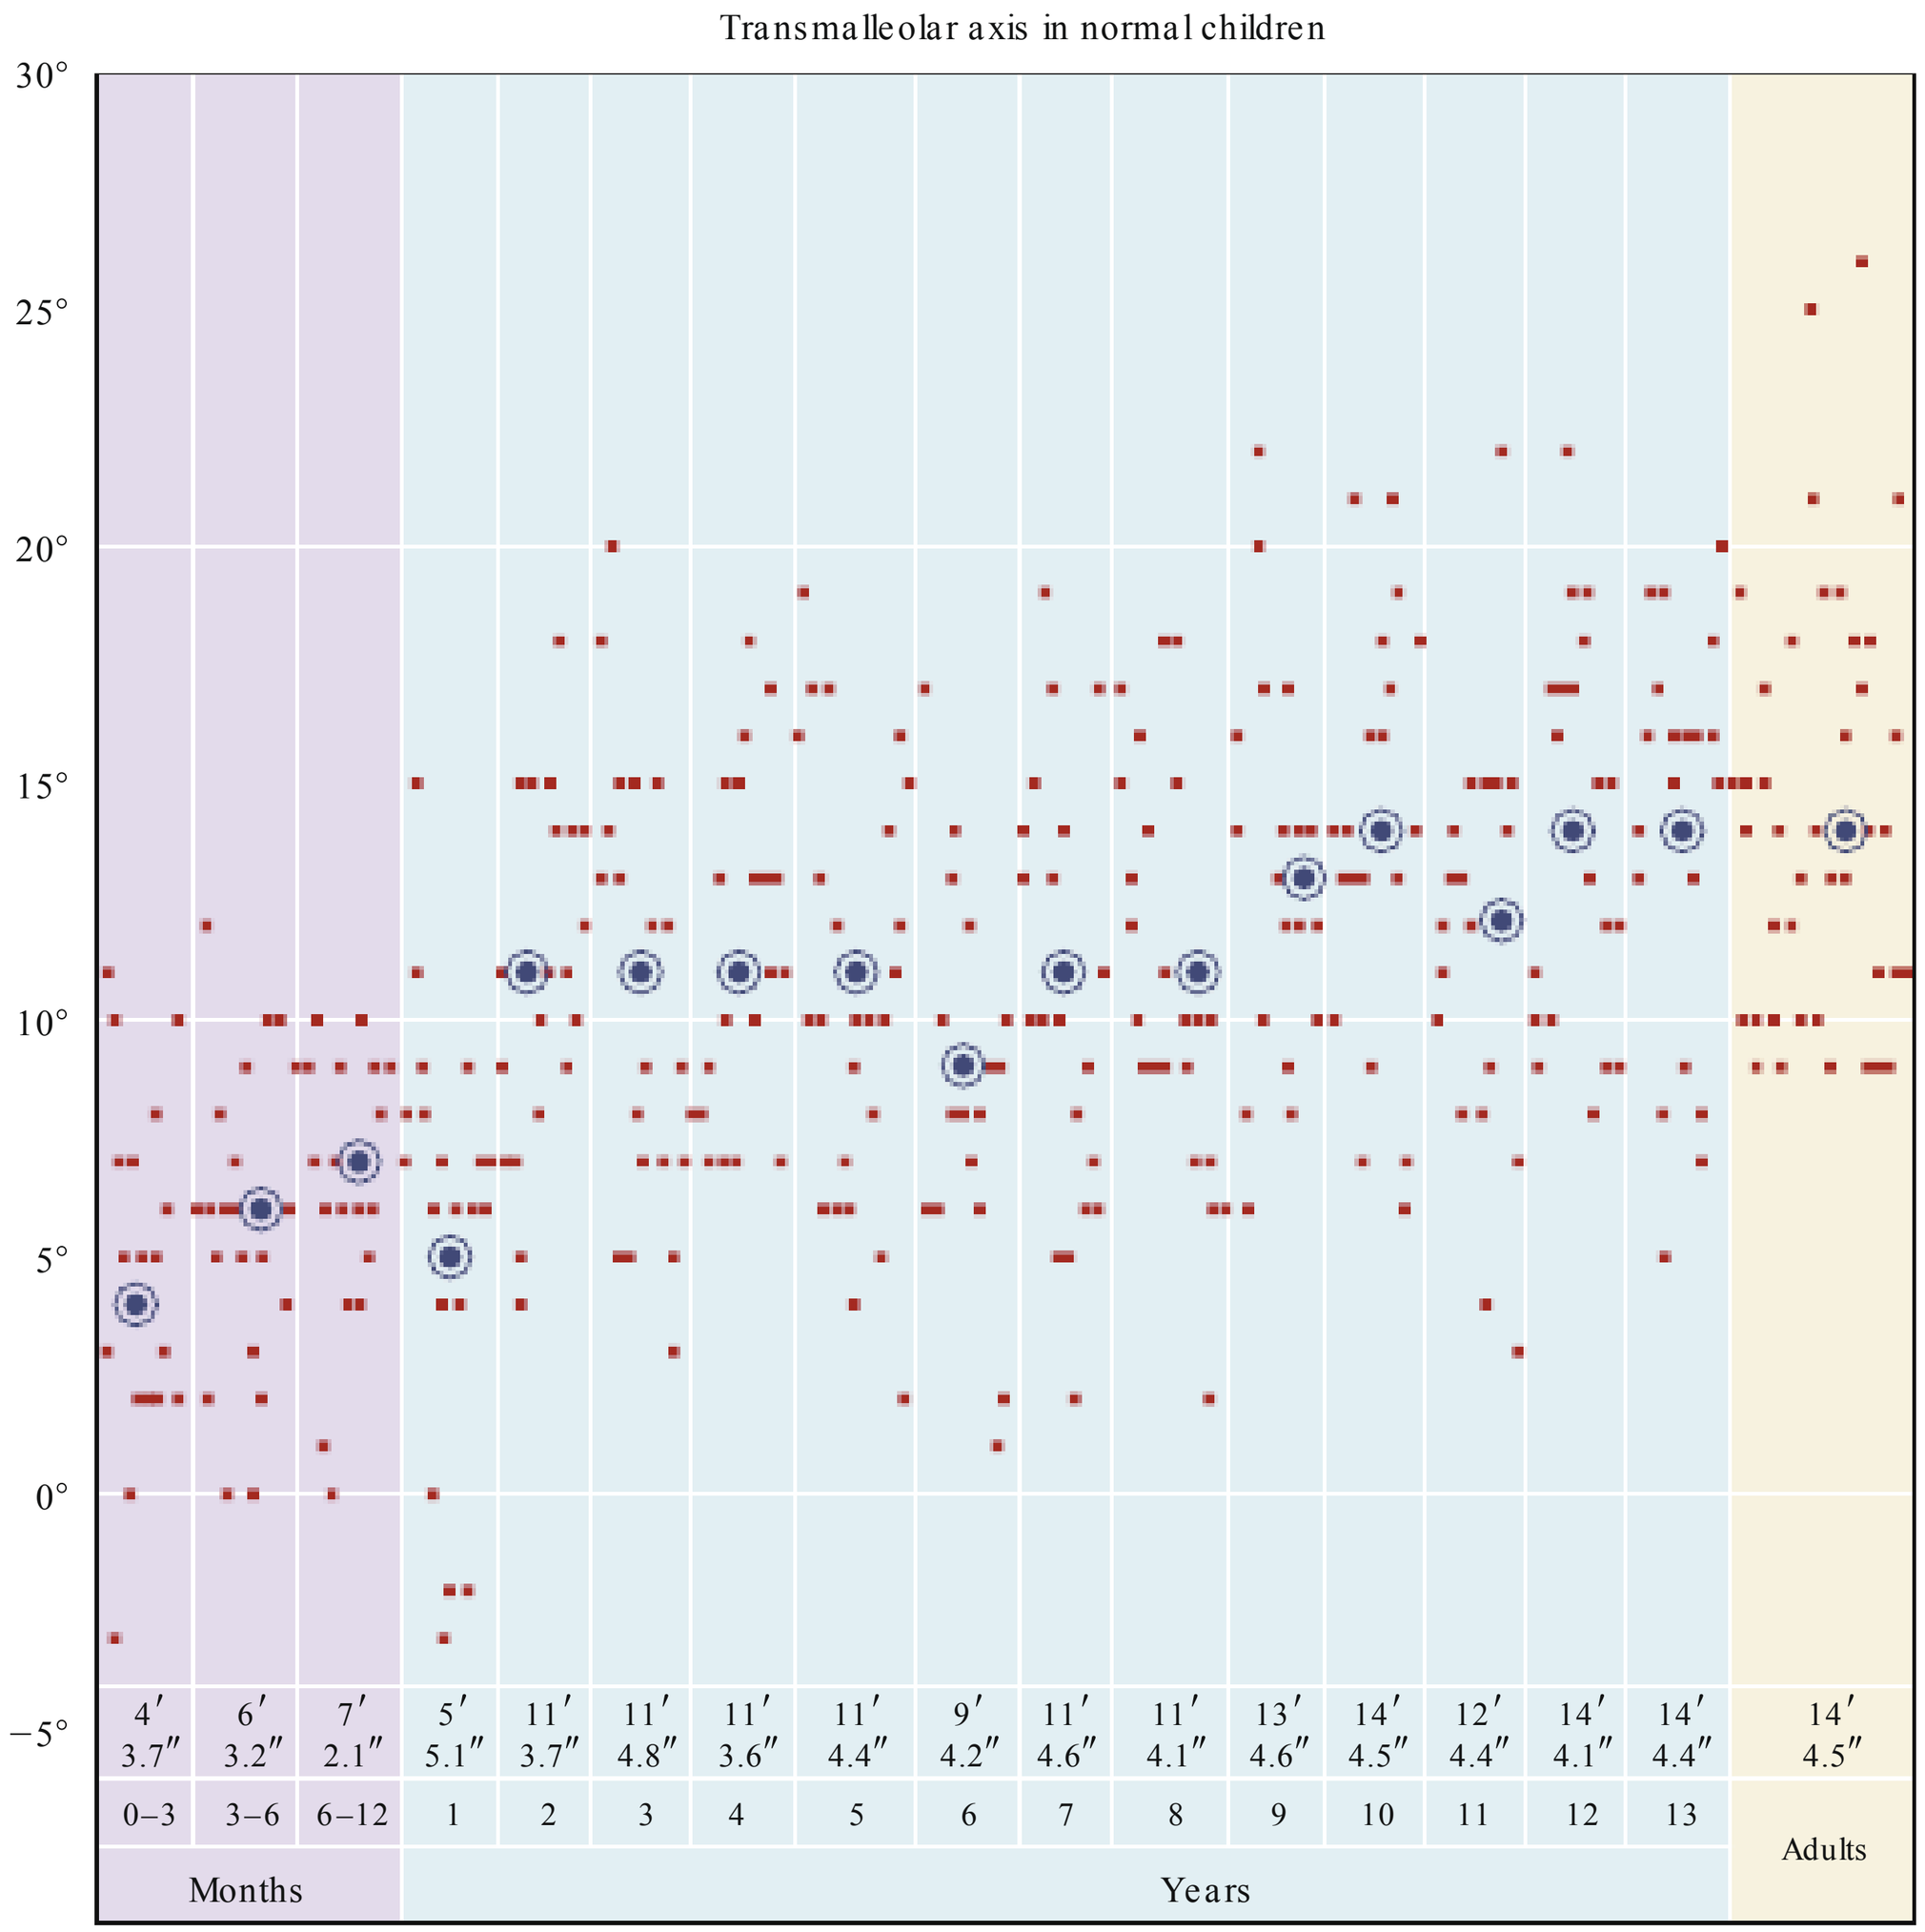

FIG. 14.10 Transmalleolar axis in normal children and adults. The mean in each age group is indicated by the larger dot and circle. ‘ = the mean age group.” = the standard deviation. (Redrawn from Staheli LT, Engel GM: Tibial torsion: a method of assessment and a survey of normal children. Clin Orthop Rel Res 86:183-186, 1972.)

It consists of well-padded straps, foot plate, and metal brace (Fig. 14.12). This device is considered more comfortable because it allows complete freedom of hip motion. It does accommodate the amount of torsion and can be adjusted periodically to continue improvement over time. Significant improvements have been seen in early studies.[198,199]

Surgical correction is a supported option in a minority of cases, where there is severe cosmetic or functional deformity or a TFA over three standard deviations from the mean.[52,186] No surgical intervention should be considered under the age of 10 years, with surgery associated with a high complication rate (avascular necrosis, osteomyelitis, overcorrection, nonunion, etc.).[201] Successful approaches have included supramalleolar tibial rotation osteotomy[44] and Haas’s multiple-longitudinal osteotomy technique.[48] Correction can occur at the proximal tibia but has more risk of complication (compartment syndrome, damage to the common peroneal nerve and major neurovascular structures posterior to the upper tibia).[77]

Metatarsus Adductus

The infant foot is malleable, making it susceptible to deformation and compression from intrauterine positioning.

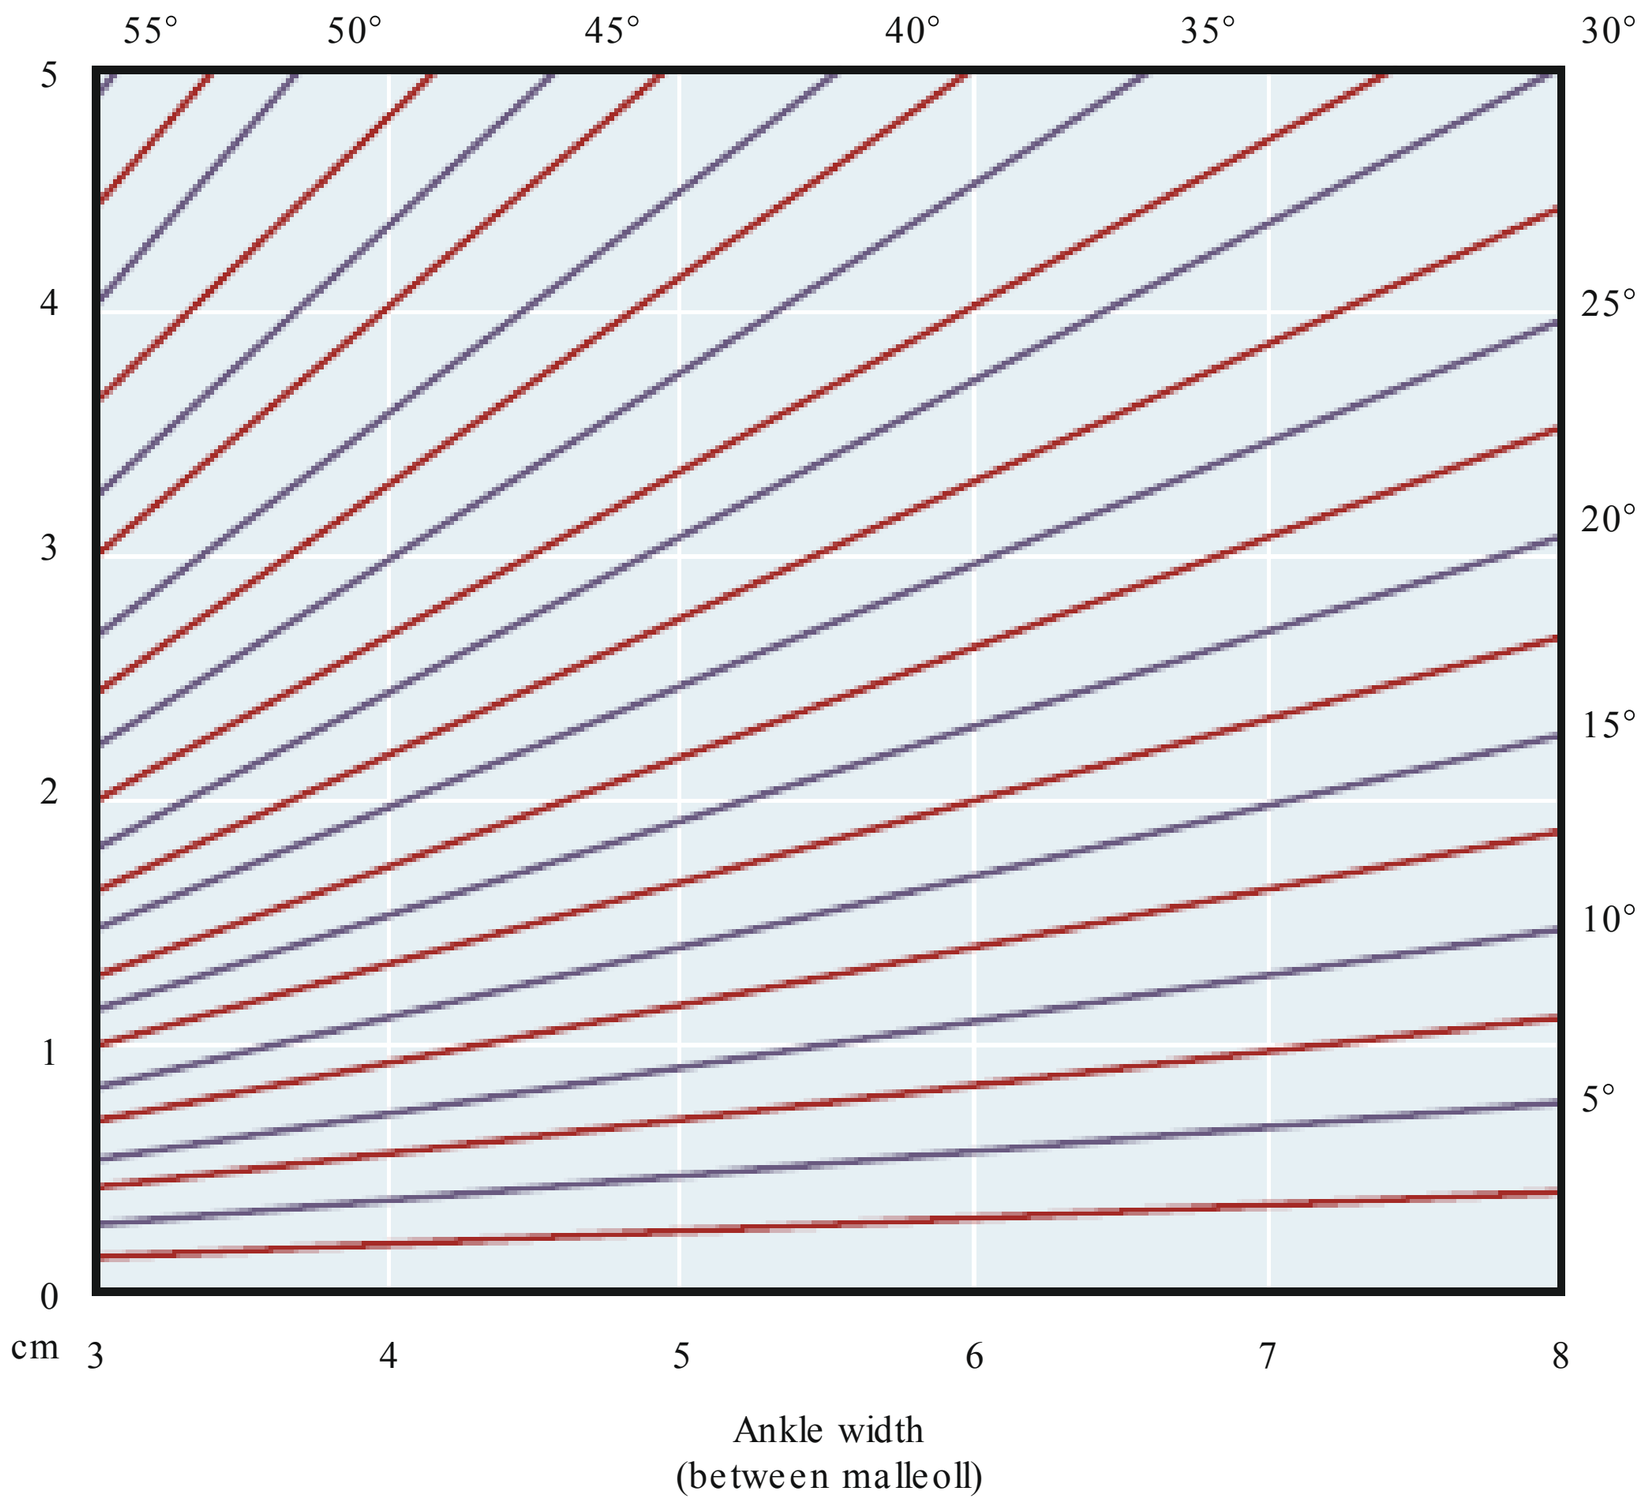

FIG. 14.11 Conversion grid for the transmalleolar axis. (Redrawn from Staheli LT, Engel GM: Tibial torsion: a method of assessment and a survey of normal children. Clin Orthop Rel Res 86:183-186, 1972.)

TABLE 14.2 Clinical Features of Common Causes of In-Toeing in Children

	Metatarsus Adductus	Internal Tibial Torsion	Increased Femoral Anteversion
Age of noticed onset	Birth to 1 year	1 to 3 or 4 years	> 3 years
Laterality	Usually bilateral; may be unilateral with left > right[51]	Usually bilateral; may be unilateral with left > right[58]	Bilateral; other conditions should be considered if unilateral[51]
Natural history	Resolves by age 1 year	Resolves by age 5 years	Resolves by age 11 years

Alterations in alignment of the foot can be a result of increased intrauterine pressure, osseous abnormality, or abnormal muscle attachments.[230] Metatarsus varus, also called metatarsus adductus (MTA), is one of the most commonly seen positional conditions in infants (occurs in 1 per 1000 live births).[46] MTA is solely a forefoot deformity and because of this can be distinguished from talipes equinovarus and skewfoot, which involve the hindfoot structures.[230] The deformity is at the tarsometatarsal joints (Lisfranc joint) of the foot, which results in contracture of the soft tissues around this joint. The forefoot is then adducted in relationship to the hindfoot. In some cases a dynamic deformity is seen only during the child's gait, called "searching great toe." The foot appears straight at rest, but forefoot varus as a result of muscle action occurs with medial motion of the great toe. This usually corrects spontaneously.[201] Patients under 3 years old have a flexible or semiflexible metatarsus adductus. Patients over 4 years old tend to develop a progressively more rigid deformity.[223]

Intervention is rarely required for mild cases (grade I), which usually resolve on their own by about 4 to 6 months. Moderate cases (grade II) may receive intervention with stretching exercises and corrective shoes (straight-last or reverse-last shoes or both). A recommended stretching technique is to face the child, cup the heel of the foot with the left hand (if right foot MTA), and abduct the foot with the right hand while keeping the heel in varus. Pressure should

be applied gently across the metatarsals.[222] Severe cases may warrant manipulation and serial casting, followed by corrective shoes. Surgery is not considered before 4 years to allow for spontaneous resoluation.[222] Although surgery should be used selectively, correction may be important in prevention of further problems as the child reaches adulthood.[214] An increased risk of stress fractures in those with MTA has been documented. [214] Patients ages 25 to 61 years who experienced metatarsal fractures had a forefoot adductor angle of 21° to 37° (normal range, 8° to 14°).[214]

Out-Toeing

Components that may contribute to out-toeing are external rotation contractures of the hip (and, rarely, femoral retroversion), external tibial torsion, and calcaneovalgus (Table 14.3).

External Rotation Contractures of the Hip/True Femoral Retroversion

True femoral retroversion in an infant is rare; it is usually tightness in the hip external rotation muscles and capsular ligaments that is producing the externally rotated position, masking the femoral anteversion.[168] In utero the hips are laterally rotated, making this a normal position in infancy. When the infant is positioned upright, the feet may turn out. If only one foot turns out, usually the turned-out foot is the normal one.[201] If this continues into the second year of life, further evaluation may be needed because retrotorsion may increase the risk of slipped capital femoral epiphysis[201] and has also been associated with degenerative arthritis of the hip[201] and stress fracture.[68]

FIG. 14.12 Tibia Counter Rotator with toe-out gait plate. (From Son SM, Ahn SH, Jung GS, et al.: The therapeutic effect of tibia counter rotator with toe-out gait plate in the treatment of tibial internal torsion in children. Ann Rehabil Med 38:218-225, 2014.)

External Tibial Torsion

ETT usually becomes worse with time because the tibia normally rotates laterally with growth[201] and becomes most problematic in late childhood and adolescence. It is the rotational deformity most likely to require operative correction.[201] ETT is most problematic and noticeable when present in combination with increased FA (malalignment syndrome).[201] The knee is internally rotated and ankle externally rotated.[201] This combination results in an inefficient gait, patellofemoral joint pain,[201] and osteochondritis dessicans.[21] Derotational tibial osteotomy is the only effective intervention but should be reserved for patients with knee pain, severe cosmetic and functional deformity, and an external TFA greater than 40°.[200]

Calcaneovalgus

Calcaneovalgus is a common positional foot problem in newborns, and more than 30% of neonates have bilateral calcaneovalgus.[209] This is an example of an intrauterine "packaging" deformity. The ankle is in excessive dorsiflexion, the forefoot is curved out laterally, and the hindfoot is in valgus. The dorsum of the foot may actually be touching the anterior surface of the leg at birth. The positional calcaneovalgus foot corrects spontaneously and does not require intervention. In cases where ankle plantar flexion limitation is more severe, casting may be an option if stretching fails.[71] Calcaneovalgus may also rarely be caused by a vertical talus. Congenital vertical talus is a very rare condition that is generally found along with other abnormalities[100] and is characterized by the talus in a vertical orientation and the navicular displaced onto the dorsal surface of the talus. The forefoot is dorsiflexed but the hindfoot is plantarflexed, and the foot bends at the instep. This characteristic position is described as a "rocker-bottom" deformity of the foot, and the foot is much more rigid than the typical calcaneovalgus foot. This may more commonly be seen in association with other

TABLE 14.3 Clinical Features of Common Causes of Out-Toeing in Children

	External Rotation Contracture of the Hip	Femoral Retroversion	External Tibial Torsion	Calcaneovalgus
Age of noticed onset	Birth to 1 year	Older than 3 years	Late childhood, early adolescence	Newborn
Laterality	Usually bilateral and symmetrical	Usually bilateral and symmetrical; when unilateral the right side is more often affected[51]	Often unilateral with the right side more often affected[51]	Bilateral
Natural history	Usually resolves by 12 months	Does not improve spontaneously; may be associated with hip or knee arthritis, stress fractures, and slipped capital femoral epiphysis	Usually does not correct spontaneously; may worsen over time, but rarely causes problems of sequelae such as patellofemoral pain or instability, arthritis of the knee	Recovers spontaneously[7]

conditions such as neural tube defects, neuromuscular disorders, or congenital malformation syndromes.[49] Without intervention, this leads to progressive foot pain in all sensate ambulators.[222] Nonambulators may be fitted for shoes that accommodate their deformity because surgery is considered the only corrective intervention.[222]

ANGULAR CONDITIONS

Genu varum (bowlegs) and genu valgum (knock-knees) are similar to torsional conditions in that they are commonly seen in developing children, and a specific natural history has been described that results in normal skeletal alignment at maturity (Fig. 14.13). A description of the natural growth and development process is in Chapter 5. Generally, the presentation of valgus is considered normal up to an age of 7 years.[182,183] After the age of 8 years, pathologic conditions should be considered if deviations from this norm are present.[15]

Clinical Examination

Subjective history of any problems will again provide valuable information.

1. Ask about noticed onset. Was there an injury or illness?
2. Is the deformity progressing? Are there old photographs that would show progression?
3. Tell me about your child's general health. Have there been any other health concerns or problems with muscles or bones? Specific pathologic disorders have been identified with genu varum and valgum. Pathologic problems are generally indicated by: asymmetrical deformity, inconsistency with the normal sequence of angular development, stature less than the 5th percentile for age, severe deformity (> 10 cm intermalleolar or intercondylar distance), history of rapid progression, or presence of other musculoskeletal abnormalities.[57,15]

Measurement of the Hip-Knee-Ankle Angle

Both clinical and radiographic documentation of the degree of varus and valgus will help provide baseline information for later comparison. For clinical measurement the child must be undressed with diaper removed for accurate documentation. For genu varum the child is placed with the medial malleoli approximated. The distance between femoral condyles is measured. Some clinicians use the distance between the knees at the knee joint line. A plastic triangle with centimeters marked on both sides is useful, allowing the examiner to easily obtain accurate measurements, especially of a wiggling child. Measurement of genu valgum can be performed with the child supine or standing, with the medial aspects of the knees lightly touching each other. The intermalleolar distance is documented. Radiographically, an anteroposterior view can be taken with the full length of the femur and tibia. The hip-knee-ankle angle is measured to document the amount of varum or valgum at the knee.[201] Other pathologic conditions may be noted on the films also.

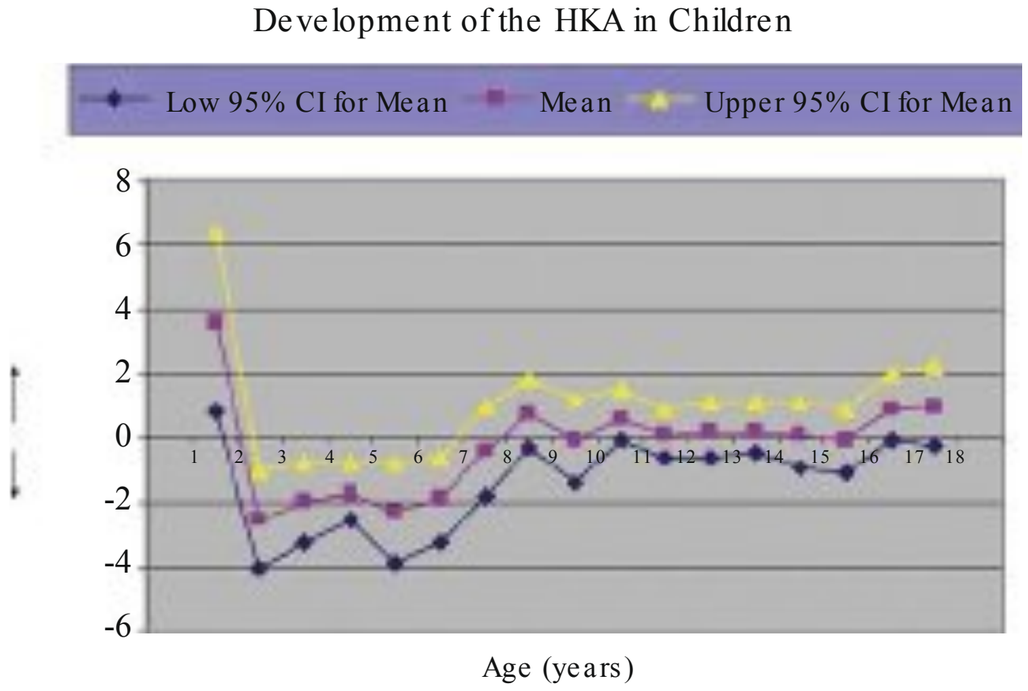

FIG. 14.13 Graphic representation of the development of the tibiofemoral angle during growth. (Redrawn from Sabharwal S, Zhao C: The hip-knee-ankle angle in children: reference values based on a full-length standing radiograph. J Bone Joint Surg Am 91:2461-2468, 2009.)

Genu Varum

When a child develops severe genu varum, especially after 4 years of age or worsening over time, pathologic disorders should be ruled out. Documented causes of pathologic genu varum are congenital tibial hemimelia, osteochondrodysplasia, partial physeal arrest related to trauma, rickets, growth plate injury due to infection, tibial vara (Blount's disease), or excessive prenatal fluoride ingestion.[15,201] Also, the presence of an anterolateral bow of the tibia should be noted and can be confirmed on radiograph.[201] This is the sign of a serious condition because the sclerotic intramedullary canal puts the tibia at severe risk of fracture in the first year of life. The tibial and fibula may fail to unite in these cases, resulting in a condition called "pseudoarthrosis of the tibia." Protective bracing and surgical intervention may be helpful, but amputation may eventually be required because of persistent pseudoarthrosis.[201]

Infants usually have ITT and genu varum, and this combination tends to make the child look "bowlegged and pigeon-toed," causing many parents and others great concern. Even when the genu varum has resolved and the child may actually have developed genu valgum, the presence of ITT may make the child look bowlegged.

Physiologic genu varum does not usually require intervention unless it persists after age 2 years and either shows no tendency to correct or is actually worsening. This latter condition may require bracing in hip-knee-ankle-foot orthoses (HKAFOs) or knee-ankle-foot orthoses (KAFOs) with no knee joint or a hinged knee joint that can be locked. Surgical correction is sometimes required, although this is rare.

Genu Valgum

Genu valgum can occasionally persist beyond the age range when one expects the legs to become generally straight. Many of the children with persistent genu valgum are overweight and have an out-toeing foot progression angle, an awkward gait, and flat feet. Causes of pathologic valgum include: congenital fibular hemimelia, osteochondrodysplasia, overgrowth or partial physeal arrest related to trauma, rickets, osteogenesis imperfecta, growth plate injury related to infection, rheumatoid arthritis of knee, or paralytic conditions such as polio or cerebral palsy leading to contracture of the iliotibial band.[15,201]

Children with significant femoral anteversion may often appear knock-kneed. Once again, a clear understanding of the

three-level concept of torsional conditions and the angular conditions is necessary to isolate the problem. Athletes have been noted to be predisposed to overuse injuries from both extrinsic factors (e.g., training errors) and intrinsic or anatomic factors, such as malalignment of the lower extremities. Variations in alignment may predispose athletes to knee extensor mechanism injuries, iliotibial band syndrome, stress fractures, and plantar fasciitis. Some adolescents with genu valgum present with anterior knee pain, patellofemoral instability, circumduction gait, and difficulty running.[205] Genu valgum can also be seen in multiple epiphyseal dysplasia.[184] Asymmetrical genu valgum may result from trauma or fracture of the lateral distal femoral epiphysis.

If severe, physiologic genu valgum can be safely and effectively corrected in the teenage years by stapling of the medial femoral growth plate and genu varum by leg stapling of the lateral growth plate.[97] This allows the unstapled side of the femoral growth plate to continue growing, and the leg gradually grows into better alignment. A second option for surgical intervention is femoral osteotomy.

FLAT FOOT

A flatfoot is considered normal during at least the first 2 years of life and often is still present at age 6 years.[157] Almost all children will demonstrate a flatfoot when they begin ambulating. Intrinsic laxity and a lack of neuromuscular control result in flattening of the arch when weight bearing.[153] With weight bearing the ligaments stretch and allow mild subluxation of the tarsal bones. Morley[145] documented flat feet in 97 percent of 18-month-olds. In a study of 835 children the incidence of flatfoot in 3-year-old children was 54 percent and in 6-year-old children was 24 percent.[166] Most will develop an arch in the first decade of life (4 percent incidence of flat feet by age 10 years).[145] After age 10 years, natural resolution is not likely and family history may be a factor.[43] In a large population-based interview study of prevalence of flat foot, the odds ratio for prevalence of flatfoot in adults in fourth decade was 1.02 although this increased to 1.04 in the group with body mass index 26 pounds/in^2 and higher.[191] This observation may be trivial but might also be noted clinically when a higher body mass index is present. Many parents will request medical consultation for their child when he or she begins to bear weight; because the normal development demonstrates changes through ages 8 to 10 years, no intervention is generally recommended until after this time period, especially when the child is asymptomatic.[43,201] The pediatric flatfoot can be divided into two categories: flexible or rigid.

Flexible Flatfoot

Flexible flatfoot is characterized by a normal arch during non–weight bearing and a flattening of the arch on stance that may be symptomatic or asymptomatic. At birth, infants have a physiologic ligamentous laxity and lack a medial arch. A fat pad is also present underneath the medial longitudinal arch and resolves between the ages of 2 and 5 years as the arch forms.[147] Children often will also demonstrate more mobility of other joints as well, such as hyperextension of the fingers, elbows, and knees.[157] In these cases the child can form an arch when asked to stand on tiptoe. The heels will roll into a varus position, and good strength of the ankle and foot muscles is measurable[43] (Fig. 14.14).

Besides ligament laxity, other factors have been identified as affecting the presence of a flexible flatfoot. Shoe wear was found to be an influence on the presence of flat feet in a study by Rao et al.[172] of 2300 children between the ages of 4 and 13 years. Those who did not wear shoes had a 2.8% prevalence while those who wore closed-toe shoes had a 13.2% prevalence of flatfoot. Shoe wear was not found to be a significant factor in a study of 560 children (ages 6 to 12 years) in Nigeria, however.[1]

FIG. 14.14 Asymptomatic flexible flat feet demonstrate a diminished arch in weight bearing with hindfoot valgus present (A). Upon weight bearing on toes, the arch reconstructs and the hindfoot moves into varus (B). (From Chaudhry B, Harvey D: Mosby's color atlas and text of pediatrics and child health, St. Louis: 2001; Mosby.)

Another factor that is found more often in children with bilateral flatfoot is obesity. In children 6 years and younger, the incidence was found to be higher by Dowling et al.[47] and Chen et al.[30] Others have found that children (ages 7 to 15 years) who are more physically active have a lower arch than those who are less active.[163] Also, children who habitually sit in the W-position have a higher rate of flat-footedness.[30] Boys are more likely to be flat-footed than girls as well.[163,166]

It has been widely documented that a low arch usually is less of a problem in adulthood than high-arched (cavus) feet. Michelson et al.[140] studied 196 college athletes with flat feet who had 227 episodes of lower extremity injury. Pes planus was not a risk factor for any lower extremity injury; therefore the use of orthotics to prevent further injury was discouraged. In a retrospective study of 97,279 military recruits, mild pes planus resulted in no greater incidence of anterior knee pain or intermittent low back pain when compared with controls.[119] Athletic performance was not hindered by flat-footedness in children 11 to 15 years in a study comparing arch height and ability to perform motor skills.[217]

Intervention of the flexible flat foot generally is not necessary.[43,157,201] Shoe modifications or inserts have been used, although studies have not shown these to be beneficial.[43] Some pediatric orthopedists who counsel parents regarding the natural history of improvement in flat feet through childhood advise the use of a lightweight running shoe as the only recommendation. Using shoes with an arch support and a strong counter will not correct the flatfoot but can help decrease wear on the medial border of the shoes, thereby decreasing the expense of frequent shoe purchase.

In order to rule out rheumatologic, inflammatory, neoplastic, or neurologic disease, the presence of morning stiffness, night pain, pain at rest, numbness, weakness, muscle wasting, constitutional symptoms, and polyarticular pain or swelling should be documented.[43] Family history of hyperlaxity or syndromes associated with flat feet, such as Ehler-Danlos or Marfan syndrome should be considered.

Children occasionally have an extra ossicle located at the medial border of the navicular, called an accessory navicular, that is frequently associated with flat feet. This condition may become symptomatic in late childhood or early adolescence, resulting in pain over the ossicle and along the medial arch, and can be corrected surgically.

Rigid Flat Feet

Rigid flat feet are present in only about 1% of flat feet in children.[221] Primary causes of this are tarsal coalition, congenital vertical talus, and neurologic, neoplastic, or posttraumatic pathologies.[43] As with asymptomatic flexible flat feet, asymptomatic rigid flat feet do not require any intervention.[43] When the hindfoot is fixed in a valgus position, symptoms such as pain, callus, ulceration, poor brace tolerance, and excessive shoe wear can be relieved by lengthening of the Achilles tendon and other surgical soft tissue and osseous procedures.[43,221]

Tarsal coalition involves two or more tarsal bones that are joined by fibrous, cartilaginous, or bony material.[43,221] This connection will reduce movement, generally at the calcaneonavicular or talocalcaneal joints. Usually, this results in a flat foot, although normal alignment or cavus can occur.[43] Passive or active hindfoot inversion results in a painful spasm of peroneal muscles so that it sometimes is called spastic peroneal flatfoot.[221] Many coalitions are asymptomatic and no intervention is necessary.[43] Symptoms may include foot pain, difficulties in walking on uneven ground, feeling of local fatigue, and peroneal spasm.[221] In these cases, casting, splints, orthoses, and modified weight bearing may be needed, and in cases where conservative measures fail, surgical options of removal of the soft tissue interposition or arthrodesis are available.[43,221]

Congenital vertical talus typically presents in infancy as a rigid rocker-bottom foot.[43] Primarily, the talus is in a plantarflexed position and the navicular is dislocated dorsally on the talus.[43] Contractures of the Achilles tendon and the extensor digitorum longus muscle support these positions.[221] Reduction of the deformity is not possible without serial casting and corrective surgeries.[43,221] This is often seen along with myelomeningocele, arthrogryposis, and congenital hip dislocation.[221]

CLUBFOOT

Clubfoot, or congenital talipes equinovarus, is a common congenital deformity affecting approximately 1–2 in 1000 births.[72] The components include forefoot adductus, hindfoot varus, and ankle equinus (Fig. 14.15). Anatomically, the talus is smaller in clubfoot than a normal foot and has a flattened superior surface with consequent decreases in talocalcaneal angle.[232] The subtalar joint facets are misshapen, and the navicular is oriented more downward and medial than in the normal foot.[232] Deformities of the tarsal bones are considered to be the primary cause while ligament and joint capsule changes adjust to the distorted position.[232] The ligaments are generally thickened and muscles hypoplastic, resulting in generalized hypoplasia of the limb with shortening of the foot and smallness of the calf.[201] The foot appears smaller as the result of a flexible, softer heel caused by the hypoplastic calcaneus.[71] Ankle valgus may evolve with growth and may be mistaken for "overcorrected clubfoot," or hindfoot valgus.[206] Severe cases of metatarsus adductus may be confused with this, but the equinus component differentiates the diagnosis.

Other musculoskeletal abnormalities commonly occur in conjunction with idiopathic clubfoot. Tibial shortening, ITT (or decreased external tibial torsion), and increased internal hip rotation have been documented.[92,175] These changes may not

FIG. 14.15 Child with clubfoot with hindfoot varus, hindfoot equinus, and forefoot varus. (Pisani G: "Coxa Pedis" today. Foot Ankle Surg 22:78-84, 2016.)

be significant in some because the external tibial torsion may increase with age and the internal hip rotation may decrease with age.[41,175] Also a factor may be the manipulation technique used to correct clubfoot; external tibial torsion increases if the corrective technique does not allow a progressive eversion of the talus underneath the calcaneus.[58] Therefore rotational malalignment should be examined and monitored, although operative correction generally is not recommended until after 7 years of age because alignment may spontaneously correct with growth.[175]

The cause of clubfoot is considered to be a combination of genetic and environmental factors.[201,222] A genetic influence is suggested because siblings have up to 30 times the risk of developing clubfoot deformity and monozygotic twins have a 33% concordance rate.[66,14,201,222] Also, a male predominance (2:1 ratio) is present although affected females are more likely to pass on the trait to their children and have siblings with clubfoot than males.[121] Higher incidence is also seen in Hispanics and a lower incidence in Asians.[201] Environmental factors have also been identified.[14,66,201] These include factors during pregnancy such as cigarette smoking, early amniocentesis, or viral infection.[66,14] Cases of clubfoot related to intrauterine positioning are generally mild and correct rapidly with intervention.[201] More severe cases are thought to be from factors occurring earlier in fetal life, while idiopathic cases are generally in the middle range of the severity spectrum.[201] Histologic anomalies have been identified in every tissue in the clubfoot, including muscle, nerve, vessels, tendon insertions, ligaments, fascia, and tendon sheaths.[98] In addition, Loren et al.[130] found congenital muscle fiber type disproportion or fiber size variation in 50 percent of peroneus brevis muscle biopsies performed at the time of posteromedial release, and those feet with such muscle variation had a significantly greater incidence of recurrent equinovarus deformity.

The goal of intervention of clubfoot is to correct the deformity and retain mobility and strength.[201] The foot needs to be plantigrade and must have a normal load-bearing area.[201] Also included in the objectives are the ability to wear normal shoes, satisfactory appearance, and avoidance of unnecessary complicated or prolonged interventions.[201] Extrinsic clubfoot (severe positional or soft tissue deformity that is supple) can often be successfully corrected with conservative intervention such as serial casting, which should be started as soon after birth as possible,[40,171,236] although some have used up to 9 years of age.[14] Casts are changed in the Ponsetti method semiweekly or weekly, and the foot should be positioned so that it can be corrected in an orderly sequence by first correcting the cavus, rotating the foot from under the talus, and finally correcting the equinus.[201] After four to six castings, many may require an Achilles tenotomy to lengthen the tendon. Most can change to a brace for 3 months at that time, followed by a sleep brace for 2 to 4 years.[66,222] This method is considered the standard approach throughout the world.[201] A second method, the French method, involves daily manipulations of the foot by a therapist, stimulation of the muscles around the foot, and temporary immobilization of the foot with plaster cast.[40] Duration of the intervention is generally 2 months[14,40] and has been found to be effective in varying stages of severity.[40] Some may require a tibialis anterior tendon transfer, usually between 3 and 5 years of age, to control dynamic forefoot supination or recurrent deformity.[66] This is considered to be a minor procedure as it does not affect the joints of the foot.[66]

In cases of intrinsic (rigid) clubfoot, manual reduction and surgery may be required.[71] Surgical techniques include Z lengthening of the Achilles and posterior tibiotalar and talocalcaneal capsulotomy to correct equinus, posteromedial talocalcaneal capsulotomy and/or subtalar release to correct hindfoot varus, release of the abductor hallucis and talonavicular joint for midfoot adduction, and plantar fascia release for cavus deformity.[222]

BLOUNT'S DISEASE/TIBIA VARA

Blount's disease, or tibia vara, is a developmental condition resulting from a deceleration of growth at the posteromedial proximal tibial physis that ultimately results in a varus deformity of the tibia, along with flexion and internal rotation of the tibia and relative limb shortening in unilateral cases.[16,181] Clinically, this disorder has been classified into three forms: infantile (onset 0 to 4 years), juvenile (onset 4 to 10 years), and adolescent (onset after 10 years).[181] The etiology of Blount's disease is unknown, but some predisposing factors have been identified.[16,181] Boys are more affected than girls, and approximately 50% of the cases are bilateral but not always symmetrical.[16] The growth inhibition at the proximal tibia may be related to excessive compressive forces medially. In infantile forms, an early walking age, large stature, obesity, or a combination of these factors has been suggested.[16] Others have suggested that various genetic, medical, biomechanical, and environmental factors contribute.[181] In adolescent forms the likely cause is a mechanical injury to the medial tibial physis, with or without a preexisting varus deformity.[16] Differential diagnoses that should be considered are rickets, renal osteodystrophy, focal fibrocartilaginous defect, and proximal tibial physeal injury.[16]

The influence of obesity should be considered in this population. In a child with genu varum, obesity will cause an increased compressive force at the medial tibia.[181] Also of note are gait deviations caused by obesity related to increased thigh girth.[181] When the thigh girth limits adduction of the hips, a varus moment results at the knees and increases the pressure at the medial part of the proximal tibial physis. Therefore late-onset Blount's disease may result from these mechanical factors and not a preexisting varus alignment.[16,181]

In children younger than 2 years of age, it sometimes is difficult to distinguish between physiologic genu varum and Blount's disease.[222] Physiologic genu varum will be demonstrated by angular deformity from the femur and the tibia, and infantile Blount's disease involves deformity isolated to the proximal tibia.[222] Radiographic findings will show varus angulation centered at the knee, mild metaphyseal beaking (appearance similar to a bird's beak), thickening of the medial tibial cortices, and tilted ankle joints. Six stages of infantile Blount's disease (from 1 through 6, least to more involved) have been described on the basis of this radiographic appearance[16,201,222] (Fig. 14.16). Also useful in the diagnosis of and choice of intervention for infantile Blount's disease is the metaphyseal-diaphyseal angle.[201,222] If the angle exceeds 16°, Blount's disease is likely to develop.[16,201] Radiographs are performed every 3 to 6 months, and improvement will be seen with physiologic varus after the child's second birthday; however, Blount's disease will progress and show metaphyseal changes.[201] In adolescent Blount's disease, the distal femur may also be angulated, and radiographs will demonstrate medial physeal and epiphyseal

FIG. 14.16 Langenskiold's radiographic classification system describes the six stages of infantile Blount's disease. (Redrawn from Langeskiöld A: Tibia vara [osteochondrosis deformans tibiae]: a survey of 23 cases. Acta Chir Scand 103:1-22, 1952.)

hypoplasia of the proximal tibia.[222] Also, a lateral or varus thrust during gait may be seen.[222]

Intervention is based on the stage of tibia vara and age of the child.[16,181,201] In children younger than 3 years of age, observation is very important, with bracing prescribed in the presence of a lateral thrust[201] or in stages 1 and 2.[222] Richards et al.[176] found a 70 percent success rate with bracing in this group. During this study, three different types of orthoses were used and included conventional HKAFOs, conventional KAFOs, and elastic Blount KAFOs (medial upright design that uses a wide elastic band just inferior to the knee joint) and the elastic Blount brace has been the choice at this clinic since its development in 1987. Surgery is recommended if the tibia vara progresses or is initially seen in stage 3 or 4.[16,181,201] This option is considered if conservative intervention has failed by the fourth birthday.[222] Surgery may be needed to correct the varus deformity, correct the ITT, restore normal joint congruity, and prevent or correct limb length discrepancy.[2] Better outcomes with operative realignment were found when surgery was performed before 4 years of age.[181,222] Also, better outcomes were documented when surgery was performed before permanent physeal damage had occurred.[88] Late-onset Blount's disease is corrected surgically with proximal tibial osteotomy and/or lateral physeal hemiepiphysiodesis (selective closure of half of the growth plate to allow the contralateral portion of the physis to correct with growth).[222]

DEVELOPMENTAL DYSPLASIA OF THE HIP

Developmental dysplasia of the hip (DDH) is a term used to describe a wide-ranging spectrum of disorders from minor acetabular dysplasia to irreducible dislocation of the femoral head, with the primary cause being instability of the hip.[39,107] It may also include hips that may have been normal or were believed to be normal at birth but subsequently were documented to have dysplasia.[170]

The term *dysplasia* describes abnormal development or growth. Normal muscle balance and a femoral head that is concentric, congruent with, and seated deep within the acetabulum are necessary prerequisites for normal hip development. The concave acetabulum develops in response to a spherical femoral head, and the depth normally increases with growth.

The incidence of hip dysplasia in the United States is 5.5 per 1000 for full-term babies within the first 2 days of life.[6] The incidence dropped to 0.5 per 1000 after 2 weeks of age, indicating that many cases improve without intervention.[6] Prompt recognition of and initiation of intervention for DDH, preferably in the newborn period, provide the best chance for subsequent optimal hip development and a normal hip at skeletal maturity, especially in those cases that do not resolve spontaneously. Ideally, DDH will be identified in the neonatal screening, but cases have been found that were clinically stable in the neonatal period but subluxed or dislocated later.[170] This finding would encourage clinicians to evaluate the hip beyond the neonatal period until the child begins to walk.[170]

The origin of DDH is thought to be multifactorial. The Subcommittee on Developmental Dysplasia of the Hip of the American Academy of Pediatrics[37] has identified four periods during which the hip is at risk. If a dislocation occurs as the fetal lower limb rotates medially during the 12th week of gestation, all elements of the hip joint develop abnormally.[37] During the 18th gestational week, the hip muscles are developing, and neuromuscular problems occurring at this time, such as myelodysplasia and arthrogryposis, can lead to dislocation.[37] During the final 4 weeks of pregnancy, dislocation can occur as the result of mechanical forces.[37] Most noted in this time frame is breech positioning, as DDH occurs in as many as 23% of breech presentations.[37] The breech position puts the child at high risk by placing the hip in flexion and the knee in extension.[37] The left hip is involved three times more often than the right hip because of intrauterine positioning with the left hip positioned posteriorly against the mother's spine, potentially limiting abduction.[37] Also related to intrauterine positioning is the increased incidence seen in firstborn children[173,188] as well as babies with high birth weights.[188] Because these are related to positioning due to limited space in the uterus, other abnormalities may coexist with DDH including torticollis, metatarsus adductus, and oligohydramnios.[188] In the postnatal period, positioning such as swaddling, combined with ligament laxity, can have a role.[37] Girls are more susceptible to the maternal hormone relaxin, which may contribute to ligament laxity[37] and possibly account for the five times higher frequency in females.[188] Also of interest is the reduced incidence of DDH among cultures in which infants are routinely carried with their hips in flexion and wide abduction in cloth slings on the mother's back or astride her hips[54] along with the increase in dysplasia noted in children who are swaddled in the first few months of life.[36] Although risk factors have been identified, all children should be considered because the majority of cases of DDH have no identifiable risk factors.[193]

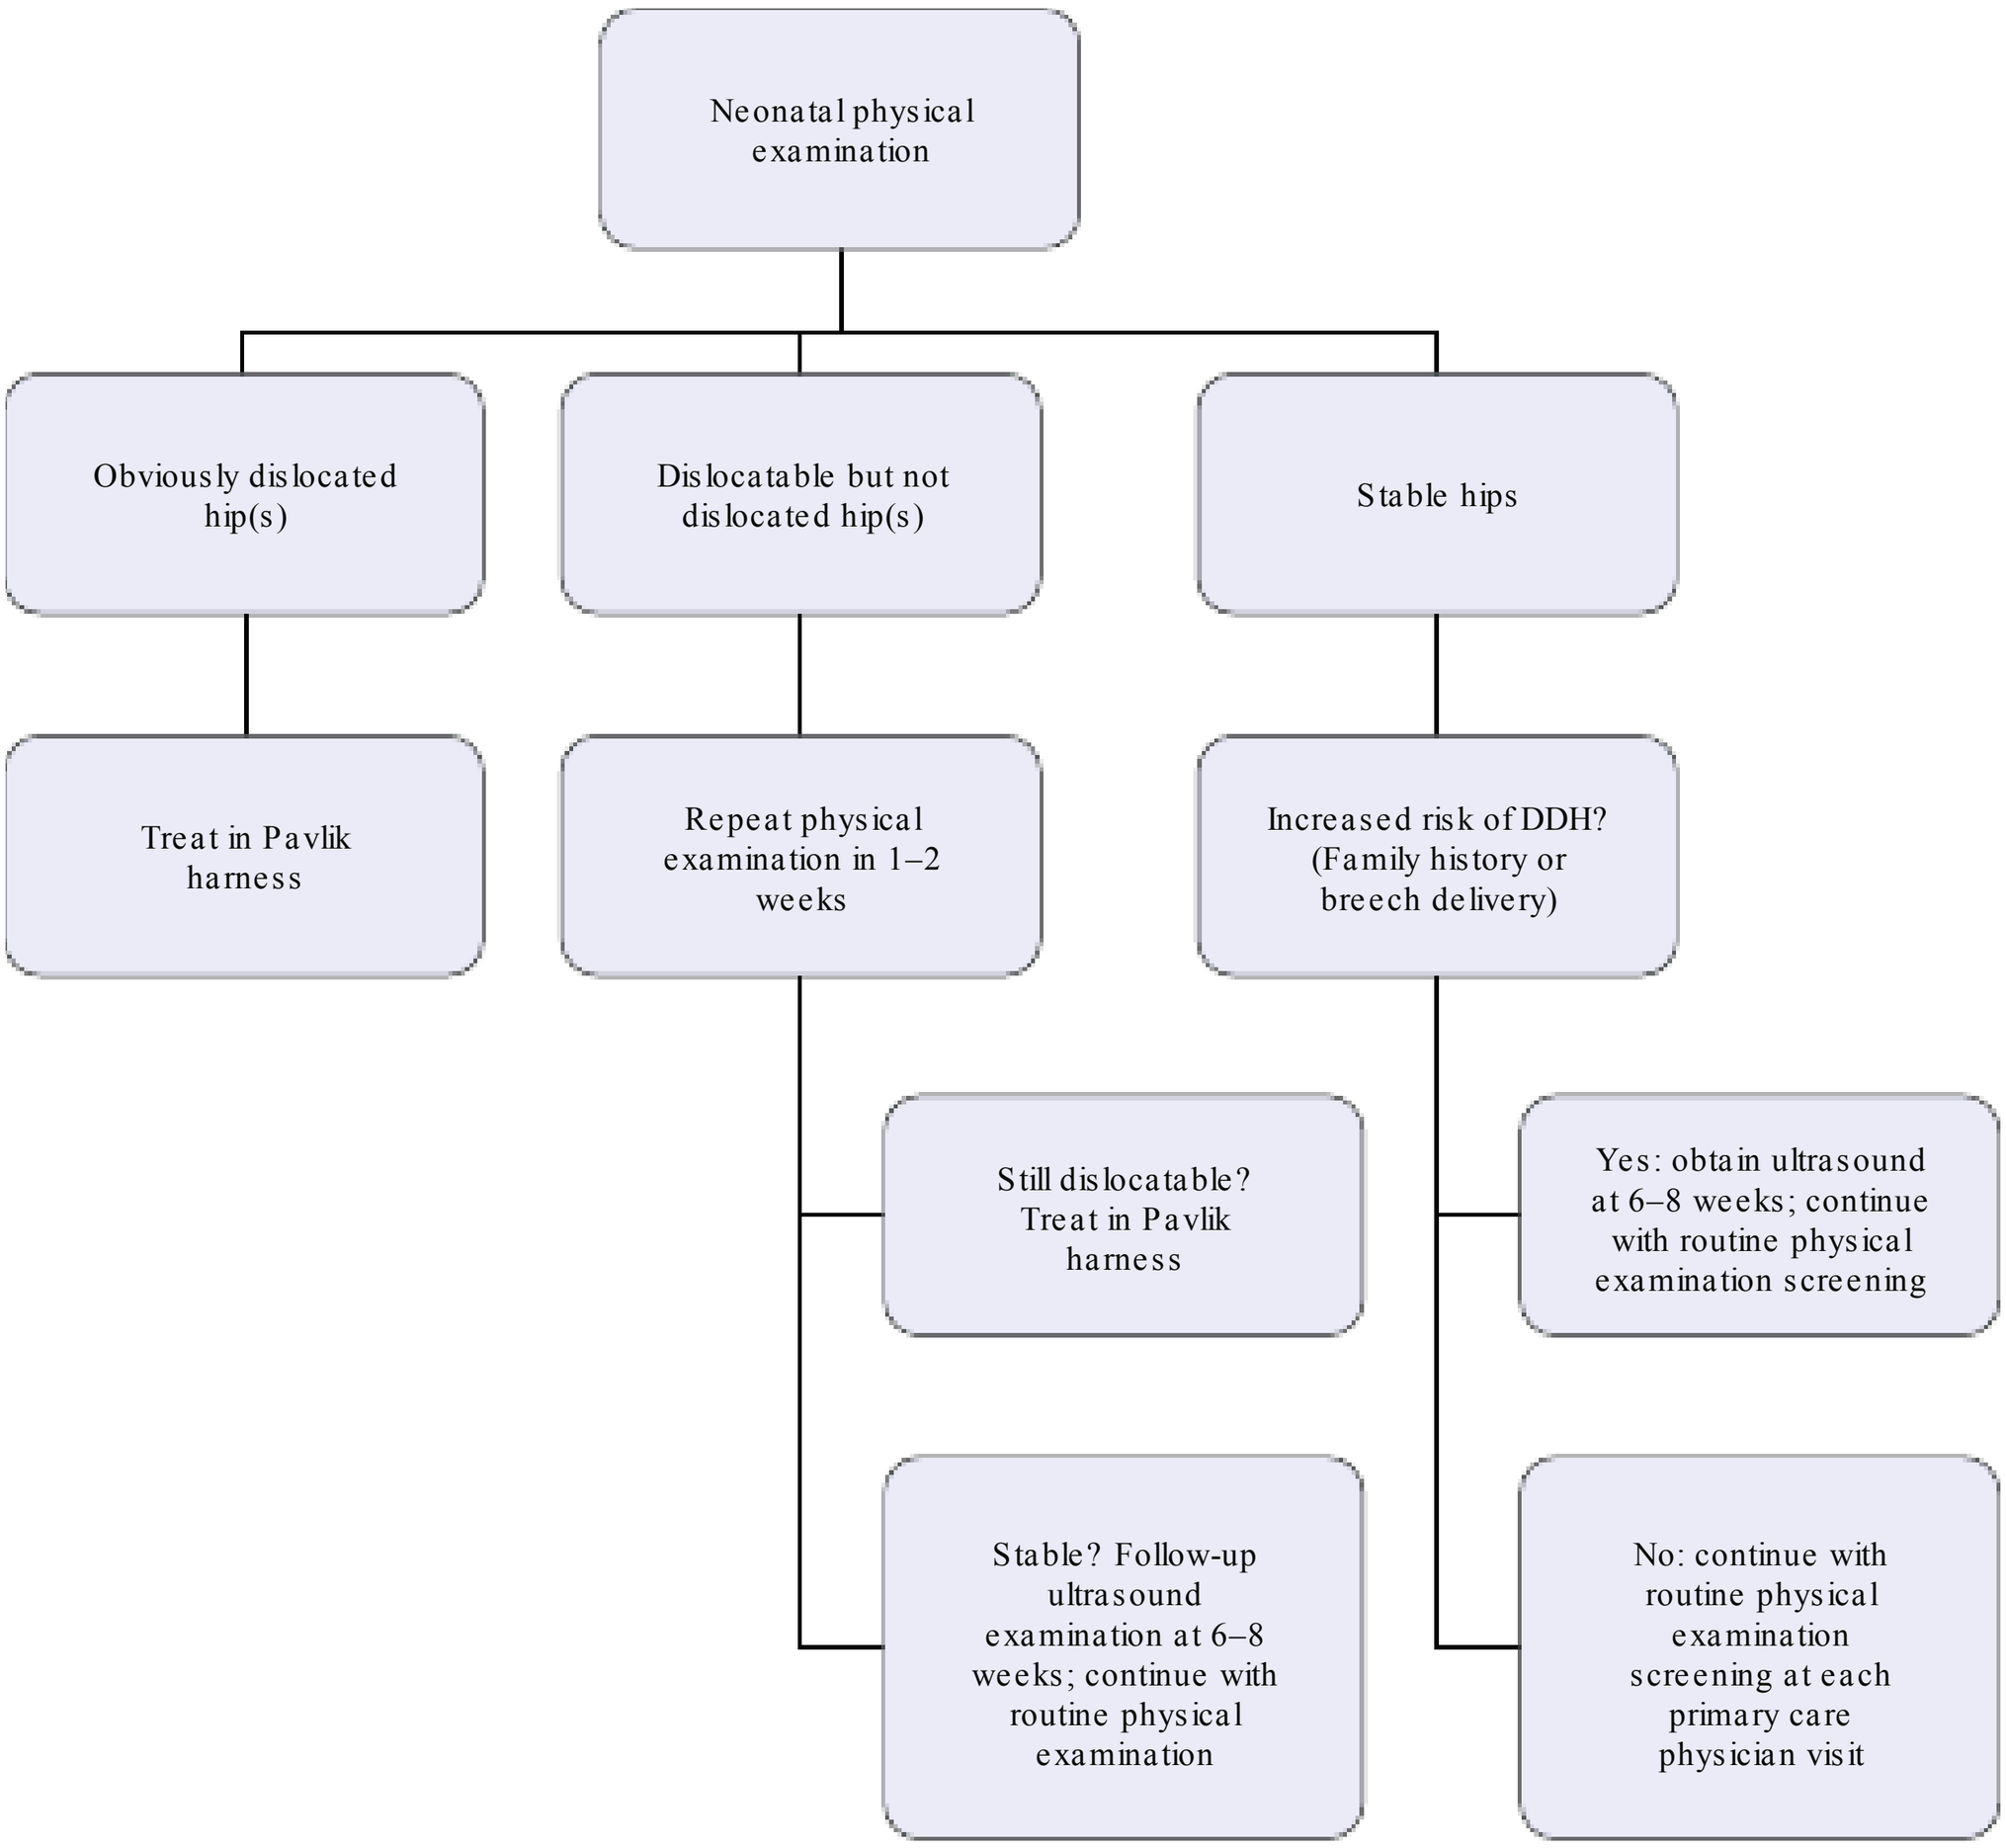

FIG. 14.17 Algorithm for neonatal physical examination screening for hip dysplasia. DDH, developmental dysplasia of the hip. (From Mahan ST, Katz JN, Kim YJ: To screen or not to screen? A decision analysis of the utility of screening for developmental dysplasia of the hip. J Bone Joint Surg Am 91:1705-1719, 2009.)

Clinical Examination

Screening for DDH has been the focus of many studies and reviews for the purpose of developing protocols that allow for early intervention when needed.[90,94,134,193,211] Generally, the accepted practice is clinical screening of all newborns and ultrasound screening on all newborns with identified risk factors.[90,94,134] An algorithm of this process is in Fig. 14.17.

Clinical screening includes performance of the Ortolani test (reduction test) and the Barlow test (stress test). Description of these tests is in Fig. 14.18. The child needs to be completely relaxed for these maneuvers to have reliable diagnostic value. Every slight muscular contraction around the hip can obscure the instability and negate the examination. The experience of the clinician with these tests has been shown to be a strong predictor of the test results.[193] Pediatricians have been shown to have a case identification rate of 8 per 1000, while orthopedists identify 11 per 1000.[126] The Ortolani and Barlow tests are often negative by 2 to 3 months of age because the hip improves in stability and stays in the socket or becomes fixed in a dislocated position. Positive tests will continue to be the most reliable clinical findings in older infants and toddlers with dysplasia. Other clinical signs at greater than 3 months of age are restricted hip abduction (<60 degrees with infant supine and knees flexed to 90 degrees), leg length discrepancy (prone and with Galeazzi test), and asymmetrical thigh and gluteal skin folds.[94]

Diagnostic studies are considered appropriate when clinical testing is positive and even with a normal clinical examination if risk factors are present. Ultrasound during the first 3 months of life is the most appropriate test due to the incomplete ossification of the femoral head.[193] Any child with a breech delivery or a family history (parent or sibling) of DDH should be considered for an ultrasound screening even

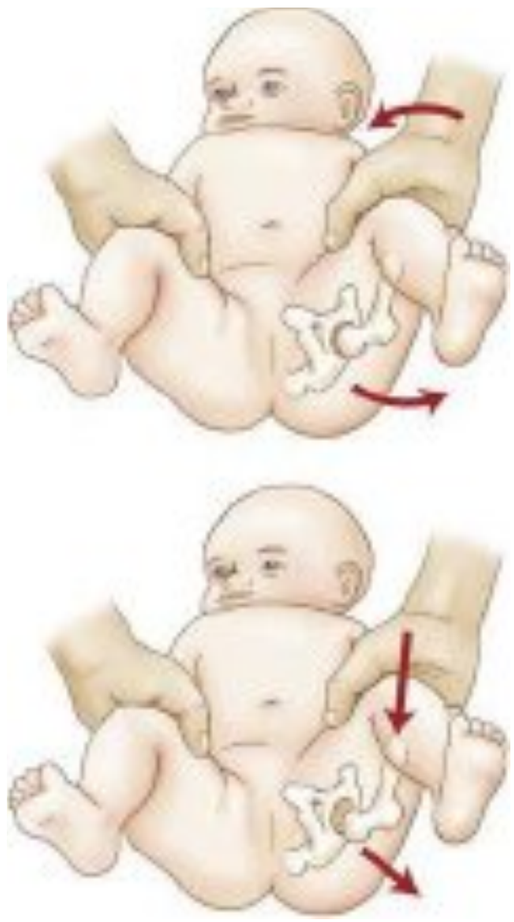

FIG. 14.18 Barlow maneuver. The hip is first flexed and abducted, then is gradually adducted, with pressure exerted in a posterior direction. Dislocation of the femoral head over the posterior acetabular rim indicates an unstable hip. The head may slide to the edge of the socket (subluxatable) or may dislocate out of the acetabulum (dislocatable). In the Ortolani-positive hip, the hip is dislocated in a position of flexion and adduction. Gentle flexion, abduction, and slight traction (the Ortolani maneuver) reduce the hip. A positive Ortolani sign indicates a more unstable hip than a positive Barlow sign. (From Hagen-Ansert SL: Textbook of diagnostic sonography. 7th ed. St. Louis, Mosby, 2012.)

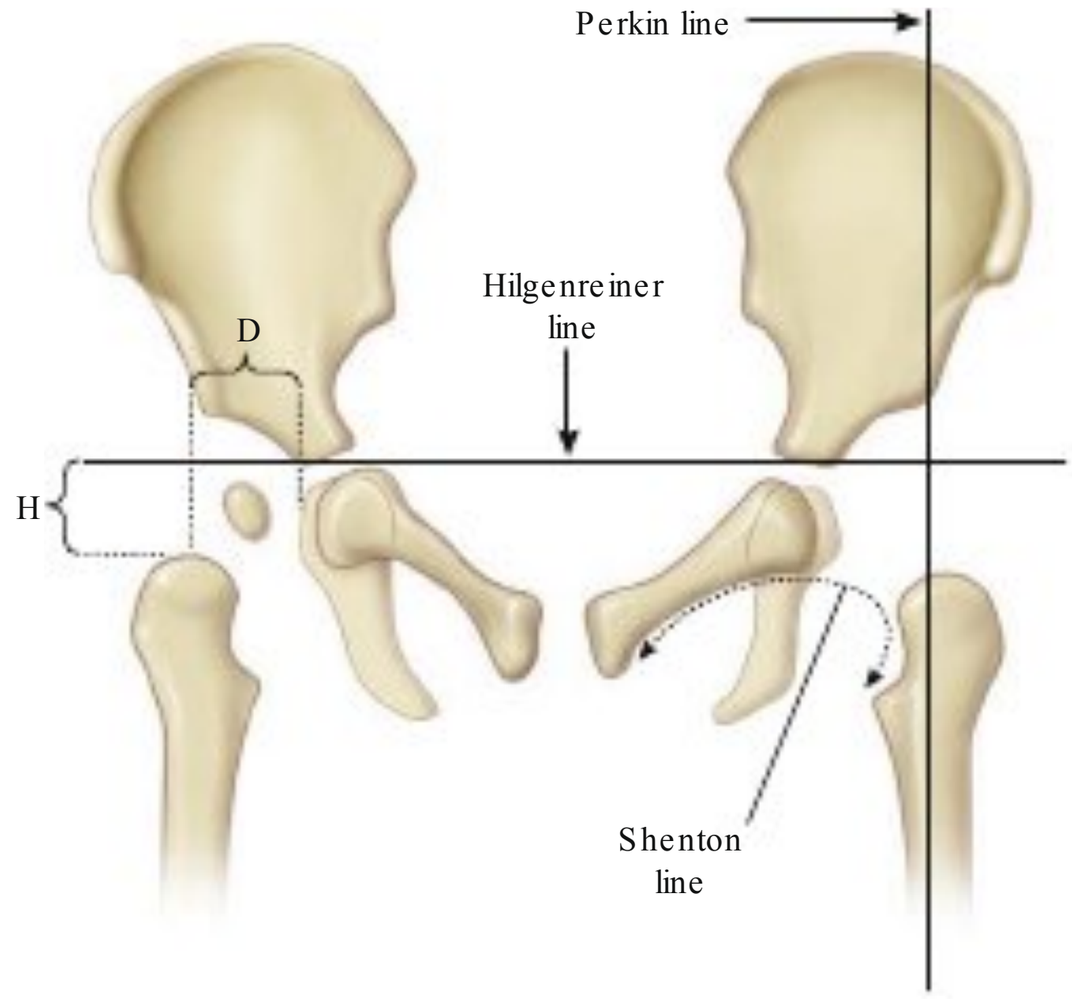

FIG. 14.19 Radiographic measurements that are useful for evaluating developmental dysplasia of the hip. The Hilgenreiner line is drawn through the triradiate cartilates. The Perkin line is drawn perpendicular to the Hilgenreiner line at the margin of the bony acetabulum. The Shenton line curves along the femoral metaphysic and connects smoothly to the inner margin of the pubis. Dimension H (height) is measured from the top of the ossified femur to the Hilgenreiner line. Dimension D (distance) is measured from the inner border of the teardrop to the center of the upper tip of the ossified femur. Dimensions H and D are measured to quantify proximal and lateral displacement of the hip and are most useful when the head is not ossified. (From Herring JA: Tachdjian's pediatric orthopaedics: from the Texas Scottish Rite Hospital for Children. 5th ed. Philadelphia, Saunders, 2014.)

if the clinical exam is normal.[94,134] Ultrasound may also be a good option if four or more of the following risk factors are identified: breech presentation, family history, female baby, large baby (> 4 kg), overdue (> 42 weeks), oligohydramnios, presence of plagiocephaly, torticollis, or foot deformities, or firstborn baby or multiple pregnancies (decreased intrauterine space).[94] Ultrasonography allows examination of the cartilaginous structures not visualized on plain radiographs and allows stress testing (to document instability), with the additional advantage of no radiation exposure. It is also useful in the management of DDH, documenting reduction of the dislocated hip in the Pavlik harness[213] and providing information on the status of the hip to aid decisions on altering or stopping intervention (Fig. 14.19). The Graf classification system is used in classifying hips with DDH (Fig. 14.20). At age 5 months and older, radiographs are the more appropriate screening tool.[94,193] Because of the need for a radiograph of the uninvolved side for comparison and because of the frequency of bilateral involvement, the standard radiograph is an anteroposterior view of the pelvis. The benefits of x-ray to monitor DDH through walking age outweigh the risks of radiation exposure.[185] The acetabular index (Fig. 14.21) can be monitored through the radiographs as well as an early finding of the "teardrop" indicating a stable, concentric reduction of the hip has been achieved.[196] The "teardrop" is a landmark in the inferior medial acetabulum on an anteroposterior radiograph.[196] Many parameters of hip development can be measured on hip radiographs.

When the clinical finding is hip instability (either reducible dislocation or dislocatable hip), the hip becomes stable spontaneously in about half the cases.[188] The other cases can be classified as dysplasia, subluxation, or dislocation.[81] Dysplasia describes a radiographic finding of increased obliquity and the loss of the concavity of the acetabulum, with an intact Shenton line. The Shenton line should be continuous with no breaks. It is drawn on radiographs along the inferior border of the superior pubic ramus and then continues along the inferomedial border of the neck of the femur.[81] A superolateral migration of the proximal femur results in a discontinuous Shenton line. Subluxation describes when the femoral head is not in full contact with the acetabulum with the presentation of a widened teardrop femoral head distance, a reduced center-edge angle, and a break in the Shenton line.[81] In these cases the femoral head is in the socket but can be partially displaced out of the acetabular rim. Dislocation refers to the femoral head not in contact with the acetabulum.[81] This can include cases where the femoral head is reduced but can be dislocated with a Barlow maneuver, dislocated but reducible (where the femoral head is out of the acetabulum at rest but can be reduced with an Ortolani maneuver), or dislocated but not reducible (which is generally related to other medical issues occurring before birth). Both subluxated and dislocated hips

FIG. 14.20 Graf classification of infant hips based on the depth and shape of the acetabulum as seen on coronal ultrasonograms. Type I: normal; characterized by a well-formed acetabular cup with the femoral head beneath the acetabular roof. Type II: immature in infants less than 3 months of age and mildly dysplastic in infants older than 3 months of age; characterized by a shallow acetabulum with a rounded rim. Type III: subluxated; characterized by a very shallow acetabulum with some displacement of the femoral head. Type IV: dislocated; characterized by a flat acetabular cup and loss of contact with the femoral head. (Redrawn from French LM: Screening for developmental dysplasia of the hip. Am Fam Physician 60:177-184, 1999. © 1999 David Klem.)

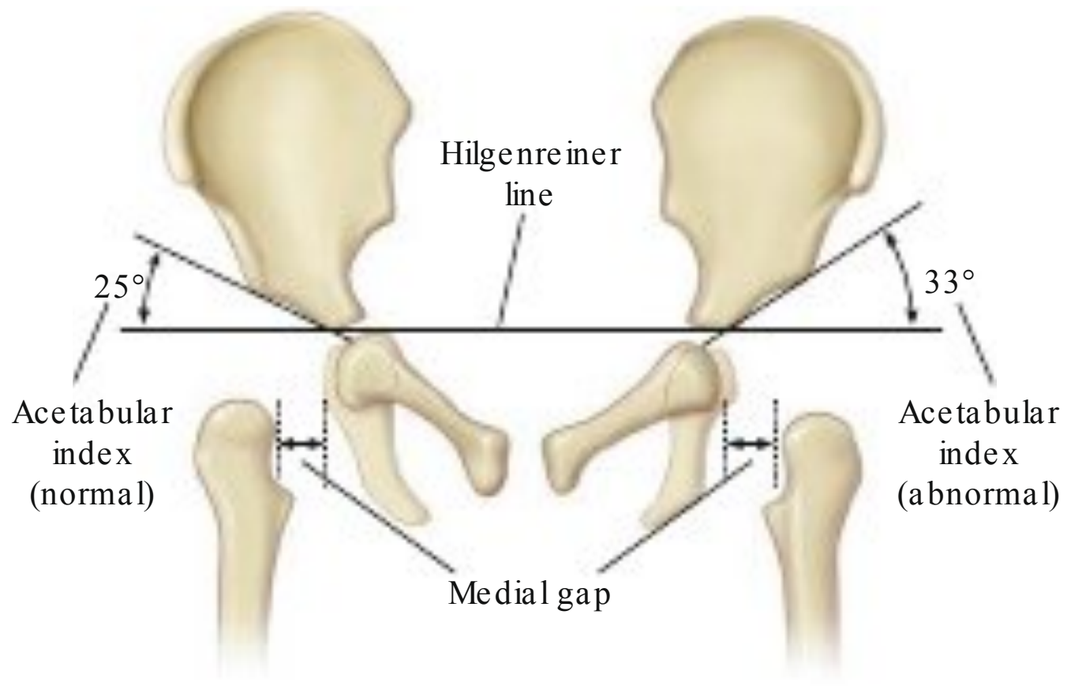

FIG. 14.21 Acetabular index. The acetabular index is the angle between a line drawn along the margin of the acetabulum and the Hilgenreiner line; it averages 27.5° in normal newborns, and it decreases with age. (From Herring JA: Tachdjian's pediatric orthopaedics: from the Texas Scottish Rite Hospital for Children. 5th ed. Philadelphia, Saunders, 2014.)

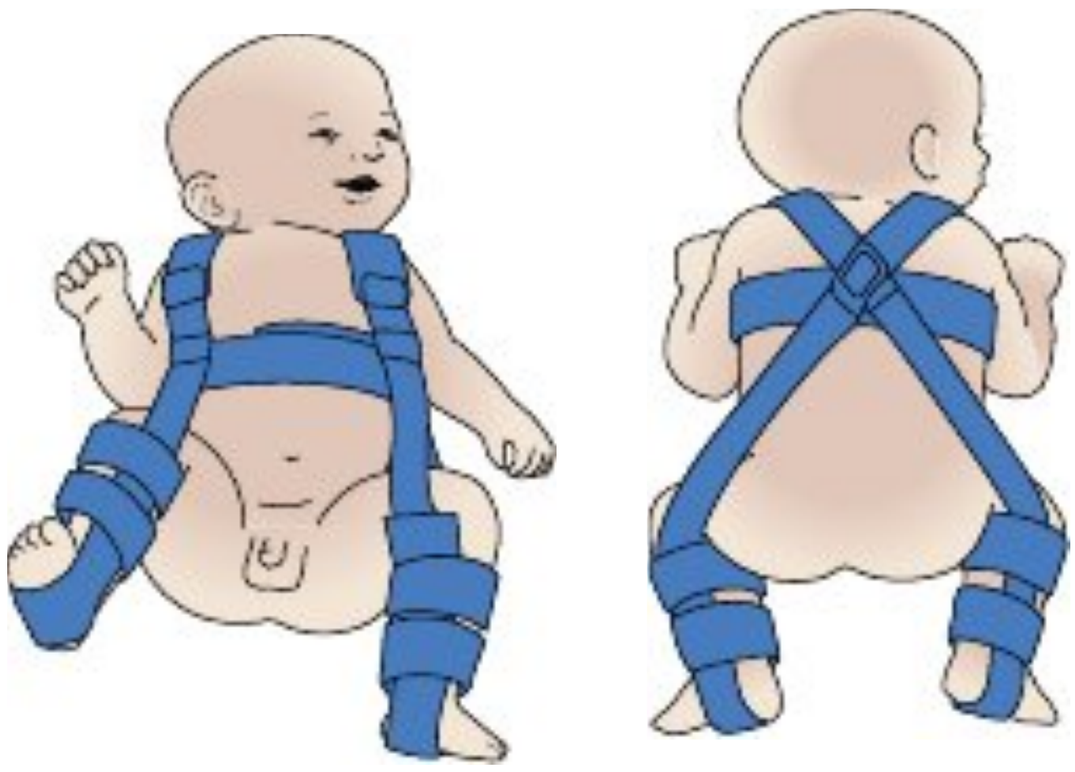

FIG. 14.22 Infant in a Pavlik harness. (From Ball J: Mosby's pediatric patient teaching guides. St. Louis, Mosby, 1998.)

have dysplastic changes.[81] Over time, the stresses on the joints will cause further problems if left without correction. Dysplastic hips without subluxation will usually become painful and develop degenerative changes. Often they will become subluxed as the degenerative disease progresses.[81] The subluxed hip will lead to symptomatic degenerative disease with gradual increasing pain starting as early as the second decade of life in severe cases and the fifth and sixth decades in the least severe cases.[81] A completely dislocated hip will demonstrate symptoms later than a subluxed hip and, in some, never become symptomatic.[81]

Intervention for DDH

Goals for Intervention

The basic goal for intervention of DDH is the same regardless of the age of the patient: reduce and maintain the reduction to provide an optimal position for the development of the femoral head and acetabulum.[224] If this reduction is maintained, the femoral head and femoral anteversion can remodel.[224] The intervention to achieve this position becomes more complex as the child ages. Also, with increasing age and complexity come more risks of complications and the likelihood of the development of degenerative joint disease.[224]

Birth to 6 months old. The Pavlik harness is the primary method of correcting DDH during infancy. The Pavlik harness was first described by Dr. Arnol Pavlik, who originally called his intervention device "stirrups." Modifications have been made in the design of the device, but the principles of intervention and the requirements of the harness remain essentially the same as described by him over 50 years ago.[164] Pavlik stressed that one of the main advantages of the harness over casts is that it allows active motion, thereby decreasing the incidence of avascular necrosis (AVN) of the femoral head.[165]

The Pavlik harness restricts hip extension and adduction that can lead to redislocation, but it allows further flexion and abduction, which lead to reduction and stabilization (Fig. 14.22). The position of flexion and abduction enhances normal acetabular development, and the kicking motion allowed in this position stretches the contracted hip adductors and promotes

FIG. 14.24 The Von Rosen splint. (Copyright © Elsevier, Inc: NetterImages.com.)

spontaneous reduction of the dislocated hip. By maintaining the Ortolani-positive hip in a Pavlik harness continually for 6 weeks, hip instability resolves in 90% to 95% of the cases of subluxation and dysplasia, and there is approximately 85% success in cases of dislocation.[150,224] The overall success rate has been described as 91.5% at a minimum of 14 years' follow-up.[150] Ultrasonography is an important tool to monitor intervention (after initial 7 to 10 days and every 3 weeks thereafter)[81,224] and to determine when intervention should be discontinued either because of successful or unsuccessful results.[39] Failure of the harness is generally thought to be from inappropriate application or persistence of intervention when not effective.[224] Complications can occur if a child is positioned in greater than 12° flexion (femoral nerve palsy or dislocation of femoral head inferiorly).[81,224] After 6 months of age, the failure rate for the Pavlik harness is over 50 percent because the active and crawling child is difficult to maintain in position in the harness.[224] The harness is contraindicated in patients with significant muscle imbalance (myelodysplasia or cerebral palsy), significant stiffness of joints (arthrogryposis), and excessive ligament laxity (Ehlers-Danlos syndrome).[224] Use of an abduction splint following the use of the Pavlik harness is advocated by some to allow further development of the acetabulum.[81] The Ilfeld splint (Fig. 14.23) and the von Rosen splint (Fig. 14.24) have shown high success rates for this.[81] Triple diapering has not shown positive effects.[81]

If the use of the Pavlik harness is not successful in reducing a dislocated hip, surgical intervention is indicated. This may include a period of 2 to 3 weeks of traction to reduce the incidence of AVN of the femoral head. Home traction is a safe, effective, and much less expensive alternative to performing traction in the hospital.[115] Surgery includes an arthrogram to define the anatomic landmarks of the femoral head and acetabulum and to detect the presence of soft tissue (pulvinar) interposition between the head and acetabulum; adductor tenotomy; closed or (if necessary) open reduction of the hip; and application of a spica cast. Luhmann and colleagues[131] reported that delaying reduction of a dislocated hip until the appearance of an ossification nucleus more than doubled the need for additional reconstructive procedures, advocating early intervention.

6 months to 2 years old. The child who is between 6 months and 2 years old who presents with a newly dislocated hip and the child who has failed conservative care to this point is managed in similar ways.[81,224] In these patients the obstacles to maintaining reduction are different, the intervention has greater risks, and the end results are less predictable.[224] The goal is still to achieve reduction, maintain that reduction to provide an environment for the development of the femoral head and acetabulum, and avoid proximal femoral growth disturbance.[81,224] The two primary methods of intervention will be closed reduction or open reduction, either of which may be preceded by traction.[81,224]

The need for the use of traction is a choice that may vary among physicians.[81,224] The purpose of traction prior to a reduction is to stretch contracted muscles, allowing the reduction to be performed without excessive force decreasing the incidence of avascular necrosis and open reduction.[224] The use for traction has been challenged because studies have shown conflicting results on its benefits when compared to no traction prior to closed reduction.[122,194] Also debated has been the effect of traction on the rate of open reductions needed.[81] In fact, this practice of traction seems to have changed significantly over the last 20 years with fewer surgeons using it routinely presurgically.[224] For those who would benefit from it, home traction is an option because it may be applied for 2 to 3 weeks, and this would allow decreased hospital admission time, although adherence of the family and patient is essential to this option.[81,224]

Closed reductions are performed with general anesthesia or deep sedation. The hip is reduced as it would be in the Ortolani maneuver with minimal force applied. The ROM that is allowed while the hip remains reduced is compared to normal ROM and a "safe zone" is determined[81] (Fig. 14.25). If the reduction is determined to be stable, the child is immobilized in a hip spica

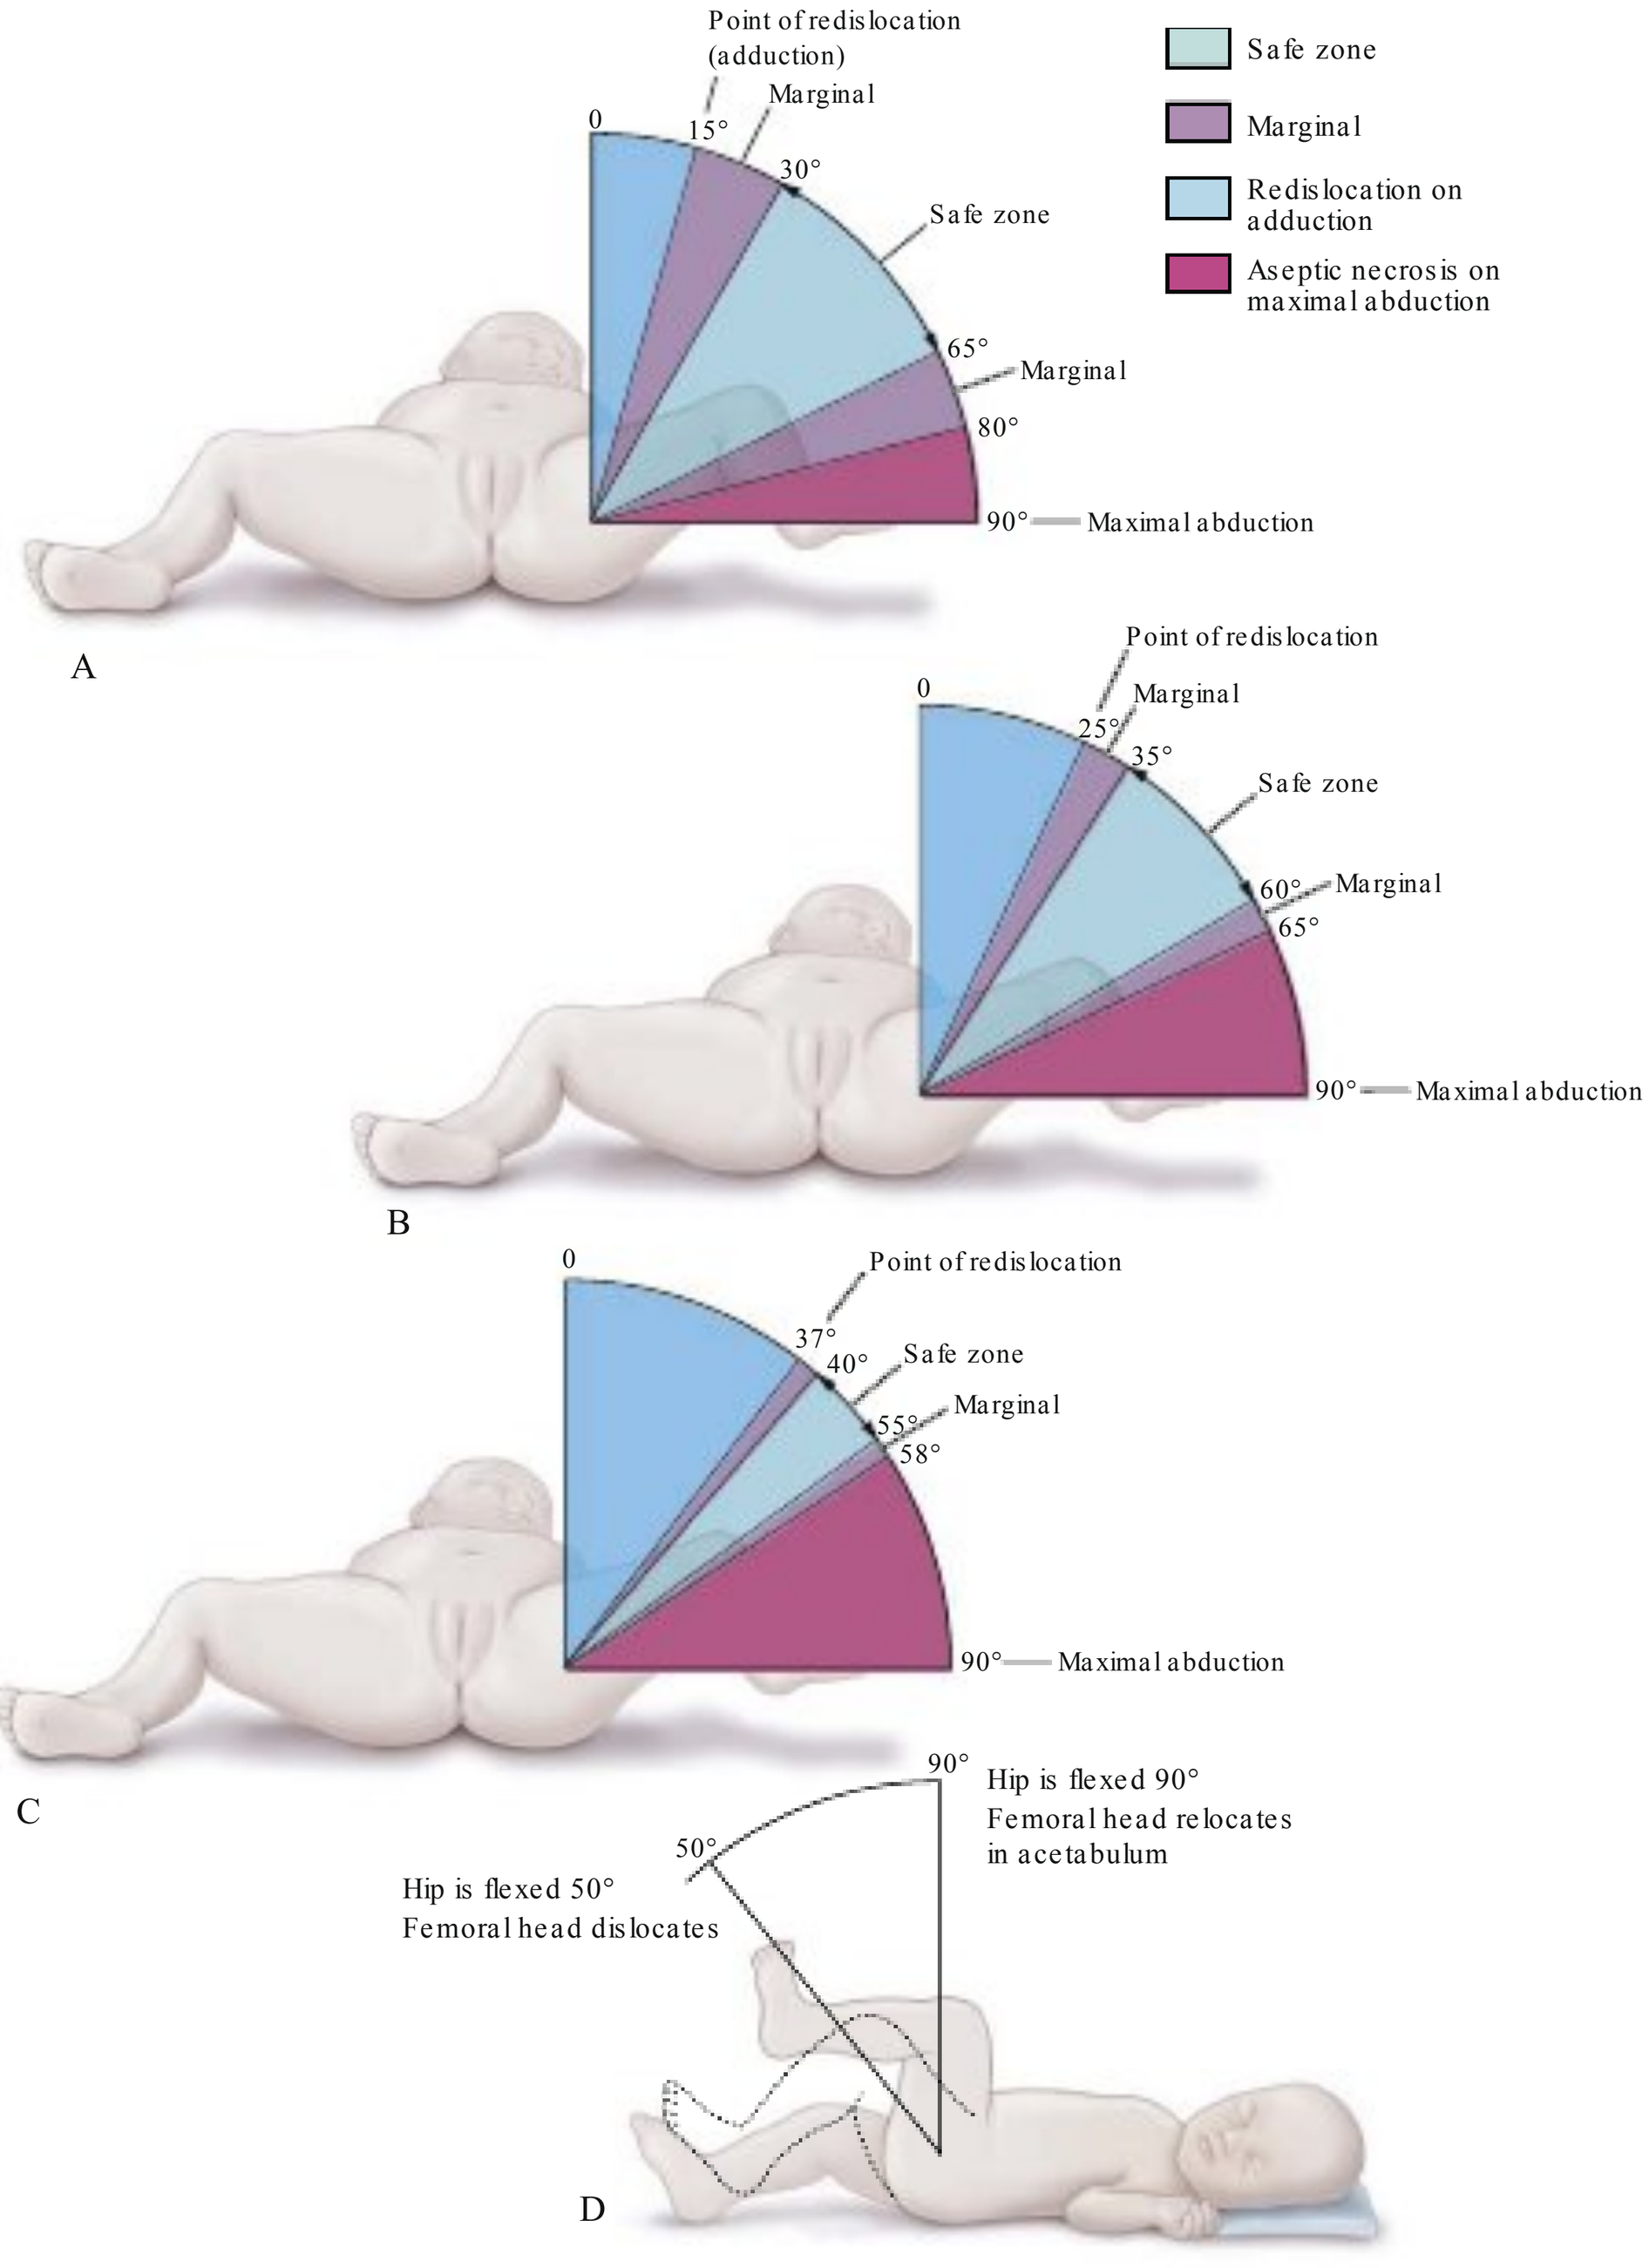

FIG. 14.25 Examination of the hip with developmental dysplasia. (A) Wide zone of safety. (B) Moderate zone of safety. (C) Narrow zone of safety. (D) Femoral head dislocation. (From Herring JA: Tachdjian's pediatric orthopaedics: from the Texas Scottish Rite Hospital for Children. 5th ed. Philadelphia, Saunders, 2014.)

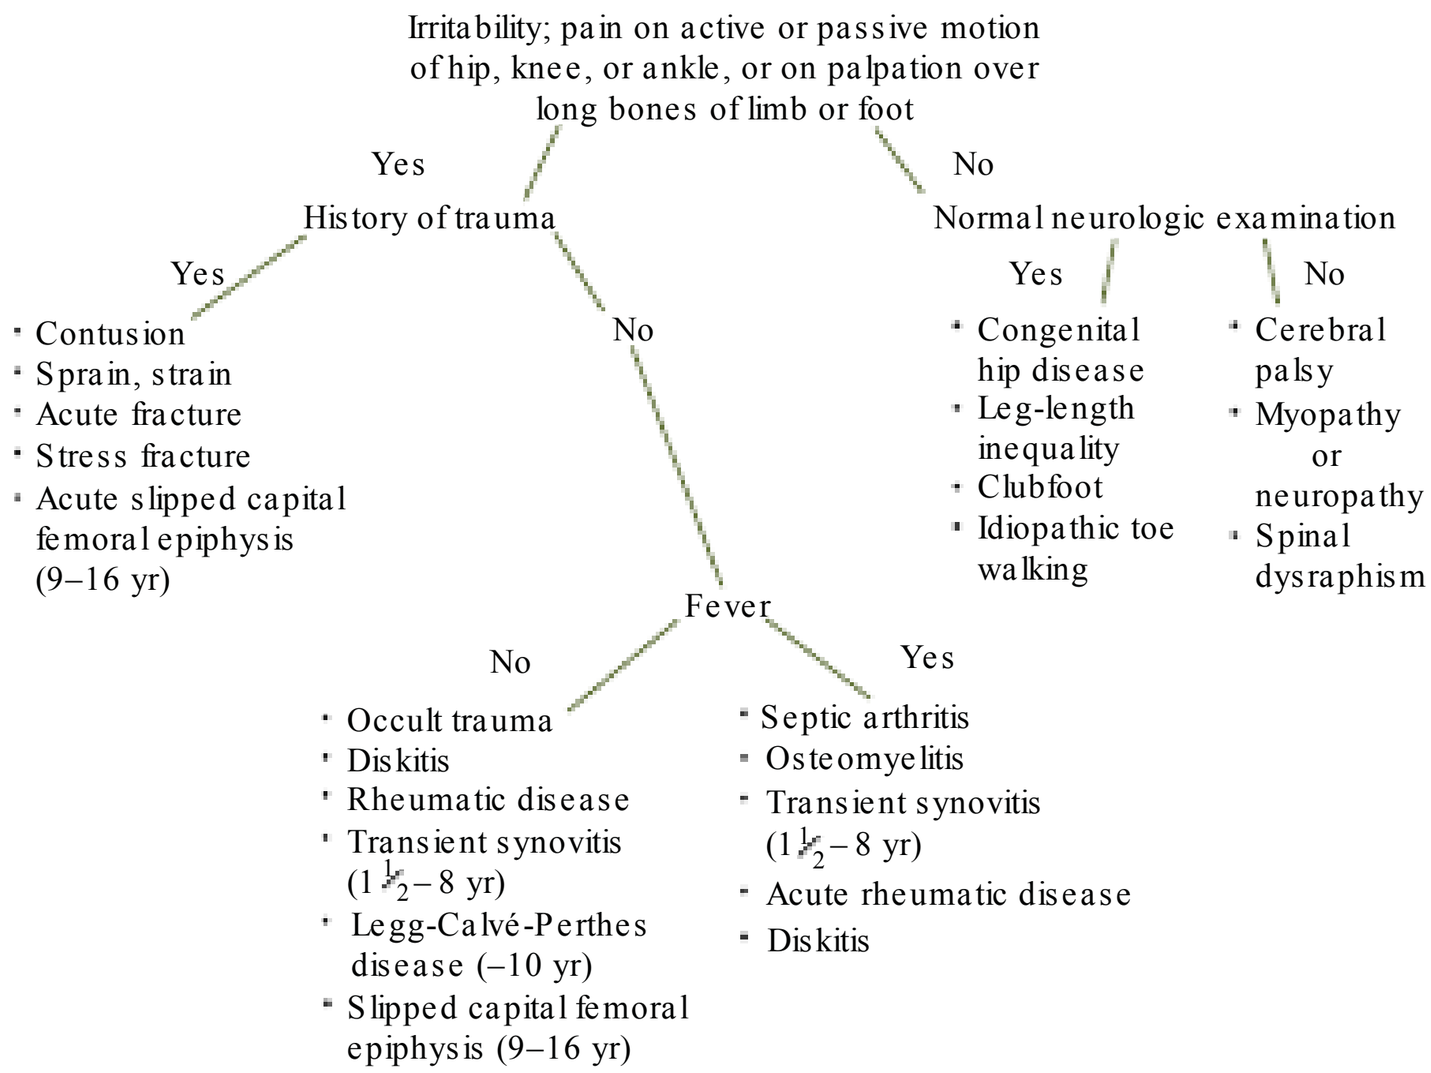

FIG. 14.26 A clinical decision tree for children with a limp. (From Scoles PV: Pediatric orthopedics in clinical practice. 2nd ed. Chicago, Year Book Medical Publishers, 1988.)

cast. The length of time in the cast will vary with each patient, but generally the first cast is applied for 6 weeks with examination at that time followed by a second cast for 6 weeks. Further immobilization will be determined at that time depending on the stability of the joint. Some will continue with abduction splinting following the casting.[81,224]

Open reduction is indicated when closed reduction fails to obtain a stable hip. This may be determined at the time of the initial closed reduction or may become evident at the cast change. The surgical procedure can be performed from an anterior or medial approach to perform a capsulorrhaphy, capsular repair, and pelvic osteotomy, if needed.[81,224] Following the surgery, casting will be applied as done with a closed reduction.[81]

Two years old and older. Intervention for older children with hip dislocation becomes more challenging. The femoral head is usually in a more proximal location, and the muscles that cross the hip are generally more contracted. Generally, a femoral shortening will need to be performed because this has shown better results than skeletal traction in this age group. Also, an acetabular reshaping osteotomy will be needed.[81] A potential complication is posterior dislocation of the hip. Good results have been reported with this intervention with low rates of avascular necrosis.[81] The upper age at which this should be performed has been debated. It may be appropriate for children up to 9 or 10 years old in unilateral cases and up to age 8 years in bilateral cases.[81] When children reach late juvenile and adolescent age, a triple pelvic osteotomy is often required for intervention.[227]

A number of children with acetabular dysplasia are never diagnosed as infants or toddlers. With mild dysplasia, they will walk without a limp, will have essentially normal hip ROM, and can actively participate in all childhood activities, including sports. However, the hip is like a tire that is out of alignment: you can drive on it for quite a few miles, but uneven wear will occur. The dysplastic hip, especially the one with subluxation, also develops uneven wear with subsequent articular cartilage damage. The person may develop degenerative arthritis, hip pain, and limp as early as the late teens. Very mild dysplasia may go undetected for many decades and may be diagnosed later in life when the patient develops degenerative hip joint disease. One area of discussion is the presence of acetabular retroversion and/or femoral acetabular impingement as a long-term outcome for those with hip dysplasia or as a result of intervention.[224] Femoral acetabular impingement can further lead to acetabular cartilage delamination and degenerative joint disease over time.[224]

CAUSES OF LIMPING IN CHILDREN

The acute onset of limp in a child is a condition that warrants evaluation. In this section chronic causes of limp, such as those due to muscle weakness, will not be addressed. Orthopedic conditions that can result in acute limping will be reviewed. Although some of these are transitory and benign, some can result in lifelong impairments, especially if not corrected promptly and effectively. Fig. 14.26 and Box 14.1 provide useful information for the initial evaluation and assist in confirming a differential diagnosis. It is important to identify those who need immediate medical or surgical attention to prevent complications. Especially for those working in a direct access situation, attention to the history and systemic symptoms are important in the determination of referral to other professionals.

History and Physical Examination

When a child has a limp, a complete and thorough evaluation is recommended. A detailed history should be taken and should include a description of any recent illness or injury that may be a contributory factor. The clinician should be aware, however, that children do fall frequently, and a fall could be related to the onset of the limp or other injury, even though it may be incidental and unrelated.

Physical examination should include an observational gait analysis. This should allow the clinician to determine which leg is involved and perhaps the location within the leg. Gait analysis

can provide much assistance in the direction of further testing. The algorithm in Fig. 14.27 demonstrates the process of generally categorizing the gait by observation with further physical examination and diagnostic testing used as confirmation.

The physical examination should also include a complete examination of the spine, hips, thighs, knees, lower legs, ankles, and feet, including the uninvolved side for comparison. Objective measurements of ROM and strength should be taken, as should observations of the presence of muscle atrophy, swelling, redness, and difference in temperature between limbs. Also, the child's subjective response of pain with palpation and with movement and muscle contraction is important. Much information can be gathered from the way a child performs functional activities, which is especially important when a child's cooperation might limit a formalized evaluation. Observation of the child moving from the floor to standing or crawling or achieving a comfortable sitting position can provide usable information. For example, a child may refuse to walk because of pain but may crawl easily, indicating that the problem is probably evident in the lower part of the leg, rather than in the hip or knee. A child might also demonstrate the use of his hands to "walk" up his body to rise to standing from the floor (Gowers' sign) because of hip and thigh muscle weakness, which could be related to neurologic disorders or other conditions causing proximal muscle weakness.

One consideration should be the various types of osteochondroses that are common causes of limp in the 5- to 10-year-old group and in the 10- to 15-year-old age group (Table 14.4). The

BOX 14.1 Diagnoses of Limping Commonly Found in Various Age Groups

Birth to Age 5 Years
Osteomyelitis
Septic arthritis
Transient synovitis
Occult fractures
Kohler syndrome

Child (4–10 Years)
Transient synovitis
Legg-Calvé-Perthes disease
Discoid lateral meniscus
Sever disease
Growing pains

Adolescent (11–15 Years)
Slipped capital femoral epiphysis
Osgood-Schlatter syndrome
Osteochondritis dissecans
Tarsal coalition
Freiberg disease
Accessory navicular

TABLE 14.4 Conditions of Osteochondroses

Ossification Center	Eponym	Typical Age (Years)
Tarsal navicular	Kohler disease	3–8
Capital femoral	Legg-Calvé-Perthes disease	4–8
Calcaneus	Sever disease	8–15
Tibial tubercle	Osgood-Schlatter syndrome	Boys 12–15; girls 8–12
Second metatarsal head	Freiberg disease	13–18
Vertebral ring	Scheuermann disease	10–12
Capitellum	Panner disease	< 10

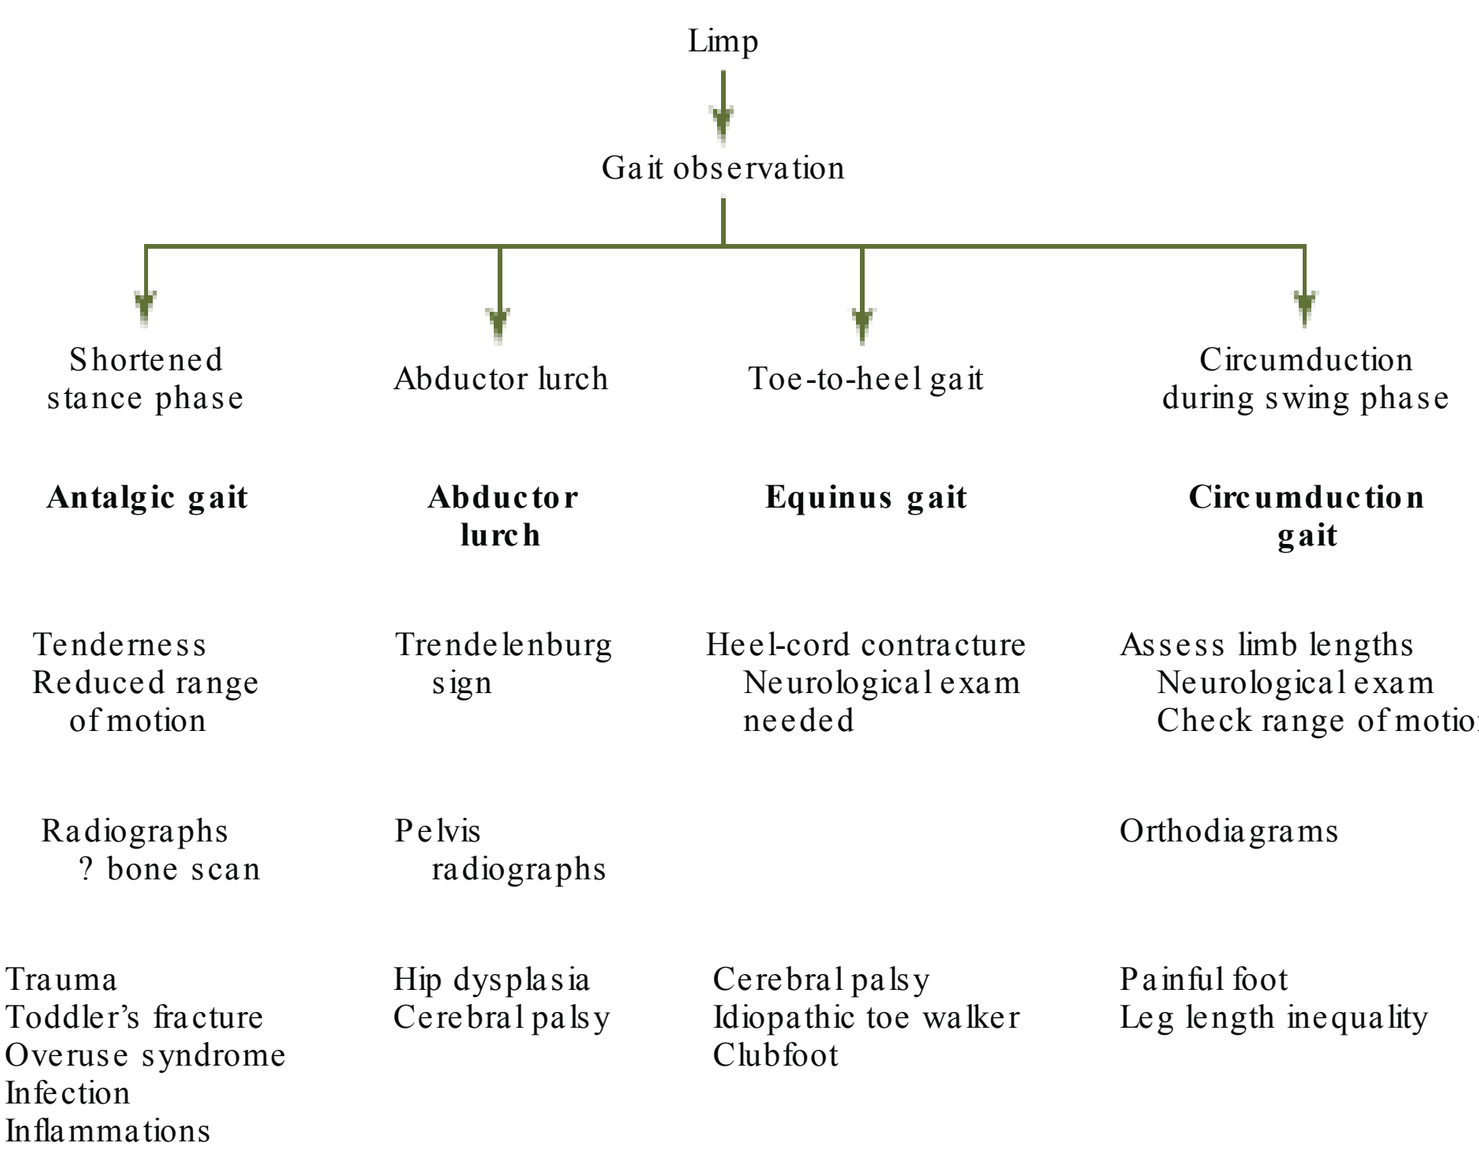

FIG. 14.27 Algorithm used for evaluation of limping. A general category can be determined by observation with physical examination and tests used to confirm the problem. (From Staheli LT: Practice of pediatric orthopedics. 2nd ed. Philadelphia, Lippincott Williams and Wilkins, 2006.)

osteochondroses represent a group of disease of children and adolescents in which localized tissue death (necrosis) occurs, usually followed by full regeneration of healthy bone tissue.[51] During the years of rapid bone growth, blood supply to the epiphyses (growing ends of bones) may be compromised, resulting in necrotic bone, usually near joints.[51] Because bone is undergoing a continuous rebuilding process, the necrotic areas are often self-repaired over a period of weeks or months.[51] Osteochondrosis is generally divided into three locations: physeal, articular, and nonarticular. Physeal osteochondrosis (Scheuermann disease) occurs at the intervertebral joints.[51] Articular diseases occur at the joints (articulations), with common forms occurring at the hip, foot, and elbow.[51] Nonarticular osteochondrosis occurs at any other skeletal location, with one example being Osgood-Schlatter disease, which occurs at the tibia.[51] Many cases are idiopathic although stress related; repetitive trauma and infection are noted causes, and occurrence generally is more frequent at times of rapid growth of the epiphysis.[51]

Other Diagnostic Tests

In addition to a careful clinical examination, other tests are often indicated. Radiographs can document fractures or other bony abnormalities, although some occult fractures are not identifiable on radiography until 10 to 14 days after onset, when a repeat radiograph may document formation of callus. Laboratory examination of blood samples provides information regarding the presence of infection or other acute processes. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) can indicate the presence of acute inflammation, as well as response to intervention. More complex diagnostic studies may also be needed to define the problem or evaluate the efficacy of interventions. These studies include bone scans, magnetic resonance imaging (MRI) (for soft tissue), and CT (for bony structures).

The cause of a limp in a child may be as simple as a foreign object in the shoe or as complex as osteogenic sarcoma. Therefore generalizations regarding management should not be made, and a diagnosis should be established as quickly as possible. Many cases may be easily corrected, and some require no intervention beyond observation. Many causes of limp are associated with specific age groups, specifically one of three groups: birth to 5 years, 5 to 10 years, and 10 to 15 years. Soft tissue injuries (i.e., contusion, ligaments, and tendon injuries) and fractures are found in all age groups.

Osteomyelitis

Osteomyelitis has the highest incidence in children under the age of 3 years.[177] It can be classified as acute (< 14 days' disease duration) or subacute (> 14 days' disease duration). Also, occurring rarely is chronic recurrent multifocal osteomyelitis (CRMO), which is an autoinflammatory bone disease that may present with pain and signs of inflammation over months or years without responding to intervention.[3,7] The incidence rate can vary regionally with approximate values of 8 per 100,000 for acute osteomyelitis and 5 per 100,000 for subacute osteomyelitis (13 per 100,000 combined).[177] The incidence of CRMO is 1 in 1 million.[7] Most commonly, osteomyelitis in children is hematogenous, which means circulating pathogenic organisms settle in the metaphyses of long bones due to slower circulation in these regions.[169] In the United States, the incidence of acute hematogenous osteomyelitis is 1 in 5000 children under the age of 13 years.[133] Nonhematogenous osteomyelitis is the result from direct inoculation of organisms into the bone due to conditions such as penetrating trauma or open fractures.[169] When trauma occurs, local edema may alter the blood flow, and the formation of a hematoma may provide a good environment for bacterial proliferation.[229] In some instances a history of recent respiratory infection, otitis media, or an infected wound is reported.[45] Boys are more susceptible than girls with an approximate ratio of 2:1.[158] When the infection spreads to the adjacent joint, septic arthritis may result, which is a more likely complication in neonates.[156] This is related to the vascular anatomy of the epiphyses in neonates; before the secondary ossification center forms, the cartilaginous epiphyses receive their blood supply directly from metaphyseal blood vessels.[156] In joints such as the hip, where the metaphysis is intracapsular, the spread of infection to the joint occurs.[156] In neonatal osteomyelitis, infection leads to damage to the epiphysis or septic arthritis in 76% of the cases.[156] CRMO will generally resolve postpubertally,[141] although long-term studies have shown that up to 25 percent have persistent disease, with complications including risk of permanent bone deformities, poorer quality of life, and difficulty in achieving vocational goals.[89,93,137,167]

The most common etiology of hematogenous osteomyelitis in children is *Staphylococcus aureus*[79,156,158] although occasionally fungi, viruses, or parasites may be involved, especially in the immunocompromised.[10,69] Since the introduction of the *Haemophilus influenzae* type b (Hib) vaccine in 1992, the incidence of *Haemophilus influenzae* infection in infants and older children is much less.[91] Of noted concern at this time is the virulent strains of methicillin-resistant *Staphylococcus aureus* (MRSA).[79] The prevalence of osteomyelitis caused by MRSA increased from 0.3 to 1.4 per 1000 hospital admissions from 2002 to 2007 in a survey of 20 metropolitan hospitals in the United States.[64] When MRSA is the etiology of osteomyelitis in children, more severe bone infection has been documented with more aggressive surgical and medical management required.[79] Another cause is *Kingella kingae*.[76] This organism has been found in several geographical regions and is difficult to culture, requiring specific testing techniques.[76,158] Some differences between the clinical findings in the presence of *Staphylococcus aureus* and *Kingella kingae* can be found in Table 14.5.[158]

Clinically, the onset of osteomyelitis is generally sudden, and the rapid progression can cause permanent damage and later consequences in the child.[45] The most common sites of osteomyelitis are the rapidly growing ends of long bones; the condition is more common in the lower extremity.[45] Therefore the metaphyses of the distal femur and of the proximal tibia are the most common sites of infection.[45,156]

TABLE 14.5 Characteristics of *Staphylococcus Aureus* Versus *Kingella Kingae*

	Staphylococcus Aureus	*Kingella Kingae*
Age	Any age group	Often < 4 years
Fever	> 38°C	Afebrile on admission
C-reactive protein (CRP)	Elevated	May be normal
White blood cell count (WBC)	Elevated	May be normal

From Pääkkönen M, Peltola H: Bone and joint infections. Pediatr Clin N Am 2013;60:425-436.

The signs and symptoms of acute hematogenous osteomyelitis are variable, according to factors such as age of the patient, site of infection, resistance of the child, and virulence of the affecting organism.[45] Generally, however, onset is sudden, with localized bone tenderness, swelling, and pain over the metaphysis of the involved bone.[45] A high fever and chills are often present, and the patient is often unwilling to use the affected limb.[45] Frequently, the child will refuse to walk when the lower extremity is affected.[45] Neonates often do not demonstrate signs of systemic illness, and signs of pseudoparalysis and pain with passive motion are difficult to detect.[45]

Initial routine blood tests, such as ESR, C-reactive protein (CRP), and white blood count (WBC), are used to determine the extent of the inflammation and also help monitor the response to antibiotic therapy.[158] All of these levels are elevated in the presence of osteomyelitis. With intervention, ESR and CRP will normalize, although the CRP value normalizes in 7 to 10 days while the ESR takes 3 to 4 weeks.[45,158] The signs and symptoms, routine blood tests, and vaccination history against Hib or pneumococcus will help in the speculation of the causative organism, but the gold standard for identification is a bacterial culture.[76,158] These should include bone samples and blood cultures.[76,158] For accuracy the blood cultures should be obtained before antibiotic therapy is initiated.[45]

Imaging can provide further information in cases of osteomyelitis. Plain radiographs are important for the purpose of excluding other diagnoses such as fracture.[76] Deep soft tissue swelling can be seen within the first few days of onset.[76,156] Osteopenia or osteolytic lesions from destruction of bone or periosteal new bone formation will not be visible until 2 to 3 weeks after onset.[76,156] Therefore other imaging techniques may be helpful. Ultrasound allows the detection of subperiosteal collections and joint effusions as early as 48 hours although it does not determine the presence or absence of infection.[156] Skeletal scintigraphy allows for a whole-body survey, which is especially helpful in those with poorly localized symptoms or if multiple foci of infection are suspected.[76,156] It does, however, require exposure to ionizing radiation and the sensitivity is lower in neonates.[76] Differentiation of the cause of the osteomyelitis as well as limited ability to diagnose community-acquired *Staphylococcus aureus* osteomyelitis are issues with scintigraphy.[76] Magnetic resonance imaging (MRI) is helpful in identifying intra osseous, subperiosteal and soft-tissue abscesses but does not differentiate these conditions from similar ones found with fracture and infarct.[76] CT is helpful in detecting sequestra (indicative of chronic osteomyelitis) and intraosseous gas and can define subperiosteal abscesses, all of which should be considered in intervention.[76,156] Also, CT may help guide aspiration and biopsy.[156]

The identification of the source of the infection is important for successful intervention. Generally, antibiotic therapy will range from 4 to 6 weeks in duration[76,156] but will be individualized according to the severity of the infection, the time elapsed between onset of the disease and initiation of intervention, the extent of bone involvement, and laboratory responses after the initial intervention.[152] Surgical intervention may be needed in cases where an abscess or a sequestra has developed, but guidelines are subjective because some of these have resolved with antibiotic course.[158] The decision to intervene will be based on the clinical presentation and response to antibiotic therapy. Persistent fevers and persistent elevation of the CRP in a patient with a periosteal abscess would be indications for surgical drainage.[158] This is more often needed when the onset of symptoms is more than a week prior to intervention.[158] Other surgical procedures may be needed if damage to the involved bone occurs (pathologic fracture, premature/asymmetrical closure of growth plate, angular deformities of bone).[76]

Septic Arthritis

Septic arthritis (pyogenic arthritis) is defined as an infection of a joint caused by bacterial organisms. This is an extremely threatening condition because a joint may be destroyed within 48 hours of onset of symptoms. Septic arthritis causes destruction of articular cartilage and long-term growth arrest. The resulting deformities may be permanent and may have a wide-ranging, lifelong impact, affecting the person's gait, participation in sports, and choice of occupation and leisure activities.

As described previously in the osteomyelitis section, septic arthritis results from osteomyelitis in 76% of the cases in neonatates.[156] Septic arthritis generally causes a rapid inflammatory response.[45] The synovial membrane responds with a hyperemia followed by excessive production of fluid and pus.[45] Pus contains enzymes that rapidly destroy articular cartilage, causing irreversible joint damage.[45] Permanent joint destruction can result in as little as 3 days.[45] Any joint may be affected, but about 80% of cases are located in the lower extremity with the hip (in the young child) and the knee (in the older child) being the most common locations.[65,109,138] Because of the lax nature of the surrounding musculature in neonates, the presence of joint effusion may lead to subluxation or dislocation of the affected joint.[156] In a newborn the cartilaginous femoral head can be completely destroyed, requiring salvage procedures later in life. Damage to the epiphysis may cause trochanteric overgrowth and leg length discrepancy when the growth plate is damaged.[45] Also, the intra-articular pressure may be increased by the accumulation of inflammatory exudate causing vascular compression that occludes the blood supply to the femoral head, causing avascular necrosis.[156]

The diagnosis of septic arthritis is based on clinical findings. Septic arthritis is most common in children ages 2 years and younger.[156] Clinical presentation for septic arthritis may have many of the same characteristics as osteomyelitis: high fever and chills, unwillingness to use the affected limb, and absence of spontaneous movement, as well as refusal to bear weight on the affected limb.[45,158] The affected joint will demonstrate swelling, redness, warmth, and local tenderness.[45] Generally, those with septic arthritis are more ill than those with osteomyelitis.[158] Table 14.6 describes the different characteristics of osteomyelitis and septic arthritis.[158]

Laboratory tests of ESR, CRP, and WBC are commonly used tools to diagnose septic arthritis.[144] Others have suggested that

TABLE 14.6 Characteristics of Osteomyelitis Versus Septic Arthritis

	Osteomyelitis	Septic Arthritis
Fever > 38.5°C	Suggestive if present	Suggestive
Malaise	Usually	Usually
Swollen joint/limited motion	Not unless concurrent arthritis	Nearly always
Edema overlying bone	Often	Absent
Back pain	Suggestive of spinal osteomyelitis	Rare
Difficulty weight bearing	Lower limb affected	Lower limb affected

From Pääkkönen M, Peltola H: Bone and joint infections. Pediatr Clin N Am 201360:425-436.

measuring the presence of procalcitonin (PCT) is helpful in differentiating noninfectious inflammation and bacterial infections.[144] Chloe et al.[31] found the specificity and sensitivity of diagnosis of septic arthritis were greater with PCT and PCT was also 100% accurate in differentiation between gram-negative and gram-positive infections, helping guide antibiotic therapy more quickly. This tool may be more useful, especially in cases involving *Kingella kingae*.[144]

Radiographs are of lesser importance in septic arthritis because they will show an enlarged joint space at most.[158] Ultrasonography is helpful to identify small joint effusions and can guide joint aspiration.[45] A bone scan may also help diagnostically to determine diffuse uptake within the joint in the early phase or a rise in intra-articular pressure.[45] The MRI is considered the most accurate diagnostic tool and provides the best anatomic detail.[144,158]

Joint aspiration is imperative for the diagnosis and should not be delayed if septic arthritis is suspected.[158] The aspirated fluid should be cultured, and drainage and appropriate intravenous antibiotics should be started quickly.[45,133] Intravenous antibiotic therapy is recommended until improvement in clinical signs is seen; at that time, oral antibiotics may be used.[133]

Transient Synovitis

Transient synovitis of the joint is a common cause of lower extremity pain, specifically the hip, in children between the ages of 3 and 8 years. It presents itself as a rapid onset of hip pain, limited joint ROM, and limping (or an inability to walk, if the condition is severe).[85] The child may have a history of an antecedent viral illness,[85] and the resulting effusion of the joint leads to a position of hip flexion and external rotation.[11] Reports have also shown referred pain in the knee with transient synovitis.[120] Males are also more likely to develop transient synovitis.[11]

In 1999, Kocher et al.[117] established a clinical algorithm to differentiate cases of septic arthritis from those of transient synovitis in 99.6% of cases. These variables were confirmed as highly predictive in a separate study published in 2004.[116] This clinical algorithm found that when four specific variables were all present, the diagnosis of septic arthritis could be confirmed at a very high rate. When only some of the variables were present, there was less certainty in diagnosing septic arthritis versus transient synovitis. These four variables are: history of fever of $\geq 38.5°C$, inability to bear weight, ESR ≥ 40 mm/hr, and serum WBC of $> 12{,}000$ cells/liter.[117] A fifth predictor, CRP ≥ 20 mg/L was later also used.[210] Sultan and Hughes[210] have since found a lower rate (59.9%) of success using this algorithm, although fever was still the best predictor. Radiographs are normally unremarkable, and ultrasound examination of the affected hip may show effusion.[85] The concern is that septic arthritis and transient synovitis could present very similarly, and caution and care should be used in diagnosing the problem. Some children will have recurrent problems, and a small percentage will develop Legg-Calvé-Perthes disease.[123,219]

Intervention is generally symptomatic, consisting of limitation of activity, bed rest, and avoidance of weight bearing in combination with the use of nonsteroidal anti-inflammatory medications. Light traction during bed rest may be of benefit, and routine aspiration of the joint has also been beneficial.[85] Clinical symptoms will usually resolve within 10 days.[85]

Occult Fractures

By definition an occult fracture is a fracture that cannot be detected by standard radiographic examination until weeks after the onset.[146] In children, several variables may limit the finding of the problem: minor trauma that may not be merited consideration by the parents, poor localization of pain by young children, difficulty with communication with child, unexplained trauma history, and physician oversight.[32] Common areas of involvement are elbow, knee, ischium, distal fibula, proximal femur, and humeral shaft.[32] Upon presentation, pain and swelling may be present; generally, radiographs are negative for 2 to 3 weeks. Ultrasound has been found to be advantageous in the early diagnosis of both soft tissue and bone injuries.[32,151] Especially in the skeletally immature, ultrasound can identify discontinuity in the cortex but cannot visualize intraosseous deformities.[32] Also, the ultrasound can be done without sedation and with some movement by the child, making it clinically less difficult than an MRI, the gold standard.[32] Diagnosing the fracture early will allow for better intervention and prevention of complications such as slower healing times, growth arrest, fracture deformity, and pain.[32]

Kohler Disease

Kohler disease is an osteochondrosis of the navicular bone of the foot. Generally, patients present between 2 and 8 years of age, and boys are 3 to 5 times more likely to be affected.[215,216] It was first described by Alban Kohler, a German radiologist.[228] The condition occurs when the navicular bone temporarily loses its blood supply. The child usually has localized pain in the area of the navicular bone and a limp. There is usually no history of previous trauma. Point tenderness may be present over the navicular bone on examination.[216] There may also be mild swelling and warmth over the dorsal midfoot.[19] Radiographic changes may be visible and include navicular sclerosis, flattening, and fragmentation.[19] These cases have all shown good resolution, with no clinical or radiologic abnormalities seen in adulthood.[190] A short leg cast for up to 8 weeks may accelerate the resolution of symptoms, although long-term outcomes are good regardless of intervention.[216]

Legg-Calvé-Perthes Disease (LCPD)

Legg-Calvé-Perthes disease (LCPD) is a condition that occurs in children, who may receive referrals for physical therapy for resulting muscle weakness, ROM limitations, and gait deviations. By definition, LCPD is a condition in which an avascular event affects the capital epiphysis (head) of the immature femur. After this event, growth of the ossific nucleus stops and the bone becomes dense. This dense bone is then resorbed and replaced by new bone. As this occurs the mechanical properties of the femoral head change such that the head tends to flatten and enlarge. Once new bone is in place, the head slowly remodels until skeletal maturity is achieved.[82]

The onset of LCPD is between 18 months and skeletal maturity with cases most often between 4 and 8 years of age.[12,225] Boys are 4 to 5 times more likely to develop the disease than girls.[12,82,225] It is found bilaterally in 10 to 12 percent of patients.[82,225] About 35% of children with unilateral Perthes disease also demonstrate changes in the unaffected proximal femur on radiographs, including small epiphysis, flattening of the epiphysis, contour irregularities, and changes in the growth plate.[108] Recurrent cases of LCPD have been noted and generally will have a poor prognosis because the entire femoral head is generally involved and recurrence occurs when the child is older.[226]

The etiology of LCPD is multifactorial.[82,225] Vascular factors include both arterial supply and venous drainage.[82,225]

The medial femoral circumflex artery is the principal vessel in the complex vascular distribution in the neck and head of the femur. Also, the vessel advances between the trochanter and the capsule, which is a narrow passage and is particularly constricted in children less than 8 years of age.[82] A synovial intracapsular ring comprised of four ascending cervical arterial groups has also been found to be incomplete in the younger group as well.[82] When the arterial flow is obstructed or compromised, as has been noted in patients with LCPD, avascular necrosis will obviously occur at the femoral head. An abnormal venous drainage through the medial circumflex vein of the head and neck of the femur has also been noted with LCPD.[82] Findings of an increased venous pressure in the affected femoral neck and associated venous congestion in the metaphysis as well as more distal exit of venous outflow through the diaphyseal veins have also been noted in cases of LCPD.[82] The presence of this obstruction in the venous flow in this population would suggest it is at least a contributing factor in LCPD.[82] Coagulation factors also contribute to blood flow in this population.[82,225] Children with changes in clotting properties commonly show avascular changes at the femur including hemoglobinopathies (i.e., sickle cell disease, thalassemia), leukemia, lymphoma, idiopathic thrombocytopenic purpura, and hemophilia.[82] Also, increased blood viscosity has been noted in patients with LCPD.[82] Abnormal thrombus formation has been documented in LCPD, specifically with deficiencies in proteins C and S and in the presence of hypofibrinolysis, which then results in venous hypertension and hypoxic bone death.[82]

Children with LCPD also seem to present with similar growth and development abnormalities.[82,225] Most commonly a delay in bone age relative to the child's chronologic age is seen.[82,225] Those who are diagnosed with the disease before age 5 years tend to normalize during adolescence while those diagnosed at an older age tend to have a smaller stature throughout life.[225] Also, the birth weight of children with LCPD is lower than unaffected children.[82] Growth hormone, specifically somatomedin C insulin-like growth factor-1 (which is responsible for postnatal skeletal bone maturation), has also been noted to be lower in those with LCPD.[82,225] These levels generally increase as children age, but this increase is not seen in the group with LCPD.[82]

Other common influences have also been noted. Trauma may be a factor in the child who may already have some predisposition to LCPD (17%).[82,225] Many of the children have been noted as hyperactive or having attention deficit hyperactivity disorder.[82,225] Environmental commonalities of urban living and lower socioeconomic groups have been found with possible link to nutrition status and secondhand smoke, which are known to affect stature and growth.[82,225] A higher frequency of occurrence is found among the Japanese, other Asians, Eskimos, and Central Europeans, and a lower frequency in native Australians, Americans, Indians, Polynesians, and persons of African origin.[225] Genetic factors have been speculated but not conclusive of effect of heredity versus environment.[82] Perinatal HIV infection is also a risk factor for osteonecrosis.[59]

Further examination of affected femurs has shown the epiphyseal cartilage to contain high proteoglycan content, a decrease in structural glycoproteins, and different size collagen fibrils compared with normal tissue, suggesting that the disease could be a localized expression of a generalized transient disorder responsible for delayed skeletal maturation.[226] These abnormalities can be primary or secondary to the ischemia, but collapse and necrosis of the femoral head could result from the breakdown and disorganization of the matrix of the epiphyseal cartilage, followed by abnormal ossification.[226] The exact cause is unknown, but it occasionally follows repeated episodes of transient synovitis of the hip. Increased joint pressure secondary to synovitis may be one of the pathologic processes that causes an interruption of blood flow in vessels ascending the femoral neck.

Patients most commonly present with an insidious onset of limp, demonstrating an abductor limp. Pain will be described as activity related and relieved by rest. Commonly, pain is localized to the groin, anterior hip region, or laterally around the greater trochanter and may be referred to the anteromedial thigh or knee. Knee involvement when pain is present should be ruled out in a clinical examination because pain in the knee is a fairly common pattern with hip issues. Because of the mild nature of the symptoms, patients may not present for medical evaluation for weeks or months after the onset. ROM is limited in the directions of abduction and internal rotation. Early in the course of the symptoms the limited motion is related to synovitis and spasms in the adductor group, but the limitation may progress with tightening of the soft tissue structures.[225] Limb shortening will be present in cases of significant collapse of the femoral head[225] and with premature closure of the proximal growth plate of the femur.[162]

In order to best predict the prognosis and make decisions on necessary interventions, classification of the hip is of great value.[139] Currently, the Herring lateral pillar classification is commonly used and demonstrates strong predictive value.[86] Using this system, patients are placed in categories of group A, B, or C based on the involvement of the lateral pillar (the lateral 5 to 30 percent of the femoral head on an AP radiograph).[29] Group A hips do not involve the lateral pillar, group B hips have limited involvement with maintenance of over 50% of the lateral pillar, and group C hips have over 50% collapse of pillar height.[29] Group B/C has also been added, defining the lateral pillar as narrowed or poorly ossified with approximately 50% of height maintained. The Stulberg classification system is used to describe the hip at skeletal maturity.[29,139] This system is based on the deformity of the femoral head and congruity in relation with the acetabulum.[29,139] Class I is defined by a normal spherical head, class II by a spherical head with coxa magna/breva or steep acetabulum, class III by nonspherical head, class IV by a flat head and flat acetabulum, and class V by aspherical incongruence.[139]

Also, four stages of LCPD can be described radiographically.[82] These can be described as follows:

Initial stage: Early signs include lateralization of the femoral head with widening of the medial joint space and a smaller ossific nucleus. Later signs include subchondral fractures and physeal irregularity. This phase normally lasts a mean of 6 months.

Fragmentation stage: Radiolucencies develop in the ossific nucleus; a central dense fragment becomes demarcated from the medial and lateral segments of the femoral head. End of the stage shows appearance of new bone in the subchondral sections of the femoral head. This phase lasts a mean of 8 months.

Reossification (healing) stage: New subchondral bone is seen in the femoral head. Reossification starts medially and expands laterally. This phase lasts until the entire head has reossified and lasts a mean of 51 months.

Residual stage: Femoral head is fully reossified with gradual remodeling of the head shape until skeletal maturity. This shape may vary from completely normal to extremely flat and aspherical. Overgrowth of the greater trochanter may be seen because the disease has disrupted growth of the capital physis.

Intervention of LCPD depends on the age and stage of presentation. The primary goals are to prevent deformity and stop growth disturbance and consequently prevent degenerative joint disease.[225] Some speculation is used in the formulation of intervention algorithms because the natural history of the condition is not well known.[29,225] Generally, 60% of patient with LCPD do not need intervention.[225] Those with early onset have a better prognosis.[29] A study by Herring et al.[182] identified three prognostic conclusions in a study of 438 patients:

1. Children with symptom onset prior to 8 years of age have good results regardless of intervention.
2. In children with onset after 8 years of age with at least 50% lateral pillar height maintenance (Herring groups B and B/C), operatively managed hips had better outcomes than nonoperatively managed hips.
3. Children with hips in Herring group C with greater than 50% collapse of lateral pillar height had poor outcomes regardless of intervention.

Prior to age 4 years, observation is generally recommended.[29] Most children will present at 4 years or older.[29] In these cases the first goal is to reduce the synovitis and symptoms.[82,29] One primary focus during this time is to restore motion.[225] Interventions to assist in this stage include limitation of activity, nonsteroidal anti-inflammatory drugs, light skeletal traction, and physical therapy for ROM.[29,82,225] Most see resolution of symptoms in 7 to 10 days.[225] This may be the only intervention needed in those patients with group A disease or those with group B disease who are under 8 years (Herring lateral pillar classification).[82,225] For those in the fragmentation and reossification stages, impaired hip motion is often due to deformity of the femoral head, and further intervention may be needed.[82]

Containment is an important principle of intervention for LCPD.[225] This describes preventing deformities of the diseased epiphysis by containing the anterolateral part of the avascular capital femoral epiphysis within the depths of the acetabulum, thereby equalizing the pressure on the head and allowing the molding action of the acetabulum to occur.[225] If supported in the acetabulum, weightbearing forces and muscular stresses across the femoral rim will not deform the femoral head.[106] It reduces the forces through the hip joint by actual or relative varus positioning.[225] Full abduction to 45° is recommended for containment, although at least 30° may show favorable results in those with limitations.[25] Containment can be achieved through nonoperative or operative methods.[82,225]

One method of nonoperative containment is bracing. Currently, this is being chosen less by orthopedic surgeons.[82,139,225] The literature has not supported its efficacy.[139] In cases where it is still used, the Atlanta Scottish Rite brace (Fig. 14.28) is generally used. It consists of a metal pelvic band, hip hinges, thigh cuffs, and an extensible bar between the thigh duffs permitting abduction of the limb but restricting adduction.[82] For mild cases the protocol is to wear the brace during the day and remove it at night, and in more advanced cases the brace may be worn 24 hours a day until there is evidence of new bone formation.[82,225] Casting the lower extremities and using bars between the legs so that the hips are abducted to 45° and rotated internally 5° to 10° is another option.[82] The casts would need to be changed every 3 to 4 months until the femoral head was in the healing stage, possibly 19 months. This may be most useful in older patients whose ROM is too restricted and painful to allow proper positioning of the femoral head in a brace.[82]

Surgical containment is advocated by many studies due to positive results as well as the advantage of early mobilization and the avoidance of prolonged bracing or casting.[225] This seems to be the preferred intervention in those who have a group B or B/C lateral pillar classification and those who are over 8 years of age.[114,139] The timing of the surgery should also be considered. Some recommend that surgery be performed within 8 months of the onset of symptoms.[129] Others have reported that premature physeal closure may occur if the femoral osteotomy is performed too early or too late in the

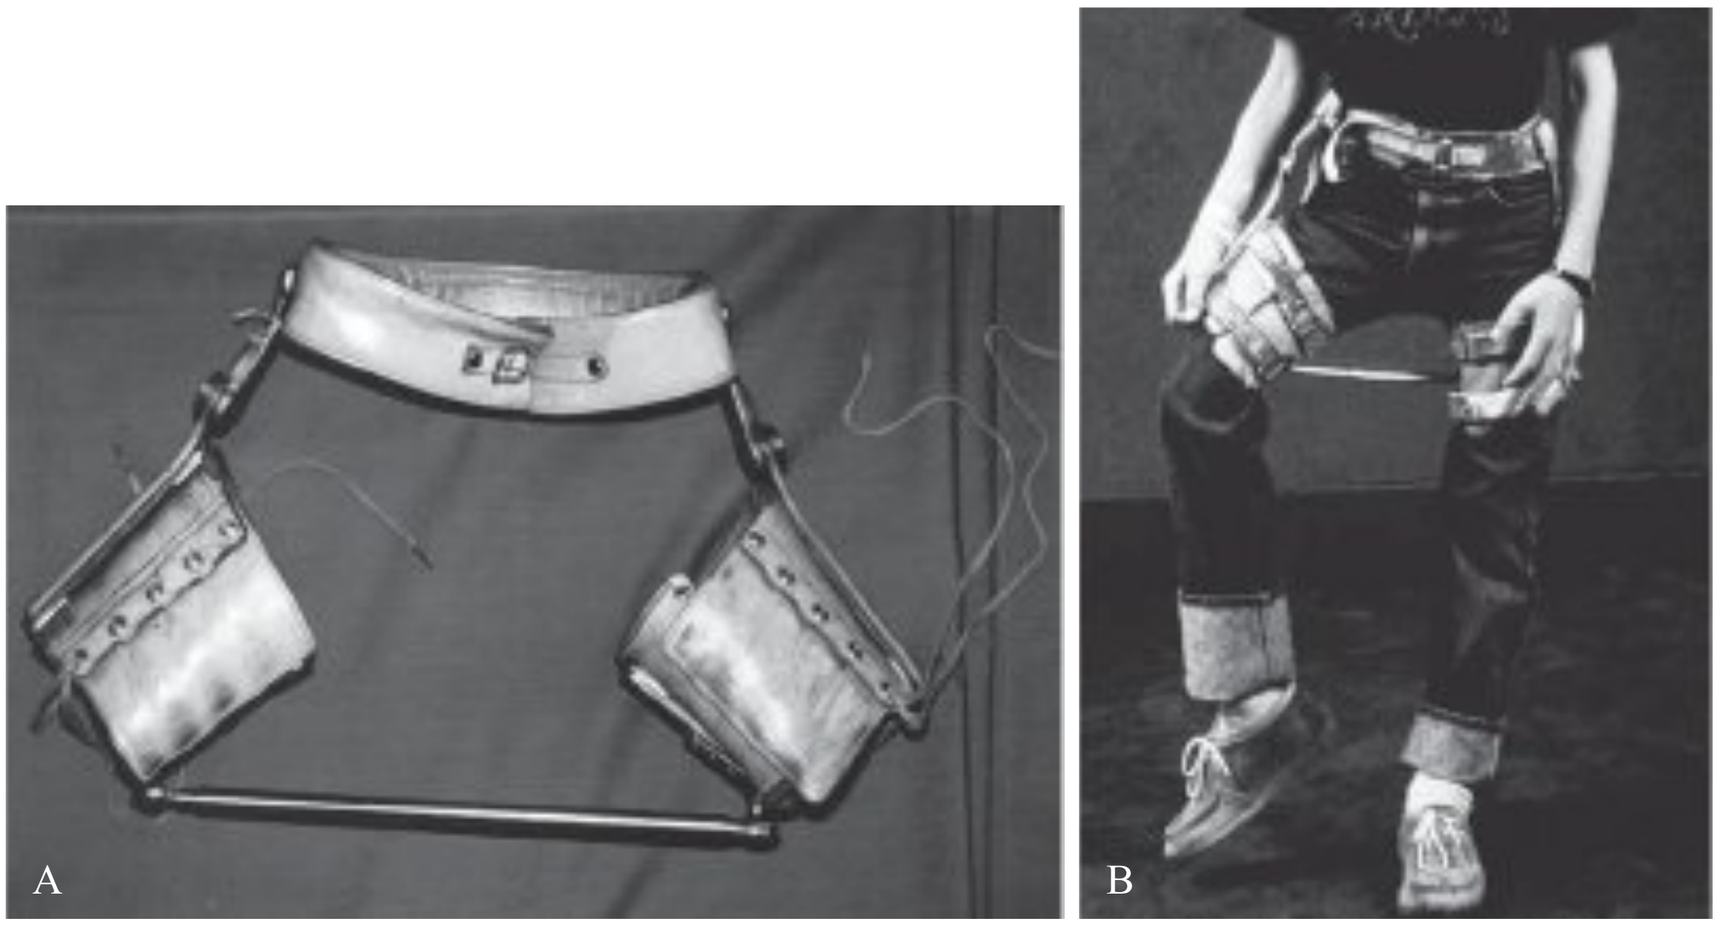

FIG. 14.28 (A–B) Atlanta Scottish Rite orthosis used for treatment of LCPD. (From Hsu JD, Michael J, Fisk J: AAOS atlas of orthoses and assistive devices. 4th ed. Philadelphia, Mosby, 2008.)

process.[13] Femoral osteotomies have the best results when performed in the initial or fragmentation stage of the disease.[82,225] In cases of hinge abduction, the femoral head cannot be contained conservatively, and serious damage may occur if this is attempted.[225] Hinge abduction occurs when the deformed femoral head impinges on the lateral margin of the acetabulum during abduction of the hip. Performance of femoral osteotomy can reduce the impingement.[139] During this procedure, trochanteric epiphysiodesis is also recommended to prevent overgrowth and resulting abductor weakness.[29,82]

Performance of an innominate osteotomy has a smaller result of limb shortening compared to femoral osteotomy.[82] This procedure assists with recontainment by redirecting the acetabulum, providing better coverage for the anterolateral portion of the femoral head.[225] For best results the femoral head should be minimally deformed, no significant restriction of ROM should be present at the hip, and it should be early in the course of the disease.[82,225] A procedure combining femoral and innominate osteotomy is an option in severely affected hips.[82,225] The dual approach may provide better containment than either procedure alone.[82] Another option is shelf arthroplasty. This option is being proposed as a primary method of management in children over 8 years of age in groups B or C with a reducible subluxation.[225] The advantage of this procedure may be better coverage of the anterolateral portion of the head allowing better remodeling, prevention of subluxation, and prevention of lateral overgrowth of the epiphysis.[225]

Generally, the time frame from initiation to complete healing is a median of 2.8 years.[106] Many progress through the stages of this disease without complications in later life, although deformation of the epiphysis can occur during the process of revascularization, resulting in degenerative arthritis in later years.[106] The physical therapist should be in communication with the orthopedist during the course of this child's treatment to determine if any precautions should be taken. Intervention will generally focus on mobility, strength, and gait.

Discoid Lateral Meniscus

Menisci are C-shaped fibrocartilaginous structures between the tibial plateau and the femoral condyles that are important for shock absorption, load sharing, reduction of contact stresses, and stability within the knee joint.[192] The lateral meniscus generally covers a larger portion of the tibial plateau than the medial side.[35] A discoid lateral meniscus is an abnormal variant in which the central area is completely filled rather than the normal C shape.[78] Also, the outer rim of the discoid meniscus is much thicker than the normal meniscal rim.[78] This condition is present in 1% to 3% of the pediatric population and is bilateral in 10% to 20%.[78] A discoid medial meniscus is much less common, with an occurrence of 0.12%.[61] The cause of a discoid meniscus is thought to be multifactorial.[78] It may simply be a congenital anomaly or malformation, but a genetic factor does seem present as well as a higher incidence in the Asian population.[61,78]

Generally, children with a discoid meniscus will present between the ages of 5 and 10 years with a snapping knee joint that is both heard and felt by the child or parent.[78] This may coexist with any combination of pain, giving way, effusion, quadriceps atrophy, limitation of motion, clicking, or locking.[78] More acute symptoms such as significant pain, knee locking, and inability to put weight on the affected extremity are most likely due to a tear in the discoid meniscus.[78] Plain radiographs may show small widening of the lateral joint space but may be normal.[78] MRI would be needed for confirmation.[78]

An asymptomatic knee with an incidental detected discoid meniscus does not require intervention.[78] Arthroscopic surgery is usually recommended in cases of mechanical symptoms with emphasis on meniscal preservation and salvage to prevent degenerative changes in the future.[78]

Sever Disease

Sever disease, or calcaneal apophysitis, is an overuse syndrome caused by repetitive microtrauma at the insertion of the Achilles tendon at the calcaneal apophysis.[103,215] Inflammation results from traction between the Achilles tendon and the plantar fascia and aponeurosis and can also involve the bursa.[104,215] In rare cases, calcaneal apophysitis without intervention can cause calcaneal apophyseal avulsion fractures at the point of attachment.[104] This painful condition generally presents in children ages 8 to 15 years but can be present as young as 6 years.[104] This timing coincides with the presence of the calcaneal growth apophysis, which appears at about 7 years of age and fuses in girls at approximately 13 years and in boys at 15 years.[103]

Symptoms are generally pain in the heel, especially with activity and greater with running and jumping with more strain at the Achilles applied. Local tenderness is present at the heel and pain may be reproduced with resistance of plantar flexion. Factors that may predispose the development of this disorder include: growth and gastrocnemius/soleus tightness with more tension at the Achilles; cavus or planus foot type causing more strain due to harder heel strike, infection, trauma, and obesity.[103]

The condition is usually self-limiting. Conservative intervention is recommended and includes rest, ice, heel cups, heel lifts, reduced activity, and Achilles tendon stretching exercises. In cases of severe pain a short leg walking cast may be helpful.

TABLE 14.7 Diagnostic Criteria for Growing Pains[197,198]

Characteristics of Pain	Inclusion Criteria	Exclusion Criteria
Nature of pain	Intermittent Some pain-free days and nights; generally occurs once or twice per week with duration of 30–120 min Totally pain free between the episodes	Persistent Increases in severity with time
Unilateral or bilateral	Bilateral	Unilateral
Location of pain	Anterior thigh, calf, popliteal fossa, shins	Pain in joints
Time of day	Evening and nights	Night pain that remains in morning
Physical examination	Normal	Signs of inflammation: swelling, tenderness, local trauma or infection, reduced joint ROM, limping
Diagnostic tests	Normal	Objective findings on x-ray, bone scan, or laboratory testing
Limitation of activity	None	Reduced physical activity

ROM, range of motion.

Growing Pains

By definition, growing pains are a clinical presentation of pain in the legs.[55,143] The diagnosis is made by several inclusion and exclusion criteria (Table 14.7). No specific testing is recommended but used to rule out more serious conditions. The prevalence rate of growing pains has varied with many variables in the reporting standards. Kaspiris and Zafiropoulou[111] found a prevalence of 24.5% among 532 children of age 4 to 12 years. Evans and Scutter[56] found a rate of 36.9% in children aged 4 to 6 years. No specific etiologies of growing pains have been identified but theoretical factors include: anatomic factors (e.g., posture, flat feet, genu valgus, scoliosis, decreased bone strength, altered vascular perfusion, joint hypermobility), fatigue or local overuse syndrome, psychological factors, and lower pain threshold.[55,143] Reassurance of the benign nature of the condition, symptomatic intervention using massage, nonsteroidal anti-inflammatory medications, muscle stretching, and time usually resolve the symptoms.[55,143] Another intervention theory is the use of vitamin supplementation in areas of deficiency.[143]

Slipped Capital Femoral Epiphysis (SCFE)

Slipped capital femoral epiphysis (SCFE) is the displacement of the femoral head relative to the femoral neck and shaft. The term *slipped capital femoral epiphysis* is technically incorrect because the femoral epiphysis maintains its normal relationship within the acetabulum but the femoral neck and shaft move relative to the femoral epiphysis and acetabulum.[84,112] The femoral proximal femoral neck and shaft generally displace anteriorly and superiorly (externally rotate) in relation to the femoral head.[84,112]

The incidence rate of SCFE is 2 per 100,000 globally[54] and 10.80 per 100,000 in the United States.[125] Also, in the United States there is a 3.94 times higher rate in black children and 2.53 higher rate in Hispanic children when compared to white children.[125] The presence in boys (13.35 per 100,000) is higher than girls (8.07 per 100,000).[125] Another factor found in the demographic data was climate.[23,125] An increased incidence is noted north of 40° latitude during the summer and south of 40° latitude during the winter.[125] Possible reasons for this include seasonal changes in activity, seasonal patterns of growth and weight gain in adolescence, and vitamin D deficiency caused by decreased cutaneous synthesis during the winter.[23,125] The age on onset is peripubertal. The average age of onset in boys is 14 years and in girls is 12 years.[84] If an onset occurs before the age of 10 years or after the age of 14 years in girls and 16 years in boys, the clinician should suspect an underlying metabolic or systemic condition as a causative factor.[112,125] Also of note is that older children generally have more severe slips.[128] The trend has been for the onset to be at a younger age, which is postulated to correlate with earlier children maturation.[161] Eighty percent of cases are unilateral.[112,125] More than 80 percent of the children diagnosed with SCFE are reportedly obese (body mass index greater than the 95th percentile).[136] This factor is of great concern because of the increasing rates of childhood obesity that are present and may affect the increasing incidence of SCFE.[149] Obesity may increase the risk of SCFE as a result of both higher mechanical loads across the femoral physis and a metabolic disorder.[154] Obese children are noted to have decreased femoral anteversion[63] and a more vertical-oriented proximal femoral physis.[142]

SCFE may be classified by the onset of symptoms or the degree of displacement of the capital femoral epiphysis on the femoral neck.[84] Classification by onset of symptoms is divided into three subtypes[84]:

1. Acute: Occurs suddenly with trauma generally not considered significant enough to result in fracture (e.g., twist of fall). Patient experiences pain in groin, thigh, or knee. This is usually a severe, fracturelike pain. Usually the patient is unable to bear weight and will report quickly for medical care. The position of comfort is usually lying with the affected limb in external rotation. Moderate shortening of the limb is apparent upon examination. Symptoms must be present for less than 3 weeks to be considered acute.
2. Chronic: This is the most frequent form. Adolescent presents with a few months' history of vague groin pain, upper or lower thigh pain, and a limp. Pain may be intermittent or constant and is exacerbated by running or sport activity. The patient generally holds the affected limb in position of external rotation. Thigh atrophy may be apparent in unilateral cases. Local tenderness will be present anteriorly over the hip joint. Loss of hip motion, especially hip internal rotation, flexion, and abduction, may be present although hip extension, external rotation, and adduction may be increased. Shortening of the limb by 1 to 2 cm may be noted.
3. Acute-on-chronic: The patient has already experienced some aching in the hip, thigh, or knee for weeks or even months as a result of a slip. Then, a sudden exacerbation of pain occurs with a further displacement of the epiphysis.

The presence of these symptoms when presenting to a rehabilitation professional warrants significant concern. Some advise that any patient between the ages of 10 and 16 years who presents with a limp and pain in the groin, hip, thigh, or knee should be considered to have an SCFE until a differential diagnosis is made.[112] No weight bearing should be allowed until a medical examination and definitive diagnosis can take place.[112] When the child presents in this manner, the clinician should limit the PT examination in order to limit the possibility of further damage. As with LCPD, the presentation of knee pain may be the primary complaint due to referral from the hip.

A second classification categorizes SCFE by the degree of displacement of the capital femoral epiphysis on the femoral neck.[84] By the Southwick method, mild slips are defined as a head-shaft angle less than 30°, moderate slips are angles between 30 and 60°, and severe slips have an angle more than 60° from the contralateral normal side.[84] Fig. 14.29 demonstrates this measurement.

The etiology of SCFE is multifactorial. Three mechanical factors are thought to predispose a child to SCFE.[84] The first of these is the thinning of the perichondral ring complex (structure surrounding the physis) that occurs with maturation. The strength of this structure may be affected by endocrinopathies (most commonly hypothyroidism), abnormalities requiring growth hormone administration, and chronic renal failure (with secondary hyperparathyroidism).[84,112] A second mechanical factor is relative or absolute femoral retroversion.[84,112] With this position an increased shear force is present across the proximal femoral physis.[84,112] A third factor is a decreased femoral neck-shaft angle with a more vertical physis present. This position increases the shear force across the physis.[84,112] A deeper acetabulum seems to also be a risk factor.[112] When the capital femoral epiphysis is anchored more deeply in the acetabulum, forces across the physis may be increased, especially at the extremes of motion. Another factor may be genetics, but this has not been confirmed.[112] Obesity is a factor that must be considered also.[84,112] Some of the endocrine changes may increase the presence of obesity and add to the risk. Chung et al.[33] found

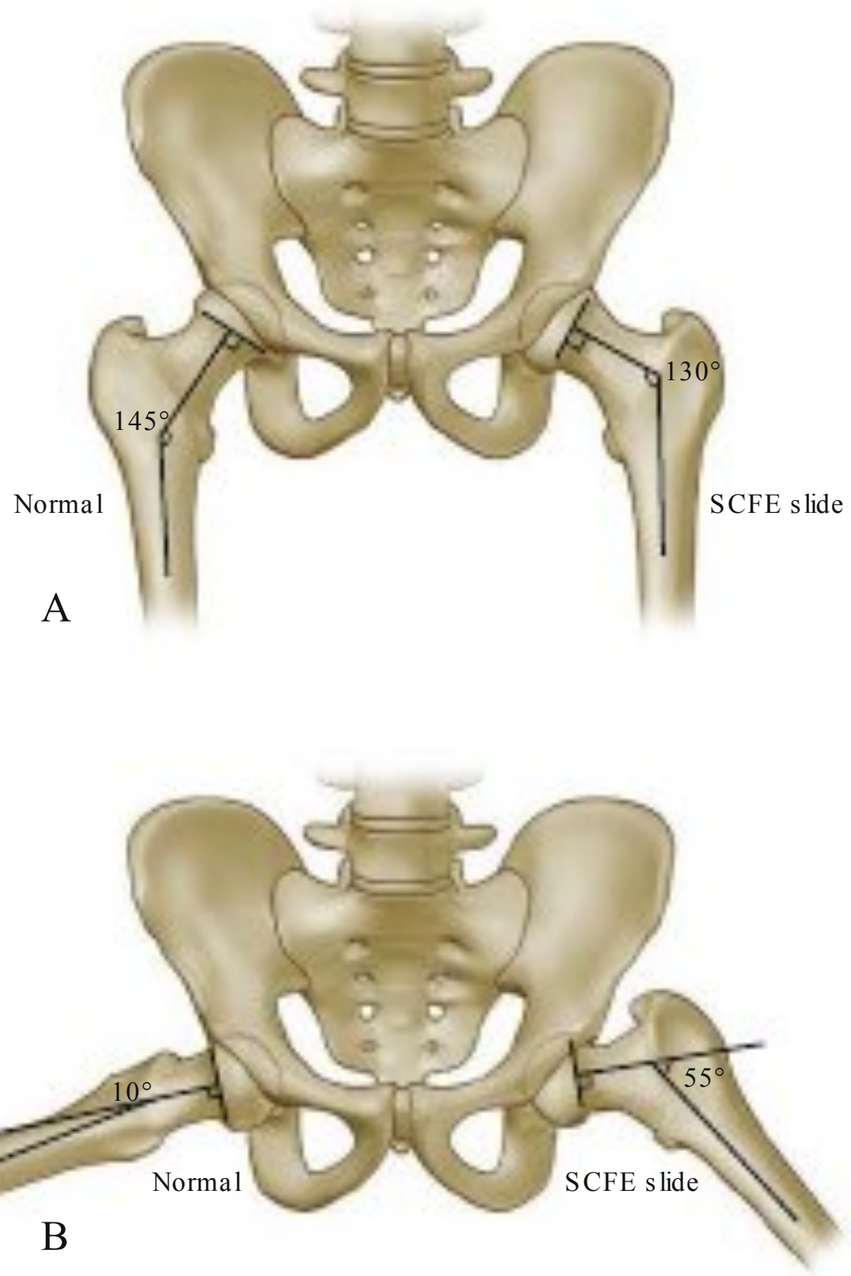

FIG. 14.29 Southwick method of measuring the head-shaft angle for determination of the severity of SCFE. (From Herring JA: Tachdjian's pediatric orthopaedics: from the Texas Scottish Rite Hospital for Children. 5th ed. Philadelphia, Saunders, 2014.)

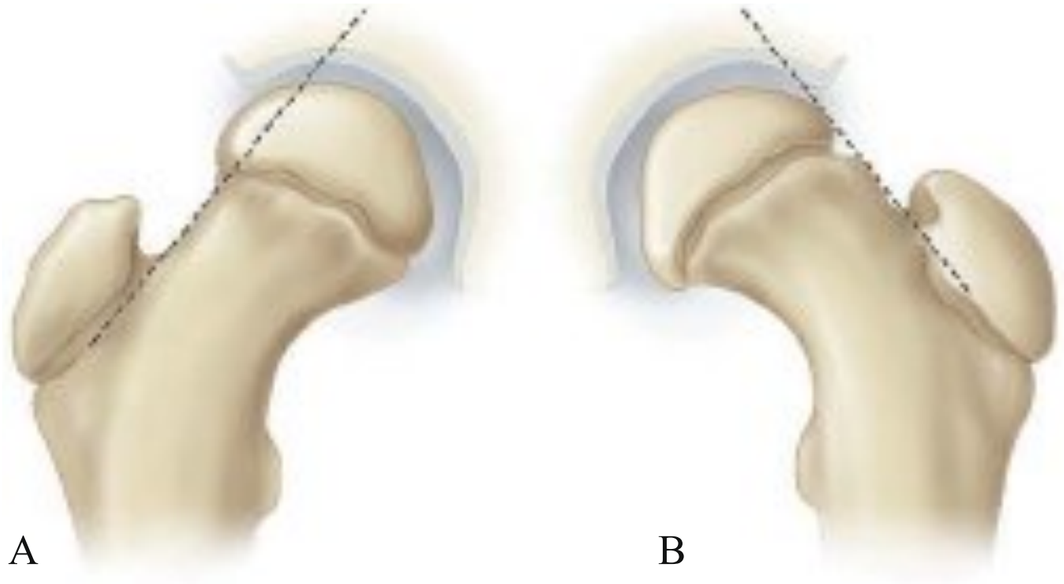

FIG. 14.30 Anteroposterior radiographic findings of a normal hip (A) and a hip with mild chronic slip (B). (From Herring JA: Tachdjian's pediatric orthopaedics: from the Texas Scottish Rite Hospital for Children. 5th ed. Philadelphia, Saunders, 2014.)

that mechanical forces across the femoral head during gait reach as high as 6.5 times body weight, and these forces may result in SCFE in a patient who is obese. Also, others report that the combination of proximal femoral varus and retroversion in a child who is overweight could result in forces leading to SCFE.[60]

In most cases, plain anteroposterior and lateral radiographs will confirm the diagnosis of SCFE.[84,112] On the anteroposterior view, widening and irregularity of the physis will be seen early, even before much displacement of the femoral neck and shaft (sometimes termed "preslip").[84,112] A decreased height of the capital femoral epiphysis when the epiphysis lies posterior to the femoral neck may also be visible.[112] In a normal hip a line drawn tangential to the superior femoral neck (Klein line) intersects a small portion of the lateral capital epiphysis.[84] When a slip occurs, this line will intersect a small portion of the epiphysis or not at all.[84] This can be viewed in Fig. 14.30. Lateral views may be more useful in detecting smaller slips.[112] The frog-leg lateral view may be difficult due to pain when positioning the child.[112] When the slip is acute, little or no remodeling of the femoral neck is present on radiographs and only the displacement will be visible.[84] CT of the upper femur may be helpful in identifying the anatomy and the decreased upper femoral neck anteversion or true retroversion.[84,112] CT may be helpful throughout the intervention process in determining if physeal closure has occurred and also postoperatively to determine whether penetration of the hip joint has occurred with the fixation devices.[84,112] Ultrasound is not commonly used for SCFE but may be an option in the absence of radiographic findings, although an MRI is often chosen.[112] An MRI does have a high specificity for finding avascular necrosis and also is helpful in identifying physeal widening, osseous edema adjacent in the physis, and anatomic deformities.[112] Bone scans also can identify avascular necrosis and chondrolysis.

The goals of intervention for SCFE are to keep the displacement to a minimum, maintain motion, and delay or prevent premature degenerative arthritis. When a child is suspected to have SCFE, immediate referral with radiology testing is recommended.[84,112] Once the diagnosis has been confirmed, absolutely no weight bearing is recommended because this can lead to osteonecrosis.[112] Spica casting is rarely used currently due to the difficulty with stabilization, the length of the intervention (over 100 days), and the complications.[112] Options for surgical management include in situ internal fixation or pinning, bone graft epiphysiodesis, and primary osteotomy through the apex or base of the femoral neck or intertrochanteric area (with or without fixation of the epiphysis to the femoral neck).[84,112] The goal of in situ pinning is to prevent slip progression.[84,112] This procedure may use one or multiple pins to provide stabilization. The screws should be placed as close to the center of the capital epiphysis as possible but remain extra-articular (Fig. 14.31). The screws do not have to routinely be removed and are generally left when asymptomatic. This is considered the intervention of choice in cases of stable SCFE regardless of the severity and also in unstable slips although the exact placement and number of pins may be altered.[84,112] Postoperative management allows those with stable slips to bear weight as tolerated and use crutches as needed. Limited weight bearing is recommended for 3 to 6 weeks in those with unstable slips. These patients can be monitored by radiographs to confirm physeal closure, and return to sporting activities is generally allowed between 3 and 6 months for stable slips and 4 and 6 months for unstable slips.[84,112]

Bone graft epiphysiodesis may be considered in more severe cases in which the insertion of the screw would require exiting the posterior femoral neck and reentering the capital epiphysis to stabilize.[84] Recovery for those with acute slips includes the possibility of traction or hip spica cast until early healing is present, possibly 3 to 6 weeks, with no weight bearing for 6 to 8 weeks.[84,112] In those who have stable slips, toe-touch weight bearing with crutches may begin 2 to 3 days postoperatively and

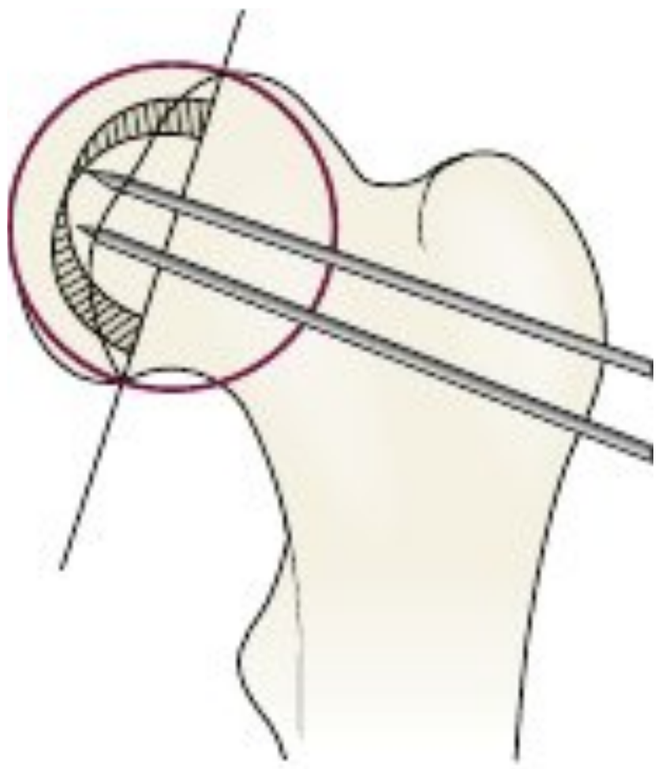

FIG. 14.31 Placement of screws in the treatment of SCFE should be near the center of the epiphysis but remain extraarticular. (From Herring JA: Tachdjian's pediatric orthopaedics: from the Texas Scottish Rite Hospital for Children. 5th ed. Philadelphia, Saunders, 2014.)

progressed with physeal healing (6 to 12 weeks).[84,112] An osteotomy may be chosen when a chronic or healed slip has resulted in a head-shaft deformity between 30° and 70° as this allows correction.[84] Following this procedure, patients are allowed protected toe-touch weight bearing until healed.[84]

Complications of SCFE are avascular necrosis and chondrolysis.[54,201] Avascular necrosis of the femoral head is more frequently associated with acute and unstable slips and is most likely due to vascular injury associated with the initial femoral head displacement, with more severe steps exhibiting greater involvement of the vascular supply.[201] Additional problems can occur with aggressive manipulation of the femoral head or penetration of the fixation device in the posterior cortex of the femoral head or articular surface.[201] Intervention should be directed at maintaining motion and preventing collapse by decreasing weight bearing until healing occurs.[201] Chondrolysis is an acute dissolution of articular cartilage in association with rapid progressive joint stiffness and pain.[201] Although this can occur in the uncorrected hip,[54,201] it has been most often found with manipulative reduction, prolonged immobilization, realignment osteotomies, and pin penetration of the femoral head.[201] The rate of these problems has decreased significantly in recent years with improved screw placement.[201] The joint space narrows, hip motion decreases, and an abduction contracture may develop.[54] Intervention should include modification of activities, use of crutches, gentle ROM to maintain motion, and anti-inflammatory medications.[201] Physical therapy may be helpful during this time to keep the patient mobile. A combination of avascular necrosis and chondrolysis is extremely devastating and usually results in hip fusion.[54]

The risk for development of degenerative arthritis in the hip with SCFE is directly related to the severity of the residual deformity at skeletal maturity.[84] Most conditions that do or do not receive intervention will result in some degree of osteoarthritis because of the presence of some biomechanical derangement.[112] The complications of avascular necrosis and chondrolysis greatly accelerate the development of osteoarthritis (OA) and may even lead to end-stage OA in adolescence.[112] Some studies are being performed to determine if OA may be prevented by restoring more normal proximal femoral anatomy by performing proximal femoral redirectional osteotomies, although long-term follow-up is not available at this time.[8]

Osgood-Schlatter Syndrome

Osgood-Schlatter disease, or syndrome, is characterized by activity-related pain at the anterior knee due to repetitive traction of the patellar tendon on the tibial tubercle ossification center or apophysis, resulting in inflammation and pain.[12] Radiographically, the severity can be classified into three grades: grade I shows slight elevation of the tibial tubercle, grade II shows radiolucency of the tibial tubercle, and grade III shows fragmentation of the tibial tubercle.[75] Several contributory factors have been suggested, including trauma, local alterations of the chondral tissue,[50] and mechanical overpull by the extensor muscles of the knee, which can result in patella alta and traction apophysitis,[9,102] eccentric muscle pull and muscle tightness,[96] reduced width of the patellar angle,[187] and increased external tibial torsion.[67]

Generally, this condition is seen in the apophyseal stage when the secondary ossification center of the tibial tuberosity appears.[75] Because this stage differs in the development of boys and girls, some differences are seen in the age of onset of Osgood-Schlatter syndrome. For boys, common ages are between 12 and 15 years and for girls common ages are between the 8 and 12 years.[75] Up to 30% may have bilateral involvement.[27] About 50% of all cases are involved in regular athletic activity.[12] Osgood-Schlatter syndrome may present as acute, severe pain, causing a child to limp, or may be noted by the child over a period of months as low-grade discomfort, usually brought on by running, jumping, or participation in sports. Direct pressure, such as kneeling, is also painful. Clinically, tenderness at the tibial tubercle and swelling may be seen. This is a self-limiting process that responds to activity modification, nonsteroidal anti-inflammatory medications, and application of ice. Stretching to improve flexibility of hamstrings and quadriceps may reduce symptoms.[12] In more severe cases, immobilization for 7 to 10 days may alleviate symptoms.[201] The symptoms will generally resolve when the tubercle fuses to the main body of the tibia, usually at around 15 years of age. For those with persistent problems after skeletal maturity, excision of the ossicle and prominence is an option.[201]

Osteochondritis Dissecans

Osteochondritis dissecans (OD or OCD) describes the separation of subchondral bone from the articular surface. It is characterized by a localized necrosis of the subchondral bone, which later revascularizes, reabsorbing and reossifying the bone necrosis.[28] Joint damage may occur because these lesions are adjacent to articular cartilage.[51] The fragment of bone can also detach, becoming a loose body in the joint.[51] The actual cause of osteochondritis dissecans is not known although several theories and factors have been proposed.[24,233] Repetitive microtrauma, including shear and compressive forces, leads to subchondral bone stress, especially in athletic persons.[155] Other factors such as genetic predisposition, ischemia that may be caused by vascular spasm, fat emboli, infection thrombosis, and abnormal ossification seem to play a causative role.[87] Patients are typically 12 to 20 years of age[87] and the male-to-female ratio is 2:1.[178] The most commonly affected areas are the knee (medial femoral condyle), the elbow joint

(capitellum), and the talus (superior lateral dome).[51] The classic location is the lateral aspect of the medial femoral condyle, possibly a result of the repetitive impingement against the prominent tibial spine.[24] Symptoms are a vague, poorly localized knee pain, with recurrent effusion.[233] Also loose bodies may result as articular cartilage breaks off causing mechanical symptoms of locking or catching of the knee.[233] Antalgic gait and an externally rotated gait pattern may also present.[24] Clinical exam may show atrophy of the quadriceps and tenderness along the surface of the affected chondral area with palpation (distal aspect of the medial femoral condyle with the knee flexed to 90°).[233]

OCD can be diagnosed with radiographs with a radiolucent area identifying an area of the lesion. Multiple views are typically recommended (anteroposterior, lateral, merchant, and notch or tunnel views) because the posterior aspect of the medial femoral condyle is more difficult to visualize.[233] MRI is useful in detecting the lesion and also in staging the lesion for determination of intervention.[24,233]

The preferred intervention in skeletally immature patients with symptomatic yet stable OCD lesions is limitation of weight bearing or even immobilization for 6 to 8 weeks followed by unloader bracing and activity restriction.[233] The important thing to communicate to the athlete is that if pain is not eliminated, the lesion is not healing.[24] Up to 90 percent of small lesions may heal spontaneously.[201] Lesions that fail conservative intervention, large lesions, or unstable OCD lesions may require surgical intervention.[233] Surgery may be needed to remove loose fragments.[51] Also, drilling the necrotic fragment may allow more rapid vascular ingrowth and replacement.[51] The drilling provides channels for adequate revascularization and healing. Fixation with hardware and bone graft are also options for stabilization.[51,201,233] In lesions that involve a large portion of weight-bearing area, OA is a risk in future years.[51]

Tarsal Coalition

Tarsal coalition is a failure of segmentation between adjoining tarsal bones. Coalitions may exist between all of the tarsal bones, but talocalcaneal and calcaneonavicular coalitions are the most common.[26] The etiology seems to have a congenital factor.[26,235] It has been found to be bilateral 50% to 80% of the time and occurs in both sexes equally.[26] It occurs in less than 1% of the population.[26] Symptoms generally present in early adolescence,[201] when the abnormal cartilaginous bar begins to ossify. The resulting fusion imposes stress on adjacent joints and consequently may result in degenerative arthritis, pain, and peroneal spasm.[201] Specifically, subtalar motion is greatly restricted in the talocalcaneal conditions and moderately limited in calcaneonavicular and talonavicular coalitions.[235] This leads to a rigid flatfoot deformity, with significant restriction of inversion.[26,235] Radiographs will generally show the bony coalitions with the three standard views of the foot.[235] In the fibrous or cartilaginous stages a CT or MRI allows for better definition and also can provide delineation of the extent of joint involvement as well as degenerative changes.[235] The goal of intervention is to limit joint ROM to reduce pain and muscle spasms.[235] Conservative intervention may include arch supports, short leg walking casts, immobilization in neutral or slight varus positions, and NSAIDs.[235] Surgical resection is an option in those who fail conservative intervention.[235]

Freiberg Disease

Freiberg disease is an idiopathic segmental avascular necrosis of the head of a metatarsal.[201] Most commonly, this occurs in adolescent girls, ages 13 to 18 years, and involves the second metatarsal.[201] It is unilateral in 90% of the cases.[12] The etiology is unknown, but factors such as trauma, repetitive stress, disruption in blood supply, or improper shoe wear may affect ossification.[12] Structural deformities, such as hallux valgus or hallux rigidus, may transfer the weight lateral to the second metatarsal increasing stress as well.[189] When microfractures occur at the junction of the metaphysis and growth plate, inadequate circulation to the epiphysis results.[222] Clinical presentation generally consists of pain in the forefoot, localized to the head of the second metatarsal, and localized swelling and limitation of motion in the metacarpophalangeal (MP) joint.[201,222] Early stages of the disease may not be detected on standard radiographs, and advanced imaging such as MRI or CT may be needed.[189,201,222] Later radiographs will show the stages of irregularity of the articular surface, sclerosis, fragmentation, and finally re-formation.[189,201,222] Conservative intervention includes offloading the metatarsal with orthotics, metatarsal pads, modified shoe gear, and removable walking boots.[189] Generally, this may take a course of 4 to 6 weeks.[201,222] If conservative intervention fails, surgical resection of the metatarsal heads is an option.[201,222]

Accessory Navicular

Accessory navicular is an extra bone that develops on the medial side of the tarsal navicular, either within the posterior tibial tendon or as a separate bone.[127,201] It is a result of the failure of the secondary ossification center of the navicular to unite during childhood.[127] This occurs in about 10% of the population.[201] Classification consists of three types:

1. Type I is a small oval to round ossicle within the posterior tibialis tendon that is seldom symptomatic.[189,201,222]
2. Type II is a larger lateral projection from the medial aspect of the navicular with a clear separation from the navicular.[189,222] The fibrocartilaginous connection between the tuberosity from the navicular is disrupted and may be mistaken for a fracture.[127,201] These are often symptomatic, and disruptions commonly occur during adolescence in relation to repetitive trauma.[127,201]
3. Type III occurs when a bony bridge is present between the accessory navicular and the navicular.[127] This may represent an end stage of type II[127] and may be prominent enough to cause irritation of the overlying skin.[201,222]
