Symptoms often begin in childhood with medial pressure of the accessory navicular against the shoe.[127] Commonly, the patient will report pain and tenderness along the medial midfoot region.[127] Swelling and erythema may also present.[127] The symptoms are usually exacerbated with weight-bearing activity.[127] Often radiographs are the only imaging modality needed for diagnosis.[127] Conservative intervention is directed toward relief of symptoms. Wider, more comfortable shoes to off-load the medial midfoot as well as orthotics may be helpful. Casting can limit pull of the posterior tibial tendon.[127] Activity modification is also recommended along with NSAIDs.[127] Surgical excision of the accessory navicular can be performed in extreme cases.[127]

Additional Causes of Limp

Other orthopedic conditions that can cause an acute limp in children from birth to age 5 years include juvenile idiopathic arthritis (see Chapter 7), nonaccidental trauma (fractures or

soft tissue injuries), hemophilia, discitis, discoid meniscus, popliteal cysts, foreign bodies, and bone tumors.

Patellofemoral pain and recurrent patellar subluxation or dislocations are common causes of limp in ages 10 to 15 years (see Chapter 15 for a more detailed discussion). Monoarticular inflammatory arthritis and gonococcal arthritis also can cause acute onset of limp in a child.

Many types of neoplasms and related bone lesions can cause a child to limp. Commonly seen conditions include osteoid osteoma, unicameral bone cyst, osteochondroma (single or multiple), enchondroma, aneurysmal bone cyst, eosinophilic granuloma, and nonossifying fibroma. Symptoms may include limp, pain, and pathologic fracture through the lesion.[201,222]

HEMANGIOMA/VASCULAR MALFORMATION

A hemangioma is an abnormal proliferation of blood vessels that may occur in any vascularized tissue. Hemangiomas that affect the musculoskeletal system are more accurately termed vascular malformations. Vascular malformations are rare congenital lesions that are caused by a defect during vascular embryogenesis. By definition, they are always present at birth but are not always clinically evident until later in life.[124,132] Skeletal changes are commonly seen with vascular malformations, although they are rarely seen with hemangiomas.[132]

At birth, vascular formations are fully formed, although the lesion may not be clinically apparent.[124,132] This type of lesion may appear later because of vessel dilation or hematoma formation, resulting in rapid enlargement.[132] Males and females are equally affected.[132] Vascular malformations can be subclassified by the predominant type of vessels found within the lesion (i.e., venous, arterial, lymphatic, capillary, or mixed) and by blood flow within the lesion (i.e., high flow versus low flow).[132] Venous malformations often remain asymptomatic although complications may include pain secondary to vessel dilation, bleeding, and hematoma formation, as well as intra-articular involvement, hemarthrosis, pathologic fractures of bone, and compression of adjacent structures.[124,132] They may also result in skeletal and soft tissue undergrowth or overgrowth in an affected limb.[132] Deep arteriovenous malformations can progress to distal ischemia, pain, and necrosis, with consequent risk for fracture, related to arterial steal of the bone.[132] The involvement of bone occurs in 20% of those with vascular malformations.[22]

Diagnostically, the first step in the imaging workup should be an ultrasound and Doppler examination.[124] This testing will allow immediate differentiation of the type of blood flow in the lesion.[124] In cases of low-flow malformations, an MRI is recommended, which helps confirm, characterize, and differentiate the malformation for planning of intervention.[124] If a high-flow lesion is detected, CT or CT angiography (CTA) may be used because they allow for accurate measurement and mapping of the feeding and draining structures and involvement of adjacent structures, which will help in interventional radiologic or surgical planning.[124] Intervention of these lesions varies widely with the extent of involvement. Conservative intervention is recommended when possible and included symptomatic intervention with compression stockings and analgesia.[22] Some cases may require surgical resection and/or intralesional transarterial embolization and amputation when involvement of muscle or bone has resulted in pain, functional impairment, or pathologic fracture.[22] Epiphysiodesis may be required in cases of skeletal overgrowth to correct for leg length discrepancy.[132]

MISCELLANEOUS CONDITIONS

Back Pain

The presence of back pain in children should be considered carefully because it can indicate serious disease in children.[212] Besides mechanical causes, pain could be the result of infection (including discitis related to bacteria), bony and spinal neoplasms, autoinflammatory and autoimmune causes such as chronic recurrent multifocal osteomyelitis, spondyloarthropathies that could progress to ankylosing spondylitis, vasculitis, or reflex neurovascular dystrophy that can manifest as back pain.[212] Findings that indicate further investigation include fever, weight loss, nighttime pain or pain that awakens the child from sleep, neurologic deficits, worsening pain over time, or inflammatory back pain.[212]

The incidence of nonspecific low back pain in adolescents has been reported as high as 74%.[105] Among mechanical causes that should be considered are spondylolysis (unilateral fracture of the pars interarticularis), Scheuermann disease (increasing thoracic or thoracolumbar kyphosis with tightness of the hamstrings and iliopsoas), sacroiliac dysfunction, and apophysitis (growth plate irritation from chronic repetitive stress localized to the iliac crests or ischial tuberosity).[212] Specifically, Scheuermann disease is a disturbance of the vertebral end plates causing anterior vertebral body wedging that results in kyphosis during a growth spurt.[12] Surgery is considered only in severe cases (greater than 75°, pain, unacceptable appearance).[12]

Another factor that has been found to directly affect the incidence of low back pain is BMI.[5,197] Akdag et al.[5] found that a BMI of 19.84 kg/m^2 was a significant factor for pain intensity in a population of children ages 10 to 18 years. Others determined that the likelihood of joint pain increased by 10% for every 10-kilogram increase of weight and an increase of 3 percent for every unit increase in BMI.[207] A detailed review of spinal conditions may be found in Chapter 8.

Idiopathic Toe-Walking

Toe-walking that persists after the age of 2 years in the absence of neurologic or orthopedic abnormalities is termed idiopathic toe walking (ITW).[220] The incidence of ITW has been reported as nearly 5%.[53] Generally, it is a diagnosis of exclusion, ruling out neurologic involvement (ankylosing spondylitis, cerebral palsy, Charcot-Marie-Tooth disease, muscular dystrophy, spina bifida, tethered cord syndrome, transient focal dystonia), neurogenic and developmental disabilities (Angelman syndrome, autism spectrum disorders, developmental coordination disorder, global developmental delay, schizophrenia), and traumatic or biomechanical conditions (soft tissue injuries, congenital talipes equinus, leg length discrepancy, puncture wounds, scarring, tumor in belly of gastrocnemius muscle, venous malformation of the gastrocnemius muscle, viruses).[231] No known cause has been identified for ITW but a family history is common[220,231] and a possible autosomal dominant genetic link has been suggested.[231] Initially, children with ITW walk on their toes but can bear weight with their foot flat on request and with concentration on their gait.[220] Over time, an equinus contracture, defined as a limitation of at least 10° of passive ankle dorsiflexion with the knee extended and the ankle in neutral position, may develop.[220] If not corrected, the contracture can develop into acquired flatfoot, metatarsalgia, diabetic foot ulceration, and plantar fasciitis.[220]

Intervention for ITW may vary due to lack of evidence for effectiveness of intervention.[85,220] Generally, it improves without intervention.[85,220] Conservative measures may include stretching of the plantar flexors including passive stretching, prolonged ankle foot orthosis, serial casting, and/or Botox injections.[220,231] Surgical lengthening of the Achilles tendon may often be performed in cases that persist.[85,220,231]

Achondroplasia

Achondroplasia (dwarfism) is the most common of a large group of conditions known as the osteochondrodysplasias, a heterogenous group of disorders characterized by abnormal growth and remodeling of cartilage and bone.[160] Prevalence for achondroplasia is 0.36 to 0.6 per 10,000 live births.[99] The disorder is an autosomal dominant trait, but 80 percent of cases are the result of a random mutation.[160] The typical presentation of achondroplasia is obvious at birth.[160] Features include:

- symmetric shortening of all long bones with proximal portions more affected and lower limb more affected than upper limb;
- epiphysis is closer to metaphyses resulting in apparent increase in the depth of the articular cartilage space; results in chevron or ball and socket relationship deformity, commonly at lower end of femur;
- hand bones appear thick and tubular with widely separated second and third digits of the hands and inability to approximate them in extension;
- pelvic cavity is short and broad;
- vertebral bodies that are cuboid shaped, which may cause narrowing of the spinal canal and cord compression, with short pedicles and associated dorso-lumbar lordosis;
- skull base that is narrowed, with narrowing of foramen magnum with relative midface hypoplasia and depressed nasal bones.[160]

Neurologic impairments and complications are possible with 10% of children showing neurologic signs by 10 years of age.[99] The altered body position does affect developmental motor skill sequencing but is consistent within this group and milestone reference tables do exist.[99] Positioning should be considered and restricted time in sitting is advised to avoid development of a fixed thoracolumbar kyphosis.[99]

Counseling to maintain appropriate weight for height is helpful in controlling orthopedic injuries.[99]

LEG LENGTH INEQUALITY

Leg length inequality (LLI) may also be called leg length discrepancy (LLD) and is often defined as a 2.5 cm or greater difference in leg length. Differences smaller than this tend not to cause clinical problems. Differences in leg length may be due to relative overgrowth or shortening.

Origin

The origin of LLI is divided into a number of categories: trauma; congenital, neuromuscular, or acquired disease; infections causing physeal growth arrest; tumors; and vascular disorders. Types of trauma include epiphyseal and diaphyseal injuries. Epiphyseal injuries with growth plate closure may be asymmetrical, as in fracture involving the medial epiphysis of the distal femur. This type of injury can result in an angular deformity (varus), as well as shortening of the femur.

Congenital disorders include hemihypertrophy, in which one half of the body (the arm and leg) is larger than the other. Conversely, in hemiatrophy, one half of the body is smaller than the other. These sometimes can be difficult to distinguish, necessitating a decision on which arm and leg best "match" the rest of the body. Proximal focal femoral deficiency, congenital coax vara, fibular and tibial hemimelia, and other focal dysplasias are additional causes of LLI (see Chapter 13). DDH can also cause a leg length discrepancy as the result of an apparent femoral shortening noted when the hip is dislocated or actual shortening caused by femoral head AVN. Surgical interventions for DDH can change the leg length; these include use of a varus derotation osteotomy (VDRO), which shortens the femur, and pelvic osteotomies, which may add up to one inch to the height of the pelvis.

Neuromuscular disorders can cause asymmetrical growth of lower extremity bones. Decreased growth in the affected leg may be due to decreased muscle forces in weak or paralyzed muscles. Examples include myelodysplasia, poliomyelitis, and hemiplegia caused by congenital or acquired cerebral palsy. However, not all cases of LLI should be corrected. A child with hemiplegia can have a short lower limb on the affected side. With weakness and spasticity in that leg, foot clearance may be difficult as a result of decreased hip and knee flexion and equinus. The shortness of the leg makes foot clearance in swing easier.

Acquired conditions such as LCPD and SCFE can also result in shortened lower extremity, usually as a result of AVN of the femoral head, or occasionally as the result of surgical intervention. Fibrous dysplasia and tumors, including benign bone cysts and malignant neoplasms, can change leg length by interfering with growth centers or secondarily as a result of fracture or surgical intervention.

Impairments

The effects of LLI vary widely among patients because of the actual amount of difference and how well the patient physically compensates for it, the possibility of progression of the inequality, the patient's perception of the problem, and the overall picture of muscle strength, motor control, and ROM. If the discrepancy is marked or compensation is limited, poor cosmesis may be evident, and a significant increase in work by the muscles may be required to walk.[4] Musculoskeletal adaptations and compensations may result. These secondary impairments include pelvic obliquity, which requires more effort by the abductor muscles of the hip and lumbar paraspinal muscles, placing more strain on the spinal ligament.[4] Others have reported the development of scoliosis, low back pain, sciatica, excessive stress on hip of knee joints, and lower extremity dysfunction such as stress fracture, plantar fasciitis, or parapatellar knee pain.[83] The development of osteoarthritis with LLI has been shown.[4] In children a gait strategy is used that puts more work on the longer limb, which may be associated with the higher number of cases of OA in the longer limbs.[4] Compensatory patterns include circumduction of persistent flexion of the longer limb, vaulting over the longer limb, toe-walking on the shorter limb, and a greater vertical displacement of the center of body mass.[4] Consequently, musculoskeletal adaptations may be observed that include pelvic tilt, knee flexion, and equinus. These problems may be significant but easily accommodated because of the inherent energy and motivation usually present in children. In adulthood, however, factors of increased size and weight, increased energy expenditure to walk, increased sensitivity regarding the poor cosmesis

of a lurching gait, and long-term effects of asymmetrical lumbosacral spinal alignment may combine to significantly reduce the ability to walk and even render a person nonambulatory.

Clinical Examination

The physical therapy examination for patients with LLI starts with obtaining a complete history, including any previous intervention. The physical examination incorporates the following elements:

- Measurement of ROM, joint stability, and muscle strength of the trunk, hips, knees, ankles, and feet
- Sensation of the lower extremities
- Anthropometric measurements: sitting and standing height, weight, and arm span; girth of thighs and calves; leg lengths
- Functional activities such as rising from a chair to standing and moving down to the floor and back up
- Clinical analysis of posture and gait, including observation of the spine and lower extremity alignment and substitution patterns; observations of the patient with and without assistive devices and shoe lift during gait on level ground, ramps, and stairs.

These tests will help determine if the LLI is structural due to a measurable difference in a lower extremity segment, functional due to asymmetry in the positioning of one lower extremity relative to the other, or a combination of these.[83]

Different methods of clinical measurement of leg length are used. One is to level the pelvis in standing, using graduated blocks under the short leg, and then to measure the height of the blocks. This method is pictured in Fig. 14.32. Measurements with a tape measure may also be taken with the child supine on an examining table from the superior iliac spine to the medial joint line and the medial malleolus or from the umbilicus to the medial malleolus (Fig. 14.33). A third method has been described by Smith[195] and labeled the thigh-leg technique. The patient is placed supine on an examining table with the hips and knee flexed 90°. Discrepancies are measured between the table and the thigh, between the thighs at the knees, and between the soles with the knees even (Fig. 14.34). Caution should be used when correcting LLI of less than 5 mm when only clinical examination methods have been used because of the inaccuracy and lack of reliability of the techniques.[20]

Radiographic measurement of leg length will provide more accurate measurements of an inequality. Computed tomography scanogram is currently used by many.[74,83] The radiation dosage for this procedure is 1% of the exposure with conventional radiography.[83] This method is quicker, which better accommodates small children, and also can be used when contractures or external fixators are present.[74,83] This compares to the standard x-ray technique in which the patient is positioned on the x-ray table with a ruler alongside the legs, and three radiographs are taken at the level of the hips, knees, and ankles, with the patient held motionless. These three views with the ruler markings next to them allow the examiner to measure the length of the femur and tibia and combine them for the total leg length. Landmarks commonly used are the top of the femoral head, the bottom of the medial femoral condyle, and the tibial plafond. A film of the left wrist and hand may also be performed at the same time for determination of skeletal age of the patient.

Measurement error is present in any of these techniques, making both clinical and radiographic leg length determinations an inexact science. Determining the percentage of growth

FIG. 14.32 Clinical measurement of leg length inequality using graduated blocks. (A) Leg length inequality in standing can be viewed with asymmetric iliac crest or posterior iliac spine heights with the patient standing erect. The patient must be standing evenly on the legs, with knees straight and feet flat on the floor. (B) A measurement of inequality can be made by using graduated blocks until the pelvis is level. (From Herring JA: Tachdjian's pediatric orthopaedics: from the Texas Scottish Rite Hospital for Children. 5th ed. Philadelphia, Saunders, 2014.)

inhibition assists in estimating the eventual discrepancy at skeletal maturity. For example, a 10% inhibition of growth in the short leg may result in minor discrepancy when the child is quite young. When the leg is 20 cm long, a 10 percent shortening is only 2 cm. However, as the child matures, when the unaffected leg is 70 cm long, a 10% inhibition of growth on the involved side will result in a shortening of 7 cm, which is significant.

If the patient can be followed with serial measurement over time, scanogram measurement of total length of both the long and the short leg and skeletal age at the time of each scanogram can be plotted on the Moseley graph, which depicts past growth and predicts future growth[148] (Fig. 14.35). Timing of epiphysiodesis is based on the predicted LLI at skeletal maturity. The effects of surgery can also be plotted on the graph to predict alteration in leg lengths and the eventual impact on discrepancy

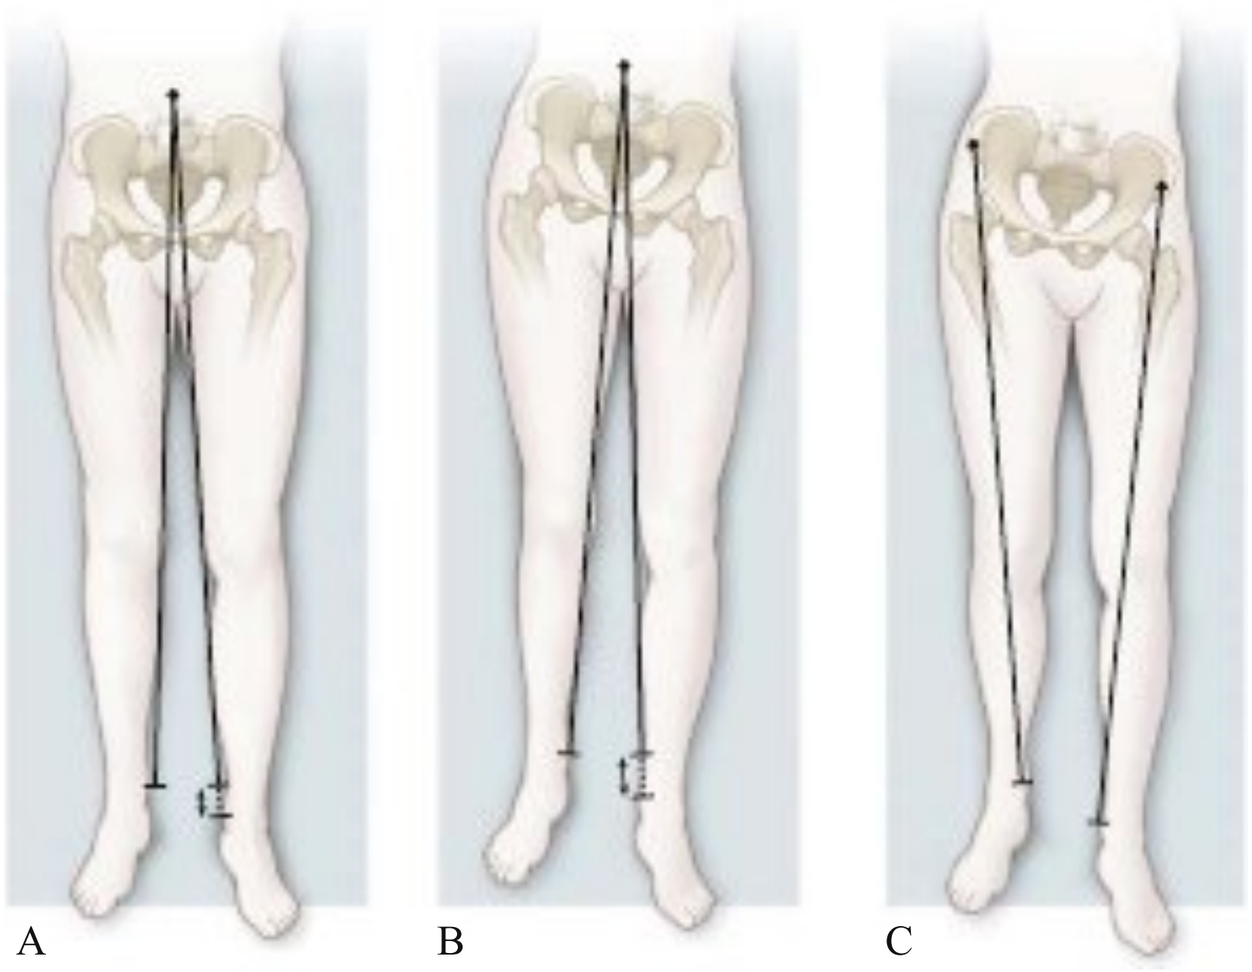

FIG. 14.33 Assessment of functional and actual leg length inequality while supine using a tape measure. Figure A represents one patient and Figures B and C represent a second patient. (A) With the legs in an extended and neutral position, lengths are uneven when measured from the umbilicus to the medial malleolus (left leg longer than right) and from the anterior iliac spine to the medial malleolus in a patient with structural leg length discrepancy. (B) In a patient with fixed pelvic obliquity but no true limb length inequality, asymmetry is noted on the measurement from the umbilicus. In this measurement, the adducted left leg is longer than the right. (C) Measurement from the anterior iliac spine to the medial malleolus demonstrates no structural length inequality. (From Herring JA: Tachdjian's pediatric orthopaedics: from the Texas Scottish Rite Hospital for Children. 5th ed. Philadelphia, Saunders, 2014.)

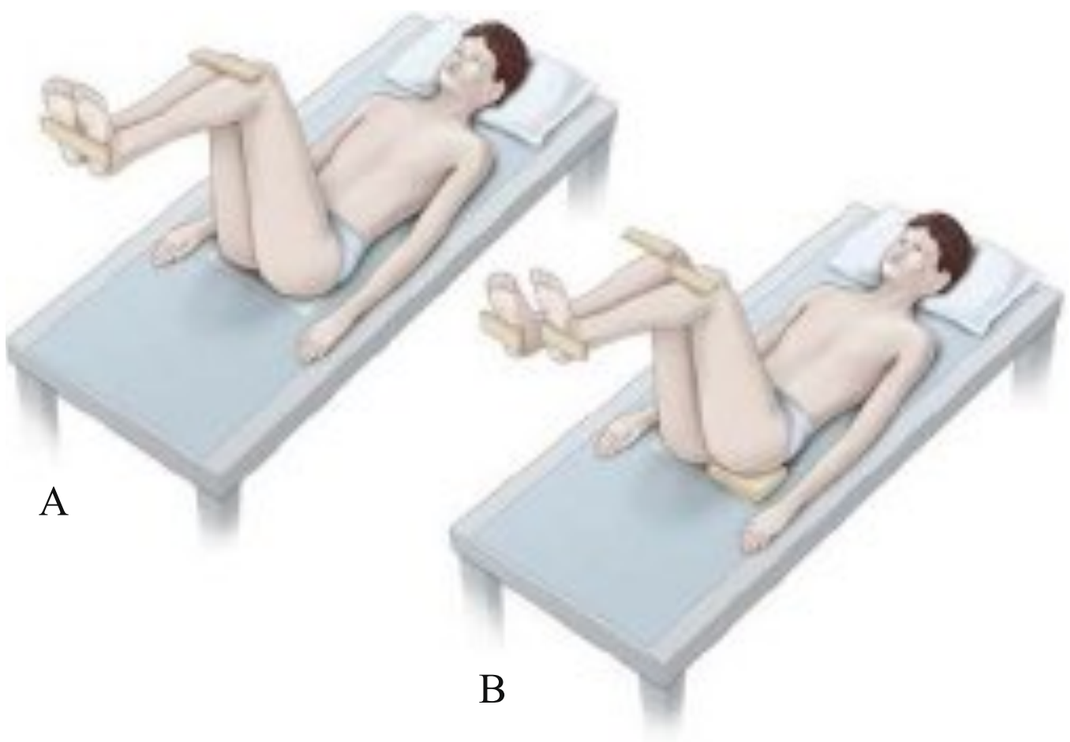

FIG. 14.34 Thigh-leg technique for measurement of leg length inequality. (A) Patient is positioned supine with the hips and knees flexed to 90°. Discrepancy between the sides is noted between the table and thigh, between the thighs and knees, and between the soles with the knees even. Figure A shows no discrepancy. (B) Discrepancy in leg length is seen with use of graduated blocks to determine amount. (From Herring JA: Tachdjian's pediatric orthopaedics: from the Texas Scottish Rite Hospital for Children. 5th ed. Philadelphia, Saunders, 2014.)

at skeletal maturity. Paley et al.[159] have developed a mathematical formula that allows these predictions to be accurately based on as few as one or two measurements (Table 14.8).

Intervention

Intervention for LLI is affected by the patient's age, current discrepancy, and the projected discrepancy at maturity.[74] During growth the family and surgeon may conservatively intervene with shoe lifts or other prosthetic devices. The three final options for intervention after skeletal maturity are: continue the prosthetic or orthotic resources as in the childhood years, shorten the long limb, or lengthen the short limb. The general guideline is:

0–2 cm: No intervention
2–6 cm: Orthotic use, epiphysiodesis, skeletal shortening
6–20 cm: Limb reconstruction (limb lengthening with or without adjunctive procedures)
> 20 cm: Prosthetic fitting (with or without surgical optimization)[74]

Another consideration is the contribution of growth by each growth center (Table 14.9).

Orthotic Intervention

Lifts inside the shoe of the short limb are usually effective for 1.5- to 2-cm correction.[74] For larger discrepancies, lifts may be applied to the outside of the shoe.[74] Lifts higher than 5 cm are not tolerated well with the weight of the lift being one factor.

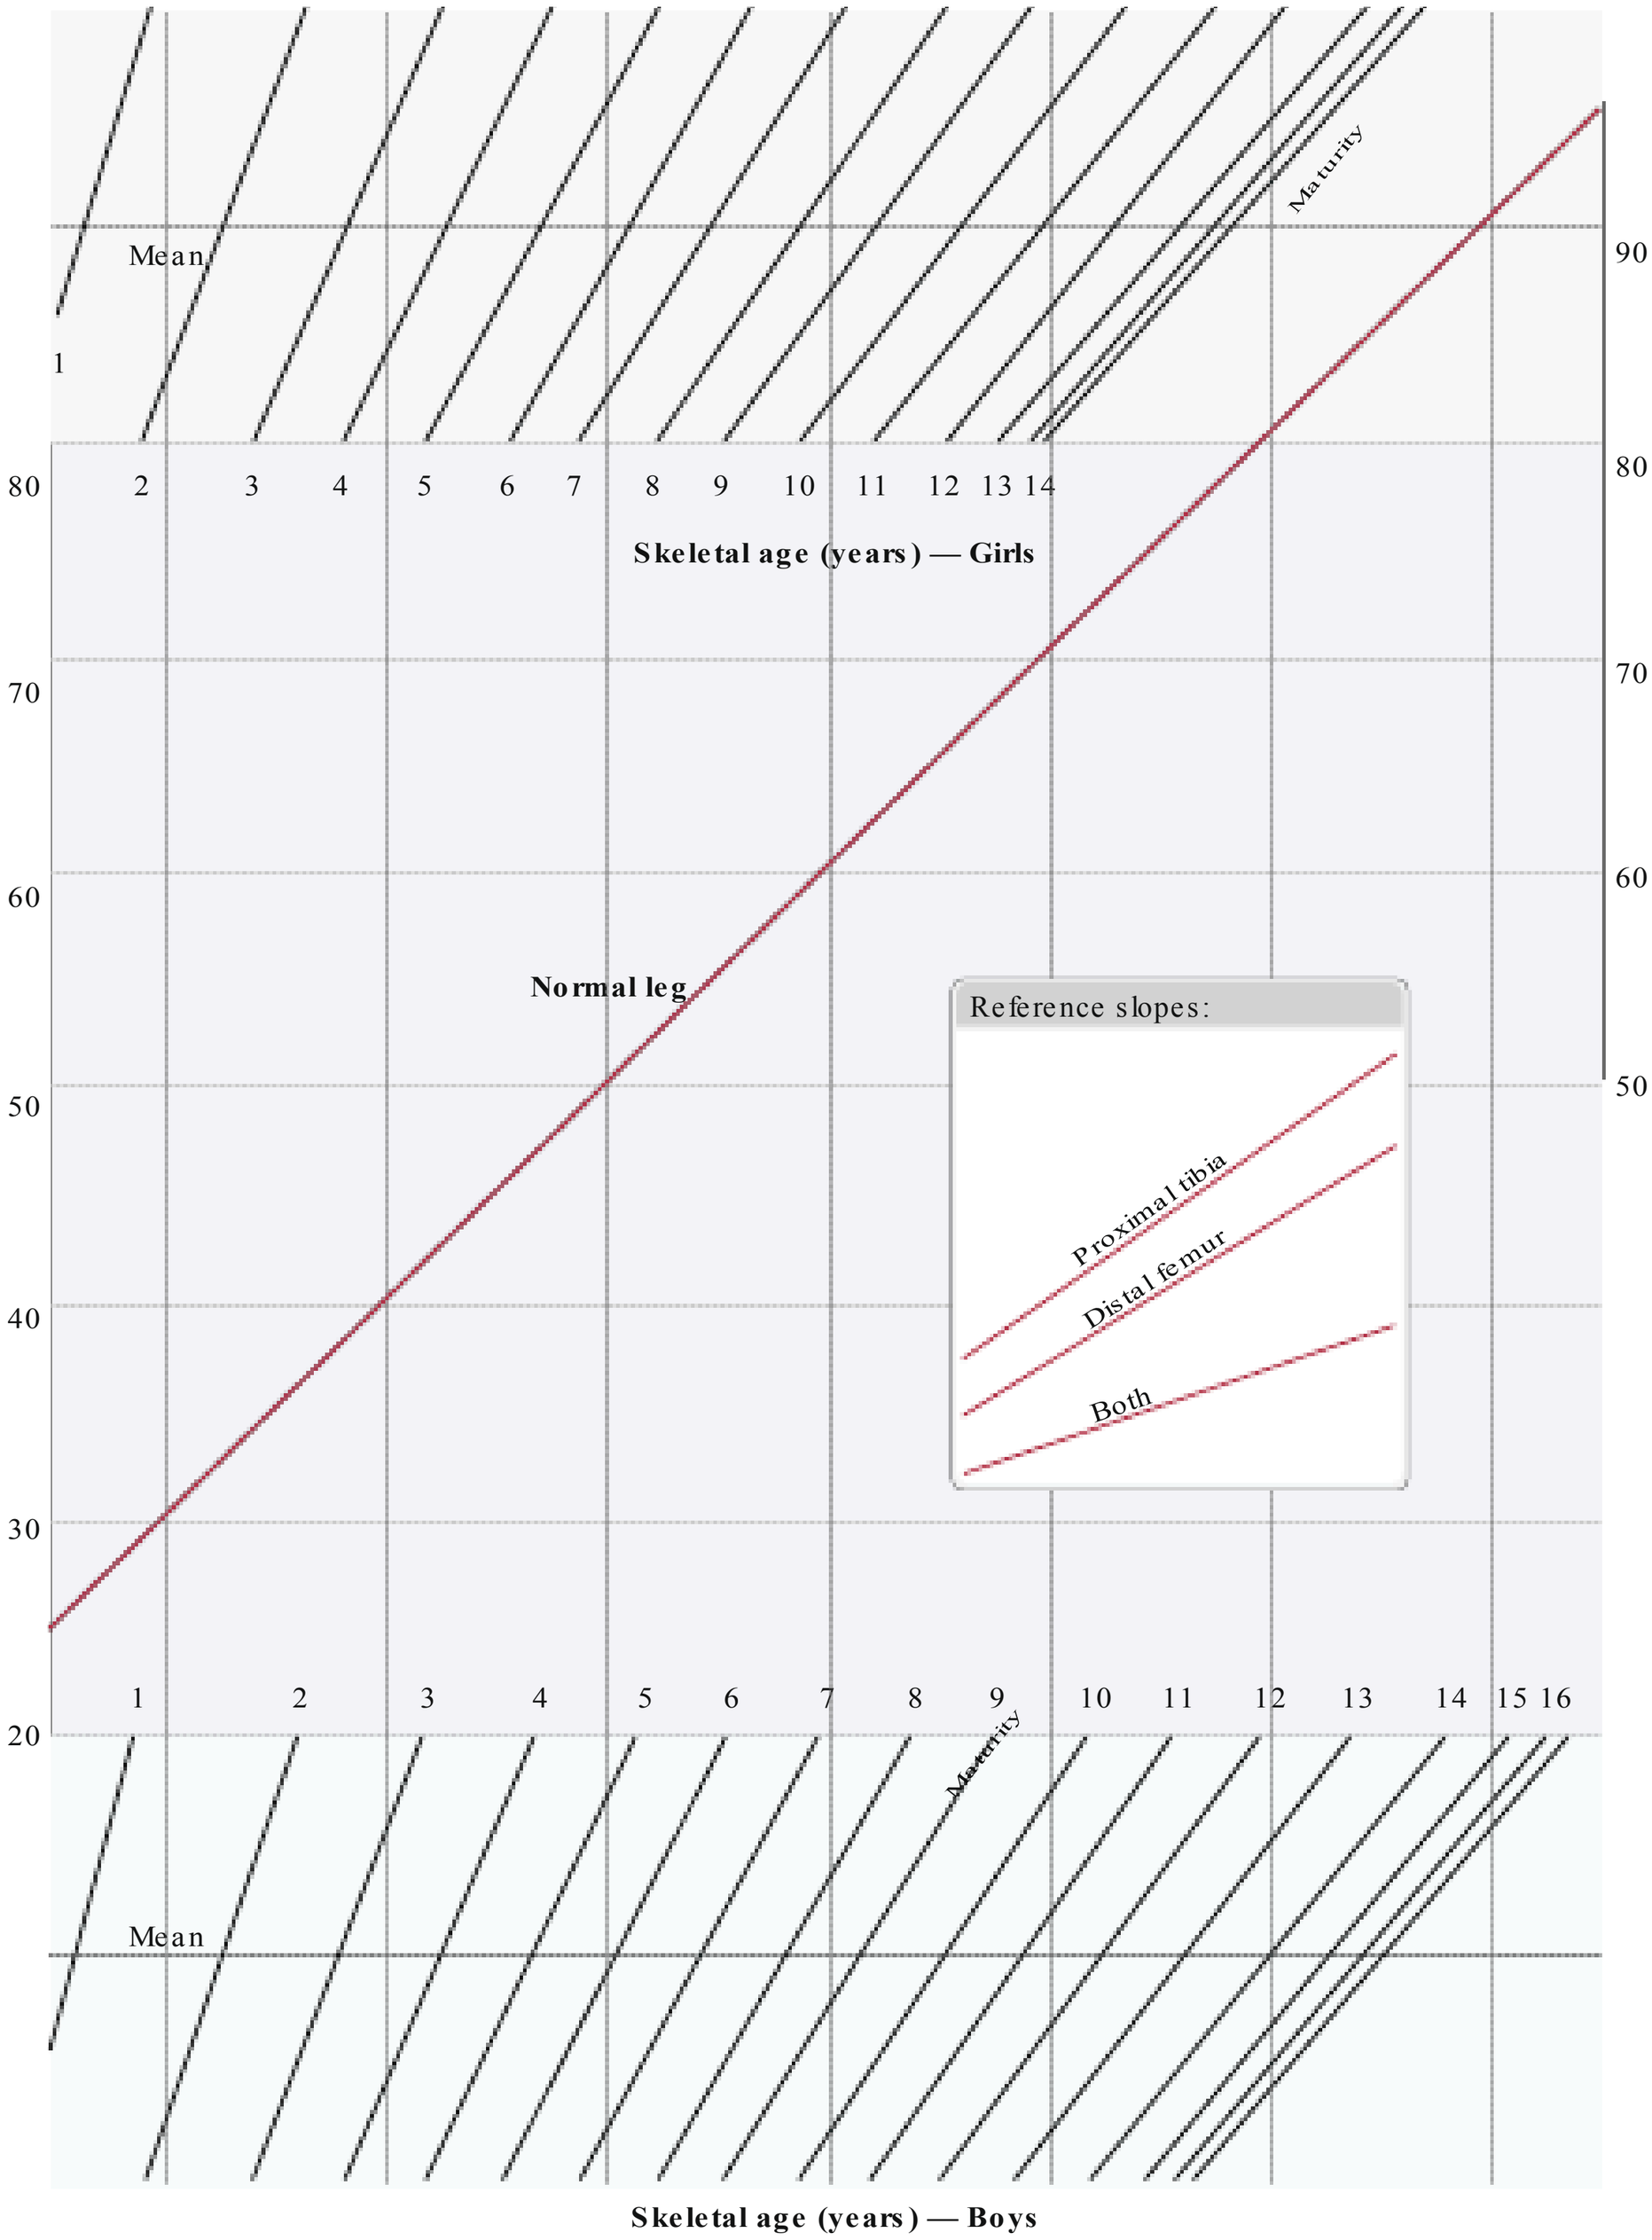

FIG. 14.35 Moseley graph used to plot a patient's serial scanogram measurements and bone ages to determine the discrepancy at maturity and the possibilities for surgical intervention. Growth of a short leg would be depicted by a line below the normal leg line. The surgical increase in the length of the short leg would allow the two legs to be approximately equal at skeletal maturity. (Redrawn from Moseley CE: A straight-line graph for leg-length discrepancies. J Bone Joint Surg Am 59:174-179, 1977.)

TABLE 14.8 Lower Limb Multipliers for Boys and Girls Used to Predict the Limb Length Discrepancy and the Amount of Growth Remaining

	MULTIPLIER	
Age (yrs + mos)	Boys	Girls
Birth	5.080	4.630
0 + 3	4.550	4.155
0 + 6	4.050	3.725
0 + 9	3.600	3.300
1 + 0	3.240	2.970
1 + 3	2.975	2.750
1 + 6	2.825	2.600
1 + 9	2.700	2.490
2 + 0	2.590	2.390
2 + 3	2.480	2.295
2 + 6	2.385	2.200
2 + 9	2.300	2.125
3 + 0	2.230	2.050
3 + 6	2.110	1.925
4 + 0	2.000	1.830
4 + 6	1.890	1.740
5 + 0	1.820	1.660
5 + 6	1.740	1.580
6 + 0	1.670	1.510
6 + 6	1.620	1.460
7 + 0	1.570	1.430
7 + 6	1.520	1.370
8 + 0	1.470	1.330

TABLE 14.9 Percentage of Growth for Each Growth Center in the Femur and Tibia

Growth Center	For Entire Leg	Total Length of Femur	Total Length of Tibia
Proximal femur	15%	30%	–
Distal femur	35%	70%	–
Proximal tibia	30%	–	60%
Distal tibia	20%	–	40%

Also, the weakness of the legs does not counter the inversion stress, and frequent ankle strains may result. More stability can be achieved by an orthotic extension up the posterior calf or above the malleoli.[74] A prosthesis is an option for those with a congenital amputation.[74] Also, amputation is sometimes chosen in cases where the femur is less than half the length of the contralateral side, if the length is projected to be > 15 to 20 cm and especially if the foot is not functional.[74] The decision for amputation is difficult for families but those who undergo surgery and prosthetic early in life show very good results with adaptation to a prosthesis.[74] Discussion with families and children who have undergone this intervention may be helpful for families making this decision.[74]

Shortening the long limb. Shortening of the longer limb in the growing child can be achieved through epiphysiodesis, the surgical physeal arrest of one or more growth centers in the long leg, which allows the short leg to "catch up" in length. This is a good way to intervene with mild to moderate discrepancy. In order for this to be an option, the child must have enough growth remaining to recoup the differences in length.[74] It is especially helpful in cases of overgrowth from fracture, inflammation, or overgrowth syndromes.[74]

Timing of the epiphysiodesis is obviously crucial. Future growth of each leg must be predicted and the surgery performed at a time when the amount of growth denied the long leg will match the amount of growth still available in the short leg, allowing them to be approximately equal in length at skeletal maturity. If the epiphysiodesis if performed too early, the long leg may actually become the short leg, with an obviously less than optimal surgical result. Epiphysiodesis can also be performed on only the medial or lateral growth part of the growth plate to correct angular deformities. For example, a fracture of the distal femur may cause damage to the medial aspect of the distal femoral growth plate. The lateral part of the growth plate continues to function normally, and the leg grows into varus, which also produces a functional shortening.

Another option for shortening the long leg is a shortening osteotomy, usually considered in a skeletally mature patient who is not a candidate for epiphysiodesis. A second option for correction of angular deformities is to staple the medial or lateral growth plate; for the limb that is in varus in the growing child, the lateral portion of the growth plate can be stapled to stop growth while the medial side continues to grow.

Lengthening the short limb. Surgical lengthening of the short leg has appeal because the surgery is performed on the affected leg, not the "normal" leg, and opportunity exists for correction of discrepancies of much greater magnitude. Criteria for leg lengthening include a discrepancy of greater than 4 to 6 cm, adequate soft tissue mobility available to allow correction, and a stable joint above and below, although unstable joints can be protected with an external frame. The femur and tibia can each be lengthened or both. The final goal is equal leg length with equal knee heights in standing.

Corrections up to 15 to 20 cm are now possible with technology.[74] Corrections can be very involved and time consuming and this should be well explained to the patient and family. Lengthening often consists of a series of operations to optimize the results with each increasing the length 10 to 20 percent of the original bone length.[74] Each lengthening attempt will require at least 1 month of fixator time for every centimeter of length gained followed by an external fixator for 6 months with rehabilitation following.[74] Opinions vary as to the best timing

for this procedure. Some support delaying limb lengthening until 10 to 12 years so that the patient can comprehend the task ahead while others suggest that lengthening at an earlier age (5 to 7 years) may allow for more normal growth post lengthening and perhaps less ultimate discrepancy.[74] Other osseous or joint deformities (e.g., hip dysplasia, ankle valgus) should be addressed prior to initiating this procedure.[74]

Methods of lengthening include distraction osteogenesis, limb lengthening with external fixation, distraction epiphysiolysis, lengthening over intramedullary rod, and intramedullary lengthening device.[74] With distraction osteogenesis, an osteotomy is performed and the bone ends are approximated for 3 to 14 days. After this period of time in which the inflammatory phase of fracture healing occurs, the osteotomy then enters the reparative stage of fracture healing and the site is distracted 1 mm per day. Maintaining motion is very important during this procedure, with some recommending discontinuation if a knee extension contracture of > 30° occurs.[74] Distraction will be continued until the goal is achieved. The patient is then in the consolidation phase and full weight bearing is allowed. The device remains on the leg until radiographs determine the strength of the bone is adequate for weight bearing.[74]

An external fixator can also be used for limb lengthening. There are several types of external fixators and techniques. One of note is the Ilizarov technique. An osteotomy is performed as described above. In this procedure, fixation is achieved by tensioned through-and-through wires attached to complete or partial rings that are attached to the limb by multiple bone pins.[74] The lengthening is performed through turning the device at a rate of 1 mm per day.

Distraction epiphysiolysis is designed to correct growth at the physis. A distraction force is applied across the physis until it fractures. Lengthening is then achieved through gradual distraction. This method is more painful, and complications of further damage to the physis are possible. It is generally used for children who are very near the end of growth.[74]

Lengthening over an intramedullary rod has the advantage of removal of the external fixator earlier and quicker recovery of knee motion.[74] The rod maintains alignment during the distraction and the consolidation phases. With the rod providing stability, the external fixator can be removed after lengthening is complete. Because the femur remains stabilized, progressive weight bearing and restoration of motion can begin.[74] The risks are damage to the femoral physis and AVN as well as the knee having a more medial placement relative to the femur during the process due to the lengthening being performed along the anatomic axis of the femur.[74] Changes in knee positioning could affect distribution of weight. Infection is also a concern.[74]

Intramedullary nailing allows lengthening and stabilization without the risks of an external fixator.[74] These are not as widely used for children because of risk of damage to the growth plates.[74] This may be the best option in those who have already experienced damage.[74]

The list of complications for limb lengthening include hypertension during lengthening, device malfunction, pin failure, pin tract infection, osteomyelitis, premature consolidation, poor bone formation, fracture after device removal, decreased growth of the limb, malalignment during lengthening, pain, soft tissue scarring, muscle tightness leading to joint stiffness contracture, dislocation, stretch paralysis of the nerves, and joint damage.[74]

Children undergoing leg lengthening as well as the family may need guidance because of the pain that may be experienced as well as the length of the process. The child may experience frustration, anger, and fear because of the temporary loss of independence inherent in the procedure. Difficult behavior may require intervention by a psychologist to assist the child and family in developing appropriate coping strategies. Candidates for surgical lengthening must be extremely motivated, with a supportive and committed family. Successful limb lengthening also mandates a comprehensive medical care system, with knowledgeable, experienced physicians, nurses, and therapists to guide the patient and family through the process.

Physical therapy may be helpful preoperatively to perform crutch-fitting and instruction in restricted weight bearing on the involved leg, instruction in home exercises, and postoperative positioning and splinting in conjunction with the patient, parents, and other caregivers, and stretching and strengthening exercises to use in preparation for surgery. Much of this may be possible through a home exercise program. Postoperatively, therapy may include instruction in functional activities, active assistive and isometric exercise, proper positioning of the extremity, gait training with progressive weight bearing as tolerated, and pin care. Modalities such as ice or transcutaneous electrical nerve stimulation (TENS) may be useful for pain management. Dynamic splinting may be used in the limb-lengthening stage to provide low-intensity, prolonged stretch to joints with significantly limited ROM. Exercise techniques that may be useful throughout the Ilizarov lengthening include closed- and open-chain exercises for strengthening and active-assistive or passive exercises for ROM. A stationary bicycle and a treadmill may be used. After removal of the fixator, the patient may require additional gait training, monitoring, and adjusting of the exercise program and possible refitting and retraining, with orthotic or prosthetic devices worn preoperatively. Throughout the course of intervention, children are encouraged to participate in their usual school and leisure activities to the fullest extent possible.

SUMMARY

The pediatric orthopedic conditions presented in this chapter represent a wide range of problems that may be encountered by physical therapists in children referred to them for a specific problem (e.g., clumsy gait) or perhaps a specific complaint that turns out to be a “red herring.” An example of this is a child referred to physical therapy for intervention for knee pain who in fact has a slipped capital femoral epiphysis. Alternatively, a child might be referred from a primary care physician or a neurologist to a physical therapist with one diagnosis (e.g., gross motor developmental delay) but also may be receiving intervention by an orthopedist for developmental dysplasia of the hip. In all these various scenarios, it is essential that the physical therapist be knowledgeable about various pediatric orthopedic conditions, including their signs, symptoms, differential diagnoses, and intervention. Physical therapists must be well informed regarding when to refer to other practitioners, such as the orthopedic surgeon in the case of a child with a suspected acute SCFE. As physical therapists, we often have the advantage of following a child intensively over a period of time, as opposed to a physician’s visit once every 6 months, and thereby have unique insights into the child’s condition and the family

dynamics surrounding it. The well-informed physical therapist can often serve to bridge the gap that sometimes occurs between various specialists following a child, including primary care physicians, orthopedists, neurologists, and physiatrists.

RECOMMENDED MEASURES FOR CHILDREN RECEIVING ORTHOPEDIC EVALUATION

Body Functions and Structures

Torsional profile of lower extremity
Hip-knee-ankle joint ROM
Ortolani test
Barlow test
Leg length
Strength
Pain
Foot progression angle
Normal progression of physical changes with growth and development (e.g., flatfoot, genu valgum, torsion of lower extremity)

Activities and Participation

Gait assessment
Physical participation in play
Self-chosen position in play

Case Scenarios on Expert Consult

The case scenarios related to this chapter address a patient with Sever disease and a patient with a vascular malformation of the lower extremity. The case with Sever disease focuses on the evaluation and treatment process, and the case with the vascular malformation focuses on the process involved with differential diagnosis of this disorder.

Sports Injuries in Children

Mark Paterno, Laura Schmitt, Catherine Quatman-Yates, Kathryn Lucas

Youth participation in sports is growing at an exponential rate. Current estimates suggest greater than 30 million to 45 million youths between the ages of 5 and 17 years of age participate in community-sponsored athletic programs.[4,321] This represents an increase from roughly 5 million participants in 1970. More than 7.6 million teenagers regularly participate in competitive high school team sports.[402]

Participation in athletics is a means for our youth to remain physically active and reap the many health benefits of activity. In 2001 the Surgeon General[396] reported the incidence of obesity in our youth was reaching epidemic proportions as approximately 15% of children ages 6 to 19 years old are classified as obese and 30% are classified as overweight.[309] More recent evidence suggests obesity rates for children between the ages of 2 and 19 years old is now 17%.[308] This resulted in a health care expense in excess of $117 billion.[131]

Current estimates from the Centers for Disease Control and Prevention (CDC) suggest fewer than 65% of adolescents participate in regular physical activity and fewer than 45% are enrolled in a physical education class at their school. Participation in sports likely increases physical activity levels, which is critical to the long-term health of our youth. In addition, participation in athletics provides children with an opportunity to enhance their physical abilities and skills as well as for social interaction with their peers. Participation in sports is linked to positive aspects of individual development and academic performance, including higher grade point averages, lower school absentee rates, and overall better behavior.

Coinciding with increased participation is the potential for increases in sports-related injury in children. Emergency room data acquired since the later 1990s suggest more than 3.5 million children between the ages of 5 and 14 years old require medical attention for acute, sports-related injuries. In 2008, one study reported nearly 500,000 sports-related injuries requiring an emergency department visit in patients between the ages of 13 and 19 years old in 1 year.[296] More concerning is the fact that more than 50% of sports-related injuries in children are likely overuse injuries[298] and would not be included in these data. Furthermore, the progression of many children to become specialized in a singular sport early in their life has raised concerns from the American Academy of Pediatrics and other health care organizations about the safety of year-round participation in a single sport with infrequent rest periods and a lack of diversity in activity.[11] Attention must be given to the management of unique injuries in this population. However, the child cannot be considered simply a small adult. Children have different structural and physiologic components that must be specifically addressed.[393] This chapter provides an extensive overview of sports medicine in children and youth for the pediatric physical therapist. The purposes of the chapter are to review the elements of injury prevention/risk reduction and to discuss those factors that increase risk for sports-related injury in children with and without disabilities. The chapter addresses the types and sites of sports injuries unique to the child and provides considerations for rehabilitation.

BACKGROUND INFORMATION

INCIDENCE OF INJURY

Appreciating the true incidence of sports-related injuries in a young, active population is a challenge because of the varying methodologies in current research. Injury incidence is defined as the number of new cases of a disease (or injury) during a specific period of time, such as an athletic season or a year.[211] Incidence can be further subdivided into clinical incidence, which reports the percentage of new cases within a defined population, and incidence rate, which describes the rate of injuries per unit of exposure to activity.[68] Incidence rate is a much more powerful descriptor of the risk of injury in a population or within a certain activity and is necessary to accurately compare the rate of injury, normalized to exposure, between populations. Unfortunately, these data in the pediatric sports medicine literature are lacking. Varying methodologies and definitions of injury have hindered development of broad epidemiologic data accurately reporting the incidence of injuries in this population. In addition, many sports with high participation rates have little or no epidemiologic reports in the literature, which limits the ability to assess a documented risk in sports participation.

A summary of studies reporting incidence rates for males and females, separated by sport, is listed in Tables 15.1 and 15.2. The highest rate of injuries in males per 1000 hours of exposure occurs in ice hockey, rugby, and soccer. Females experience the highest rate of injury per 1000 hours of exposure in basketball and gymnastics. When injury data are normalized to the number of athletic exposures rather than hours of exposure, higher incidence rates are noted in cross-country running for males and soccer and cross-country running for females.[69] With respect to age and participation level, young males appear to experience higher rates of injury as they age.[68] Authors theorized that as males grow in body mass, strength, and speed, they have the ability to create greater forces and increase the risk of injury.[68,69] Females also grow with respect to height and mass through pubertal maturation, but they may not experience the coinciding development of strength and speed at the same pace as males. This may result in a similar change in risk of injury; however, the increase may be derived from a different mechanism than that theorized in males.

Anatomic Location

In regard to anatomic location, the incidence of lower extremity injury in children is greatest across many sports, including basketball, football, gymnastics, soccer, and track and field.[68] Other sports, such as baseball,[68] snowboarding,[169] judo,[332] and tennis,[206] result in a greater incidence of upper extremity injuries. Still others, such as wrestling, result in a higher incidence of head injuries.[182] Collectively, the anatomic location with the greatest incidence of injury in children is the lower extremity, particularly the knee and ankle.[68]

Incidence of Acute Injuries

Acute injuries, often from emergency room visit data, have been reported in the epidemiologic literature for years. Taylor and Attia[399] reviewed all sports-related injuries in children between 5 and 18 years of age seen in an emergency room over a 2-year period. They reported 677 injuries, 71% in males. Sports most commonly implicated were basketball (19.5%), football (17.1%), baseball/softball (14.9%), soccer (14.2%), inline skating (5.7%), and hockey (4.6%). Sprains and strains were the most frequent types of injuries, followed by fracture, contusions, and lacerations; these accounted for 90% of all injuries. The National Health Interview Survey estimated that the sports-related injury rate for 5- to 24-year-olds was 42% higher than the estimates based on emergency room visits. The highest rate (59.3%) was for 5- to 14-year-olds.[96] Lenaway and colleagues[234] noted that middle school/junior high students had the highest injury rate, followed by elementary school students and then high school students. Sports, which accounted for 53% of all injuries, were an increasing cause of injury as grade level increased. Location of injury was the playground for elementary ages, the athletic field for middle school students, and the gym for high school students.

Incidence of Overuse Injuries

Of more recent concern is the rising incidence of overuse injuries in the pediatric population. Once thought to be a rare occurrence in children, overuse injuries are now estimated to make up more than 50% of injuries in this population.[298] This measure is likely a conservative estimate because, unlike acute injuries, which often require immediate medical attention and facilitate data tracking, overuse injuries are often self-managed and as a result are typically underreported. Micheli and Nielson[277] reported the mechanism behind this increase in overuse injury is likely due to increased participation in sports and, more specifically, a tendency toward sports specialization in greater numbers of children. Other factors may include an increase in complexity and duration of training at a young age, which increases stress to a growing body, and a lack of appropriate coaching and skill training. Specific risk factors for stress fractures and other overuse injuries typically seen in a younger, athletic population are outlined later in this chapter.

Alternative Sports

Children and adolescents are becoming more involved in extreme variations of sports as well as increased risk-taking with everyday sports. Various authors have noted significant injury rates with cycling,[150,430] exer-cycling,[40] riding in all-terrain vehicles,[60,204,289] diving,[102] snowboarding and skiing,[117,177,297,387] and inline skate, skateboard, or scooter use.[255,297,301,338] Although many of these injuries are contusions, fractures, and sprains/strains, authors noted significant cases of abdominal trauma with damage to the kidney, pancreas, or liver; head and neck injury; and hand trauma. A multicenter study[235] evaluating pediatric cervical spine injuries reported that sports accounted for as many cervical spine injuries as motor vehicle crashes among 8- to 15-year-olds.

Catastrophic Injuries

The incidence of catastrophic injuries and fatalities at the high school and college level has been documented for the years 1982 through 2013, with 2101 catastrophic sports-related injuries and illnesses.[288] The majority of these injuries were at the high school level (80.8%) and directly attributed to the sport-related activities (66.3% acute traumatic). Of these injuries, nearly 42% were fatal with the remaining nonfatal injuries (1221) leading to permanent functional disability or dysfunction (47%) or full recovery (53%). The most recent data from the National Center for Catastrophic Sport Injury Research report 41 catastrophic injuries in high school (n = 29) and college (n = 12) level sports, a rate of 0.53 injuries per 100,000 participants.[288] Football is associated with the greatest

number of catastrophic injuries, although data from the 2012 season indicate lower numbers of catastrophic injuries compared to previous seasons. Brain and cervical spine injuries account for most direct injures, with heart and heat-related illness as the major causes of indirect deaths. Head injuries are the primary anatomic area injured in ice hockey at the high school level, with body checking being the primary mechanism for all ice hockey injuries.[39] National Amateur Baseball Catastrophic Injury Surveillance Program data showed annual fatality, nonfatal catastrophic injury, and serious catastrophic injury rates of between 0.03 to 0.05 per 100,000 participants, with an average of 2 deaths per year in youth baseball from 1996–2006.[351] These deaths resulted from impact to the head and from blunt chest impact.[351]

Sex Differences in Injury Rates

Significant attention has been directed to differences in types and rates of injuries in males and females. A recent study[395] compared differences between males and females in pediatric sports-related injuries that included a random sample of 2133 medical records of children aged 5 to 17 years from 2000 to 2009 at a large pediatric hospital. Female athletes had a higher percentage of overuse injuries (62.5%) compared with traumatic injuries (37.5%), whereas the opposite was observed in male athletes (41.9% vs. 58.2%, respectively).[395] By body region, females sustained more injuries to the lower extremity (65.8%) and spine (11.3%) compared to males (53.7% and 8.2%, respectively).[395] In the upper extremity, males had a greater percentage of injuries compared to females (29.8% vs. 15.1%, respectively).[395] At the hip/pelvis, female athletes sustained more overuse (90.9%) and soft tissue (75.3%) injuries compared to males, who sustained more traumatic (58.3%) and bony (55.6%) injuries.[395] In particular, the percentage of females with patellofemoral pain was approximately three times greater than males (14.3% vs. 4.0%, respectively), while males were twice as likely to be diagnosed with osteochondritis dissecans (8.6% vs. 4.3%, respectively) and fractures (19.5% vs. 8.2%, respectively).[395] The percentage of males and females who sustained anterior cruciate ligament injury was nearly equal (10.0% vs. 8.9%).[395] When evaluating injury rates between males and females by sport, Loes and colleagues[111] reported that the risk of knee injury was significantly higher for women ages 14 to 20 years than men of the same age in cross-country and downhill skiing, gymnastics, volleyball, basketball, and handball. Hosea and colleagues[186] reported increased risk for grade 1 ankle sprains in women basketball players.

Sex differences in incidents of anterior cruciate ligament (ACL) injuries have been a focus of pediatric sports-related research. There has been an increase in the incidence of ACL rupture in skeletally immature athletes over the past 20

years.[126,212,213,382,383] Among skeletally immature athletes, ACL tears are more common in males. It is thought that this is a result of males participating in more demanding organized sports at an earlier age than females.[342] However, this trend reverses upon reaching skeletal maturity, with females sustaining more complete ACL tears than males.[342] Skeletally mature females are 2 to 10 times more likely to sustain an ACL injury than their male counterparts.[349] The underlying mechanism of female sex disparity in ACL injury risk may be rooted in sex-specific changes that occur during pubertal development. Risk factors for primary ACL noncontact injury, specifically for the female athlete, include structural/anatomic,[180] hormonal,[183] biomechanical, and neuromuscular factors.[181]

PREVENTION OF INJURIES

The key to management of sports injuries in children is prevention. As discussed in Chapter 6, children need proper physiologic conditioning, strength, and flexibility to participate safely in an organized or recreational athletic endeavor. Although lack of fitness, strength, and flexibility does not preclude participation, remediation must be built into conditioning and training programs to decrease the risk of injury. The major elements in the process of injury risk management are preparticipation examination, conditioning and training, proper supervision, protection of the body, and environmental control.[391]

Preparticipation Examination

The preparticipation examination (PPE) is a step in the process of injury prevention. The American Medical Association Committee on Medical Aspects of Sports constructed a Bill of Rights for the Athlete, one part of which is a thorough preseason history and medical examination.[16] The underlying goal of a PPE is to ensure the safety and health of athletes during training and athletic participation.[388] The original primary objectives of the PPE were to (1) determine the general health of the athlete and detect conditions that place the participant at additional risk, (2) identify relative or absolute medical contraindications to participation, (3) identify sports that may be played safely by the individual, (4) serve as a limited general health screening, (5) fulfill legal and insurance requirements, and (6) evaluate physical maturation.[245] Although the goals and implementation of the PPE have evolved over the years, and continue to do so, most agree that they involve the "attempt (of the PPE) to identify those conditions that may place an athlete at increased risk and affect safe participation in organized sports."[95]

The fourth edition of the Preparticipation Physical Evaluation (PPE-4)[10] contains the most current guidelines for implementation of the PPE, with the primary objectives of screening for conditions that may be life threatening or disabling and screening for conditions that may predispose to injury or illness.[270,367] Although the efficacy of the PPE pertaining to these objectives is debated,[95] recent work[429] highlights the need for a comprehensive and uniformly administered approach to PPE, thought to allow for the best opportunity to screen health risk.[10,367] Most states require either an individual examination or a multistation screening, with a protocol that should be comprehensive within available resources.[10] The primary physician performing an individual examination knows or has access to the athlete's health records, can discuss sensitive health or personal issues, and may be most qualified to oversee any necessary follow-up care. The time and cost are a disadvantage of the individual examination.

TABLE 15.3 Preparticipation Physical Examination Stations and Professional Experts for Athlete Assessment

Station	Personnel
Sign-in/instructions	Ancillary personnel/coach
Height/weight/vital signs	Nurse, nurse practitioner, exercise physiologist, athletic trainer, or physical therapist
Visual examination	Nurse, nurse practitioner, or coach
Dental examination	Dentist
Medical examination	Internist or family practitioner
Orthopedic evaluation	Physician or physical therapist
Flexibility assessment	Physical therapist or athletic trainer
Strength evaluation	Physical therapist, athletic trainer, or exercise physiologist
Body composition	Exercise physiologist, physical therapist, or athletic trainer
Speed, agility, power, balance, endurance	Exercise physiologist, coach, or athletic trainer
Assessment/clearance	Physician

Additionally, disparate knowledge and interest among physicians regarding sports and the requirements to participate may hinder effective evaluation for all participants. The multistation approach to PPE is more cost and time efficient and provides a thorough and appropriate screening for all potential participants. Professional experts assess each athlete in the area of her or his specialization (Table 15.3), with the team physician consulting the appropriate specializations.[367] State regulations may dictate which medical has the final decision for clearing an athlete for participation, as well as what other providers, aside from physicians, can perform evaluations.[367] The timing and frequency of the PPE are often debated and vary depending on level of the athlete. PPE should be performed with enough time prior to the athletic season to allow for the treatment or rehabilitation of identified problems,[367] with recommendations of at least 6 weeks prior to the start of participation.[245,324] At the collegiate level, athletes often undergo a comprehensive health examination prior to entry with annual examinations thereafter, as dictated by university/college policy.[367] Younger athletes may be required to participate in a comprehensive PPE annually, or every 2 to 3 years with annual updates.[10,367] In this model a complete entry-level examination and evaluation are followed by annual reevaluation that includes a brief physical examination, a physical maturity assessment, and an examination/evaluation of all new problems. The American Academy of Pediatrics[12] has recommended a biannual complete evaluation followed by an interim history before each season. The schedule that meets the primary objectives of the academy, however, is a complete entry-level evaluation followed by a limited annual reevaluation that includes a brief medical examination (to evaluate height, weight, blood pressure, and pulse; perform auscultation; examine the skin; and test visual acuity) and an evaluation of all new problems.

The components of the PPE are the medical history; the medical examination, including cardiovascular and eye examinations; a musculoskeletal assessment; body composition and height and weight determination; specific field testing; and an assessment of readiness, both physical and psychological. Research has identified alterations in movement mechanics, landing patterns, and functional performance that are associated with increased risk of sports-related injuries.[322] As such,

dynamic functional performance assessments may be implemented into PPE, although this is not standard practice. The components of the examination should be tailored to the specific demands of the sport.

History

The medical history is the cornerstone of the medical evaluation [85,245] and identifies the majority of problems affecting athletes.[157] Short forms that are easy to complete, written in lay terms, and understandable to young athletes are preferable. Forms should be completed by both the athlete and parent/guardian to obtain an accurate and complete history.[85] Content areas that should be particularly noted include exercise-induced syncope or asthma; family history of cardiac problems including heart disease or sudden death; history of loss of consciousness, concussion, or neurologic conditions; history of heat injury or stroke; medications; allergies; history of musculoskeletal dysfunction or activity-related injury or joint trauma; history of acute illness; dates of hospitalizations or surgery; absence or loss of a paired organ; immunizations; female maturation including menstrual history; and eating/dieting patterns. A standard form is recommended by the PPE-4.[10]

Medical Examination

The medical examination is used to evaluate areas of concern identified in the history.[17] The minimally sufficient examination includes cardiovascular (including blood pressure, pulse, respiration) and eye examinations, and a review of all body systems. Both the American Heart Association[258] and PPE-4[10] describe cardiovascular screening procedures and recommendations. It is recommended that athletes with heart rate over 120 beats/minute, arrhythmias, or systolic or diastolic murmurs be referred for further examination.[367] Asthma screening should also be completed, including documentation of medications.

Visual acuity is often tested using a Snelling chart and should be correctable to 20/200. Any inequality of pupil diameter or reactivity should be noted so responses after potential injury can be compared with this baseline value. Uncorrectable legal blindness (acuity less than 20/200 or absence of an eye) requires counseling regarding participation in collision or contact sports. The importance of protective eyewear for athletes who wear glasses or have unilateral vision should be stressed.[33]

Abdominal assessment determines rigidity, tenderness, organomegaly, or the presence of masses. Participation by any athlete with organomegaly is restricted until further tests determine the cause of the enlarged organ.[33]

Careful examination of the skin is vital in examination of all persons, but it is particularly important for those who will participate in contact sports. Participation in these sports should be deferred for children with evidence of any communicable skin disease, such as impetigo, carbuncles, herpes, scabies, and louse or fungal infections.[245]

Genitourinary examination of males is used to assess the child for testicular presence, descended testicles, and possible inguinal hernia. The genital examination is deferred in girls unless a history of amenorrhea or menstrual irregularity warrants referral. A maturational index, such as Tanner staging, is no longer recommended as part of a routine PPE because there are no data to indicate this leads to injury reduction.[91]

A more thorough neurologic examination is performed in athletes with a history of head injuries or neuropraxias.[324] Documentation of baseline values is important should a subsequent injury occur. Examination may include neck/upper extremity range of motion, strength, sensation, reflexes, and other special tests.[10,324]

A musculoskeletal and orthopaedic screening and examination may be combined for asymptomatic athletes with no history of previous injuries.[95] If an athlete has an injury history or other signs of symptoms during a general screening, a more site-specific examination should be performed.[95]

Musculoskeletal Examination

Although no specific components are required, tests/examinations of flexibility, gait, muscle performance, and joint laxity, as well as a review of prior injury, are frequently included.[367] Assessment of posture with particular attention to atrophy, spinal asymmetry, pelvic level, discrepancy of leg lengths, and lower extremity deformities such as genu valgus or varus, patellar deformities, and pes planus is also part of a musculoskeletal examination. Gait should be examined with the athlete walking and running, as well as walking on toes and heels. Passive range of motion and two-joint musculotendinous flexibility should be screened. Muscle strength can be assessed using a manual muscle test, handheld dynamometer, or isokinetic device. Special stability testing of the shoulders, knees, and ankles should be conducted if the child has had a previous injury or if the current assessment indicates that instability may be present. Dynamic functional performance assessments, general and sports specific, may also be implemented to identify potential injury risk.

Medication Use

The PPE can be utilized to screen for involvement in risky health behaviors such as tobacco and alcohol use and use of recreational drugs or ergogenic aids. All medications and supplements currently used by the athlete should be reviewed by the examiner.[95]

From 3% to 12% of adolescent males and 1% to 2% of females report having used steroids.[24,432] The most compelling reasons for taking steroids are to increase body weight and muscle mass, decrease fatigue, and increase aggressive behavior. The adverse effects of steroid use include hypertension, hepatitis, testicular atrophy, loss of libido, hepatic carcinoma, and premature epiphyseal closure.[48] Warning signs of steroid abuse include irritability; sudden mood swings; puffiness in face, upper arms, and chest; sudden increases in blood pressure and weight; yellowish coloration around the fingernails and eyes; hirsutism; and deepening of voice and acne in girls.[262] Other substances that have been utilized to increase muscle performance include DHEA (dehydroepiandrosterone), branched chain and essential amino acids, creatine, growth hormone, and dietary supplements containing nandrolone and testosterone. Designer steroids have been introduced to provide the effects of steroid use but avoid detection. Other dietary substances including ephedra and carnitine have been utilized to increase energy and endurance, suppress appetite, and promote weight loss.[38,170] These natural elements have been touted in popular literature as aids for growth, performance, immunity, and healing and are used by both high school and college athletes, as well as professional athletes. Research has not supported the efficacy of these substances for performance enhancement with the exception of creatine[378] and carnitine.[218] Existing research has examined these substances in young adults; no research has been done in the pediatric population under the age of 18 years. Research has reported potential risk and harm with ingestion

of substantial amounts of several substances, including steroids and nandrolone, ephedra, and branched chain amino acids. The use of ephedrine-containing compounds has been banned by most professional and collegiate sports organizations, as well as the National Federation of State High School Associations.

Diuretics are frequently used to "make weight" for an event or to mask drug usage. Performance may, however, decrease as a result of dehydration or electrolyte losses.[48,262] Likewise, stimulants such as caffeine and amphetamines are commonly abused in an effort to increase performance in sports. They serve only to mask normal fatigue and to increase aggression, hostility, and uncooperativeness and can lead to addiction and death.[419]

The use of barbiturates, antidepressants, and beta-blockers has been noted in sports in which fine control is required, such as shooting and archery. Although they do calm the nervous system and lower heart rate, even therapeutic doses may cause bronchospasm, hypotension, and bradycardia.[280]

The use of recreational drugs, including nicotine, smokeless tobacco, alcohol, marijuana, cocaine, and even heroin, is increasing among youth. Symptoms such as agitation, restlessness, insomnia, difficulty with short-term memory or concentration, and decline in performance might signal behavior indicative of substance abuse.[89,160]

Specific Field Tests

Field testing is done to assess specific athletic potential in a specific sport. The components assessed are muscle strength, muscle power, endurance, speed, agility and flexibility, and cardiovascular performance. Field test performance has been shown to identify deficits from previous injury that standard physical examination may not define.[295]

General muscle strength can be assessed with a maximal activity pertinent to the sport, such as bench presses, pull-ups, or push-ups for the upper extremities and leg presses or sit-ups for the lower extremities. Endurance can be assessed by performing as many repetitions of the task as possible. Muscle power can be evaluated with vertical jumping, performing a standing long jump, or throwing a medicine ball, as appropriate.

Speed is evaluated using a 40- or 50-yard dash, and agility can be assessed with the Vodak agility test[147] or a similar battery of tests. The most common, standardized methods of assessing flexibility are the sit and reach test, which has norms for children, and active knee extension performed in a supine position with the hips flexed to 90°.[189] Cardiovascular performance is most easily assessed using a submaximal test on an appropriate device, such as a cycle ergometer, treadmill, or upper-body ergometer. A field test for cardiovascular performance is the 12-minute run or the timed 1.5-mile run.[33,65,229] Field tests that involve jumping and sprinting have been correlated to laboratory results.[29]

Limitations and Outcomes of the PPE

Despite efforts to create a thorough and comprehensive PPE, it is not without limitations. The PPE is designed to identify life-threatening contraindications to sports participation. In addition, the PPE is able to identify various static musculoskeletal deficiencies. However, often some PPE settings do not address more dynamic risk factors. More concerning is the lack of follow-up that may occur if deficits are identified. McKeag et al.[269] reported 10% of athletes receiving a PPE present with a musculoskeletal disorder; however, others have noted that only 1% to 3% of athletes are referred for intervention following a PPE.[390] Although many athletes are identified with musculoskeletal deficits, the deficits are often not addressed. Future work should focus on increasing the ability of the PPE to identify dynamic risk factors for injury and create a more seamless approach to recommend intervention for those athletes who are identified at risk.

The outcome of the PPE determines the level of clearance to participate in sports. Clearance can be unrestricted for any sport or restricted to specific types of sports in the following manner: (1) no collision (violent, direct impact) or contact (physical touching), (2) limited contact or impact, or (3) noncontact only. The American Academy of Pediatrics has developed a classification system for sports activities and recommendations for restriction of participation that are excellent guides in making decisions for individual athletes.[11]

Training Program

The preseason examination clearly defines the individual athlete's areas of strength and limitations (Fig. 15.1). The next appropriate step in prevention is the development of an individualized training plan designed to address the particular problems of the athlete as they relate to the requirements of the sport(s) (Box 15.1). This program could be developed by a sports physical therapist, athletic trainer, or exercise physiologist involved in the preseason screening. Once developed, it should be taught to the athlete, the parent, and the coach.

The training program should be a systematic, progressive plan to address the athlete's weaknesses and to maximally condition the athlete for participation. Training consists of off-season, preseason, in-season, and postseason programs for year-round conditioning and for development of appropriate peak performance. Components should include energy training (aerobic foundation and anaerobic training), muscle training (strength, endurance, flexibility, and power), speed, and proper nutrition. A well-developed, variable, and well-paced program will help the young athlete to avoid boredom and potential overuse injury. The psychological effects of year-round training, or exercise in general, are controversial and not well documented. The risk-benefit ratio, however, tends to favor exercise for improvement of mood, self-concept, and work behavior when competition is sensibly controlled.[282]

BOX 15.1 Text Box for Examination

Body Functions and Structures

- Range of motion with goniometry
- Muscle strength, power, and endurance with isokinetic assessment
- Ligament integrity/stability with manual assessment
- Joint laxity with the Beighton-Horan screening
- Posture
- Gait with visual observation
- Dynamic movement assessment with visual assessment
- Functional Performance Testing with single-leg hop testing

Activities and Participation

- Tegner Activity Scale
- Marx Activity Scale
- HSS Pedi-FABS

Other (e.g., Environment, QoL when applicable)

- PedsQL

QoL, quality of life.

Athletic fitness scorecard for boys

FIG. 15.1 Athletic fitness for boys and girls. (From Gaillard B, Haskell W, Smith N, et al.: Handbook for the young athlete. Palo Alto, CA, Bull Publishing, 1978.)

Energy Training

The basis of energy training, a strong aerobic base, should be developed during the off-season. Good training consists of low-intensity, long-duration activity with natural intervals of low- and moderate-intensity work that is sport-specific. Swimming would be a good choice for the field athlete, and cycling or running is appropriate for those in track, soccer, and football. Training on hills or performance of similar resistance efforts should be executed in moderation or in an interval fashion with other activities. Children exhibit less efficient movement patterns and a lower maximal acidosis level. Their greater surface area–to–body mass ratio facilitates greater heat gain on hot days and greater heat loss on colder days. Children produce less sweat and less total evaporative heat loss. Children

produce more metabolic heat per pound of body weight during exercises, such as walking and running. Finally, although children can acclimatize, they do so at a slower rate than adults.[125] Consequently, intense training in the extreme heat and hard training involving long durations should be minimized until puberty.

Anaerobic training programs consist of exertion at 85% to 90% of maximal heart rate for short periods. Anaerobic fitness is a person's ability to generate a high level of mechanical power over a short period of time. Optimal training levels to achieve peak anaerobic fitness are often debated; however, biweekly anaerobic training is often recommended for maximal benefit. Methods including interval training, fartlek (speed play, or alternate fast and slow running in natural terrain), and pace training are variations of the anaerobic method. Sport-specific anaerobic skills should be developed during preseason and early-season activities.[288] Young children are less capable to see significant increases in anaerobic fitness due to anatomic and physiologic differences in the skeletally immature athlete. As a result, this training is difficult for young athletes and has less impactful fitness benefits until they mature. Some training should be used, however, to achieve relaxation and mechanical efficiency at these levels.

Resistance Training (Strength Training)

The use of resistance training (strength training) in prepubertal children has been controversial. Historically, clinicians and researchers believed individuals with growing bones and open growth plates should not participate in resistance training because it could potentially place the open growth plates at risk for injury. In 1983 the American Academy of Pediatrics issued a position statement that suggested that resistance training in a prepubescent athlete may not only be a high-risk activity but also may be unlikely to result in a significant increase in strength because of the lack of circulating androgens in this population. Importantly, recent evidence suggests both of these fears are unfounded, and several professional organizations now advocate appropriately implemented resistance training as an intervention for young athletes.[243]

With regard to efficacy of resistance training, several research studies have demonstrated that strength can be improved by systematic overload of muscle in postpubescent athletes with results similar to training in adults.[42,282] The mechanism of this gain in strength is likely related to neural adaptations in the muscle and not secondary to an increase in cross-sectional area or hypertrophy of muscle tissue.[122] Similar to an adult who initiates a resistance training program, initial gains in strength in the first 4 to 6 weeks after onset of training are due to neural adaptations in the muscle. Only after this initial neuromuscular change do adults see a change in their muscle diameter, which may result in continued progression of strength. Children have the potential to experience a similar neuromuscular adaptation, which can increase strength despite the absence of circulating androgens, once thought to be necessary to see any increase in strength.[123,167]

Safety during resistance training is a priority in a population of young athletes. Initial epidemiology data regarding injuries during resistance training suggested a high incidence of injury in a population of young individuals. However, more recent evidence suggests the incidence of injury is relatively low and, with certain precautions, this risk can be reduced even further.[290] Many of the injuries reported by Myer and colleagues identify accidents as the primary cause of injury in the weight room with a young population. As a result, current guidelines regarding resistance training in young athletes suggest appropriate supervision be present at all times to minimize the chance of these accidental injuries. In fact, professional organizations such as the American College of Sports Medicine, the National Strength and Conditioning Association, and the American Academy of Pediatrics suggest that resistance training is a safe and effective intervention in young athletes.[122] Furthermore, resistance training has also been shown to be effective in reducing various lower extremity injuries.[233]

Through the joint contributions of these professional organizations, a general consensus on the safe initiation of resistance training in a young population has been issued.[290] These recommendations suggest a young athlete should have sufficient emotional maturity to accept and follow directions prior to initiating a resistance training program. Appropriate supervision should be available at all times to reduce the risk of accidental injuries and also to provide regular feedback regarding the "technique" of each lift. A primary goal of the onset of a resistance training program is to develop good lifting technique at an early age. Supervision is necessary to ensure this development. Finally, a dynamic warm-up is always recommended, and an appropriate volume and intensity of each activity should be initiated and monitored. Specifically, young athletes should avoid executing one maximum repetition and should focus on the use of lighter weight with higher sets and repetitions rather than using lower sets and striving to gain power. Together, these factors have resulted in a safer and more efficacious algorithm for resistance training participation by young athletes.

Speed

Current evidence suggests the proportion of fast twitch fibers in muscle is largely determined by genetic code, with little potential to change fiber type. Hence speed is somewhat genetically determined. All athletes, however, can train the intermediate muscle fibers and improve the components of reaction and movement time. This can result in relative improvements in speed and quickness.[227] Faster reactions are taught in sport-specific practice drills, such as starts, acceleration drills, or play drills, that gradually narrow choice. Movement time is enhanced from a base of flexibility and strength with ballistic motions, sprint loading (explosive jump or throw), overspeed, or resisted sprinting.[381]

Proper Supervision

The first in the series of supervisors is the coach, the key to a successful sports program. However, 2.5 million adult volunteers with varying levels of expertise coach approximately 20 million children. The American Academy of Pediatrics has stated that coaches should encourage preparticipation screenings annually, enforce use of warm-up procedures, require suitable protective equipment, and enforce rules concerning safety. In addition, it recommends completion of a certification program that covers teaching techniques, basic sports skills, fitness, first aid, sportsmanship, enhancement of self-image, and motivational skills.[12]

Qualified officials and professional medical personnel at games and practices are the second level of supervision. These individuals provide game control and immediate injury containment onsite. Medical personnel could include physicians,

physical therapists, or athletic trainers who have certification in basic first aid and cardiopulmonary resuscitation techniques in addition to their medical skills.[12,343]

Protection

Outfitting the child athlete with proper equipment should be mandated and enforced for the protection of the participants. Equipment must be appropriate for the sport. High quality and proper fit are essential to correct function. Proper footwear with adequate cushioning, rearfoot control, and sole flexibility for the sport should be required.[282] Protective padding in contact or kicking sports, such as shoulder and shin pads, should be required.

Protective headgear for contact and collision in football, baseball, and hockey is necessary to limit the number of head and neck injuries. Schuller and colleagues[375] have demonstrated a lower risk of auricular damage in wrestlers wearing headgear (26% incidence) versus those with no headgear (52% incidence). Helmets should be approved by the National Operating Committee on Standards for Athletic Equipment (NOCSAE) and the American National Safety Institute.[307,327]

Eye injuries remain a common occurrence in athletics with nearly 40,000 sports-related eye injuries reported in the National Electronic Injury Surveillance System Database.[416] It is estimated that as many as 90% are preventable.[331] Eye protectors that dissipate injury to a wider area without reducing visual field should be required in racquet sports, ice hockey, baseball, basketball, and football and during use of air-powered weapons. They should be cosmetically and functionally acceptable and made of impact-resistant material. Polycarbonate is the most impact- and scratch-resistant material. A list of high-risk sports and recommended protection is given in Table 15.4. All eye protectors should be approved by either the Canadian Standards Association or the American Society for Testing and Materials.

Studies have highlighted the incidence of oral and facial injuries in many sports, particularly football, hockey, baseball, basketball, wrestling, and boxing.[148] Before mandatory use of mouthguards, oral trauma constituted 50% of all football injuries.[272] The mandatory use of mouthguards has cut the injury rate of oral trauma in football to fewer than 1% of all injuries.[205] The mouth protector serves to prevent injury to the teeth and lacerations of the mouth. Because it absorbs blows to the oral and facial structures, it also prevents fractures and dislocations. It should position the bite so the condyles of the mandible do not contact the fossae of the joints. These mouthguards should be inexpensive, strong, and easy to clean and should not interfere with speech or breathing. They should be used alone in field hockey, rugby, wrestling, basketball, and other field events and used in conjunction with face protectors in football, ice hockey, baseball, and lacrosse.

Environmental Control

Assessment and control of the environment are also vital to the safety of the child athlete. The playing area should have adequate lighting and be maintained for safety. Surfaces should be free from obstacles and smooth and even, with good shock-absorbing qualities (wood as opposed to concrete). Modifications of equipment that have been shown to decrease injury (e.g., breakaway bases) should be installed. Sports equipment and playing environments should be scaled down to the size of the athlete.[282]

TABLE 15.4 Risk Level for Eye Injury With Recommendations for Protective Eyewear

Risk	Sport	Protective Wear
Unacceptable	Boxing	Not applicable
Very high	Ice hockey	Helmet with full visor
	Squash	Polycarbonate sports protector
	Badminton	Polycarbonate sports protector
	Basketball	Polycarbonate sports protector
	Men's lacrosse	Helmet with full visor
High	Racquetball	Polycarbonate sports protector
	Baseball	Polycarbonate sports protector
	Cricket	Helmet with full visor
	Field hockey	Helmet with full visor
	Rugby football	Debatable
	Soccer	Debatable
	Water polo	Polycarbonate goggles
	Shooting	Polycarbonate sports protector
	Women's lacrosse	Helmet with full visor
Moderate	Tennis	Plastic lens spectacles
	American football	Helmet with polycarbonate visor
Low	Golf	Sports protector if one-eyed
	Volleyball	Sports protector if one-eyed
	Skiing	UV filter goggles ± helmet
	Cycling	Sports protector ± helmet
	Fishing	Polycarbonate protector if one-eyed
	Swimming	Goggles if in water for long periods
	High diving	Not feasible
	Track and field	None required

From Jones N: Eye injury in sport. Sports Med 7:163-181, 1989.

Ambient temperature and humidity should be carefully monitored. During exercise, children require more fluid replacement per kilogram of body weight than adults to avoid dehydration. Children have a greater surface area per body weight, so their rate of heat exchange is greater with lower ability to endure exercise in climatic extremes. They also have a distinctly deficient ability to perspire, so they carry a larger heat load. They acclimatize less efficiently and require more "exposures" for acclimatization to occur.[350] Exercise should be modified if the wet bulb temperature (an index of climatic heat stress) is above 75°F.[13]

Dehydration can be avoided by drinking plenty of liquid before, during, and after play. Thirst is not a valid indicator of the amount of water needed, so every pound (16 oz) lost should be replaced with two cups (16 oz) of water.[329] The American College of Sports Medicine[8] recommends that 400 to 500 mL of water be ingested before distance running. It further recommends water intake every 35 to 45 minutes of football practice and nude weighing before and after practice. If residual weight loss from day to day exceeds 2 to 3 lb, practice is restricted until water is replenished. Recommendations for hydration include prehydration of 3 to 12 oz (3 to 6 oz for < 90 lb; 6 to 12 oz for > 90 lb weight) 1 hour before activity, and 3 to 6 oz just prior to activity. During activity 3 to 9 oz (3 to 5 oz for < 90 lb; 6 to 9 oz for > 90 lb) should be ingested every 10 to 20 minutes relative to the temperature and humidity. Eight to 12 oz should be consumed for each pound of weight lost in 2 to 4 hours following activity (Table 15.5).[75]

TABLE 15.5 Recommended Fluid Intake and Availability for a 90-Minute Practice

WEIGHT LOSS		Minutes Between Water Break	FLUID PER BREAK	
Lb	Kg		Oz	Ml
8	3.6	*		
7.5	3.4	*		
7	3.2	10	8–10	266

*No practice recommended.
From Peterson M, Peterson K: Eat to compete: a guide to sports nutrition. Chicago, Year Book Medical, 1988,

Successful hydration programs involve not only fluid intake but also fluid availability. Cool fluids infuse into the system more readily, so accessible liquids should be chilled or ice provided. Education of everyone involved with the activity, including parents and participants, is of paramount importance to ensure continued compliance. Knowledge of the common signs of dehydration—irritability, headache, nausea, dizziness, weakness, cramps, abdominal distress, and decreased performance—assist those involved with early recognition and intervention.[75]

RISK FACTORS FOR INJURY

Injury can be the result of a single macrotrauma or of repetitive microtrauma.[277] Seven risk factors for repetitive trauma, or "overuse," have been identified: (1) training errors; (2) musculotendinous imbalances of strength and/or flexibility; (3) anatomic malalignment of the lower extremity; (4) improper footwear; (5) faulty playing surface; (6) associated disease states of the lower extremity such as old injury or arthritis; and (7) growth factors.[249,275,398]

Training Error

Training error is frequently the cause of overuse injuries in children, as it is in adults. Dramatic increases in the total volume of activity, an increase in the rate of progression of training, or an attempt to participate at a level above the capacity of the athlete is a often identified as a mechanism of overuse injury.[4,277] The evolution of sports specialization has contributed to this phenomenon because more children are attempting to participate in several seasons of a single sport throughout the year. This results in few rest periods throughout a year and an increased focus on intense training. A sudden transition from casual, free play to 6 or 8 hours of intense participation daily, as may occur in a camp setting, has also contributed to the increased incidence of overuse injury in children.[185]

Muscle-Tendon Imbalance

Muscle-tendon imbalance can occur in strength, flexibility, or training. Until recently, little attention was paid to conditioning in children. This position may have been appropriate for free play activities but not for organized sport. The repetitive, often predictable, demands of a sport may result in imbalances of muscle and tendon unless the child is on a well-designed training plan. For example, an overhead athlete, such as a swimmer who does breast stroke, might develop a loose anterior capsule and a tight posterior capsule. This imbalance can lead to secondary shoulder impingement or excessive anterior shoulder laxity and even subluxation. Similarly, repetitive running can create strength and tightness in the quadriceps femoris and triceps surae muscles with relatively weaker hamstrings. This could be problematic if pace and hence stride length are increased.

Anatomic Malalignment

Anatomic malalignment, such as leg length difference or abnormal frontal and rotational plane alignments, can be a factor in the occurrence of injury. Anatomic malalignments may result in compensations for abnormally high forces created by the altered alignment under the demands of a sport. For example, femoral anteversion in a young dancer can cause compensatory excessive tibial external rotation and ankle pronation as substitutes for natural hip external rotation. Hyperlordosis of the spine or hyperextension of the knee creates abnormal loading on portions of the joint, leading to pain and increased risk of injury. Pes planus can increase the valgus moment at the knee, as well as allowing the weight of the body to land on a flexible foot. This malalignment can cause pain and abnormal wear on the medial knee joint and foot.

Improper Footwear and Playing Surface

Well-fitting shoes with a firm heel counter, slight heel lift, and flexible toe box are essential for the young athlete. Inadequate footwear that does not support the structures of the foot can lead to a number of foot and lower extremity problems. The shoe should compensate for changes in alignment and shock absorption. Likewise, improper playing surfaces can predispose the child to knee pain, shin splints, or stress fractures. These symptoms have been associated with playing on hard, banked surfaces or synthetic courts, as opposed to clay and hardwood surfaces.[282]

Associated Disease States

Associated disease has the potential to result in compensatory movement patterns during physical activity that may predispose athletes to overuse injuries. Conditions such as Legg-Calvé-Perthes disease (see Chapter 14) or juvenile idiopathic arthritis (see Chapter 7) may result in abnormal lower extremity alignment or abnormal movement patterns during dynamic activities, which may exacerbate joint pain or synovitis. Evaluation of dynamic movement patterns is an appropriate screening in these athletes to attempt to determine their risk for future injury.[292]

Growth Factors

The first aspect of growth that is a factor in overuse injuries is the articular cartilage (Fig. 15.2). Clinical and biomechanical evidence suggests that growing cartilage has low resistance to repetitive loading, resulting in microtrauma to either the

FIG. 15.2 Sites of susceptibility of the growth cartilage. (Redrawn from Micheli L: Overuse injuries in children's sports: the growth factor. Orthop Clin North Am 14(2):337-360, 1983.)

cartilage or the underlying growth plate. Damage may result in osteoarthritis or growth asymmetry.[275]

Growing articular cartilage is also less resistant to shear, particularly at the elbow, knee, and ankle. Repetitive shear has been implicated in osteochondritis dissecans of the capitellum in Little League pitchers and of the proximal and distal femur and talus in runners. Debate exists in the literature as to the etiology of osteochondritis dissecans; however, some authors postulate that a segment of subchondral bone becomes avascular and separates with its articular cartilage from the surrounding bone to become a loose body.[433] Shear stress has also been implicated in epiphyseal displacement.[433] The final site of growth cartilage weakness is the apophysis. The apophysis is a point of attachment of the tendon to the bone and represents an ossification center of the bone. Apophysitis is inflammation secondary to microavulsions at the bone-cartilage junction caused by repetitive motion and overuse at times of rapid growth. The apophysis will ultimately fuse as the child matures; however, until this time it is vulnerable to overuse injuries.[43] Increasing evidence suggests that traction apophysitis, such as Osgood-Schlatter disease, Sever disease, and irritation of the rectus femoris or sartorius muscle origins, is the result of degeneration of the growth center with tiny avulsion fractures and associated healing.[316,321]

The second element of growth involved in overuse injury is abnormal stress created by longitudinal growth. Long bone, longitudinal growth occurs initially in the bones, with secondary elongation of the soft tissues. During periods of rapid bone growth ("growth spurts"), the musculotendinous structures tighten and cause loss of flexibility. A coincidence of overuse injury and growth spurt has been noted.[275]

The biomechanical properties of bone also change with growth and maturation. As bone becomes less cartilaginous and stiffer, the resistance to impact decreases. Sudden overload may cause the bone to bow or buckle. The epiphysis, defined as the area of growth in the long bones, is more susceptible to injury and may shear or fracture. Examples of this process include avulsion fracture of the ACL, avulsion fracture of the ankle ligament, and growth plate fractures. Because fractures through the epiphysis can be difficult to visualize on radiographs, any injury to the epiphyseal area is considered a fracture and is treated as such in order to avoid potential growth disturbance.[250] Growth plate fractures are typically classified with a Salter-Harris classification system. Salter-Harris I fractures represent a traction injury to the growth plate. More significant Salter-Harris II–V fractures involve additional portions of the bone and may represent more significant injuries that may affect growth.[364]

TYPES OF INJURIES

Although injuries in children have some similarity to those in adults, several are unique to the growing child. These specific injuries fall into three categories: (1) fractures, (2) joint injuries, and (3) muscle-tendon unit injuries.[152,275]

Fractures

A relatively new injury in children is the stress fracture, which usually results from repetitive microtrauma or poor training. Repetition causes cancellous bone fractures as opposed to cortical bone fatigue in adults.[90,249] These cancellous bone fractures are often imperceptible on radiographs until 6 to 8 weeks after the onset of pain. Clinical signs and symptoms indicative of a stress fracture can be confirmed by imaging tools, such as a bone scan or magnetic resonance imaging (MRI), to appropriately diagnose this condition. Stress fractures cause persistent, activity-related pain that can be reproduced by indirect force to the bone.

Growth plate or epiphyseal fractures are unique to the child. The cartilaginous growth plate is less resistant to shear or tensile-deforming force than either the ligament or bony cortex, so mechanical disruption frequently occurs through the plate itself, usually in the zone of hypertrophy.[249] This disruption can be caused by a single macrotrauma, such as jumping, or by repetitive microtrauma as in distance running. The potential for problems from epiphyseal fracture depends on the specific plate involved and on the extent of the injury. Physeal fractures are often classified according to a system proposed by Salter and Harris (Type I, fracture line within the physis; Type II, fracture line also extends to metaphysis; Type III, fracture line begins in physis and exits through epiphysis toward the joint; Type IV, involves a vertical split of the epiphysis, physis, and metaphysis; and Type V, involves crush injuries to the physeal plate).[119,364] The risk of growth disturbance following a physeal injury will vary depending on the nature of the injury and the individual's characteristics (i.e., injury during adolescence when growth is accelerated).[119] Shaft fractures are more common in the older child who is approaching adult status.[133]

Joint Injuries

Joint injuries in the young athlete include fractures (discussed above), ligamentous sprains, and other internal derangement. These injuries may result from a single discrete injury or from repetitive microtrauma. The diagnosis of ligament sprain must be made carefully in the child. During a growth spurt, ligaments may be stronger than the growth plate, so excessive bending or twisting forces cause the growth plate rather than the ligament to yield. Careful clinical examination and evaluation including physical examination (with special testing) and assessment of the mechanism of injury can assist in accurate differential diagnosis. Differential diagnosis can be further aided by imaging studies. The clinical assessment of ligamentous integrity can be complicated by the variability in anatomy and tendency for greater physiologic laxity, emphasizing the importance of side-to-side comparisons with ligamentous and soft tissue integrity examination. Often concomitant with ligament injuries are internal derangement of the joint, including meniscus (in

the knee) and chondral injury. Although the true incidence of meniscus tears (knee) and chondral involvement in children is not known, there is a rise in the occurrence or recognition of these injuries in the pediatric and adolescent population.

Muscle-Tendon Unit Injuries

Another area at particular risk of injury in the growing child is the insertion of the musculotendinous unit into the bone through the apophyseal cartilage. Growth occurs at the apophyseal growth plate, where tendons and ligaments are attached. During growth spurts the increased tension on the attachments often leads to detachment of the structure at the apophysis (avulsion fracture). Tendonitis occurs much less frequently in the child than in the adult because the insertion becomes symptomatic before the tendon.[4]

Irritation of the insertional area of the musculotendinous unit, the enthesis, can cause pain and inflammation. This area is highly vascular and metabolically active. Pain and inflammation can cause inhibition of muscle activity with resultant weakness and loss of flexibility, potentially initiating a cycle of greater irritation and pain. In addition to experiencing acute injuries, children can overuse muscles, resulting in strain, just like adults. Children may also sustain injury or irritation to growth plates due to traction apophysitis from muscle attachment; such is the case with Osgood-Schlatter disease and Sinding-Larson-Johansson disease.

SITES OF INJURY

Mechanism, presentation, and management of injuries in children are often unique when compared to adult populations secondary to their developing anatomy and periods of rapid growth. The following sections will discuss the unique aspects of these various conditions in the pediatric and adolescent athlete.

Concussions

Concussion was defined at the Fourth International Conference on Concussion as "a complex pathophysiologic process affecting the brain, induced by traumatic biomechanical forces."[268] Generally, a concussion results from either compression, tensile, or shearing forces imposed on the brain and can be caused by a direct blow to the head, face, or neck or an impact to any body part that results in an impulsive force that is transmitted to the head.[268] It is important to recognize that a concussion may or may not result in a loss of consciousness.[268] Symptoms and signs from a concussion often emerge immediately following the injury; however, they may also evolve and develop over several hours, days, or even weeks.[82,268] Diagnosis of a concussion is typically indicated by new onset or worsening of at least one of the following criteria after a suspected head injury has occurred[254,268]:

- Any period of loss of or decreased level of consciousness
- A loss of memory for events immediately before or after the injury
- Any alteration in mental state at the time of injury such as confusion, disorientation, slowed thinking
- Signs or symptoms such as headache, slowed reaction times, dizziness, nausea, vomiting, sleep disturbances, irritability, emotional lability, feeling like in a fog, difficulty concentrating, visual disturbances, sensitivity to light or sound

Historically concussions have been viewed as relatively benign injuries. However, mounting evidence indicates that concussions can lead to multiple short-term impairments and potential long-term adverse outcomes such as cognitive declines, persistent motor control deficits, and actual structural changes in the brain (e.g., chronic traumatic encephalopathy).[35,103–105,252,267,268,271] Life-threatening complications from concussion include intracranial hemorrhage such as epidural and subdural hematoma. The leading cause of death from head injury is intracranial hemorrhage. Cantu and Mueller[73] reported that 86% of brain-injury deaths resulted from subdural hematoma. Symptoms of an epidural hematoma include initial preservation of consciousness with increasingly severe headache, lethargy, and focal neurologic signs. An acute subdural hematoma is the most common fatal head injury and should always be considered as a possible diagnosis in the athlete who loses and does not regain consciousness. A chronic subdural hematoma should be suspected in the athlete who is demonstrating abnormal behavior for days or weeks after a head injury. Signs may include progressive, worsening symptoms or new neurologic signs, persistent vomiting, deteriorating mental status, and the onset of seizures.[266,268] These conditions represent medical emergencies, and these patients should be immediately transported to emergency medical facilities.

Concussions Incidence

An estimated 1.6–3.8 million sport-related traumatic brain injuries occur in the United States each year,[228] a majority of which are mild traumatic brain injuries or concussions.[228] Pediatric patients make up a large portion of concussion injuries, with approximately 100,000 emergency department visits for concussion occurring for school-age children in the United States each year.[274,359] The actual incidence of concussions in youth is likely much higher because a large percentage of concussion injuries go unrecognized, unreported, or untreated.[359] Concussion rates differ by sport and gender, with boys experiencing more sports-related concussions overall, while girls have a higher concussion rate when comparing similar sports.[241,257,359] Football, ice hockey, lacrosse, and wrestling have been reported as sports with the highest risk for concussion for boys, and soccer, lacrosse, ice hockey, field hockey, and basketball are reportedly the highest-risk sports for girls.[257,359] Attempts to classify the severity of concussions have been controversial because these approaches are often dependent upon loss of consciousness and amnesia, both of which have been shown to be poor predictors of injury severity.[154]

As of February 2014, all 50 states and the District of Columbia have enacted legislation designed to help protect youth athletes. Most of these laws mandate that a child should not return to play the same day a suspected head injury has occurred and that a licensed health care provider must medically clear the athlete. Coinciding with an increase in the media attention surrounding concussive injuries and the enactment of the legislation, there has been a significant rise in health care utilization for concussive injuries as evidenced by the rates of pediatric concussion referrals to neurologists increasing by approximately 150% between 2008 and 2012.

Concussion Evaluation

Evaluation of a concussion is a multifactorial process, and a wide array of assessment tools are available to assist in the diagnosis and monitoring of concussive injuries. The initial assessment of the injury should occur on the field or at the time of injury if a potential head injury is suspected. There are a variety of sideline assessment tools that are now available such as the Sport

Concussion Assessment Tool (SCAT3) and the Child-SCAT3 (for ages 5 to 12 years).[81,368] The SCAT 3 and Child-SCAT3 are standardized tools for evaluating individuals with a suspected head injury that were designed for use by medical professionals. These tools provide specific, detailed instructions about how to conduct and record results for a series of background questions, the Glasgow coma scale, and cognitive and physical evaluation strategies.

Concussions are generally considered to represent a functional rather than a structural brain injury because in many cases conventional neuroimaging techniques such as computed tomography (CT) and MRI result in no abnormal findings.[359] However, various advanced neuroimaging techniques have demonstrated microstructural and functional brain changes in concussed individuals.[359] Even so, imaging is not often recommended for most patients with concussions as the cost and time to administer these tests do not typically result in changes in clinical management.[268,359]

It also recommended that a few days after injury patients be reassessed with neurocognitive screening techniques, symptom indices, and physical assessments. This is an area where the role of physical therapists in postconcussion care is evolving. Physical therapy evaluations for identification of postconcussion impairments in the postural control,[76-78,164,165] musculoskeletal,[373] vestibular/oculomotor,[377,415] and cardiovascular systems are becoming more common.[217,230-232] Much like the screening tools that are available for sideline assessments of concussions, a variety of options and strategies for screening for potential postconcussion impairments in patients in physical therapy clinics are also available (Table 15.6). Evaluation order and strategies may be individualized according to patient-specific symptoms, goals, and medical history.

Concussions Management and Recovery

Animal models suggest that there is a brief window of brain vulnerability following a concussion that appears to resolve gradually over 7–10 days.[82,359] It is unclear how well these findings generalize to the human population. Nevertheless, it is generally recognized that a typical recovery period for concussion is approximately 7–10 days for adults and about 2–4 weeks for children. Second impact syndrome is a potentially fatal condition that results from a second head injury being sustained before full resolution of an initial concussion. Young brains may be especially vulnerable to the rare but catastrophic occurrence of second impact syndrome.[265,266] Consequently, current recommendations for initial management of concussions focus on rest until symptoms resolve or are back to baseline in a resting state.

Specific return-to-activity recommendations are controversial because the progression to activity should be individualized to each patient and focused on symptom and impairment recovery rather than days since the injury occurred. A gradual return to activity program is generally accepted as the safest way to help progress a patient back to preinjury activity levels (Table 15.7). If symptoms arise during this progression, modification should be made to allow the symptoms to resolve. Special consideration should be given to the individual who has suffered multiple concussions, and the potential disqualification for contact sports should be considered. In general, young athletes represent a unique population in the presence of concussions. The brain of a young athlete is still developing, and as a result the effect of a concussion in this population is still unknown.[82,112,166,171] General consensus in the literature does suggest that a more conservative approach to concussion management should be implemented in this younger population.[253] Therefore advancement through rehabilitation including time to return to play is often slower in this population. Future research needs to focus on better understanding the effects of concussion on a developing brain and developing more evidence-based guidelines related to management and return to activity following a concussion in a young athlete.

Approximately 10% to 30% of individuals who sustain a concussion will continue to experience persistent traumatic brain injury symptoms for months to years after the injury.[386] Individuals whose symptoms last for more than 4 weeks and fit the World Health Organization's diagnostic criteria are often diagnosed with postconcussion syndrome (PCS).[314,315] A rapidly emerging field of practice in physical therapy is the treatment of patients with PCS using physical therapy interventions. There is early evidence supporting such interventions as vestibular therapies, manual therapy, therapeutic exercise, and progressive aerobic training leading to growing recognition that physical therapy may facilitate recovery in patients with PCS.[8,9,28,145,146,372,373] At this time, specific evidence-based guidelines regarding physical therapy strategies for treating PCS are not currently available. Future research is needed to further develop an evidence base that can provide strong conclusions in these regards.

TABLE 15.7 Return to Activity Program

Rehabilitation Stage	Functional Exercise at Each Stage of Rehabilitation	Objective of Each Stage
No activity	Complete physical and cognitive rest	Recovery
Light aerobic exercise	Walking, swimming, or stationary cycling keeping intensity < 70% MPHR. No resistance training	Increase HR
Sport-specific exercise	Skating drills in ice hockey, running drills in soccer. No head impact activities	Add movement
Noncontact training drills	Progression to more complex training drills (e.g., passing drills in football and ice hockey). May start progressive resistance training	Exercise, coordination, cognitive load
Full-contact practice	Following medical clearance, participate in normal training activities	Restore confidence, assessment of functional skills by coaching staff
Return to play	Normal game play	

HR, heart rate; MPHR, .

Cervical Injuries

The incidence of central nervous system injury in children is low, varying from 1% to 5% of sports-related injuries, but these cases constitute 50% to 100% of the deaths from injury. Cervical spine injuries result in 30% to 50% of cases of childhood quadriplegia.[61] The rate of spinal cord injuries in children younger than age 11 years is low, but it escalates dramatically in the 15- to 18-year-old age bracket. The largest percentage of traumatic spinal cord injury in children ages 10–14 years old was due to sports injury,[86] with as many cervical spine injuries occurring in sports as seen in motor vehicle accidents in children between 8 and 15 years old.[235] Because the brain and spinal cord are largely incapable of regeneration, these injuries take on a singular importance.[72]

Participation in several sports carries a particularly high risk for head and neck injuries. Sports-related injuries account for 14% of all head trauma cases seen in pediatric emergency departments in the United States.[155] American football accounts for a large percentage of all concussion injuries in school sports, with as many as 9.6% of all injuries in football being diagnosed as concussions.[115] Although 69% of deaths between 1945 and 1999 were from brain injuries, the incidence of serious head injuries has decreased since the late 1980s.[73]

Severe spinal injuries may result in paralysis and total disability. A population-based study over 7 years identified 32 children younger than 15 years of age who sustained spinal fracture, dislocation, or severe ligamentous injury; sports were the cause of all injuries in children over the age of 10 years.[130] Rugby, a popular collision sport outside the United States, has head and neck injury rates similar to those of American football. Wrestling has the second highest injury rate of all high school sports, although the central nervous system injury rate is low. The rate of catastrophic wrestling injuries (cervical ligament injury, spinal cord contusion, severe head injury, or herniated disk) is 2.11 per year (1 per 100,000 participants) as a result of direct blows or falls.[52] Football, soccer, and basketball account for a large number of concussions secondary to collision, although exact incidence figures have not been reported. Diving accounts for 3% to 21% of all cervical spine injuries in young people.[49] Noguchi[303] noted that swimming and gymnastics accounted for 51% and 22.8%, respectively, of all spinal injuries in persons younger than 30 years of age.

Most neck injuries are caused by hyperflexion or hyperextension. Hyperflexion injuries, which are the most common, result from spearing (Fig. 15.3). Because of the undeveloped musculature in young athletes relative to adults and the commonly associated fracture, hyperflexion injury can be serious.

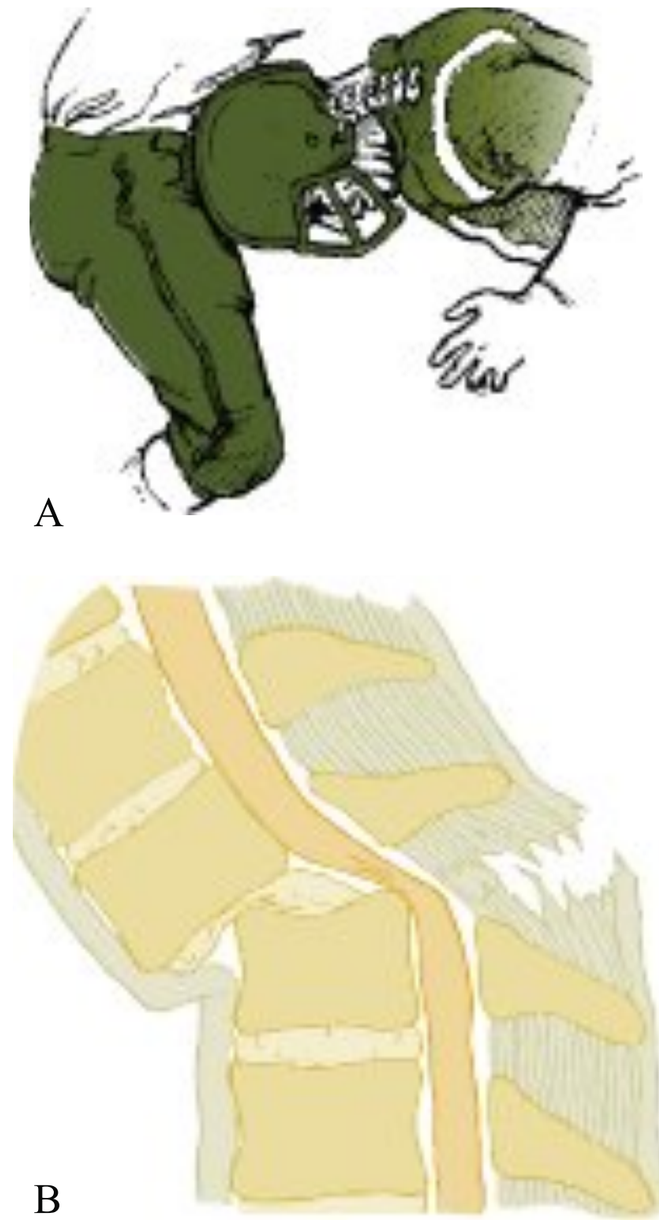

FIG. 15.3 Hyperflexion damage from head butting. ([A] From Birrer R, Brecher D: Common sports injuries in youngsters. Oradell, NJ, Medical Economics, 1987. [B] From Black JM, Hawks JH: Medical-surgical nursing, ed 8, St. Louis, 2009, Saunders.)

Hyperextension injuries often occur even in the absence of severe force because the anterior neck musculature is weaker than the posterior musculature. Common causes are face or head tackling (Fig. 15.4). Hyperextension injury with a rotatory component is the most common cause of nerve root damage.[48,394] Evaluation of these injuries should always include radiographs of the cervical spine. In the adolescent the second cervical vertebra is normally displaced posteriorly over the third secondary to hypermobility. This pseudosubluxation is normal and not the result of injury[72] but should be referred for assessment.

Another common injury is a "stinger" or "burner," which is a traction injury to the brachial plexus. It is caused by a forceful

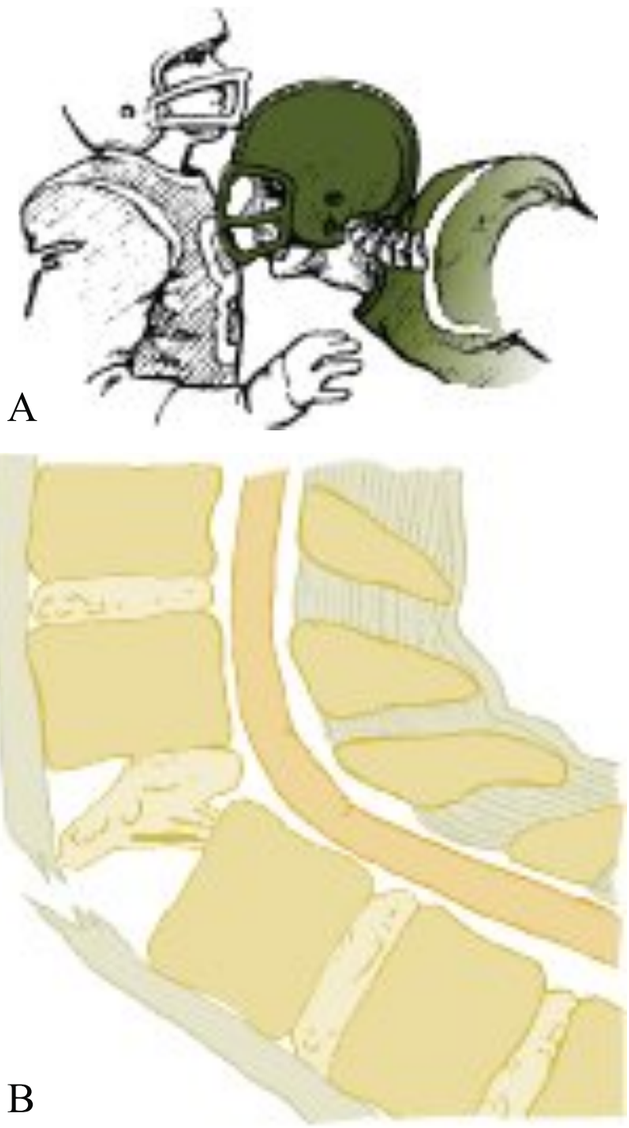

FIG. 15.4 Hyperextension injury from face blocking ([A] From Birrer R, Brecher D: Common sports injuries in youngsters. Oradell, NJ, Medical Economics, 1987. [B] From Black JM, Hawks JH: Medical-surgical nursing, ed 8, St. Louis, Saunders, 2009.)

blow to the head from the side creating lateral deviation of the head or from depression of the shoulder while the head and neck are fixed. Repeated injuries may cause weakness of the deltoid, biceps, and teres major muscles, which should be resolved with strengthening exercises. The use of a collar, a change in technique, and cervical/scapulothoracic strengthening are appropriate interventions to help resolve symptoms. If symptoms persist or if repeated injuries occur, restriction in ability to return to play is warranted.[93] Return to play in a collision or contact sport following any type of cervical injury should be closely monitored.[74,93]

Thoracic and Lumbar Spinal Injuries

Back injuries in children are different from those in adults and require careful evaluation.[219,420] Spinal injuries can occur in both the thoracic and the lumbar areas, although thoracic injuries are rare. Costovertebral injury secondary to compression of the rib cage may occur in sports such as football or from a forceful takedown in wrestling. Complaints include pain and muscle spasm along the associated rib with potential complaints of pain with thoracic rotation. Axial compression forces on a preflexed spine, as in sledding or tobogganing, can fracture the vertebrae, particularly at the vulnerable T12–L1 level. These injuries can cause pain but at times are asymptomatic.[48,394]

The most common injuries in the lumbar spine are spondylolysis and spondylolisthesis. One study of 3132 competitive athletes ages 15 to 27 years noted an incidence of spondylolysis of 12.5%.[360] Repeated and excessive hyperextension in football blocking, clean and jerk lift, diving, pole vaulting, wrestling, high jump, or gymnastic maneuvers can place excessive forces on the pars interarticularis and cause a stress fracture. Spondylolisthesis is described as a fracture and slippage of one vertebra on another, usually L5 over S1 or L4 over L5. Loading of a bilateral spondylolysis, in which there is a defect in the bony connection of the posterior arch with the vertebral body, can cause a spondylolisthesis, as can traumatic or repetitive bilateral loading of a normal spine. The slippage is graded from 1 to 4, depending on the degree of slippage. Athletes with grade 2 or greater slippage should be counseled against participation in activities requiring excessive lumbar extension such as weight lifting, baseball, diving, gymnastics, or wrestling. Participation in basketball or football is permissible with use of a brace.[107,113,219,273] The growth spurt in the spine causes lumbar lordosis secondary to the enhanced anterior growth with posterior tethering by the heavy lumbodorsal fascia. This biomechanical situation increases the tendency of posterior element failure at the pars.[278] Athletes with spondylolysis are managed in a brace or, at minimum, with restricted activity until healing occurs. Physical therapy is indicated to maintain flexibility in the lumbosacral spine and the spinal and hip musculature and to improve trunk and abdominal muscle strength and core stability while braced. Surgery is indicated only in cases of unstable lesions or nerve root compression.[48,142,310]

The incidence of disk lesions in young athletes is unknown, but several studies have demonstrated that disk herniation can occur, with 95% of these cases occurring at L4/L5 or L5/S1. Although acute trauma may precede the diagnosis of disc herniation, degenerative changes of the vertebral bodies and intervertebral joints may be the contributing factors, with trauma being the acute precipitating incident.[139] Conservative management of this condition is often successful in the pediatric and adolescent population; however, if symptoms persist, surgical management may be necessary.[139]

Shoulder Injuries

Specific shoulder injuries can be predicted based on the biomechanics of the sport and the age of the athlete.[190,215] Participation in football, wrestling, and ice hockey may increase the likelihood of upper extremity fractures, subluxations, and dislocations. Sports with repeated overhead activities, such as volleyball, swimming, gymnastics, and baseball, are more likely to result in overuse injuries.[1,26,336] The hyperelasticity of juvenile joints, particularly the shoulder, makes them vulnerable to passive and dynamic instability patterns that can predispose the shoulder to injury.[190,323] The presence of disease processes or pathology that potentially increase this hyperelasticity, such as Ehlers-Danlos syndrome, can exacerbate this presentation.

Acromioclavicular (AC) sprains may occur in the immature athlete without clavicular fracture; however, it is more common in skeletally mature athletes. The most common mechanism is direct force from a fall or blow to the lateral aspect of the shoulder or a fall on an outstretched arm.[48,142,215,275] Grade I and II sprains are more common in the athlete whose skeleton is immature. Grade III sprains commonly rupture the dorsal clavicular periosteum, but the acromioclavicular and coracoclavicular ligaments remain intact.[215,323] There is some controversy regarding optimal management of AC joint separations. These lesions are often treated symptomatically with rest, ice, compression, and elevation (RICE) in a sling. Some cases may require surgical stabilization if conservative management fails.[55] Exercises are often necessary to increase scapulothoracic and glenohumeral mobility and strength after the sprain is healed.

Fractures are most common in the middle third of the clavicle from a direct blow. These can be actual fractures in the older child or greenstick fractures in the youngster. They are managed with a figure-of-eight strap or sling stabilization until healed.

The proximal humerus is an area of bone growth in children and is typically not as strong as the surrounding capsule and ligamentous structures. Therefore fractures are more common in children than in adults, who are more prone to dislocation. Epiphyseal displacements occur in the younger child, and metaphyseal fractures are more common in the older child or adolescent.[275] Once bony healing is identified, therapeutic intervention to normalize mobility and strength of the scapular, shoulder, and elbow muscles is frequently indicated.[323]

Little League shoulder, a relatively common injury in young pitchers and catchers, involves an injury of the proximal humeral growth plate secondary to rotatory torque. A skeletally immature athlete who complains of proximal shoulder pain in the absence of trauma should be suspected of having an epiphyseal injury until proved otherwise. The athlete should limit throwing and rotational activities until the pain subsides[190,215,323]; however, strengthening of the parascapular and core musculature is indicated to facilitate a smoother transition back to sports once the pain has subsided.

Frank anterior subluxation and dislocation of the glenohumeral joint are rare in children but common in adolescents. Because of the laxity of juvenile joints, a blow or forceful maneuver in abduction, external rotation, or extension can dislodge the head of the humerus.[48,142,323] This condition is common in contact sports, gymnastics, and overhead throwing sports. Patients with posterior glenohumeral instability respond better to conservative strengthening of appropriate musculature than those with anterior instability, although a program of scapular and shoulder muscle strengthening in a biomechanically correct range of motion should be attempted. Motion should be limited to ranges that prevent chronic subluxation. Surgery is more often an option with anterior or multidirectional instability but may occur in the case of posterior instability.[215,323] Debate exists in the literature regarding the most appropriate timing of arthroscopic stabilization following first-time shoulder dislocations in adolescent athletes.[108,221] Future research will need to identify if immediate surgical stabilization is indicated after first-time dislocation or if a trial of conservative management would be successful in some athletes.

Rotator cuff tears are not as common in the skeletally immature athlete as in the older athlete. They occur in throwing and racquet sports, as well as from direct contact blows in collision sports. These tears can be treated successfully with arthroscopic surgery and rehabilitation that includes strength and endurance training for all scapular and shoulder muscles, as well as training with correct biomechanical movements of the shoulder complex.[215]

Rotator cuff impingement syndrome (Fig. 15.5) is a frequent injury in athletes younger than 25 years of age. More than 50% of swimmers aged 12 to 18 years complain of shoulder pain.[48,142] Unlike adults who typically present with impingement resulting from a mechanical compression in the subacromial space (primary impingement), children often present with impingement symptoms caused by excessive laxity or mobility in the shoulder joint complex described as secondary impingement. This may be due to a laxity of the static stabilizers in the shoulder with an inability of the dynamic shoulder stabilizers to compensate appropriately. Others theorize altered arthrokinematics of the shoulder may be due to a contracture around the shoulder with loss of internal rotation at 90° of abduction and with increased external rotation in all positions of abduction. This might reflect a tightened posterior and a loosened anterior capsule, suggesting a tendency to translate anteriorly during functional movement patterns. Conservative physical therapy with a focus on improved strength and muscle activation of the dynamic shoulder-stabilizing musculature, along with normalization of mobility and dynamic movement patterns, has been successful in addressing the underlying instability.[215,275,323] All positions of impingement (anterior, lateral, or overhead) should be modified until the athlete is pain-free.

Elbow Injuries

Supracondylar fracture of the humerus is the second most common fracture in the skeletally immature client. Most of these fractures occur in the age group of 5 to 10 years. They are often the result of falling on an outstretched arm with significant forces into extension. Avulsion fractures of the medial epicondyle are also common in the population and are associated with elbow dislocations or throwing injuries. Anatomic reduction is indicated with internal fixation, when appropriate. Loss of motion is a common impairment following these injuries; therefore early protected range of motion to avoid loss of extension is critical.[152,215] Subsequent to healing, normalization of mobility and strength of the shoulder, elbow, and forearm are necessary for full function.

Repetitive microtrauma from pitching may result in epiphyseal injury of the radial head. Loss of extension and supination with a history of repetitive compressive loading of the radiocapitellar joint may indicate this injury. A radial head pathology is treated with rest.[101,190] Forceful distraction of the arm of a child younger than 7 years old can subluxate the radial head because of the poor development of the annular ligament, often referred to as "nursemaid's elbow."[418] Children who have sustained this injury often position the injured arm in flexion and pronation, dangling it at the side of the body.[48,142,215,394]

Elbow dislocation is seen in contact sports secondary to a fall on an abducted, extended arm. Early reduction will avoid neurovascular damage, and further evaluation and radiographs are necessary to assess the presence of associated fracture. Early protected mobility is necessary to preserve normal elbow motion.[48,142,215] Physical therapy to normalize elbow and

forearm mobility and to improve strength at the elbow, forearm, and hand is appropriate.

Little League elbow commonly results from the extreme valgus stress placed on the epicondyles during the acceleration phase of pitching (Fig. 15.6). If this is not recognized and regular throwing continues, mild separation of the medial epicondyle with hypertrophy, irregularity, fragmentation, and avulsion can occur. The most serious damage occurs with the compressive loads experienced in the lateral joint between the radial head and the capitellum. This injury may occur in as many as 8% to 10% of young pitchers. This compressive mechanism can result in osteochondritis of the capitellum, avascular necrosis of the radial head, and loose bodies within the joint. Treatment is RICE and rest from throwing with an ultimate progression to rehabilitation to focus on restoration of full mobility and strength through the upper extremity.[48,142,152,310] Eventual alteration of throwing mechanics may be necessary.

Lateral epicondylitis, or tennis elbow, is seen in a variety of racquet sports as a result of repeated injury to the lateral epicondyle. Repetitive microtrauma to the wrist extensors, as often seen with faulty backhand strokes in tennis, can initiate the process. The resulting tensile overload in the wrist extensors as well as friction between the extensor muscles, the lateral epicondyle, and the radial head causes irritation, microtears in the extensor muscle origin, and adhesions between the annular ligament and the joint capsule. Using tightly strung racquets, racquets with small handles, and old tennis balls can aggravate the situation. Rehabilitation to decrease acute inflammation and chronic irritation, reduce adhesions, and strengthen the forearm and hand musculature is required. Alteration of technique and equipment, such as enlargement of the racquet grip area or reduction of string tension, is helpful.[142,152,190]

Wrist and Hand Injuries

The hand and wrist joint is an inherently complex anatomic structure. As a result, potentially serious injuries may be missed or underdiagnosed. Careful diagnosis using knowledge of anatomy, biomechanics, and pathomechanics of the wrist and hand is crucial.[48,152,215,394]

Fractures about the wrist follow an age-related pattern. In the young child a torus, or buckle fracture, of the distal radial epiphysis is common after a fall. Clinical signs include varying degrees of pain and tenderness, so careful radiologic examination is necessary. Simple splinting is adequate for healing.[48,215,310] Metaphyseal fractures of the distal radius and ulna are more common in the child. Often displaced, they require reduction with the use of anesthesia. In the younger adolescent, fractures through the growth plate are common, again from falls, and require operative reduction to minimize trauma to the growth plate.[215] Rehabilitation to regain normal forearm and wrist mobility as well as wrist and grip strength is desirable. Posttraumatic arthritis of the wrist and hand has been documented in active children. Management requires careful monitoring with nonoperative techniques to permit extensive remodeling, although occasionally surgery is necessary.[326] Stress injuries to the distal radial epiphysis, triangular fibrocartilage complex (TFCC) tears, as well as ligamentous injury in the carpal region have been noted in athletes such as gymnasts who bear weight on their hands. Complaints of wrist stiffness and pain with wrist dorsiflexion are common. Radiographs may demonstrate a widened epiphysis, cystic changes, and breaking of the distal metaphysis with distal radius injury. Carpal ligament and TFCC injuries often require MRI to confirm the diagnosis. Management of these conditions often consists of modification or avoidance of gymnastics with or without casting.[215] Rehabilitation and, at times, surgical management may be required.

Although fracture of most carpal bones is rare, fracture of the navicular or scaphoid bone is common in children from 12 to 15 years of age. This fracture results from a fall on the dorsiflexed hand of an outstretched arm. Although the fracture may not be initially visible on a radiograph, early diagnosis is important because of the high incidence of avascular necrosis and nonunion. If tenderness in the anatomic snuffbox occurs with a high degree of suspicion of fracture, use of a short-arm spica cast is the typical initial management.[48,142,153,394] Surgical management may be necessary in the cases of nonunion.

Because the hand and fingers are so essential in most sports, they absorb tremendous forces with sports participation, resulting in frequent injuries.[48,310,394] Dislocations are uncommon in the child's hand because as the child's developing bony anatomy is often more vulnerable than the ligamentous structure at this age. If dislocations do occur, it is usually in the older adolescent who is approaching skeletal maturity and in patterns similar to those in an adult. Thus the most common dislocation occurs

FIG. 15.6 Little Leaguer's elbow. Avulsion fracture of medial epicondyle (1), compression fractures of the radial head (2), and capitellum (3). (Left, Redrawn from Connolly JF: DePalma's management of fractures and dislocations, Philadelphia, Saunders, 1981. Right, from iStock.com.)

at the carpometacarpal joint of the thumb, usually secondary to axial compression forces on the thumb tip in contact sports. Although reduction is easy, chronic instability can result. The thumb is put in a short-arm thumb spica, and participation in sports should be avoided for 6 weeks. Splint stabilization is advisable for the initial 6 weeks of reentry to play.[215]

Dorsal dislocation of the thumb metacarpophalangeal joint is the most common dislocation in the hand of a child. A fall or forceful contact hyperextends the metacarpophalangeal joint. If the proximal phalanx is parallel to the metacarpal, the volar plate has been avulsed and surgical reduction is necessary. Cast immobilization for 3 weeks with sports participation permitted is adequate for healing. Physical therapy may be indicated to normalize thumb mobility and strength following casting. Metacarpophalangeal dislocations in the fingers are rare except for those that affect the index finger. After this injury is reduced, splinting in flexion for 3 weeks with immediate mobilization after splint removal is the treatment of choice.[48,142,394]

Joint injuries are common in ball sports and skiing. The metacarpophalangeal joint of the thumb is the most commonly injured joint in skiers. The majority of these injuries in youth are bony gamekeeper's thumb in which the ulnar collateral ligament avulses a segment of bone, as compared with the purely ligamentous injury in adults. If the bony fragment lies close to its origin, good results are obtained with use of a short-arm thumb spica cast for 6 weeks, followed by exercises to normalize mobility and strength. Athletic participation may continue in some cases and can be facilitated by the use of a custom-molded splint to protect the healing tissues. If the radiograph is negative, integrity of the ulnar collateral ligament must be established by assessing radial deviation in extension and 30° of flexion. Deviation of greater than 30° indicates at least a partial tear. No firm end point in full extension or greater than 45° of deviation in flexion indicates full ligamentous tear with volar plate injury, which will require surgical repair.[48,215,394] Hand therapy is necessary to regain normal mobility, strength, and pinch.

"Jammed" fingers are common injuries in all age groups. Axial compression force to the fingertips causes distal interphalangeal flexion with proximal interphalangeal hyperextension. Reduction is easily accomplished by distal traction. Buddy taping will allow the athlete to return to play.[79,394] Caution should be exhibited, however, because fractures through the growth plate of the phalanx are common. These intra-articular, or neck, fractures have a great tendency to displace and then require open reduction with internal fixation.[275] In the absence of a fracture or dislocation, damage to the collateral ligaments can occur and is managed in similar fashion. Jamming at the distal interphalangeal joint can result in "mallet finger," or tearing of the terminal extensor tendon with or without a bony fragment. This injury is initially managed with use of a dorsal extension splint for 6 to 8 weeks. If active and passive extension ranges are equal at 6 weeks, active flexion can be initiated. If not, splinting is continued for another month. Participation may be permitted if a splint is in place.[48,142,215,394]

Pelvis and Hip Injuries

Pelvis and hip injuries account for 10% to 24% of injuries in the pediatric athlete, with high incidence in ballet, running, soccer, football, and hockey.[56] Because the hip and pelvis have complex ossification patterns and fuse late in childhood, the potential for injury is high. The acetabulum has three sections joined by triradiate cartilage. Likewise, three ossification centers exist on the femoral head: the capital femoral epiphysis, the greater trochanter, and the lesser trochanter. The circular vascularity of the femoral head and neck also creates risk for injury in the growing child.[318,376,422] Hip pain in the pediatric population is typically caused by skeletal (dislocation, avulsion, fracture), soft tissue, nontraumatic (slipped capital femoral epiphysis, Legg-Calvé-Perthes disease, developmental dysplasia) or neoplastic etiologies.[318,376,422]

Traumatic hip dislocations in children are most commonly posterior,[376] with clinical presentation of a limb that is flexed, adducted, and internally rotated. Prompt reduction of the dislocation is key to minimize risk of avascular necrosis.[376]

Fractures are uncommon but can occur in the epiphyseal plate, the femoral neck, or the subtrochanteric area. Fractures of the neck or subtrochanteric area can be the result of severe trauma, usually incurred during contact sports such as football and rugby. Often surgical reduction is required to obtain adequate reduction and promote proper healing.[376] Slipped capital femoral epiphysis (SCFE) is not caused by sports but must be suspected in any athlete with persistent hip or knee pain and a limp. SCFE typically occurs during the period of rapid growth in adolescence in either obese or very thin males, but it can occur in females as well. Surgical reduction with internal fixation is necessary (see Chapter 14).

The most common type of fracture in this region in the young athlete is an avulsion fracture. Avulsion fractures of the apophysis occur in 14% to 40% of athletes in sports[37,376] as a result of forceful contraction or excessive stretch of the muscle originating about the involved apophysis. The most common sites are the anterior-superior iliac spine (origin of the sartorius), the ischium (hamstring origin) (Fig. 15.7), the lesser trochanter (insertion of the iliopsoas), the anterior-inferior iliac spine (rectus femoris origin), and the iliac crest (abdominal insertion).[284] These injuries are classic in sprinting, jumping, soccer, football, and weight lifting. A majority of these injuries are managed nonoperatively with rest and activity modification, reducing tension in the involved area, followed by gradual increase of excursion to full mobility, progressive resistance exercise, and return to activity.[48,376] One less traumatic overuse parallel of avulsion is iliac apophysitis, which usually affects adolescent track, field, or cross-country athletes or dancers. Repeated contraction of the tensor fasciae latae, rectus femoris, sartorius, gluteus medius, and oblique abdominal muscles causes nonspecific pain and tenderness over the iliac crest. Rest helps this problem,[48,142] but often exercises to increase strength and normalize two-joint muscle flexibility are required.

Stress fractures and osteitis pubis are being diagnosed more frequently as a result of repetitive microtrauma in runners or athletes who have suddenly increased their involvement in jumping or kicking activities. Persistent pain and tenderness in the groin with limited mobility and activity-related increases in pain could signal either of these conditions. Radiographs showing inflammation, demineralization, and sclerosis confirm the diagnosis of osteitis pubis, but a bone scan is necessary to diagnose a stress fracture. Stress fractures have been seen in the pelvis at the junction of the ischium and pubic ramus and in the femoral neck and shaft.[48] Relative rest, use of crutches, and restriction from percussive activities (running and jumping) are required for resolution of these disorders.

Snapping hip syndrome is an overuse problem noted in gymnasts, dancers, sprinters, and sports with a rotational component. The term *snapping hip syndrome* can refer either to irritation of the iliotibial band over the greater trochanter with

FIG. 15.7 Avulsion of the ischial tuberosity. (Left, from Birrer R, Brecher D: Common sports injuries in youngsters. Oradell, NJ, Medical Economics Books, 1987. Right, from iStock.com.)

hip motion or to tenosynovitis of the iliopsoas tendon near its femoral insertion. Usually, relative rest or activity modification, use of appropriate modalities, stretching, and improved muscle strength overcome these symptoms, with surgical intervention considered with failed conservative management.[191,275]

A serious condition seen in the young athlete age 5 to 12 years is avascular necrosis of the femoral head. Activity can irritate the synovium, leading to joint effusion and reduction of the blood supply to the femoral head. The initial complaint is nonspecific hip pain, but radiographs demonstrate periosteal rarefaction followed by sclerosis and irregular collapse of the femoral head. Bracing or surgery may be required, depending on the degree of progression of the problem[142] (see Chapter 14).

Contusions are common, but the most frequent is the hip pointer. This iliac crest contusion, occurring typically in football or hockey, is caused by a driving blow by a helmet. The overlying muscle is damaged with a resultant subperiosteal hematoma. RICE and padding will resolve this problem with time.[142] Occasionally, use of ultrasound and soft tissue mobilization with stretching may be necessary.

Knee Injuries

As the largest joint in the body and one with minimal anatomic protection, the knee is the focal point of stress forces applied along the tibia and femur. The knee is the second most commonly injured body site in young individuals, and sports-related knee injuries are among the most economically costly sports injuries, commonly requiring surgical intervention and/or rehabilitation.[111,127,193,345,397] However, these data are likely an underestimation of the prevalence of knee injuries in the young population because overuse injuries account for as many as one half to one third of sports-related injury[248,335] and are often not registered in hospital or sport-specific settings.[200]

Fractures about the knee, although not frequent, are significant for their possible influences on growth.[401,434] Overall, physeal fractures account for 30% of fractures in children less than 16 years old,[256] with distal femoral fractures accounting for 1% to 6% of all physeal fractures.[100,156,256] Acute fractures of the tibial tubercle are also relatively uncommon, with a reported incidence of 0.4% to 2.7%.[31,53,83,84,172,286,311] The mechanism of injury for fractures of the distal femoral physis is high-energy trauma, but older children and adolescents may sustain this type of fracture during lower-energy trauma, often sports related.[119] A fracture line that traverses through the physis and runs obliquely through the metaphysis (Saltar-Harris Type II[119]) is common during sports participation resulting from a valgus force producing medial physeal separation and is often concomitant with medial collateral ligament sprains.[119,246,276] In the proximal tibia, acute avulsion fractures are the most common occurring during athletic activity involving jumping or landing, either by a forceful quadriceps contraction against a fixed foot or by a forceful knee flexion against a tightly contracting quadriceps muscle.[138,237] There is a strong predominance of males with this injury.[119,138] Management of fractures in the distal femur or proximal tibia is dictated by the fracture type and displacement. Particular attention is given to restoration of joint alignment to minimize risk of growth disturbance.[119,138] Nondisplaced fractures can be managed with immobilization and protected weight bearing. Displaced and/or unstable fractures may be managed with either closed or open reduction, including percutaneous pin fixation, transphyseal pins, or internal fixation.[119,138] Displaced tibial tubercle fractures are typically managed with open reduction internal fixation to facilitate anatomic reduction and appropriate alignment and length of the extensor mechanism.[119,138] Rehabilitation will vary with regard to medical management and addresses primary and secondary impairments associated with the injury and management strategy, likely focusing on joint mobility/range of motion, muscle strengthening and activation, pain and effusion management, and functional movement progression.

Ligament injuries are becoming more common in the young athlete, with one study reporting medial collateral ligament injury in children as young as 4 years of age.[282] All ligament injuries should be assessed for coincident physis fractures. Medial collateral ligament tears in youth can include both the superficial and the capsular components of the ligament. Nonoperative treatment with splinting and avoidance of valgus stress has been successful in adolescents, so it may be possible to obtain equally good results in younger children.[142] Physical therapy to improve lower extremity strength and functional movement retraining is often indicated.

The incidence of ACL midsubstance tears in children has increased dramatically. The mechanism of injury is either noncontact, occurring during movements that involve deceleration or change of direction that results in valgus loading in combination with some anterior tibial shear.[181,197] This mechanism of injury may result in either an avulsion fracture at the tibial insertion or midsubstance tears of the ligament.[5,20] The fracture of the tibial spine usually occurs through the cancellous bone, demonstrating avulsion of the tibial spine on a radiograph. Diagnosis of midsubstance tears is done through clinical examination and MRI. Management of midsubstance ACL injuries relies on nonsurgical management or surgical reconstruction. Physical therapy is the focus of nonsurgical management, with an emphasis on acute injury management, strengthening and neuromuscular training, and functional progression for return to desired activity. In cases with recurrent instability, traditional reconstructive procedures are avoided in the adolescent under the age of 15 years because of fear of injury to the growth plate with the proximal tibial drill hole.[168,216] Instead, a modified ACL reconstruction will be performed to respect the still-open physes of the skeletally immature child, including partial transphyseal, physeal-sparing, and all epiphyseal-sparing techniques. These surgical procedures are utilized to provide mechanical stability to the knee and reduce the risk of secondary injury to the surrounding articular cartilage and meniscus during physical activity.[213] Postsurgical rehabilitation with a focus on joint projection, strengthening and neuromuscular development, and functional and return-to-play phases is key to optimize outcomes.

Juvenile osteochondritis dissecans is a focal lesion or injury of the subchondral bone region, with the risk of instability and disruption of the adjacent articular cartilage. The most common location is on the posterolateral aspect of the medial femoral condyle, where 70% of lesions occur.[163,214] There is increased incidence and prevalence in youth involved in sports activities, with boys being more affected than girls (5:3 ratio) and 25% of cases being bilateral with asymmetric lesion location.[188,214] The etiology of juvenile osteochondritis dissecans is still an enigma. Compression of the tibial spine against the medial femoral condyle, interruption of the vascularity, genetic predisposition, chronic inflammatory response, anatomic variations in the knee, and abnormal subchondral bone are all possible causes. The condition usually causes pain, recurrent swelling, and possibly catching in the knee. Pain is generally poorly localized and is exacerbated with activity. Physical examination may reveal tenderness over the anteromedial aspect of the knee with varying degrees of knee flexion. Because these lesions have a poor prognosis after skeletal maturity, every attempt should be made to gain healing before growth plate closure. In the child younger than 15 years of age, diminished activity to the point of not bearing weight is suggested. Drilling of the condyles with removal of fragments is recommended in children older than 15 years of age.[67] This procedure usually necessitates restriction of running, jumping, and other physical activity for a period of time, with concomitant intensive rehabilitation to regain strength, balance, and agility in the lower extremity.[142,370]

The challenge of meniscal injuries in the young athlete is accurate diagnosis.[287] Meniscus injuries are often concomitant with other acute knee injuries,[19,368] such as anterior cruciate ligament tears, chondral injuries, and tibial fractures. The preponderance of literature supports a management strategy that preserves as much of the meniscus as possible.[407] Rehabilitation management focuses on restoration of joint motion, strength, neuromuscular control, and endurance of the involved limb. If indicated, surgical management (repair versus debride) is dictated by tear location, chronicity of the tear, patient age, and other patient-specific factors. Postsurgical rehabilitation works to restore joint motion, strength, neuromuscular control, and endurance of the involved limb. Discoid lateral meniscus is a common abnormal meniscal variant in children.[224] Discoid lateral meniscus can create joint line tenderness, decreased joint mobility, effusion, and, most notably, a prominent snap in the lateral compartment as the knee is extended.[224] The complete type of discoid meniscus, producing symptoms in late adolescence, is distinguished by intact peripheral attachments. Good results are obtained with saucerization of the meniscus. The Wrisberg type of discoid meniscus, which is more common in the pediatric group, has an attachment only through the ligament of Wrisberg and can be resolved by cutting the ligament and removing the portions with no peripheral attachments.[224,304] Among the most common knee conditions in children are disorders involving the patella and patellofemoral joint.[41] Macrotrauma, repetitive microtrauma, and growth all can contribute to the disorders of the patellofemoral joint. Patellofemoral pain is the most frequent problem in the young athlete, with adolescent females being 2 to 10 times more likely than males to have patellofemoral pain.[51,124,143,144,356] Overuse of the extensor mechanism or extensor mechanism is a major cause of patellofemoral pain. Several other anatomic and biomechanical factors can increase stress in the patellofemoral joint and lead to pain (Fig. 15.8). Malalignment of the patellofemoral joint is the major cause of this pain. Several factors can cause or contribute to this malalignment. Anatomic factors such as patella alta, large Q angle, hip anteversion, flattened lateral femoral condyle, shallow femoral groove, or pes planus and hyperpronation can cause abnormal tracking of the patella during knee motion.[328] The malalignment of the patella in relation to the femoral groove can be the result of a more laterally positioned patella or a more internally rotated femur.[340] Biomechanical factors related to muscle strength (e.g., weak hip musculature) or altered movement strategies (e.g., dynamic knee valgus) can contribute to increased patellofemoral stress.[291,328] Nonoperative management is the standard of care for patellofemoral pain. Medical management may include nonsteroidal anti-inflammatory medications and bracing. A meta-analysis of randomized studies of physical therapy treatment in individuals with patellofemoral pain showed a positive effect for exercise on pain reduction,[175] with successful rehabilitation programs incorporating active stretching, lower extremity strengthening, balance, proprioception, and neuromuscular control activities with an emphasis on trunk, hip, and thigh musculature.[175]

Lateral patellar instability and subluxation/dislocation are common in young athletes, with an incidence of 107 per 100,000 in those 9 to 15 years old.[400] Injury occurs either by direct contact with the medial aspect of the knee, or indirect, noncontact mechanisms that relate to biomechanics and/or anatomic factors

that result in a tendency for patellar lateralization. Sport-related movements, such as cutting or pivoting, that result in dynamic knee valgus place high strain on medial patellar restraints and are associated with lateral subluxation/dislocation.[400] Other factors such as pes planus or subtalar joint pronation are also thought to contribute to altered knee loading and to instability.[400] Other contributing factors include anatomic factors that reduce contact of the patella with the groove (e.g., trochlear dysplasia, patella alta, increased patellar tilt) and/or lateralize the pull of the quadriceps (e.g., increased quadriceps angle, high tibial tuberosity to trochlear groove).[109,400] The risk of recurrent instability is high, with studies reporting a 60% redislocation/subluxation rate for 11- to 14-year-olds and a 33% rate for 15- to 18-year-olds.[302,400] After primary dislocation, nonoperative management is considered, but early surgical intervention with a medial patellofemoral reconstruction procedure may also be considered, particularly if anatomic variations exist.[412] A medial patellofemoral reconstruction is often considered in those with recurrent instability. Rehabilitation management following acute dislocation focuses on pain/effusion management and activities that progress range of motion, strength, and neuromuscular control. Postoperative management will be dictated by the procedure performed but will include joint protection and pain/effusion management, as well as progressive range of motion, strengthening, and neuromuscular control activities.

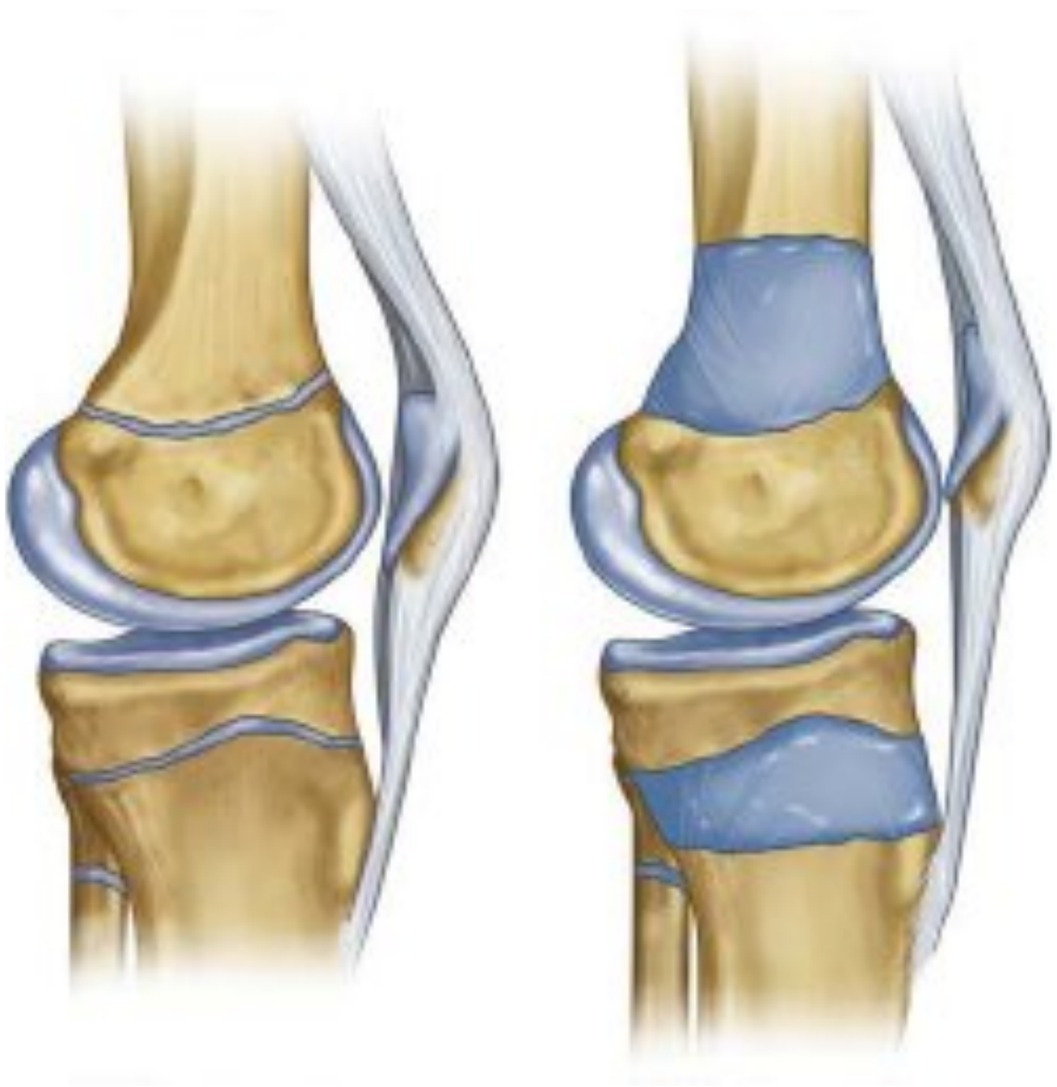

FIG. 15.8 Tension resulting from growth. Pain may occur at the patella (A), lower pole of the patella (B), or patellar tendon insertion on the tibia (C). (Redrawn from Micheli L: Overuse injuries in children's sports: the growth factor. Orthop Clin North Am 14(2):337-360, 1983.)

Apophysitis, or irritation and inflammation of the secondary ossification centers where tendons attach, is common in the knee at the tibial tuberosity (Osgood-Schlatter disease) and inferior pole of the patella (Sinding-Larsen-Johansson syndrome) where localized pain and tenderness are clinical features of these conditions. Osgood-Schlatter disease (see Chapter 14) typically presents in boys age 12 to 15 years and girls age 8 to 12 years, is more common in boys than girls,[151,223,421] and is most often seen in sports involving repetitive running and/or jumping where there is a strong pull of the quadriceps muscles[106,151,380] (see Chapter 14). Sinding-Larsen-Johansson typically presents in adolescents between 10 to 14 years old but most often in males who participate in sports.[198] Relative rest, activity modification, ice/nonsteroidal anti-inflammatory medications, improving flexibility of surrounding muscles (particularly the quadriceps and rectus femoris muscles), and maintenance of quadriceps muscle strength or progressive quadriceps strengthening with pain-free exercise are treatment options.[48,389]

Ankle and Foot Injuries

As a result of their growing skeleton, children may suffer from foot and ankle problems not often seen in adults.[260] Injuries to the distal tibial and fibular growth plates are common in the young athlete. Gregg and Das[161] have classified growth plate injuries into a clinically useful system (Fig. 15.9). The

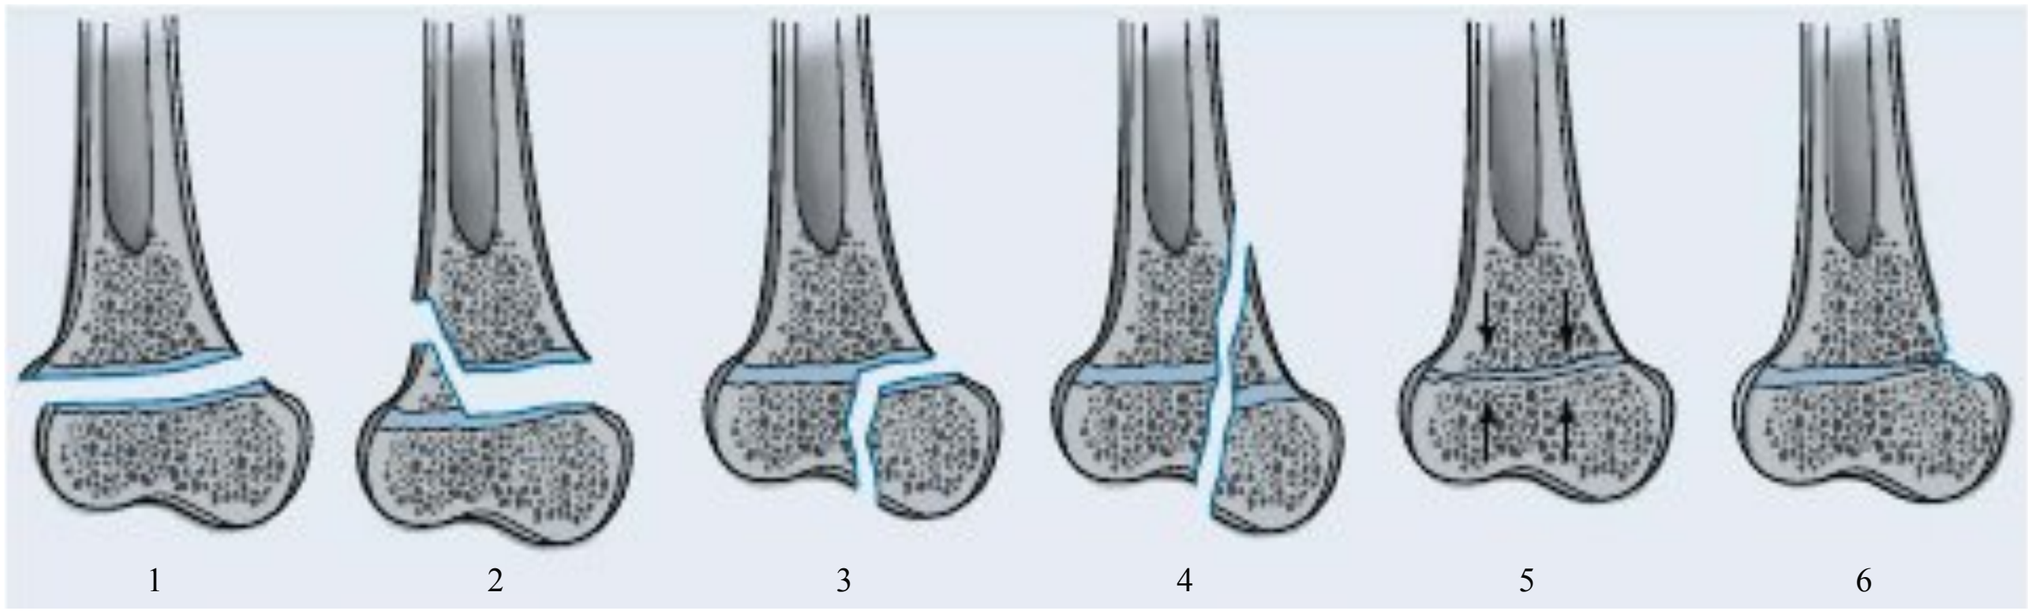

FIG. 15.9 Modified Salter-Harris classification of growth plate injuries: 1, Disruption entirely confined to the growth plate; distraction or slip injury. 2, Fracture line runs partially through the growth plate then extends through the metaphysis. 3, Fracture line runs partially through the growth plate then extends through the epiphysis. 4, Combined disruption of metaphysis, growth plate, and epiphysis. 5, Crush or compression injury of growth plate. 6, Abrasion, avulsion, or burn of the perichondrial ring of the growth plate. (From Marchiori D: Clinical imaging: with skeletal, chest, & abdominal pattern differentials, ed 3, St. Louis, Mosby, 2014.)

most common fractures to the ankle in the skeletally immature athlete are the Salter-Harris I and II injuries to the distal fibula. Although these fractures can occur with adduction and abduction injury to the distal tibia, they frequently occur alone as a result of inversion injury. The Ottawa rules for prediction of need for radiograph to rule out fracture have been validated in children.[239] The Ottawa rules state that an ankle series is indicated only for patients with pain in the malleolar zone and any of the following findings: (1) bone tenderness at the posterior edge of either the medial or lateral malleolus or (2) inability to bear weight immediately after injury and in the emergency room. The rules further state that a foot series is required only with midfoot pain and any of the following findings: (1) bone tenderness at the base of the fifth metatarsal, (2) bone tenderness at the navicular, or (3) inability to bear weight immediately and in the emergency room. Treatment with immobilization in a short leg cast for 2 to 6 weeks is suggested.[202] Physical therapy after casting to increase ankle and foot mobility and strength and to improve balance may be indicated. Increasing incidence of osteochondral defects of the talar dome may necessitate a review of surgical options for treatment of this condition.[403]

Type II injury of the distal tibia is a result of a variety of mechanisms, including supination and external rotation, supination and plantar flexion, and ankle pronation and eversion, to name a few. Common in football and soccer players, this injury is frequently associated with greenstick fracture of the distal fibula. Care must be taken to reduce these fractures and immobilize them in a long leg cast with knee flexion to prevent impaction of the tibial metaphysis into the growth plate. The results of this type of fracture are unpredictable; occasionally angulation or premature closure of the plate occurs.[142] The most common mechanism of injury in type III and IV fractures of the medial malleolus is ankle supination or inversion. Adduction injuries appear in approximately 15% of these injuries and are characterized by medial displacement of part or all of the distal tibial epiphysis. The affected children are usually young, so the incidence of growth disturbance is higher. Internal fixation with restoration of ankle joint congruity is critical.[236]

Because of the porosity of the bones of the foot in a child, stress fractures are common in the metatarsals in all jumping and distance-running activities. If suspected by local tenderness that is aggravated with activity, these injuries should be immobilized for 3 weeks. After immobilization, one can progressively and slowly increase activities to former levels over 3 more weeks.[142] Several types of ischemia can occur in the bones of the child's foot. Freiberg infarction, or avascular necrosis of the metatarsal epiphysis, occurs in those who walk or perform on their toes. Initial synovitis is followed by sclerosis, resorption, plate fracture and collapse, and bone reformation. It does not affect children younger than 12 years of age. Most commonly affected is the second metatarsal head. Treatment consists of cessation of toe-walking, wearing high-heeled shoes, and jumping. A negative-heel shoe is fitted. Kohler disease is seen in active boys age 3 to 7 years who have a tendency to cavus feet (see Chapter 14). Focal tenderness and swelling around the navicular bone are noted clinically. The radiograph reveals sclerosis and irregular rarefaction indicative of ischemia. Conservative treatment calls for use of a walking cast for 6 to 8 weeks followed by use of an arch support and limitation of activity for another 6 weeks.[282]

Although ankle sprains can occur in the young athlete, epiphyseal fractures are more common. Sprains occur in the older adolescent near the end of skeletal maturity. The common cause of injury is landing on the lateral border of a plantarflexed foot (Fig. 15.10). Management is similar to that in adults. Surgery is indicated only in multiple sprains with gross instability limiting function or causing pain.

Sever disease, or apophysitis of the calcaneus, is comparable to Osgood-Schlatter syndrome in the knee (Fig. 15.11). It is seen most frequently in basketball and soccer players with complaint of heel pain on running. The usual age of occurrence is 8 to 13 years. Frequently, tight heel cords, a tendency toward in-toeing, and forefoot varus are noted. Treatment consists of heel cord stretching and initial use of a heel lift in well-constructed shoes (see Chapter 14).[142]

FOREGROUND INFORMATION

REHABILITATION AND RETURN TO PLAY

In adults, rehabilitation following common sports injuries and subsequent medical treatment (i.e., ACL injury and reconstruction) is described in the literature. Commonly, rehabilitation guidelines that are accepted practice in adults are often applied to children and adolescents. However, rehabilitation in a child or adolescent requires age-appropriate modifications, specifically related to relevant anatomy, surgical procedures/modifications performed (if applicable), protection and preservation of future bone growth, as well as the unique psychosocial aspects of the pediatric or adolescent patient.

Children and adolescents require supervised rehabilitation programs that begin with first aid on the field of play. The goal of first aid is to contain the extent of injury and reduce any possibility of further harm. Following, or in conjunction with medical management of the injury, the long-term goal of rehabilitation is return to play in a safe manner with minimal risk of further injury. In healthy individuals, studies indicate that comprehensive training programs utilizing components of strength, balance, and core stability training, as well as biomechanical technique and plyometric training, induce changes in movement mechanics that are associated with reducing injury risk.[178,180,292] Similar principles are utilized when establishing a rehabilitation program for individuals following injury. Following injury, successful rehabilitation that advances toward unrestricted activity and sport participation requires a comprehensive, progressive, and criterion-based plan of physical therapy care.

A comprehensive rehabilitation program and individualized plan of care maximize outcomes. The physical therapy plan of care will vary based on the individual's unique characteristics and attributes within the context of his or her injury and relevant anatomy (e.g., open versus closed epiphyseal "growth" plates). Physical characteristics such as anatomic alignment, skeletal age, body mass, severity of impairments, and injury history are considered in rehabilitation planning.[348,426] Also considered are psychosocial attributes such as motivation, maturity level, patient/family goals, kinesthetic awareness, and demonstration of fear avoidance or kinesiophobic movement patterns. The young athlete's specific goals, as well as the magnitude of his or her impairments and functional limitations, will guide the specific interventions and pace of rehabilitation progression. For the young athlete, communication among the health care providers, as well as with the patient, family, coaches, and other involved personnel, will ensure effective collaboration with the recommended plan of care. Given the limited information available regarding injuries in young individuals, the rehabilitation specialist plays a large role in the education of the patient, patient's family, and the teaching and coaching staff involved with the young athlete.

Successful physical therapy management requires adherence to a systematic and criterion-based progression of interventions and considerations for the unique psychosocial and anatomic aspects of a young patient. This approach to rehabilitation will protect injured tissues, promote healing, maximize outcomes, and ultimately preserve long-term tissue and joint integrity.[348,426] A rehabilitation program that is developed and advanced based on criterion-based decision making, rather than time-based decision making, is advocated to ensure adequate tissue healing and adequate accommodation of the injured tissues to the forces associated with activity.[348,426] A thorough history and clinical examination are important to establish accurate differential diagnosis and to develop an individual plan of care based on severity of impairments and functional limitations.

Acute and Intermediate Phases of Rehabilitation

Protecting the injured tissue or joint during the early phases of healing is important for successful outcome. Adherence to necessary activity modifications may be a challenge for young, active patients. Patient and family education are important for effective cooperation with the plan of care. Resolution of impairments and progression toward functional activities are the goals of these phases of rehabilitation. Each patient's specific goals, as well as the magnitude of their impairments and functional limitations, will guide the specific interventions and pace of rehabilitation progression.

Advanced Stages of Rehabilitation

The long-term goal of rehabilitation is a safe transition and reintegration into sport following injury. The objective of the return-to-activity phase of rehabilitation is successful transition from advanced rehabilitation to safe participation in sports with minimal risk of injury. Criterion-based progression through the advanced stages of rehabilitation depends on achievement of clinical milestones, with consideration of the participation demands for the activity and position for which the individual desires to return (e.g., the amount of cutting/pivoting, amount of overhead throwing, amount of contact, and level of activity [elite versus recreational]). Advanced stages of rehabilitation should realize resolution of pain, effusion, range of motion, and joint-loading or weight-bearing restrictions. During the advanced stages of rehabilitation, the young athlete should be progressed through a functional program (based on activity- and position-specific demands) that optimizes strength and muscle performance in terms of intensity, frequency, and duration of activity.[293] Functional activities that progress neuromuscular control, including plyometric and technique training, should also be implemented.[293]

Return to Activity

Determination of timing for return to desired sports activities following injury should be based on objective measures during a comprehensive functional evaluation.[225,293] Patient reintegration into sport and activities is considered when there is demonstration of adequate tissue healing, resolution of impairments (such as pain, effusion, range of motion), adequate muscle strength and performance, and acceptable levels of functional

performance necessary for the demands of the desired activity. Muscle strength should be objectively measured (via dynamometry), and the recommended criterion for return to activity is involved muscle strength that is 85% to 90% of the contralateral muscle.[203,225,285,306,358]

Patient-reported outcome tools and performance-based functional assessments are also utilized in physical therapy clinical decision making.[132] A number of region-specific patient-reported outcome measures are valid and reliable measures of function during activities of daily living, recreational activities, and sport activities, although most measures were developed based on adult patient populations. A recent study[371] demonstrated the internal consistency and validity of the International Knee Documentation Committee (IKDC) Subjective Knee Evaluation Form in young individuals, ages 6 to 18 years. Measures of general health assessment, such as the Pediatric Quality of Life Inventory 4.0 Generic Core Scales (PedsQL),[410,411] are valid, responsive, and reliable measures of health-related quality of life in children and adolescents (age 2 to 18 years). In addition to patient-reported measures of function, performance-based assessments are often used to determine readiness for return to sport and activity. Physical performance is often evaluated via jumping, hopping, or cutting tasks, depending on the demands of the activity of which the patient desires to return. Single-limb hop tests (such as the single hop, triple hop, crossover hop, and 6-meter timed hop[305]) are often used because of their convenience and reliability.[54,347] Recommended criteria for return to sport are performance of involved limb that is at least 85% to 90% of the uninvolved limb.[225] Additional performance measures may also be useful. Performance on the Star Excursion Balance Test has been associated with risk of lower extremity injury,[209,334] and a composite reach distance of > 94 is recommended to reduce injury risk.[209,334] Altered movement patterns and neuromuscular control have been associated with increased risk of injuries,[179] and movement and technique assessment during high-level activities are important for safe return to activity. The drop vertical jump task has been used repeatedly as an assessment tool of lower extremity biomechanics during a plyometric task.[120,136,179,294,313,317] The tuck jump exercise has been advocated as another clinician-friendly and reliable tool to identify lower extremity landing technique faults during a plyometric activity.[290,293]

For young athletes participating in overhead sports such as baseball, softball, and volleyball, a progressive return to overhead activity or throwing program is warranted following resolution of identified impairments and limitations. For overhead and throwing athletes, analyzing appropriate technique and addressing identified deviations are important to prevent further injury.[361,427] During the advanced and return-to-sport stages of rehabilitation, adherence to a progressive return to throwing or overhead activity program[22,427] will maximize performance and mitigate risk of further injury.

The clinical decision making for reintegration into sport activities utilizes a comprehensive and criterion-based approach that includes assessment of impairments as well as functional performance Box 15-2. A rehabilitation plan that culminates with a progressive reintegration of the young individual into the desired activity is advocated. A progressive approach toward unrestricted activity participation may be initiated with modification of activity participation, such as time of participation and demands of participation. Appropriate communication among the health care team and with the patient, family, and other involved persons (e.g., coaches) is important during the advanced stages of rehabilitation to ensure collaboration with the progressive plan of care.

BOX 15.2 Textbox for Intervention

Body Functions and Structures

- Static and dynamic stretching
- Open and closed kinetic chain strengthening
- Gait retraining
- Neuromuscular reeducation

Activities and Participation

- Functional return to activity progression

Other (e.g., Environment, QoL when applicable)

- Environmental integration to activity specific tasks

QoL, quality of life.

THE YOUNG ATHLETE WITH A PHYSICAL DISABILITY

The number of children with disabilities in the United States has continued to rise, with the greatest population living in lower socioeconomic status environments.[187] Children with disabilities benefit from physical activity similarly to their able-bodied or typically developing peers. Yet individuals with disabilities are less physically active and display higher risk for ailments associated with inactivity.[2,6,34,50,226,300,428] Children with intellectual impairments, especially those of low socioeconomic status, exhibit obesity rates among the highest in the nation.[2,134,300,355]

Despite increasing rates of participation in Paralympics and Special Olympics, individuals with disabilities still have limitations in accessing school and community resources.[2,21,34] According to a systematic review by Bloemen et al. in 2015, both positive and negative factors involving physical ability, sporting modification, and opinions toward wellness influence individuals' participation in physical activities (Table 15.8).[50,57,59,87,98,199,281,369,385] Many of these factors are similar to those affecting typically developing peers, yet medical impairments complicate normal requirements such as transportation and create a fear of trying a new activity. Health care providers are encouraged to promote healthy behaviors with patients, including strength, cardiovascular, and injury prevention training. Through collaboration with recreational therapists, occupational therapists, coaches, teachers, parents, and community advocates, therapists can best advocate for patients to safely participate in fitness, sports, and recreational training.

Both psychological and physiologic benefits of sports participation have been demonstrated in individuals with disabilities. Athletes with and without disabilities report improved social acceptance and enjoyment of participation in physical activities.[208] Fitness programs assist with cardiovascular fitness, mobility throughout the aging process, bone health, and muscle strength, and they decrease the risk of ailments of inactivity such as hypertension, fatigue, and difficulty performing daily activities.[114,355,357,414,425] Self-concept and self-acceptance were shown to be equal or greater in athletes as compared to nonathletes with disabilities.[174,363] According to a systematic review by Sahlin et al. in 2015, confidence, identity, competence, self-worth, life satisfaction, and community integration all increase through sports and recreational activities for individuals with neurologic pathologies.[363] Consistent with a systematic review performed in 2014, exercise can also help individuals with intellectual disabilities limit challenging behaviors associated with their cognitive impairments.[312] A variety of sports and recreational experiences promote social interactions, cognitive function, self-esteem, and skill acquisition through experience in the sport or recreational activity.[45,374]

TABLE 15.8 Personal, Environmental, and Other Factors Influencing the Physical Activity for People with a Disability

Barriers to Physical Activity

Social Influence
Physical activity and sports are not a priority at this time

Health Conditions
Presence of a cognitive impairment
Concerns of pain, Injury
Medical complications
Current injury or disability
Individual is currently in poor health
Poor joint positioning or integrity

Self-Efficacy
Feeling insecure/lacking confidence
Feeling an attractive sport is too difficult

Attitude
"Being active is not good for the body"
Fear of increasing risk for injury
Fear of injury, safety, or incontinence
"I need to rest in my spare time"

Fitness
Fatigue
Lack of energy and endurance
Lack of motor skills
Poor physical condition
Lack of skills

Motivation
Poor motivation
Preferences for sedentary behavior
Physical activity/sports "are not fun"

Age
As individuals age, they report more fear and lack of motivation of participating in a new physical activity

Time
Lack of time
Learning new skills is too time consuming
Time to shower/change

Other Personal Factors
Awareness of differences from peers
Resisting asking for help
Feeling like an outsider/being ashamed
Not accepting (extent of) disability
Unsure how to use equipment
Not knowing how to exercise
Self-conscious/embarrassed
Inconvenience of sweating

Family
Reliant on parents for transport and entrance to facilities
Lack of parental support
Lack of time of parent to assist
Parents not accepting extent of disability
Parents concern for child's safety
Parents feeling dissatisfaction with environment, fear of child "not fitting in," challenges with managing, and hesitating to ask for help from trainer(s)
Low parental level of education

Facilitators to Physical Activity

Social Influence
Parents are aware of the benefits of physical activity
Parents desire their child to have a sense of normalcy, belonging to a group "like" them
Physical activity assists with weight control, health

Health Conditions
Physical activity assists in fundamental movement skills

Self-Efficacy
Being able to independently negotiate barriers in the community
Being able to adapt and teach others to help
Feeling confident/gaining self-confidence
Feeling competent in a sport
Improving the ability to move without assistance from others

Intention
Desires to be active

Attitude
Motivation to be healthy
Recognizing importance of physical activity
Belief that symmetrical movement is beneficial
Maintaining a healthy body

Socialization
Opportunity for social interaction
Feeling accepted as part of a group

Abilities
Achieving fundamental movement skills

Other Personal Factors
Accepting disability
Having perseverance
Activities gives a sense of freedom

Family
Family resilience
Doing physical activity with parents
Parental encouragement and motivation
Parental support: getting them to places, helping with transfers, perseverance in exploring options, assertiveness (advocating for child), having a positive attitude
Encouragement to be active

Support From and Contact with People
Good teachers and instructors support
Skilled helpers
Motivation from PT teacher and friends
Peer socialization
Being accepted by peers and other parents
Making friends
Positive attitude of schoolmates, teachers, and other people
Having someone who can provide support
Having someone to do physical activity with

Sports
Activity type/sports they enjoy doing
Chances to join competition
Opportunities for sport/physical activity

TABLE 15.8 Personal, Environmental, and Other Factors Influencing the Physical Activity for People with a Disability—cont'd

Barriers to Physical Activity	Facilitators to Physical Activity
Support from and Contact with People	Sports facility: having good trainer, communication between trainers and coaches, training in small groups
Not being accepted or being bullied by peers	Advantages of wheelchair sorts: impact on child's confidence, community building, friendship, future aspirations, having necessary equipment, sport/club participation on weekend days
Teachers and instructors giving negative comments	
Lack of role models	**Environment**
Lack of physically active peers to play with	Adaptive equipment
Lack of professionals who know how to and can teach sport skills	Access to sport/physical activity in community
Professionals are not assisting child in physical activity	Accessible community recreation facilities
People's misconception or unfriendly attitude	Accessible to suitable facilities
"There's no one to do it with"	
Sports	**School**
Activity is too competitive	Participation in PE classes at school
Activity not adequately adapted	
Lacking necessary equipment/clothing	**Transport**
Lack of opportunities (rules, regulation)	Transport (living close to the city)
Sports facility: teams are too big, there's a waiting list, not allowed to play matches, limited locations to exercise	Having transportation
No space to exercise (with peers)	**Other Environmental Factors**
	Appropriate group activities
Environment	Disability-adopted programs
Environment not adequately adapted	Opportunities away from home
Not suitable accessibility to facilities	
No showering/changing facilities	
School	
Lack of professional training in physical education	
PE teachers only select students with better sport skills or performance	
Not suitable facilities at school	
Having a lot of homework	
Transport	
Lack of transportation	
Financial Support	
Financial restrictions	
High cost of sports/recreational activities	
Other Environmental Factors	
Stigma of disability	
Time commitment	
Inappropriate weather/too hot or cold	

Adapted from Bloemen MA, Backx FJ, Takken T, et al: Factors associated with physical activity in children and adolescents with a physical disability: a systematic review. Dev Med Child Neurol 57(2):137-148, 2015.

Between 11% and 61% of individuals with a lower extremity amputation participate in physical activity and/or sports.[58] The same pathologic process that caused the amputation may limit some individuals' ability to participate in activities after the amputation.[58] Yet improvements in strength, rehabilitation progressions, quality of life, aerobic and anaerobic fitness, as well as the body mass of individuals are all achieved through physical activity in individuals with amputations.[58] Once individuals start to participate in sport or recreational activity, there are improvements in the number of social contacts, their knowledge of sporting equipment, and motor skills, as well as a sense of acceptance of their disability.[58] Among children with limb deficiencies, athletic competence was one predictor of higher perceived physical appearance, lower levels of depression, and higher self-esteem.[363,409]

Individuals with Down syndrome are at a higher risk for inactivity, cardiac muscle atrophy, and obesity than those without disabilities or other diagnoses with intellectual impairments.[159,330,417] In a case series by Alesi et al., children with Down syndrome improved in both motor and intellectual scores after a 2-month training program that included cardiovascular warm-up, basic motor training, cognitive training games, and a breathing cool down.[7] Adolescents with Down syndrome displayed improved strength and agility after completing a 6-week fitness routine 3 days per week.[240] Therefore physical activity, cardiovascular fitness, strengthening, and motor training in a social environment are recommended for individuals with Down syndrome.[159,240]

Disability often causes a reduction of overall fitness relative to the general population.[129,162,333,346,354] According to Buffart et al., aerobic fitness in adolescents and young adults with spina bifida was 42% lower than in typically developing age-matched peers, with 39% of the participants with spina bifida classified

as inactive and another 37% as extremely inactive.[63] Marques et al. attribute this lack of physical activity to feelings of a lack of competence in physical activity.[259] Similarly, individuals with cerebral palsy displayed an increased tendency toward sedentary behaviors, with lower bone density compared to typically developing individuals. The largest disparities are found in those with the greatest physical impairments and in those with a tendency toward sedentary behavior as they get older.[6,251]

Adaptive Sports

Legislative actions such as the United States of Public Law 94-142, the Rehabilitation Act of 1973, the Americans with Disabilities Act in 1991, and the National Park Service Director's Order #42 in 2000 have provided individuals with disabilities improved access to educational and community resources.[94,118,325,379] In 2013 the Department of Education issued a clarification regarding the Americans with Disabilities Act: that is, students must not only be provided equal access to educational opportunities but also to extracurricular activities.[353] This has increased the opportunities for individuals with disabilities to participate in sports and recreational activities and has advanced the possibilities for individuals with disabilities to obtain college scholarships and compete as NCAA athletes.[299]

Aside from the NCAA and local recreational opportunities, Special Olympics and Paralympics offer individuals with disabilities global recognition of their accomplishments through sports and recreational activities. Since the first Special Olympics world games in 1968, the number of competitors has more than doubled on the global stage. Special Olympics' mission is to provide year-round sports training and competitions for individuals with disabilities. Qualifications for Special Olympics include verification of a medical diagnosis of intellectual impairment. Athletes compete based on their skill sets for specific sporting activities. Some teams are unified, with individuals with and without disabilities competing on the same team. Paralympics, meaning parallel to the Olympics, began after World War II, with the first world games in 1948. Since that time, Paralympics has assessed individuals through classification processes of the individual's medical impairment in order to provide fair play. Originally, this was based on the medical diagnosis, but more recently it is based on an assessment of motion, strength, and coordination required for the specific sporting activity. Most United States Paralympic sports are managed through the same Olympic governing body as the Olympics.

Sports and recreational activities can be adapted either by the rules of the game or the equipment permitted in play. For example, runners with visual impairments are provided a guide runner to assist the athlete in safely completing the course. Size of the competition area, number of athletes, and additional personnel such as a sign language interpreter are other examples of modifications made to allow individuals to compete in the sport safely. Besides addressing strength, motion, and mobility impairments associated with physical disabilities, therapists can assist children and adults in appropriate adaptations to the physical activity in order to allow the individual to participate. Examples of such adaptations include providing a bicycle handlebar modification to allow an individual with a limb deficiency ample control of the bike, seen in Fig. 15.12A.[30] Paralympic adaptations are very specific and must be cleared with an official before use. Examples of this include a track and field throwing chair pictured in Fig. 15.12B, which may or may not have a seat back or hand pole depending on the thrower's needs.[140,141,431] An important differentiation for therapists to note is between a handcycle, seen in Fig. 15.12C, which can only be used in cycling events, and a racing chair, pictured in Fig. 15.12D, which is appropriate only for running events. The biggest difference between these two chairs is that the handcycle has gears for the athlete to shift, allowing the athlete to have an easier push up and down hills, while the racing chair does not provide athletes this luxury.

Although Special Olympics and Paralympics offer individuals with physical and intellectual impairments opportunities to participate in sports and recreational activities, the incidence of obesity has continued to rise at a greater rate in individuals with disabilities than their peers without disabilities.[134,355] Education provided on the importance of physical activity and other health promotion interventions should be encouraged. This can include nutrition and promoting increased movement in more typical sedentary behaviors such as playing video games, cooking, and socializing through technological activities.[134,355,425] Fitness groups, off-season conditioning, cross training, active social gatherings, and wellness programs would benefit individuals with disabilities and assist in promoting activity.

Risk of Injury

The epidemiology of injuries of athletes with disabilities not only depends on the sport or activity the athlete is performing but also on the underlying pathology of the athlete's long-term impairment.[121,423] Generally speaking, wheelchair competitors have more upper extremity injuries, specifically injuries to the shoulder and spine, while ambulatory competitors have a higher incidence of lower extremity injuries, specifically injuries to the knee.[121,128,423] A systematic review by Webborn et al. in 2014 found that 5-a-side football had the greatest rate of injury at 22.4 injuries/1000 athlete-days and shooting had the least at 2.2 injuries/1000 athlete-days in summer Paralympic sports.[423] Skiing and sledge hockey had the greatest incidence of injury in winter Paralympic sports.[121,423] Ramirez et al. investigated injury rates of high school athletes with medical impairments including autism, emotional disturbances, and seizure disorders participating in basketball, softball, soccer, and field hockey.[344] They found the rate of injury in this population was 2.0 injuries/1000 athletic exposures, with abrasions and contusions accounting for over half of the injuries. The highest injury rate in this population was while playing soccer, recorded at 3.7/1000 athletic exposures.[344]

For athletes who compete in wheelchairs, shoulder pain may not only limit the individual in sport but also in mobility and activities of daily living.[99,121] In a survey of female wheelchair basketball players, over 90% of the 46 athletes reported experiencing shoulder pain since beginning wheelchair use, with 52% expressing current shoulder pain.[99] Nonambulatory athletes and individuals who do not regularly participate in physical activity are at high risk for low bone mineral density and fractures, which should be evaluated in the event of collision- or fall-related injuries.[80]

Head and neck injuries are of significant concern of contact wheelchair sports.[176,423] Out of 263 wheelchair basketball players, 6.1% reported sustaining a concussion in a single season, which is higher than the concussion rate in nondisabled basketball players. Most of those who did sustain a concussion did not report it, with female players sustaining concussions much more frequently than males.[424]

FIG. 15.12 Examples of appropriate adaptations to physical activities in order to allow individual participation. (A) Bicycle handlebar adaptation. (B) Track and field throwing chair. (C) Handcycle (for cycling events). (D) Racing chair (for track and field, road races). ([A] From Baker SA, Calhoun, VD: A custom bicycle handlebar adaptation for children with below elbow amputations. J Hand Ther 27(3):258-260, 2014. [B] From Chung C, Lin JT, Toro ML, et al.: Making assistive technology and rehabilitation engineering a sure bet/Uniform throwing chair for seated throwing sporting events. RESNA Annual Conference, June 26–30, 2010, Las Vegas, NV. Copyright © 2010 RESNA, Arlington, VA. [C–D] Courtesy Invacare Top End Wheelchair, Elyria, OH.)

Individuals with higher-level spinal cord injuries are at increased risk for heat intolerance. In cool conditions or at rest, trained individuals dissipate heat similarly to nondisabled trained athletes. However, due to the lack of thermoregulation and ability to dissipate heat through sweat below the level of injury, individuals with spinal cord injuries are at increased risk of heat-related injury.[341,354] It is recommended to keep athletes cool and shaded prior to competition and to provide ample cooling through cool misting stations, ice bags, or ice vests to limit heat illnesses.[220]

For athletes with spinal cord injuries at or above the sixth thoracic vertebra (T6), a life-threatening condition called autonomic dysreflexia should be monitored.[47,149,220] Autonomic dysreflexia arises when a noxious stimulus is not sensed due to a lack of sensation, and the sympathetic nervous system responds by increasing blood pressure and heart rate. It has been associated with increased performance, so is sometimes done as a method of performance enhancement, termed "boosting."[149] Boosting is performed before an event as a method of raising the blood pressure of the athlete to dangerous levels, placing the athlete at risk of stroke, heart attack, or even death. It is treated in Paralympic competitions as a doping method. Screenings before the events are performed at times to detect boosting, with a positive doping test noted when the systolic blood pressure is at or above 180 mm Hg.[47]

Overuse injuries such as tendinitis and muscle strains are common in athletes with disabilities and can be avoided through training modifications and conditioning.[23,121] The mechanism of the overuse is highly variable depending on the specific activity. For example, when comparing populations with reports of shoulder pain, scapular positioning and function may vary greatly in wheelchair basketball, amputee soccer, and disabled table tennis athletes.[15] Amputee soccer players competing on crutches had the best scapular positioning and function, likely due to differences in muscular demands and positioning of the shoulder.[23] Core stability, including scapular stabilizers and hip musculature, should be evaluated in combination with joint positioning and the athletic demands of the participant's sport.

Preparticipation Examination and Classification

Prior to initiating a physical activity program, all athletes should be screened by a physician for a medial release form in order to rule out neurologic, systemic, visual, auditory, or cardiovascular pathologies that would make it dangerous to participate in certain sports.[110] In order to qualify for Special Olympics, individuals must be at least 8 years of age and diagnosed with an intellectual impairment. Athletes are divided into teams or categories based on gender, age, and ability level.[192] In comparison, Paralympics classifies based on neurologic, visual, intellectual, or physical impairments with medical and technical classifiers evaluating the

athlete's ability to participate in each sport. Minimal disability criteria qualify athletes to participate in Paralympics.[405]

Prior to participation, specific diagnoses may require additional screening. For individuals with Down syndrome, Special Olympics requires cervical radiographs to screen for atlantoaxial instability or other cervical spine instabilities prior to participation in certain sports, such as diving, high jump, equestrian, artistic gymnastics, football (soccer), power lifting, snowboarding, judo, skiing, and pentathlon.[192] The most recent recommendations from the American Academy of Pediatrics do not include routine radiographic screenings if a child is asymptomatic, unless it is required for specific Special Olympic sporting activities.[64] If a child becomes symptomatic, he or she is immediately referred to a pediatric neurosurgeon or pediatric orthopedic surgeon who has expertise in atlantoaxial instability to evaluate if a fusion is necessary.[64] Because individuals with Down syndrome often exhibit muscular hypotonia and joint hypermobility with poor stabilization, joint integrity should be evaluated for safety in positioning and participation in the sporting activity, including orthotics as needed.[3,70,247]

For individuals who compete with prosthetics, terminal overgrowth, bone spurs, socket fit, skin integrity, and abnormal sensations should be assessed in those with congenital limb deficiencies or acquired amputations.[62,238] Socket fit is critical for injury prevention for those competing with a prosthetic, especially when the prosthetic extends around bony prominences.[238] Socket modifications may be warranted as an individual prepares for increased physical activity.[238]

Athletes competing in a wheelchair should be screened for shoulder muscle imbalances in order to limit the risk of shoulder pathology through sports and recreational activities.[66,283] Similarly, athletes with a spinal cord injury should be assessed for motion, strength, and sensation to provide appropriate mobility and safety throughout participation in the sport.[71] For individuals with arthrogryposis or limited joint range of motion, joint integrity should be assessed prior to competition in sport.[44]

Sport-specific form should be assessed in both gross motor and fine motor movements of the sport with focus on limiting compensations. Equipment should be assessed for safety, size, fit, appropriate function for the athlete, and adherence to sporting rules and regulations.[140,141,408] Each athlete's needs are unique, so equipment that is adjustable is preferred over equipment that is fixed while an athlete is growing or learning a new skill.

Training Programs

When evaluating performance enhancement, a comprehensive assessment of strength, motion, nutritional analysis, body composition, and exercise capacity may best provide for the athlete. Testing should be impairment and sport specific with arm crank, wheelchair, or single-leg ergometry assessments provided as appropriate.[46,116,320]

Medical personnel in health facilities have traditionally provided fitness programs for individuals with disabilities.[425] However, people with disabilities benefit from sport-specific training, wellness, or conditioning programs just as do those without disabilities.[137] There are significant benefits to transitioning to more community-based fitness opportunities such as recreational sports, fitness clubs, or workout facilities including the promotion of self-efficacy in a sustainable workout routine.[425] It is recommended that fitness programs not only address mobility impairments but also promote healthy eating habits, strength training, cardiovascular fitness, and the individual's community engagement.[2,34,137,158] If organized sport and recreational training programs are not available, after-school fitness programs are also a way to improve the health and wellness of children with disabilities.[173]

Several studies have evaluated the efficacy of these training programs in various groups with disabilities. Agility, aerobic capacity, strength, self-competence, functional movement, and quality of life all improved with an 8-month training program for ambulatory individuals with cerebral palsy.[413] Similarly, improvements in cardiovascular endurance and strength were found in a 10-week fitness program for children and adolescents with spina bifida.[18] In a study done by Baran et al., individuals with intellectual disabilities were able to improve in both fitness and sport-specific skills with the use of an 8-week training schedule of individuals training 3 times per week in soccer skills.[32] For youth with disabilities, task- or function-specific exercises that are fun and motivating yield greater results in functional outcomes.[201,207]

For older athletes, more traditional strength and conditioning tactics may yield greater gain. In a study of eight males with spinal cord injuries and eight male control subjects, both groups displayed similar improvements in strength and power with an 8-week heavy resistance training program, with improvements also noted in a 10-meter sprint.[404] Therefore as for able-bodied athletes who would not train the same for a 10-meter sprint or a 10,000-meter run, training programs should be individualized to the athlete's specific goals and sporting needs.

Biomechanical analyses of movement patterns are becoming more common in sports and recreational activities. Individuals with limb deficiencies have been specifically analyzed for running, swimming, and long jump. Runners and swimmers display decreased step length and stroke length on the involved side compared to the uninvolved side.[58] This is not associated with increased injury at this time, while runners with transfemoral amputations with low back pain display impaired frontal and transverse pelvic and lumbar motion.[374] Therefore not only are strength, power, anaerobic, aerobic, and sport-specific training appropriate, but biomechanical analysis of sport-specific movement patterns should also be evaluated with coaching provided as needed.

SUMMARY

Young athletes are not small adults. They have unique issues in sports participation that must be specifically addressed. Recognition of these unusual qualities is necessary for effective prevention and management of sports-related injuries.

Physical therapists should play a significant role in the total management of the child athlete. The broad-based and eclectic medical background of physical therapists makes them ideal professionals for the assessment and rehabilitation of sports injuries in athletes with full or altered physical capabilities. Depending on advanced experience or certification in sports physical therapy, athletic training, or exercise physiology, they may be the primary medical professionals to administer total management, from prevention to return to participation after injury.

A physical therapist is an important part of the comprehensive medical team that manages sports-related injuries in young athletes. Physical therapists may work with certified athletic trainers or exercise physiologists to provide comprehensive sports safety management. The certified trainer is appropriately skilled to assist

with preparticipation screenings and to provide onsite coverage of practices and games with immediate triage and injury management. The exercise physiologist plays an integral part in preseason screening and in conditioning and training programs. The physical therapist can provide assessment and total rehabilitation of sports injuries and aid in phasing the athlete back to play with appropriate progression, supportive devices, or medical limitations. The certified trainer or the exercise physiologist often works with the physical therapist in the return-to-play planning and follow-up.

The goal of these programs is to promote the health and safety of the young athlete. All those involved should work in a manner appropriate to their education, skills, and practice statutes as members of a team, including coaches and parents, toward the goal of safe, rewarding, and successful participation in sport and recreation.

Case Scenarios on Expert Consult

Three case scenarios are presented:

- The post-concussion management of a 16-year-old elite swimmer.
- Management of a 10-year-old boy with osteochondritis dissecans at the knee.
- Postoperative management of anterior cruciate (ACL) reconstruction in a young female athlete.
- Video is also presented that addresses examination and includes both procedures and scoring protocols.

Pediatric Oncology

Victoria Marchese, Kristin M. Thomas, G. Stephen Morris

INTRODUCTION

The most common pediatric (children and adolescents 0–19 years of age) cancers are leukemia (specifically acute lymphocytic leukemia), lymphomas (Hodgkin's and non-Hodgkin's lymphoma), sarcomas, and central and peripheral nervous system tumors. The combined 5-year relative survival rate for all pediatric cancers has improved markedly since the 1980s, increasing from 61% for cases diagnosed between 1975 and 1977 to 83% for cases diagnosed during 2005 and 2011.[29] Although overall mortality has decreased, these rates vary widely depending on the type of cancer, age of the child, stage of disease at diagnosis, and presence of other comorbidities. For example, the 5-year survival rate for children with acute lymphoblastic leukemia (ALL) exceeds 90% and is 97% in children with Hodgkin's lymphoma, but it is only 71% and 72% in children with osteosarcoma and brain and central nervous system (CNS) tumors, respectively. (Note: All frequency, incidence, and prevalence numbers appearing in this chapter have a common reference: American Cancer Society: *Cancer Facts & Figures 2014,* Atlanta: American Cancer Society, 2014.)[1]

Pediatric cancers are treated with several therapeutic interventions (surgery, radiation, chemotherapy, and targeted therapy), either singly or in combination with one another. The increased survival rate of children with cancer is largely attributable to improvements in the efficacy of these interventions.[13,46,47] However, these interventions are increasingly recognized for the adverse effects that can result from their use, including functional impairments, cognitive changes, and morphologic alterations.[52,54,55,61,74] It is important for the physical therapist (PT) to recognize that these changes are superimposed on infants, children, and adolescents who are still growing and developing physically, mentally, and socially, which adds treatment complexities not typically seen in adults with cancer. It is also important for the PT to recognize that a child's cancer diagnosis significantly impacts the whole family. Treatment may require that the family travel away from home and remain absent for extended periods of time. Treatment and accompanying adverse effects may prevent the child from participating in age-appropriate play, school, sports, and family activities. Pediatric physical therapists and physical therapist assistants (PTAs) practice within this complex environment, making pediatric oncology a thoroughly unique specialty area within oncology rehabilitation specifically and physical therapy in general.

Increased survivorship in the pediatric cancer population has resulted in substantial growth in the number of adult survivors of childhood cancer, now estimated to be 350,000. Improved survival rates have revealed previously unknown late effects and comorbidities related to the disease, its treatment, or both. Specifically, research has shown that survivors of childhood cancer are at a greater risk for experiencing cognitive deficits, functional impairments, cardiovascular disease, pulmonary disease, and early onset frailty than their siblings.[30] Growth in the numbers of these survivors has highlighted their need for increased screening and regular follow-up care to identify potential impairments as early as possible and provide mitigating care. Screening and treatment guidelines have been developed for health care professionals, including PTs and PTAs, to guide the care and treatment of survivors and limit, as much as possible, late effects and additional impairment.[42] Specifically, the Children's Oncology Group Long-Term Follow-Up Guidelines for Survivors of Childhood, Adolescent, and Young Adult Cancer (COG LTFU Guidelines) assist in addressing the specialized and unique needs of survivors of childhood cancer.[11]

Since the 1990s, there has been an increased interest in the specialized practice area of pediatric oncology physical therapy. This is evidenced by an increase in the number of publications in the area of pediatric oncology rehabilitation, expansion in the number of centers providing pediatric cancer rehabilitation, and membership in the Oncology Section of the American Physical Therapy Association (APTA). PTs and PTAs are an essential part of the health care team that manages the care of children with cancer both during and after medical treatment. Pediatric PTs and PTAs play a key role in helping the children and their families manage the myriad of challenges they face, specifically related to functional mobility and participation in age-appropriate recreation. A pediatric PT and PTA provide patient and family education, treat acute or chronic impairments, and address gross motor delays and mobility limitations, all the while encouraging patient and family participation in daily life activities. Importantly, studies demonstrate that physical therapy interventions are effective and safe for children with cancer regardless of the stage of their disease or type of medical treatment received.[17,19,38,59,63]

Pediatric oncology physical therapy is a growing field, and to move the profession forward with new, cutting-edge tools and interventions, clinicians and researchers need to work together. Clinicians and researchers are encouraged to develop clinical pathways, practice guidelines, and models of care for infants, children, and adolescents who are being treated for a cancer diagnosis or are cancer survivors within and across all pediatric practice settings.

This chapter introduces the reader to the signs and symptoms of pediatric cancers, the most common medical interventions used to treat these diseases, the PT examination, and common therapeutic interventions.

BACKGROUND INFORMATION

COMMON PEDIATRIC CANCERS

In 2014, the American Cancer Society estimated that there were 15,780 new cancer cases in children (ages 0–14; 10,450) and adolescents (ages 15–19; 5330). Cancers of blood cells accounted for the majority of cancer cases in both children (41%) and adolescents (35%). Brain and CNS tumors accounted for 31% (children) and 10% (adolescents), respectively. Bone tumors occurred more frequently in adolescents (7%) than in children (4%).[1] The following discussion briefly describes the pathophysiology of these common pediatric cancers and some less common types of pediatric cancers seen in pediatric oncology physical therapy settings.

Leukemias

Leukemia is a form of cancer that begins in the blood-forming cells found in the bone marrow. This disease occurs when defective, nonfunctional white blood cells or leukocytes are produced in very large numbers. These defective leukocytes migrate from the bone marrow into the bloodstream, displacing the healthy leukocytes. Leukocytes play a central role in helping the body defend itself against infectious agents including viruses, bacteria, and fungi, and as the numbers of functional leukocytes in the blood decline, the body's ability to protect itself against these infectious agents also declines. This deterioration in immune function is reflected in several of the common symptoms of leukemia (Table 16.1).

Leukemia is categorized as either acute or chronic and by the type of cancerous cells (lymphoid or myeloid). Chronic lymphoblastic leukemia (CLL) or chronic myelogenous leukemia (CML) is less common in children. The two most common types of pediatric leukemia are acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML). ALL is the most common, accounting for 80% of all pediatric leukemia cases and occurring most frequently in children between the ages of 2 and 5 years. ALL is considered acute because the proliferation of immature, nonfunctional leukocytes is rapid. If left untreated, death occurs quickly in these patients. Significant advances in the effectiveness of chemotherapeutic agents have increased the survival rate of patients with ALL to over 90%. However, treatment protocols for children with ALL often require a child to receive chemotherapy for 2 to 3 years and may result in multiple short- and long-term body function impairments, activity limitations, and participation restrictions.[18,20,30,36,53,60,71]

AML is the second most common pediatric leukemia and is also known as acute myelogenous leukemia, acute myelocytic leukemia, myeloblastic leukemia, granulocytic leukemia, or acute nonlymphocytic leukemia. This form of leukemia is characterized by the presence of defective and nonfunctional granulocytes (bacteria-destroying cells) or monocytes (macrophage-forming cells). As with ALL, AML compromises the body's immune system, increasing the patient's risk for infections. AML accounts for about 5% of all pediatric cancers and occurs most frequently during the first 2 years of life. Symptoms of AML are similar to those of ALL (see Table 16.1). AML is treated with chemotherapy, and the survival rate for pediatric patients with AML is approximately 63%, somewhat less favorable than that of children with ALL.

Lymphomas

Lymphomas, like leukemia, are cancers involving blood cells. In these particular diseases, the cancer occurs in lymphocytes, another subtype of mature white blood cells that play a major role in the body's immune function. Lymphocytes include B cells, which synthesize antibodies, and T cells, which activate phagocytes and inflammatory processes and can become cancerous. Because lymphocytes are found throughout the lymphatic system, lymphomas can occur in specific lymphatic structures including lymph nodes, spleen, bone marrow, and the thymus as well as within the lymphatic structures present in many organs including the brain, the gastrointestinal tract, and the liver.

Lymphomas are the third most common type of cancer found in children, accounting for approximately 10% to 12% of pediatric cancers. Signs and symptoms include pain-free swelling of lymph nodes (lymphadenopathy), which can occur anywhere in the body, fever, night sweats, and weight loss (see Table 16.1). Definitive diagnosis is made by examining a biopsy of lymph tissue for the presence of abnormal tissue architecture and lymphocytes.

There are two major types of lymphoma: Hodgkin's lymphoma (HL, 3% of childhood cancers) and non-Hodgkin's lymphoma (NHL). HL, which is the less common of these two lymphomas, is identified by the presence of abnormal B lymphocytes called Reed-Sternberg cells and typically begins in lymph nodes found in the chest, neck, and abdomen. HL is rare in children younger than 5 years, but the incidence rises rapidly in adolescents, accounting for 16% of the cancers in this age group. Treatment involves both chemotherapy and radiation. Current survival rates are about 97%.

NHL is a heterogeneous group of blood cancers that adversely impacts both B and T lymphocytes and includes all forms of lymphoma except HL. NHL occurs more frequently in children over the age of 3 years and presents with painless supraclavicular or cervical adenopathy, a nonproductive cough, fatigue, anorexia, and pruritus (see Table 16.1). Medical conditions or treatments that result in immune suppression, inherited immunodeficiency diseases, and HIV infection increase the risk for developing NHL. Chemotherapy, sometimes accompanied by radiation, is the main form of treatment for most forms of NHL and has resulted in a survival rate for children with NHL of approximately 87%.

TABLE 16.1 Signs and Symptoms of Common Pediatric Cancers

Type of Cancer	Signs and Symptoms
Leukemias	Enlarged lymph nodes (lymphadenopathy), enlarged liver or spleen (hepatosplenomegaly), fever, easy bleeding or bruising, night sweats, weight loss
Lymphomas	Painless enlargement of lymph node, night sweats, persistent fatigue, fever and chills, unexplained weight loss, anorexia, pruritus
Sarcomas (soft tissue and bone)	Intermittent pain that often worsens at night, swelling, decreased range of motion or altered gait pattern, swelling
Brain and central nervous system tumors	Headache, vomiting (especially in the morning); vision, speech, and hearing changes; worsening balance; unsteady gait; unusual sleepiness; weakness

Brain and Central Nervous System Tumors

Brain and spinal cord tumors are the second most common pediatric cancer, accounting for 21% of all pediatric cancer cases, and the third most common type of cancer found in adolescents. These tumors are classified by the type of cell or tissue in which they originate or by the tumor's location in the CNS. It is important to note that any tumor, including CNS tumors classified as benign, can cause significant adverse effects largely because the growth may cause compression of adjacent healthy, functioning tissue. The signs and symptoms of brain and CNS tumors depend on tumor location, the developmental stage of the child, the communication ability of the child, and the presence of increased intracranial pressure. Symptoms may include morning headaches, nausea and vomiting, vision loss, speech or hearing impairments, increased rate of loss of balance, occurrence of seizures, unusual sleepiness, and personality changes (see Table 16.1). Medical imaging plays a central role in diagnosing these tumors.

Three common categories of CNS tumors found in children and adolescents include astrocytomas, medulloblastomas, and ependymomas.

Astrocytomas

Astrocytomas are the most common CNS tumor found in children and adolescents, accounting for about 35% of CNS tumors in these age groups. These tumors arise in neural support cells known as astrocytes. These are neuroglial, star-shaped, non-neuronal cells that maintain brain homeostasis and the microarchitecture of the brain parenchyma, regulate the development of neuronal cells, and provide for brain tissue repair and protection. The pathogenicity of astrocytomas can range from low grade (less invasive) to high grade (more invasive). Because astrocytes are found throughout the CNS, tumors involving these cells also appear throughout the brain. Headaches, seizures, memory loss, and changes in behavior are the most common early symptoms of an astrocytoma (see Table 16.1). Treatment of astrocytomas, like that for all CNS tumors, depends on cancer type, grade, location, and size and other tumor-specific factors. Whenever possible, these tumors are first surgically resected, and then the patient is often treated with chemotherapy or radiation therapy.

Medulloblastomas

Medulloblastomas are a group of highly invasive embryonal tumors that are rare in adults but common in children, particularly those under 10 years of age. These tumors typically arise in the cerebellum but can spread throughout the central nervous system and account for about 18% of childhood cancers. Early symptoms include headaches, vomiting, and lethargy. More specific symptoms are dependent on the region of the brain invaded by the tumor.

Ependymomas

Ependymomas are tumors that arise from glial cells lining the ventricular system of the brain or the central canal of the spinal cord and can range in severity from low to high grade. These tumors account for about 5% of all childhood brain cancers. In addition to directly damaging brain tissue, these tumors can disrupt normal flow of the cerebral spinal fluid resulting in increased intracranial pressure and further CNS damage. Overall, the survival rate for these and other CNS tumors exceeds 70%; however, the survival rate for these tumors is variable, depending on tumor location, patient age at time of diagnosis, and responsiveness to treatment.

Embryonal Tumors

These are rapidly growing tumors that arise from embryonic tissues that fail to mature but continue to grow.

Neuroblastomas

This group of tumors includes neuroblastomas (accounting for 6%-10% of all childhood cancers), which are neuroendocrine tumors that arise from neuroblasts, or neuron precursor cells, and are found throughout the developing sympathetic nervous system.[64] This tumor begins most frequently in the adrenal gland but can begin in or spread to other areas including the neck, chest, abdomen, or pelvis. Neuroblastomas most commonly affect children under the age of 5 years, though they may occur in older children. Several disease characteristics are used to place children with a neuroblastoma into one of three risk groups—low, intermediate, and high—with prognosis becoming poorer and treatment more involved with increasing risk status.

Retinoblastomas

Retinoblastomas (2% of childhood cancers)[1] are tumors that originate in the retina, arising when immature retinoblasts mutate into cancerous cells. Retinoblastomas are most frequently diagnosed in children younger than 4 years of age, and 40% of these cases arise from a heritable gene defect located on chromosome 13.[5] Symptoms include a pupil that appears red or white instead of black, a crossed eye, vision changes, and an enlarged pupil. Retinoblastomas are commonly diagnosed during a baby's well-baby check, and treatment may include chemotherapy, radiation, and surgery.[12]

Wilms' Tumor or Nephroblastoma

Wilms' tumor or nephroblastoma (5% of childhood cancers) is the most common form of kidney cancer in children, with the majority of cases diagnosed in those younger than 5 years of age. These tumors tend to be unilateral and large when diagnosed. Symptoms typically include an asymptomatic, unilateral abdominal lump or mass, blood in the urine, fever, diarrhea, urogenital infections, and systemic symptoms including fever and malaise.[14] Treatment is dependent on the stage of the tumor but frequently involves both surgery and chemotherapy.

Bone Tumors and Soft Tissue Sarcomas

Sarcomas are solid tumors that arise in connective tissue (muscle, bone, cartilage, and fat) in the body. Pediatric sarcomas collectively account for 7% of all tumors found in children and adolescents. The most common childhood sarcomas include osteosarcoma (2% of childhood cancers), Ewing's sarcoma (1% of childhood cancers), and rhabdomyosarcoma (3% of childhood cancers).[1]

Osteosarcomas

Osteosarcomas are tumors found in bone that arise from the inappropriate growth and development of immature bone cells. The resulting bone tissue is weaker than normal bone tissue and more susceptible to fracture (Fig. 16.1). Osteosarcomas typically affect the distal femur or proximal tibia (metaphyseal area) with the next most common site being the proximal humerus. An osteosarcoma weakens the healthy bone increasing the risk for a pathologic fracture, which often is the first presenting sign. Long-term bone or

FIG. 16.1 X-ray of a 14-year-old female with osteosarcoma of the distal femur. (Courtesy Children's Hospital Colorado, Center for Cancer and Blood Disorders, Ortho-Oncology Program.)

FIG. 16.2 Resection of tibial osteosarcoma with intercalary allograft reconstruction and gastrocnemius myoplasty. (Courtesy Children's Hospital Colorado, Center for Cancer and Blood Disorders, Ortho-Oncology Program.)

joint pain that worsens at night is symptomatic of osteosarcomas, and adolescents who are active in sports tend to complain about pain in the lower femur or right below the knee prior to the diagnosis of an osteosarcoma. If the osteosarcoma is large enough, it can visibly appear as a swelling (see Table 16.1). Treatment for osteosarcomas focuses on surgically removing the tumor using limb-sparing techniques with the aim to preserve as much of the bone and surrounding tissue as possible, thus preserving use of the affected limb (Figs. 16.2, 16.3, and 16.4). Occasionally the limb will be amputated if the neurovascular system is extensively involved.

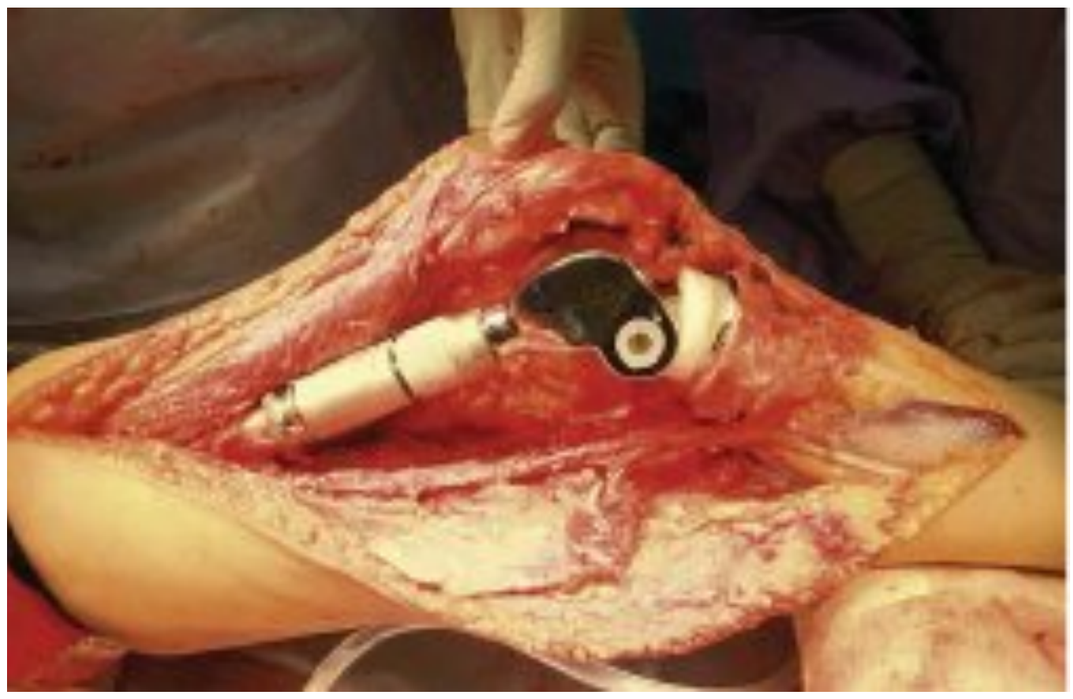

FIG. 16.3 Prosthetic reconstruction following proximal tibia osteosarcoma resection. (Courtesy Children's Hospital Colorado, Center for Cancer and Blood Disorders, Ortho-Oncology Program.)

FIG. 16.4 X-ray of a prosthetic reconstruction of resection of a distal femur osteosarcoma. (Courtesy Children's Hospital Colorado, Center for Cancer and Blood Disorders, Ortho-Oncology Program.)

Rotationplasty (the Van Nes procedure) is an option in certain situations when the child would require an amputation but the surgeon and family choose to use the foot/ankle as the knee joint (for a more detailed discussion of this procedure, see Chapter 13) in order to assist with increasing functional mobility and giving the child a functional, neurovascularly intact knee joint, which greatly improves function and decreases energy expenditure with a prosthesis.[27] Chemotherapy may be administered before surgery to reduce the size of the tumor and is almost always administered following surgery. Radiation treatment is typically not effective in managing osteosarcoma.

Ewing's Sarcoma

Ewing's sarcoma is a malignant cancer found in both bone and in soft tissue. It is the second most common malignant bone tumor found in children and adolescents, and it occurs about equally in the bones of the extremities and bones in other parts of the body. Pain at the site of the tumor is typically the first symptom, sometimes with a mass or swelling present. Ewing's sarcoma may also arise in soft tissues. These tumors metastasize in about 25% of the cases, migrating to the lung, bone, and bone marrow. Metastases significantly reduce the chance of cure and survival.[10] Chemotherapy may be administered before surgery to reduce the size of the tumor and is almost always administered following surgery. Radiation treatment is typically not used to manage these tumors.[9]

Rhabdomyosarcoma

Rhabdomyosarcoma is a soft tissue sarcoma that arises from mesenchymal cells destined to become striated muscle cells. These tumors are found in children, adolescents, and young adults and can occur anywhere in the body. In children and adolescents, these tumors occur most frequently in the head and neck region and in urinary and reproductive organs. Treatment consists of surgery, chemotherapy, radiation therapy, or some combination of these interventions.

MEDICAL MANAGEMENT OF PEDIATRIC CANCERS

Once a child receives a diagnosis of cancer, decisions must be made regarding medical treatment. The medical treatment is dependent on the type of tumor present, its location, and the extent of the disease. Physicians use *staging* classification systems to describe the severity of a child's cancer, with larger stage numbers indicating greater disease severity. Staging classifications offer the medical team information on the size or extent or reach of the original tumor (i.e., whether or not the cancer has spread to other areas of the body). Oncologists use staging classifications to assist in determining the best treatment protocol to use for each patient. Understanding disease severity and treatment protocols allows the PT to better anticipate adverse effects of treatment and enables the PT to develop plans consistent with current and anticipated impairments and activity/limitation. Children are typically on treatment protocols that have been developed either at leading pediatric hospitals such as St. Jude Children's Research Hospital or from clinical trials undertaken by groups such as the Children's Oncology Group (COG) or a National Cancer Institute–supported clinical trials group. These protocols provide the medical team with a projected treatment and assessment time line for a specific medical treatment. Treatment options include surgery, radiation therapy, chemotherapy, and, more recently, alternative and complementary therapies. Some patients will require only one type of primary medical treatment intervention, but more typically a combination of treatments is required to successfully treat the disease.

The following section briefly describes these different medical treatment options.

Surgery

Surgery, in the context of cancer treatment, involves the resection or removal of a solid tumor (sarcomas, brain and CNS tumors, Wilms' tumors, etc.) along with sufficient amounts of the surrounding tissue to ensure that all tumor cells have been

removed. For pediatric solid tumors, including CNS tumors and sarcomas, surgery remains the principal treatment strategy. However, some tumors may be too large to resect or may be located where surgical resection poses a significant risk for further injury to the tissue adjacent to tumor. Examples of the latter include brain stem gliomas or neuroblastomas that extend into the spinal cord. In these cases, alternative treatment options such as chemotherapy or radiation therapy may be used.

To ensure complete tumor resection and removal of all cancerous cells, surgeons resect the tumor along with a "clean" tissue margin (i.e., cancer-free, healthy tissue adjacent to the resected tumor). Clean margins suggest that all cancer cells have been removed. To further ensure that this is the case, chemotherapy and radiation therapy are frequently administered following a tumor resection. Radiation and chemotherapy may also be used prior to surgery in an effort to reduce the size of the tumor, making resection less difficult, and reducing surgical damage to surrounding, healthy tissue. In some cases surgery is used to debulk or resect as much of the tumor as possible, and chemotherapy and radiation therapy are then used to further shrink the remaining tumor. In cases of advanced or incurable cancers, surgery may be used to relieve side effects caused by a tumor, rather than to cure the disease itself. Many surgical procedures are used to treat pediatric cancers, and it is beyond the scope of this chapter to examine them. PTs treating pediatric patients with a surgical history for cancer treatment need to know where the tumor was located, what tissues (both cancerous and healthy) were resected, and what tissues were spared. Such understanding helps to identify impairments and possible impairments, thus providing guidance in developing physical therapy examination strategies and intervention plans.

Surgical interventions may play a tangential role in the diagnosis and treatment of some pediatric cancers. For example, tumor biopsies are often surgically acquired and subsequently used to stage and grade a tumor as well as determine its genetic makeup. Cerebrospinal fluid and bone marrow aspirates for analysis are typically collected surgically as well. Indwelling devices intended for long-term use such as implantable ports, central lines, Hickman catheters, or a peripherally inserted central venous catheter (PICC) line are often surgically implanted and then used to deliver drugs and collect blood samples. Medical shunts, such as a ventriculoperitoneal shunt, which drain cerebrospinal fluid from the brain into the abdominal cavity, are also surgically placed under either general or local anesthesia. Care must be taken not to dislodge these catheters during PT activities and to keep the area where they puncture the skin clean, dry, and protected from injury. Many pediatric patients receive anesthesia or light sedation prior to undergoing these procedures as well as imaging studies or radiation treatment. Following anesthesia, a child is at risk for a decrease in balance and postural control, thus increasing the risk of falling. Extra care should be taken if a PT session follows a procedure that requires anesthesia.

Radiation

Radiation has been a mainstay of cancer treatment for well over a century. This therapy exposes tumors to ionizing radiation, which damages the DNA of the irradiated cells, thus limiting the ability of these cells to successfully replicate. This treatment may be used to completely eradicate a tumor (curative), to reduce tumor size making resection less difficult or even possible, or to prevent tumor recurrence. Radiation therapy can be delivered from either an external or an internal source; however, the majority of pediatric cancers are treated with radiation from an external source. Most doses of radiation required to successfully treat patients with cancer are too strong to be tolerated in a single dose. Rather, the total required radiation dose is usually *fractioned* or divided into smaller doses and delivered over a period of multiple days. Typical fraction schemes have the total dose divided into 30 equal units, delivered 5 times per week for 6 weeks; however, individual treatment doses can be increased or decreased depending on the patient response and the number of treatments received. Fractionation causes fewer toxic effects and often allows the patient to successfully receive needed amounts of radiation.

Radiation therapy may be used alone, or more frequently, in combination with surgery or chemotherapy. Regardless, radiation does not distinguish healthy tissue from cancerous tissue. As a result, healthy tissue can be damaged and destroyed by this intervention. Technological advances that allow more of the radiation beam to reach the tumor itself and less to strike healthy tissue has decreased collateral radiation damage. Despite these advances, radiation therapy often causes adverse side effects. These acute side effects include nausea and vomiting, diarrhea, hair loss, mucositis (inflammation of the mucus membranes lining the digestive tract), fatigue, and skin changes at the site irradiated (Table 16.2). Once treatment has been completed, these adverse effects typically diminish. Increased survivorship has led to the recognition that radiation used to treat pediatric cancers may cause adverse effects that do not

TABLE 16.2 Short-Term and Late Effects Associated With Receiving Radiation Therapy

Short-Term Effect	Late Effects
Skin: redness, blistering, dry skin	Cardiac and vascular disease, metabolic impairment (low growth hormone), obesity, dyslipidemia Gurney JG, Ness KK, Sibley SD et al. Metabolic syndrome and growth hormone deficiency in adult survivors of childhood acute lymphoblastic leukemia. Cancer, 107(6): 1303-1312, 2006
Myelosuppression	Pulmonary fibrosis, restrictive lung disease
Fatigue	Osteoporosis, joint contractures, altered tooth development
Cognitive deficits	Cognitive deficits (impaired executive function), memory impairments Long-term decline in intelligence among adult survivors of childhood acute lymphoblastic leukemia treated with cranial radiation. Krull KR, Zhang N, Santucci A, Srivastava DK, Krasin MJ, Kun LE, Pui CH, Robison LL, Hudson MM, Armstrong GT. Blood. 2013 Jul 25;122(4):550-3. doi: 10.1182/blood-2013-03-487744. Epub 2013 Jun 6
Pain	Pain
Impaired digestive tract function (nausea, vomiting, mucositis diarrhea, difficulty swallowing)	Infertility
Hair loss	Increased risk for developing other cancers

Please note that this is not a complete list of adverse effects.

manifest themselves until years after the radiation therapy has been completed. Radiation is well recognized as causing fibrosis with resulting tissue injury; therefore, knowing the radiation field (area irradiated) allows a PT to anticipate, and ideally prevent, possible impairments to that area. For example, irradiation of the lungs in patients with mediastinal lymphoma can result in pulmonary fibrosis with accompanying respiratory defects; irradiation of the heart can cause fibrotic injury to the valves, coronary arteries, and myocardium, reducing cardiac function and increasing risk of cardiac disease; and radiation involving joints can result in fibrotic injury to the connective tissue components of the joint, thereby reducing joint range of motion and increasing the risk of osteoporosis in the involved bones. Cranial radiation can cause cognitive deficits during treatment, and these deficits may remain or reemerge after treatment has been completed. Abdominal and pelvic radiation can lead to kidney dysfunction and infertility in both males and females. A partial listing of these late effects is presented in Table 16.2.

Chemotherapy

Chemotherapy (CTX) refers to the use of drugs to either eradicate a tumor (curative) or to slow tumor growth, which may prolong life and reduce its immediate adverse effects (palliative). A large number of naturally occurring and synthesized compounds are used to treat pediatric cancer patients. These drugs (often simply referred to as "chemo") are perhaps best known for causing a number of adverse effects including nausea and vomiting, hair loss, and myelosuppression, a condition in which bone marrow activity is decreased, resulting in fewer red blood cells, white blood cells, and platelets. Chemotherapeutic agents can be administered as the primary treatment intervention. They can also be administered in conjunction with other primary therapies either before administration of the primary therapy, so-called neoadjuvant therapy, or after completion of the primary therapy, which is called adjuvant therapy. The purpose of delivering neoadjuvant therapy is to reduce the size of the tumor prior to delivery of the primary treatment (e.g., to shrink the tumor prior to surgical resection). Adjuvant therapy is provided in an effort to ensure that any cancer cells remaining after completion of primary therapy are killed, thus reducing the likelihood of recurrence. Chemotherapeutic agents act either by interrupting the cell cycle and hence cell division or by targeting specific proteins and disrupting metabolic processes that render the cells cancerous.

Traditional chemotherapeutic agents are cytotoxic (i.e., toxic to cells) and act by disrupting DNA structure, inhibiting DNA/RNA synthesis, or preventing cell division, thereby slowing or preventing tumor growth. Chemotherapy drugs are most effective against rapidly dividing cells, but they typically lack specificity for the cancer cells, thus they damage and kill rapidly dividing, healthy cells as well as cancer cells. There are a number of well-recognized acute adverse effects including damage to the bone marrow (causing myelosuppression, immune suppression, and increased frequency of bruising and bleeding), digestive tract (loss of appetite, nausea and vomiting, constipation/diarrhea, and mucositis), and hair follicles (alopecia) (Table 16.3). Children may experience a generalized myelosuppression resulting in decreased cell numbers of different blood cell types or may experience reductions in the number of specific types of blood cell types resulting in neutropenia (low number of neutrophils), thrombocytopenia (low platelet count), or anemia (low red blood cell count). When anemia is present, the patient may experience early fatigue, excessive tiredness, reduced endurance, headaches, and dizziness that may limit participation in the PT examination or treatment session. Leukopenia, a decrease in total number of white blood cells, is often used to identify the presence of an infection and as a signal of reduced infection-fighting ability. However, the cell numbers of neutrophils, the subpopulation of white blood cells most responsible for fighting infections, provide a better indicator of an individual's risk for developing an infection. The best estimate of neutrophil numbers is provided by the absolute neutrophil count (ANC), the product of the total white blood count and the contribution of neutrophils to the total blood cell count (%). Although an ANC value of 500 cells/mm^3 or lower signals an increased risk of infection, a decreasing ANC that includes this value is of more concern than a rising ANC that includes this value. It is important to remember that normal ranges for the different blood cell types vary by age and gender (Table 16.4).

Other adverse effects of chemotherapy can include hearing loss, peripheral neuropathy, neurocognitive changes, myopathy, and osteoporosis[3,4,9,56] (see Table 16.3). Platinum-based chemotherapeutic agents such as cisplatin are known to cause hearing loss, and all children taking this drug or class of drugs are at risk for permanent hearing loss, but those under 6 months of age are at particular risk. Children who are receiving cisplatin undergo routine hearing assessments from an audiologist. Both cisplatin and vincristine are known to cause peripheral neuropathy and loss of muscle strength (resulting in weakness). Functionally, these drugs impair gait, reduce endurance, and impair fine motor skills.[25] Glucocorticoid such as dexamethasone can cause a myopathy in proximal limb muscles and reduce blood flow to bones.[70] The resulting ischemic insult results in the death of bone cells or osteonecrosis, a condition associated with the loss of bone structure and rigidity, which increases the risk for the occurrence of pathologic fractures. Osteonecrosis can occur in the hips, knees, or ankles and may present with or without symptoms. In patients with ALL, it is more common in those aged 10 years or older.[33] There are limited data to support a relationship between joint pain and clinical symptoms of osteonecrosis such as decreased range of motion; therefore, PTs must be aware of the risk of osteonecrosis and avoid excessive high-impact activities during treatment sessions.[39] Children treated with vincristine often develop a chemo-induced peripheral neuropathy (CIPN), an adverse effect that typically presents with a loss of deep tendon reflexes, motor weakness (specifically decreased ankle dorsiflexion strength and handgrip strength), ankle dorsiflexion range of motion, paresthesias in hands and feet, and gait impairments (foot drop and increased hip flexion).[2,25] The onset of vincristine-induced CIPN can occur at any age, occur within a week of receiving the first dose of vincristine, or occur only after multiple doses have been received. The level of neuropathy can range from mild to moderate to severe, with the level of impairment paralleling the severity of the neuropathy.

Many chemotherapeutic agents cause cancer-related fatigue (CRF), a fatigue that is more severe, more distressing, and less likely to be relieved by rest than fatigue experienced by healthy people,[51] CRF is a complex, multidimensional problem arising from a number of factors including nutritional deficiencies, sleep disorders, depression and anxiety, anemia, and pain. Other acute, adverse effects of chemotherapy treatment include weight changes; skin changes; sores in the mouth, throat, and

TABLE 16.3 Chemotherapeutic Agents Used to Treat Specific Diseases With Resulting Short- and Late-Term Adverse Effects

Chemotherapeutic Agent	Diseases Treated	Short- and Late-Term Adverse Effects
L-asparaginase, Elspar	Leukemia, lymphoma	Drowsiness Nausea, vomiting, and cramping Allergic reaction: rash or increased breathing effort
Busulfan, Myleran	Leukemia	Fatigue, tiredness Decreased appetite Hair loss Nausea/vomiting Diarrhea Myelosuppression
Cisplatin (cisplatinum, Platinol, Platinol-AQ)	Osteosarcoma, HL, neuroblastoma, NHL, astrocytoma	Myelosuppression Allergic reaction: rash and increased breathing effort Nausea and vomiting that usually occurs for about 24 hours Tinnitus and hearing loss Fluctuations in blood electrolytes Kidney damage
Cyclophosphamide (cytoxan, Neosar)	HL, AML, Ewing's sarcoma, neuroblastoma,	Nausea, vomiting, and abdominal pain Decreased appetite Sore mouth and taste changes Diarrhea Hair loss (reversible) Bladder damage
Cytarabine (Ara-C, cytosine arabinoside, Cytosar-U)	Leukemia, lymphoma	Nausea, vomiting, and diarrhea Decreased appetite Decrease in blood cell counts Fever and flulike symptoms
Daunorubicin (Cerubidine), Doxorubicin (Adriamycin PFS, Adriamycin RDF, Rubex)	Lymphoma, AML	Nausea/vomiting Hair loss Red-colored urine (not bleeding but a drug effect) Myelosuppression Heart failure
Methotrexate (MTX)	Osteosarcoma, leukemia	Nausea/vomiting Decrease in blood cell counts Diarrhea Skin rashes Dizziness, headache, or drowsiness
Dexamethasone	ALL	Osteonecrosis, myopathy (typically proximal)
Vincristine (oncovin), vinblastine (Velban, Velbe)	Leukemia, HL, NHL, neuroblastoma, rhabdomyosarcoma	Weakness Loss of reflexes Nausea and vomiting Hair loss (reversible) Diarrhea or constipation, abdominal cramping Myelosuppression Peripheral neuropathy

AML, Acute myeloid leukemia; HL, Hodgkin's lymphoma; NHL, non-Hodgkin's lymphoma.

TABLE 16.4 Normal Ranges for Key Blood Parameters

Types of Cells	Purpose	Symptoms	Normal Ranges
White blood cells (leukocytes)	Fight infection	Leukopenia infections	4–11 k/ul
Neutrophil (absolute neutrophil count [ANC])	Fight infection	Leukopenia infections	1500–8000 cells/ml
Red blood cells (erythrocytes)	Transport of oxygen and nutrients	Anemia Pallor Fatigue Short of breath	3.8–6 million cells/ul
Hemoglobin	Transport of carbon dioxide and oxygen	See red blood cells	10–13 g/100 ml
Platelets (thrombocytes)	Helps blood to clot	Increased bruising Petechiae Bleeding from nose and gums	150,000–400,000 cells/mm^3

Normal reference ranges for these cell counts may vary slightly between institutions.

TABLE 16.5 Diagnosis-Specific Body Structure/Function Impairments and Activity Limitations

Diagnosis	Body Function and Structure Impairments and Activity Limitations
Leukemia/lymphoma	Bone pain from buildup of blast cells in the bone marrow Decreased ankle dorsiflexion strength/ROM and handgrip strength, balance/postural control from vincristine peripheral neuropathy: pain, decreased hip, knee, ankle ROM from corticosteroid-induced osteonecrosis Decreased gross and fine motor skills Decreased mobility Decreased ability to carry or move objects Increased fatigue
Osteosarcoma/Ewing's sarcoma	Biomechanical changes to a limb causing increased energy expenditure for locomotion Neuropathic and nociceptive pain from tumor impingement, surgical pain, osteoporosis Decreased sensation from surgical nerve damage Decreased strength and ROM from slow wound healing, immobility, nerve damage, scar adhesions, CNS metastases Altered gait pattern/decreased ambulation Decreased stair climbing
Central and peripheral nervous system tumors	Pain from surgery, nerve impingement Decreased strength and ROM from tumor impingement, surgical pain, fear, immobility, inactivity Poor motor control, abnormal muscle tone

CNS, central nervous system; ROM, range of motion.

gums; and pain. Acute adverse effects vary from child to child, and most side effects are typically temporary, usually diminishing once chemotherapy has been completed. Symptoms of some adverse effects, however, including CIPN and CRF, may persist for months to years after the completion of chemotherapy.

Targeted therapies are a newer type of chemotherapy involving drugs that *target* molecular markers or cellular processes found exclusively or primarily in cancer cells thus allowing them to target cancer cells while sparing normal cells. This selectivity increases efficacy and decreases both short-term (myelosuppression, infection, and nausea, and vomiting), and long-term (neurocognitive impairment, infertility, cardiovascular morbidity and mortality, obesity, and second cancers) toxic effects.[6]

Table 16.3 lists common therapeutic agents used to treat pediatric and adolescent cancers and lists short-term and long-term adverse effects associated with these chemotherapeutic agents. PTs can use this information to guide their examination and assist in developing optimal interventions. Although the presence of these adverse effects may prevent delivering patient care, they more frequently require a modification of the interventions delivered (Table 16.5). For example, a PT treating a survivor of AML who received an anthracycline such as doxorubicin should carefully evaluate cardiac function, endurance, and fitness levels in this survivor, know the patient's blood cell counts, include exercise (reconditioning) as a treatment intervention, and carefully monitor the patient for the appearance of adverse cardiac signs and symptoms during each treatment session.

Chemotherapy drugs can be administered in a number of different ways. Standard intramuscular, intra-arterial, and intravenous delivery are sometimes used, but because these drugs are frequently given for extended periods, they are more frequently delivered via ports or central lines that provide long-term venous access. Because these lines puncture the skin, they can introduce bacteria into the bloodstream, resulting in sepsis. It is imperative that PTs treating patients with ports or central lines practice appropriate hand hygiene and clean toys and equipment before and after being used during an intervention session or examination. Some chemotherapy drugs may be delivered orally. Many chemotherapeutic agents used to treat brain tumors do not cross the blood–brain barrier and must be delivered through an intrathecal catheter. These catheters are usually located in the lumbar spine or brain and are able to deliver drugs directly to the cerebral spinal fluid.

Chemotherapeutic agents are rarely given individually; rather they are typically given in combination with other chemotherapeutic agents. This multidrug strategy increases the likelihood that all cancer cells will be killed and reduces the chances of the cancer cells developing a resistance to these drugs. Because of cytotoxicity, these drugs are often given for a fixed period of time and then withheld for a period of time before restarting treatment. Such cycling allows the patient to recover from the deleterious effects of treatment. A course of chemotherapy treatment consists of a predetermined number of such cycles.

Chemotherapy has increased the long-term survivorship of pediatric cancer survivors. As these survivors have lived longer, it has become increasing obvious that they are at high risk for developing late adverse effects—impairments that can be linked to the chemotherapy regimen but emerge only years after completion of treatment. These late, chronic, adverse effects are common and can have potentially severe effects on the physical, cognitive, and psychosocial health of these survivors. These adverse health outcomes include pulmonary, cardiac, endocrine and reproductive dysfunction, osteoporosis, and neurocognitive/neurosensory loss.[25,30] In an effort to identify and screen for these late effects, long-term follow-up is now an established part of the posttreatment care of childhood cancer survivors.[66] For example, the Children's Oncology Group provides risk-based, exposure-related clinical practice guidelines for screening and managing late effects resulting from therapeutic treatment for pediatric malignancies.[34] Both the adolescent/young adult and the family need to be made aware of the risk of developing these late effects and understand the importance and need for ongoing screening and management of these late effects as well as preventive measures.

Bone Marrow Transplantation/Stem Cell Transplantation

Some pediatric patients with leukemia, HL, or NHL may not respond to available chemotherapy and thus become eligible for a stem cell (SC) transplant. SCs, once infused, repopulate the bone marrow and give rise to the array of mature blood cells found in the circulation. The transplant process first involves the elimination of all or nearly all blood cells and stem cells in the recipient, a process called the conditioning phase. This is

accomplished by having the patient undergo whole body radiation therapy or a short-term, high-dose chemotherapy. Younger children do not receive whole body radiation due to the complex side effects of radiation to their growing bodies. The conditioning phase leaves the patient severely myelo- and immune suppressed. Immediately after completing this phase, the patient receives SCs by intravenous (IV) infusion. Transplanted SCs can be collected from three different sites including bone marrow, peripheral blood, or cord blood from the patient prior to treatment or from a donor. Stem cell transplants are characterized by the donor of the SCs. If the infused stem cells are harvested from the patient receiving them, the process is termed an *autologous* stem cell transplant; if the stem cells are harvested from another individual, it is termed an *allogeneic* transplant. Allogeneic transplants are also characterized by the quality of the relationship between the donor and the recipient. Those in which the donor and recipient are related and share common blood characteristics are referred to as matched transplants, and those from a nonrelative that matches the blood characteristics of the recipient are referred to as matched unrelated donors (MUDs).

Once infusion is completed, the stem cells migrate to the bone marrow, take up residence, establish a population of healthy stem cells, and begin producing functional, mature blood cells. During this time, called the *engraftment* period, the patient remains hospitalized (typically 28–35 days) and the SCs engraft, multiply, and cause a progressive increase in the number of functional blood cells found in the blood. Because the patients are often myelosuppressed and, as a result, severely immunocompromised, they receive medication prophylactically to prevent infections, including antivirals, antibiotics, and antifungals, as well as platelet infusions to limit bleeding and bruising, to prevent rejection (cyclosporine, methotrexate, tacrolimus, mycophenolate mofetil), and to manage adverse effects of these drugs and the transplant. An important milestone in this engraftment process occurs when the absolute neutrophil count is >500 cells/μL for at least 2 days in a row.[62,69] At this point, the patient is considered "neutrophil engrafted," a sign that the immune system is starting to recover. This process typically continues until the body can produce normal or nearly normal numbers of mature, functioning blood cells, which may take multiple months.

Patients who receive SC transplants are at risk for a disease called graft-versus-host disease (GVHD).[35,49,69] Cells that provide immunity to the recipient are eliminated during the conditioning phase and are subsequently replaced by the transplanted SCs. Immune protection now becomes a function of the blood cells arising from the transplanted SCs. This is a different scenario from that which occurs in a solid organ transplant, a situation where the recipient retains his or her own blood cells, giving the recipient the capacity to reject the transplanted organ. GVHD occurs when the transplanted stem cells give rise to blood cells, which recognize tissue of the recipient as foreign and reject those tissues. It occurs most frequently in patients receiving an allogeneic transplant and has a higher likelihood of occurring as the histocompatibility or tissue compatibility between donor and recipient decreases.[69] SC recipients can experience GVHD shortly after receiving the transplant, resulting in acute GVHD or aGVHD. The patient with aGVHD can experience a rash, itchy skin, skin discoloration, dry mouth, mouth ulcers, diarrhea and weight loss, joint contractures, and malabsorption. Antirejection drugs are given prophylactically during the engraftment period to prevent the occurrence of aGVHD, but when rejection does occur, the liver, skin, and gastrointestinal tract are severely impacted. aGVHD is treated with high-dose glucocorticoid therapy, a treatment that has a number of adverse effects including infection, diabetes, sleep disorders, osteoporosis, hyperglycemia, and water retention.[35,49,69]

FIG. 16.5 Chronic graft versus host disease in a child following a stem cell transplant. (Courtesy Children's Hospital Colorado Pediatric Bone Marrow Transplant Program.)

GVHD can also arise after completion of the acute phase of recovery from the transplant or simply persist after the transplant has engrafted, causing a disease known as chronic GVHD or chronic graft versus host disease (cGVHD), which typically occurs 1 year or more posttransplant. cGVHD lasts longer than acute graft versus host disease (aGVHD) and presents with similar symptoms (Fig. 16.5). Prednisone or other similar anti-inflammatory or immunosuppressive medications are used to treat cGVHD.[35,49] Adverse effects of long-term glucocorticoid treatment have been previously noted.[70]

SC transplantation (stem cell rescue) is also used in the treatment of patients with high-risk neuroblastoma or medulloblastoma who have been treated with high doses of chemotherapy or radiation. Stem cells used in these patients are collected from the recipient's own bone marrow (autologous transplant) before chemo or radiation treatment begins and are then transplanted when needed. The transplantation procedure is similar to that described earlier. Although the risks are less than for those receiving allogeneic transplants, these patients remain at increased risk for infection. This SC rescue process allows for the use of higher doses of chemotherapeutic agents and radiation, ideally creating a greater likelihood of remission and cure.[23]

FOREGROUND INFORMATION

PHYSICAL THERAPY EXAMINATION

Children and adolescents who are undergoing cancer treatment, recovering from treatment, or are survivors may require PT services. These services are delivered in a number of different rehabilitation settings (acute care, in-patient rehabilitation hospital, out-patient, home, child care facilities, or school). Each cancer diagnosis presents with its own treatment protocols, systems

involvement, and long-term effects, all of which influence the location and type of PT intervention provided. PTs treating these children must have the knowledge and skills necessary to perform a comprehensive physical therapy examination specific to the needs of the infant, child, and adolescent. Such knowledge and skills include typical age-appropriate gross/fine motor skills; musculoskeletal, neuromuscular, and cardiopulmonary development; understanding of the disease and medical protocols and short- and long term side effects of treatment; the essential role of the family–medical team relationship; and how to deliver these services in the context of family-centered care.[57,58] This information guides the PT in gathering an appropriate and detailed history, selecting correct assessment and outcome measures, developing a plan of care, and providing an evidence-based intervention program.[24,65,68]

History

The history section of the PT examination for a child with cancer will include all the typical key areas (past medical history, social history, home/school/child care environments, and family challenges/supports). PTs will want to take into consideration that children with cancer and their families have generally already shared their history with many health care professionals. Keeping this in mind, PTs should make every effort to gather information from the medical record and discussion with other health care professionals prior to talking with the child and family. Making this effort will help build mutual respect between the PT and the child and family and allow for more time during the initial physical therapy evaluation to focus on specific child/family needs. The PT will want to take note of the specific medical protocol the child is receiving with the medical management time lines for specific types of medications, surgeries, radiation, or other medical interventions. These protocols will help guide the physical therapy plan of care.

During the history-taking process, the PT should be aware of the child's blood cell counts. Children will have blood drawn regularly to determine the blood cell counts; however, these values can change daily and therefore the PT needs to know if the child is at risk for low blood cell counts and adapt evaluation appropriately. Cleaning all toys and mats prior to use and engaging in appropriate hand hygiene are the two most important ways to prevent the development and spread of infection. A child who is severely immunocompromised may need to be seen in an isolated area, and the therapist may need to wear a mask. In addition, if the child presents with low platelets, the PT will want to modify the examination so as not to put the child at risk for falls or apply resistance to an extremity to prevent bruising. If the red blood cell count is low, the child may present with fatigue and have decreased tolerance to physical activity.

Systems Review

Because children undergoing active treatment for cancer often have nausea, fatigue, and general malaise, the PT will want to quickly identify areas of concern during the initial evaluation. Due to the complex nature and involvement of multiple systems with the majority of oncologic diagnoses, the systems review is beneficial in prioritizing areas of impairments, activity limitations, and participation restrictions.[31,32] Areas of focus with this particular patient population typically include the following:

1. Musculoskeletal changes are observed easily through noticing asymmetries, decreased strength, and range of motion during standing, walking, or crawling.
2. Neuromuscular symptoms such as pain, neuropathies, decreased sensation, proprioception, and auditory delays are often noted when the child avoids movement in a particular body part, refuses to bear weight on an extremity, does not respond to the PT's requests due to not hearing the instructions, or does not understand the instructions due to a neurocognitive delay.
3. Cardiopulmonary limitations are often identified by observing that the child uses a stroller or is excessively carried by the parents, or by noting increased work of breathing, nasal flaring, and changes in skin color during physical activity.
4. Integumentary changes such as bruising and pale complexion often indicate decreased platelets and red blood cells. Poor wound healing, edema, or open sores are common in children with cancer, thus the PT is advised to perform a thorough skin check as part of the physical exam.

BOX 16.1 Recommended Measures for Children With Cancer

Body Functions and Structures

- Musculoskeletal: range of motion (goniometry), strength (handheld dynamometry)
- Neuromuscular: pediatric modified Total Neuropathy Score (peds-mTNS)
- Cardiopulmonary: endurance (heart rate, rate of perceived exertion)

Activities and Participation

- Timed up and down stairs
- Timed up and go
- Gross Motor Function Measure (GMFM)
- Bruininks-Oseretsky Test of Motor Proficiency (BOT-2)
- PedsQL
- SF-36v2
- Musculoskeletal Tumor Society (MSTS)
- Toronto Extremity Salvage Scale (TESS)

Other

- Functional Mobility Assessment (FMA)

Tests and Measures

Children with cancer will require a comprehensive, neuromuscular, musculoskeletal, cardiopulmonary, integumentary, developmental, and gait/functional mobility examination. The typical physical therapy test and measures are used for this population; additionally, a few tests and measures have been developed specifically for children with cancer (Box 16.1).

Neuromuscular

PTs assess muscle tone and spasticity using the Ashworth scale; pain with an age-appropriate scale (FLACC = face, legs, activity, consolability scale, FACES = Wong Baker FACES pain scale, visual analog scale); and sensation with light touch, sharp dull, and two-point discrimination. Visual and hearing examinations include eyes tracking in all directions and hearing quiet/loud sounds on the right and left sides.

The Pediatric modified Total Neuropathy Score (peds-mTNS) is an assessment scale used to measure CIPN in children with non-CNS cancers.[25,26] This tool assesses sensory symptoms, functional symptoms, autonomic symptoms, light touch sensation, pin sensibility, vibration sensibility, strength, and deep tendon reflexes. The ped-mTNS scores are reported to correlate with functional measures of balance and manual

dexterity, and it is the most sensitive tool for assessing CIPN in this patient population.

Musculoskeletal

PTs determine range of motion (ROM) with a goniometer or inclinometer, strength by manual muscle testing or handheld dynamometer, function by visual observation during the performance of functional movements, and limb-length inequality by measuring leg lengths using a tape measure.

Children with a history of lower-extremity sarcoma (osteosarcoma or Ewing's sarcoma) require ongoing examination of their leg lengths. These growing children will typically have an expandable internal prosthesis (Repiphysis). The noninvasive expandable prosthesis allows expansion via external activation of a spring mechanism in the structure of the implant, allowing the leg to be lengthened without surgery through a fluoroscopic imaging procedure performed by the physician. The PT plays a role in this process by frequently measuring the child's leg length and notifying the physician when a limb length inequality is present.

Cardiovascular and Pulmonary

PTs use respiratory rate, heart rate, work of breathing (nasal flaring, accessory muscle breathing, belly breathing), physiologic cost index (PCI), rate of perceived exertion (RPE), and measures of endurance (2-, 3-, 6-, or 9-minute walk test, 30-second step test) to assess endurance and tolerance to activity in children with cancer.

PTs will want to assess fatigue with an age-appropriate assessment tool. The Parent Fatigue Scale (PFS) is often used for children 3 to 6 years of age. This scale consists of 17 items that ask the parents about their perceptions of the amount of fatigue experienced by their child in the past week on a 5-point Likert scale. The Childhood Fatigue Scale (CFS), a 14-item questionnaire, is used for children ages 7 to 12. The instrument is typically read to the child and the child is asked to rate how much the problem bothers him or her using a 5-point Likert scale ranging from "not at all" to "a lot." Scores range from 0 to 56 with higher scores reflecting greater amounts of experienced fatigue. The Fatigue Scale-Adolescent (FS-A), for adolescents 13 to 18 years of age, was specifically created to comprehensively measure cancer-related fatigue in adolescents who are receiving cancer treatment.[51] PTs can use the information obtained from these assessments to help develop intervention programs and evaluate the impact intervention programs have on cancer-related fatigue.[48]

Integumentary

PTs may assess edema with a tape measure, document wound size using pictures taken with a digital camera equipped with a grid scale, visually assess skin color, and determine bogginess and texture with manual palpation.

Gross Motor Development/Functional Mobility

PTs use the Timed Up and Go (TUG), Timed Up and Down Stairs (TUDS), Bayley Scales of Infant Development (BSID II), Peabody Developmental Motor Scales (PDMS-2), Gross Motor Function Measure (GMFM)[72], Bruininks-Oseretsky Test of Motor Proficiency (BOT-2),[73] and other common developmental tools to examine gross motor skills in children with cancer.

The Musculoskeletal Tumor Society (MSTS) is a tool used to identify the functional abilities of children following reconstructive surgery secondary to a tumor resection (osteosarcoma or Ewing's sarcoma). The MSTS examines factors pertaining to pain, physical function, emotional acceptance, use of supports (brace, cane, and crutches), walking ability, and quality of gait. This test involves patient observation by clinicians (nurse, physician, physical therapist) and patient report on pain, emotional acceptance, and support, and it is considered a subjective measure versus an objective measure of assessment.[27]

The Functional Mobility Assessment (FMA) was designed specifically for use with children and adolescents with a lower-extremity sarcoma and assesses six domains: (1) pain; (2) function using two specific measures, TUDS and TUG; (3) supports/assistive devices; (4) satisfaction with walking quality; (5) participation in work, school, sports; and (6) endurance as measured by results on the 9-minute run-walk test.[44] Heart rate (HR) and rate of perceived exertion (RPE) are both measured during the TUDS and TUG. Physiologic cost index, HR, and RPE are measured during the 9-minute run-walk. The FMA has norm-referenced values that allow health care professionals to compare the functional abilities of children, adolescents, and young adults with lower extremity sarcoma to age- and gender-matched healthy peers.[43] These comparisons assist the PT in identifying the need for physical therapy services, assisting the patient/family in setting goals, and initiating/progressing physical therapy intervention programs.

The Toronto Extremity Salvage Scale (TESS) is a self-administered questionnaire that allows patients to indicate the level of difficulty experienced in dressing, grooming, mobility, work, sports, and leisure. This tool measures patients' impressions of their level of physical disability. The 30 items are rated on a scale ranging from 1 (worst) to 5 (best).[27] Physical therapists use these types of measures to assist in identifying areas of importance to children with cancer or following the completion of cancer treatment.

Quality-of-Life Measures

SF-36v2 is a questionnaire consisting of 36 items combined into eight subscales that include physical functioning, role functioning (physical), pain, general health, vitality, social functioning, role functioning (emotional), and mental health. These subscales can be scored individually; aggregate physical component scales (PCSs) or mental health component scales (MCSs) can also be calculated as well as total Short Form-36 (SF-36) v2 score. PedsQL is a health-related, quality-of-life measure that incorporates a generic core and disease/symptom-specific modular approach for pediatric chronic health conditions.[38] Quality-of-life measures will guide the PT in focusing the intervention strategies. PTs will also want to explore factors that influence childhood cancer survivors' choice of occupation and choice to attend college to assist with guiding in enhancing physical activity to match career choices.[21,40,41]

PHYSICAL THERAPY INTERVENTION

Physical therapy intervention for children with cancer has been shown to be safe and effective in improving body structure and function impairments, activity limitations, and participation restrictions.[8,16,17,19,37,49,59,63,67] Due to the acute and long-term side effects of the cancer itself and the medical interventions used, physical therapists are essential members of the medical team and should be introduced into the medical plan of care starting at the initial diagnosis.

Numerous studies support the benefits of exercise and physical activity for children and adults with cancer.[15,17,28,37,50,75] The role of the health care team must extend beyond traditional recommendations of advising patients to be physically active. If children are medically stable, the PTs can recommend that they participate in physical activities during school such as gym class (modified if needed) and playing outside on the playground. If the children are in active medical treatment and do not feel as well, the PT can suggest physical activity such as encouraging parents to have their children walk, holding the child's hand versus carrying the child or pushing the child in a stroller. Parents are often concerned that their child will experience additional harm from overexertion or are hesitant to encourage them to participate in active play when their child is not feeling well. PTs provide patient and family education regarding safe physical activity and functional mobility that can be performed throughout treatment and should educate patients and their families on the importance of remaining as physically active as possible throughout the treatment process (Box 16.2). In addition physical activity is known to assist with decreasing cancer-related fatigue (CRF).[51]

PTs often are asked questions regarding when exercise and what exercise intensity is appropriate for children with myelosuppression. Currently available exercise guidelines for typically developing children recommend 60 minutes or more of physical activity per day at a moderate-to-vigorous intensity.[7] However, these guidelines are not often met by children with cancer. General recommendations for patient participation in exercise with depressed blood cell counts have been developed[1] and are shown in Table 16.6. Even when blood cell counts are low, there are still beneficial interventions the PT can provide, such as family education, pain management, supportive positioning, functional mobility, and addressing equipment needs. It is safe, effective, and important to encourage and provide opportunities for children with cancer to maintain their activity level and participation in age-appropriate recreation.

The PT bases the decision to progress a child's physical exercise, functional mobility, and intensity based on three primary factors: (1) the child's medical stability (cardiac, respiratory, hematologic, cognitive, surgical protocols), (2) the child's level of motivation, and (3) child and family goals. PTs have the responsibility to educate patients and families by letting them know that there will be good days and bad days (or weeks) but that in every situation it is important for the child to perform as much independent activity as is safe and possible. This will vary for each child, and one week it may mean walking to the bathroom with assistance, whereas in another week it may mean completing multiple flights of stairs or actively participating in sports and other age-appropriate activities (Fig. 16.6).[22] Due to the long treatment duration, PTs in the pediatric oncology setting have the unique opportunity to positively impact the child through many important stages of development and growth, all while maximizing functional mobility, independence, and participation.

BOX 16.2 Recommended Interventions for Children With Cancer

Body Function and Structure
- Range-of-motion exercises
- Strengthening exercises
- Balance/coordination exercises

Activities and Participation
- Aerobic activity (walking, biking, swimming)
- Participation in sports and age-appropriate recreational groups (dance classes, taekwondo)
- Physical education classes

Communication Considerations for Physical Therapists
- Family and patient
- Other members of medical team (physicians, nurses, social work, child life, advanced care providers)
- Schoolteachers
- Primary care physician
- Other therapists from physical therapy or different disciplines

Physical Therapy Intervention by Specific Cancer Diagnoses

Leukemia

Children with leukemia are likely to receive a PT referral at initial diagnosis due to decreased functional mobility because of severe bone pain from the buildup of cancer cells in the bone. Initiation of chemotherapy tends to lessen bone pain, but these children still frequently experience delays in gross motor function and functional mobility. The role of the PT during this period is to identify age-appropriate gross motor skills, employ therapeutic interventions that will help the child at least approach if not achieve these skills, encourage the child to achieve these skills, and involve the family in the pursuit of these goals. The PT educates the family on using toys and handling techniques to encourage the infant to crawl or the toddler to walk. The goal of the physical therapy intervention is to return the child to functional levels prior to a diagnosis of leukemia.

During medical treatment, children with leukemia are at risk for peripheral neuropathy impacting ankle dorsiflexion and handgrip ROM and strength. Research studies have found that daily ankle dorsiflexion stretching held for 30 seconds, 5 days a week, increased and prevented limitations in active ankle dorsiflexion.[38] In addition, performing lower-extremity

TABLE 16.6 Recommendations for Participation in Exercise Interventions With Below Normal Blood Cell Counts and Hemoglobin Levels

BLOOD PARAMETER	EXERTIONAL LEVEL		
	No Aerobic Exercise	Light Aerobic Exercises	Resistance Exercises[a]
White blood cells	<5 k cells/mm^3 and fever is present	>5 k cells/mm^3	>5 k cells/mm^3
Platelets	<20,000 cells/mm^3	20,000–50,000 cells/mm^3	>50,000 cells/mm^3
Hemoglobin	<8 g/dl	8–10 g/dl	>8 g/dl

Depending on the physical therapist's facility and individual protocols, these values may vary.
[a]Participation in resistance exercise interventions is recommended only if these levels are exceeded.
Garritan S, Jones P, Kornberg T, et al: Laboratory values in the intensive care unit, Acute Care Perspect 3:7-11, 1995.

FIG. 16.6 A 20-month-old with an embryonal brain tumor ambulating (A) and playing (B) while using a posterior walker due to ataxia and weakness. (Courtesy Children's Hospital Colorado-Center for Cancer and Blood Disorders Physical Therapy Program.)

strengthening exercises such as mini-squats and step up and off a step for three sets of 10 repetitions, 3 days per week, improved lower-extremity strength.[38] PTs will also want to include a balance and coordination component to the intervention program to facilitate challenging ankle strategies and the use of vision and the vestibular systems when the somatosensory system is compromised to assist with preventing falls. When CIPN is significant and the child is not able to actively dorsiflex to neutral or is at risk for falls, the PT will recommend an ankle-foot orthosis and in severe cases the child may require forearm crutches. The primary goals of the stretching, strengthening, and balance/coordination exercises are to improve ROM, strength, and functional mobility while making the exercises fun and encouraging the child to incorporate the activities into the child's daily routines.

PT intervention that addresses aerobic endurance and fatigue is oftentimes challenging. PTs frequently recommend aerobic activity daily and should specify intensity and duration in their recommendations to ensure children are receiving the maximum benefit. PTs should encourage the child to select activities of interest, such as bike riding or dancing, to improve motivation and sustainability. PTs need to feel comfortable reassuring children and families that it is safe and important to work at a therapeutic intensity that is high enough to create positive changes in cardiovascular endurance, activity tolerance, and muscle strength. PTs may recommend heart rate monitors or measures such as rating of perceived exertion to encourage the appropriate exertional level for the individual child.

Osteonecrosis can occur in the hips, knees, or ankles and may present with or without symptoms in patients with leukemia[33,39]; therefore, PTs must be aware of the risk factors of osteonecrosis and avoid excessive high-impact activities during treatment sessions until osteonecrosis has been definitively ruled out by an MRI.[39,70] When a child does have osteonecrosis, the physician will often recommend non-weight-bearing or decreased weight-bearing periods; therefore, the PT will have to provide instruction on gait training with crutches. In addition, PTs provide instructions on ROM exercises to improve or prevent limitations in active and passive ROM and limit strength losses caused by the weight-bearing status. Therapeutic interventions should focus on strengthening the muscles stabilizing the joint with the osteonecrosis to provide support and protection. The goal is to prevent or delay the need for surgical intervention. These exercises will help to increase blood flow to the area and decrease pain.

Children with leukemia who require a stem cell transplant will receive PT intervention during the engraftment period. Physical therapy is appropriate and should focus on using exercises and play to limit a loss of strength and endurance.[8,49] Due to the risk of thrombocytopenia and anemia, PT interventions during this phase of medical intervention will typically incorporate active ROM, body-supported (no weights) strengthening, and aerobic exercise according to the patient's tolerance. The PT session requires creative strategies because these children have to stay in their hospital rooms. Rehabilitation interventions must be delivered in the context of myelosuppression (practice good hand hygiene), fatigue (provide treatment when the patient's energy levels are highest), and nausea and vomiting (coordinate treatment in conjunction with the pharmacologic management of these symptoms).[8]

Lower-Extremity Sarcoma

Children and adolescents will receive physical therapy upon the initial diagnosis of upper- and lower-extremity sarcoma. PTs provide the child with crutch training consistent with the child's weight-bearing status on the involved lower extremity. Depending on the type of surgery (amputation, limb-sparing, rotation-plasty), the child might have non-weight-bearing or weight-bearing-to-tolerance orders. Children who have undergone limb-sparing procedures involving the femur typically begin knee ROM activities following surgery, but if the tumor involves the tibia, then the knee is typically immobilized for a period of time (according to the surgeon's preference, this phase usually lasts between 6 and 9 weeks), preventing such

ROM activities. Children with osteosarcomas receive intensive physical therapy to increase ROM, strength, and functional mobility. Temporary or permanent nerve damage may occur during limb-sparing surgery, therefore the PT may also provide the child with a modified ankle-foot orthosis to accommodate areas of wound healing.

ROM exercises are an important component of a physical therapy program for children and adolescents with lower-extremity sarcoma. ROM has been reported to correlate with functional mobility and quality of life in patients with lower-extremity sarcoma after limb-sparing surgery.[45]

Brain Tumor

Children with brain tumors, specifically medulloblastoma and less commonly astrocytoma or ependymoma, are at risk for posterior fossa syndrome following surgical resection of the tumor. These children may experience delays 1 to 5 days after surgery, causing apraxia of speech, dysarthria, mutism, irritability, ataxia, changes in muscle tone (hemiplegia, hypertonia), and poor motor coordination. Their skills will typically improve over many months, but some children have impairments for years. The PT will intervene to assist the family in positioning, use of assistive devices (orthotics, wheelchair, walker), and transfer training. The PT will work intensively with the child on functional mobility, balance, and coordination. During this time period, the PT's primary goal is to assist the child with positioning to prevent skin irritation, safety management to prevent falls, and family education. Because these are complex patients, the PT should strongly advocate for referrals to other health care providers including occupational therapists and speech language pathologists.

SUMMARY

This chapter has discussed multiple aspects of childhood cancers. Signs and symptoms are discussed. Specific cancer diagnoses and medical interventions including chemotherapy, radiation, and surgery are addressed. Survivorship is rising for many types of cancers, so children with these complex diagnoses often need and can benefit from physical therapy during the different stages of their treatment. They are at risk for complications such as musculoskeletal, neuromuscular, cardiopulmonary, integumentary impairments, and physical functional delays, which can be addressed by physical therapy. This chapter details specific physical therapy examinations and interventions used for children with cancer. The chapter also emphasizes working collaboratively with the other members of the medical team as well as how to include the family during therapy sessions, goal setting, and therapeutic education. The increased number of childhood cancer survivors has made it imperative that physical therapists be well educated and well prepared for this complex and rewarding specialty area.

Case Scenario on Expert Consult

The case scenario related to this chapter presents a 10-year-old girl with vincristine-induced peripheral neuropathy (VIPN) during treatment for high-risk acute lymphoblastic leukemia. It covers background information on peripheral neuropathy, the medical history, initial physical therapy examination and evaluation, and physical therapy intervention and management over the course of her treatment with a focus on family-centered care and evidence-based examination and decision making.

Developmental Coordination Disorder

Lisa Rivard, Nancy Pollock, Jennifer Siemon, Cheryl Missiuna

Pediatric physical therapists evaluate and manage care for children presenting with a variety of motor challenges. They observe children's movement patterns and skills and ask key questions about children's motor abilities and development to differentiate among motor behaviors that are characteristic of particular conditions. This differentiation guides their selection of a course of intervention. Some of the children whom physical therapists observe are quite a "puzzle" to figure out. These children frequently trip over their feet and bump into others with clumsy, awkward movements. They may have an unusual gait pattern or a unique way of "fixing" or stabilizing their joints. Despite these differences, they are often observed to reach their motor milestones within normal age limits. Many of these children appear to have difficulty generalizing learned motor skills across settings or transferring skills to other contexts. Each child with motor difficulties such as these presents a little differently from the others, making it difficult to develop and apply a treatment approach. The children who are captured by this description are those who have developmental coordination disorder (DCD).[3]

Approximately 5% to 6% of school-age children have movement difficulties unrelated to specific neurologic conditions or cognitive impairment that limit their potential and affect their long-term academic achievement.[3] Recently, the prevalence rate for the most significantly impaired children in a UK birth cohort of 6990 children aged 7 to 8 years was close to 2% of the population.[107] These children struggle with everyday functional tasks such as handwriting,[9] dressing,[61,120] throwing and catching balls,[5,6] and learning to ride a bicycle.[114,128] They experience daily frustration with activities that are effortless for their peers, and, as a consequence of their motor problems, they may demonstrate additional difficulties, including poor perceived competence,[186,187] social isolation,[33,170] low self-worth,[57,153,155,187] anxiety,[54,132,171] and depressive symptoms,[57,108,125] even at early ages. These difficulties are characteristic features of DCD, a condition in which poorly developed fine and/or gross motor coordination has a substantial impact on motor skill performance with far-reaching consequences for daily life activities and scholastic achievement.[3] Although it was once believed that these difficulties would diminish with time and maturation, compelling evidence now suggests that DCD is a lifelong condition,[25,37,44,54] making this disorder one that warrants significant attention.

Physical therapists have a unique service to offer children with DCD and their families. Therapists' understanding of normal and abnormal motor control, motor learning, and motor development can be used to identify and evaluate the condition and to plan programs for children with DCD. Through education of children with DCD and their families, teachers, and others in the community, physical therapists can help children with DCD become more active and successful participants in their home, school, and community life.

The information presented in this chapter is intended to increase awareness, recognition, and understanding of children with DCD. The complex nature of DCD and its challenges for clinical management are described. The role of the physical therapist in managing children with this disorder and intervention approaches shown to be effective with children with DCD are explored. Evidence is presented to support the need for a multidisciplinary assessment and tailored, child- and family-centered intervention with collaborative consultation is emphasized. Three cases found on Expert Consult illustrate the heterogeneity of the disorder—a factor that greatly influences the decision-making process and strategies employed in the management of a child with DCD. Resources available for children with DCD and their families, as well as health professionals involved in their care, are provided on the Expert Consult website.

BACKGROUND INFORMATION

HISTORICAL BACKGROUND

A disorder of "clumsiness" whose key feature is poor motor coordination has been recognized and described for over a century. Much of our current understanding of DCD, however, has resulted from an explosion of research in the field over the past two decades.[115] DCD is a childhood disorder that is of interest to numerous professionals in the medical, rehabilitation, and education fields. Clinicians and researchers, each adopting various perspectives on the condition, have utilized diverse theoretical frameworks in their study of children with DCD. This wide-reaching interest in DCD has provided fertile ground for the development of knowledge about the condition. Historically, however, this diversity in perspectives also led to a lack of consensus, impacting the progression of research in the field. Different labels have been ascribed to children with DCD over the years, including the clumsy child syndrome,[69] the

physically awkward child,[229] developmental dyspraxia[30] sensory integrative dysfunction,[7] disorder of attention, motor and perception (DAMP),[64] and minor coordination dysfunction,[233] each reflecting the perspectives of professionals who work with these children.[135] In 1994 an international consensus exercise was undertaken[163] and the term *DCD* was adopted to unify descriptions of children with significant motor incoordination. This decision, in part, was grounded in the recognition that DCD had become an officially recognized movement skills disorder.[3] In 2006, a second international consensus conference recommended maintaining use of the term *DCD*.[216] Although *DCD* is the term now most widely used in the literature, other terms have continued to persist, highlighting the diverse perspectives of researchers who study children with motor difficulties.

BACKGROUND INFORMATION

DEFINITION AND PREVALENCE

DCD is a chronic condition involving impairment in gross motor, postural, and/or fine motor performance that affects a child's ability to perform the skilled movements necessary for daily living, including the performance of academic and self-care tasks. By definition, DCD is not attributable to a known neurologic or medical disorder.[3] The manifestation of the disorder varies across children, with a spectrum of severity.

Research performed in many countries around the world has confirmed that large numbers of children are affected by this childhood motor disorder.[56,86,93,107,252] Attention is increasingly being paid to this disorder because of the impact of children's primary motor limitations on everyday life. The American Psychiatric Association (APA) estimates that DCD affects 5% to 6% of school-age children. Although it is commonly accepted that boys with DCD outnumber girls by a 2:1 ratio,[3] a recent population-based study of children with DCD would suggest that more equal numbers of boys and girls may be affected.[126] The prevalence of DCD appears to be substantially higher than average in preterm/low birth weight populations.[48,241,250] It has also been noted that, over time, preterm/low birth weight infants tend to exhibit poor coordination and many of the physical consequences associated with DCD such as decreased aerobic fitness, strength, and physical activity levels.[183]

Etiology and Pathophysiology

Although much has been learned regarding the body structure and function deficits of children with DCD and the potential sensory, motor control, and motor learning processes affected, the etiology of the disorder remains poorly understood.[227,256] Currently, no specific pathologic process or single neuroanatomic site has been definitively associated with DCD, but many behavioral studies, in particular studies on co-occurring conditions and possible subtypes of DCD, have led researchers to speculate as to the underlying mechanism(s) involved in DCD. Some researchers have postulated that diffuse, rather than distinct, areas of the brain may be affected, resulting in the variable expression of the disorder and the different profiles seen in children with DCD (including co-occurring conditions).[95] This would imply that the specific combination of co-occurring disorders depends on the location and severity of neurologic insult. This theory, however, does not take into account cases where developmental disorders occur alone.[227] Recent work conducted in the area of subtyping has suggested that subcortical structures such as the thalamus may play a role.[223] Other researchers highlight the strong association between motor, attention, and perceptual processes and point to the possible role of neuroanatomic structures such as the cerebellum and basal ganglia.[64]

Research studies employing a dual-task paradigm indicate a lack of automatization of motor actions in children with DCD when attentional demands increase.[34,104] These findings implicate the cerebellum as a possible site of pathophysiology in children with DCD, given its known role in the automatization and learning of motor tasks.[26,102,191] The thinking behind the interference seen in dual-task paradigms is that performance of one task will be negatively affected by the second if both tasks need to make use of the same "pool" of resources, including visual and cognitive resources. Concurrent work examining motor adaptation, or the ability of children with DCD to adapt performance to changing environmental contexts, comes to a similar conclusion with respect to the potential role of the cerebellum in children with DCD. In these studies, children with motor difficulties show poor adaptation to gradual changes in environmental stimuli.[13,26] Given the rapid growth and vulnerability of the developing cerebellum to external events in the first year of life, theories regarding the possible link between cerebellar involvement and motor impairments are plausible.[66] Although the proposed link between motor coordination difficulties and the role of the cerebellum appears to be strong,[256] especially in situations of co-occurring conditions,[148,156] testing of causal models will be necessary to confirm these hypotheses.

Another avenue of research includes the investigation of motor imagery deficits in children with DCD. Understanding in this area has led to a proposal that impaired feed forward models could be a potential mechanism underlying DCD (efference-copy-deficit hypothesis).[246,249] In this theory, motor imagery deficits seen in children with DCD are related to difficulties in generating efference copies of motor commands through feed forward models, pointing to the possible involvement of the posterior parietal cortex.[246]

Recently, increasing interest in the possibility of impaired internal models can be seen in the DCD literature.[1,94] Internal models have been defined as neural representations of the visual-spatial coordinates of intended motor actions.[121] It has been hypothesized that children with motor impairment may have inadequate forward (predictive) modeling of movements and are unable to form, access, or update their internal models, which results in poor "online" error correction and ultimately affects motor learning over time.[209,248] It has been postulated that internal models may be located in the cerebellum or parieto-cerebellar network.[248,256] Findings from a recent metaanalysis of research conducted from 1997 to 2011 strongly suggest involvement of the cerebellum, given the pattern of deficits observed in DCD including poor predictive modeling and "online" correction, difficulties with rhythmic timing, executive function, posture and gait, catching and interceptive skills, as well as visual and tactile processing.[248] Parallel work investigating the role of "mirror neurons" (which are housed in the ventral premotor and posterior parietal cortices) has shed additional light on how motor representations are formed not only during the performance, but also in the observation, of movements.[121,181] Mirror neurons in the posterior parietal cortex may work in concert with internal models in the cerebellum through extensive neural projections between these two brain structures to code and update movement.[121]

Taken together, behavioral studies implicating different cortical and subcortical areas and the recent discovery and understanding of the role of mirror neurons suggest that a complex and shared interplay may occur between different neuroanatomic regions of the brain when learning, executing, and correcting movements. Research studies employing neurodiagnostic technologies such as functional magnetic resonance imaging, diffusion tensor imaging, and electroencephalography are becoming more prevalent in the literature investigating possible mechanisms involved in DCD.[40,97,149] These experimental studies are demonstrating differences in brain activation patterns between children with and without DCD.[106,256] Combined with behavioral research, this work is beginning to shed more light on the specific neuroanatomic sites that may be involved in the pathophysiology of DCD.

In the end, why are there so many plausible theories regarding the origin of DCD and so many proposed sites of neurologic abnormality? The production of well-coordinated, smooth motor movements is a complex process requiring multiple levels of information processing, each of which requires different abilities such as sensory acuity, memory, decision making, attention, perception, as well as feedback and feed forward mechanisms. It is likely that children with DCD may have impairments in one or more of these functions and in related brain areas and that different groups of children may have abnormalities in different neural correlates.[66,87,256] Other possible influencing factors have already been alluded to earlier in this chapter. The heterogeneity of the disorder and the presence of co-occurring conditions give rise to different profiles of impairment, which may indeed have different underlying neural mechanisms.

DIAGNOSIS

DCD is present when (1) motor impairment and/or motor skill delay significantly impacts a child's ability to perform age-appropriate complex motor activities, (2) adequate opportunities for experience and practice have been provided, and (3) no other explanation can be offered for the motor impairment. In most states and provinces a diagnosis of DCD can be made only by a physician because it is critical to rule out any other underlying neurologic or medical reasons for the observed motor impairment. Four distinct criteria must be met for a diagnosis of DCD to be given, as outlined in the *Diagnostic and Statistical Manual of Mental Disorders* (Box 17.1)[3]: (1) The learning and performance of coordinated motor skills are not what would be expected based on a child's age and experiences/opportunities for motor skill development; (2) the motor difficulties have a significant impact on self-care activities, academic achievement, leisure, and play; (3) the difficulties begin early in development; and (4) the observed motor challenges are not better explained by intellectual or visual impairment or neurologic conditions that impact movement abilities.[3] In situations where more than one developmental or behavioral disorder is present (i.e., developmental coordination disorder with co-occurring attention deficit disorder, or autism spectrum disorder, etc.), it has been recommended that all diagnoses should be given.[11,216] Physical therapists have an important role to play in facilitating a diagnosis of DCD by providing physicians with an assessment of a child's motor coordination and the impact of motor challenges on everyday life activities. This will be discussed in greater detail later in this chapter.

BOX 17.1 Diagnostic Criteria for Developmental Coordination Disorder (DCD)

The acquisition and execution of coordinated motor skills is substantially below that expected given the individual's chronologic age and opportunity for skill learning and use. Difficulties are manifested as clumsiness (e.g., dropping or bumping into objects) as well as slowness and inaccuracy of performance of motor skills (e.g., catching an object, using scissors or cutlery, handwriting, riding a bike, or participating in sports).

The motor skills deficit in Criterion A significantly and persistently interferes with activities of daily living appropriate to chronologic age (e.g., self-care and self-maintenance) and impacts academic/school productivity, prevocational and vocational activities, leisure, and play.

Onset of symptoms is in the early developmental period.

The motor skills deficits are not better explained by intellectual disability (intellectual developmental disorder) or visual impairment and are not attributable to a neurologic condition affecting movement (e.g., cerebral palsy, muscular dystrophy, degenerative disorder).

American Psychiatric Association: Diagnostic and statistical manual of mental disorders (5th ed.). Washington, DC, Author, 2013.

BOX 17.2 Developmental Coordination Disorder (DCD): Differential Diagnosis

Coordination difficulties are likely not DCD when a history of any of the following is reported:

- Recent head injury or trauma
- Deterioration in previously learned or acquired skills
- Headaches, eye pain, blurred vision
- Global developmental delays
- Increased muscle tone, fluctuating tone, or significant hypotonia
- Asymmetrical tone or strength
- Musculoskeletal abnormality
- Neurocutaneous lesion
- Avoidance of eye contact, unwillingness to engage socially
- Gowers' sign (difficulty rising to a standing position)
- Ataxia, dysarthria
- Absence of deep tendon reflexes
- Dysmorphic features
- Visual impairment (untreated)

From Missiuna C, Gaines R, Soucie H: Why every office needs a tennis ball: a new approach to assessing the clumsy child. Can Med Assoc J 175, 471-473, 2006.

DCD usually is not considered to be present if (1) recent head injury or trauma has occurred, (2) progressive deterioration in previously acquired skills is evident, or (3) increased or fluctuating muscle tone is present. DCD also would not be suspected routinely where there is a history of headaches or blurred vision, when evidence of asymmetrical tone or strength is observed, or when musculoskeletal abnormalities or Gowers' sign is present (Box 17.2).[70,130] If children do not show any of these signs but demonstrate uncoordinated movements and motor abilities below those expected for their age, they may have DCD, and it is important for these children to be seen by a physician. A medical practitioner can rule out other possible causes for poor coordination, including genetic causes (e.g., Down syndrome), neurologic disorders (e.g., cerebral palsy), degenerative conditions (e.g., muscular dystrophy, brain tumors), musculoskeletal abnormalities (e.g., Legg-Calvé-Perthes disease), sensory impairments (e.g., impaired visual acuity), cognitive impairment (e.g., developmental delay), pervasive developmental disorder (e.g., autism), and head injury (e.g., traumatic brain injury) (Box

BOX 17.3 Developmental Coordination Disorder

Medical and neurologic disorders that can be associated with motor incoordination must be excluded before a formal diagnosis of DCD is made. These include the following:

- Genetic disorders (e.g., Down syndrome)
- Neurologic disorders (e.g., cerebral palsy)
- Degenerative conditions (e.g., Duchenne muscular dystrophy, brain tumor)
- Musculoskeletal disorders (e.g., Legg-Calvé-Perthes disease)
- Physical impairments (e.g., impaired visual acuity)
- Cognitive impairments (e.g., developmental delay)
- Pervasive developmental disorders (e.g., autism)
- Injuries (e.g., traumatic brain injury)
- Environmental contaminants (e.g., lead, pesticides)

17.3).[70,130] See respective chapters in this volume for further information on these other conditions.

CO-OCCURRING CONDITIONS

Strong associations have been demonstrated between DCD and attention deficit hyperactivity disorder (ADHD),[42,158,172,220] speech/articulation difficulties (specific language impairment [SLI]),[58,81,156,235] and language-based learning disabilities (LDs) (in particular, reading disability).[90] When a child has any of these conditions, the likelihood that DCD is also present is at least 50%. When criteria for more than one disorder are met, more than one diagnosis should be given.[3,216] It is recognized that the presence of co-occurring conditions may increase the probability of negative outcomes. In particular, children who have DCD in addition to ADHD have a significantly poorer outcome in terms of academic achievement and mental health than children with ADHD alone.[75,172,220] It is important to determine whether motor coordination problems are present and whether they are occurring in combination with another recognized condition. Knowledge of a child's complete profile (including associated conditions) will assist in the identification process and will help to determine intervention and management strategies. The frequently documented association between other developmental disorders and DCD underscores the need for a multidisciplinary assessment.

LONG-TERM PROGNOSIS

Longitudinal research clearly demonstrates that, without intervention, children with DCD do not "grow out of" the disorder. Strong evidence indicates that the motor problems of childhood persist into adolescence and adulthood.[25,37,44,54] In fact, children with DCD are at risk of developing serious negative physical, social, emotional, behavioral, and mental health consequences that are not limited to the presenting motor difficulties. Multiple studies have shown that, over time, children with DCD are more likely to demonstrate poor social, academic, and physical competence[186,232,255] social isolation,[33,210] academic and behavior problems,[172] poor self-esteem,[232] low self-efficacy,[49] victimization,[153] and higher rates of psychiatric and mental health problems.[125,172,204]

Children with DCD engage in less vigorous play and spend significantly more time away from the playground area than peers.[68,180] They spend more time alone on the playground and spend less time in formal and informal team play.[210] Many researchers have shown that they are less likely to be physically fit[180] or to participate voluntarily in motor activity,[231] predisposing them to an inactive lifestyle. Reduced physical activity participation[20,21] and the associated risks for long-term obesity [19,80,198] and poor cardiovascular health in children with DCD [50,51,91] are now being documented. Although this picture of the numerous consequences associated with motor impairment appears dire, the potential exists for positive trajectories and pathways of resilience.[138] The long-term outcome of the disorder is influenced not only by the severity of impairment and co-occurring conditions but also by the presence of supportive environments and the strengths of individuals with DCD, including coping mechanisms. It is possible to "tip the scale" in favor of more positive outcomes,[133] and physical therapists can be instrumental in preventing secondary impairments, which often become areas of greater focus as children mature.

The increased risk for children with DCD of secondary health issues and academic failure highlights the need to identify children with DCD as early as possible.[140] Early identification may facilitate the education of teachers and parents about how to make tasks easier and how to ensure that activities are matched to children's capabilities. In this way, children with DCD can be provided with optimally challenging situations that emphasize mastery and avoid multiple failed attempts.[141]

DESCRIBING CHILDREN WITH DCD

The International Classification of Functioning, Disability, and Health (ICF) provides a useful framework for understanding and describing the difficulties experienced by children with DCD.[251] In the ICF model, observable sensory/perceptual and motor impairments at the level of body structure and function can lead to difficulties with skill acquisition and task performance or activity limitations. These activity constraints, in turn, can place limitations on participation in the many aspects of daily life, conceptualized in the ICF framework as participation restrictions. In addition, personal and environmental factors are seen as important mediating factors at each of these levels (Table 17.1).

Body Structure and Function

Any description of children with DCD is influenced by the heterogeneity of the condition. The presentation of DCD is somewhat age dependent, is highly variable across children, and is complicated by the possible presence of co-occurring conditions. This variability in presentation has led investigators to examine multiple sensory and motor processes that contribute to the development of motor coordination. In a recent review of research into possible underlying mechanisms for DCD, primary impairments at the level of body structure and function have been proposed in the sensory, motor, and sensorimotor domains (Table 17.2).[227]

Primary Impairments

Sensory/perceptual de*fi*cits. Early research on children with DCD indicated deficiencies in kinesthetic processing and poor proprioceptive function.[110,197] Children with DCD have also been shown to have impairments in visual-spatial processing,

TABLE 17.1 Relationships Among Body Structures and Function, Activity, and Participation for a Child With Developmental Coordination Disorder (DCD)

Health Condition	Body Structure and Function	Activity Limitations	Participation Restrictions: Environmental Factors	Participation Restrictions: Personal Factors
Unknown/possibly heterogeneous nervous system insult (of prenatal, perinatal, or postnatal origin)	Neurologic "soft" signs Poor strength Poor coordination Jerky movements Poor visual perception Joint laxity Poor spatial organization Inadequate information processing Poor sequencing Poor feedback and feed forward motor control Poor memory	Awkward, slow gait Delayed and poor quality of fine and gross motor skills, such as hopping, jumping, ball skills, and writing Delayed oral-motor skills	Doors too heavy to open Physical education is competitive and skill oriented Time to dress and undress reduces participation in recess and readiness for home and community activities Slow and messy written communication in class limits academic performance	Depressed Quits trying to participate, unmotivated Low self-esteem Poor fitness Activities performed without concern for time restrictions Vocational anxiety

TABLE 17.2 Impairments of Body Structure and Function Identified in Children With Developmental Coordination Disorder (DCD)

Body Function	Reference
Visual-perceptual, visuospatial, and visuomotor impairment	Mon-Williams et al., 1999[143]; O'Brien et al., 1988[147]; Wilson and McKenzie, 1998[247]; Wilson et al., 2013[248]
Inefficient use of visual feedback in fast, goal-directed arm movements	van der Meulen et al., 1991[225]
Impaired visual memory	Dwyer and McKenzie, 1994[47]
More dependent on visuospatial rehearsal to memorize	Skorji and McKenzie, 1997[205]
Difficulty with visual and motor sequencing tasks requiring short- and long-term recall	Murphy and Gliner, 1988[144]
Impairments of size-constancy judgments, spatial position, and visual discrimination	Lord and Hulme, 1987[110]
Slow performance related to reliance on information feedback rather than feed forward programming	Missiuna et al., 2003[140]; Smyth, 1991[213]
Slow reaction time and movement time related to impaired response selection	Raynor, 1998[174]; Van Dellan and Geuze, 1988
Prolonged response latency related to the process of searching for and retrieving the correct responses with reliable timing	Henderson et al., 1992[77]
Poor timing, rhythm, and force control	Volman and Geuze, 1998[228]; Williams et al., 1992[240]
Impaired performance on kinesthetic acuity, linear positioning, and weight discrimination	Hoare and Larkin, 1991[84]
Prolonged burst of agonist activity and delayed onset of antagonist activity	Huh et al., 1998[85]
Reduced power and strength	Raynor, 2001[175]
Reduced ability to successfully inhibit an action	Mandich et al., 2002[116]

including difficulties determining object size and position, a limited ability to use visual rehearsal strategies,[43] and deficits with visual memory.[47] More recent research suggests that in children with DCD, visual feedback is managed differently and is processed more slowly than in typically developing children.[254] Several studies have confirmed that children with DCD demonstrate a heavy reliance on visual feedback to guide task performance.[52,77,124] This predominant use of vision to control movement is observed well beyond the age at which typically developing children would rely on vision.[124,205,212] As a result, children with DCD lack automation in movement patterns and remain at an early stage of motor learning for much longer.

Because both visual and kinesthetic perceptual deficits have been demonstrated in groups of children with DCD, it has been suggested that the deficit may not be confined to one specific sensory modality but may be multisensory in nature.[242] This seems plausible given that fluent, coordinated movements require multiple processes to plan, execute, and, when necessary, correct motor activity. Further, the motor impairments could be accounted for by impaired perception-action coupling or poor integration of the senses,[202,211,254] including poor "mapping" of visual and proprioceptive information with the motor system.[143,184]

Research examining different profiles, or subtypes, of children with motor impairment has contributed to understanding in the area of possible sensory/perceptual deficits. Although studies have differed on the specific clusters of children identified and the individual characteristics of the subgroups,[44,83,112,142,223] there appears to be general agreement that there is a group of children who demonstrate a generalized, and often significant, perceptual deficit, including both visual and kinesthetic difficulties. Questions remain, however, because these specific perceptual deficits have not been shown to be present in all subgroups with motor impairment. This again serves to underscore the heterogeneity of the condition and suggests that different profiles of motor coordination problems may exist in children with DCD with varying sensory/perceptual impairments.

Motor deficits. Children with DCD move awkwardly and slowly, with a rigid, jerky movement quality.[5,94,238] They frequently bump into objects and people and have a tendency to trip and fall.[100] Poor balance, especially pronounced during

single-leg stance, and difficulty maintaining postures are often noted (see video of Bill on Expert Consult for an example of a child with similar problems).[238] To compensate for balance instability, children with DCD may demonstrate many associated movements.[100] On physical examination, decreased muscle tone and neurologic soft signs can often be observed. This constellation of physical signs, combined with the possible sensory deficits outlined previously, has led many to hypothesize that the origins of the motor impairments seen in children with DCD may lie in faulty motor control and motor learning processes.

Motor control deficits. Children with DCD demonstrate inappropriate and ineffective neuromuscular strategies, both in muscular activation and in sequencing, using atypical postural control strategies,[82,84,229,238] including when balance is challenged.[239] An increased level of muscle co-contraction has also been described, with children with DCD demonstrating a much less effective method of muscular organization than peers, which did not improve with age.[151,175] Children with movement difficulties tend to "fix" or stabilize joints during task performance.[175,201] This deliberate joint stabilization leads to lack of movement fluency[140] and contributes to a stiff, awkward, and clumsy appearance[201]; it also increases the time it takes them to adapt to changes in their movement environment.[124] Fixing can be thought of as a strategy to control the multiple degrees of freedom of joints and muscles for efficient functioning. Children with DCD who "fix" joints during task performance are more likely to experience fatigue[150] and to demonstrate inconsistency in task performance.[124,201] Overall, the postural fixation and atypical muscular activation and sequencing seen in children with DCD result in less efficient movement patterns and reflect a less skilled stage of movement acquisition than is typical of age-matched peers.

When performing reaching tasks, children with DCD use different neuromuscular strategies than typically developing age-matched peers, contributing to slower and more variable movement and reaction times, as well as movement inaccuracy.[77,88,111,224,236,240] Evidence from subtyping and other research would suggest that, although some children with DCD exhibit problems primarily in execution and control of movements, others have difficulties related to motor planning processes.[61,209,213]

Children with DCD display gait differences that have also been suggested to be due to movement variability.[189] Decreased and variable force control and difficulties with temporal precision (both movement production and time perception) have also been noted in the motor control literature.[60,77,88,236,240]

As can be seen from extensive motor control research, in comparison with typically developing peers, children with DCD demonstrate variations in movement speed, timing, and force across a series of different tasks, resulting in qualitative differences in movement and motor control patterns. Difficulties with error detection and movement correction during the execution of motor skills are especially evident when motor tasks are complex and involve spatial uncertainty.

Motor learning deficits. In addition to poorly controlled movements, children with DCD exhibit limited movement repertoires, lacking both adaptability and flexibility in motor behavior.[103] This, along with the variability and inconsistency in motor performance, suggests difficulties in motor learning processes.[6]

Although children with DCD may achieve motor milestones within normal time limits, they have difficulty learning new motor skills.[76,124] They fail to see the similarities between motor tasks and thus are unable to transfer learned skills from one activity to a closely related activity. They also experience difficulty generalizing from one context or situation to another. Both of these processes reflect an early, more cognitive stage of motor learning (see Chapter 4 for more information on motor learning).[124,131,132] According to motor learning theory, as skills are learned, feedback requirements lessen and change, with proprioceptive and kinesthetic feedback relied on more than visual input.[53] Children with DCD continue to rely predominantly on visual information, as if they were still in the early stages of motor learning. As a result, the motor performance of children with DCD is sometimes more similar to that of younger children than to that of age peers.

Children with coordination difficulties have also been described as repeating tasks the same way over and over again, regardless of success with the task.[76,119] They appear to have difficulty understanding the demands of a task and its component parts, interpreting environmental cues, and selecting the best motor response for a task.[65] As a result, they do not effectively use the feedback originating from knowledge of past performance to prepare for upcoming actions (anticipatory preparation), and they have difficulty adapting to situational demands.[63,65,131] It has been postulated that children with DCD might attend to the wrong cues and not to the more salient aspects of available feedback.[65] Others have suggested that the problem might lie in the failure of children with DCD to use anticipatory control strategies for motor tasks[238]; as a result, they might have to rely heavily on a feedback or closed loop strategy to control movement.[184,209]

Secondary Impairments

Physical. Although slow, awkward movements are typical of children with DCD and are easy to casually observe (e.g., see video of Bill), what is less evident is the extra effort that motor skills seem to require and the struggle that children have in making adaptations and in "fine-tuning" movements.[28] Secondary impairments related to the primary motor coordination difficulties are of considerable concern and include lack of energy and fatigue, as well as decreased strength, power, and endurance.[175,180] Children with DCD complain of being tired more easily than peers and are often exhausted by the end of the day as they must exert more effort during motor-based activities at school and at home.[100] They can often be observed leaning against the wall or on other children when standing, or assuming a slouched posture when sitting (Fig. 17.1). Recent strong empirical evidence indicates a progressive decrease in strength and power in children with DCD over time, which is already apparent between the ages of 6 and 9 years.[175] Obesity in children with DCD and the relationship between motor difficulties and cardiovascular risk factors have begun to be studied in greater detail.[19,51] As will be discussed later in this chapter, these secondary sequelae are precursors for participation restrictions in sporting and/or leisure activities, reduced opportunities for social interaction, and diminished physical fitness across the life span. Secondary impairments in children with DCD may be preventable and are appropriate targets for physical therapy.

Social/Emotional/Behavioral. Often children with DCD demonstrate associated behavioral problems that become the focus of concern, especially in the classroom.[179] Children with DCD may be quiet and withdrawn at school, with avoidance of schoolwork and frequent "off-task" behaviors.[31,32,128]

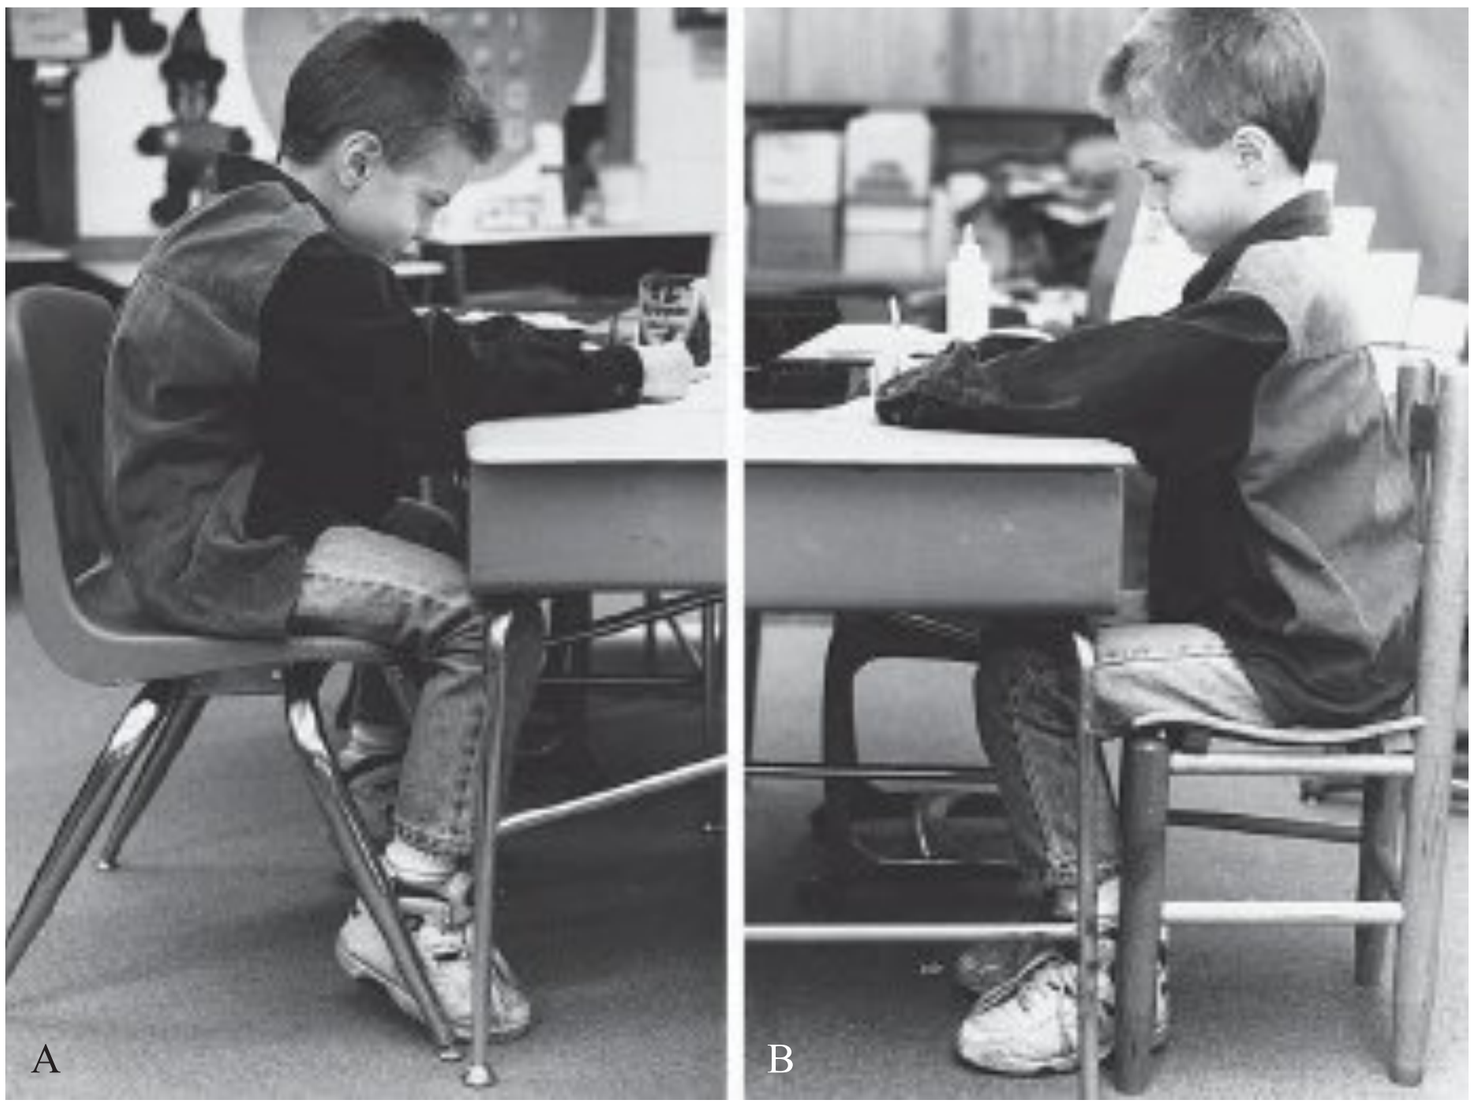

FIG. 17.1 (A) This child demonstrates poor posture that interferes with fine motor classroom activities. (B) A different desk and chair improve this child's posture and improve the precision of his fine motor activities.

Alternatively, children may act out in class, disrupting the teacher and/or others.[120] Learning new skills in physical education is a continuous challenge (e.g., see video of Bill), and children may try to avoid these classes with complaints of illness or problem behaviors. Avoidance of written work can result in "behaviors" such as needing to sharpen the pencil multiple times, talking and asking questions, attention seeking, and interference with other children. Low frustration tolerance, decreased motivation, and poor self-esteem are commonly observed.[204] Children with movement difficulties give up on tasks easily, which occasionally leads to angry, aggressive classroom behavior. Task initiation and task completion are often major issues, both at home and at school.[128]

Like the physical impairments outlined previously, these associated social, emotional, and behavioral difficulties can be significant but are not inevitable. All efforts should be made through early identification and management to prevent their occurrence.

Activity Limitations

How do the proposed body structure and function deficits manifest themselves in a practical sense? Children with DCD tend to have the greatest difficulty with skills that must be taught. In particular, skills requiring accuracy and refined eye-hand coordination and that require constant monitoring of feedback pose significant challenges for the child with DCD.[132,216] Children with DCD may experience difficulty with fine motor activities, gross motor activities, or both (see video of Bill).[113] These activity limitations are readily observable in the classroom, on the school playground, and at home.[31,128]

Fine Motor Activity Limitations

Self-care. The ability of children with DCD to perform self-care activities such as doing up snaps, zippers, and buttons, tying shoelaces, opening snack containers, and managing juice boxes is poorer than expected for their age. Tying shoelaces is an example of a skilled activity required at school by the time a student is in first grade. Children with impairments in sequencing skills cannot correctly sequence the steps in shoe tying, even though they may have practiced it many times before. When children with DCD make a mistake in one step of the sequence, they have to start over again rather than simply redo the last step. Or they might omit a different step in the sequence each time they try to tie shoes (Fig. 17.2). At home, parents notice difficulties when children are using cutlery, and there is a tendency to spill liquid from drinking glasses or when pouring from a container. Parents also describe problems

FIG. 17.2 This 8-year-old boy still cannot independently tie his shoes. His verbal cues were "loop around and go through." He forgot to "loop around" and forgot to make a second loop.

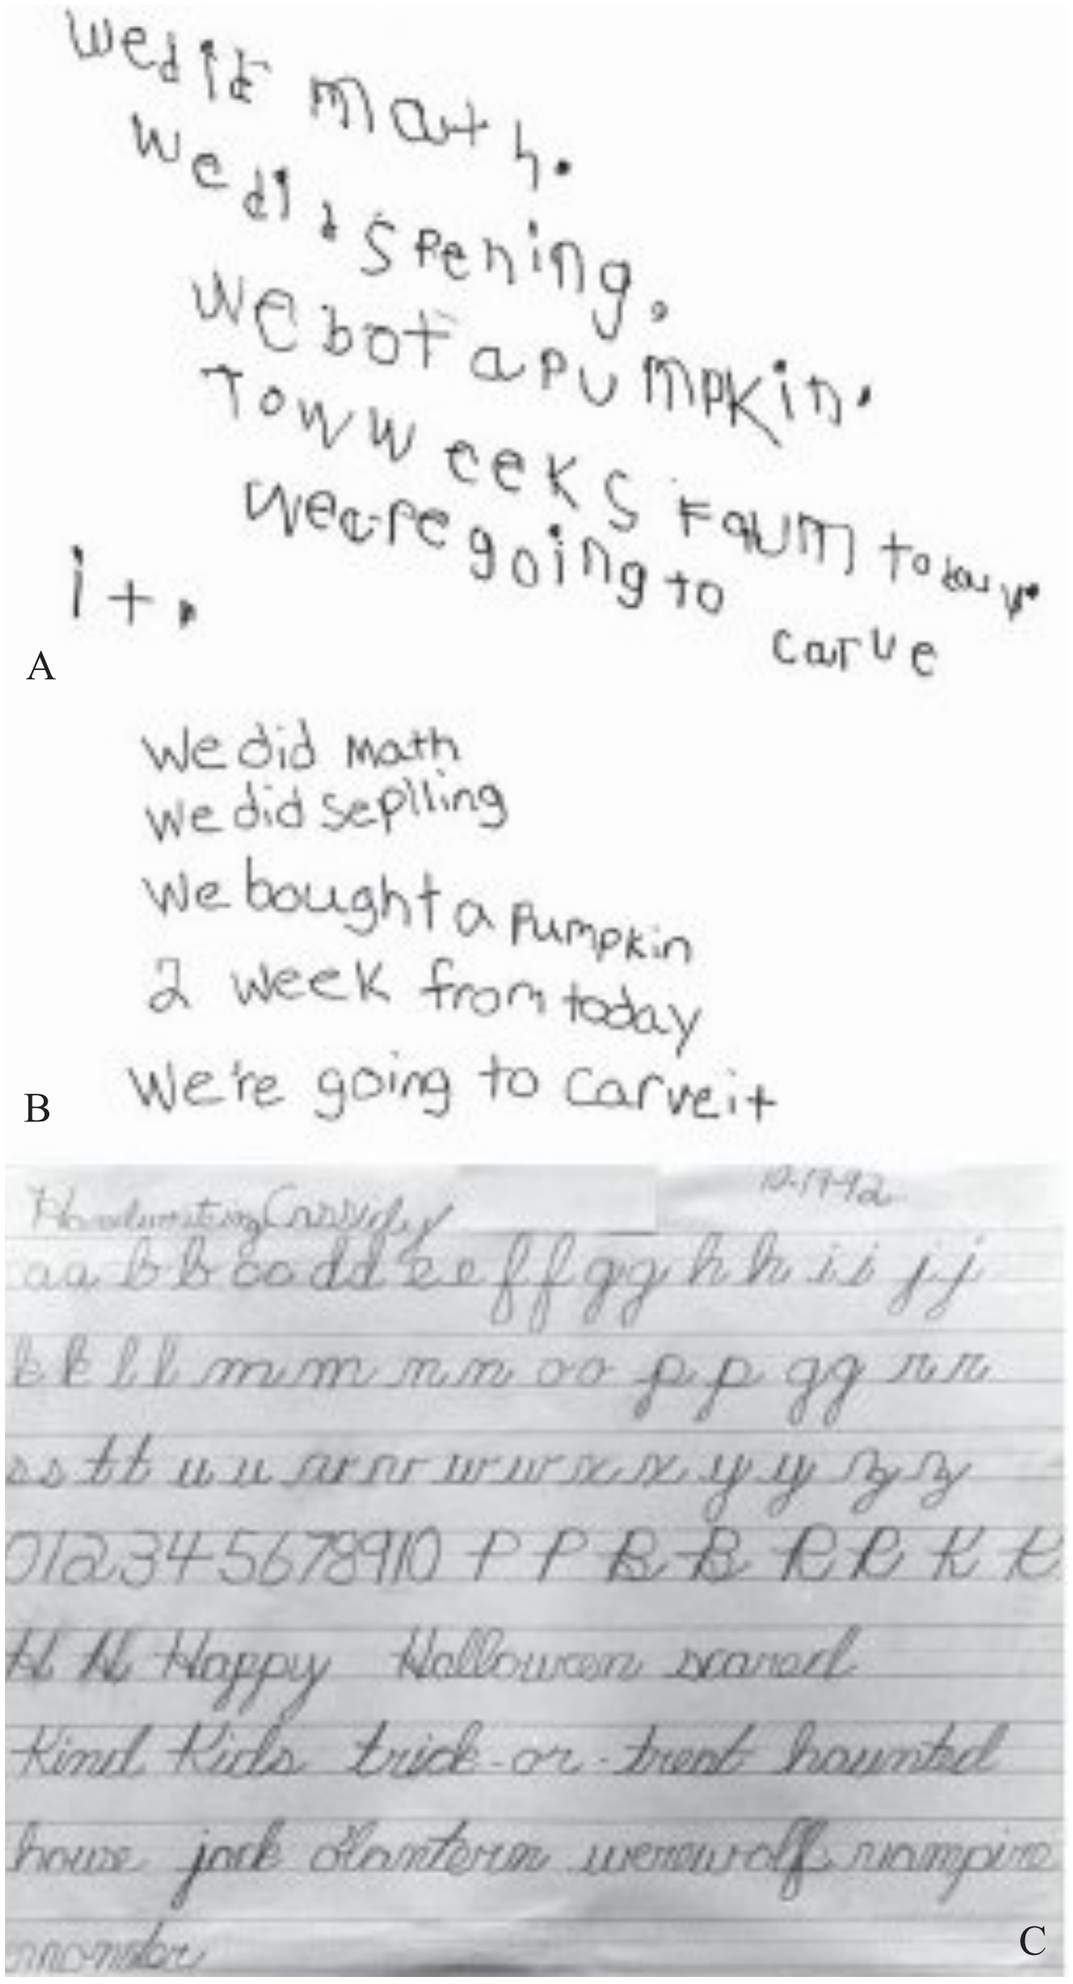

FIG. 17.3 (A) Handwriting sample of a third-grade child with developmental coordination disorder and a learning disability. (B) Handwriting sample obtained for comparison from a randomly selected third grade peer without motor difficulties. (C) Sample of cursive writing from another peer without motor difficulties demonstrates an even more advanced expectation of third grade students.

with grooming such as bathing, combing hair, and brushing teeth.[120,128,218] At school, children with movement difficulties are often the last to get snowsuits, jackets, and boots on or to get knapsacks organized to go home at the end of the day.

Academic. Classroom fine motor difficulties include problems with printing and handwriting (Fig. 17.3).[8,122] Written work is illegible and inconsistent in sizing and requires great effort.[188] Frequent erasures of work, inaccurate spacing of words, and unusual letter formation are evident.[100] Pencil/crayon grasps are awkward, and written work is not well aligned. Pencils may be dropped frequently and pencil leads broken or paper torn as the result of excessive pressure on the page.[28,100] Because of this, teachers and parents often note that children with DCD have difficulty finishing academic tasks, including homework, on time. Children with these difficulties tend to rush through tasks or may be unusually slow (see video of Bill). Academic tasks that have a motor component require extra effort and attentional resources. Children with DCD can become fatigued and frustrated, as they work harder than children their age to complete the same activity. Teachers often describe a large discrepancy between oral and written work. Copying from the board and other fine motor tasks such as completing puzzles and turning door handles or washroom taps are also affected. Many children with DCD tend to avoid art projects and craft activities that require coloring, cutting, and pasting.[120,134]

Overall, children with DCD, in comparison with typically developing children of the same age, have been noted to require more support and assistance from those around them to complete motor-based self-care and academic tasks at home and at school.[129,218]

Gross Motor Activity Limitations

Lacking good balance and postural control, children with DCD often have difficulties with the flexibility and adaptability required for gross motor activities. They may show delays each time they learn a novel skill such as riding a push toy, learning to ride a tricycle or bicycle, and pumping a swing.[100,120,128] They demonstrate poorly coordinated running, skipping, hopping, and jumping and may have difficulty managing stairs, especially when they must maneuver around others (Fig. 17.4).[8,31] Coordination of eyes and hands at a whole body level is problematic, so children with DCD have difficulty with throwing, catching, and kicking a ball accurately.[4,5,26] Given current understanding about the etiology of DCD, difficulties with ball skills may result from challenges in a number of areas, including the ability to judge the amount of force required to throw/kick a ball to an intended distance, coordinating timing of limbs to intercept a ball, forward prediction of limb position when reaching for or striking a ball, and correction of limb trajectory as needed while in motion. As a result, performance on these tasks is often more like that of a younger child (see www.cmaj.ca/cgi/content/full/175/5/471, and click on "videos" in right-hand menu; also see video of Bill). Children with DCD have more difficulty with gross motor activities that require constant changes in body position or adaptation to changes in the environment, such as when playing baseball or tennis or jumping rope.[128] Activities that require the coordinated use of both sides of the body are difficult (e.g., stride jumps, swinging a bat, handling a hockey stick).[128]

The fine and gross motor activity limitations of children with DCD can be understood in the context of associated body structure and function deficits, according to the ICF model (Table 17.3). An appreciation of the link between underlying deficits and their expression in activities of daily living can be instrumental when planning effective and targeted interventions.

Participation Restrictions

In the context of the ICF framework, the fine and gross motor activity limitations seen in children with DCD in school and home environments can lead to participation restrictions that prevent them from having opportunities for optimal physical, social, and cognitive development.[114] When parents of children

FIG. 17.4 (A) Managing stairs can be challenging for children with developmental coordination disorder because of difficulties with posture and balance. (B–C) Stair climbing is made more challenging when children with developmental coordination disorder must maneuver around others in a crowded environment.

TABLE 17.3 Examples of Activity Limitations and Related Body Structure and Function Deficits in Children With Developmental Coordination Disorder (DCD)

Activity Limitations	Related Body Structures and Functions
Self-Care Activities	
Eating:	Poor body awareness
Frequent spills, messy eating	Poor postural tone
Leaning on the table	Difficulties with in-hand manipulation
Poor use of cutlery when spreading/cutting	Difficulties judging force and distance, targeting
Dressing:	Poor use of dominant-assistant hands
Slow and disorganized	Poor body awareness and proprioception
Trouble with fasteners (buttons, zippers)	Lack of balance
Clothes twisted or on backward	Poor finger dexterity and strength
Shoes on wrong foot	Difficulties with touch perception, sequencing
Academic Activities	
Printing/handwriting:	Muscle tone and postural issues
Slow, poor legibility	Poor fine motor control
Awkward grasp	Overreliance on vision
Reduced volume of work	Use of attentional resources to maintain posture
Frequent erasures	Language and learning issues
Avoidance behaviors	Low muscle tone, fatigue
Sitting at a desk/in circle time:	Decreased postural control
Slumped posture	Poor body awareness
Holding head	Need for boundaries, increased sensory feedback
Leaning on others, lying down	Need to move to maintain muscle activity
Wiggling	
Falling out of chair	
Sports and Leisure Activities	
Ball-related activities:	Poor management of multiple degrees of freedom
Miss the ball, get hit by the ball	Timing issues
Slow to react	Difficulties correcting errors, poor generalization
Can't keep up	Difficulties attending to body position
Fatigue	Passivity response a coping mechanism
Passive—watch rather than play	Need to avoid failure, possibility of humiliation
Interact with adults rather than with peers	

with DCD are asked what their concerns are, they frequently identify restricted participation.[182,200] As a result of motor difficulties, children with DCD have reduced interest in physical activities and usually begin to withdraw from, and avoid, motor and sports activities at an early age.[21,180] Because of difficulties with self-care tasks at school, they are often slow to get to the playground for recess, restricting physical participation and further diminishing opportunities for physical and social interactions.

Complicating their physical challenges, children with motor difficulties often do not know how to play physical games, nor do they understand the rules of games,[100] limiting both physical and social participation with peers. They are often the last to "get picked" for teams and are not sought out to play with others.[120,231] As a result, these children can quickly become isolated from peer groups.[100] Difficulties in relating to peers have been noted in children with DCD.[100] This may be the result of not being chosen to participate in motor-based activities or because clumsy, less predictable movements may disrupt play with others.[120] Typically, children with DCD tend to watch more than play, preferring to wander the playground periphery or talk to teachers rather than engage in active play with others and socialize with peers[96]; this may be related to decreased self-confidence.[169] With fewer opportunities for social interaction, they often appear not to have learned the "intuitive" rules of social situations.[100]

Personal Factors

Children with DCD often self-impose restrictions on participation. They perceive themselves to be less competent than peers and have lower self-worth and greater anxiety.[154,204,255] When poor gross motor skills lead to inactivity and avoidance of physically challenging games, the child with DCD becomes less fit and further avoids physical activity. Avoidance of games requiring fine motor skill leads to decreased opportunities for practice, preventing ongoing academic skill development. Parents have reported that the more difficulty their children had with motor skills, the less willing they were to engage in physical activity.[160] Self-imposed isolation becomes a self-perpetuating cycle of poor skill development, limited skill practice, poor performance, and further isolation.[167]

Environmental Factors

With younger children, the environment tends to be more accepting of motor difficulties because of the wide range of normal variation. Early signs of incoordination may be viewed as part of normal developmental awkwardness or normal but slower maturation. As preschoolers become elementary school children, however, peers, parents, teachers, and/or communities may create unwarranted restrictions, artificial barriers, or rigid expectations.[170] If a physical education class or a community recreation program strictly adheres to performance criteria for group activities such as baseball, basketball, or dance class, a child with DCD can be prevented from participating with peers. If parents restrict their child's outdoor play to certain environments or to certain activities because they are afraid the child will get hurt, another barrier is established and peer relationships are potentially limited. If a family feels uncomfortable eating out at a restaurant or with relatives and friends because of a child's difficulty using utensils and messy eating[218] and restricts these opportunities to certain environments, social interactions will be unduly limited. Indoor manipulative play can pose just as much of a problem. When limitations exist in fine motor skills, activities such as coloring, cutting, stacking objects, imaginative play with paper, handling small toys, or building blocks are very difficult. When children are not allowed to play with modified toys or when individualized expectations are not acceptable, a child's experiences can be artificially limited.

FOREGROUND INFORMATION

ROLE OF THE PHYSICAL THERAPIST

Physical therapists are skilled in the observation of gross motor task performance and can help to identify children whose poor motor performance leads to activity limitations and participation restrictions. Physical therapists can observe the lack of adaptive flexibility, the lack of premovement organization, and the "fixing" that is so characteristic of children with DCD in the early years.[140] These observations can facilitate early identification, which can help to prevent the development of secondary impairments. Physical therapists can provide education and guidance that will encourage the engagement of children with DCD in the typical activities of childhood, thereby reducing the risks of decreased physical health, as well as decreased self-esteem, self-efficacy, and social participation, that have been noted at an early age.[11,82]

Identification and Referral to Physical Therapy

The recognition of DCD will depend on the extent to which physical, social, and attitudinal factors have influenced motor skill acquisition. Although DCD must be considered at least theoretically to be present from birth, children differ with respect to the apparent age of onset because the developmental progression will vary depending upon the environmental and task demands placed upon the child in the early years. Because DCD is a disorder that has an impact on the development of movement skills, children with motor impairments often do not display the full extent of their functional difficulties until they are of school age. Limitations observed in the preschool years may be seen as "slow development" or temperamental differences. However, poor performance on everyday activities is tolerated less and less as children with DCD reach school age. Coordination difficulties may not be easy to observe until they reach the point at which they attempt to learn and perform skills that require adaptations in speed, timing, and grading of force. As has been mentioned, the presence of secondary impairments and co-occurring conditions can complicate the identification process.

Typically, children with motor difficulties are identified and referred to physical therapy via one of two principal routes—through the health care system or through the educational system. In the medical pathway, children with motor difficulties may have been investigated for possible musculoskeletal, orthopedic, or neurologic concerns. These may include concerns regarding ligament laxity, low tone, or an unusual gait pattern, or the results of regular monitoring after premature birth or low birth weight.[152] In the education system, referrals are usually made when poor motor performance affects academic functioning. Sources of initial identification within each of these pathways are varied and may include primary care physicians, community and developmental pediatricians, and hospital and infant programs, as well as classroom, physical education, and resource teachers, educational psychologists, and occupational therapists (OTs). Although some children are identified by the health care system, a significant number of the children referred

to physical therapy for investigation of motor problems are referred through the educational route.

Although parents are often keenly aware early on of their child's activity limitations and participation restrictions,[2,182] classroom and special education teachers may be the initial source of referral to rehabilitation professionals when they notice poor skill development interfering with classroom work and overall academic performance.[217] Often, the structured demands of the classroom with expectations of increasingly precise motor skills and shorter time frames for performance stress a child with DCD to his or her limit. In fact, children with DCD are commonly underrecognized until academic failure begins to occur[70,122] and often are not identified before age 5.[122] In addition, teachers have many opportunities to compare the performance of children with poor motor coordination with that of more typically developing peers. At school age, poor written communication is frequently the first activity limitation that educators identify, so children with incoordination are most often referred to OTs for handwriting difficulties. This is often, however, just the "tip of the iceberg" because children commonly experience other challenges at school, on the playground, and at home. In the school setting, children with motor impairments may be referred to physical therapists for assistance with physical education programming and for safety concerns, as well as for strength and endurance issues. A physical therapist working in an educational setting has the advantage of screening children in natural environments while the children participate in everyday, functional activities. Immediate collaborative consultation with the classroom and/or physical education teacher can occur to gather information regarding the nature and extent of the motor concerns. After this, an appropriate physical therapy examination allows more comprehensive observation of function and functional difficulties in the classroom, at recess, and in physical education class. When children with possible DCD are referred and examined in a clinic setting, in-depth interviewing of parents and teachers regarding motor difficulties, as well as observation of functional activities, is needed to accurately identify concerns related to body structure and function and activity limitations.

Examination and Evaluation

History and Systems Review

Given the heterogeneous nature of DCD, it is important for a physical therapy examination to utilize multiple sources of information.[136] As part of the history, physical therapists should obtain information about motor development and medical background (pregnancy, delivery, and past and current health status); results of previous musculoskeletal and neuromuscular examinations; and a history of current functional status from the family and from school personnel. As part of the diagnostic process, physical therapists must differentiate the motor behaviors of children with DCD from those of other movement disorders. Children referred in the early years with poor coordination and/or motor delay may have disorders such as cerebral palsy, muscular dystrophy, global developmental delay, or DCD. Physical therapists must make evaluation hypotheses regarding the origin of the coordination difficulties. Some key questions may help therapists focus on differentiating among each of these patterns of motor behavior. In a young child, it would be important to ask and to observe during the systems review: (1) Is there evidence of increased or fluctuating tone? (observed alterations in muscle tone might be suggestive of a condition such as cerebral palsy), (2) Are the delays more global in nature, rather than occurring in the motor domain alone—a situation in which global developmental delay might be suspected? (with a preschool- or school-aged child, questions might center around the history of the poor coordination), (3) Have the difficulties been present from an early age? (4) Are the motor concerns appearing to worsen over time? (5) Has there been a loss of previously acquired skills? (if so, this might be suggestive of a condition like muscular dystrophy). (See chapters in this volume on specific conditions noted here for further information on differential diagnosis.)

The following example suggests the process used in the examination of a young child who is demonstrating movement difficulties. A typical initial referral in a school-based service delivery environment might be made by a physical education teacher regarding a 5-year-old kindergarten student, Sarah, who is falling often. Initial hypotheses concerning why Sarah is falling more often than her peers might include the following: (1) She has mild cerebral palsy, spastic diplegia, or hemiplegia; (2) she has early symptoms of muscular dystrophy; (3) she has DCD; (4) she has characteristic symptoms of ADHD, and as a result she is impulsive and distracted to the extent that she bumps into people and objects; (5) her shoes are too big and she trips over the laces; or (6) she has a perceptual or visual impairment. Given the number of working hypotheses regarding the underlying cause of Sarah's difficulties, it will be important to conduct further physical examination and observation, with referral to additional health care professionals as warranted.

Direct observation of Sarah on the playground and during physical education class could rule out falling related to improperly fitting shoes (hypothesis 5) or significant impulsivity and distractibility possibly related to ADHD (hypothesis 4). Additional observation could identify a positive Gowers' sign and large calf muscles, suggesting further medical referral for possible muscular dystrophy (hypothesis 2). Observation of movement patterns during play may suggest typical symmetrical synergies of hip adduction and internal rotation with knee flexion and ankle plantar flexion (more suggestive of cerebral palsy, spastic diplegia; hypothesis 1), or unilateral shoulder retraction, internal rotation and adduction, elbow flexion with forearm pronation, wrist and finger flexion, and hip adduction and internal rotation with knee flexion and plantar flexion (indicative of cerebral palsy, hemiplegia; hypothesis 1). If none of these observations is made, the likelihood increases that Sarah has DCD (hypothesis 3).

Direct observation of functional activities in naturally occurring situations is an important part of the physical therapy examination. If the examination must be performed in a hospital or clinic setting, behavior might also need to be observed in a noisy, distracting, fast-paced environment such as a busy waiting room or a children's play area. Putting a coat on while surrounded by 25 other 7-year-old children, all struggling in a small space to get dressed and get outside for recess first, is much different from putting on a coat in a quiet room with one adult giving positive encouragement and will provide information on a child's ability to complete motor tasks in more usual settings.

Additional information obtained from parents (and where possible, teachers) is vital. A parent may describe her daughter as having a pattern of general incoordination with delayed speech, messy eating, and general clumsiness present from a young age but without a medical diagnosis related to a neurologic

impairment (suggesting hypothesis 3). Suspicion that a child is demonstrating the characteristics of DCD would lead to questions about other developmental concerns as well (fine motor, self-care, leisure). It will be important to inquire whether or not difficulties are observed at home, such as struggling with buttons, using eating utensils, or tying shoelaces. Parents can provide information on the amount of effort required to complete motor tasks and whether their child participates in organized sports or other physical activities. The parent interview (combined with information from a teacher) can confirm the presence of a significant problem with academic achievement or activities of daily living—a key diagnostic finding in DCD.

Direct examination by the physical therapist might identify muscle hypertonicity that increases with faster movements (possible cerebral palsy; hypothesis 1). On the other hand, if direct examination suggests low muscle tone with shoulder, elbow, and knee hyperextension, DCD again becomes a valid hypothesis (3). If muscle testing reveals a weak gastrocnemius and pseudohypertrophy, the hypothesis of muscular dystrophy (2) would be supported. During direct examination the therapist may be able to relate the most striking activity limitations to difficulties in following directions when asked to perform a motor task or to poor attention to task. Children with DCD often cannot imitate body postures or follow two- or three-step motor commands. Frequent demonstration and actual physical assistance may be needed to accomplish items on standardized tests.

Tests and Measures

Initial screening.

To identify children with motor challenges so that early and effective interventions can be implemented, the use of reliable and valid screening instruments is critical. To meet this need, several screening tools have been developed to elicit parent, teacher, and child perceptions of children's motor concerns.

Parent report.

Parents know their children's developmental history, have observed functioning in multiple environments, and can provide important diagnostic information during screening for potential DCD.[56] The Developmental Coordination Disorder Questionnaire (DCDQ)[245] is a parent-report screening tool (at the ICF activity level) that measures the functional impact of a child's motor coordination difficulties. As a screening tool, the DCDQ can assist the clinician in determining the need to conduct a further, more in-depth evaluation of motor coordination. The DCDQ has recently been revised as the DCDQ'07.[243] Originally intended for use with parents of children 8 to 14 years of age, this 15-item tool has now been extended to include children 5 through 15 years old. Each item of the DCDQ describes tasks that are often of concern with children with motor impairment (e.g., catching a ball, riding a bicycle, writing), and parents are asked to compare their child's coordination to that of children the same age by choosing ratings on a 5-point scale. Percentiles are provided to assist the clinician in determining whether the child is demonstrating definite motor difficulties, is "suspect" for having motor difficulties, or is unlikely to have motor difficulties. The DCDQ is quick to complete and can provide valuable information to the family's physician regarding the impact of motor coordination difficulties on activities of daily life when a DCD diagnosis is being sought (i.e., Criterion B of the DSM-5).[3] Research performed on the original version of the DCDQ provides evidence of internal consistency of the test items, construct validity, and concurrent validity with both the Movement Assessment Battery for Children (MABC) test of motor impairment[78] and the Bruininks-Oseretsky Test of Motor Proficiency (BOTMP),[15] as well as high sensitivity and specificity for identification of risk for DCD versus no DCD in populations of children in several different countries.[35,38,67,194] The new version of the DCDQ'07 was developed with a population-based sample from Alberta, Canada, and validated with typically developing children, as well as children with, or likely to have, coordination difficulties. The new DCDQ'07 was again noted to have high sensitivity and specificity, as well as construct and concurrent validity.[243] Findings from more recent studies of the criterion-related psychometric properties of the DCDQ have been conflicting.[22,109] This may relate, in part, to the fact that the DCDQ measures the functional impact of poor coordination, whereas several of the criterion standards to which the DCDQ has been compared measure difficulties in skill performance directly. The DCDQ'07 is available online at no charge (http://www.dcdq.ca/pdf/DCDQ_Administration_and_Scoring.pdf). The tool has been translated into many languages and validated for other cultural contexts.[27,96,145,173,222] In addition, the DCDQ has been modified for use with preschool children (The "Little" DCDQ)[177,244] and adults (Adult Developmental Coordination Disorder/Dyspraxia Checklist (ADC).[101] Evaluation of the psychometric properties of both of these modified versions is ongoing.[101,244]

Although teachers identify some children who have DCD, they have been shown to be inaccurate in some cases.[46,92,157] In one study of children 9 to 11 years of age, classroom teachers were able to identify only 25% and physical education teachers identified only 49% of the children with DCD.[157] This discrepancy is partially explained by the different environments on which the two types of teachers based their observations and may also be related to the fact that teachers may not be able to observe all functional tasks included in checklists. The popular teacher checklist (ICF activity level) used in this study, the Movement Assessment Battery for Children Checklist (MABC-C),[78] is also limited because it is somewhat lengthy, making it time consuming for teachers to complete. With regard to studies of the psychometric properties of this checklist, the results have been mixed. The MABC-C has been shown to demonstrate internal consistency, construct validity, and concurrent validity when measured against the MABC[78] test of motor impairment.[196] However, the checklist has been noted to have poor sensitivity, meaning that many of the children at risk for motor problems may not be identified.[92] The MABC checklist has recently been revised (MABC Checklist-2) [79] and includes fewer items, along with a new standardization sample of 395 children. Determination of the new checklist's psychometric properties will be important to determine whether the issues raised above have been addressed. Despite the limitations noted above, the MABC Checklist items may be useful to guide conversation and discussion with teachers when determining a child's functional difficulties.

Recently, the Children Activity Scale for Teachers (ChAS-T) has been developed for younger children 4 to 8 years of age.[188] In addition, the Motor Observation Scale for Teachers (MOQ-T) (previously known as the Groningen Motor Observation Scale) has been revised and new norms developed.[192] This checklist is intended for use with teachers of 5- to 11-year-old children. Only preliminary work has been conducted to examine the reliability and validity of these tools.[188,193] Until further validation studies have been done on these teacher checklists,

caution should be exercised when relying only on the judgment of classroom or physical education teachers to identify children with DCD.

The Children's Self-Perceptions of Adequacy in, and Predilection for, Physical Activity Scale (CSAPPA)[72] is a brief 19-item child self-report measure of self-efficacy with regard to physical activity. It is intended for use with children aged 9 to 16 years. Specifically, the CSAPPA is a participation measure of children's perceptions of adequacy in performing, and desire to participate in, physical activity. It contains three subscales: perceived adequacy, predilection to physical activity, and enjoyment of physical education class. The CSAPPA uses a structured alternative choice format wherein children choose from two statements the one that best describes them (i.e., "some kids are among the last to be chosen for active games" versus "other kids are usually picked to play first") and then indicate whether the statement is true or very true for them. The tool has been shown to have high test-retest reliability, as well as predictive and construct validity.[72] The CSAPPA tool has been used in screening large groups of school-age children, primarily for research purposes, and scores on the CSAPPA have compared well with scores on a standardized test of general motor ability.[73] Several research studies suggest that the tool may be useful in the clinical setting for identification purposes.[20,23,73,74] Although it is possible to use only the subscales when screening for motor impairment, the use of additional sources of information on motor performance has been recommended to increase the specificity of the tool.[23]

Regardless of the type of screening tool used (parent, teacher, or child report), it should be noted that screening tools are just the first step in identifying potential DCD. Children identified through these tools as having possible motor impairment should undergo more detailed tests and measures intended for use with children with DCD to confirm motor difficulties (Criterion A).[216] When multiple measures are employed to confirm motor impairment (such as a checklist or questionnaire for initial screening followed by a test of motor ability), it should also be remembered that different tools may measure different constructs, including a child's capability (what the child can do, as measured by a standardized assessment) and the child's actual performance (what the child does do in everyday life and in multiple contexts or environments).[35] It is important to know a tool's strengths and limitations and to use a tool suited for the examination purpose. Each of these different tools can provide valuable information in understanding the complete picture of a child's difficulties.

Norm-Referenced Tests and Measures

One of the DSM-5 discriminating criteria for DCD is that motor coordination is markedly below expected levels for the child's chronologic age.[3] As such, a standardized, norm-referenced test must be used to determine whether a child experiencing motor difficulties is delayed compared to age-matched peers. Currently, there is no widely accepted standard to identify gross motor delay in children with DCD,[38,95,113,136] in part because of the heterogeneous nature of DCD and the frequent presence of co-morbidities. It is important to note that studies have reported inconsistencies in the numbers and types of children identified using different standardized tools specifically designed for children with DCD.[38] Without a gold standard to identify these children, researchers have often used more than one tool to confirm the DCD diagnosis in research study samples.[252] It has been recommended that any examination of children with DCD should include information from a number of sources, including standardized tests, functional task analysis, and examination of tasks in natural environments.[38,136] The next sections describe a number of tests that are used with children with DCD. Further information on norm-referenced standardized tests can be found in Chapter 2.

A diagnosis of DCD is not recommended for children under 5 years of age.[11] However, it is important to identify children demonstrating early motor skill delays who are at risk for DCD and who may require ongoing monitoring, intervention, and reevaluation.[140] The Peabody Developmental Motor Scales–Second Edition (PDMS-2)[55] is a diagnostic and evaluative measure for children ages birth to 71 months and is an appropriate choice to monitor children at risk of DCD in this age group.

The Movement Assessment Battery for Children (MABC-2)[79] is a norm-referenced, multi-item test recommended for school-aged children suspected of DCD.[11] The MABC-2 (ICF activity level) contains three sections, and each section includes eight items for each of three age bands: 3 to 6 years, 7 to 10 years, and 11 to 16 years. Items are divided into manual dexterity (three items), aiming and catching (two items), and balance (three items) and include activities such as threading beads, putting pegs in a pegboard, catching and throwing a beanbag, balancing on one leg, jumping, hopping, and heel-to-toe walking. The total score is used to determine if performance is within normal ranges, if motor performance is borderline or at risk, if a motor impairment is present, and if the motor impairment is significant. When performance on the MABC-2 indicates risk for DCD, a child should be monitored and reevaluated for progression in the development of motor skills. If, during follow-up, progress continues to fall short of what is appropriate for their age and/or if movement quality is suspect, intervention may be warranted. When MABC-2 scores suggest that motor impairment is present, encouraging the family to follow up with their family physician to rule out other medical causes for the impairment and to seek a DCD diagnosis is important (see later sections in this chapter for long-term management of DCD), as is intervention. The form of intervention and setting in which it should take place will depend on a number of factors, including the severity of the impairment, the child and family goals, and the specific functional difficulties, but should in all cases include education and consultation with significant others in the child's life (see later sections in this chapter on intervention).

The original version of the MABC demonstrated good test-retest reliability and concurrent validity with the BOTMP.[38,39,78] In addition, numerous studies conducted worldwide have demonstrated that the MABC identifies children with DCD at the same prevalence rates as would be predicted,[185,207,252] and the body of evidence examining the use of the MABC has been steadily growing. After a literature review of 176 publications, Geuze and colleagues[62] concluded that the MABC is the best assessment tool for DCD in spite of the fact that it omits tasks related to handwriting—an important task to assess.[216] With regard to the newer MABC-2, two studies undertaken by the test developers demonstrate acceptable test-retest reliability (the tool was less reliable when the younger age band was used); information regarding other forms of reliability, however, is not available.[79] Although recent investigations of pilot versions of the lower and upper age bands of the updated MABC-2 provide some evidence of interrater, intrarater, and test-retest

reliability, issues related to translation of the test items into other languages, cross-cultural examination, and use of single bands of the assessment tool in these studies have all been identified as issues influencing these results. To date, evidence of the new tool's construct and concurrent validity has not yet been firmly established.[14] Additional studies regarding these properties are emerging and include research on the concurrent validity of the MABC-2 with the MABC-C and the BOT-2, factor analytic validation, and further investigation of test-retest reliability.[199,208,226]

The MABC-2 has several advantages over other tools. The age bands for this instrument cover from 3-0 to 16-0 years, but testing time is short because the assessor presents only activities appropriate for that child's age. The original version has been shown to identify more children with coordination difficulties than the BOTMP[43] and appears to identify more readily those children who have additional learning or attention problems.[38] One of the key contributions of the MABC-2 is the inclusion of qualitative descriptors of motor behavior (i.e., impairment level descriptions) that the therapist can focus on during the administration of each test item. The MABC-2 also contains a behavioral checklist that can provide insight into the effects of motivation on test results and overall compliance with testing. Each of these unique features of the MABC-2 is of value to the clinician in identifying children with, or suspected of having, motor impairment. Although the MABC-2 demonstrates many clinical benefits, given that the psychometric properties of the MABC-2 have yet to be firmly established, therapists are encouraged to make use of several sources of information, including the MABC-2, in clinical decision making.[14]

Single-Item Activity Level Tests and Measures

Although initial tests of motor impairment can screen for, and confirm the presence of, significant motor difficulties, these tools do not provide a complete profile of a child's motor functioning,[89] an understanding of which is important for program planning and intervention.[234] In addition, the definition of DCD,[3] with its emphasis on the impact of motor coordination difficulties on daily life functioning, implies that a comprehensive evaluation of the child with DCD will include some examination of the child's ability to perform functional, everyday tasks in natural environments. Only a few assessment measures are available that include this functional and contextual emphasis, such as the Vineland Adaptive Behavior Scale, Second Edition (VABS).[214] Where secondary physical impairments are also present and significantly limit a child's activity and participation, it may be important to perform additional examinations at a body structure and function level (e.g., strength, physical fitness measures) to plan interventions to address these secondary issues specifically.[56] For more information on single-item activity level outcome measures, see Chapter 2.

FACILITATING A DIAGNOSIS OF DCD

It is not within the scope of practice of physical therapists to formally diagnose DCD. Nevertheless, physical therapists, through examination and evaluation of test results, are in an ideal position to recognize the motor and behavioral characteristics of potential DCD and can provide useful information to the child's physician regarding Criteria A and B of the diagnostic criteria.[3] Criterion A of the DSM-5 indicates that a significant delay in motor coordination must be present, which can be difficult to determine in a physician's office.[3] Physical therapists can observe and test for motor delay and provide information to both the family and the physician. The DSM-5 Criterion B states that the motor impairment must interfere with academics, self-care, leisure, and play. The therapist can gather information from parents, teachers, and the child about what tasks are difficult for the child to perform and can relay this information to the physician.

Although health professionals may be hesitant to label the observed difficulties as DCD, a strong case can be made for the need to identify and recognize the disorder and for the role of the therapist in facilitating formal recognition of the motor difficulties.[138] DCD has a significant impact not only on the child but on the entire family.[133,134,218] Parental concerns are not often heard or acknowledged,[2,182] and parents are often frustrated with the health care and educational systems as they pursue answers to their concerns.[56] Significant family stress can occur regarding daily activities at home and around schoolwork. Parents not only are aware of the difficulties their child experiences from an early age[1,2,182] but are searching for answers and access to resources and are often relieved once they have a greater understanding of their children's difficulties. Recent research has shown that in pursuing answers to their concerns, parents are often involved with multiple education and/or health professionals before a diagnosis is made.[2,134]

Facilitating a diagnosis is critically important for the prevention of secondary consequences: in particular, self-esteem issues for the child. A diagnosis can help to initiate education, intervention, and accommodations for the child and allows parents to access resources. Equally important, the diagnosis can help to facilitate a long-term relationship with the family's primary care physician. This is critical for follow-up of potential secondary issues that may develop as the child matures and for identifying other developmental conditions that often coexist with DCD (e.g., expressive and receptive language difficulties, attention deficit disorder). Referral to other health care providers can then be made as appropriate. If DCD is suspected, the physical therapist should encourage the family to have the child seen by their primary care physician.

REFERRAL TO OTHER DISCIPLINES

As has already been discussed in this chapter, it should not be assumed that DCD is an isolated motor problem. An examination performed by any of the following individuals may be needed: (1) a family physician or neurologist when neuromuscular or musculoskeletal concerns are identified; (2) an occupational therapist when fine motor, self-help, or motor planning areas need further examination; (3) a speech and language pathologist when speech, oral-motor dysfunction, or possible cognitive-linguistic problems are observed; (4) a psychologist when intellectual or behavioral issues have surfaced; or (5) an adapted physical education teacher when more thorough gross motor skill training is needed.

INTERVENTION

Direct Intervention Approaches

According to the ICF model, physical therapy interventions can be directed toward remediating impairment, reducing activity limitations, and/or improving participation.[251] In the past, interventions used with children with DCD were aimed primarily at

changing impairments of body structure and function by trying to improve either the child's sensory processing abilities (vision, kinesthesis) or the difficulties in individual motor components (balance, strength) that were believed to contribute to poor performance. These have been referred to as "bottom-up" interventions because they tend to address movement problems by emphasizing the building of foundational skills.[117] Examples of bottom-up interventions include perceptual-motor training, process-oriented approach, sensory integration (SI), and neurodevelopmental therapy (NDT). These interventions reflect more traditional theories of motor development and are based on the theoretical belief that, by changing these underlying deficits, task performance will be improved.[117] Some of these bottom-up interventions are still employed by therapists today when working with children with DCD, but several recent and comprehensive systematic reviews on the effectiveness of these approaches have found them to produce minimal change in functional outcomes and to offer no clear advantage of one approach over the other.[56,82,117,161,162,206] When gains are seen after the use of these approaches, the question has been posed as to whether they may be more a function of the skill of the therapists or application of general learning principles than of the treatment itself.[203,215] Physical therapists are challenged to rethink the importance of implementing intervention strategies for children with DCD that serve only to change primary impairments.

Dynamic systems theorists have proposed that improvement in functional tasks relies on many variables and tends to be environment-specific.[221] This way of thinking emphasizes that intervention must be contextually based, with intervention occurring in everyday situations and being of significance to the individual child. More recent interventions for children with DCD reflect these beliefs and now tend to emphasize the development of specific skills rather than underlying skill components alone. These have been referred to as "top-down" interventions,[117] which focus on motor learning principles in combination with other theories that emphasize the role of cognitive processes in the learning of new movement skills.[131] Top-down interventions include task-specific interventions and cognitive approaches. See Chapter 4 for more information on motor learning and task-specific intervention.

When selecting an intervention approach for children with DCD, physical therapists need to consider the motor learning difficulties that are particularly evident in this population such as the decreased ability to transfer and generalize skills and learn from past performance. It would seem reasonable from a motor learning perspective that giving feedback at the right stage of learning as well as opportunities to solve movement problems are instrumental guiding principles for interventions with children with movement difficulties.[131] It is likely that interventions that directly target the transfer and generalization of new skills and that emphasize motor learning will be the most successful. Many techniques to foster motor learning can be incorporated into intervention; these include providing verbal instructions, positioning, handling, and providing opportunities for visual or observational learning. Physically demonstrating or modeling movement sequences as well as helping children to learn strategies for managing feedback and organizing their bodies so they can attend to the most salient environmental cues may also be helpful, especially when intervening with young children. The use of frequent practice, practice in variable settings, and consistent provision of feedback should be key elements in any intervention approach for children with DCD. It is important to create practice opportunities in a variety of environments so that each repetition of the action goal becomes a new problem-solving opportunity.[131]

Task-Specific Approaches

A growing body of research demonstrates the value of task-specific interventions.[159,176,203,206] Movement educators have found task-specific intervention to be a useful way to teach children with DCD specific gross motor skills[176]; they also emphasize its indirect effect in enhancing general participation in physical activity.[103]

Task-specific interventions have as their focus the direct teaching of functional skills in appropriate environments with the intended goal of reducing activity limitations and, by implication, increasing participation levels. Task-specific interventions are individualized approaches that attempt to increase the efficiency of movement by optimizing the way in which skills are performed, given the constraints within each of the several systems that interact during task performance—the child, the task itself, and the environment.[103] As children attempt to solve a movement problem, they may discover several ways to complete a motor task (Fig. 17.5). Children explore a variety of solutions to motor problems and are encouraged to experience the effects of using different aspects of their bodies or the environment. The therapist guides the child in choosing which of these different ways of performing represents the most efficient, optimal way for him individually and in a specific environment.

In task-specific interventions, the therapist is directive, providing verbal instructions, visual prompts, or physical assistance by guiding and directing movement so that children can appreciate the "feel" of efficient movement. Based on tasks that the child needs or wants to perform, the goal of task-specific instruction is to teach "culturally normative tasks in mechanically efficient ways" (p 238),[103] with the result that children will be less clumsy and will derive more enjoyment from the performance of tasks that were previously performed poorly.[176] Neuromotor task training[195] is one example of a task-oriented intervention that emphasizes components of motor learning such as verbal feedback and variable practice. Although there is good evidence that children learn the tasks that are taught through a task-oriented approach (and because they are culturally normative skills, this is important), there is not much evidence for transfer or generalization in this approach.[176] The latter are significant considerations when choosing an effective intervention for the child with DCD; more research is needed on how to best achieve these effects.

Cognitive Approaches

Like the task-oriented approaches described previously, interventions employing cognitive approaches also address activity and participation goals. Cognitive approaches, based on theoretical frameworks from cognitive and educational psychology as well as motor learning principles, use direct skill teaching but differ in their unique problem-solving framework that attempts to help children develop cognitive strategies, acquire tasks, and generalize from the learning of one skill to the next.[132] Cognitive approaches are based on the premise that children with DCD may be deficient in what has been termed "declarative knowledge" related to motor tasks: that is, they lack knowledge of how to approach a task, how to determine what is required for the task, and how to develop strategies to use when learning and

FIG. 17.5 (A) After many therapy sessions with verbal and physical prompts, this child is still unable to sit on the floor and cross his legs independently. (B) After being reminded of the verbal cues he needs to say to himself, he now successfully crosses his legs.

performing a motor task. Intervention approaches using cognition stress the importance of children learning to monitor performance and use self-evaluation. Mediation is used wherein children are guided to discover problems, generate solutions, and evaluate success independently.[141]

Evidence has been shown the effectiveness of a cognitive approach known as cognitive orientation to daily occupational performance (CO-OP).[165] This approach guides the child in discovering verbally based strategies that help him problem solve in new movement situations.[118,123,164,190] CO-OP emphasizes a child-centered approach with goals that are ecologically valid and performed in a realistic setting. Practice focuses on the child's ability to select, apply, evaluate, and monitor task-specific cognitive strategies with emphasis on facilitating transfer and generalization of the newly learned strategies (for a more in-depth review of the specific CO-OP protocol and the essential components of this approach, including the development of global and task-specific cognitive strategies, the reader is referred to Polatajko et al., 2001).[165] This cognitive approach was shown to be effective in a research clinic setting and, of note, demonstrated some generalization and transfer of skills in children with DCD.[164] Additional research studies have begun to investigate its suitability for use with younger children in clinical settings.[10,230]

The way in which cognitive intervention approaches are used by physical therapists will depend on the age of the child. For younger children, a participatory or consultative approach may be most effective. Using the principles of motor learning, it is important to provide appropriate feedback to children with DCD and to help them to focus on the salient aspects of a given activity by modeling and/or providing them with verbal guidance as they proceed through it. For older children, direct intervention with a more cognitive approach can be used to encourage them to think independently through motor problems. Whether a direct or consultative method of intervention is used, increasing a child's self-efficacy should be a major aim of therapy. Finally, consultation with the child's family as outlined below will be critical to ensure that strategies learned through the cognitive approach can be transferred and generalized to home, school, and community settings to maximize participation.

Tools for Goal Setting and Measuring Intervention Effectiveness

Depending upon the target of intervention, several measures can be used to set collaborative goals and evaluate the efficacy of intervention. Whenever possible, goals should be child- and family-centered, as well as environmentally referenced to a problem related to participation in real-life situations.[56] The Canadian Occupational Performance Measure (COPM)[105] may be used as both a goal-setting and outcome measure and is therefore very appropriate for this population. This semistructured interview is used before intervention to have the child and/or family identify areas of functional difficulty (i.e., activity limitations or participation restrictions) and to rate the child's current performance of, and satisfaction with, each task. After intervention the rater is asked to reflect upon his performance and satisfaction for each targeted goal, and a change score can be generated. The COPM is best suited for use with children older than 8 or 9 years of age. With children younger than this, the Perceived Efficacy and Goal Setting System (PEGS)[166] may be a more appropriate goal-setting tool. In this pictorial measure, children reflect on and indicate their competence in performing 24 tasks that they need to do every day. They then identify any other activities that are difficult for them and select and prioritize tasks as goals for therapy. Using the PEGS, young children have been shown to be able to rate their competence at performing motor tasks and set goals for intervention.[137,139] The PEGS includes companion questionnaires that can be completed by caregivers and teachers. Research evidence

indicates that children's goals often differ from those of parents and teachers, so the views of significant others may need to be solicited.[45,137]

Goal attainment scaling (GAS) is increasing in usage as a rehabilitation outcome measure with regard to the evaluation of individualized client outcomes and programs.[11,99] With GAS, five possible levels of specific functional attainment are developed for a child to create a criterion-referenced individualized measurement. To date, its use with children with DCD has been described mainly at a programmatic level. In this population, GAS that focuses on the levels of activity and/or participation, not on primary impairment, is warranted.

A measure that can be used to describe or evaluate activity and/or participation is the School Function Assessment (SFA).[36] The SFA has been used to describe the participation patterns of children with DCD,[253] but its use in a pre- to postintervention study of change has not been reported.

Parent/Child Instruction

An important, perhaps even primary, benefit of an evaluation for DCD is the follow-up consultation that allows the physical therapist the opportunity to discuss restrictions in activity and participation with the child, the parents, and school personnel.[43] Education and consultation with the family, school personnel, and the community lessen the impact of environmental and personal-contextual factors that may restrict participation.[56] Family members and school personnel are key players in identifying and improving outcomes for children with DCD. The physical therapist should always provide parents and school personnel with information about the disorder and its impact on functional activities and should provide additional resources regarding DCD tailored to the child's and family's needs, including print and web-based educational materials (see resources provided on Expert Consult website). After collaborative goal setting and intervention planning, written recommendations for home and school would also be helpful for families and school staff. When working toward the acquisition of specific skills, meaningful learning takes place over time and in multiple environments. Daily environmental modifications and task adaptations are critical for improved performance and motor learning for the child with DCD.[43]

Helping parents to understand their child's strengths and limitations is an important component of secondary prevention and risk management.[140] Family and cultural expectations can be inconsistent with a child's motor abilities. Expecting proficiency in competitive sports or dance or valuing perfect penmanship can lead to frustration and stress for everyone. Physical therapists can help families and children match interests and skills with expectations that lead to success. When parents are able to look at a play situation in their neighborhood or community recreation program and understand which motor skills are interfering with their child's ability to participate, the play situation can be adapted to maximize the child's participation and help prevent the imposition of societal limitations on full participation in community activities. Consultation with parents and teachers regarding promoting physical activity participation in children with DCD is addressed specifically in a later section in this chapter.

Coordination/Communication/Consultation

Communication with other disciplines is also an important component of physical therapy intervention for children with DCD.[56] DCD is a multifaceted disability, and more than one service provider may be involved with a child at any given time. If delays in speech and poor social language skills are associated with developmental incoordination, intervention by a speech/language pathologist may be appropriate. If oral-motor impairment is present, goals may be directed at improving articulation and fluency of speech.

OTs are able to contribute in a variety of ways when children are experiencing difficulties with self-care, academic performance, and social participation. Evaluations typically conducted by OTs will provide useful information about diagnostic Criterion B.[138] OTs are frequently asked to assist teachers in the evaluation and management of handwriting. OTs can also address classroom and home modifications that may remediate problems related to organization and spatial orientation in changing environments.[128]

Adapted physical education teachers can consult with regular physical education teachers to help modify the curriculum so that the child with DCD can participate and experience success. As has been discussed, children with DCD have a lower activity level than peers,[180] have decreased anaerobic power, and have decreased muscle strength.[175] For example, if a child cannot run fast enough or safely without falling, games such as baseball can be modified so that a designated runner is used or players are grouped into teams for all activities with one person hitting and one person running or one person catching and one person throwing. In addition, peer helpers can be identified to help the child with DCD practice basic motor skills such as hopping, jumping, or skipping.

If distractibility and attending to task are identified problems, a school psychologist can assist the physical therapist in managing disruptive or otherwise negative behaviors that interfere with learning motor skills. When concerns regarding distractibility and hyperactivity arise, a referral to a physician should be considered for evaluation of possible attention deficit disorder, or ADHD. Many children with ADHD but not DCD will appear clumsy. If they attend poorly, they will bump into and trip over objects in their environment. When ADHD is associated with DCD, the term DAMP (dysfunction of attention, motor control, and perception) has been used.[64] If behavioral and/or emotional problems such as poor self-esteem, depression, and anxiety become apparent, follow-up by the child's primary care physician is important. If the level of depression or anxiety is serious, psychiatric intervention, medication, and/or counseling might be needed. Physical and mental health complaints should be taken seriously, and previously unidentified medical conditions should be ruled out before other approaches to deal with the symptoms are implemented.

Recently, innovative service delivery models have begun to be explored, incorporating therapists in primary care settings (physician's office) as part of a multidisciplinary team. These service delivery models have the potential to increase awareness of DCD in the community, facilitating accurate and early identification and referral of children with DCD.[59] Other alternative service delivery models include those aimed at building capacity among families and educators, including through collaborative consultation and coaching in context (the "4 Cs," Partnering for Change) and focusing on graduated intensities of intervention,[127] as well as incorporating community level interventions.[24] These new methods of service delivery provide models to enhance collaboration among the many individuals involved in the management of children with DCD.

Consultation Regarding Physical Activity

Task-specific and cognitive approaches target intervention at the level of activity limitation. To increase participation levels, a key role for the physical therapist lies in early consultation with physical educators about strategies for the school environment and education for families about appropriate leisure activities that will likely be most successful for children with DCD.[56] These strategies emphasize participation without the risk of injury and are aimed at preventing the physical effects of inactivity.[8,140] In so doing, it may be possible to prevent many of the detrimental consequences that have been documented in children with DCD, including decreased physical activity,[180] participation,[21] strength,[175] and fitness,[180,198] as well as poor self-competence and self-esteem.[186,187,232] Although it may not be possible to change or "fix" the primary impairments of the child with DCD (such as low tone), the decrease in strength and fitness that can result from avoidance of physical activity is not inevitable and might be improved through promotion of an active lifestyle at home, at school, and in the community.[167]

Physical Education Class

Although teachers can often modify or adapt academic activities in which motor performance is not the primary focus, it may not be as easy to decrease the motor requirements in physical education class. Strategies can be used, however, to encourage children with DCD to make progress within their own range of abilities, to foster self-esteem, and to promote the value of physical activity for long-term fitness and health. As a general strategy, teachers can learn how to "MATCH" tasks to fit the needs of individual children with DCD to encourage maximal participation.[141] With the MATCH strategy, teachers are encouraged to Modify the task, Alter expectations, Teach strategies, Change the environment, and Help by understanding. (The reader is referred to the CanChild Centre for Childhood Disability website at http://www.canchild.ca for downloadable educator resources by grade level. These resources provide examples of different ways to adjust, i.e., MATCH, a task to improve fit with the abilities of a child with DCD.)

When physical activities are taught to children with DCD, emphasis should always be placed on encouraging fun, effort, and participation rather than proficiency. Noncompetitive games in which goals are measured against one's own performance and not that of other children may be helpful.[168] Another strategy is to divide the class into smaller groups when practicing skills because fewer obstacles will need to be avoided. When a new skill is taught to the class, children with DCD can be models while instructions are given so that they have an opportunity to experience the movement in addition to observing.[134] With ball skills, modifying the equipment will decrease the risk of injury and increase the likelihood of successful participation; beanbags, Nerf balls, and large balls can all be used effectively.

The School Playground

For outside play, introducing children with movement difficulties to playground equipment on an individual basis and teaching them how to use the equipment when in a relaxed environment will increase motivation to try independently. Children with DCD often avoid playground apparatus from an early age and have not had the experience of discovering how the equipment can be used.[231] The addition of moving objects (in this case, other children) increases the complexity of the environment significantly. Guiding them toward activities where they are more likely to have success (e.g., running or tag instead of ball games) will foster positive self-esteem and reward participation.

Sports and Leisure Activities

From what is now understood about the specific body structure and function impairments of children with DCD, it is possible to predict those types of functional tasks that are more likely to be problematic and to understand why certain sports and leisure activities may be more or less successful for them. It is important, first, to make the distinction between two types of motor behaviors. Early milestones such as sitting, crawling, and grasping (which are considered basic motor abilities) appear to develop relatively spontaneously in these children without any teaching (although milestones sometimes may be delayed and movement quality may not be optimal). Coordination difficulties appear to be much more evident when skills have to be purposefully learned. These skills include such things as catching or kicking a ball and playing baseball. Children with DCD experience particular difficulty with skills that require greater precision, continuous adaptability, and eye-hand coordination.[17,131] It is also important to appreciate the requirements of individual tasks. Some require constant monitoring of feedback during task performance, and others, once learned, do not require adaptations in response to environmental feedback. As one might expect, tasks with a heavy reliance on integrating feedback from the senses will be difficult for children with DCD.[131]

When recommending sporting and leisure activities for children with DCD, the type of task, as well as the degree of teaching involved, needs to be taken into account. Activities like swimming, skating, skiing, and cycling require some initial teaching of the skill and may pose a challenge for children with DCD during early learning of the skill because all novel skills are difficult for them and they do not generalize easily from previous learning.[178] Without encouragement and individualized attention, children with DCD may express dissatisfaction with these activities. Children with DCD, as well as parents, can be helped to understand that, because these sports contain a sequence of movements that are very repetitive and these activities do not require constant monitoring of feedback during performance, children with DCD can become very successful with these activities.[71,140] These are important "lifestyle" sports that individuals with DCD can continue to participate in throughout their lifetime (see the online PT DCD educational module at http://canchild.ca/elearning/dcd_pt_workshop/index.html for helpful tips on how to teach sports such as cycling applying evidence-based principles). In addition, because many of these sports tend to be taught through verbal guidance, they may be easier for children with DCD to learn. In contrast, activities such as hockey, baseball, football, and basketball (and other ball-related sporting activities) contain a high level of unpredictability. When the environment is changing or variable, the child not only has to learn the movement but also must continuously monitor the environment to adapt to change. Any time a player is required to hit or catch a baseball, contact a hockey stick to a puck, or move quickly around other players, changes must be made in the direction, force, speed, and distance of the movement. Even when the skill is

learned, children must continue to adapt to changes in the environment and their place in it. Activities with a high degree of spatial and temporal uncertainty or unpredictability are likely to be challenging for the child with DCD.[74] The need for ongoing adaptation to changes in the environment is always a consideration; running on a smooth surface like a road or track, for example, will be much easier for a child with DCD than running on a forest trail.[140]

Parents of children with DCD have found that their child's involvement in organized sports is greatly enhanced if coaches are flexible about the child's role (e.g., having the child with DCD be the goalie).[134] Self-esteem is promoted through participation in organized sporting activities, and children appreciate when effort and personal mastery are emphasized.[29] Resources regarding ways to promote increased participation in community sports and leisure activities are available for parents, service providers, coaches, and community leaders on the CanChild website (http://www.canchild.ca).

TRANSITION TO ADULTHOOD AND LIFELONG MANAGEMENT OF DCD

High school classes, learning to drive a car, and vocational exploration present new challenges for the adolescent with DCD. It is now apparent that issues related to DCD are lifelong for many, if not all, individuals with DCD.[37] Physical therapy reexamination needs to include discussion of the prevention of secondary problems in adolescents with DCD. Identification of strategies to prevent impairments in body function from limiting activity or restricting participation can be one of the most important outcomes of physical therapy. Musculoskeletal or neuromuscular problems that would signal the need for future physical therapy care should be discussed because the changing environment and variables related to growth may place new demands on these systems. Preventive initiatives are needed because adults with DCD often have decreased strength, experience pain, and have poor aerobic capacity and endurance. Appropriate leisure activities that foster strength, endurance, and joint protection should be encouraged. The physical therapist can assist the individual with DCD to identify and participate in appropriate community fitness programs. Goals for lifelong leisure and recreational activity should be discussed with young adults. Activities should minimize competition and the need for quick motor responses. Swimming is likely to be more fun and more successful than playing tennis and therefore more likely to provide health benefits. Singing in a community choir may be a better choice than playing in a community basketball league. Riding a bike for exercise and enjoyment would be more appropriate than participating in a volleyball competition. Additional practical suggestions have been outlined in books for adolescents[100] and adults.[44]

Vocational choices are important decisions for individuals with DCD. Jobs that minimize the need for changing motoric and environmental expectations should be emphasized. Based on Henderson and Sugden's four-level categorization of motor skill difficulty, vocations that involve skills in which neither the individual nor the environment is moving or changing would be top choices.[78] Vocations in which the individual is moving and the environment is changing would be more challenging for the young adult with DCD (Table 17.4).

TABLE 17.4 Examples of Occupations Categorized by Motor Skill Difficulty

	ENVIRONMENT	
Individual	**Stable**	**Changing**
Stationary	Secondary school and college teaching Managerial occupations Psychologist Data processor Budget analyst	Air traffic controller Preschool and early elementary teaching Taxi driver in urban areas
Moving	Custodian Mail carrier Gardener Nurse Restaurant waiter	Fire fighter Physical education teacher Athlete in competitive sports

SUMMARY

DCD is a chronic condition affecting approximately 5% to 6% of the regular school-age population. A motor impairment disorder, its impacts are seen in academic underachievement and poor performance of everyday motor-based tasks. The exact etiology and pathophysiology are unknown, but DCD appears to have both motor production and motor learning components. Physical therapists have an important role to play both in identifying the impairments of body function and the activity limitations associated with DCD and in providing intervention to prevent or minimize the participation restrictions related to the person and the environment that might otherwise occur. DCD is a lifelong disability that presents challenges for adults, as well as for children and adolescents. Physical therapists function as members of the comprehensive team needed to manage the multiple ramifications of DCD and its many associated learning and medical problems.

Case Scenarios on Expert Consult

The cases scenarios related to this chapter describe several typical presentations of DCD. They are presented to demonstrate the variable nature of DCD and the different challenges that arise for physical therapy management.

ACKNOWLEDGMENTS

The authors are grateful to Doreen Bartlett, PhD, PT (Western University, London, Ontario, Canada), for her contributions to the ideas presented in this chapter and to Kathryn Steyer David for her work in previous editions of this chapter.

Children with Motor and Intellectual Disabilities

Mary Meiser, Melissa Maule, Irene McEwen, Maria Jones, Lorrie Sylvester

Children with intellectual disabilities often have secondary or associated delays in motor development and may have problems with motor learning and motor control. This is especially true of children whose intellectual functioning is moderately or severely limited. Some children's motor problems are minimal, requiring little, if any, physical therapy. Other children have cerebral palsy and other neurologic, musculoskeletal, and cardiopulmonary impairments that require considerable attention by physical therapists and other members of service delivery teams.

Many of the physical therapy examination and intervention methods used with children who have intellectual disabilities differ little from approaches used with any child who has similar motor characteristics, as described in other chapters of this volume. The learning characteristics of children with intellectual disabilities, however, can make it necessary to modify or supplement these approaches. These aspects of examination and intervention, along with current evidence-based and "best" practices for children with intellectual disabilities, are the foci of this chapter. The chapter will cover background information, including the definition, incidence, prevalence, origin, pathophysiology, and prevention of intellectual disabilities in children, and foreground information, including examination, determining outcomes and goals, and interventions to reduce impairments and activity limitations, prevent secondary complications, and promote participation. The chapter ends with consideration of the transition to adulthood.

BACKGROUND INFORMATION

DEFINITION OF INTELLECTUAL DISABILITIES

The definition of intellectual disabilities and the means by which children are identified as having intellectual disabilities are, and have been, highly controversial.[165] Much of the controversy surrounds the risk of inappropriately classifying children of cultural and linguistic minorities as having intellectual disabilities. The validity of this concern is supported by overrepresentation of children from cultural and linguistic minorities among children who have been identified as having intellectual disabilities and children placed in special education.[130,219]

Children with motor and sensory impairments also are at risk for being identified as having intellectual limitations when they do not or for being classified as having a greater degree of intellectual disability than actually exists. This is especially true if an examiner uses tests that require motor and spoken responses or has neither experience nor skill in examining children who require alternative input modes, such as manual signs, or alternative response modes, such as a voice output device.

In the United States, some organizations and educational and social service agencies still use the term *mental retardation* to refer to the condition of people with intellectual disabilities. The term *intellectual disability,* however, is being used increasingly, particularly since President Obama signed Rosa's Law (Public Law 111-256) in 2010,[156] which required changing references to "mental retardation" in health, education, and labor policy to "intellectual disability." The change has been gradual as laws and documents are revised.

The definition of intellectual disability has evolved over the years from a primary emphasis on intelligence test scores to an emphasis on individual functioning within natural environments. The American Association on Intellectual and Developmental Disabilities (AAIDD) proposed the most widely accepted definition, which has served as a basis for many other definitions, including those used by school districts for placement of students in special education.[164] AAIDD defines intellectual disability as being "characterized by significant limitations in both intellectual functioning and in adaptive behavior as expressed in conceptual, social, and practical adaptive skills originating before the age of 18" (p 1).[164]

This definition is based on the supports people need within authentic environments and natural routines, rather than on an intelligence quotient (IQ)–derived level of intellectual functioning, and incorporates the dimension of participation. Although an IQ of 70 to 75 or below still is required for a diagnosis of intellectual disability, the definition also includes adaptive skills, participation, interactions and social roles, health, and context consistent with the International Classification of Function, Disability, and Health (ICF).[216] Application of the definition depends on the following five assumptions:

1. Limitations in present functioning must be considered within the context of community environments typical of the individual's age, peers, and culture.
2. Valid assessment considers cultural and linguistic diversity as well as differences in communication, sensory, motor, and behavioral factors.
3. Within an individual, limitations often coexist with strengths.
4. An important purpose of describing limitations is to develop a profile of needed supports.
5. With appropriate personalized supports over a sustained period, the life functioning of the person with intellectual disability generally will improve.[164]

The assumptions emphasize the identification of the changing supports one needs over a lifetime to live successfully in the community, rather than simply on classification of the individual. Children identified as having intellectual disability who

require supports to learn in school settings, for example, might not be labeled in adulthood when participating independently in home, work, and social roles.[164]

Other definitions of intellectual disability or mental retardation have coexisted with the AAIDD definition, including those used in the United States to qualify students for special education and for services for individuals with developmental disabilities. In the United States, Public Law 98-527, the Developmental Disabilities Act of 1984, authorized states to provide habilitation, medical, and social services for children and adults with intellectual disabilities and, in some states, for people with other disabilities. The term *developmental disabilities* was defined in the most recent version of the Developmental Disabilities Assistance and Bill of Rights Act of 2000 (Public Law 106-402) as "a severe, chronic disability that is attributable to a physical or mental disability that is likely to continue throughout the person's life and results in functional limitations in three or more areas of life activities" (Sec. 102[8][A]).[184] The only important difference between this definition and the AAIDD definition of intellectual disability is that the definition of developmental disability has no IQ requirement and the age of onset can be as high as 22 years.

Because of varying definitions of intellectual disability and eligibility criteria, confusion can exist both within and between states as to who is considered to have intellectual disability and who qualifies for which services. For this reason, physical therapists often need to seek information about programs in their own areas to determine the criteria for eligibility and who is qualified to classify a child as having an intellectual disability. Some programs provide wheelchairs, orthoses, and other equipment for children with intellectual disabilities; other programs pay for services such as physical therapy, respite care, and recreational activities.

For any child, a label of intellectual disability primarily is useful as a "passport" to early intervention, special education, and other educational, social, and medical programs. Such a label provides little, if any, insight into the strengths of the individual or the services needed and may limit a child's opportunities if the label causes others to have inappropriate or inadequate expectations of the child's capabilities.

INCIDENCE AND PREVALENCE OF INTELLECTUAL DISABILITIES

Reported estimates of the incidence and prevalence of intellectual disabilities vary widely. These differences are thought to be due to a number of factors, including variations in the definition; the methods employed; the sex, age, and communities of the samples; and the sociopolitical factors affecting the design and interpretation of the studies.[92] The US National Institute of Medicine[194] estimates that about 1% to 3% of the population have intellectual disabilities. Among students age 6 to 21 who received special education services under the Individuals with Disabilities Education Act (IDEA) in 2012, 7.3% were classified as having an intellectual disability and 2.2% were classified as having a multiple disability, which often includes an intellectual disability.[194] Mild intellectual disability is the most common (about 85% of those with intellectual disability). About 10% have moderate intellectual disability, 4% severe disability, and 4% profound disability.[104] Among children with cerebral palsy, approximately 50% have intellectual disability.[201]

ETIOLOGY AND PATHOPHYSIOLOGY OF INTELLECTUAL DISABILITIES

Multiple causes of intellectual disabilities exist, many of which have been identified and many of which have not. Shevell[169] reviewed retrospective and prospective studies and concluded that causes could be identified for approximately 50% of intellectual disabilities in children. Understanding the origin of a child's intellectual disability may assist physical therapists and others to better predict current or future needs for support and life planning and to identify other health-related problems that might be associated with a given diagnosis.[164]

More than 350 causes for intellectual disabilities have been identified that can be broadly categorized into prenatal, perinatal, and postnatal. Prenatal causes have been further classified as chromosomal disorders, genetic syndromes, inborn errors of metabolism, developmental disorders of brain formation, and environmental influences. Perinatal causes include intrauterine disorders and neonatal disorders. One meta-analysis of 15 studies that examined intellectual outcomes of children born prematurely provides evidence that prematurity alone may be associated with reduced scores on intellectual tests.[18] Pooled data demonstrated that test scores of children born at full gestation were significantly higher than scores of children born prematurely. Classifications of postnatal causes of intellectual disability include head injuries, infections, demyelinating disorders, degenerative disorders, seizure disorders, toxic-metabolic disorders, malnutrition, environmental deprivation, and hypoconnection syndrome.[164] Down syndrome, fetal alcohol syndrome, and fragile X syndrome are the most common causes of intellectual disability.[201]

Movement dysfunction is more often associated with some causes than with others, and in general, children with more severe intellectual disabilities are likely to have more severe motor delays and disabilities.[172] Years ago, Ellis[52] proposed that the relatively poor motor performance of people with intellectual disabilities is the result of their limited capacity to process information and the rapid decay of that information over time. Others have also proposed a relationship between intellectual and motor function, with cognitive processes affecting "attention, executive function, visuomotor skills, timing, and learning" (p e954).[172]

Prevention

Some forms of intellectual disability and associated disorders can now be prevented, such as those resulting from phenylketonuria, rubella, and lead poisoning. In addition, amniocentesis, ultrasound, and other techniques have enabled prenatal diagnosis of many conditions, which may help decrease morbidity, such as delivery of a child with myelodysplasia by cesarean section. Genetic counseling also can be offered.

Although the factors known to cause intellectual disabilities may be present in a given child, complex and powerful interactions between those factors and later environmental events can alter the actuality or the severity of intellectual limitations and associated impairments. In a review of research and theories on the development of intelligence, DiLalla[45] suggested that about half of a person's IQ may be influenced by environmental factors. Some infants, for example, who have severe medical problems during the postnatal course, with documented neuroanatomic pathology during this period, have few if any sequelae. On the other hand, children with no known pathology but who

experience one or more environmental risk factors may eventually be classified as having intellectual disability. Two of the most common environmental causes of intellectual disability are early severe psychosocial deprivation and antenatal exposure to toxins, such as drugs or alcohol.[169]

In the United States the family-centered services directed by Part C of the IDEA[191], described in Chapters 28 and 29 of this volume, reflect a belief in the power of early social and physical environments to influence a child's development.[55] Part C regulations also imply confidence in the capability of physical therapists and other service providers to assist families in providing environments that both help to prevent unnecessary disability and promote the achievement of a child's potential.

PRIMARY IMPAIRMENT

The time at which impairments in intellectual functioning and movement become recognized varies widely, both within and between medical diagnoses. In some cases, prenatal or neonatal diagnosis can predict disabilities that may not yet be apparent, such as with children with Down syndrome or myelodysplasia. In other cases, a medical diagnosis will not be made until after impaired functioning is noted, perhaps not until months or years after birth.

Diagnosis/Problem Identification

Delay in achievement of developmental motor milestones or abnormal motor behaviors may be an early indication of intellectual disability that was present prenatally or perinatally. This is particularly true for children with severe intellectual disabilities. Some children, such as those with Rett syndrome or Tay-Sachs disease, will appear to develop normally for a period of time and then regress. In these cases, too, motor manifestations of the condition may be the first indication of a more global developmental problem.[50] Many children with autism, for example, have intellectual disabilities,[58] and studies have shown motor deficits in children with autism as early as during infancy.[138] Chapter 23 provides detailed information on autism.

Neuromotor Impairments of Children with Intellectual Disabilities

Children with intellectual disabilities are at high risk for motor impairments. One study, for example, found that 82% of children with mild intellectual disabilities scored below the 5th percentile on a test of motor coordination.[172] Although the study did not include children with greater than mild intellectual disabilities, children with more severely limited cognitive function are likely to have more severely limited motor skills.

The movement impairments of children with intellectual disabilities are as diverse as their primary and associated conditions. Many of the movement problems have their basis in central nervous system pathology that can lead to impairments in flexibility (too much or too little), force production, coordination, postural control, balance, endurance, and efficiency. Cardiopulmonary and musculoskeletal impairments also may contribute to movement problems, as well as cognitive processes that affect attention, executive function, timing, and learning.[172] Many children also have associated problems, such as vision and hearing disabilities, cerebral palsy, low levels of arousal, seizure disorders, and various other problems that can further negatively influence motor development, motor learning, and motor performance.

Although the type and degree of movement and related problems vary greatly, certain medical diagnoses are likely to be associated with specific constellations of neuromuscular, musculoskeletal, and cardiopulmonary impairments. Table 18.1 summarizes impairments that are common among children with selected diagnoses who often receive physical therapy. Box 18.1 summarizes common motor, cognitive, language, and medical characteristics of children with Down syndrome. A source of good information, including growth charts for children with Down syndrome, is the National Down Syndrome Society at http://www.ndss.org/. The National Association for Down Syndrome also has useful information at http://www.nads.org/.

Physical therapy examination of the movement impairments of children who have intellectual impairments is similar to that of other children who have problems addressed by physical therapists. Observation, criterion-referenced instruments, norm-referenced tests, and other formats are used, depending on the age of the child, the problem being assessed, and the purpose of the assessment.

Although the same examination methods[2,3,5,19,23,24] and tools may be used for children with and without intellectual impairments, recognizing that a child's intellectual impairment may affect performance of motor activities is important. This is especially the case when a child has to follow directions or perform motor tasks that have major intellectual components. Examination of infants and young children may be less affected by intellectual abilities than that of older children and adolescents, and intellectual disability may require more modification of methods to examine activity or participation than to measure impairments.

Relationship Between Environmental Exploration and Intellectual Abilities

Children who have motor impairments that restrict or prevent exploration of their environments may be at risk for secondary delays in domains that are not primarily affected, especially cognition, communication, and psychosocial development.[81] Campos and Bertenthal[31] suggested that independent mobility is an organizer of psychological changes in typically developing infants, especially developmental changes in social understanding, spatial cognition, and emotions. They also proposed theoretical links between independent mobility and the growth of brain structures, self-awareness, attachment to others, and ability to cope with the environment.

Relationships between mobility and spatial cognition have received considerable research attention. Several studies have demonstrated that locomotion, not age per se, is related to changes in such spatial intellectual tasks as recognition of cliffs[1] and slopes[3] and object permanance.[17] Results of individual studies were supported by a meta-analysis, which found that self-produced locomotion has an effect on spatial cognitive performance in typical children.[217] Self-produced locomotion also has been shown to influence social-communicative behaviors of infants[32] and to be linked to cognitive memory.[37] The proposed theoretical link between mobility and development of brain structures has been supported by studies demonstrating that experience shapes the brains of animals; for a review, see Kolb, Forgie, Gorny, and Rowntree.[90] Further research is needed to determine the relative contributions of innate mental capability and sensorimotor experiences on various aspects of intellectual development. It may be that the inborn intelligence

TABLE 18.1 Common Neuromuscular, Musculoskeletal, and Cardiopulmonary Impairments of Children with Intellectual Disabilities Caused by Selected Conditions[a]

Condition	Neuromuscular	Musculoskeletal	Cardiopulmonary
Angelman syndrome[197] Genetic mechanism with deletion of chromosome 15 as the most frequent cause; estimated prevalence 1 in 10,000 to 20,000. Up to 26% have no genetic cause and are diagnosed clinically.	Hypotonia and feeding problems within first 6 months followed by developmental delay. Tremulous movements, ataxia, hand flapping, and distinctive gait; microcephaly and seizure disorder	Facial abnormalities, flat occiput, strabismus, scoliosis, pronated or valgus at ankles	Vagal hypertonia resulting in cardiac rhythm disturbances
Cornelia deLange syndrome[119] Caused by mutations in the NIPBL, SMC1A, and SMC3 genes; estimated to affect 1 in 10,000 to 30,000 newborn infants.	Spasticity, intention tremor, seizure disorder (10% to 20%), microcephaly	Severe growth retardation; decreased bone age, small stature, small hands and feet, short digits, proximal thumb placement, clinodactyly of fifth fingers, other arm and hand defects, limited elbow extension	Neonatal respiratory problems, congenital heart disease, recurrent upper respiratory infections
Cri du chat syndrome[40] A rare chromosomal disorder (1 in 50,000 live births) caused by loss of chromosomal material from region 5p (5p12).	Hypotonia in early childhood, sometimes hypertonia later	Facial and minor upper extremity anomalies, scoliosis	Congenital heart disease is common
Cytomegalovirus (prenatal)[62] One of the most common causes of prenatal infections in developed countries, with incidence estimated to be between 0.15% and 2.0%.	Cerebral palsy, seizure disorder, microcephaly (hearing problems)	Secondary to neuromuscular problems	Pulmonary valvular stenosis, mitral stenosis, atrial septal defect
Fetal alcohol syndrome[66] Caused by prenatal exposure to alcohol, the estimated prevalence of fetal alcohol syndrome is about 1%.	Fine motor and visual motor deficits, balance deficits	Minor facial abnormalities, joint anomalies with abnormal position or function, maxillary hypoplasia, poor growth	Heart defects
Fragile X syndrome[135] The most common form of inherited mental retardation, it is primarily caused by expansion of a sequence in the FMR1 gene of the X chromosome.[135]	Poor coordination and motor planning, seizures	Connective tissue abnormalities, which may lead to congenital hip dislocation in infancy and later to scoliosis and pes planus	Mitral valve prolapse
Hurler syndrome[80] Autosomal recessive storage disorder with lack of lysosomal hydrolase α-l-iduronidase.	Hydrocephalus	Joint contractures, clawlike deformities of hands, short fingers, thoracolumbar kyphosis, shallow acetabular and glenoid fossae, irregularly shaped bones	Cardiac deformities, cardiac enlargement because right ventricular hypertension is common, death frequently due to cardiac failure
Lesch-Nyhan syndrome[98] Caused by a genetic deficiency of hypoxanthine-guanine phosphoribosyltransferase located on the X chromosome.	Hypotonia followed by spasticity and chorea, athetosis, or dystonia; compulsive self-injurious behavior	Secondary to neuromuscular problems	
Phenylketonuria (PKU)[178] Inherited metabolic disease, autosomal recessive disorder caused by mutation to the PAH gene. Treated with dietary means, enzyme therapy, and pharmaceutical supplementation. Occurs in 1 of 10,000 to 20,000 newborns. Neonates are screened for PKU. Progressive in untreated.	Tremors, microcephaly, epilepsy, hyperactivity	Reduced growth, eczema, distinct odor	
Prader-Willi syndrome[35] A chromosomal microdeletion disorder that occurs in 1 in 10,000 to 15,000 live births. It is the leading genetic cause of obesity.[35]	Severe hypotonia and feeding problems in infancy, excessive eating (usual onset 1-6 years) and obesity in childhood, poor fine and gross motor coordination, average age of sitting 12 months and walking 24 months	Small hands and feet, sometimes tapering fingers; scoliosis, kyphosis, or both are common; hip dysplasia in 10%; osteoporosis is frequent	Upper airway obstruction, sleep apnea, and oxygen desaturation are common
Rett syndrome[137] Definitive diagnosis is accomplished by mutation analysis on leukocyte DNA for the gene MECP2.	Deceleration in rate of head growth in infancy, gradual loss of acquired skills after 6 to 18 months of age, loss of purposeful hand skills, stereotypic hand movements (clapping, wringing, clenching), apraxia, teeth grinding, seizure disorder	Scoliosis/kyphosis, growth failure, bone demineralization	Breathing irregularities, such as hyperventilation and breath holding
Williams (elfin facies) syndrome[115] Caused by mutation or deletion of the elastin gene at 7q11.23; it occurs in 1 in 20,000 live births	Mild neurologic dysfunction, hypotonia, hyperreflexia, cerebellar dysfunction	Facial abnormalities, slow and abnormal growth, connective tissue abnormalities, radioulnar stenosis, spinal deformities, joint hyperextension when young, contractures when older	Supravalvar aortic stenosis, hypertension, peripheral pulmonic stenosis, and mitral valve prolapse

[a]Not all children with each condition exhibit all impairments.

BOX 18.1 Common Characteristics of Children with Down Syndrome

Motor Development

Hypotonia[199]
Hyperflexibility[199]
Problems with postural control and balance[199]
Delayed gross and fine motor development[131]
Gross motor development begins to level off after age 3 years[131]
Usually follow sequence of typical motor development[131]
Require more time to learn movements as complexity increases[131]
Atypical patterns of movement to maintain postural stability[199]
Reduced strength[199]
Better motor performance with visual than verbal instructions[109]
Perceptual-motor deficits in perception of complex visual motion cues[109]

Cognitive Development

Usually moderate to severe intellectual disability, although some have been reported to be within typical range[199]
Intelligence test scores progressively decrease with age[136]
Early onset (4th decade) of dementia is common[200,202]
Motivation may be low[199]

Language Development

Usually poor; below other areas of development and when compared with typical children or children with other causes for intellectual disabilities of the same mental age[199]
Impairment of verbal memory skills and other verbal processing abilities[202]
Language comprehension less impaired than expressive language[199]

Medical Problems[155]

Congenital heart disease (66%)
Vision deficit (60%)
Hearing impairments (60% to 80%)
Obesity (60%) and low levels of physical fitness
Skin conditions (50%)
Seizure disorder (6%)
Atlantoaxial instability (subclinical 14%; symptomatic 1%)
Hypothyroidism (subclinical 30% to 50%; overt 7%)
Periodontal disease

Other

Increased risk of early onset Alzheimer-type dementia[199]
Perhaps increased incidence of autism spectrum disorders[177]

of some children enables them to compensate for their motor limitations, thus making them less vulnerable to effects of sensorimotor deprivation than children whose intellectual capacities are more limited.

Learning in Children with Intellectual Impairments

By definition, *impaired learning* is what distinguishes children with intellectual impairments from other children. Although their motor problems often are similar to those of children without intellectual impairments and they respond to intervention based on the same physical therapy principles, the application of those principles must be sensitive to the children's learning characteristics and current theories on motor learning as explored in Chapter 4.

The degree and types of learning disabilities of children with intellectual limitations vary considerably, but several common learning characteristics have been identified. Compared with typically developing children, children with intellectual disabilities have been found (1) to be capable of learning fewer things; (2) to need a greater number of repetitions to learn; (3) to have greater difficulty generalizing skills; (4) to have greater difficulty maintaining skills that are not practiced regularly; (5) to have slower response times; and (6) to have a more limited repertoire of responses.[129] People with mild intellectual disabilities learn at about 50% to 66% the rate of people without intellectual disabilities, people with moderate intellectual disabilities at about 33% to 50% the rate, those with severe intellectual disabilities at about 24% to 33% the rate, and those with profound intellectual disabilities at about 25% the rate of people without intellectual disabilities.[201] Implications of these learning characteristics for physical therapy are described in later sections of this chapter.

Assessment of Intellectual Functioning

Determining if a child has an intellectual disability requires a standardized, norm-referenced measure of intelligence, which usually is administered by a psychologist or psychometrist. Even though most physical therapists do not administer intelligence tests, they are often able to promote an environment in which children with motor disabilities can perform optimally, such as by providing positioning to enhance a child's communication and eye and hand use[171] or by assisting the examiner to determine alternative response modes for use by children who have motor impairments.

Assessment of Infants

Physical therapists might be involved in the administration of tests designed to assess the intellectual abilities of infants because many of these tests focus on an infant's perceptual-motor development, such as accomplishment of motor developmental milestones or coordination of vision and hearing with body movement.[43] The Bayley Scales of Infant and Toddler Development[16] and the Test of Infant Motor Performance[30] discussed in Chapter 2 of this book are instruments that measure motor abilities and are often used to identify delay in infants.

Unfortunately, perceptual-motor–based infant evaluations are poor predictors of intellectual ability at later ages, with little, if any, relationship found between scores on infant tests and children's subsequent scores on intelligence tests for preschool or school-age children.[53] Hack and colleagues compared intellectual functioning of extremely low birth weight infants at 20 months corrected age and 8 years of age, using the Bayley Scales of Infant Development. They found that 80% of children born with extremely low birth weights, without neurosensory impairment, and with subnormal intellectual scores at 20 months demonstrated higher levels of intellectual functioning at 8 years.[70] The scores of children with extremely low birth weights and with neurosensory impairment were stable.[70] The limited stability of test scores in infants and young children is also influenced by other factors such as environment, experience, and rapid nature of developmental progress at early ages.[117]

Some tests of infant intellectual abilities attempt to measure infants' intellectual functioning through evaluation of their information-processing capacity rather than their perceptual-motor skills. These tests use infants' responses to novel and previously presented stimuli to assess their visual or auditory memory and their ability to discriminate among stimuli.[69] These tests are based on the tendency of infants, almost from birth, to respond for shorter periods of time to stimuli to which they have been previously exposed. Thus, if an infant has a longer response to a new stimulus than to one presented previously,

memory for the familiar stimulus and discrimination of the two stimuli are demonstrated. Visual attention to stimuli is often assessed, as with the Fagan Test of Infant Intelligence (FTII),[54] but changes in physiologic status, like heart rate, respiration, and level of alertness can also be used to interpret response to stimuli.

One advantage of information-processing tests for infants is that they are essentially motor- and language-free, making them more appropriate for infants with motor and hearing impairments than many other tests.[53] Another advantage is that their predictive validity is much better than that of tests that focus on perceptual-motor behaviors; they may be most predictive when infants are tested at around 9 to 10 months corrected age.[69] These tests tap information-processing capacities similar to intelligence tests for older children. As noted by Sattler, cognitive development is highly changeable birth through age 5; after age 5, cognitive development can still change, but to lesser degrees.[162]

Assessment of Children

The Stanford-Binet Intelligence Scale V[152] for children ages 2 to 23, the Wechsler Intelligence Scale for Children V[84] for children ages 6 to 16.11, and the Differential Abilities Scale—Second Edition[51] for children ages 2.6 to 17.11 are common measures for assessing the intelligence of children.[162] Standardized administration of these and most other intelligence tests requires spoken and motor responses; however, these requirements seriously limit their usefulness with children who have communication and motor impairments.

A few intelligence tests have been developed that require children only to indicate a choice from among an array of alternatives. DeThorne and Schaefer provide an overview of intelligence testing that does not require an oral response in *A Guide to Child Nonverbal IQ Measures*.[44] Tests included meet five requirements: (1) used for testing of general cognitive functioning; (2) provides a standardized score of nonverbal ability; (3) developed or updated within the last 15 years; (4) suitable for preschool- or school-age children; and (5) developed for the population at large rather than specific groups. The Comprehensive Test of Nonverbal Intelligence,[73] the Pictorial Test of Intelligence,[60] and the Test of Nonverbal Intelligence[26] are tests that do not require manipulatives or verbal responses and, instead, require the student to indicate a pictorial response.

Raven's Progressive Matrices,[146] which requires selection of missing elements of abstract designs, and the Leiter International Performance Scale[153] are other non–language-based tests with minimal motor requirements. They may, however, suggest spuriously low intellectual abilities in children who have visual-perceptual deficits or visual impairments. It is also important to be aware that intelligence tests with limited motor and language requirements sample only a narrow range of abilities compared with more traditional tests of intelligence. Most intelligence tests have significant limitations in testing children who have lower levels of ability.[175] Current methods of testing inadequately address the needs of children with motor, visual, and/or communication impairments.[42] Capturing intelligence scores for these children continues to be elusive, requiring multiple assessment approaches to better gain a comprehensive and accurate picture of the child's strengths, needs, and performance abilities.

Assessment of Adaptive Behaviors

Although examiners often emphasize intelligence test scores in the diagnosis of intellectual disability, adaptive behaviors are also central in the assessment of intellectual functioning. The AAIDD defines adaptive behavior as the collection of conceptual, social, and practical skills necessary for daily function.[6] Assessment of adaptive behavior relies heavily on professional judgment, in both the selection of means to assess adaptive behaviors and in their interpretation. As with intelligence testing, psychologists and psychometrists typically administer tests of adaptive behavior when determining intellectual disability.

Instruments to measure adaptive behaviors have been developed that are of more recent vintage than many of the intelligence tests and are fewer in number. The AAMR Adaptive Behavior Scale-School (ABS-S:2)[75] is commonly used for older children to measure adaptive abilities. Results of a validity study of the ABS-S:2 indicated that the personal independence and social behavior scales of the tool demonstrated the largest difference between typical children and children with intellectual disabilities.[203] The Diagnostic Adaptive Behavior Scale (DABS) is under development by the AAIDD. The DABS measures three domains of adaptive behavior identified by the AAIIDD: Conceptual Skills, Social Skills, and Adaptive Skills.[7] Another test frequently used for older children is the Vineland Adaptive Behavior Scales, Second Edition (VABS-II).[176] The VABS-II is administered as a questionnaire or rating form that asks about activities of daily living, cognition, language, play, and social competency.

Physical therapists often can provide information about a child's adaptive behaviors, such as self-help and mobility skills, and may also be instrumental in providing assistive devices that can improve a child's adaptive skills. The Pediatric Evaluation of Disability Inventory (PEDI),[72] described in Chapter 2, is frequently used by physical therapists. The PEDI is a norm-referenced measure of adaptive behaviors in the areas of self-care in children age 6 months to 7.5 years with physical or combined physical and intellectual disabilities. The PEDI also can be used as a criterion-referenced test with older children whose function is below that of a typical 7-year-old.

Intellectual Referencing

Intellectual referencing is an assessment approach that has been used to determine whether children are eligible for services, especially for physical therapy, occupational therapy, and speech pathology, in public schools.[13,83] The approach is based on an assumption that children's potential for gains in motor and communication development is related to their intellectual abilities and that children whose intellectual abilities are lower than or equal to their motor or communication abilities would not benefit from services, so they are not eligible for them. Many children with intellectual disabilities could be declared ineligible for physical therapy services under such an assumption. Critics have been supported by at least one study that examined the association between IQ scores and progress in occupational therapy or physical therapy over the course of one school year.[13] Children were divided into two groups based on their IQ scores, and children received similar dosing of physical therapy for motor impairments with both groups showing significant change in their age-equivalence scores. There was not a significant correlation between IQ and change in motor test scores. The US Department of Education, Office of Special Education Programs (OSEP), declared intellectual referencing to be an unlawful means of determining whether a child should receive

related services in public schools.[143] In the 2004 reauthorization of IDEA,[55] using cognitive referencing to identify severe discrepancies in ability was removed from federal policy.[120]

FOREGROUND INFORMATION

PHYSICAL THERAPY EXAMINATION

The complex problems of children with both intellectual and motor disabilities usually require a team approach for examination and for planning, implementation, and evaluation of intervention.[38,144] The team always will include the child's family or another caregiver, with other team members as required by the nature and severity of the child's problems, the child's age, and the service delivery setting. Many children need the services of two or more teams at the same time, such as a clinically based health care team and an early intervention or school team. Often, the health care team focuses on the child's body functions and structures, whereas the early intervention or school-based team is responsible for addressing activity limitations and ongoing efforts to promote the highest possible level of family and community participation. These teams, unfortunately, frequently function independently of each other,[68,125] creating overlaps and gaps in care while consuming considerable resources of time and money.[174,192] When the teams have mutual responsibilities and concerns, disagreements can occur, resulting in confusion for the family and an unnecessary expenditure of limited resources. Working toward family-centered care, understanding and appreciating the roles of each team, and integrating care across the care teams are important to achieve coordination of care for the child and family.[77,144] Regardless of team responsibility, the examination of a child with both intellectual and motor impairment should be guided by the ICF.[216]

History and Systems Review

As shown in Table 18.1, intellectual disability can be associated with a variety of causes and neuromuscular, musculoskeletal, and cardiopulmonary impairments. A child's history—obtained from family members, medical records, early intervention/education records, social service agencies, and any other relevant source—can help to identify systems on which to focus the systems review and examination. As with children without intellectual disabilities, the history also can identify activity and participation levels, prior interventions and outcomes, surgical procedures, family and child goals, and other information to help decide which tests and measures to use.

Tests and Measures: Activity

The norm- and criterion-referenced tools described in other chapters of this volume that are used to measure activity and participation among children with other types of disabilities can be used with many children with intellectual impairments. Depending on a test's properties, it can identify activity limitations and abilities, provide baseline data to measure change over time or change following intervention, predict future performance,[89] and/or help identify specific goals of intervention.

Norm-referenced tools, which compare a child's performance with the performance of other children of the same age, are primarily useful as discriminative measures to determine if a child's development is delayed and, if so, in what areas. The Peabody Developmental Motor Scales,[57] for example, frequently is used as part of an early intervention evaluation to determine if a child is eligible for services based on delays in gross and fine motor skills. The functional skills scale of the PEDI,[72] which measures mobility, self-care, and social function, is norm referenced for children from age 6 months to 7 years. The PEDI also can be used as a criterion-referenced test for older children whose function is below that of a typical 7-year-old. A newer computerized version of the PEDI, the PEDI-CAT, measures an additional domain of responsibility, which includes organizational skills, management of daily activities and health needs, as well as maintaining personal safety.[71]

The PEDI and other criterion-referenced tools, such as the Gross Motor Function Measure,[160] are useful as discriminative tests to identify a child's current performance of motor-related activities and also as evaluative tests to determine if change in performance occurs over time or following intervention. A few criterion-referenced tools, such as the Test of Infant Motor Performance[30] and the Gross Motor Function Classification System[132] are useful predictive measures that indicate what a child's future motor performance is likely to be. This information is particularly useful for intervention planning.

Tests and Measures: Participation

Examination of a child's participation often is best conducted in the environments in which the child actually participates or in environments in which children of similar age and social background participate.[108,144] Examination in natural environments is increasingly advocated to support the enablement model for all children who have disabilities, including children with intellectual disabilities, who have difficulty generalizing skills from one setting to another.[64] Because children function in multiple environments, episodic examination to address participation deficits or needs within a specific context may be necessary. Shummay-Cook and Woollacott note that motor-control challenges are best addressed through examination of both the task and the environment in which the task occurs.[170] An ecologic assessment can be a helpful way to examine a child's participation within the context of an identified goal. Table 18.2 shows an ecologic assessment for a young man whose goal is to shop independently for groceries at a neighborhood store.

If a child's and family's goals are related to participation, several tools are available to use as baseline and outcome measures. If a goal is for the child to participate in recreation and leisure activities outside of school, for example, the Children's Assessment of Participation and Enjoyment (CAPE) and Preferences for Activities of Children (PAC)[88] can provide useful information about participation of children and youth age 6 to 21. The CAPE measures the diversity, intensity, enjoyment, and context of the activities. The PAC measures preferences for involvement in activities. The Caregiver Assistance Scale of the PEDI[72] also measures participation related to mobility, self-care, and social function in the home environment. The School Function Assessment[41] measures participation, activities, and necessary task supports in the school environment of children in kindergarten through sixth grade.

Tests and Measures: Body Structures and Functions

Assessment of body structures and functions can help to identify reasons for activity and participation limitations. Methods for examination of body structures and functions of children described in other chapters of this volume are applicable to children with intellectual impairments. Modifications are often necessary, though, if a child has difficulty responding to verbal requests and directions. When determining pain levels, for

TABLE 18.2 Example of a Goal-Focused Ecologic Assessment

Name: Jeff
Goal: Grocery shopping independently
Environment: Dan's One-Stop

Steps Required	Jeff's Current Performance	Steps Can Acquire	Steps May Not Acquire	Compensatory Strategies	Intervention[a]
Go from home to Dan's and back using electric wheelchair.	Can open front door (outward), go down ramp, and drive to the corner. Cannot go down curb (no curb cut), cross street safely, or go up curb. Once on the sidewalk, can drive to Dan's. Cannot open door from outside. Can maneuver inside store and open door when leaving (outward). Cannot open door of home when returning.	Open doors of home and store when the door opens toward him. Go down curb. Ask for assistance and tell someone how to help him up a curb. Cross the street safely.	Go up a curb without assistance.	Curb cuts	Teach Jeff to open doors, go down curbs, and cross streets safely (PT, PCA). Talk with city about making curb cuts and with store and house manager about modifying doors (Jeff, CM). Program communication aid to request help with curbs and give instructions (mother, PT).
Select items in the store.	Does not always remember what he needs to get and cannot make or read a shopping list. Can get items that are at hand level, cannot shift weight or extend arm to reach low or high items.	Make and use shopping list. Improve ability to reach high and low items. Ask for assistance to get out-of-reach items.	Reach items that are very high or very low.	A reacher?	Teach Jeff To make and use a shopping list (OT, PCA), To use a reacher, if it seems feasible (OT, PCA), and To reach to higher and lower shelves (PT, PCA).
Carry items to checkout stand.	Cannot maneuver shopping cart. Items slide off lap, does not want to use tray.	Carry items in a bag or other container on lap or chair.	Push a grocery cart without endangering store and other people.	Bag or other container that is accessible to Jeff	Find container and teach Jeff to use it (OT and PCA).
Put items on counter.	Can put items on counter but is very slow, which annoys people in line behind him.	Put container on counter so clerk can remove items, or Ask for assistance.	Increase speed sufficiently, or Lift full container to counter.	None	Try to improve speed and lifting of container (PT, PCA), and Program communication aid and teach Jeff to ask for assistance (mother and PCA).
Pay for purchases.	Cannot get wallet out of pocket, cannot get money out of wallet. Does not recognize denominations of bills or coins, cannot pay correct amount or check change.	Get money out of suitable container. Recognize bills and coins. Give sufficient money to cover the purchase.	Get wallet out of pocket or money out of wallet. Determine if change is accurate.	Use an accessible container for money. Ask personal care assistant to compare bill and change occasionally.	Find accessible container for money, and teach Jeff to use it (OT, PCA). Teach Jeff to use money (OT, mother, PCA).
Carry purchases home.	Can carry small bag on lap, cannot carry large bag(s).	Carry purchases in container attached to chair.	Carry large or multiple bags on lap.	Alternate container (probably the same as in row 3, above).	Find appropriate container for purchases (OT, PCA).
Put purchases away.	Can open cupboards with flat surfaces or knobs, drawers with knobs, and the refrigerator. Cannot open high or low cupboards or drawers with flat surfaces. Can put purchases away in places he can open and reach.	Open all drawers he can reach. Put items away in higher and lower places.	Put items in very high or low places.	Make adaptations to allow Jeff to open kitchen drawers he can reach. Rearrange cupboards and drawers so items Jeff uses are accessible.	Discuss adaptations and rearrangement with house manager (OT). Improve Jeff's reach (also in row 2 above) (PT, PCA).

[a]Note: Those involved with each intervention are determined after the intervention is identified. At this time, Jeff has the assistance of his personal care assistant (PCA), case manager (CM), mother, occupational therapist (OT), and physical therapist (PT).
Format from Baumgart D, Brown L, Pumpian I, Nisbet J, Ford A, Sweet M, et al.: Principle of partial participation and individualized adaptations in educational programs for severely handicapped students. J Assoc Severely Handicapped 7:17-27, 1982.

example, the therapist might need to rely on the child's facial expressions or body movements, as well as caregiver input.[196] Similarly, a child with intellectual impairment may be unable to replicate standardized strength testing protocols. Instead, strength deficits might be identified by the child's inability to complete a functional skill, such as maintain a position against gravity or climb a step. For ambulatory children with intellectual disabilities, a treadmill can be a reliable way to measure cardiorespiratory endurance, after allowing for practice.[128] In children with severe motor impairments, measurements of vital functions including heart rate and respiratory rate may be helpful in identifying endurance deficits. Use of the 9-point Beighton Hypermobility Score was found to be reliable and feasible in children with intellectual impairments, when provided

prompting, guided movements and modification of the forward flexion testing position.[139] Examination of the integumentary system in children with intellectual and motor impairments is necessary because they may have several risk factors for skin breakdown including paralysis, immobility, insensate areas, poor nutrition, exposure to moisture from incontinence, shear from transfers, and use of accessory devices such as wheelchairs and splints.[105,148] *Smith's Recognizable Patterns of Human Malformation*[80] is a comprehensive resource of genetic abnormalities often with associated intellectual disability that can be useful for identifying body structure and function impairments that children with various conditions are likely to have that should be examined.

Tests and Measures: Contextual Factors

The AAIDD definition of *intellectual disability* requires consideration of function within context.[6] Similarly, the ICF views outcomes as resulting from interactions between health conditions and contextual factors. Contextual factors include both personal and environmental factors.[216] Environmental factors outside the child can profoundly affect child development, test scores, and intervention planning.[110] Brooks-Gunn and colleagues[23] found, for example, that differences between IQ test scores of African American and Caucasian children at age 5 years were nearly eliminated after adjustments were made for poverty and home environment.

Physical therapists often have less experience examining the social and attitudinal aspects of the environment than the physical aspects. Children rarely function alone in their environment, however, so social and attitudinal factors need to be considered. Young children are a part of their families, and older children spend their time in classrooms, in after-school activities, and in the community with their peers, family, and other community members. Acknowledgement of the complex relationship between the individual with a health condition and the environment has led to a shift toward greater emphasis on the environment in examination and intervention.[166]

In the ICF model, personal factors include those aspects of a person that are not part of the health condition, such as gender, race, coping styles, and those things that are intrinsically motivating.[216] Physical therapists need to consider such personal factors including motivation, self-efficacy, age-related interests, and engagement to effectively promote children's chosen activities and participation within the context of family, school, and community.[91] A tool that is helpful for identifying the level of supports that adolescents and adults with intellectual disabilities and other developmental disabilities need for quality participation in society is the Supports Intensity Scale (SIS).[5,185] The tool was normed with people age 16 to over 70 years and measures the supports needed in daily life activities and exceptional medical and behavioral support needs. A supplemental protection and advocacy scale also is included. The SIS-C, a version of the scale for children 5 to 15 years with intellectual disabilities, is currently being field tested.[8]

Determining Intervention Goals and Outcomes

Functional goals have been emphasized for many years in early intervention, special education, and physical therapy.[108,144,145] Functional skills have been defined as age-appropriate activities or tasks that someone else will have to do if the child does not[25] and should reflect the needs and interests of the child and family. Some children can learn to complete a task or activity, whereas others will be capable of learning to carry out only a part of it. A child may, for example, be unable to transfer independently but can learn to unbuckle a seat belt and support weight in standing. Another child may be unable to put a DVD into a player but can learn to turn it on using a switch.

Outcomes of interventions to improve a child's abilities to participate in life must represent specific functional skills that the child will acquire. Team members cannot assume that interventions directed toward remediation of impairments, such as improving postural responses, range of motion, or strength, or toward reducing the degree of activity limitation indicated by failed items on a developmental test, will necessarily lead to meaningful outcomes.[108,144,145] This is especially true of children with intellectual disabilities who need many repetitions to learn, who forget easily, and who generalize poorly. These characteristics make it difficult or impossible for a child with intellectual disabilities to synthesize isolated activities or components of movement into meaningful skills.

Campbell[29] proposed a "top-down" approach to determining outcomes, in which the desired functional outcomes are determined first, then obstacles to their accomplishment are identified, and then intervention to overcome the obstacles is planned and implemented (Fig. 18.1). This process is similar to the decision-making process of the hypothesis-oriented algorithm for clinicians (HOAC II),[158] in which a person's goals for intervention are identified first, then the person is examined to generate a hypothesis about why the goals can or cannot be met at the present time.

Functional outcomes can be anything that is of high priority and meaningful to the child and family, is age appropriate, and is, or could be, a home, community, recreation-leisure, or vocational activity. Giangreco and colleagues[63] proposed five valued life outcomes for all children, including those with severe disabilities:

1. Having a safe, stable home in which to live now or in the future
2. Having access to a variety of places and engaging in meaningful activities
3. Having a social network of personally meaningful relationships
4. Having a level of personal choice and control that matches one's age
5. Being safe and healthy

Teams usually have the most difficulty determining meaningful outcomes for children with profound multiple disabilities, who often have extremely limited repertoires of behavior and movement. Even these children, however, can accomplish outcomes that require active behavioral changes, such as indicating a choice of food or activity or using body movements to activate switches. Such active outcomes lead to acquisition of skills that increase participation and are in contrast to passive activities that are done to the child, such as sensory stimulation, range of motion exercises, and positioning (often stated as something the child will "tolerate"). Passive activities may be part of the intervention to help a child accomplish a skill, but only the child's active behavior can increase true participation.

One helpful tool for assisting families to identify meaningful outcomes and to measure whether they have been accomplished is the Canadian Occupational Performance Measure (COPM).[94] The COPM was designed as an individualized measure of performance and satisfaction in self-care, productivity (work, household management, play/school), and leisure.

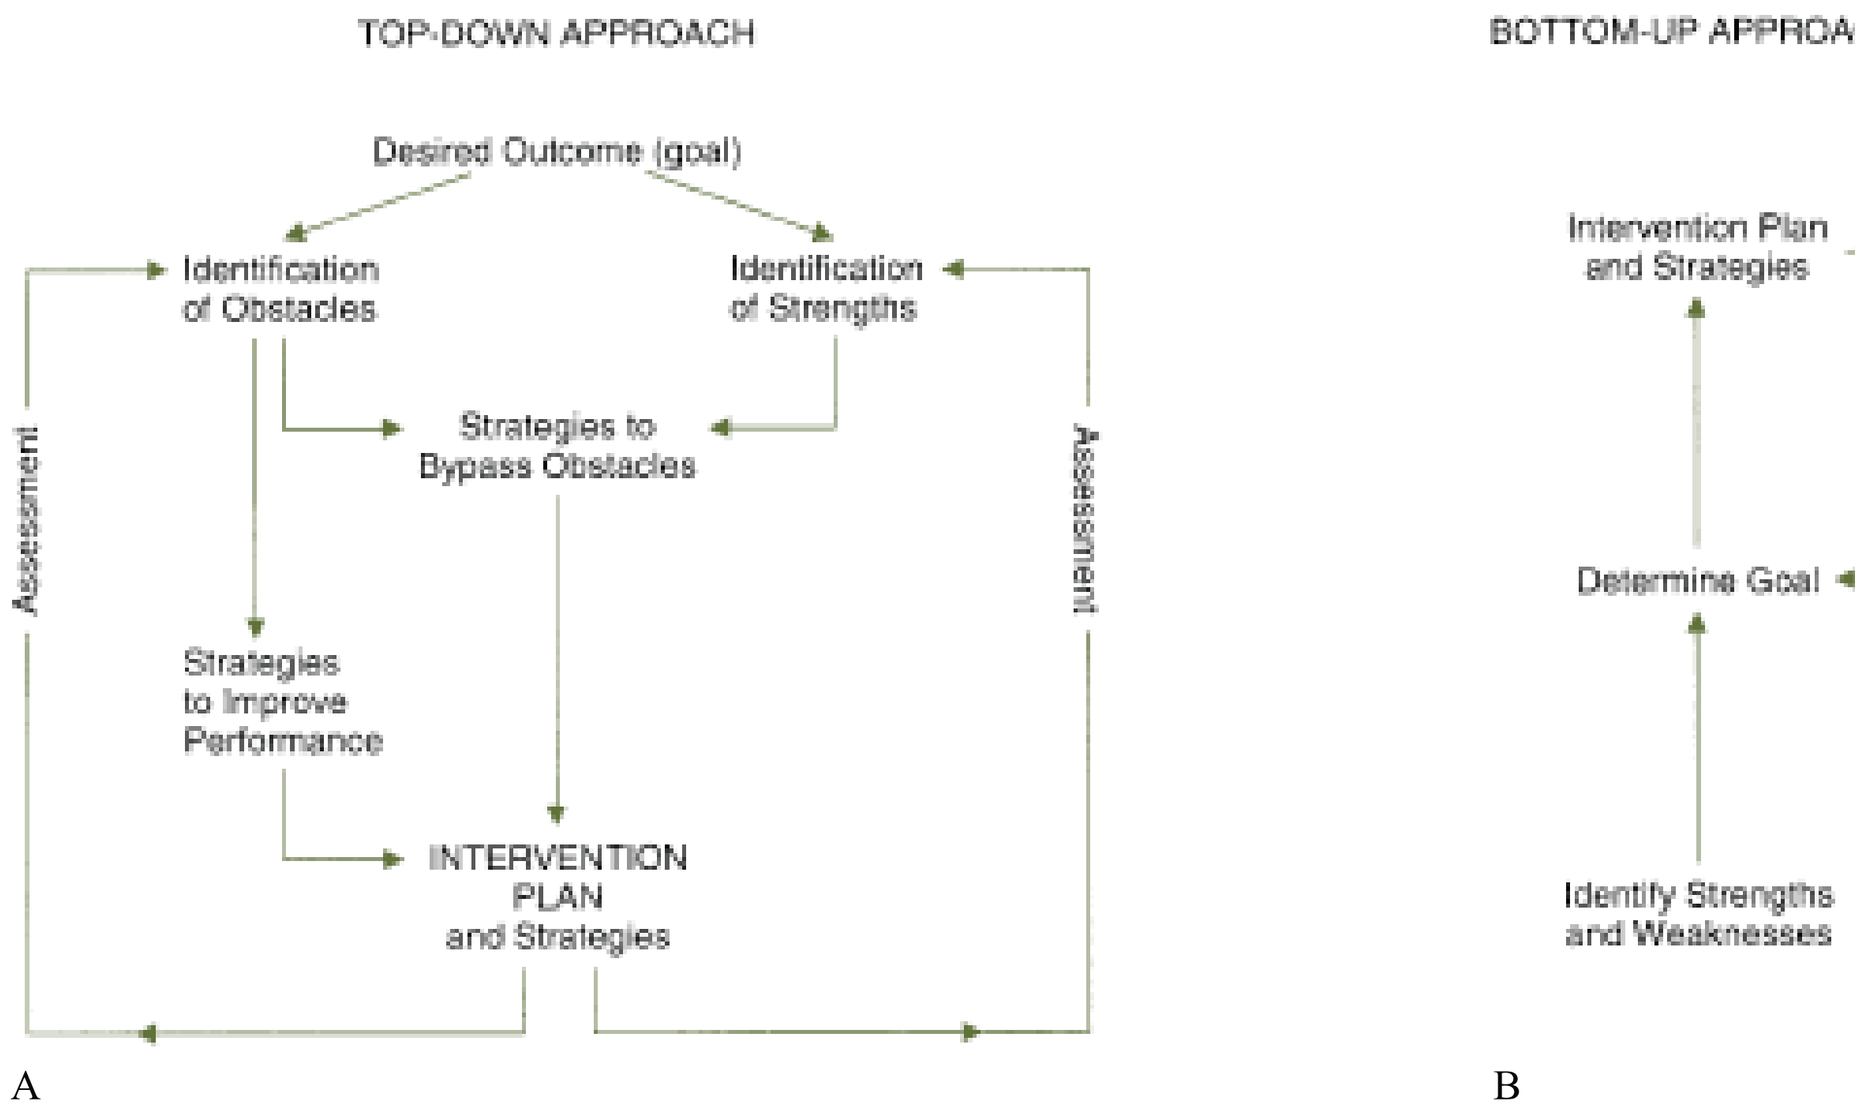

FIG. 18.1 Comparison of a top-down approach (A), in which assessments identify means to achieve desired outcomes, and a bottom-up approach (B), in which assessment results determine outcomes. (From Campbell PH: Evaluation and assessment in early intervention for infants and toddlers. J Early Intervent 15:42, 1991. Copyright ©1991 by Division for Early Childhood, the Council for Exceptional Children.)

Although the COPM was intended for occupational therapists, it is an equally useful tool for physical therapists. Another tool that is useful for children with receptive language at the 5-year level is the Perceived Efficacy and Goal Setting System (PEGS).[113] The PEGS uses a questionnaire format to help children rate their competence in everyday tasks and to select goals important to them.

When desired outcomes are determined first, they are discipline-free: that is, they describe the skills the child will accomplish without regard for discipline-related concerns. Only after team members identify the highest-priority outcomes do they decide which disciplines will be needed to help the child accomplish each one.[144] This team-oriented process for determining outcomes is not necessarily inconsistent with processes described in the HOAC II[158] or the *Guide to Physical Therapist Practice*[9] because both the HOAC II and the Guide describe primarily a unidisciplinary approach in which the physical therapist makes decisions in collaboration with the patient and perhaps the patient's family. When working with children whose complex problems require teams of professionals, the process must include other professionals as well.

INTERVENTION

During planning and implementation of intervention for children with intellectual disabilities, it is important to keep in mind what are widely regarded as best practices for working with children who have intellectual disabilities and other developmental disabilities. Some of these practices have been discussed previously and include families and children as full and equal team members, testing in natural environments[47] whenever possible, and emphasizing functional outcomes with active participation by children.[108] Intervention based on environmental assessment and occurring in natural environments is far more likely to result in improved abilities to participate in everyday activities and in age-appropriate life roles than intervention that takes place in an isolated or clinical setting, is based on a normal development sequence, or focuses primarily on identification of impairments, such as range of motion, postural responses, or retention of reflexes.[24,86,108,144] Successful physical therapy services depend on more than developing intervention focused on the physical aspects of a task. Rather, successful intervention often depends on opportunities to practice within supportive social and attitudinal environments.

Other considerations that influence intervention for children with intellectual disabilities include interventions to limit impairments and promote activity and participation, use of teaching methods that are most likely to result in acquisition of skills by children with intellectual disabilities, and the role of physical therapists in promoting development in nonmotor domains.

Interventions for Impairments of Body Structures and Functions

Early identification of neuromuscular, musculoskeletal, and cardiopulmonary problems, at whatever age they occur, allows for intervention designed to limit the impairments, thus restricting the development of secondary impairments and activity limitations. Primary impairments are those associated with a condition at the time of diagnosis.[216] Secondary impairments are often the result of primary impairments, may develop over time, and can sometimes be avoided or reduced by intervention.[15] For example, children with Down syndrome are often

BOX 18.2 Physical Therapy for Children with Down Syndrome

Interventions for children with Down syndrome should be targeted to helping children achieve measurable goals identified with the parents and with the child when the child is old enough to have an opinion. Children's need for physical therapy and specific interventions changes as children age. Interventions are likely to be direct and more intensive for infants and toddlers and then involve more consultation than direct therapy as the child attends preschool and school.

Infants and Toddlers (Age Birth to 3 Years)

Early intervention services from the time the infant is medically stable to provide the parents with information about resources, the development of children with Down syndrome, and methods to promote their child's motor development and development of functional skill.[215]
Arrange access to parent-to-parent support.[116]
Attempt to prevent compensatory movements.
Consider treadmill training starting at about 10 months, which research has shown can reduce delay in walking and may promote developmental benefits of independent locomotion.[190]
When the child starts to stand, consider flexible supramalleolar orthoses to improve postural stability.[102]
Coordination and communication with other members of the early intervention team, such as speech/language pathologists, for strategies to promote communication development. Consider manual signs[202] or other forms of augmentative communication if the child is not communicating at age-appropriate levels.
Provide adaptive seating or other positioning devices to compensate for lack of postural control to facilitate reaching and hand function so the child can participate in learning activities.
Facilitate parent–child interactions.
Promote early perceptual-motor competencies such as eye gaze and joint attention to people, objects, and the environment.[200]
Coordinate and communicate with any day care or preschool providers.

Preschool

Coordinate and consult with preschool teachers about how to include the child in motor activities that will continue to promote motor development.
Consult with parents to involve child in active play, such as trike riding, swimming, etc.
Consider the need for orthoses to improve stability as necessary for development of higher-level motor skills.[102]
Consider manual signs or augmented assistive technology for communication.[202]

School Age

Prevention of problems associated with aging is important.[14]
Coordinate and consult with physical education teachers and parents to include the child in activities that promote fitness.
Promote regular physical activity including cardiovascular, flexibility, strengthening, balance, and agility.[49]
Minimize the risk of injury by structuring exercise of longer duration, greater frequency, and less intensity compared to that of typical peers.[49]
Refer to physician if child has symptoms of myelopathy (neck pain, head tilt, gait changes, weakness) due to increased risk of atlanto-axial subluxation.[4]
Choose a variety of activities that are enjoyable and motivating for the child.[49]
Teach and engage child in typical motor activities like bicycle riding.[189]
Consider a short-term exercise training program to improve strength and agility.[95]
Involve in organized programs that culminate in Special Olympics, Unified Sports, and inclusive events.

born with hypotonia and joint hypermobility.[199] The combination of these two factors can lead to joint instability, resulting in secondary musculoskeletal deformities including hip and patellar instability, scoliosis, and foot deformity.[61,112] Primary impairments in children with intellectual and motor impairments vary greatly and depend on the condition. Table 18.1 identifies impairments related to specific conditions and on consequences that often follow the natural history of these conditions. Pain,[126] diminished cardiopulmonary fitness,[128] obesity,[149] fatigue,[195] integumentary impairment,[105,150] impaired bone density,[87] and musculoskeletal deformity[127] are some of the many impairments that may occur secondary to the child's condition and may warrant physical therapy intervention.

Physical therapy intervention can potentially impact the development of secondary impairments as well as minimize the effect of the secondary impairment on activity, function, and participation. Continuing with the example of the child with Down syndrome, intervention designed to enhance postural control and force production may help promote accomplishment of motor milestones and decrease secondary impairments.[154] The use of foot orthoses can be helpful in improving stability and alignment for stance and gait,[102] reducing the risk of orthopedic problems. Box 18.2 provides recommendations for physical therapy for children with Down syndrome from infancy through school age.

Physical therapy intervention is often directed toward reducing the likelihood, severity, and impact of secondary impairments. Children with intellectual and motor disabilities can benefit from aerobic exercise interventions to increase cardiopulmonary fitness and endurance.[151] Strength training in children with intellectual and motor disabilities can improve functional mobility and muscular endurance.[159] Rowland and colleagues outlined strength protocols for children with Down syndrome, spina bifida, cerebral palsy, Duchenne muscular dystrophy, and autism.[159] Intervention also might focus on providing positioning equipment and supports as well as educating caregivers on the use of equipment, repositioning, and promoting alignment to help minimize pressure and positional causes of skin breakdown. The use of a standing frame has often been advocated as an intervention to help prevent osteoporosis in children with severe motor impairments. In one study a 6% increase in bone mineral density in the lumbar spine was observed with increased standing, but tibial bone density did not improve.[34] The use of a standing frame also can provide pressure relief, and standing can improve opportunities for socialization.[180] Additional information on intervention related to specific conditions and impairments is described in other chapters of this volume, including the effects of intervention on the musculoskeletal system (Chapter 5), management of spinal and orthopedic problems (Chapters 8 and 14), coordination impairment (Chapter 17), and impairments associated with cerebral palsy (Chapter 19).

Physical Therapy Interventions to Address Intellectual, Communication, and Psychosocial Limitations

If we assume that exploration and manipulation of the environment influence intellectual, communication, and social-emotional development, physical therapists play an obvious role in supporting the development of these nonmotor domains of children who have motor impairments. One means is through

intervention strategies designed to improve motor performance, as described in Chapters 3 and 4 of this volume. Intervention specific to diagnoses that are often comorbid with intellectual disabilities is described in other chapters of this volume, including cerebral palsy (Chapter 19), myelodysplasia (Chapter 23), and autism (Chapter 24). Another potentially important strategy is to provide alternative means of mobility when children's motor impairments prevent exploration of the environment at an age when other children are crawling and walking.

Use of Power Mobility to Prevent Activity Limitations

Butler[27] asserted that self-produced locomotion can have such a powerful impact on development that functional means of mobility should be provided for all young children who have mobility restrictions, regardless of whether or not the child is expected to walk eventually. More recently, physical therapists and others are advocating for use of power mobility in very young children with severely delayed locomotor milestones and limited prognosis for independent ambulation.[81,97,100,157] Aided mobility is not seen as "giving up" on walking for young children but as providing critical assistance at a time when it is needed to promote age-appropriate activity and participation.

Several reports have demonstrated that very young children can learn to use power mobility devices by 7 to 11 months of age.[10,81,100,141] Use of power mobility is associated not only with increased mobility but also with improved social skills,[65,81] increased communication,[81,82,100] increased peer interaction,[142,213] and improved cognition.[81,100] Jones, McEwen, and Neas[82] studied the effects of power wheelchairs on the development of children who were 14–30 months of age at the beginning of the study and who used power wheelchairs for 1 year. The experimental group's *Battelle Developmental Inventory*[121] receptive communication, and their *Pediatric Evaluation of Disability Inventory*[72] mobility functional skills, mobility caregiver assistance, and self-case caregiver assistance scores improved more than the control group's scores from baseline to 1 year.

Although young children in these studies were believed to have normal intelligence, other studies have demonstrated that children with intellectual disabilities also can become independent users of power mobility devices.[20,124] Certain intellectual abilities probably are necessary to achieve independent power-aided mobility, but the specific abilities that are necessary and the means to assess them have not been determined. Because typically developing children learn to crawl and become independently mobile well before their first birthday and because children have become independently mobile using power mobility devices before age 2, children with intellectual disabilities who have adequate vision and the intellectual skills typical of an 18-month-old (or perhaps younger) are likely to be capable of learning to use powered means of mobility, given appropriate equipment, instruction, and opportunities. The rate of learning, however, varies, and the factors that influence the rate of learning require further study.[82] Tefft and colleagues[182] investigated intellectual predictors associated with young children who learn to use power mobility independently after six training sessions in a clinical setting. They found spatial relations and problem-solving abilities were better among children who learned to maneuver a chair than in those who did not. Children with poorer spatial relations and problem-solving abilities may be able to learn to use power mobility, but they also may require more frequent practice opportunities in their everyday settings and may take longer to achieve mobility independence. When designing such practice opportunities, physical therapists should remember how frequently typically developing children practice and the miscues they make when learning to walk.[2]

Use of Assistive Positioning to Promote Environmental Interaction

Seating and other assistive positioning devices, as described in Chapter 33, also can influence interactions with physical and social environments through such variables as communication,[106] respiration,[96] self-care, fine motor function, and play.[148] Research suggests that positioning also can influence child communicative behaviors and opportunities for communication. After 1 month of age, infants looked at their mothers for longer periods of time when they were semireclined in supine on the couch than when held by the mother.[93] Similarly, children with profound intellectual disabilities and physical disabilities interacted with attentive teachers and classroom assistants for longer periods of time when they were in the supine position than when they were seated in wheelchairs or positioned in a sidelyer.[106] The reason for these findings is not known, although the environment might have been less distracting when children were in a supine position, or, in the case of children with disabilities who had inadequate head control, the supine position might have provided head support necessary to maintain eye contact and interact. Because a supine position may be socially isolating and physically detrimental, it should be monitored carefully and used only while the child is actively engaged in social interaction. Teachers were found to initiate interactions at higher rates when children were positioned in wheelchairs than when they were in sidelyers or supine on a mat.[106] Observations suggested that wheelchairs promoted interaction by placing students nearer the normal interaction level of adults, in contrast to being positioned on the floor.

Positioning might influence child interaction with the environment due to the impact of position on behavioral state or arousal. Low levels of arousal and behavioral states that interfere with attention to environmental stimuli are common among children with the most severe intellectual and motor disabilities.[67] Guess and colleagues[67] observed that children with multiple disabilities in upright positions demonstrated behavioral states that were more compatible with learning than when these children were placed in recumbent positions. When school-based therapists were surveyed, Taylor found that 90% of 386 respondents considered social interaction, self-esteem, and access to activities as benefits for a child utilizing a stander for upright positioning.[180] Although research concerning effects of positioning with children who have multiple disabilities is limited, it suggests that positioning may influence children's interactions with and participation within the environment through a variety of mechanisms. A systematic review of outcomes associated with adaptive seating found that although many studies linked positive effects of adapted seating on activity and participation of children with severe cerebral palsy, further investigation was needed to determine effects of adaptive seating on participation outcomes.[11]

Supporting Participation of Children with Intellectual and Motor Impairments

Many children with combined intellectual and motor disabilities will require extensive and pervasive supports as they grow up. Physical therapy services are likely to be intermittently provided across the life span and supports at all ages to mediate a child's adaptive behavior, health, context, and participation

are important to consider.[212] Services frequently are initiated in infancy or early childhood, then support the child in the school environment, and eventually transition to support the individual in community, home, and work settings.

Provision of services in the least restrictive environments also is important to consider. The concept of least restrictive environments has its roots in the US Constitution, which affirms that the government shall intrude into peoples' lives in the least restrictive manner possible.[181] Since the 1960s, this concept has been incorporated into state and federal laws affecting services for people with intellectual disabilities, mandating that, to the extent possible, people with disabilities will go to school, live, and work in environments with people who do not have disabilities.

The definition of the *least restrictive environment* for people with intellectual disabilities has been moving steadily away from segregated services and toward full inclusion in community-based settings, as evidenced by closure of many institutions for people with intellectual disabilities and court-ordered inclusion of children with intellectual disabilities in general education classrooms. In 1992 a judge of the US Court for the District of New Jersey ordered a New Jersey school district to develop a plan to include an 8-year-old boy with Down syndrome in his neighborhood elementary school, with any needed supplementary aids and services. One of the court's findings was that "school districts … must consider placing children with disabilities in regular classroom settings, with the use of supplementary aids and services … before exploring other, more restrictive, alternatives."[179] The IDEA amendments of 2004 placed additional emphasis on the need for individualized education program (IEP) teams to consider whether a child's needs could be addressed in the general education classroom with supplementary aids and services.[55] Physical therapists are involved in the team considerations and decision-making process relative to a child's educational placement. Giangreco and colleagues[63] have written a helpful "how-to" manual for inclusion of children with severe disabilities in general education classrooms that addresses provision of physical therapy and other related services. Downing and associates[46] also provided practical and creative suggestions for including children with severe disabilities in typical classrooms.

Physical therapy services can assist in improving function in children with intellectual and motor disabilities as they transition between community settings and neighborhood schools. Collaboration and communication between school-based and habilitative service providers can be a powerful relationship in facilitating enhanced functional capacity and helping to ensure consistent and successful integration within community environments, such as religious, work, recreational, and social. As an example, after identifying child and family interests, the therapist might communicate with staff at a local YMCA, a scout leader, or a church youth group. Subsequently, the physical therapist might coordinate with the YMCA staff to establish a fitness program, with community transportation to schedule appropriate transportation to scout meetings, or with the church facility manager to facilitate ease of access to the youth club room. The physical therapist might provide specific education and training to community agency personnel in transfer, access, safety, and level of participation. Child-specific instruction might include skills needed for the YMCA fitness program, getting on/off the community transport van, or mobility within the church. Documentation by the team, including the physical therapist, of progress and problems encountered will be important when evaluating the current plan of integrating the child into a specific community setting. Adjusting related procedures including community partner responsibilities, the need to consult with additional providers, frequency of physical therapy intervention, and the expected duration of services will all require consideration by all parties including the child and family, the community agency, and the physical therapist.

Teaching and Learning Considerations

Much of what physical therapists do to address activity limitations and participation restrictions involves teaching children to move more effectively and efficiently. Educational researchers have identified a number of teaching strategies that optimize the learning of students with intellectual disabilities and that might help physical therapists when designing and implementing intervention plans. Although most of these strategies were designed for educational programming, they can also be applied to motor learning. These strategies are closely related to current motor learning principles including antecedent verbal instruction and demonstration, providing feedback, allowing for error and consequences, and specificity of task in natural environment (see Chapter 4 on motor learning). Physical therapists should also communicate with other team members to identify opportunities for children to practice motor skills throughout their daily routine and should provide client and caregiver instruction so that these individuals are able to promote learning during those opportunities. Behavioral intervention is one of the areas in which physical therapists should take advantage of the expertise of other members of service delivery teams, such as teachers and psychologists. Physical therapy educational prerequisites and curricula rarely provide more than superficial information about behavioral strategies, and this limits the extent to which many physical therapists can use them effectively to promote the development of motor skills by children with intellectual disabilities.

Instruction in Natural Environments

Over 50 years ago, Mead, as cited in Dunst, et al. (2001),[48] observed that variations in natural environments and varied learning opportunities were related to differences in skill acquisition and generalization. Because students with intellectual disabilities may take a long time to learn a few things and because they have difficulty generalizing and maintaining skills, traditional curricula that build sequentially on fundamental nonfunctional skills have not generally led to meaningful gains.[46] Children are often unable to generalize such nonfunctional activities as putting pegs in pegboards, for example, to functional activities such as putting coins in a machine to get a soft drink. Practicing "prerequisite" skills, such as writing the letters of the alphabet, also often fails to result in such functional outcomes as the ability to sign one's name or select the correct restroom in a public place.

Children with severe motor impairments encounter similar difficulties when nonfunctional or presumed prerequisite skills are the focus of physical therapy. For instance, developing the skill of ascending and descending a set of therapy steps is vastly different from climbing a set of stairs at a library or other community setting due to contextual factors affecting the child's performance.[64,74] Contextual factors could include noise, visual distractions, other individuals, and inconsistencies in physical nature of stairs.[167] Little research supports generalization (carryover) of skills demonstrated during isolated physical therapy

sessions to other settings or synthesis of presumed components and prerequisites of movement into measurable functional motor activities.[76]

When an emphasis is on acquisition of specific functional skills in natural environments, generalization is unnecessary or less difficult, and skills are likely to be maintained by natural reinforcers and ongoing occasions for practice.[85] If several people work with the child on the same skills using consistent methods, learning may be enhanced by providing more opportunities to learn (repetitions) and by varying the stimulus conditions under which the skill is practiced, thus promoting generalization. Providing client and caregiver education including strategies and daily opportunities to practice during routine, typical activities is critical to promote achievement of functional skills. These principles serve as a basis for integrated models of service delivery that have been advocated for a wide range of interventionists including physical therapists.[139] Although limited research has been conducted to support the effectiveness of teaching motor skills in natural environments, research in other areas, such as life skills, language, and social interaction, has suggested that such an approach would be valuable. [74,168]

Behavioral Programming Intervention

Behavioral programming is based on the assumption that behaviors are learned through interactions with social, physical, and biologic environments; by manipulating such environments, behaviors can be taught.[19] After a review of research on the effectiveness of motor skills instruction for children with neuromotor impairments, Horn[76] concluded that physical therapists and occupational therapists should develop procedures to incorporate behavioral techniques into their intervention programs. This recommendation was made based on the relative success of interventions using behavioral techniques compared with the neuromotor and sensory stimulation techniques that occupational therapists and physical therapists commonly use. By incorporating behavioral techniques into other intervention strategies, physical therapists not only may be able to increase the rate at which children with intellectual disabilities acquire motor skills and the number of skills they acquire but also may promote generalization and maintenance of motor behaviors.

Positive reinforcement. A child is positively reinforced by a stimulus if a behavior that preceded the stimulus increases.[134] Possible reinforcing stimuli are unlimited, ranging from tangible items, such as food and toys, to social reinforcers, such as attention or descriptive praise, and activity reinforcers, such as watching a video.[163] With children who have intellectual disabilities, especially severe or profound intellectual disabilities, common reinforcers such as praise, access to activities, and food often fail to lead to increases in behaviors, and identification of reinforcers can be a challenge.[79,173] Reinforcement has not been shown to result in acquisition of behaviors not previously in the child's repertoire. A combination of reinforcement with antecedent techniques and modification of consequences has, however, resulted in new behavioral responses.[173]

Antecedent techniques. The first step in shaping a new behavior is to prompt the desired behavior or an approximation by providing instructions, models, cues, or physical prompts.[173] Instructions can take a variety of forms, such as verbal or gestural instructions (e.g., "Reach for the toy") or verbal instructions paired with models, cues, or physical prompts (e.g., "Reach for the toy," paired with facilitation of movement at the shoulder). Modeling provides a demonstration of a behavior that the child attempts to imitate. Cues direct a child's attention to a task that can result in the desired behavior, without a physical prompt. To cue the child to reach for the toy, the toy could be tapped on the table or held above the child to encourage the child to reach or to assume an erect posture or a standing position. Many of the techniques used by physical therapists provide physical prompts for motor behaviors.

For optimal learning to occur the type and amount of prompting must be matched to the skills of the child, with the least amount of help necessary being the most conducive to the child's learning.[173] Prompting should be faded as the child responds so that natural cues eventually provide the stimulus for response. A natural cue is the least intrusive prompt (e.g., the presence of a friend serving as a cue for a child to look up) and is the level of prompt required for independent behaviors. Physical prompts, often used by physical therapists, are the most intrusive.

Providing consequences. Once a behavior has been prompted, it can be improved or expanded through shaping or chaining techniques. Shaping and chaining can also be used to build new behaviors through reinforcement of behaviors that successively approximate the desired behavior.[173]

New behaviors can be shaped by reinforcing behaviors that are increasingly similar to the target behavior, such as reinforcing components of standing up from a chair, or chaining to link standing, walking, opening doors, and other behaviors necessary to accomplish a goal of walking to lunch. Backward chaining, in which the last step in the sequence is learned first, is often a useful technique because children receive the reward of task completion, often a natural reinforcer, throughout the process of learning the skill.[173]

Positive behavior support. Positive behavior support is another approach to intervention for children with developmental disabilities, including intellectual disabilities, who may lack knowledge, communication, or the social skills necessary to function effectively in their everyday environments. Lucyshyn and colleagues[99] hypothesized that children with these limitations may develop unwanted behaviors as a means of getting needs and wants met and for limiting aversive events. Positive behavior support interventions involve the use of methods to redesign children's social and attitudinal environments, and sometimes their physical environments, to enhance their ability to enjoy life with behaviors that are more acceptable to others. Intervention is aimed at replacing problem behaviors with more socially acceptable behaviors and making problem behaviors ineffective and undesirable.[33]

Positive behavior support shows promise as an intervention that encourages participation in everyday routines without limiting children's personal preferences. The interventionist begins by observing the child in the child's everyday environments to look for antecedents that may be triggering a problem behavior and identifying any environmental influences on the behavior.[33] The interventionist must work closely with family members or other primary care providers to develop hypotheses about causes of problem behaviors, learn what motivates the child, and develop a plan that is acceptable for the people in the environments in which the child spends time.[99] An effective plan redirects the child before the problem behavior occurs by adapting the task, the environment, or the demands.

Case studies have described the use of positive behavior support in a variety of everyday environments.[39,198] Vaughn and colleagues[198] utilized video task analysis of a child to identify the problem behavior and recurring antecedents, as well as the

consequences, during a family routine that produced undesirable behavior. Hypotheses were developed as to the cause and function of the undesirable behavior and the identification of appropriate positive reinforcers. Interventions were put in place employing the positive reinforcers to decrease the disruptive behavior and enhance overall engagement in the family routine. Cole and Levinson[39] found that providing choice in aspects of unpleasant tasks (such as where to stand in line) reduced occurrence of problem behaviors in two children with developmental disabilities.

Bradshaw, Mitchell, and Leaf presented results from a randomized controlled study focusing on positive behavior support programs in schools over a 5-year period that showed reductions in suspensions and discipline referrals when positive behavior programs were carried out with fidelity.[21] This research and the case studies suggest that positive behavior support has promise to assist families, teachers, and other care providers in helping children with intellectual disabilities participate more successfully in everyday routines. As members of teams, physical therapists may participate in task analysis, developing an intervention plan and using the intervention while working with children. One important aspect of positive behavior support is promoting children's communication abilities so they can express desires and needs in behaviorally acceptable ways.

Promoting Children's Communication Development

When working with children who have intellectual disabilities, all team members are responsible for promoting development in areas often not considered part of their disciplinary domains. One of the most effective ways physical therapists can contribute to the overall development of children with intellectual disabilities is to assist efforts to improve communication abilities. At its most basic level, communication enables children to influence their social and physical environments to control what happens to them. All children, even those with the most profound multiple disabilities, can communicate.[118] Communication may be both aided and unaided and can be achieved in many forms including facial expression, body language, gestures, and both electronic and nonelectronic devices (see Chapter 33). The ability of children to control their environment and their interactions is key to prevention or reduction of these children's pervasive passivity or "learned helplessness," a condition that can result in difficulty with problem solving and mastering tasks.[218] Learned helplessness occurs when the child believes he or she is unable to accomplish a given skill and therefore is unwilling to try, relying on others. Learned helplessness can be the result of repeated failures, believing others are in control, or having others manage daily needs.[147] Providing environmental supports that give children the opportunity to make choices, solve simple problems, and promote self-regulation can help limit learned helplessness and promote self-determintaion.[133]

The importance of communication and the need for all team members to participate in communication development were recognized by creation of the National Joint Committee for the Communicative Needs of Persons with Severe Disabilities. Representatives of seven organizations, including the American Physical Therapy Association, served on the original joint committee and developed guidelines that cross traditional disciplinary boundaries and reflect a "shared commitment to promoting effective communication by persons with severe disabilities, thus providing a common ground on which the disciplines of the member organizations can unite their efforts to improve the quality of life of such persons" (p 1).[118] These guidelines, as well as the Communication Bill of Rights, were recently updated and continue to provide support to professionals and teams serving individuals with severe disabilities.[22] Physical therapists are responsible for promoting effective communication, not only through such traditional means as positioning and improving motor skills to enable access to communication aids but also through provision of environments that acknowledge and address the Communication Bill of Rights (Fig. 18.2) of children who have communication disabilities.[118]

Evaluation of Outcomes

Because children and young adults with intellectual disabilities, particularly those with severe disabilities, often progress slowly, using outcome measures that are responsive to small changes is important. This is necessary not only to determine if progress is being made but also to prevent expenditure of time and effort on intervention strategies that are not leading to meaningful improvement for the child and family. Three related methods that are especially useful for assessing outcomes of physical therapy for children with intellectual disabilities are (1) accomplishment of behavioral objectives and goal attainment scaling, (2) use of the Canadian Occupational Performance Measure,[94] and (3) single-subject research methods.

Use of Behavioral Objectives and Goal Attainment Scaling

Assessment of outcomes can be relatively straightforward if functional goals and behavioral objectives leading to them are identified before intervention. As described by Randall and McEwen,[145] the components of behavioral objectives should enable therapists to monitor a child's progress toward accomplishment of a goal, determine if it is necessary to modify an intervention, and determine when and if goals have been met. Once a goal, such as "David will go to the kitchen and make himself a peanut butter sandwich," has been identified, behavioral objectives leading to achievement of the goal can be developed by comparing David's abilities with the goal's requirements. Breaking goals into behavioral objectives helps team members determine if children with intellectual disabilities, who tend to change slowly, are making progress.

Behavioral objectives have five components: (1) Who will do (2) what, (3) under what condition, (4) how well, and (5) by when.[145] These five components permit a measurable evaluation of whether the objective is being met within the projected time frame. One of David's behavioral objectives, leading to the sandwich-making goal, might be to move himself from the living room to the kitchen, which could be written, "David will walk using his reverse walker from the living room to the kitchen in less than 2 minutes on four of five consecutive days after school by December 14, 20__." Assessing whether this objective, or part of it, is accomplished, regardless of the intervention methods used, should not be difficult.

To allow detection of smaller gains, objectives can be scaled using goal attainment scaling (GAS).[188] Starting with the behavioral objective that the child is expected to achieve, four additional objectives are determined: two that exceed the behavioral objective and two that fall below it. By identifying objectives above and below a child's anticipated achievement, a range of outcomes related to a general goal can be assessed. Information on goal attainment scaling can be found in Chapter 2, Tests and Measures. Table 18.3 shows an example of GAS with David's objective.

All persons, regardless of the extent or severity of their disabilities, have a basic right to affect, through communication, the conditions of their own existence. Beyond this general right, a number of specific communication rights should be ensured in all daily interactions and interventions involving persons who have severe disabilities. These basic communication rights are as follows:

1. The right to request desired objects, actions, events, and persons and to express personal preferences or feelings.
2. The right to be offered choices and alternatives.
3. The right to reject or refuse undesired objects, events, or actions, including the right to decline or reject all proffered choices.
4. The right to request, and be given, attention from and interaction with another person.
5. The right to request feedback or information about a state, an object, a person, or an event of interest.
6. The right to active treatment and intervention efforts to enable people with severe disabilities to communicate messages in whatever modes and as effectively and efficiently as their specific abilities will allow.
7. The right to have communication acts acknowledged and responded to, even when the intent of these acts cannot be fulfilled by the responder.
8. The right to have access at all times to any needed augmentative and alternative communication devices and other assistive devices and to have those devices in good working order.
9. The right to environmental contexts, interactions, and opportunities that expect and encourage persons with disabilities to participate as full communicative partners with other people, including peers.
10. The right to be informed about the people, things, and events in one's immediate environment.
11. The right to be communicated with in a manner that recognizes and acknowledges the inherent dignity of the person being addressed, including the right to be part of communication exchanges about individuals that are conducted in his or her presence.
12. The right to be communicated with in ways that are meaningful, understandable, and culturally and linguistically appropriate.

FIG. 18.2 Communication bill of rights. (From National Joint Committee for the Communication Needs of Persons With Severe Disabilities. (1992). Guidelines for meeting the communication needs of persons with severe disabilities [Guidelines]. Available from www.asha.org/policy or www.asha.org/njc.)

TABLE 18.3 Example of Goal Attainment Scaling

GOAL ATTAINMENT SCALING[156]

5-Point Scale based on the performance of the objective

OBJECTIVE: David will walk using his reverse walker from the living room to the kitchen in less than 2 minutes on four of five consecutive days after school by December 14, 20__.

Score	Objective
−2 Much less than expected	David will walk from the dining room to the kitchen in more than 3 minutes on four of five consecutive days after school by December 14, 20__.
−1 Somewhat less than expected	David will walk from the dining room to the kitchen in less than 3 minutes on four of five consecutive days after school by December 14, 20__.
0 Expected level of outcome	David will walk using his reverse walker from the living room to the kitchen in less than 2 minutes on four of five consecutive days after school by December 14, 20__.
+1 Somewhat more than expected	David will walk using his reverse walker from the living room to the kitchen in less than 1 minute on four of five consecutive days after school by December 14, 20__.
+2 Much more than expected	David will walk using his reverse walker from the living room to the kitchen in less than 30 seconds on four of five consecutive days after school by December 14, 20__.

Canadian Occupational Performance Measure

The COPM[94] was designed to help identify and measure individually meaningful goals for people in the areas of self-care, productivity (work, household management, and play/school), and leisure. More information on the COPM can be found in Chapter 2, Tests and Measures. In children with intellectual and motor impairments, gains in participation are often incremental and include partial completion of a task. The COPM can capture small changes in performance and resulting satisfaction of the child or family. As an example, a teen might identify participation in the cheer and pep squad as an important and meaningful goal. Rather than the ability to remember and perform intricate cheerleading maneuvers, meaningful participation gains and increased satisfaction might include the ability to sit with the pep squad in the bleachers, maintaining balance while using pom-poms. The COPM can measure the difference between how the teen perceives involvement in cheering on examination compared to the perception of participation following physical therapy intervention aimed at sitting on the bleachers, whether through improved sitting balance, if achievable, or with the use of adapted equipment.

Single-Subject Research Methods

Single-subject research methods are another useful means of assessing intervention outcomes in clinical, educational, and other service settings. These methods can be used to assess the outcomes for a single child or can assess effects of intervention across several children. Unlike case reports, single-subject research designs have controls that allow identification of cause–effect relationships among interventions and outcomes.[107] Several types of single-subject designs exist, including A-B, withdrawal, alternating treatment, and multiple baseline.[140]

Many examples of single-subject research exist in rehabilitation literature.[59,186,187] Meiser and McEwen,[111] for example, used an A-B-A single-subject design to compare the effect of ultralight and lightweight wheelchairs on the preference and propulsion of two young girls with myelodysplasia. Nearly all of the measured propulsion variables, including speed, distance, and effort, favored the ultralight wheelchairs, and the children and their mothers preferred them. A physical therapist in the home setting could use a similar design when choosing specialized equipment for the child at home. Likewise, school-based therapists could use a single-subject design to measure the impact of using a stander or gait trainer on the participation and social interaction of a child within the classroom. Textbooks and research articles are good resources for anyone interested in using single-subject research methods to measure outcomes of intervention. An excellent reference on single-subject methods is found in the text by Portney and Watkins.[140]

TRANSITION TO ADULTHOOD

Some people with intellectual disabilities, especially those with severe and profound multiple disabilities, may receive physical therapy, as a related service within special education, throughout their childhood years and during their transition to adulthood. Others will receive short episodes of physical therapy services as their abilities and needs change over time. The types of services provided, the intensity of services, and the model of service delivery should be individualized to the needs of the person. Therapists working in public schools are especially likely to be involved in the transition to adulthood because Part B of IDEA (2004) requires that transition planning begin by at least age 16 for all students with disabilities.[55] Transition services for students who have IEPs must promote movement from high school to meaningful community living, postsecondary education, training, and employment. The role of physical therapists, along with other IEP and interagency team members, should be to enable students to function meaningfully and as independently as possible in their current and possible future environments. See Chapter 32 in this volume for more information on postsecondary transition planning.

The transition to adulthood is difficult for many young people, regardless of their abilities or disabilities. Until recently, most young adults with intellectual and neuromotor impairments had few options available to them, and the greater their intellectual disabilities, the fewer options they had. Historically, employment options did not exist or were limited to sheltered workshops or activity centers. Although the decade between 2000 and 2010 revealed positive trends for young adults with disabilities for postsecondary employment, education, and independent living, students with intellectual and developmental disabilities were not expected to attend college and fewer than 10% achieved competitive employment.[123] Residential options usually included staying at home with aging parents or moving into a large residential facility, and few adults with intellectual and developmental disabilities expressed the desire or ability to live independently.[28,123] Young people also had few choices about how they spent their time, with whom they spent time, or where they could go. Thirty-five percent of youth with multiple disabilities reported no community engagement at all.[122]

In recent years, more employment and community life options have become available for people with severe intellectual disabilities, including those with the most severe multiple disabilities. To be able to take full advantage of these options, young people need to prepare for transition to adult life throughout their years in school and then should continue to receive support as the transition takes place and the new life begins. Physical therapy supports often can make a difference in the options available to young people with both intellectual and motor disabilities as they pursue successful transitions to adult life. Self-determination is often key to students' achieving their desired employment, educational, or adult living outcomes.

Self-Determination

Youth with disabilities often have difficulty achieving goals that their peers without disabilities achieve relatively easily, such as independent living, higher education, and employment. People with disabilities should have the same promise of self-determination as all people. Self-determination is defined by the Arc as having "opportunities, respectful support, and the authority to exert control in their lives, to self-direct their services to the extent they choose, and to advocate on their own behalf."[183] The Arc position statement is found in Box 18.3. Wehmeyer defined self-determination as "volitional actions that enable a person to improve their quality of life by acting with their own volitional intent."[206] Teaching and supporting self-determination have been found to improve school, employment, and community adult outcomes for youth with disabilities, including youth with intellectual disabilities.[204,207,211]

Self-determined people demonstrate four essential elements: autonomous behavior, self-regulated behavior, initiation and response to events, and self-realizing behavior.[206] These elements compose the *Self-Determined Learning Model of Instruction,*[205] which is a useful resource that has been validated in a variety of educational and employment settings.[103]

People exhibit self-determination by making everyday decisions and life decisions for themselves.[209] In a review of the self-determination literature, Malian and Nevin[101] found six curricula for teaching self-determination skills that have been field tested. Overall, the studies suggested that direct instruction in self-determination skills can lead to positive changes in the knowledge, attitudes, and behaviors associated with self-determination. Wehmeyer and Schwartz[210] examined the relationship between scores on a self-determination rating scale and outcomes of youth with intellectual or learning disabilities 1 year after leaving school. In their sample of 80 participants, students with higher scores on a self-determination rating scale were more likely to be employed and earn more per hour than students who achieved lower scores on the scale.

Wehmeyer and Bolding[208,209] also studied the relationship between environment and self-determination. In one study, they matched adults by intelligence, age, and gender to examine the relationship between living and working environments and self-determination. They found that those living or working in general community-based settings reported greater self-determination and autonomous function than matched peers living or working in segregated community-based settings or non–community-based segregated settings. This study suggested that environments and, in particular, inclusive community environments were important for greater self-determination and autonomy for people with intellectual disabilities. Wehmeyer and Bolding[209] also studied change in self-determination with changes in work or living environments. When 31 people moved from a restrictive environment (such as a nursing

BOX 18.3 The Arc Position Statement on Self-Determination

People with intellectual and/or developmental disabilities (I/DD)[a] have the same right to, and responsibilities that accompany, self-determination as everyone else. They must have opportunities, respectful support, and the authority to exert control in their lives, to self-direct their services to the extent they choose, and to advocate on their own behalf.

Issue

Many individuals with intellectual and/or developmental disabilities have not had the opportunity or the support to make choices and decisions about important aspects of their lives. Instead, they are often overprotected and involuntarily segregated, with others making decisions about key elements of their lives. Many individuals with I/DD have not had the experiences that would enable them to learn decision-making skills, take more personal control in their lives, and make choices. The lack of such learning opportunities has impeded people with I/DD from becoming participating, valued, and respected members of their communities, living lives of their own choosing.

Position

People with intellectual and/or developmental disabilities have the same right to self-determination as all people and must have the freedom, authority, and support to exercise control over their lives. To this end, they must:

In their personal lives have:

- opportunities to advocate for themselves with the assurance that their desires, interests, and preferences will be respected and honored.
- opportunities to acquire and use skills and knowledge which better enable them to exercise choice.
- the right to take risks.
- the right to choose their own allies.
- the lead in decision-making about all aspects of their lives.
- the option to self-direct their own supports and services and allocate available resources.
- the choice and support necessary to hire, train, manage, and fire their own staff.

In their community lives have:

- the right to receive the necessary support and assistance to vote.
- opportunities to be supported to become active, valued members and leaders of community boards, advisory councils, and other organizations.
- opportunities to take leadership roles in setting the policy direction for the self-determination movement.
- the right to representation and meaningful involvement in policy-making at the federal, state, and local levels.

Adopted: Congress of Delegates, The Arc of the United States, 2011

[a]"People with intellectual and/or developmental disabilities" refers to those defined by AAIDD classification and DSM IV. In everyday language they are frequently referred to as people with cognitive, intellectual, and/or developmental disabilities although the professional and legal definitions of those terms both include others and exclude some defined by DSM IV.

From the Arc Position Statement on Self-Determination. Retrieved June 15, 2015 from http://www.thearc.org/who-we-are/position-statements/rights/self-determination.

home or sheltered workshop) to a less restrictive environment, self-determination increased when compared with premove test scores.

Physical therapists can help children with intellectual disabilities recognize what is important to them in their daily lives.[9] Providing physical therapy under this construct is best accomplished through a team approach that identifies priorities for the child and family and considers the environments in which the child does or will spend time. Self-determination is something that does not start in adolescence. It needs to begin early, with young children being offered opportunities to make choices in any way they are able to indicate preferences. Older children should be expected to be responsible for their choices, and young adults should be expected to thoughtfully decide what is best for them, and then others should support their choices.

Employment

Employment for individuals with intellectual and motor disabilities should include paid employment, including supported employment or self-employment, in integrated community settings.[184] Employment options in the United States for people with intellectual disabilities and multiple disabilities have expanded over the past several years, particularly in some parts of the country. This improvement was reflected in a 2013 report by the US Bureau of Labor Statistics,[193] which showed unemployment of people with intellectual and developmental disabilities (IDD) dropped from 15% in 2011 to 13% and the number of employed people with IDD rose from 4.9 million in 2011 to 5.1 million in 2013. Yet only 1 in 10 youth with developmental disabilities worked in integrated settings, and 5 in 10 were waiting for adult employment supports.[28,161,214]

Many places still primarily offer sheltered workshop and activity center alternatives, even as a first option out of high school,[28,114,161,214] but progress is being made nationwide as federal, state, and other public and private initiatives support development and expansion of employment opportunities for people with disabilities.[123] The Association of Supported Employment (APSE) supports *Employment First,* a concept that aims to facilitate full inclusion of people with the most significant disabilities into competitive work.[12] *Employment First* presumes that all people, regardless of disability, should have the opportunity to participate in community-based, competitive, integrated employment, with the appropriate supports in place, as a first and preferred employment option.

The Developmental Disabilities Act (2000)[184] described supported employment services as those that enable individuals with developmental disabilities to perform competitive work in integrated work settings when competitive employment has not traditionally occurred; when competitive employment has been interrupted or intermittent as a result of significant disability; or when intensive or extended supports are needed in order for a person to perform competitive work. Supported employment has helped to increase employment options for many people who have severe disabilities. Rather than working on prerequisite or prevocational skills in sheltered settings until they are "ready" for a job, people in supported employment learn real job skills, in competitive employment settings, with ongoing support from team members to learn and maintain the job.[56] The US Department of Health and Human Services described and verified supported employment as an evidence-based approach to enabling individuals with disabilities to achieve gainful employment.[192]

Even though supported employment received significant support from the Vocational Rehabilitation Act Amendments of 1986 (PL 99-506), which authorized new funds for states to provide supported employment services to people with severe disabilities, as yet few communities offer a supported employment alternative to sheltered workshops and day activity centers for those with the most severe disabilities. In 2000, Cimera reviewed 21 studies that investigated the economic value of supported employment. These studies overall continued to suggest that supported employment programs were cost effective from the perspective of the worker and the taxpayer. His review also found that supported employment was cost efficient for all individuals with disabilities, but those with more severe disabilities were less cost efficient than their peers with milder disabilities.[36]

Physical therapists can play a pivotal role in the successful employment of individuals who have both intellectual disabilities and limited motor skills. Physical therapists can assist employment specialists to assess an individual's abilities to perform job-related motor skills and to identify jobs that are compatible with those skills. They can also identify assistive technology and environmental modifications that may enable the person to perform a job that might not be possible otherwise. Physical therapists can include vocational planning assessment tools in their repertoire of skills and can also help develop training for job-related motor skills and for self-care and mobility during working hours.

SUMMARY

Regardless of their medical diagnoses, children with intellectual disabilities have learning characteristics that physical therapists need to consider for effective physical therapy management. Compared with typically developing children, children with intellectual disabilities have been shown, for example, to be able to learn fewer things, to need more repetitions for learning to occur, to have greater difficulty generalizing skills from one environment to another, to have greater difficulty maintaining skills that are not practiced regularly, to have slower response times, and to have a more limited repertoire of responses. Physical therapy intervention strategies that address these learning characteristics, which include motor learning principles, and that promote communication, inclusion, and self-determination can have an important role in the meaningful outcomes and participation of people with intellectual and motor disabilities. Although children with intellectual and motor impairments will likely need considerable support across their life spans, physical therapy services can often help expand the options for children and families, ease the child's transition into and participation in the community, and promote independence across environments in which people choose to live and work.

Case Scenario on Expert Consult

The case scenario related to this chapter illustrates assessment measures and modifications used to assess and establish a physical therapy plan of care for a child with an intellectual and motor impairment. Family concerns and participation in both assessment and intervention planning are included. A video of a portion of the assessment accompanies the case.

Cerebral Palsy

Marilyn Wright, Robert J. Palisano

Physical therapists have an important role in the specialized interdisciplinary services to help children with cerebral palsy (CP) reach their full potential in their home, educational, and community environments. Children with cerebral palsy vary considerably not only in the nature of the movement disorder but also in their motor, communication, and cognitive abilities. Although the neurologic disturbance is static, there is risk of secondary musculoskeletal and neuromuscular impairments and environmental considerations change with age. As a consequence, goal setting and decisions on interventions are often complicated. This chapter provides background information on the etiology, diagnosis, prognosis, and characteristics of the movement disorders in children with CP, using the framework of the International Classification of Functioning Disability and Health. The Foreground Information section presents a framework for family–therapist collaboration for goal setting and intervention planning to achieve desired outcomes for activity and participation. Evidence-informed decision making is modeled. Comprehensive management is addressed during infancy, childhood, and adolescence. Topics include (1) communication and coordination with the child, family, health professionals, and educators; (2) the examination and evaluation process, including selecting tests and measures; (3) evidence-based interventions; and (4) supporting the child and family to engage in desired home and community activities. Physical therapists have great potential to influence the immediate and future lives of children with CP and their families.

BACKGROUND INFORMATION

"Cerebral palsy describes a group of permanent disorders of the development of movement and posture, causing activity limitations that are attributed to non-progressive disturbances that occurred in the developing fetal or infant brain" (p 9).[313] Although the brain lesion is static, secondary musculoskeletal impairments such as muscle/tendon contractures, bony torsion, hip displacement, and spinal deformity often contribute to activity limitations.[201,313] Factors that contribute to secondary impairments include physical growth, muscle spasticity and weakness, and the cumulative effect of biomechanical forces though joints.[313]

Motor impairments associated with CP are often accompanied by disturbances of cognition, behavior, communication, sensation, epilepsy, and perception.[313] Cognitive delays (IQ < 70) are present in 23% to 44% of children with CP, and behavioral issues have been recognized in 25%—a rate five times greater than that typically seen in children. The prevalence of impaired speech (42%–81%), hearing (25%), and vision (62%–71%); seizure disorders (22%–40%); urinary incontinence (23%); and constipation (59%) is increased. Tactile sensory impairments, including problems with stereognosis, proprioception, and two-point discrimination, have been reported in 44% to 51% of children with CP. Visual-spatial and visual-perceptual problems are common—90% and 60%, respectively.[298] Rates of coexisting impairments vary with different subtypes. Children with more significant motor problems experience proportionately higher rates of associated impairments. The degrees of physical and cognitive disability are also related to lifetime costs.[203] Health care, social care, and productivity costs of people with CP contribute to significant societal financial burden.

CP is the most common childhood motor disability with a prevalence of 2 to 2.5 per 1000 live births. Oskoui et al.[272] performed a meta-analysis of 49 studies and reported an overall prevalence of 2.1 per 1000 live births. Prevalence was highest among children born before 28 weeks gestation (111.8 per 1000 live births) and children with a birth weight of 1000 to 1499 grams (59.2 per 1000 live births). Although the prevalence of CP is highest among children born preterm, they account for only 35% of children with CP. Life expectancy is associated with severity of motor, cognitive, and visual impairment. A 2-year-old with severe impairments has approximately a 40% chance of living to age 20, in contrast to a child with mild impairments, for whom the chance is 99%.[174] A decline in mortality of children with severe impairments has been noted since the 1990s, particularly for those with feeding problems, reflecting better management of feeding and swallowing difficulties and overall improvement in the care of medically fragile persons. People with CP have an increased incidence of mortality due to external causes such as drowning and being struck by motor vehicles.[348,349]

ETIOLOGY

There are multiple causes of CP, many of which are not fully understood. The exact cause for individual children is often not known. Originally CP was largely attributed to acute hypoxia during labor or birth; however, current evidence indicates that most lesions occur in the second half of gestation, an active period of brain development.[149]

Intrauterine pathology is attributed to environmental triggers such as bacterial and viral intrauterine infection, intrauterine growth restriction, antepartum hemorrhage, and tight nuchal cord, factors that are difficult to determine in retrospect.[228]

Evidence of genetic causes is emerging and may increase as technology improves.[228]

Advances in magnetic resonance imaging (MRI) have furthered understanding of the causes and timing of the pathogenesis of CP through visualization of physiologic and pathologic morphologic changes that occur during brain development.[200,201,261] The pathobiology of CP differs by nature, timing, and location of the brain insult.[201,261,262,321] Recognition of the impact of prenatal factors is increasing. Many perinatal complications occur secondary to preexisting central nervous system pathology. During the first and second trimesters of gestation, brain pathology is characterized by genetic or acquired impairments. From the late second trimester onward, disturbances are more often a result of infectious or hypoxic-ischemic mechanisms that result in lesions.[201] In infants born at term, CP most often results from prenatal influences.

Current evidence suggests that a multiplicity of risk factors contribute to CP rather than a single event. Single events such as uterine rupture, cord prolapse, or major placental abruption resulting in hypoxic insults to the brain account for a small proportion of cases.[261] Although birth asphyxia can result in CP, it is not a common antecedent. When it is the cause, hypoxic damage is typically bilateral and widespread, including the basal ganglia and gray and white matter, resulting in total body involvement with spastic and dyskinetic features. Additional factors such as inflammation can interact with asphyxia, multiplying the risk of CP.[261]

It has become increasingly clear that cerebral vascular events occurring within the first 28 days after birth are a significant cause of CP. The advent of neuroimaging has contributed significantly to further understanding in this area because neonates with strokes do not present clinically with hemiparesis. In contrast to the adult population, approximately one third of perinatal strokes are bilateral. Placental pathology such as thrombotic lesions may be an important factor.[261,262]

Infections such as toxoplasmosis, rubella, cytomegalovirus, herpes virus, hepatitis B, syphilis, human immunodeficiency virus, and streptococcus B can be transmitted from mother to infant, affecting the brain and resulting in CP. Placental inflammation (chorioamnionitis) has also been linked with adverse neurologic outcomes.[261,262] Children with CP have more congenital abnormalities, such as brain malformation, cleft lip or palate, and gut atresia, compared with children who do not have CP. This suggests further the significant contribution of prenatal factors to the origin of CP.[321] Maternal trauma resulting in direct fetal injury, placental abruption, or prenatal vascular insult can also cause CP. Possible mechanisms include reduced placental blood flow or placental embolization.[164] Maternal thyroid disease has been linked with cerebral palsy.[169]

Premature birth increases the risk of CP. In such cases, the underlying brain pathology is white matter injury in sensorimotor pathways. Prolonged rupture of the membranes predisposing to intrauterine infection is an important antecedent. Multiple gestation practices, increasingly common as a result of reproductive technology, can contribute to the risk for CP as a result of the tendency for premature birth or the death of a monozygotic fetus, causing malformation in a surviving infant due to vascular collapse.[261,262] The potentially complex medical course, including the use of postnatal steroids, adds to the risk of events that can disrupt development of the brain.

Infants with atypical intrauterine growth, either small or large for gestational age, are at increased risk for CP. Small birth weight can be associated with infection, preeclampsia, maternal vascular disease, or thrombophilia. Large babies may experience problematic deliveries. Maternal diabetes is a risk factor for macrosomia, but it is not a risk factor for CP. Excessively small or large babies are also at greater risk for perinatal stroke.[261]

Genetic factors can influence the risk of CP at a number of points along the causal pathway. Risk factors with a genetic component include preterm birth, placental abruption, preeclampsia, chorioamnionitis, and thrombophilias or the presence of certain genotypes such as apolipoprotein E.[206] Future research examining gene–gene and gene–environment interactions may provide important information.[261,262] A form of hereditary spastic paresis has also been identified.[96]

Reported rates of various brain pathologies vary. A study of a cohort of 154 children diagnosed with CP for whom MRI was available indicated the following proportions of brain scan findings: 16% normal, 31% periventricular white matter injury, 16% focal ischemic/hemorrhagic lesions, 14% diffuse encephalopathy, 12% brain malformations, 2% infections, and 8% unclassifiable.[304] Sixty-six percent of the children were born at term. Children with brain malformations were more likely to have been born at term and had more severe motor disabilities than other children with a CP diagnosis.

PROGRESS IN PREVENTION

Despite advances in neonatology and obstetrics, the prevalence of CP has not changed. Interventions such as cesarean section, earlier emergency delivery, and continuous electronic fetal monitoring during labor do not appear to address the cause of the brain disturbance for most children with CP. There is evidence of the effectiveness of antenatal magnesium sulphate therapy as a neuroprotective factor in women likely to give birth at less than 37 weeks' gestational age and therapeutic induced hypothermia (brain cooling). A Cochrane review[77] analyzed 37 randomized controlled trials involving 3571 women to determine the effect of antenatal magnesium sulphate therapy in women likely to give birth at less than 37 weeks' gestational age. The conclusion is that magnesium sulphate does not significantly delay birth or prevent preterm birth and has no apparent advantages for a range of neonatal and maternal outcomes. Antenatal magnesium sulphate, however, is effective in helping women who develop preeclampsia (high blood pressure and protein in the urine) and for helping to protect babies' brains. A Cochrane review[178] of 11 randomized controlled trials involving 1505 infants compared therapeutic hypothermia with standard care in term or late preterm infants with peripartum hypoxic ischemic encephalopathy. The conclusion is that therapeutic hypothermia initiated within 6 hours after birth for 48 to 72 hours reduces the combined outcome of mortality or major neurodevelopmental disability at 18 months of age. Nanomaterials such as dendrimers have been proposed as a means for targeted drug and gene delivery to cells responsible for neuroinflammation and injury.[14] Preclinical studies using several types of stem and adult cells have demonstrated some regenerative capacity; however, there are gaps in knowledge of the optimal source and type of cells, timing of treatment, and possible mechanisms of action.[113]

A social class gradient has been noted in the prevalence of CP, along with an association between birth weight and socioeconomic status, suggesting that improvements in the education, health, and prenatal care of mothers at risk could improve outcomes. Avoidance of multiple fetus implantations during in vitro fertilization could decrease the incidence of CP due to multiple births.[262]

DIAGNOSIS

Neuroimaging findings and prenatal risk factors can assist in making a diagnosis of CP, but the sensitivity and specificity of single or combined risk factors, such as neonatal seizures, low birth weight, or maternal infection, in predicting CP have been disappointing.[287] As a result, CP remains a clinical diagnosis made when a child does not reach early motor milestones and exhibits abnormal muscle tone or qualitative differences in movement patterns.[309,310] Physical therapists can play an important role in the diagnosis of CP through their involvement in clinics for high-risk infants and early therapy intervention programs.[158] Assessment of asymmetry, involuntary movements, abnormal primitive reflexes, and the late development of postural responses can contribute to the clinical diagnosis.

Research on the General Movement Assessment suggests that the pathologic movement qualities characteristic of cerebral palsy can be reliably identified in the first few months of life with a sensitivity of 95% and specificity of 96%.[56,152] Prechtl and colleagues developed an assessment of general movement that characterizes the movement pattern in cerebral palsy as being one of "cramped synchrony," with a paucity of selective joint movements, especially in the rotational components.[55] Their work has also demonstrated that clinical examination of children with known signs of brain pathophysiologic impairment can identify the effects of such lesions on movement. These effects can then be qualitatively and quantitatively described longitudinally and used to predict recovery or nonrecovery from early disturbances in the neuromuscular system.

Predictive and discriminative infant neuromotor tests can augment clinical judgment to assist in prediction and identification of CP, respectively. The Alberta Infant Motor Scales (AIMS) assessment demonstrates good psychometric properties, especially between corrected ages 4 and 10 months, and has clinical utility in comparing an infant's development with that of other infants of the same age.[56] The Test of Infant Motor Performance (TIMP) and the NeuroSensory Motor Developmental Assessment (NSMDA) can be used before as well as after term.[57,70] Prechtl's Assessment of General Movements (GM) has the best combination of sensitivity and specificity for predicting CP in the early months, but the AIMS and the NSMDA are better predictors when the infants are older.[342]

Precise diagnosis can be difficult, especially early in development. No consensus has been reached on how early CP can be identified reliably,[56] although it has been postulated that an experienced physical therapist or pediatrician should be able to identify the signs of CP in all but the mildest cases by 6 months of age.[329] Nevertheless, variation in motor development must be considered and respected and a definitive diagnosis made cautiously in consideration of alternate explanations, while not withholding appropriate services.[59,310] It is important to differentiate between atypical motor trajectories that indicate CP and other situations such as recovery from early medical complications, including those associated with premature birth. For example, AIMS norms adjusted for gestational age at birth reflect variation in the gross motor trajectories of infants born preterm.[368] Physical therapists may also play a role in recognizing alternative diagnoses. Transient dystonia presents with similar but resolving neurologic signs of CP.[100,158,310,368]

Diagnosis should be confirmed by a pediatric physician specialist to rule out other causes of similar clinical signs such as brain tumors or metabolic disorders. Follow-up is necessary to ensure a nonprogressive nature. It is recommended that all children with CP have a brain MRI in cases of unknown origin. Metabolic workups should be considered in children who appear to have CP but have normal brain imaging, because genetic muscle disorders and mitochondrial disease may present similarly to CP.[200,304] Prenatal, perinatal, and postnatal medical complications that increase risk for cerebral palsy are addressed in Should state "Chapter 29, The Neonatal Intensive Care Unit".

CLASSIFICATION OF FUNCTIONAL ABILITIES

Children with CP demonstrate considerable variation in functional abilities. Four five-level classification systems have been validated for classifying gross motor function, manual ability, communication function, and eating and drinking ability of children and youth with cerebral palsy through age 18 years. Each system is based on the perspective that classification of children with CP on functional abilities and limitations should enhance communication among professionals and families with respect to (1) goal setting and intervention planning, (2) efficient utilization of medical and rehabilitation services, (3) assistive technology, and (4) comparing and generalizing research. The terms *functional related groups, severity of disability, case-mix complexity,* and *risk adjustment* refer to methods of grouping patients with the same diagnosis into subgroups for evaluating internal quality standards and comparative analysis of intervention outcomes. Because classification levels are based on performance in daily life, collaboration between parents, children/youth, and professionals is recommended to classify a child's levels of function. All four classification systems are available at no cost and have been translated into several languages. Collectively they provide an overview of a child's current functional abilities. It is important to recognize that the classification systems are *not* outcome measures and the goal of intervention *should not* be change in the child's classification level.

The *Gross Motor Function Classification System* (GMFCS) [281, 282] is available on the CanChild Centre website (www.canchild.ca).[58] Videos of young and older children functioning at each of the GMFCS levels are included on Expert Consult. The GMFCS was developed for children with cerebral palsy who are 12 years of age and younger and subsequently expanded to include a 12- to 18-year age band and revised to include environmental and personal considerations for the 6- to 12-year and 12- to 18-year bands. A summary of the descriptions for the 6- to 12-year age band is presented in Fig. 19.1. A classification is made by determining which of the five levels best represents the child's current abilities and limitations in gross motor function in home, school, and community settings. Classification is based on the child's self-initiated movement with emphasis on sitting and walking. The description for each level is broad and not intended to describe all aspects of the motor function of individual children. For each level, separate descriptions are

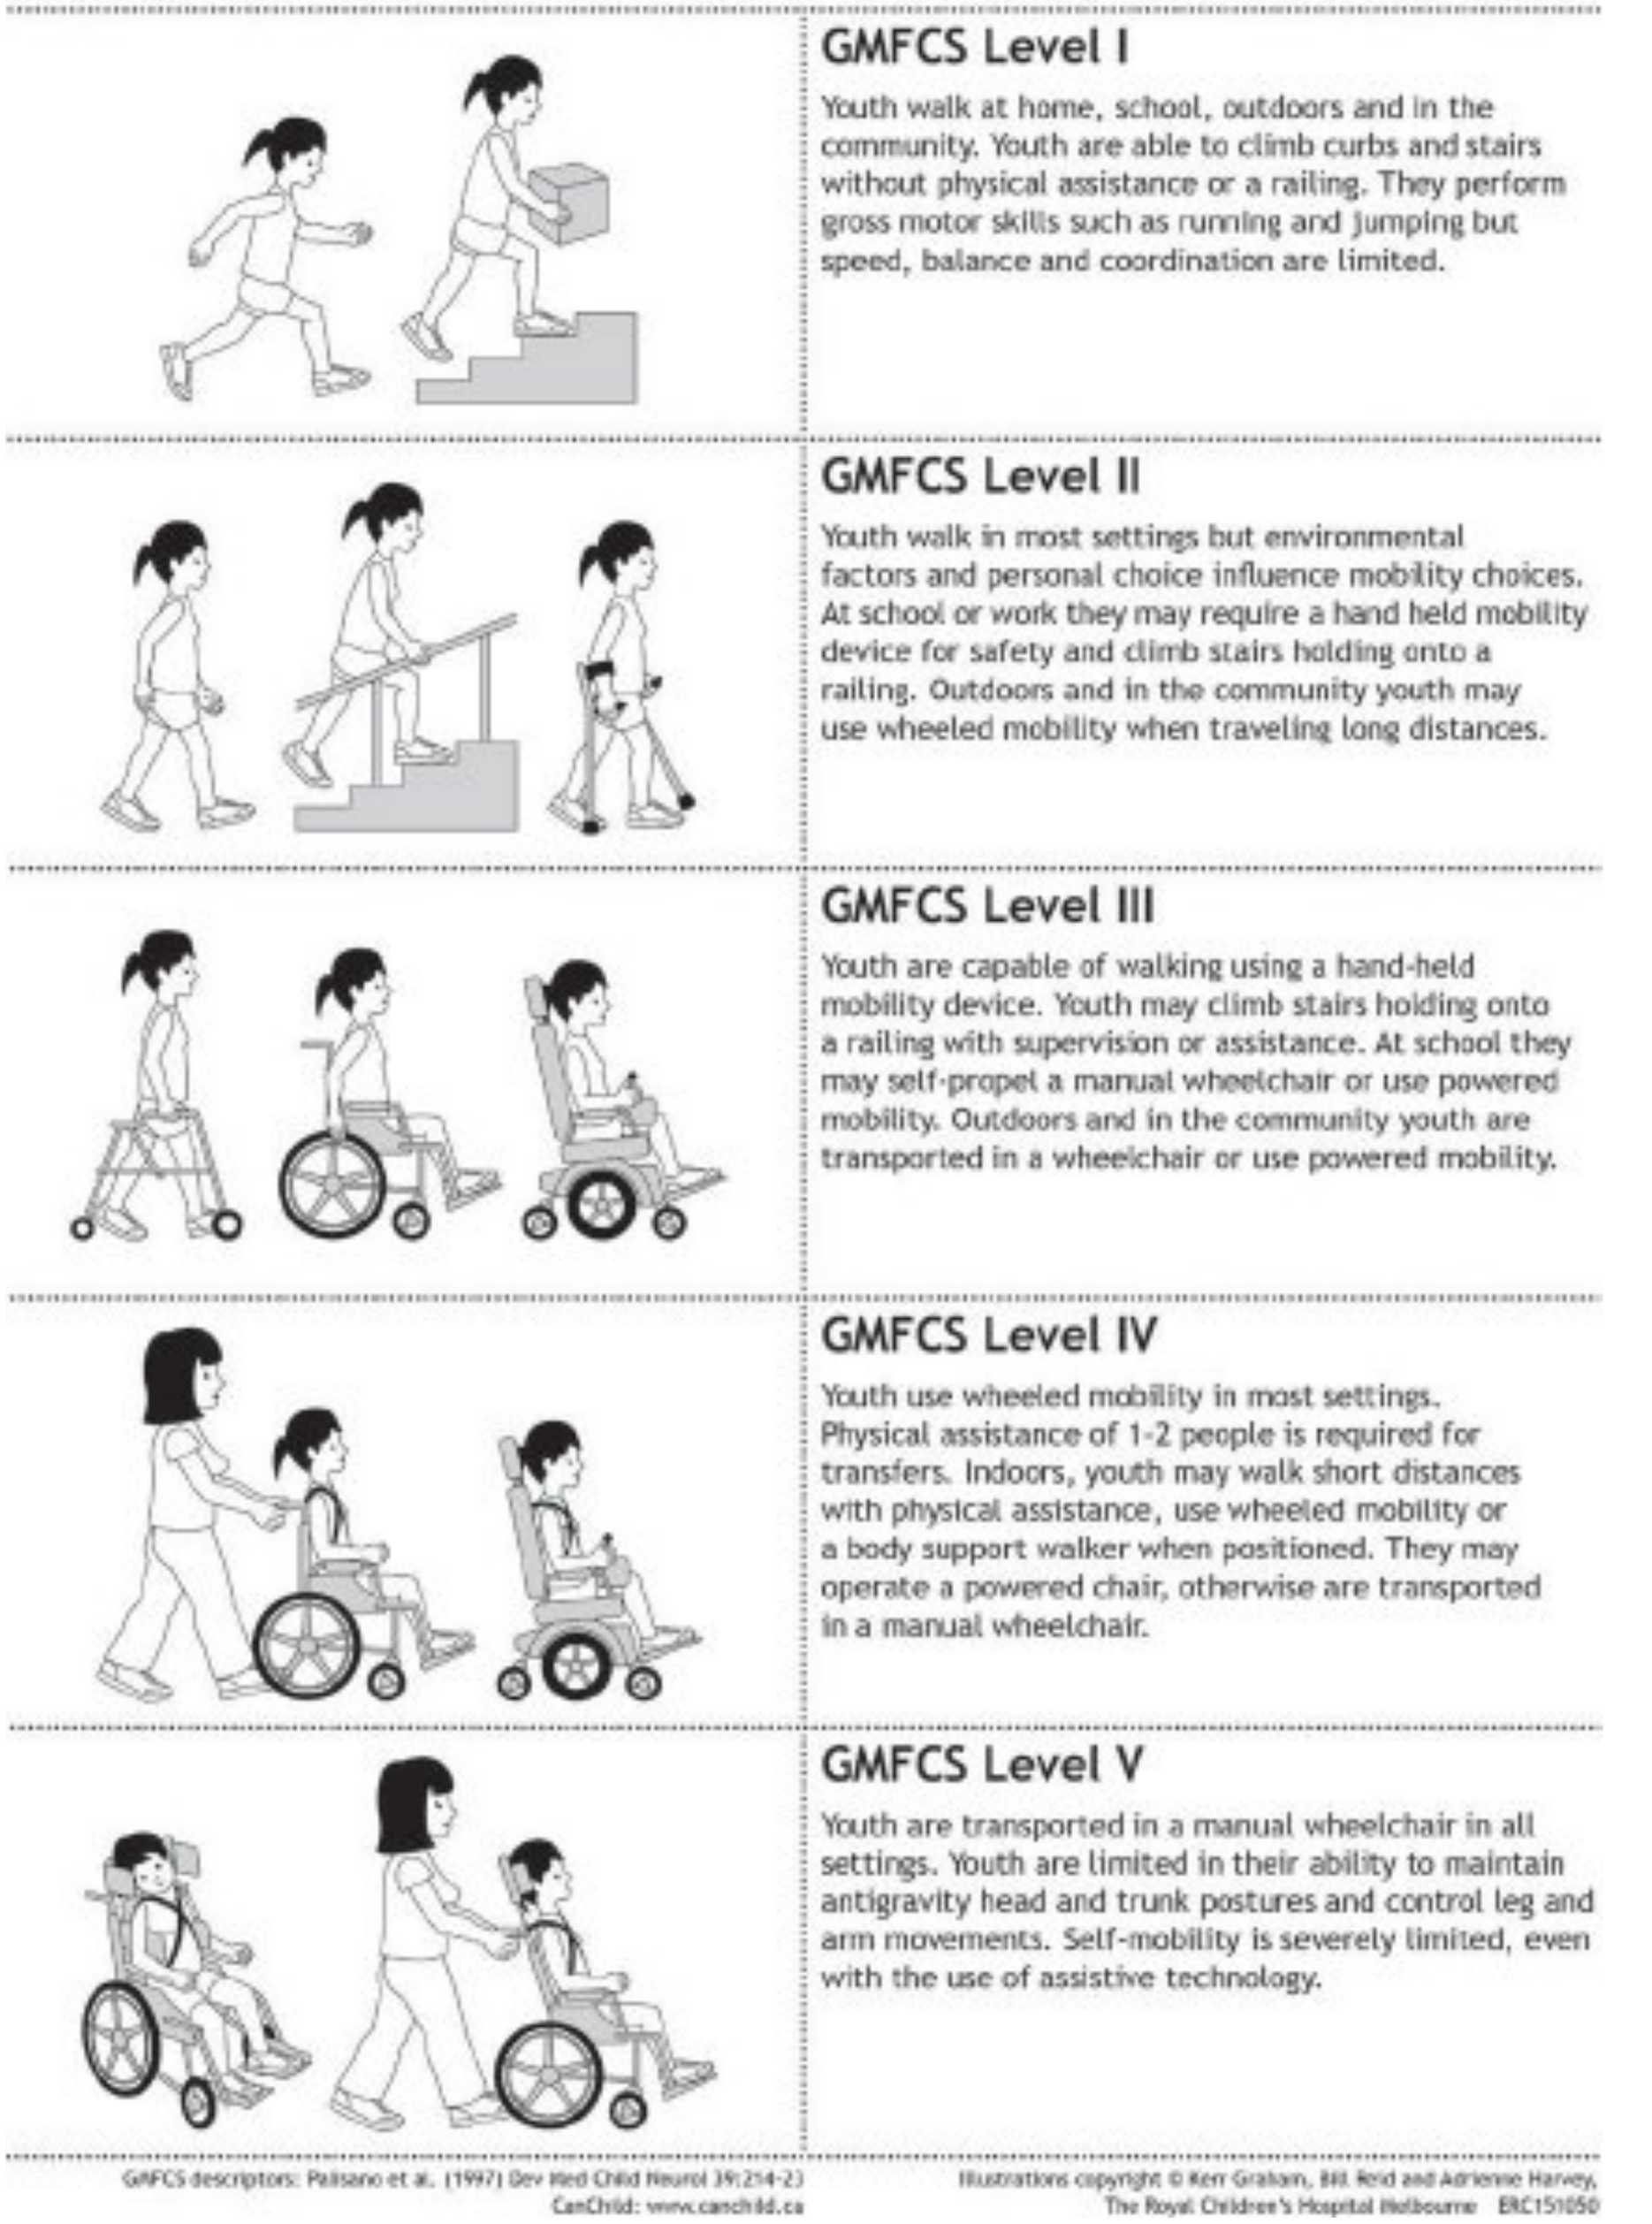

FIG. 19.1 The Gross Motor Function Classification System–Expanded and Revised for children ages 12 to 18 years of age. (CanChild Centre for Childhood Disability Research.)

provided for children in the following age bands: less than 2 years, 2 to 4 years, 4 to 6 years, and 6 to 12 years. Distinctions among levels of gross motor function are based on functional limitations, the need for handheld assistive mobility devices (walkers, crutches, canes), wheeled mobility, and, to a lesser extent, quality of movement. The scale is ordinal with no intent that the distances between levels be considered equal or that children with cerebral palsy are equally distributed among the five levels. Parents can apply the GMFCS reliably to their own children's functional status[127] and value being able to understand their child's level of function and what that means in terms of understanding future needs. Evidence of interrater reliability, stability, content, construct, and predictive validity has been reported.[239,281,282,286] Gorter et al.[141] found that classification of infants younger than 2 years of age is less precise than classification of older children and recommended reclassification at age 2 or older as more clinical information becomes available.

The *Manual Ability Classification System* (MACS)[109] is a five-level system to classify hand use of children with cerebral palsy, 4 to 18 years of age (www.macs.nu). Classification is based on the child's typical performance in handling objects during daily activities. Distinctions among the levels are based on the child's ability to handle objects and the amount of assistance or adaptation the child needs to complete tasks of daily living. Reliability and validity of the MACS have been demonstrated.[109,296] The authors of the MACS are in process of adapting and validating the MACS for children with CP below 4 years of age (Mini-MACS).

The *Communication Function Classification System* (CFCS)[167] is a five-level system to classify usual communication function of individuals with cerebral palsy (www.cfcs.us). A classification is based on everyday performance for all methods of communicating, including speech, gestures, eye gaze, facial expressions, and augmentative and alternative communication. Distinctions among the levels are based on the performance of sender and receiver roles, the pace of communication, and the type of conversational partner.

The *Eating and Drinking Abilities Classification System*[334] combines a five-level ordinal scale that describes the eating and drinking ability of people with CP, ages 3 to adulthood, and a three-level ordinal scale describing assistance required in bringing food and drink to mouth (www.EDACS.org). Distinctions between levels are based on ability to move food and drink in the mouth and coordinate breathing and swallowing. There is evidence of interobserver reliability between parents and speech and language therapists. [334]

Children with CP also are categorized by topographic distribution of impairments in body functions and structure and atypical movement. Topographic distributions include diplegia (lower limbs affected more than upper), hemiplegia or hemiparesis (upper and lower limbs on one side of the body), and quadriplegia or tetraplegia (all limbs). Although these designations focus on the limbs, involvement of the head and trunk muscles is typical. A more recent European classification designates spastic CP as bilateral or unilateral.[59] Lack of standardized definitions for topographic designations limits their reliability and validity.[142]

Movement differences are related to the location of brain damage. Types include spastic, dyskinetic, ataxic, and mixed.[59,330,331] Spastic CP results from involvement of the motor cortex or white matter projections to and from cortical sensorimotor areas of the brain. Spasticity and exaggerated reflexes result in abnormal patterns of posture and movement. Dyskinesia reflects involvement of the basal ganglia. Dyskinetic features include atypical patterns of posture and involuntary, uncontrolled, recurring, and occasionally stereotyped movements of affected body parts. Dyskinetic CP may be classified further into subtypes: dystonic or athetotic. Dystonic movement is dominated by involuntary sustained or intermittent muscle contraction with repetitive movements and abnormal postures. Athetosis is characterized by slow, continuous, writhing movements that prevent maintenance of a stable posture. A cerebellar lesion produces ataxia—an inability to generate normal or expected voluntary movement trajectories that cannot be attributed to weakness or involuntary muscle activity about affected joints.[330] It results in general instability, abnormal patterns of posture, and lack of orderly, coordinated, rhythmic, and accurate movements.[59] In mixed CP, symptoms of spasticity and dyskinesia may be present.[59] The term should be used with an elaboration of the component motor disorders. Proportions of the various subtypes of CP vary with the reporting and sampling sources. Rates also change over time, as causes of CP are altered by advances in prevention and changing rates of prematurity and other medical problems associated with the diagnoses.

CHARACTERISTICS OF THE MOVEMENT DISORDERS IN CEREBRAL PALSY

The *International Classification of Functioning, Disability, and Health* (ICF) provides a common language and conceptual framework for describing complex interactions among body functions and structures, activities, and participation of individuals with CP in the context of personal and environmental factors. The ICF is applicable to clinical practice, research, teaching, and program evaluations.[129,332] A comprehensive core set and brief core sets grouped by age have been developed for children with CP to provide a systematic description of their functional profiles while considering the developmental trajectories of this population. [332]

Body Functions and Structures

Physical therapists address multiple body function and structure impairments in their comprehensive care of children with CP. Impairments can be primary or secondary. Primary impairments are an immediate result of the existing pathology, whereas secondary impairments such as contractures or skeletal malalignment develop over time as the result of other factors.[23] An understanding of these processes is integral to the prevention of unnecessary disability in children with CP. The following sections discuss the impairments addressed most often by physical therapists.

Muscle Tone and Extensibility

Tone is a clinical term used to describe the neural and mechanical properties of muscle. *Muscle tone* is defined as normal resting tension or resistance of muscle to passive movement or muscle lengthening.[59] It excludes resistance as a result of joint, ligament, or skeletal properties. Hypotonia is characterized by diminished resting muscle tone and decreased ability to generate voluntary muscle force. Hypertonia is an abnormal increase in resistance to an external force about a joint resulting from a number of factors, including neurally mediated reflex stiffness, passive muscle stiffness, and active muscle stiffness, all of which

contribute to resistance of the muscle to stretch.[123] It is difficult to classify abnormal tone as a primary or secondary impairment because (1) it develops over time and with increasing attempts to overcome the force of gravity and gain mobility (except in those with severe impairment) and (2) the early neurally mediated abnormality of tone that is one of the signs leading to the diagnosis of CP is compounded over time by the addition of muscle stiffness and contracture. In children with CP, muscle tone has been found to increase up to 4 years of age and then decrease up to the age of 12.[151]

Spasticity is neural resistance to externally imposed movement, which increases with increasing speed of stretch and varies with the direction of joint movement. Resistance may rise rapidly above a threshold speed of passive movement or joint angle, resulting in a spastic catch that may represent the threshold for onset of the stretch reflex.[331] Spasticity may be associated with clonus, pathologic reflexes and particular patterns of posture and movement. Supraspinal and interneuronal mechanisms appear to be responsible for spasticity. Pathophysiologic mechanisms include reduced reciprocal inhibition of antagonist motoneuron pools, decreased presynaptic inhibition, and decreased nonreciprocal inhibition.[331,333]

Passive muscle stiffness is the sense of abnormally high tone or hypoextensibility of muscles resulting from abnormal mechanical properties. The muscle offers resistance to passive stretching at a shorter length than that expected in a normal muscle. In addition, if greater than normal amounts of force are required to produce a change in length, the muscle is said to have increased stiffness. This is represented as the passive tension curve for CP (p,CP) in contrast to the normal passive tension curve (p,N) in Fig. 19.2D, in response to moving the ankle from a position of plantar flexion to one of dorsiflexion. When it is not possible to manually stretch the muscle through a normal range using reasonable amounts of manual force, the muscle group is deemed to have a contracture. This is represented as *contracture,* the difference between the joint angle at which this extreme resistance is encountered in the CP muscle and that of the normal muscle. Fig. 19.2 shows hypothetical active force-length characteristics of spastic plantar flexors (a,CP; see Fig. 19.2B) and normal plantar flexors (a,N; see Fig. 19.2E)—that

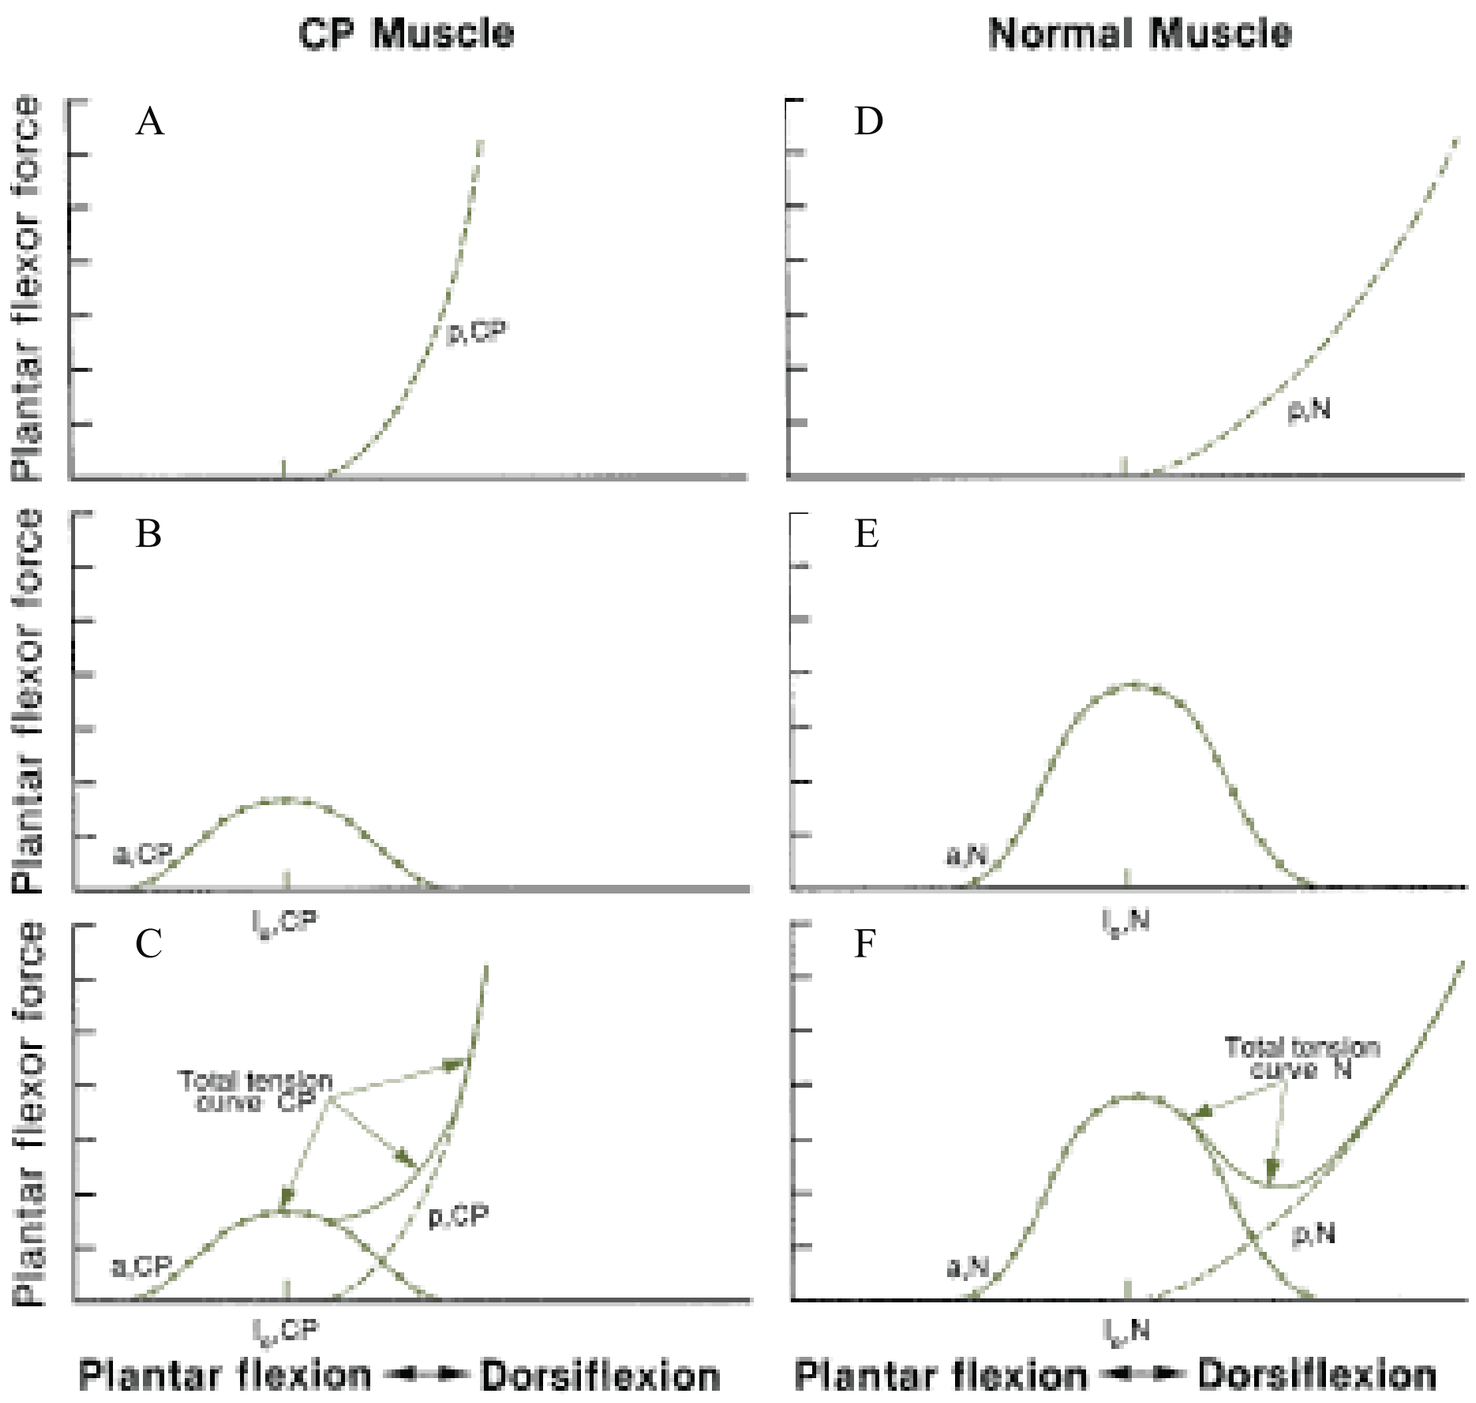

FIG. 19.2 Representation of force capabilities of ankle plantar flexor muscle at different joint angles in normal muscle (N) and spastic muscle (CP). A, Resistance to passive stretch of spastic muscle (p,CP) increasing with more dorsiflexion. B, The force of active contraction (a,CP) varying with the joint angle l_0 denoting resting length. C, The sum of passive and active effects in spastic muscle. D, Resistance to passive stretch in normal muscle (p,N). E, Force of active contraction in normal muscle (a,N). F, Total tension curve comprising the sum of passive and active effects in normal muscle. Note that (1) the slope (i.e., the stiffness) of p,CP in A is greater for the spastic muscle than for normal muscles (p,N) in D; (2) the maximal active force achieved by the spastic muscle (a,CP) in B is less than the maximal active force of normal muscle (a,N) in E; and (3) the maximal active force for spastic muscle (a,CP) shown in B occurs at a more plantarflexed position than that of the normal muscle (a,N) shown in E.

is, the force generated by the contractile elements of the muscle over the range of muscle lengths from a shortened position (plantarflexed) to a longer position (dorsiflexed). Note that the maximal force is lower for the CP muscle, and that the peak force occurs at a more plantarflexed position in the CP muscle than in the normal muscle. The sum of the combined effects of active force output and passive stiffness for the CP muscle is shown as total tension curve CP, and the corresponding curve for the normal muscle is shown as total tension curve N (Fig. 19.3). The complexity of the representation in Fig. 19.3 underscores the difficulty in determining the cause of increased tone through clinical methods such as passive manipulation of the limb and clinical assessment of muscle strength. The underlying mechanisms of these muscle extensibility alterations in CP are important in developing a rationale for interventions.[123]

Complex interactions among neurologic, mechanical, and biologic factors influence the structural integrity of muscle. This interplay between muscle innervation, altered loading, and impaired growth influences the development of contractile and noncontractile components of muscles in cerebral palsy.[143] The muscle structure has been characterized by alterations of sarcomere properties, muscle fiber size, type, variability, alignment, distribution, volume, and cell stiffness.[21,215] A proliferation and poor organization of extracellular materials with inferior mechanical properties have been noted in spastic muscle.[123] These abnormal collagen characteristics have been identified in the muscles of children with CP.[40]

Muscles grow and respond to the amount and type of activity during movement. Regular stretching of relaxed muscle under normal physiologic loading occurs in typically developing children. The muscles in children with CP may not relax during activity and may be subject to chronic muscle imbalance, abnormal posturing, and static positioning resulting from spasticity, weakness, and abnormal reflex activity. Muscle growth may not keep up with bone growth during periods of rapid linear growth, thereby contributing to hypoextensibility; conversely, some muscles may become overlengthened as the result of repeated mechanical stretch or orthopedic surgery.[405] Although patterns of tightness vary, the muscles most commonly at risk for contracture are the shoulder adductors; the elbow, wrist, and finger flexors; the hip flexors and adductors; the knee flexors; and the ankle plantar flexors. A population-based study of adolescents with CP demonstrated that although those with lower gross motor function tended to have greater limitations in range of motion (ROM), variation within GMFCS levels could be seen. Some adolescents functioning at GMFCS level I had contractures; others functioning at level V did not.[401]

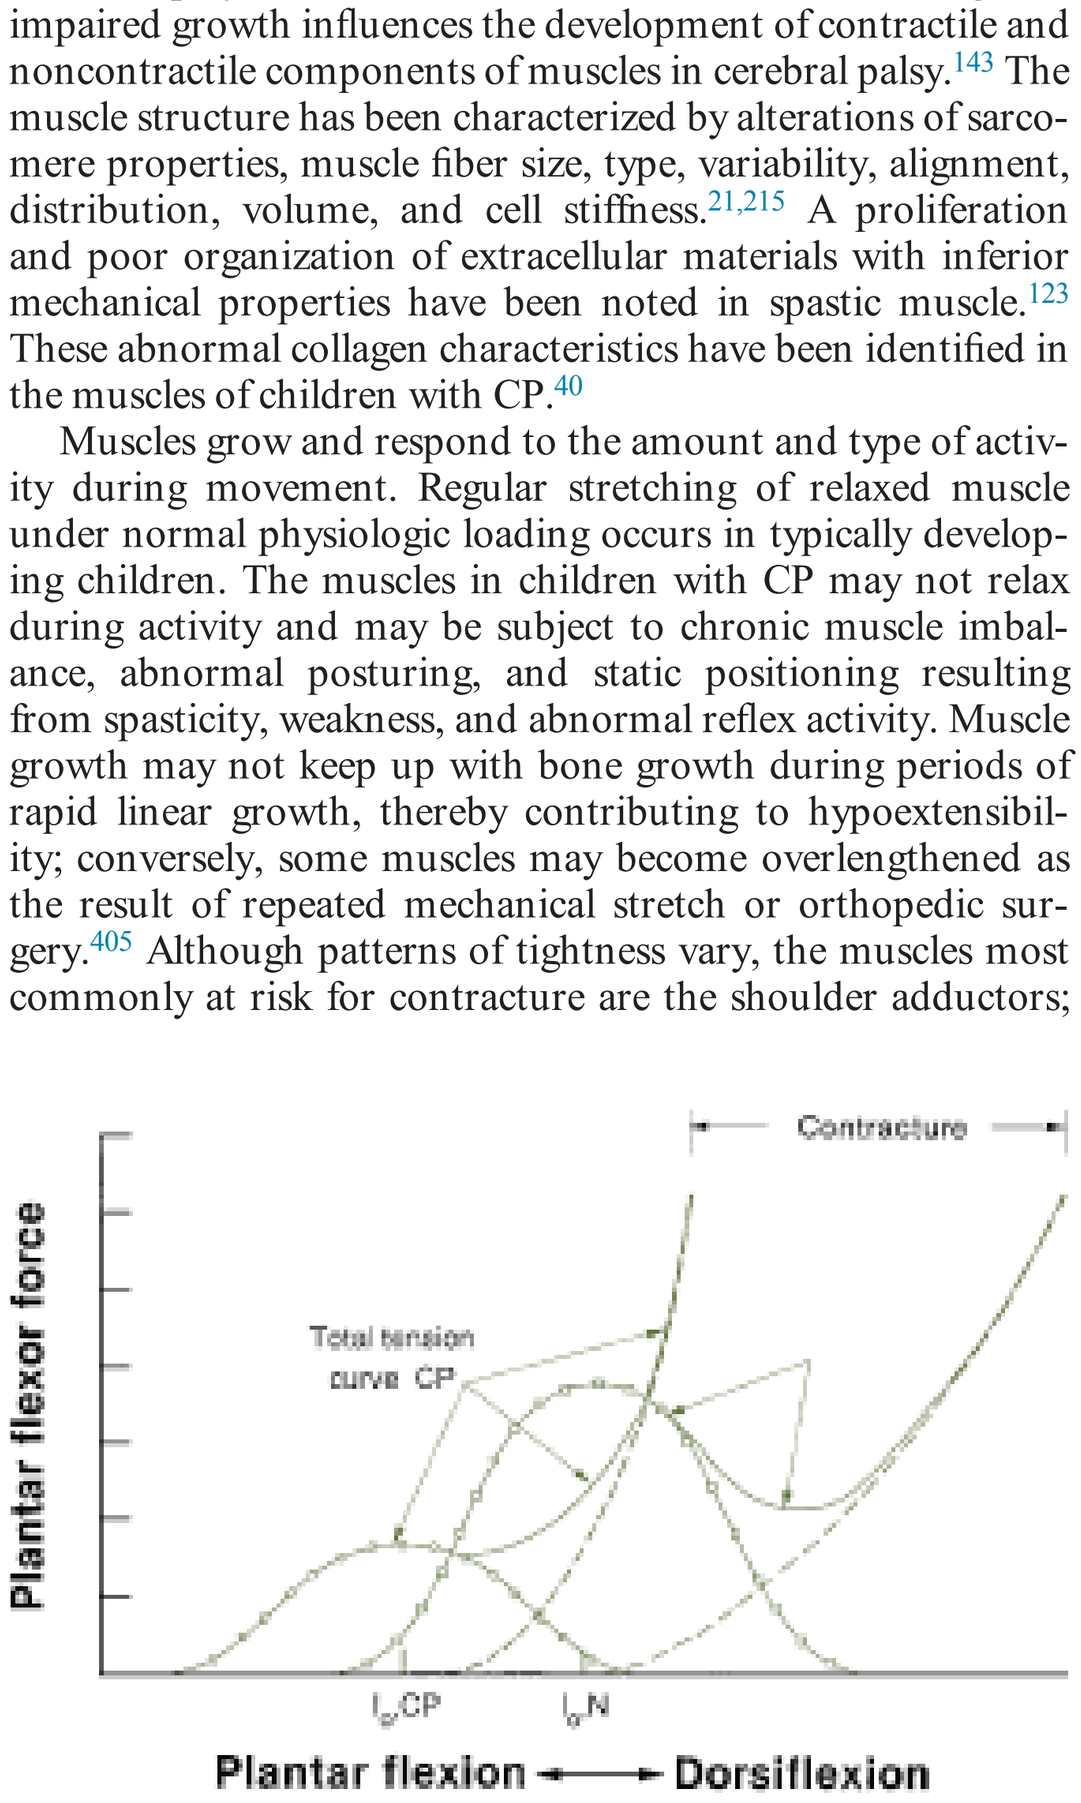

FIG. 19.3 Complete representation of force capabilities of ankle plantar flexor muscle at different joint angles in normal muscle (N) and spastic muscle (CP) shown in Fig. 19.2. a,CP = Force of active contraction of spastic muscle; l_o,CP = resting length of spastic muscle; l_o,N = resting length of normal muscle.

Muscle Strength

Considerable evidence suggests that children with CP are unable to generate normal voluntary force in a muscle or normal torque about a joint.[315,330] This impairment may be expressed as decreased moment of force output, a deficiency in power, or, when considered over time, a deficiency in work.[270] The term *strength* may refer to any of these measurable factors, and diminished force production capability is now understood to be a primary impairment in CP. Muscle weakness is consistent with low levels of electromyographic (EMG) activity and has been attributed to decreased neuronal drive, inappropriate co-activation of antagonistic muscle groups, secondary myopathy, and altered muscle tissue properties.[108,111,123,125,315,343] Additionally, muscle shortening and skeletal deformity can lead to changes in lever arm biomechanics, resulting in reduced output of muscle force in terms of torque.[269] Greater weakness has been reported in the distal musculature compared with the proximal musculature, for concentric versus eccentric contractions, and in faster versus slower speeds of movement.[85] Strength has been linked with activity capabilities such as walking speed and gross motor function.[84,269] Strength deficits can also contribute to bone deformity; for example, hip weakness is a postulated cause of hip deformity in ambulatory children and young adults.[240]

Skeletal Structure

Impairments such as weakness, spasticity, abnormal extensibility, and disturbed reflexes can result in excessive and abnormal biomechanical forces. Structures such as joint capsules, ligaments, and bones can become compromised. Torsion of long bones, joint instability, and premature degenerative changes in weight-bearing joints can occur. Alignment of the spine and extremities can be affected, particularly during times of physical growth. The prevalence of scoliosis in individuals with CP increases with age and GMFCS level and is greater than 60% in children with spastic quadriplegia.[10,216] Another concern is the lack of standing and ambulation on the growth and development of hip joint, putting children with CP at risk for subluxation and dislocation. Hip displacement can be painful and impact mobility, positioning, and activities of daily living.[391] A linear relationship exists between GMFCS and risk of hip instability. The overall prevalence of hip displacement (migration percentage greater than 30%) is 30%; however, children classified as GCMAS level V have a risk close to 90%.[403] Children with CP also have low bone mineral density and can be at risk for fragility fractures due to decreased weight bearing, the use of anticonvulsants, poor nutrition, and decreased exposure to sunlight.[115]

Selective Control

Normal movement is characterized by orderly phasing in and out of muscle activation, co-activation of muscles with similar biomechanical functions, and limited co-activation of antagonists during phasic or free movement. Children with CP have poor selective control of muscle activity. This is defined as

the impaired ability to isolate the activation of muscles in a selected pattern in response to demands of a voluntary posture or movement. Individuals with poor selective control exhibit reduced speed of movement, mirror movements, or abnormal reciprocal muscle activation.[124,330,333] They may be unable to move their hip, knee, and ankle joints independently of one another and exhibit coupled flexor and extensor patterns when attempting functional movement.[124] Deficiency in the control of selective movements is a major contributor to impaired motor function. For example, selective control of the lower extremity is related to the ability to extend the knee while flexing the hip and dorsiflexing the ankle at late swing and initial contact in gait.[124] Selective control is an important predictor of success for interventions such as dorsal rhizotomy[110] or orthopedic surgery.[124]

Postural Control

Postural control is the ability to control the body's position in space for stability or orientation, balancing the center of mass over the base of support.[101] (See Chapter 3, Motor Development and Control.) The sensory, motor, and musculoskeletal systems participate in coordinating postural activity through synergies and strategies. Children with CP have dysfunction in responding to postural challenges and have difficulty fine-tuning postural activity.[95] Reactive postural adjustments occur in response to unexpected external postural perturbations. Responses in children with CP vary with level of severity. Children with CP functioning at GMFCS levels I and II have some ability to produce direction-specific adjustments to counteract forces disturbing equilibrium through reactive control, whereas these abilities decrease with higher GMFCS levels and are largely absent in children with GMFCS level V.[45] Anticipatory postural adjustments are related to expected internal postural perturbations preceding the onset of voluntary movement. In healthy individuals, changes in posture are preceded by preparatory muscle contractions that stabilize the body and allow weight shifts in anticipation of movement, while keeping the center of mass within the stability limits of the body. Children with CP exhibit characteristic disorganization or adaptations, including cranial-caudal recruitment of postural muscles, excessive antagonistic co-activation, and reduced or absent capacity to adapt the degree of muscle contraction as appropriate to the specific task or situation.[45,95]

Pain

Acute and chronic pain can have a negative impact on accomplishment and satisfaction with daily activities, physical activity, mental health, social life, sleep, energy, and overall quality of life of people with CP.[23,104,356, 399] Pain can result from neuromuscular, orthopedic, or gastrointestinal impairments; overuse syndromes; and interventions such as surgery, bracing, and injections.[351] It can also be related to exercise, with stretching frequently being reported as painful.[351] Pain has been reported by 64% of girls and 50% of boys in adolescents with cerebral palsy, most frequently in the feet, ankles, knees, and lower backs of those functioning at all GMFCS levels as well as the lower back of those at levels I to IV and had a negative impact on daily activities.[104]

Fatigue

Fatigue of physiologic origin can results from high rates of energy expenditure. Possible underlying mechanisms in people with CP include decreased force production capacity and increased energy expenditure due excessive co-contraction and inefficient movement patterns.[49] Fatigue has the potential to impact participation in many aspects of life and can become more problematic with maturation as increased size and more demanding activities require greater physical exertion.

Activity and Participation

Physical therapists focus on motor activities and how they impact activity and participation in the domains of mobility, general tasks and demands, self-care, domestic life, and other life areas. Factors that contribute to variance in the motor abilities of children with CP are spasticity, quality of movement, postural stability, force production, range of motion, and endurance as well as distribution of involvement, adaptive behavior (GMFCS levels III-V only), and participation in community programs (GMFCS levels I-II only).[24]

Participation in children with disabilities is a complex phenomenon that allows them to pursue the learning of skills, to develop social engagement, and to find satisfaction in their lives.[175] Opportunities for children and adolescents with CP to participate in home, school, and community activities are increasing. Many have positive peer experiences.[176] This can be attributed to advances in technology and a legacy of striving for inclusion that has influenced social attitudes and policies regarding funding and environmental adaptation. Nevertheless, children and adolescents with CP experience restrictions in participation compared with children in the general population.[28,176,243] They may be overprotected, excluded from playing with peers, or bullied.[176] Adults with CP experience restrictions in participation. They can have challenges integrating socially, experiencing intimate and partner relationships, and securing paid employment.[305]

Many factors are associated with participation in life activities. Physical environment (Fig. 19.4), GMFCS level, hand function, toileting needs, pain, communication, cognition, attitudinal barriers, parental vigilance, and child motivation are important predictors[112,175,176,251] with walking ability being particularly significant.[112] Participation can vary significantly across countries even when other factors were controlled for. Denmark has higher rates of participation in all areas except relationships, most likely reflective of its policies and programs supporting the principle of equal access through public transportation, accessibility, assistive technology, and financial assistance. Such findings illustrate the impact of the social and legislative environment on the lives of people with disabilities.

RESEARCH EVIDENCE FOR INTERVENTIONS

Evidence-based practice is the standard for pediatric physical therapy. In the Foreground Information section of this chapter, research is applied to physical therapy management of infants, children, and adolescents with CP using the model of evidence-informed decision making described in Chapter 1. This section presents considerations for applying research to decision making for individual children.

The increase in the number of studies on interventions for children with CP has led to a proliferation of systematic reviews and meta-analyses. Systematic review is a retrospective appraisal of all research on an intervention in an effort to determine the overall effect. Meta-analysis refers to the use of

FIG. 19.4 Environmental adaptations to playgrounds can facilitate participation in normal childhood activities. (Courtesy Landscape Structures, Delano, MN.)

statistical methods to analyze the combined data from all studies to determine an overall effect. A current meta-analysis is a valuable resource for practitioners. A systematic review where results are analyzed descriptively requires more judgment in determining the overall effectiveness of an intervention.

Although systematic reviews are essential for evidence-informed decision making, the strength of evidence and effect size for physical therapy interventions for children with CP preclude prediction of outcomes for individual children. In other words, as will be presented in the Foreground Information section, research supports several interventions based on group data. The effect size for most interventions, however, is small to medium, indicating considerable overlap in outcomes between the children who received the intervention and the children in the comparison/control group. For this reason, the response of an individual child should not be inferred from group data.[80]

Also important is recognition that a systematic review is only as good as the quality of the research. Randomized controlled trials on the effects of interventions for children with CP are expensive and difficult to conduct. There is often variation in the ages and abilities of participants, the intensity of intervention, how the intervention is provided, and the outcomes measured. Sample size is often small and methodologic quality is variable. A concern when data are aggregated from studies with disparate features is applicability to evidence-informed decision making.

The caution urged when attempting to predict the response of an individual child from research evidence in many cases reflects the lack of knowledge of characteristics of children most likely to achieve the desired outcome, the age(s) when the intervention is most effective, the optimal intensity of intervention, and family and environmental factors associated with optimal outcomes. We encourage therapists to reflect on these considerations as part of the decision-making process.

FOREGROUND INFORMATION

EXAMINATION AND EVALUATION

Physical therapy examination of children with CP involves the identification of strengths and abilities, as well as participation restrictions, activity limitations, impairments of body structure and function, and environmental and personal factors as determined through interviews, observations, informal assessments, and objective measures.[192] Evaluation involves the integration of these findings with prognostic knowledge and consideration of contextual factors, which can be facilitators or barriers. It is important to differentiate among capacity (what someone can do in a standardized environment), capability (what someone can do in one's daily environment), and performance (what someone does do in daily life).[168] Capacity can exceed capability and capability can exceed performance. The gap between performance and capacity represents a therapy opportunity to enhance function and participation; however, an improvement in capacity may, but does not necessarily, translate into an improvement in capability or performance as personal factors such as age or motivation and physical or societal environmental factors impact change.[340] When motor skills are assessed, the use of equipment to carry out an activity should be taken into consideration. For example, wearing orthoses may substantially affect walking abilities.[320]

Ongoing assessments provide feedback for therapists, children, and their families that can be motivating, indicative of areas that need more attention, and helpful in determining prognosis; these assessments therefore guide ongoing shared and informed clinical decision making.[192] In addition to clinical practice, measurement is the foundation for research and

can be used to enhance service delivery and allocation of health resources.[192]

The ICF provides a framework to guide the selection of measures. Selection should be consistent with the purpose of an examination: discrimination, prognosis, or evaluation. Measurement tools need to be psychometrically rigorous but also feasible for specific clinical or research situations. Cost, training, time to administer and score, amount of handling, and child and family acceptance must be considered.

An ever-increasing number of measurement tools are available. The concept of a toolbox of outcome measurements for children with cerebral palsy suggests a core set of outcome tools framed within the ICF.[397] Video and photographic recording of assessments can provide records for future comparison. Families can also use these techniques to share information about their child's functioning in environments outside the clinic setting. A selection of measures applicable to children and youth with CP will be reviewed (Box 19.1). A comprehensive compilation is available in Measures for Children with Developmental Disabilities–an ICF-CY Approach.[229]

Body Functions and Structures

Muscle Tone and Extensibility

No method of measuring muscle tone is universally accepted or has strong psychometric properties.[120] Choices depend on the purpose of measurement. It is important to consider both neurologic and passive mechanical components of tone and to measure accordingly. In the clinical setting, spasticity is assessed typically by measuring the resistance to passive movement imposed through available range. The modified Ashworth scale is an undifferentiated, ordinal measure of spasticity and extensibility. It has been shown to have variable levels of reliability for children with CP depending on muscle group and only fair to moderate interrater reliability for the plantar flexor muscles. It does not quantify spasticity exclusively as anatomic, and biomechanical factors such as intrinsic stiffness of the muscles can contribute to hypertonia in addition to a heightened, velocity-dependent stretch reflex response.

Measurements evaluating resistance at several speeds may be more useful for planning and evaluating interventions, particularly those that aim to reduce spasticity or manage contracture.[84,273] The modified Tardieu scale measures the point of resistance or "catch" to a rapid velocity stretch, giving an indication of the dynamic neural component of tone or the overactive stretch reflex and is sometimes referred to as "R1." Moving the limb slowly into a lengthened position indicates the mechanical component of tone or muscle length at rest, commonly known as passive ROM or "R2."[42] A large difference between the initial catch and the point of mechanical resistance indicates a large reflexive component to motion limitation, and a small difference suggests a more fixed muscle contracture.[42] The Tardieu scale has been found to be more reliable than the modified Ashworth scale, particularly for the plantar flexors, but wide intersessional variations between dynamic and static differences limit use as an outcome measure. Various biomechanical and neurophysiologic assessment tools such as dynamometers or electromyography, respectively, can also be used to quantify spasticity.[120] The Barry-Albright Dystonia Scale provides a tool for rating dystonia.[20] It is a 5-point ordinal scale based on severity of posturing and involuntary dystonic movements in eight body regions.

Goniometry is the most common measurement tool for ROM; however, measurement error necessitates caution when interpreting serial measurements to determine outcomes and or make clinical decisions.[87] Some researchers have suggested that a change of more than 15° to 20° between sessions is required to be 95% confident that a true change in ROM has occurred in many joints of children with CP.[191] Consistent positioning and procedures should be used for measuring and documenting ROM and skeletal alignment particularly for rotational movements and biarticular muscles. Relaxation of a child and consistency in therapists can also contribute to accuracy.

Visual estimation may be used for ease of measurement and has been shown to be correlated adequately to goniometry for assessing ankle dorsiflexion, hip extension, and the popliteal angle.[229] The Spinal Alignment Range of Motion Measure (SAROMM) is a discriminative tool that uses estimations of spinal alignment and ROM limitations to give a summary score. The SAROMM indicates whether the child has normal alignment and ROM; flexible deviation; or mild, moderate, or severe fixed limitations.[22] It is considered to be sufficiently reliable and valid for use with children with CP.

Strength/Endurance

Testing muscle strength in children with CP may be difficult because of age, cognitive level, spasticity, hyperactive reflexes, abnormal muscle and joint extensibility, or poor selective control. Isokinetic muscle strength testing is available in some settings, allowing for precise stabilization and quantification of strength at different speeds and for different types of contractions.[11] Clinically, muscle strength is more often measured isometrically by manual muscle testing using an ordinal 6-point scale, or with handheld dynamometry if a child can exert a maximal effort in a consistent manner.[84,125] A make test is more reliable than the break test for lower extremity muscles when

handheld dynamometry is used. It has been shown to have high within-session reliability and variable between-session reliability depending on muscle group, positioning, and stabilization.[76,376] As a result, changes in strength should be considered based on measurement error for particular muscle groups.

Strength can also be assessed in a functional context. Observation of activities such as moving between sitting and standing positions, or ascending and descending stairs, helps to assess both concentric and eccentric power. Counting the number of repetitions of a functional movement performed over a specific period of time can quantify functional muscle strength. Interrater reliability of 30-second repetitions of lateral step-ups, sit-to-stand, and standing through half kneeling is acceptable.[376] Muscle strength may differ depending on posture, joint angle, speed of movement, or presence of contracture. Ability to generate force may deteriorate as a result of early fatigue of muscles, reduced endurance, or an inability to generate a sufficiently rapid increase in force, and in some cases it may be important to measure both the ability to maintain force over time and the ability to generate a brief rapid force.

Endurance and efficiency of movement become increasingly important when children venture into the community on their own or with peers. Submaximal endurance can be evaluated by observing the ability to walk or propel a wheelchair for age-appropriate distances. The 10-meter, 1-minute, 6-minute, and 10-minute walk tests, 600-yard walk-run test, and 6-minute push test have been found to be reliable in children with CP.[65,357] Ambulation measured over longer distances more closely simulates community ambulation and therefore the ability to participate in community activities.[357] Shuttle run, wheeling, cycling, or ergometry tests have been validated as maximal exercise tests for children and adolescents with CP, and muscle power sprint running tests or Wingate tests can provide information about anaerobic muscle power.[372] Accelerometers can be used to measure physical activity levels of ambulatory children with CP.[177] Physiologic measures such as the energy expenditure index provide energy cost information in a clinically feasible manner, but these measures have limitations because heart rate may not be an accurate substitute for energy expenditure under all conditions.[125] They may be useful when two or more mobility options are compared for the same person. It is important to conduct exercise testing over time to track improvement or decline in exercise capacity.[372]

Selective Control and Postural Control

Examination of selective control of muscle activity, anticipatory regulation of postural muscle groups, and ability to learn unique movements may be broad—using measures of balance, coordination, and motor control—or specific—for example, using the selective motor control test to quantify active ankle dorsiflexion.[42] The Selective Control Assessment of the Lower Extremity (SCALE) is an objective tool used to quantify lower extremity selective voluntary motor control. It rates the ability to perform specific isolated movement patterns as normal, impaired, or unable and has been shown to be valid and reliable.[15,124,127]

Postural control is measured in many standardized and nonstandardized ways at impairment or activity levels.[101] Sway or response to perturbations can be assessed by disturbing the supporting surface or by perturbing the subject or environment. Visual observation; kinematic, kinetic, and center of pressure measures; or electromyography (EMG) can be used to assess responses. Analysis of EMG activity during perturbations makes it possible to detect abnormal responses in the timing of muscle activity onset and duration, in the sequencing of agonists, and in the co-contraction of antagonists. Various balance tests such as the Automatic Reactions section of the Movement Assessment of Infants, the Pediatric Balance Scale, or the Early Clinical Assessment of Balance[233] can be used for children with CP. The Test of Infant Motor Performance (described in Chapter 29) includes assessment of primitive reflexes and automatic postural reactions.

Pain

Therapists should inquire about pain routinely, as people with CP may assume chronic pain to be the norm and not offer information spontaneously.[61] Self-report is optimal and can be verbal or through questionnaires or analog scales. Motor, cognitive, and communication problems can complicate but should not preclude the assessment of pain as behavioral cues or physiologic responses such as facial expression; vocalizations; or changes in cardiorespiratory status, sweating, movement, tone, affect, sleeping, and eating can indicate pain, despite the challenge of interpretation due to individual responses. The Non-communicating Children's Pain Checklist provides a standardized tool. The Pain Assessment Instrument for Cerebral Palsy is an instrument that allows self-report of pain and may indicate the range of potentially painful activities more accurately than proxy report.[38]

Activity and Participation

Pediatric physical therapists use a variety of tests to assess activity and participation. Some, such as the Test of Infant Motor Performance[254] (see video associated with Chapter 2 for an example of this test), the Alberta Infant Motor Scale,[89] the Movement Assessment of Infants,[63] and the Peabody Developmental Motor Scales[380] (see Chapter 2, Measurement) are not specific to CP. These are standardized measures normed on children with typical development to identify infants and children with delays in motor development or qualify children for services in early intervention and educational settings. For children with identified health conditions characterized by motor impairments and activity limitations, the value of such measures to plan interventions and document change is controversial. An alternative approach for measuring change over time or in response to an intervention in children with physical disabilities is to compare performance with expectations for children of the same age with a similar disability. This approach is dependent on disability-specific data.

The most widely used research and clinical tool for assessment of children with CP is the Gross Motor Function Measure (GMFM).[157] The GMFM is a reliable and valid criterion-referenced evaluative instrument designed to detect change in children with CP.[58,318] It has been validated on children 5 months to 16 years of age. The original GMFM has 88 items grouped in five dimensions: A: Lying and Rolling, B: Sitting, C: Crawling and Kneeling, D: Standing, and E: Walking, Running, and Jumping; these dimensions are scored on a generic 4-point ordinal scale. A gain of 5 to 7 percentage points is considered a medium positive, clinically important change for an individual child. The GMFM-66 is an interval-level version of the original GMFM developed and validated through Rasch analysis. Relative to the GMFM-88, the GMFM-66 demonstrates improved scoring, interpretation, and overall clinical and research utility; it requires fewer items to be tested and estimates

the difficulty of items.[10] A computer program, the Gross Motor Ability Estimator (GMAE), converts scores to an interval scale, plots scores graphically or on an item map, and provides 95% confidence intervals. Item sets of the GMFM-66 (GMFM-66-IS) have been developed to further improve the efficiency of administration.[319] An algorithm with three decision items indicates which set to use. Another short form version uses a basal-ceiling approach (GMFM-66-B&C).[23]

A Challenge Module has been developed as an adjunct to the GMFM to target performance of higher-level gross motor skills in children functioning at GMFCS levels I and II. Items such as running around pylons are indicative of skills that facilitate participation in play and sports with peers.[138,392]

The Quality Function Measure (Quality FM) is an adaptation of the Gross Motor Performance Measure, a measure developed to rate qualitative aspects of motor skills. It is based on viewing video recordings to evaluate the quality of alignment, dissociated movement, coordination, stability, and weight shift in dimensions D: Standing and E: Walking, Running, and Jumping of the GMFM.[396] This reliable and valid tool assesses how well young people with CP move and what areas of function to target to enhance quality of motor control.

Walking is subject to more specific assessment, as it is a focus of many physical therapy interventions and is perceived by children and parents to impact quality of life.[182] *Gait analysis* is a broad term that refers to many different methods of measuring and studying primary and secondary walking deviations and compensatory patterns (Fig. 19.5). Three-dimensional instrumented gait analysis is promoted as an objective and accurate measurement tool that improves clinical decision making and allows critical evaluation of interventions aimed at better outcomes for children with CP, particularly around major decision making regarding orthopedic or selective dorsal rhizotomy surgery and as an outcome measure for these interventions.[223,259,303]

FIG. 19.5 Child taking part in gait analysis. Electromyography shows patterns of muscle activities and aids identification of the presence of co-contraction of muscle groups. Markers at joints allow computer calculation of joint movements; force platforms embedded in floor permit measurement of individual muscle group contributions to the work of walking. (From Chang FM, Rhodes JT, Flynn KM, Carollo JJ: The role of gait analysis in treating gait abnormalities in cerebral palsy, Orthop Clin North Am 41:489-506, 2010.)

A comprehensive gait analysis includes a clinical examination of physical impairments, including spasticity, ROM, bony deformity, strength, and selective control, coupled with a dynamic assessment of the biomechanical and physiologic aspects of walking. Findings from these measures are considered in relation to functional mobility performance outside the gait laboratory and in the context of a child's environment and participation in life activities. Visual observation can be used for subjective descriptions of stability and balance, speed and control, symmetry and movement patterns, weight transfer, foot placement, and the influence of assistive devices. The use of instrumentation to document and quantify temporal, spatial, kinematic, kinetic, and electromyographic information results in objective measures of multiple joints and limb segments simultaneously, providing complex data that could not be detected by visual inspection alone.[64,98] An understanding of power generation and absorption of muscle groups is of particular importance in assessing outcomes[406] (see Chapter 34, Development and Analysis of Gait and accompanying video on Expert Consult).

Although findings facilitate a wide range of clinical and research applications, clinical utility is controversial because of high costs and the questionable validity of laboratory results for representing daily function.[259] Proponents consider it to be the gold standard measure for clinical practice and research and believe computerized three-dimensional gait analysis is a requirement for the optimal treatment of problems related to ambulation in CP.[264] Others consider it to be an expensive tool that does not contribute sufficiently to warrant its use clinically.[71]

Video-based gait assessment is a simpler and less expensive alternative for basic description of key gait parameters that has been found to have moderate interrater reliability and validity based on three-dimensional gait analysis.[223] It can provide opportunities for frequent monitoring, to document change over time, the impact of treatments and interventions, and the impact of orthotics. It can be useful for very young children or those with behavioral or cognitive issues that could preclude fully instrumented gait analysis.[160] Observational gait scales have been developed to make video gait analysis more objective and reliable. The Edinburgh Gait Score was developed for people with CP and includes ratings of gait components in sagittal, coronal, and transverse planes of movement. It is the strongest tool psychometrically and correlates well with three-dimensional gait analysis.

Tests such as the Timed Up and Go, Timed Up and Down Stairs, and running tests provide measures of functional activities.[5] They may be useful in school or community settings because of their simplicity and are significant predictors of community mobility.[118]

The Activity Scale for Kids is a child or parent self-report measure for children with musculoskeletal disorders between the ages of 5 and 15 years and is robust psychometrically for children with CP. It has capacity and performance versions, which assess daily physical activities, including personal care, dressing, eating and drinking, play, locomotion, standing skills, climbing stairs, and transfers.[162,404]

The Pediatric Evaluation of Disability Inventory (PEDI) uses structured interviews to collect parental reports of functional skills in young children with disabilities.[379] The PEDI-CAT is a computerized version that selects items based on previous responses, thereby reducing the number of overall items. The

Functional Independence Measure for Children (WeeFIM), a pediatric version of the Functional Independence Measure, measures function as quantified by burden of care for children with developmental disabilities.[12] Chapter 2 provides more information on these tests. The Pediatric Outcomes Data Collection Instrument determines levels of various skills, including transfers and basic mobility, sports, and physical function, and it includes a participation component.[19]

Participation is a complex construct, but measures help to ensure that function in home, school, and community settings is recognized. They can help with goal setting, treatment planning, and overall patient care.[327] The Child Engagement in Daily Life is a parent-completed measure of frequency and enjoyment of participation in family and recreational activities and the degree a child participates in the self-care activities of feeding, dressing, bathing, and toileting for children 18 to 60 months of age.[66] The Assessment of Life Habits (LIFE-H) determines the daily life experiences of children.[248,263] It was developed from a theoretical framework aligned with the ICF and rates 11 domains of daily activities and social roles on levels of accomplishment, type of assistance, and level of satisfaction.

The Children's Assessment of Participation and Enjoyment (CAPE), a child-report instrument, captures diversity, intensity, location, and enjoyment of participation, including with whom the child participates, in formal and informal activities using five scales: recreational, active physical, social, skill-based and self-improvement, and educational. It does not incorporate assistance needed into the scoring system.[195] The Participation and Environment Measure for Children and Youth (PEM-CY) examines participation in home, school, and community settings and the environmental factors that support or hinder participation specific to these settings.[73] The Lifestyle Assessment Questionnaire for CP measures physical dependence, restriction of mobility, educational exclusion, clinical burden, economic burden, and restriction of social interaction. The contextual items provide information on the impact of disability on participation of the family unit.[227,248] The School Function Assessment may be used to assess participation, adaptations, assistance, and activity performance in educational settings, providing information about the environment as well as participation.[93,327]

Although the use of these standardized tools is important for diagnosis and quantification of outcomes, child and caregiver interviews remain important clinical tools for collecting useful and meaningful information about participation and environments. A family's recounting of their activities in a typical day and night, including accommodations made for their child with CP, is invaluable.[30,292,394] Information about the influence of personal and environmental attributes on enabling or creating barriers to function can be gathered through a description of daily activities. These range from specific factors internal to a child and family such as caregiver stress, family supports, and finances to broader factors such as community physical environments and societal attitudes toward children with disabilities.[30,385]

Health-Related Quality of Life

Measures of health-related quality of life (QOL) take into account various factors and values believed to be important by health care professionals, parents, and children themselves that contribute toward well-being and ability to fulfill certain life roles.[232,260,382] The Pediatric Quality of Life Inventory (PedsQL), version 3.0, Cerebral Palsy Module, measures health-related QOL dimensions specific to CP. It includes five dimensions: daily activities, movement and balance, pain and hurt, fatigue, and eating.[369] The Caregiver Priorities and Child Health Index of Life with Disabilities (CPCHILD) is a measure of health status and well-being of children with severe activity limitations.[260] The Cerebral Palsy Quality of Life Questionnaire for Children has self-report and parent proxy versions to assess seven domains of QOL, including social well-being and acceptance, feelings about functioning, participation and physical health, emotional well-being, access to services, pain and feeling about disability, and family health.[381] The Child Health Questionnaire is a health-related QOL measure that has been used in children with CP. Various health-related QOL measures such as the Short Form (SF)-36 have been used to study adults with CP.[179]

Individualized Outcomes

Individualized criterion-referenced measures are available to assist in formulating goals and measuring their attainment. The Canadian Occupational Performance Measure can be used to document and quantify goals that are relevant to a family and to determine whether they are achieved.[213] Goal Attainment Scaling can be used to evaluate whether specific individualized treatment goals or outcomes have been met.[97,279,344] These forms of assessment are highly responsive to clinically meaningful change in short time periods[192] and complement but do not replace standardized measures.

Evaluation of service delivery and environmental factors can provide valuable information to inform practice. The Measuring Processes of Care tool captures parental satisfaction with family-centered aspects of services. A 20-question version (MPOC-20) assesses five areas of care: enabling and partnership, providing general information, providing specific information about the child, providing coordinated and comprehensive care, and providing respectful and supportive care.[78] Giving Youth a Voice is an evolution of the MPOC designed to provide youth with disabilities an opportunity to give feedback.[132,337] The perceptions of service providers can be captured with the Measure of Processes of Care for Service Providers.[395] The Craig Hospital Inventory of Environmental factors (CHIEF) measures environmental barriers in school, work, and physical environments; policies; services and attitudes; and supports. The Supports and Services Inventory assesses the services families and children receive and their perception of the adequacy of services to meet their needs.

Physical therapy sessions can be described and evaluated in systematic, standardized, and reliable ways. Examples include determining the proportions of time spent facilitating movement versus challenging the production of motor behaviors in infant treatment or time spent in family involvement and education[35,103] or the Paediatric Rehabilitation Observational measure of Fidelity, which measures the degree to which interventions are delivered as intended.[102] These applications are used to increase research rigor and therefore better assess clinical effectiveness.

PROGNOSIS FOR GROSS MOTOR FUNCTION

Measurement findings coupled with knowledge of prognosis for gross motor function in children with CP can facilitate communication with families regarding outlook for gross motor

function, facilitate collaborative and realistic goal setting, inform the selection of appropriate interventions, and evaluate intervention outcomes.[279] One of the first concerns for parents of children with CP is whether their child will walk. Walking ability varies by type of CP. Children with hemiplegic and ataxic CP are more likely to walk, whereas those with dyskinetic and bilateral CP are less likely to do so. Cognitive functioning, visual and hearing impairments, and epilepsy are also predictors of walking ability for all types of CP.[29] Independent sitting by 24 months remains the best predictor of ambulation for 15 meters or more with or without assistive devices by age 8 years.[383] If independent sitting is not achieved by age 3, there is very little chance of achieving functional independent walking. Some people with CP experience a decline in their walking abilities in adolescence or adulthood as a result of pain, fatigue, musculoskeletal deterioration, poor surgical outcome, weight and height gains, or fear of falling.[219]

Gross Motor Development Curves

The GMFM-66[318] and the GMFCS enabled researchers at the CanChild Centre for Developmental Disability Research to create gross motor development curves for children with cerebral palsy. Prospective longitudinal studies on a cohort of children with cerebral palsy randomly selected from an accessible population of 2108 children in the province of Ontario (Canada) were constructed. Children were stratified by age and GMFCS level. Each child's classification level at the start of the study was used to create five motor development curves. The first study[314] included 657 children who were administered the GMFM-66 an average of 4.3 times. The model that provided the best fit of GMFM-66 scores was nonlinear and included two parameters: the *rate parameter,* an estimate of how fast children approach their limit of gross motor function, and the *limit parameter,* an estimate of maximum potential for gross motor function.

A subsequent study was completed that followed 229 of the 343 older children in the original cohort for an additional 5 years during adolescence and early adulthood.[155] A consideration in deciding how to model the curves was the possibility that some youth might demonstrate a decline in gross motor function. To account for this possibility, a model was examined that included a third parameter to allow for a peak and decline in GMFM-66 scores, prior to a long-term limit. The data were modeled using both two and three parameters. The two-parameter model provided the best fit for children and youth in levels I and II, whereas the three-parameter model provided the best fit for children and youth in levels III, IV, and V. The gross motor development growth curves are presented in Fig. 19.6.

The gross motor development curves represent the average pattern of development for children and youth in each of the five classification levels. It should not be assumed, however, that the average patterns apply to all children with CP because there is large variability within levels. For all five curves, children progress faster to their maximum GMFM-66 score at younger ages and then demonstrate a leveling of scores (levels I and II) or a decline followed by a leveling (levels III-V). The predicted average maximum GMFM-66 score differs significantly for each level. On average, children in level I achieve a maximum score of 90, whereas children in level V achieve a score of 24 at age 6, which then declines to 17 age 21. Children and youth in levels III, IV, and V are predicted, on average, to demonstrate a decline in GMFM-66 score of 4.7 to 7.8 points. The gross motor development curves have important implications for evaluation

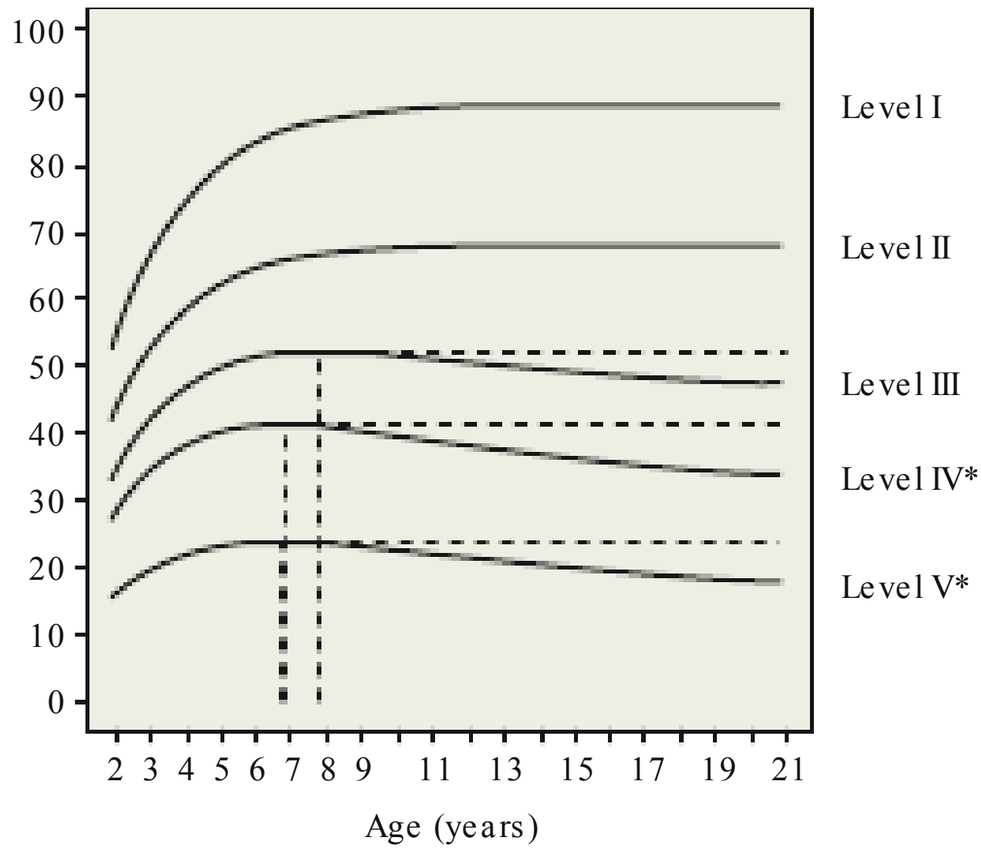

FIG. 19.6 Gross motor development curves for children and youth with cerebral palsy. (From Hanna SE, Rosenbaum PL, Bartlett DJ, et al.: Stability and decline in gross motor function among children and youth with cerebral palsy aged 2 to 21 years, Dev Med Child Neurol 51, 295-302, 2009.)

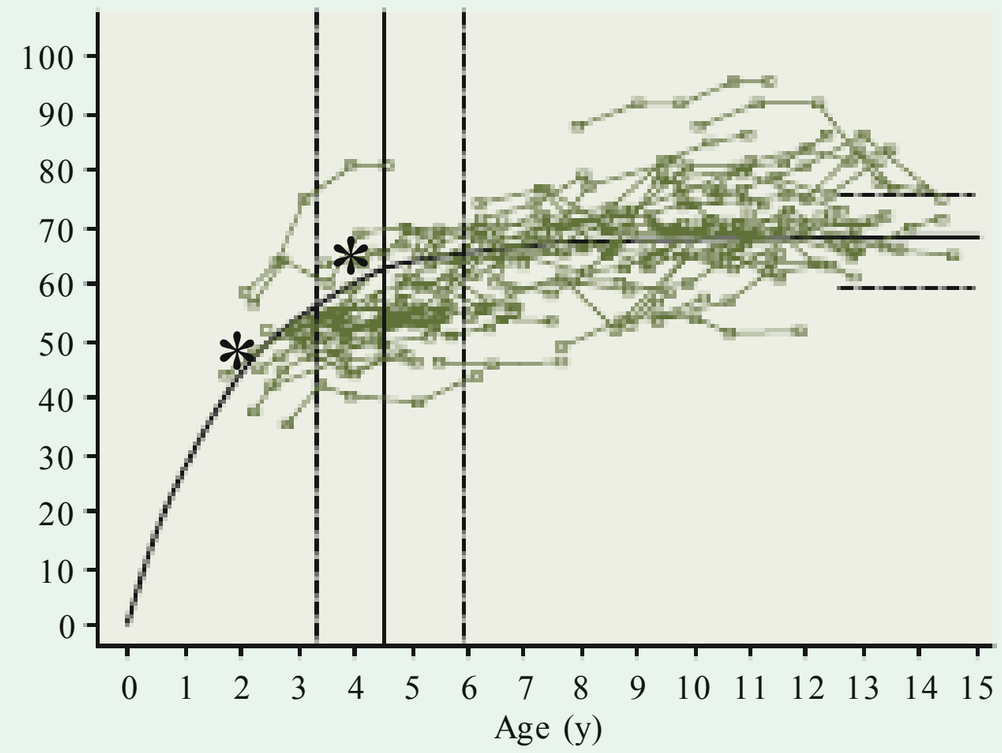
of interventions by providing evidence of the extent to which a particular intervention improves a child's gross motor function beyond what is predicted by the curves.

When sharing the gross motor curves with children, families, and other health care providers, therapists must clearly explain *what the curves do* and *do not measure*. The GMFM-66 measures activities, specifically what a child *can do* in a standard condition without shoes or orthotics. The activities measured are usually achieved by age 5 in children without motor impairments. The number of children below age 2 and the number above age 18 were low; therefore, the ends of the curves may not reflect actual development.

An example of the application of GMFCS, GMFM-66, and gross motor development curves to physical therapist examination, evaluation, and prognosis is provided in Box 19.2. The example is described in more detail by Palisano.[279] Prognosis for goals and outcomes such as wheeled mobility, ambulation with mobility aids or orthoses, movement efficiency, or performance of mobility during daily activities and routines *should not* be inferred from the motor development curve as these are not measured by the GMFM-66.



Reference percentile curves have been developed to provide further interpretation of GMFM-66 scores within GMFCS levels but should be used with caution and only as additional information becomes available to assist with the interpretation of change over time.[154] (Tabulated reference percentiles for the GMFM-66 are available at http://motorgrowth.canchild.ca/en/MotorGrowthCurves/percentiles.asp.)

The curves were based on data from children living in Canada; however, similar patterns of gross motor development were found in a Swedish study of 319 children between the ages of 1 and 15 years. Variability in GMFM-88 scores was noted among GMFCS levels, and most children reached a plateau at 6 to 7 years.[28] Such studies reflect descriptions of developmental trajectories as influenced by the intervention strategies available in developed countries.

BOX 19.2 Application of the Gross Motor Function Classification System (GMFCS), Gross Motor Function Measure (GMFM-66), and the Gross Motor Development Curves to Physical Therapist Examination, Evaluation, and Prognosis

Teresa Spataro is a 17-month-old twin born at 31 weeks' gestational age with a birth weight of 1570 g. She was recently diagnosed as having cerebral palsy and referred for physical therapy. During the initial interview, Mrs. Spataro identified the following needs and priorities: (1) information on when Teresa will walk, (2) concerns about leg stiffness, and (3) recommendations for what to do. Teresa crawls on hands and knees with leg reciprocation and is beginning to pull to stand and cruise. Using the GMFCS, the therapist classified Teresa's gross motor function at level II. The therapist uses the algorithm developed by Russell et al.[319] to identify the item set to administer (set B, which includes 29 items). Teresa achieved a GMFM-66 score of 44. As illustrated, her score is slightly above the average score predicted at 17 months of age for children in level II. Children with a GMFM-66 score of 56 have a 50% chance of walking 10 steps unsupported. On average, children at level II achieve a score of 56 at age 3 years. The therapist shared this evidence with Mr. and Mrs. Spataro when addressing their question, "When will Teresa walk?"

At age 4, Teresa continues to be classified at level II. She walks indoors and short distances outdoors. She has difficulty with initiation of walking, changing directions, and stopping. GMFM-66 item set C (39 items) was administered, and Teresa achieved a score of 60 on the GMFM-66. Hanna et al.[154] created percentiles for the GMFM-66 for children with cerebral palsy ages 2 to 12 years (not pictured). Teresa's score is at the 80th percentile. The therapist shares this information with Teresa and her parents. Teresa is proud saying she only has "a little cerebral palsy," and her parents express their delight at Teresa's progress in gross motor function.

Probability Estimates for Methods of Mobility

Another type of data useful for decision making is performance of mobility in daily life. Performance of mobility or how children actually move at home, school, and in the community involves the interaction of the child and environment. Performance, therefore, is potentially influenced by several factors, including the child's physical capacity; the physical, social, and attitudinal features of the environment; and the child's (or family's) personal preference and choice. As part of the two longitudinal studies that led to creation of the motor development curves, parents of a population-based sample of 642 children reported their children's mobility at home, school, and outdoors at 6- or 12-month intervals for a mean of 5.2 times.[277] The data were analyzed to model the probabilities that children and youth with cerebral palsy walk (with or without mobility devices), use wheeled mobility (self-propelled or self-powered mobility), or use methods of mobility that require physical assistance (e.g., carried, takes steps with assistance, transported) as a function of age and environmental setting.

By age 3, almost all children in level I walked in all environmental settings, whereas only a small number of children and youth in level V moved without physical assistance of a person (powered mobility). Usual method of mobility varied by age and environmental setting for children and youth in levels II, III, and IV. Fig. 19.7 presents the estimated probabilities for children and youth in level III. At younger ages, there is a high probability that children are transported or carried outdoors. The probability of walking increases from age 4 and peaks at age 9 in the school setting (68%), age 11 in the outdoors setting (54%), and age 14 in the home setting (52%). The probability of walking at age 18 is about 50% in all three settings. At home, youth who do not walk as their usual method of mobility are more likely to move with physical assistance than use wheeled mobility. At school and outdoors, youth who do not walk as their usual method of mobility are almost as likely to use wheeled mobility as assisted mobility.

The probability estimates provide evidence that usual methods of mobility of children and youth with cerebral palsy are influenced by age and environmental setting. The probabilities are modeled from a population-based sample and, therefore, are likely to generalize to populations elsewhere whose resources and services are comparable to those in Ontario, Canada. The results have implications for long-term planning, clinical decision making, and family-centered services. Discussion of mobility options with children and families and involving children in decision making is recommended, with the understanding that the method of mobility that optimizes participation in one setting may not be the preferred method in another setting. Efficiency, safety, self-sufficiency, and environmental features such as distance and time requirements are important considerations when making decisions regarding goals and interventions for mobility. Therapists are encouraged to evaluate features of everyday environments when planning interventions to improve mobility.

Prognosis for overall functioning as an adult is dependent on many variables, and reports vary greatly. Mean values summarized from six studies showed that 31% of adults with CP lived independently, 12% were married, 24% achieved a tertiary/vocational level of education, and 28% had paid employment.[219] Positive prognostic factors for employment include mild physical involvement, good home support, education, vocational training, and good cognitive skills.[255] Increasing success rates in education and employment over the years have been attributed to advances in and access to technology such as power wheelchairs and computers, environmental access, and supportive legislation.

INTERVENTION

Framework for Evidence-Informed Decision Making

Planning effective physical therapy interventions for children and youth with CP is a complex process. Many approaches and treatments are available to address the physical therapy

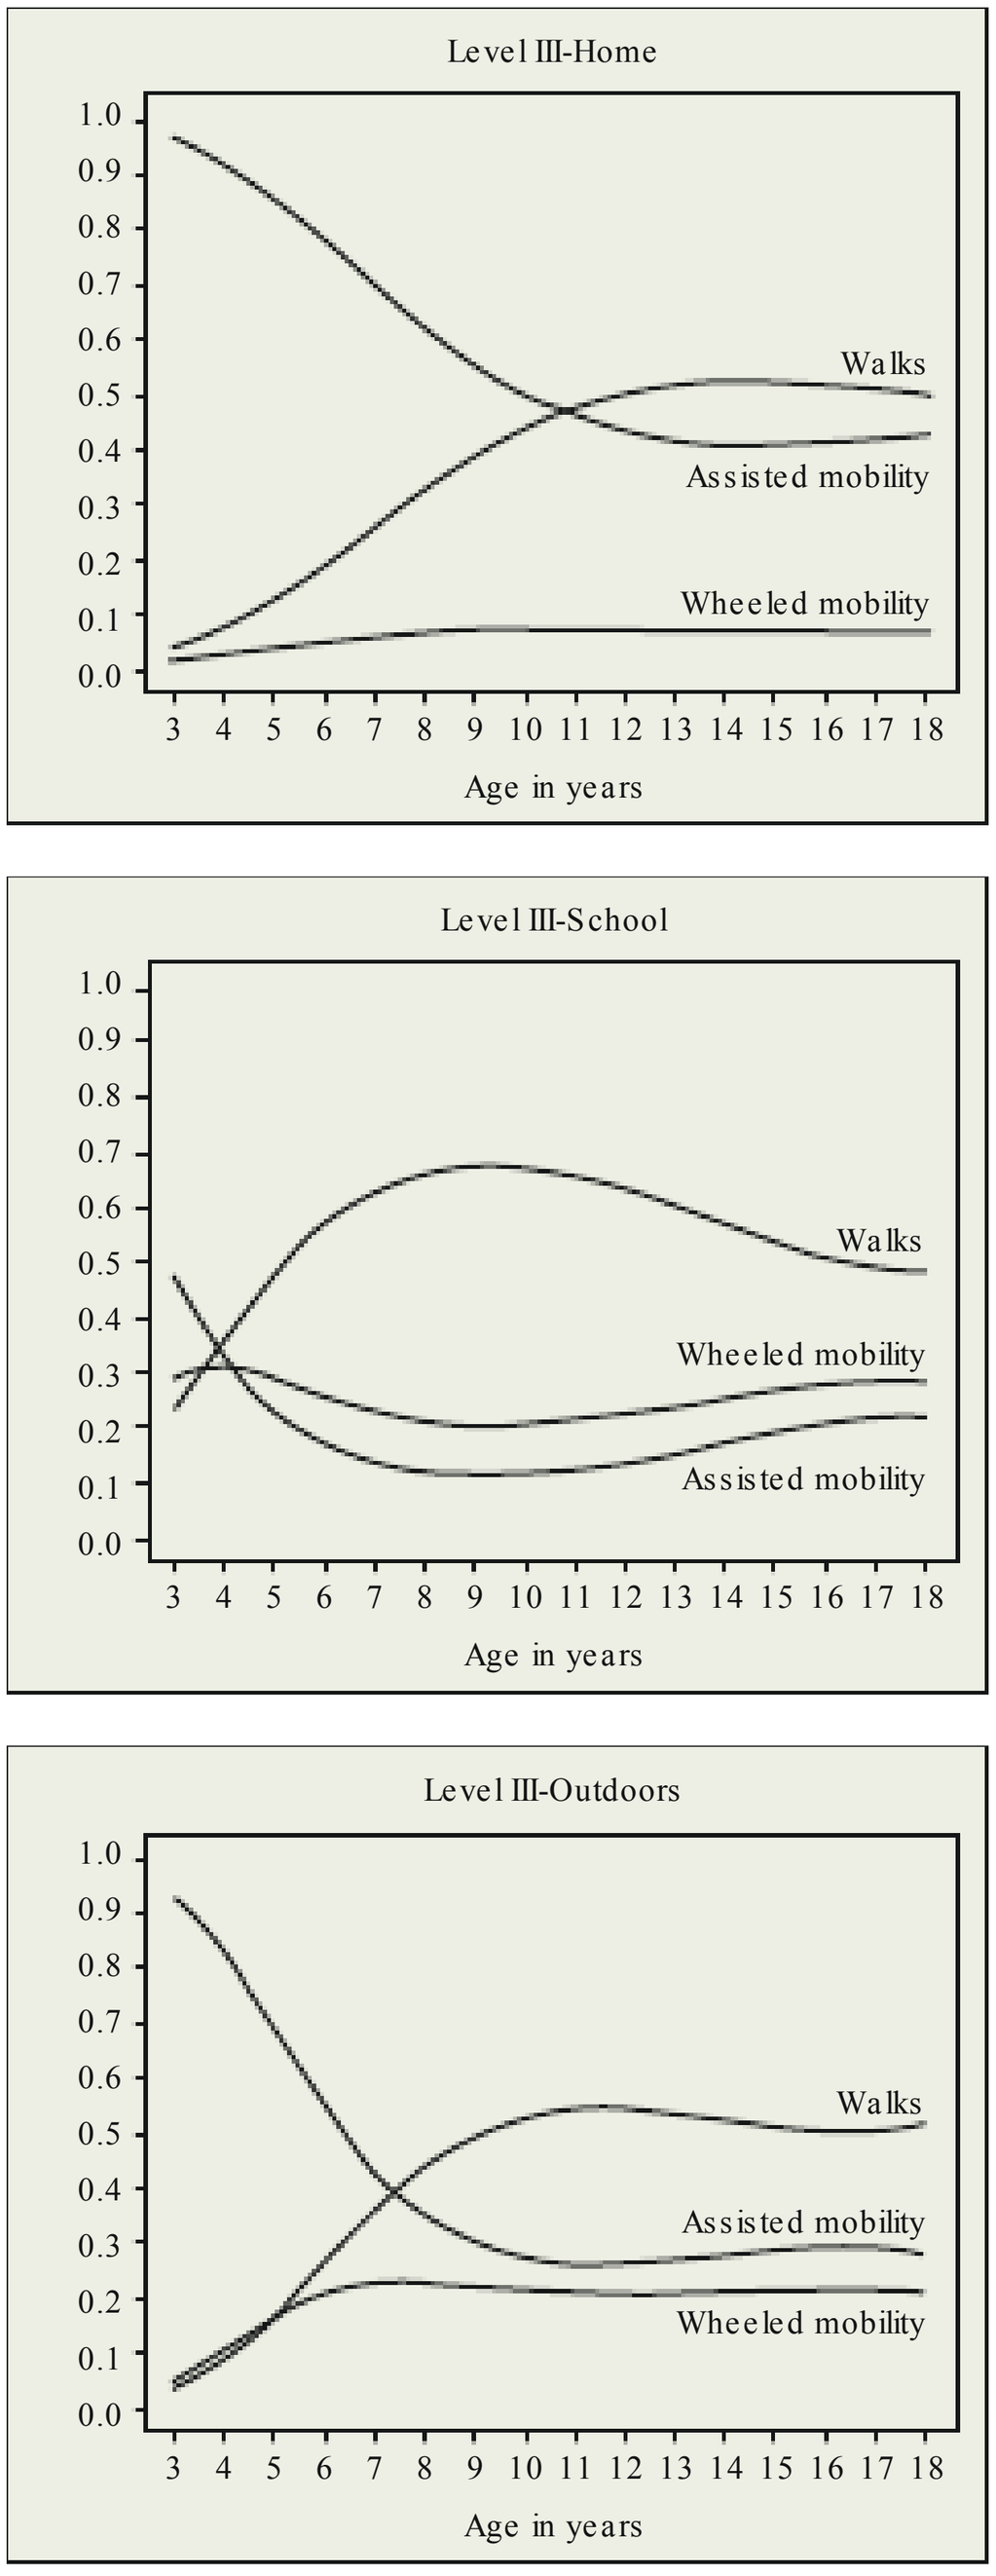


FIG. 19.7 Estimated probabilities of walking, wheeled mobility, and mobility with physical assistance as a function of age and environment for children and youth in GMFCS level III. (From Palisano RJ, Hanna SE, Rosenbaum PL, and Tieman B: Probability of walking, wheeled mobility, and assisted mobility for children and youth with cerebral palsy, Dev Med Child Neurol 52, 66-71, 2010.)

needs of a population that is heterogeneous in presentation of motor functioning, potential for change, and access to resources. In addition to these variances, characteristics of physical and social environments change as children get older and depend as well on what children want to do or need to do at their school and in the community. It can be challenging to determine what works best for whom and at what stage of life.[231] There is no singular right way to provide physical therapy interventions for children with cerebral palsy.[231] Evidence-informed decision making not only takes into consideration research evidence but also the therapist's clinical expertise and the values of a child and family, professionals, and society. These may overlap.

Family and Relationship-Centered Services

Family-centered care encompasses a set of values that improves parents' satisfaction with services and reduces parental stresses.[214] Therapists recognize that each family is unique and that parents know their child best. Therefore, they respect and encourage the family's roles and responsibilities as advocates for their child and are accepting of their autonomy in making choices.[16,196,279] Therapists strive to provide coordinated, collaborative, and comprehensive care in a respectful and supportive manner and are responsive to information needs, sharing general and specific information in a way that is most useful and meaningful to the family. Families value a therapist's honesty, commitment to their child, and belief that what they are doing is making a difference for their child.

Relationship-centered care recognizes that the formation and maintenance of relationships that value the perspectives of all players in the service delivery process are central to care and can be a source of satisfaction and positive experiences for all.[27,196] These include relationships between and among families, practitioners, organizations, and communities. Positive relationships result in mutually supportive interactions characterized by respect, trust, agreed-upon goals, and shared planning and decision making.

Collaboration in Setting Goals and Intervention Planning

Family–therapist collaboration in setting goals and deciding on how to achieve them can increase children's goal attainment, parental feelings of competency, and parental awareness of learning opportunities in daily activities. Goals should be meaningful to children and families in their everyday lives and are therefore determined based on a their concerns, needs, expectations, priorities, and values.[279,311] The process of goal setting is iterative. Goal attainment should be evaluated regularly in order to modify the intervention plan based on progress or lack thereof and the child and family's input.[367] The latter can be promoted by drawing attention to the gains the child is making, listening to parental concerns, and recognizing the personal values and strengths of the child, the family, and the community.[247] Parents value interventions that focus on short-term, realistic, small, and achievable goals.[202] If a family's goals are not realistic, therapists need to offer hope but be honest; sometimes they may serve as an outlet for a family's anger and fear.

Across the life span, physical therapy goals for people with CP encompass all components of the ICF: minimizing the impact of impairments, preventing secondary impairments and physical deterioration, maximizing motor function, and

addressing environmental factors[273] with the overall aim of participation in age and developmentally appropriate home, leisure, educational, social, and employment activities and optimizing quality of life. Achievement of these goals includes the optimization of musculoskeletal function, enhancement of functional postures and movements, and attainment of fitness and overall health. Physical therapists must also be cognizant of environmental and personal factors that could be facilitators or barriers to activity and participation when planning interventions.

Physical therapy interventions for children with CP have evolved through research and knowledge of movement science, ecology, and family systems. Earlier assumptions based on neuromaturational theories suggesting that the development of movements and motor skills result from the neurologic maturation of the central nervous system have evolved. More recent theories describe motor development and coordination as emerging from the interaction of many subsystems in a task-specific context, suggesting a more active model of motor learning.[128] Motor control theory, dynamic systems theory,[88] neuronal group selection theory,[150] grounded cognition,[222] and motor learning strategies have provided newer conceptual frameworks for physical therapy interventions for children with CP.[103] For example, neurodevelopmental treatment (NDT) treatment, an approach that has evolved from the early work of the Bobaths, incorporates more recent principles and practices.[37,170] Physical therapists use goal-oriented, activity-focused, task-oriented, context-focused, child-focused, and ecologic interventions that have emerged based on contemporary knowledge and research.[128] Application of contemporary theories of motor development and control are described in Chapter 3.

An approach to formulating an intervention plan to address goals is to (1) identify child, family, and environmental strengths specific to the goal; (2) identify aspects of the child, family, and environment that need to change to achieve goals; and (3) evaluate strengths and what needs to occur to achieve the goals.[278] Some goals may be achieved by focusing on personal attributes or modifying environmental factors. Personal factors might include the child's interest in and understanding of the goal and motivation to improve performance. A child's body functions and structures may need to be addressed to achieve other goals. It cannot be assumed that treatment of a specific impairment will lead to improvement in the ability to perform tasks in daily life.[273,400] Therapists use clinical reasoning skills to determine which intervention or combination of interventions is appropriate to achieve goals.

Treatments can be eclectic, including combinations of interventions for an individual child, while adhering to common principles. Despite the variety of approaches espoused and followed, any treatment plans and practice for children with cerebral palsy can be underpinned. We recommend an evidence-informed decision-making process for intervention planning that reflects child and family values, research evidence, and clinical expertise. General recommendations are included in Box 19.3.

BOX 19.3 General Recommendations for Planning Interventions for Children and Youth With Cerebral Palsy

- Family-centered and relationship-focused services
- Address child and family priorities and information needs
- Effective communication and coordination with other service providers
- Goal-focused
  - Meaningful to and set collaboratively with child and family
  - Achievable
  - Revisited regularly
- Individualized intervention plans
- Attention to relationships among body functions and structures, activities and participation within the context of personal and environmental factors
- Management of health and co-morbidities
- Prevention of secondary impairment or functional deterioration
- Goal-related activities as follows:
  - Age and developmentally appropriate
  - Active rather than passive
  - Functional
  - Fun and motivating
  - Challenging
- Incorporate motor learning strategies
  - Problem solving
  - Task specificity
  - Active trial and error
  - High-frequency of practice
  - Self-correction, exploration
- Learning and practice in real-life environments
- Compensations, task modifications, or environmental adaptations to accommodate a child
- Life span approach

How Much, How Often?

Decisions on the amount of physical therapy (how often, how long, over what period of time) are difficult and require consideration of many factors. To a large extent, decisions for both public funded services and services reimbursed by health insurance plans are constrained by policy, resources, and costs. Episodes of care focused on achievement of specific goals are an alternative to the traditional practice of regularly scheduled sessions for long periods of time. Short concentrated periods of intensive intervention during times of readiness have been advocated. Group sessions for children with similar goals have the potential to increase interest, motivation, and learning through peer modeling as well as reduce costs. The amount of direct therapy service may be less important than the total amount of practice and the opportunity for practice in natural environments. Similarly, the child's physical activity throughout the day and participation in community recreation and sports may be a consideration in the decision-making process.

Therapists must consider various ethical principles when providing services. Beneficence (doing what is best for the greatest number of people), non-maleficence (doing no or the least harm), and justice (doing what is fair and equitable, including moral and responsible use of family and institutional resources) must be considered when making decisions about service delivery at individual, programmatic, and institutional levels. Many of these issues involve some amount of physical therapy, which varies depending on the resources available, complementary programming, client goals, parental needs and desires, and the child's response to intervention. Optimal frequency is unknown, but periods of more intensive intervention have resulted in attainment of specific treatment goals at levels that were maintained when frequency was decreased, provided the skills were incorporated into daily

functional activities. Families and therapists must consider costs, accessibility, time, and the effect of the intervention on family dynamics. A regimen of short periods of intensive therapy separated by periods without therapy may allow for optimal motor gain and may be less demanding for the children and their families.[69,361]

The research on intervention intensity provides some guidance for developing service delivery models; however, the treatment frequencies in studies are often much higher than are realistically available in many situations. Intensive therapy, more than three times a week, compared to less intensive frequencies, may improve functional motor outcome as measured by the GMFM but with a modest effect size of questionable clinical significance, which must be considered in the context of fatigue—and can be tiring and stressful for children and families, with consequent low compliance and high costs for health care systems.[8] Many studies investigating the frequency of treatment or gross motor function have shown equal improvements between intervention provided and conventional therapy, and those with significant results in favor of intensive training tend to have a high risk of bias.[360]

One recommendation for children with CP who demonstrate continuous progress toward goals is one to two times per week or every other week; however, more intense frequencies or a less frequent consultative model will be appropriate in differing situations.[13] Families may need more intense input for specific circumstances such as pre-, peri-, and postsurgery. Periods of change and transition, such as school entry, are critical times, which may require extra support.[300] Episodes of more intensive frequencies are often alternated by periods of monitoring and consultation.

Models of service delivery, public health funding, private resources, and available family time can also impact decisions on amount of therapy.[277] Children with CP often receive therapy in more than one setting.[277] They often receive services at a treatment center and in a school setting, either with the same or a different therapist. Some families may purchase additional private services to augment or substitute for publicly funded services if these are deemed insufficient.[117] Ideally concurrent therapists can enter into cooperative relationships with each other; however, they may find themselves in situations of conflicting rehabilitation principles and practices. Collaboration and communication can help to avert such situations.[398]

Parents often consider complementary or alternative therapies for their children. The primary reason is to complement conventional approaches. Other reasons include a desire for more therapy, dissatisfaction with present therapy, the belief that their child could do better, and relief of symptoms.[173,328] Many complementary or alternative interventions lack research evidence.[265] Some families may pursue treatments even when shown to be ineffective. For example, some parents have had their children participate in hyperbaric oxygen programs, despite studies showing this treatment to be ineffective and associated with adverse effects.[234] Families may engage in treatments, such as massage, that do not achieve specific therapy goals but may improve feelings of well-being for children and their parents. [128] Alternative and complementary therapies are often expensive, and some professionals may not consider certain choices appropriate. If families choose to take an approach other than the one offered by a therapist, it is necessary to respect their choice. Therapists should not react defensively but rather should provide impartial, objective information about the therapies in question.

The following sections summarize interventions for children with CP at different ages. In addition to research evidence, child and family values and preferences, environmental strengths and potential barriers, and therapist practice knowledge are among the factors discussed when collaborating with families to make evidence-informed decisions.

INFANCY

Infants grow and develop in response to being loved and nurtured by parents and caregivers in a home environment. Despite being dependent in most aspects of life, infants interact with and develop an understanding of the people in their lives, their surroundings, and themselves. From the time of birth, a child with CP may not demonstrate the usual activities associated with infancy. As a result, parents of infants with CP may not receive some of the positive aspects of the nurturing experience and the satisfaction of observing the development of typical motor skills. Parents must cope with the impact of the diagnosis and the grieving process that accompanies the awareness that some of their hopes and expectations for their child may not be realized. They may be overwhelmed with the uncertainty that the future holds for them, their child, and their family. Many parents are also concerned with the immediate issues of providing basic infant care and may be challenged with the incorporation of the specialized care necessary for their child's optimal development while establishing relationships with health care professionals.

Physical Therapy Examination and Evaluation

Examination provides information on which to base prognosis, sometimes diagnosis, and establishes a baseline for the monitoring change through growth, maturation, and intervention. Therapists must determine the environment of an infant and the resources and the competencies and concerns of the family.

Various elements of movement and posture combine to produce gross motor skills. These skills include the ability to align one part of the body on another; to bear weight through different parts of the body; to shift weight; to move against gravity; to assume, maintain, and move into and out of different positions; and to perform graded, isolated, and variable movements with an appropriate degree of effort. When functional motor skills are examined, proficiency in incorporating these elements into purposeful and efficient movement must be evaluated. The effects of reflexes and postural reactions on positioning, handling, and movement should be considered. Standardized testing using the GMFM can be introduced in infancy and results shared as appropriate for an individual family's journey. Assessments of seating, feeding, or respiratory problems may be necessary for infants with problems in these areas. Growth is often affected in children with CP, as it is influenced by feeding, exercise, and energy efficiency.[205] Therefore therapists should be mindful of an infant's growth. When assessing infants, it is important to be aware of the influences of temperament, behavioral state regulation, and tolerance of handling on performance.

Physical Therapy Goals, Outcomes, and Intervention

A primary goal is to educate families about CP so they have the necessary information to make decisions related to physical therapy management of their child[103] (www.afcp.on.ca/guide.html).

Infancy is an important time to introduce the concepts of collaborative goal setting and ongoing communication. It may be difficult for families to contemplate specific goals while they are coping with a diagnosis of CP and are uncertain or even unrealistic about prognosis. Parents' goals may be overly optimistic during infancy. Therapists must be realistic about the prognosis and the efficacy of physical therapy while remaining positive, hopeful, and supportive.

Movement is an important component in the learning and interactions of infants. In babies who have CP, the nature and extent of their impairments affect their potential to develop and learn through movement, develop gross motor skills, and interact with their parents and their environment. Physical therapy focuses on facilitating parental caregiving and interactions and providing opportunities for optimal sensorimotor experiences and skills in enhanced environments. These allow infants to achieve their potential in developing relationships with others, developing play skills, and exploring their environment. Early intervention, within the first 2 years, is advocated to take advantage of the time when the brain is most plastic due to active sprouting and pruning in response to activity[236,245,365] despite there being no definitive support for its efficacy in changing outcomes.[54,342] Infants not diagnosed but at risk for CP should have access to early intervention. The observations of a physical therapist can facilitate making a diagnosis, and waiting for an absolute diagnosis of CP may preclude them from receiving intervention at a time of greater brain growth and plasticity.[103,245]

Everyday handling and positioning of infants by caregivers will influence development.[222] Activities such as prone positioning, promoting head control, weight bearing, encouraging sitting and standing, and midline hand activities provide enhanced perceptual-motor experiences to promote abilities including strength, postural control, hand activity, and social interaction.[222] Therapy should focus on the development of well-aligned postural stability coupled with smooth mobility to allow the emergence of motor skills such as exploration of one's and other's bodies, reaching during play, object interaction, and optimal transitional movements and postures. These skills allow infants to gain information about the interrelationships among their own bodies, objects, and people[222] and attain optimal mobility to facilitate play, language development, social interaction, and exploration of the environment.

Movements that include all planes of movement (anterior-posterior, then lateral, then rotational), selective control of body segments, weight shifting, weight bearing, and isolated and bimanual movements should be incorporated into gross motor exercises and activities. Abnormal postures and movements can make some infants challenging to handle and position. Physical therapists can promote ease and confidence in the handling and caring of infants with these problems. Parents are coached in positioning, carrying, feeding, and dressing techniques that promote comfort and symmetry, limit dysfunctional posturing and movement, facilitate postural stability and functional motor activity, and limit secondary impairments. They must learn how to be sensitive to their child's behavior and response to being handled.[103] The principles guiding these methods are to use a variety of movements and postures to promote a sensorimotor experience, to frequently include positions that promote the full lengthening of spastic or hypoextensible muscles, and to use positions that promote active, functional movement. The principles of central nervous system plasticity suggest that intensive, repetitive, task-specific intervention should be incorporated into practice. Even at a young age, focus on self-exploration, active trial and error, variability of practice, testing limits, and high frequency of practice are desirable components of treatment.[103,222] Some treatment approaches facilitate movements through handling, to guide self-generated movement, which is withdrawn as these children initiate them on their own, whereas others refrain from handling, allowing infants to learn through trial and error, using adaptive motor strategies and their own motor learning processes without concern about quality of movement.[103] Clinicians need to find a balance between hands-on and hands-off techniques.[231]

Some children will move through the typical developmental sequence of rolling, sitting, crawling, standing, and prewalking skills, whereas other children will be limited in their gross motor trajectories and require environmental adaptations. The stage at which this happens depends on the severity of the impairments; in some children, it may occur early in life.

Some infants will require environmental adaptation to achieve interaction with their bodies, object, or people. In children classified as level V on the GMFCS, slight gains in head control may be a goal, whereas a progression through the motor development sequence is expected for children classified as level I. Therapeutic interventions should not limit infants' spontaneous desires to move and play and explore their environments, because even very young children need to be able to assert themselves and manipulate their world.[55] Useful examples of various activities and strategies are noted by Dirk,[103] Lobo, [222] and Cameron et al.[54]

Ongoing support and encouragement are essential. Clearly written, illustrated, and updated home programs can be beneficial. Incorporating therapeutic activities into daily routines can ease the burden on home programs on families. Computer-generated programs or taking a video can be used to produce personalized, effective, and efficient information regarding activities, positioning, and exercises.

Equipment may facilitate activities when impairments otherwise prevent their development. For example, the sitting position promotes visual attending, upper extremity use, and social interaction. Infants with CP may be unable to sit independently, may sit statically only with precarious balance, or may not be able to be positioned in commercially available infant equipment. Customized seating or adaptations to regular infant seats may be necessary to allow function in other areas of development to progress. Infants who function at GMFCS levels IV and V should be provided with postural management programs for sleeping, sitting, and standing with postural support for sitting at 6 months of age and standing at 12 months.

The care of an infant exhibiting asymmetry, extensor posturing, and shoulder retraction illustrates these approaches. Such an infant should be carried, seated, and fed in a symmetrical position that does not allow axial hyperextension and keeps the hips and knees flexed; however, a variety of postures are necessary to allow elongation of all muscle groups and experiences in different positions. The therapist should work to ensure that no one position dominates daily activity. Positioning of or playing with the upper extremities to allow these infants to see their hands, practice midline play, reach for their feet, or suck on fingers or mouthing toys can promote sensorimotor awareness. Toys may need to be adapted to facilitate age-appropriate activities.

The frequency of intervention should be tailored to meet the needs of a family. Intensive therapy may help parents become comfortable with handling skills but may be challenging for parents to commit to, may be limited by resources, and does not necessarily demonstrate better motor outcomes compared with less frequent interventions.[365] Some settings may provide home-based early intervention programs that emphasize coaching parents in managing daily routines that include therapeutic input.

Role of Other Disciplines

At all ages, physical therapists work together with specialists from other disciplines to provide interprofessional care. Occupational therapists may be involved in upper extremity function, particularly as it relates to play and eye-hand coordination, as well as in sensory modulation/regulation. Speech and language therapists address early communication development. Various team members may address oral-motor and feeding issues. Community infant development workers may be involved in home-based programs to promote all areas of progress. Social workers may help parents through the grieving process, explain programs, and direct them to appropriate resources. Parent support groups or meetings with parents who have been through similar experiences may be helpful. A variety of medical and surgical specialists may be consulted, depending on individual needs.

PRESCHOOL PERIOD

During the preschool years, the development of locomotor, cognitive, communication, fine motor, self-care, and social abilities promotes functional independence in children. This developmental process is a dynamic one in which all of these areas constantly interact with one another. The children's environments remain oriented toward the parents, family, and home during this period, but they begin to interact with the outside world. Child care centers, babysitters, nursery schools, siblings, and playmates may become part of a preschooler's world.

For children with CP, limitations in motor activities may restrict participation in learning and socialization and limit independence. Parents become more aware of the extent and impact of their children's difficulties in all areas of development. These may include their child's ability to participate in and become integrated into preschool and community recreational activities, their child's development of cognitive and communication skills, and the long-term effect of their child's disability on future life and independence.

Physical Therapy Examination and Evaluation

Assessment of activity assumes a primary focus, but it is important to determine the interaction of impairment and activity and relation to participation. Through examination and evaluation, therapists document change and collaborate with families to ensure that goals and interventions address family priorities and concerns. Examination may focus on positioning and mobility for functional skills; however, therapists need to be cognizant of a child's communication, fine motor, self-care, sleep, and social functioning and how these interrelate with gross motor skills. The child's need for the caregiver assistance, adaptive equipment, and environmental modifications necessary to perform activities are important components of evaluation. Factors such as location of the examination, people present, and the child's behavior, attention, and cooperation may affect the examination and evaluation process. Parents or other caregivers should be asked to comment on whether a child's performance is characteristic of his or her abilities.

Physical Therapy Goals, Outcomes, and Intervention

During the preschool years, a child's potential for attaining motor skills can be predicted with a greater degree of accuracy than during infancy, as the influences of impairments, activity limitations, and personal and environmental factors are more apparent. Families become more skilled at collaborative goal setting and comfortable communicating with service providers. Therapists can work with families to develop goals that are meaningful, realistic, noticeable, and measurable. The continued development of these skills empowers parents to make decisions, solve problems, and set priorities, as well as to become effective advocates for their children and themselves.

Physical therapy goals focus on promotion of control and alignment of postures and movements conducive to musculoskeletal development, fitness, gross motor, manual, and self-care activities, and participation. Muscles need to be extended to their limits on a regular basis to maintain range and used adequately and frequently to optimal strength; bones need compressive forces to stay strong; and the cardiovascular system needs to be challenged regularly at levels intense enough to maintain endurance and fitness.[86,125,388] During the preschool years, the focus of physical therapy is often on a child's ability to achieve independent mobility. Specific mobility goals will depend on the GMFCS level. Goals for children functioning at GMFCS levels IV and V may be achieved by using special equipment and adapted toys, rather than progressing through the normal developmental sequence.

In many cases, achievement of physical therapy goals serves as a building block for interventions by other disciplines to improve communication, self-care, social interaction, and problem solving. Therapists respect the priorities of children and families as well as other professionals when determining goals, as it may not be possible to work on all areas at once. Interventions should be goal directed, functional, motivating, and fun for the child.[82,189]

Home programs continue to be important for regular practice of activities to maximize potential and build confidence. These programs may also be carried out in other settings such as child care, preschool, or recreational sites. This can promote learning in a child's natural environment and lessen the burden on families as parents can struggle the stresses of balancing therapy programs and everyday life.[202]

Managing Primary Impairments and Preventing Secondary Impairments

Spasticity management may be introduced during the preschool years with the goals of preventing secondary impairments such as contractures and pain, ensuring comfort and ease of positioning and caregiving, improving functional movement, and reducing the need for orthopedic surgery. However, reducing spasticity will not necessarily improve motor function or participation, as only a single impairment in a multi-impairment condition is addressed.[400] Coexisting impairments such as weakness and selective motor control and contextual child and environment factors influence function.

Stretching has been shown to cause a short-term decrease in spasticity, but changes are minor and not sustained.[295]

Longer-lasting interventions are operative or pharmaceutical. Various oral, intramuscular, and intrathecal medications are used to reduce spasticity in people with cerebral palsy. A widely used method of spasticity intervention is the injection of small quantities of botulinum toxin A (Botox) into muscles to prevent the release of acetylcholine at the neuromuscular junction and impact activation for up to 4 months with peak effects observed 2 weeks after injection. The drug is expensive but covered often by insurance. Targeted muscles are those that have good ROM but exhibit spasticity that interferes with function and those most prone to developing contractures.[223] Evidence exists for injections of the calf muscles for equinus, the upper extremities, and the hip adductors for spasticity and pain control in children undergoing adductor-lengthening surgery.[25,116,225,339] Some studies of lower limb multilevel injections, including the iliopsoas, hamstrings, and rectus femoris muscles, have also demonstrated small improvements in gross motor functioning measured by the GMFM-66 and gait analysis.[98,324,333] Botox combined with therapy has been shown to be effective in improving positioning, ease of care, and comfort for nonambulatory children.[72] Botox addresses the impairment of spasticity and therefore outcomes are optimal when combined with interventions such as casting, orthotics, night splinting, positioning (prolonged stretch), and targeted motor training focus on coexisting impairments such as hypoextensibility and weakness in conjunction with functional motor activities.[97,223] Phenol injections may be used in conjunction with Botox to allow an increase in the number of injections at the maximal recommended dose.[139] Treatment algorithms can provide strategies to treat spasticity with Botox.[75] Studies following children who have received repeated injections of Botox over a period of a few years have had methodologic challenges and report varying results. Continued reduction in spasticity and improved ROM and gross motor function have been noted.[163]

Some have questioned whether Botox can prevent contractures and even question whether repeated injections may have a cumulative adverse effect on muscle growth in children with CP.[355] Longitudinal studies of the effects of Botox on muscle growth and morphology are needed. A systematic review of randomized controlled trials (RCTs) concluded that respiratory infection, bronchitis, pharyngitis, asthma, muscle weakness, urinary incontinence, seizures, fever, and unspecified pain have been related to the use of Botox in children with CP.[1] However, the rate of adverse effects has been determined to be no greater than those typically experienced by this population.[268] Discussion of potential advantages and disadvantages of options for spasticity management is recommended as part of the decision-making process.

The use of oral medications has been poorly studied, but they may be appropriate for some children.[106,370] Children must be assessed carefully for appropriateness and monitored closely for side effects. A pilot study showed that Artane in children with dystonic CP did not alter their dystonia or upper limb function but was associated with achieving therapeutic goals.[301] Baclofen, a synthetic agonist of gamma aminobutyric acid, has an inhibitory effect on presynaptic excitatory neurotransmitter release, reducing spasticity in individuals with CP.[294,370] Oral doses high enough to give the proper concentration in the cerebrospinal fluid can, however, cause side effects such as drowsiness.

If this is a problem, baclofen can be administered intrathecally by a continuous infusion pump implanted in the abdomen that releases the drug at a slow, constant rate into the subarachnoid space once a child weighs 15 kilograms.[370] Intrathecal baclofen reduces spasticity most noticeably in the lower extremities. Improvements in function and ease of care and a reduced need for orthopedic surgery have been documented.[51] It is used most often in children with quadriplegic CP but has also been shown to improve the quality of gait and ability to perform gross motor activities in ambulatory children.[44,294] Complications related to catheter and pump malfunction, infection, leaks, or dosing have been reported. Some are associated with significant morbidity, but others are common and manageable in most cases.[199] Intrathecal baclofen has also been beneficial in treating patients with generalized dystonia, a difficult problem to manage. Levels of evidence are low but in addition to improved dystonia, subjective improvements have been reported in QOL, ease of care, speech, swallowing, posture, and upper and lower extremity functioning.[2,253]

Selective dorsal rhizotomy (SDR) is a neurosurgical procedure in which up to 60% to 70% of the sensory nerve rootlets for the lower extremities are cut selectively to reduce afferent drive to the reflex arc aiming to create a balance between the elimination of spasticity and preservation of adequate strength.[6,303] SDR is considered a safe procedure that offers significant and lasting functional gains to properly selected children. Selection criteria vary among institutions; however, it may be most effective for children functioning at GMFCS levels I to III, aged 3 to 8 years, with spastic diplegia, a history of prematurity, good selective control of muscles, lack of contracture or deformity, good cognitive abilities, motivation, parental support, and access to therapy.[148] Intensive postoperative physical therapy is necessary to address the resulting weakness (Fig. 19.8). Abnormalities in patterns of muscle activation may persist after SDR because of continuing problems with motor control and coordination. Long-term studies of 15 to 20 years have demonstrated lasting improvements in lower limb muscle tone, gait, gross motor function, and performance of activities of daily living; however, most children remain within their GMFCS level.[6]

All methods of spasticity management are considered to be optimized by therapy co-interventions. Therapy interventions include strengthening, stretch through exercise or prolonged

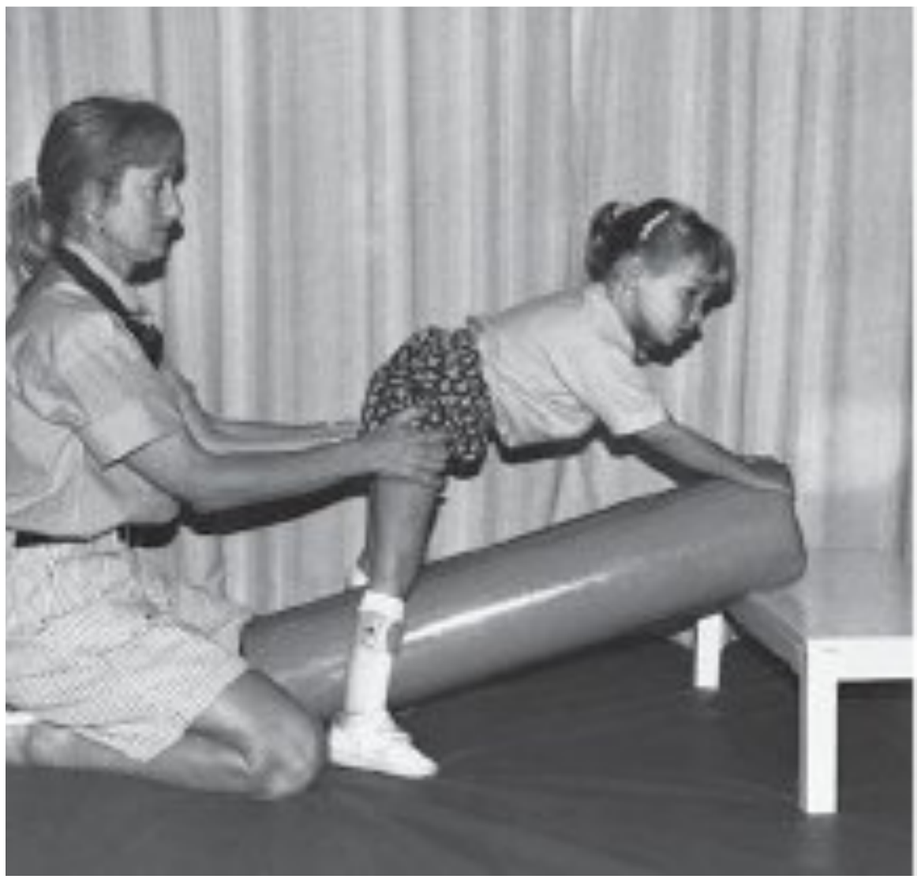

FIG. 19.8 Exercises after rhizotomy are frequently directed toward increasing force generation of extensor muscles.

positioning through splinting, orthotics, or casting, and interventions to improve gait and functional motor skills.[295] Physical therapy to optimize muscle strength involves the child performing activities that produce both concentric and eccentric muscle forces. These may include transitional movements against gravity, ball gymnastics, treadmill use, tricycle riding, scootering, and ascending and descending stairs.

Limitations in ROM can be observed in preschool children, particularly those in GMFCS levels IV and V. Considerable resources are directed toward maintaining or regaining muscle extensibility and joint mobility.[388] Ideally, range of motion is maintained through activities that involve active movements through full range of motion. A classic study by Tardieu found that plantar flexor contractures in children with CP were prevented if the muscles were stretched beyond a minimum threshold length for at least 6 hours during daily activity.[352] Threshold length was the length at which the muscle began to resist a stretch. However, the data prompting this statement are suggestive rather than conclusive. Stretching is unlikely to happen spontaneously in children with spastic CP who have limited active movement, particularly those at GMFCS levels IV and V. Knowledge is lacking on whether prolonged stretching and other interventions within the scope of physical therapy practice are effective in preventing muscle shortening in children with CP, particularly during periods of growth.

Consequently, combinations of approaches are often used, making it difficult to assess the usefulness of individual approaches.[33] Passive stretching programs are often recommended to maintain muscle length, but evidence of effectiveness and clinical relevance is limited and conflicting.[295,388] Some parents report that ROM exercises cause pain,[351] whereas others believe they relieve muscle cramps.[295]

Sustained low load passive stretching of longer duration has been shown to be more effective in increasing ROM and in reducing spasticity.[295] It can be achieved through casting, orthoses, or positioning. It is important to not position muscles at their fully lengthened state, as this can cause discomfort. A position just short of the initial catch has been advocated. This can be altered as muscle lengthening occurs. A single cast application or serial casting (the successive application of casts with progressive increases in the amount of stretch) has been used as a method of providing prolonged stretch to the calf muscles.[33,47] After serial casting of the foot and lower leg for equinus, often from 3 to 6 weeks, children with CP demonstrate decreased resistance to passive stretch and increased dorsiflexion end range.[47,362]

Peak strength will occur at longer muscle lengths. Substantial reduction in gains may occur following cast removal, suggesting the need to follow casting with orthoses.[362] Although it is clear that at least temporary mechanical changes result from casting, the precise nature of the changes and whether they involve an increase in the number of sarcomeres are unknown.[33] Casting has also been used for other muscle groups, such as the hamstrings and the upper extremity musculature. Research on the impact of casting on gait or motor function is inconsistent and lacks participation outcomes.[33,362] Clinically, casting has been observed to prevent surgery, but this has not been substantiated by research. Concern has been expressed that immobilization of growing muscle in a lengthened position can result in sarcomere loss and a reduction of the muscle belly girth with adaptation by lengthening of the tendon, exacerbating the altered morphology.[144]

Positioning, serial casting, and Botox injections are often used in combination to achieve optimal improvement.[33] Clinical reasoning suggests that Botox addresses spasticity and casting decreases contracture, but currently, no clear evidence indicates that casting, Botox, or the combination of both is superior to other options in the treatment of equinus. Analysis of research is complicated because of differing protocols and other methodologic problems. Ultimately, treatment choices should depend on research evidence combined with considerations such as availability, cost, convenience, family preference, and therapists' expertise and experience with the treatments and follow-up care.[33] Likewise, it is difficult to validate the effectiveness of interventions such as muscle strengthening and functional activities in conjunction with spasticity intervention, but the clinical value of these practices has been observed, and they are strongly advocated.[211]

The integrity of joints, particularly the hips, is a concern even at a young age. Early identification of subluxation can help prevent progression to dislocation, the complete lateral displacement of the femoral head from under the acetabulum through timely referral for orthopaedic assessment and management.[152,391,403] A program of surveillance based on GMFCS level and radiologic assessment of hip migration percentage, coupled with a clinical assessment of changes in ROM, muscle tone, spinal alignment, sitting tolerance, gait, pelvic obliquity, leg length discrepancy, or hip pain, is recommended. Clinical orthopedic assessment at diagnosis and an anteroposterior radiograph at 12 to 24 months of age or at diagnosis if older than 24 months and ongoing follow-up based on GMFCS level and clinical signs are recommended.[403]

Physical therapists provide education for families and may be involved in coordination of hip surveillance services.[134] They are often the first to recognize clinical warning signs of hip changes. Nonoperative interventions such as sleep positioning, seating, abduction bracing, and botulinum injections have not been shown to reduce the need for surgery or improve hip structure in a RCT,[391] but they may have value in positioning for comfort and function, maintaining muscle extensibility, and reducing early hip problems.[42,244] The impact of prophylactic interventions has been explored in a prospective study of groups of children receiving differing management.[152] Proactive practices—including early treatment of spasticity through rhizotomy, Botox injections, and intrathecal baclofen—and early detection and surgery to prevent dislocation were associated with improved ROM in nonambulatory children; a decrease in orthopedic surgery for contracture, rotational deformity, and foot deformity; and a reduction in salvage operations for dislocated hips, from 40% to 15%.

Lower extremity orthoses may be used to reduce primary impairment, prevent secondary impairment, and facilitate efficient and effective walking and other functional activities. Specific goals are to limit inappropriate joint movements and alignment due to spasticity or weakness; prevent contracture, hyperextensibility, and deformity; enhance postural control and balance; reduce the energy cost of walking; and provide postoperative protection of tissues.[247] In most studies, the use of ankle-foot orthoses (AFOs) compared with a barefoot condition has shown positive effects on gait kinematics and kinetics, including improvements in ground reaction forces, plantar flexion moments, stride length, foot clearance in swing, heel strike at initial contact, equinus during midstance, related hip and knee movement, temporal-spatial measures, and sometimes function

measured by the walking, running, and jumping dimensions of the GMFM.[119,247,249] Research suggests that only orthoses that extend to the knee and have a rigid ankle, leaf spring, or hinged design with plantar flexion stop can prevent equinus deformities.[247,249] Little more than anecdotal observational evidence suggests that using orthoses to control movement into plantar flexion prevents muscle shortening and therefore joint contractures or deformity. Controlled trials are difficult to carry out, as contractures develop over many years. Despite these dynamic benefits, orthoses do not show clinically significant changes in the static bony alignment of the foot and ankle during weight bearing based on radiologic examination.[386] Results are variable depending on the specific gait problems of the child and the type of orthosis, demonstrating the need for individual assessment and prescription.

Many variations of AFOs are available. Decisions are made based on the biomechanical and functional needs of a child. Therapists and orthotists work together closely to decide on the optimal orthoses based on treatment goals. Solid AFOs are used if maximum restriction of ankle movement is desired. Children who would benefit from freedom of movement at the joint can use hinged AFOs, sometimes with stops to prevent movement into excessive plantar flexion. Hinged AFOs permit dorsiflexion, which allows stretching of the plantar flexor muscle group during walking, and have been found to promote a more normal and efficient gait pattern than rigid orthotics without a predisposition to crouch gait. Dynamic, energy storage and release, or posterior leaf spring orthoses, which are intended to prevent excessive equinus while mechanically augmenting push-off, have been found to reduce equinus in swing, permit ankle dorsiflexion in stance, and absorb more energy during midstance, but they actually reduce desirable power generation at push-off.[271] Foot orthoses, or supramalleolar orthoses, may be used for children with calcaneal valgus alignment or pronation but do not require the ankle stabilization of an AFO. Materials from a consensus conference on lower limb orthotic management of CP are available at www.ispoweb.org.[249]

Tape or elasticized garments have been used to assist children biomechanically and facilitate postural control function. Kinesio taping has been shown to improve dynamic activities, possibly through enhancement of the cutaneous receptors of the sensory system to improve proprioception resulting in improvement of voluntary control.[186] Garments made of spandex or neoprene can apply dynamic compression and are also hypothesized to provide somatic inputs, specifically proprioceptive and deep pressure, improving body awareness and muscle activation and therefore postural control.[226] In a perspective article, MacKenzie[226] stated that the limited research suggests an immediate benefit to motor function and quality of movements with some studies demonstrating short-term carryover. Skin tolerance may be an issue, and children and families sometimes find the garments uncomfortable and inconvenient for independent dressing and toileting.[122]

Children should have a variety of positions in which they can safely and comfortably function, travel, and sleep. Positioning needs vary greatly depending on GMFCS levels and personal and environmental factors.[323] Children functioning at GMFCS levels IV and V should have individually tailored postural management programs to prevent or ameliorate the secondary impairments of positional contractures and deformity, prevent skin breakdown, and facilitate function and participation.[134] Children with higher motor function may need some alterations to seating to optimize postural control outcomes, hand function, self-care, and play.[5,323] At all ages, decreased ability to change body position during sleep can cause discomfort, pain, and respiratory problems, which can result in disrupted sleep for children with CP and their families.[399] Physical therapists may be involved in promoting safe, comfortable, and biomechanically optimal sleep positions. Orthoses, splints, and bed positioning systems have been used during sleep, but care must be taken to avoid overstretched muscles, disrupted sleep, or discomfort.[145]

Comfortable and safe sitting, standing, lying, and floor play positions are important for the preschooler's development. Children having difficulty with postural control may need adaptive seating systems. These can have a positive effect on children by improving communication, upper extremity function, feeding, toileting, independence, safety, social interaction, and contentment. These benefits translate into improvements in the lives of families through valuation of their children's well-being and the added benefits of expending less parental energy in caregiving and supervision. Adaptive seating should be individualized because of the wide variation in postural abilities and alignment. Specific suggestions are included in Chapter 33, Assistive Technology. Approved car seats and restraints are necessary for safe and comfortable vehicular transportation.[224] Positioning can also contribute to pulmonary health. Children with limited movement are at risk for chest complications because of chest wall biomechanics, feeding difficulties, immobility, and poor coughing abilities. Adaptive seating or orthoses have been shown to improve pulmonary functioning, but research is very limited.[18]

Weight bearing is thought to reduce or prevent secondary impairments. Optimally, standing involves movement and activity to provide intermittent loading and muscle strain. Maintenance of lower extremity weight bearing may allow continued ability to participate in standing transfers and reduce the need for lifting when children are older. Standers are often used, starting when children are as young as 9 to 10 months and are not able to bear weight effectively on their own. Dosing recommendations based on limited research and clinical expertise include the following: 45 to 60 minutes a day to maintain or increase hip, knee, and ankle range of motion; 60 to 90 minutes a day to affect bone mineral density; 60 minutes a day in 30° to 60° of total hip abduction to influence hip stability; and 30 to 45 minutes for short-term decrease in spasticity.[275] There may also be benefits to bowel bladder function, alertness, circulation, or interactions with peers.[275] It is important to determine the actual weight being borne through the lower extremities when in a stander. This has been shown to vary from 23% to 102%, with a mean of 68% body weight.[166]

Lifelong management of pain should begin in early childhood. As noted, seating, positioning, and spasticity management can provide immediate comfort and long-term pain management through the prevention of secondary impairments such as skeletal malalignment. Therapists should ensure physical therapy interventions are as pain-free as possible but in situations when discomfort cannot be avoided, such as postoperative mobilization, the development of a positive therapeutic relationship can influence children's ability to cope with uncomfortable therapeutic procedures. Behavioral approaches such as distraction, imagery, breathing, or relaxation along with empathy, praise, and breaks can be helpful.[351]

Promotion of Activity

Complex relationships exist among the impairments of spasticity, strength, sensation, ROM, selective motor control, and cognition impacting the ability to analyze movement and provide instruction to improve performance.[358] These problems, as well as the lack of opportunity to experience motor skills in variable settings, contribute to the ability to learn movement strategies and therefore gross motor function and achievement of tasks in mobility, self-care, and social function. A child with CP may have to use different or additional cognitive strategies when planning and performing motor skills.

Physical therapy to promote activity is often intensive during the preschool years. Therapists need to recognize when it is realistic to work on a child's impairments to achieve success in an activity and when it is necessary to adapt a task or the environment. Intervention often involves components of both; however, children functioning at GMFCS levels I and II may need very little adaptation, whereas children functioning at level V may require considerable adaptation and environmental modifications. Components of the dynamic systems theory, motor control theory, and motor learning principles and strategies should be integrated into activity-oriented treatment (see Chapters 3 and 4).

Motor learning comprises a set of processes associated with practice or experience that leads to relatively permanent changes in the ability to produce skilled action (see Chapter 4). Children with CP can be constrained in their ability to learn movement strategies due to impairments of muscle tone, strength sensory processing, perceptual-motor skills, and cognition, as well as the lack of opportunity to perform motor skills in variable settings. They have difficulty analyzing their own movement and utilizing feedback to improve performance.[358] Motor memory is frequently impaired.[107] As a consequence, children with CP may use different or additional cognitive strategies when planning and performing motor skills. Limited research exists on the cognitive aspects of motor learning in children with neurologic disability, and more research is needed.[358]

Motor learning principles advocate the encouragement of movement exploration and child-initiated solutions to motor tasks, adaptation to changes in the environment, and repetitive practicing of goal-related functional tasks that are meaningful to the child.[189] Ample and variable practice in home, school, and community settings is important. Feedback is important in the process of learning skilled movement. Information is received intrinsically through a child's sensory receptors and extrinsically from external sources. Knowledge of results contributes information about movement outcome, and an understanding of performance supplies feedback about the nature of the movement. Trial and error can form the basis for selecting efficient movement patterns.[45] Feed forward mechanisms must also be considered, as movement skills have a cognitive component. In some instances, cognitive strategies may be able to compensate for the inherent motor limitations. Children with CP may understand concrete instructions much more readily than abstract ones. Transfer between tasks may be limited, particularly in children with cognitive impairments, so practice of a targeted skill is recommended.[366] Integration of skills into functional and cognitively directed tasks may promote carryover.

Therapists should focus on time periods when the child demonstrates prerequisite abilities (readiness) associated with a particular task and engage the child in goal setting and intervention planning. [329] Therapy should be challenging and interesting to maintain motivation. Embedding activities into daily routines supports the principles of motor learning.[278] For example, kicking a soccer ball is a more functional and fun method of developing balance skills than practicing while standing on one foot. A task can be achieved through many different means based on the child's unique movement capabilities, provided the action is safe and will not cause secondary impairments over time.[366] Ketelaar and colleagues found that children receiving interventions based on these principles demonstrated greater improvement in both capability and performance of self-care and mobility activities in daily situations when compared with children receiving intervention designed to normalize movement quality.[189]

Although the body of literature on many aspects of therapy for children with CP is growing, optimal strategies and interventions are not known. Consequently it is important to analyze the child, task, and environment to identify what needs to occur to achieve the goal. Practice-based, goal-directed interventions such as constraint-induced therapy (restraining the unaffected limb of children with unilateral CP while encouraging high-repetition active arm and hand movements of the more involved extremity) or bimanual training (using motor learning principles to promote use of the more affected arm and hand as an assist) have evidence of improving arm function and hand movement quality and effectiveness associated with cortical reorganization as measured by functional magnetic resonance imaging and magnetoencephalography.[265,327,350] Functional relevance, cognitive engagement, massed practice, high intensity of training, age-appropriate activities, peer engagement, and the incorporation of home programs are aspects of successful programs.[3,86,327,360] See Chapter 4 for more information.

Physical therapists may be involved in a variety of roles related to health and well-being. Children with CP are at risk for a wide range of feeding, hydration, and nutritional problems due to problems with oral-motor control and swallowing, drooling, aspiration, impaired self-feeding, and difficulties in expressing hunger or food preferences.[9,205] Feeding problems coupled with impaired movement can impact growth, particularly in children with GMFCS levels III, IV, and V. Poor growth is associated with poorer health, increased use of health care resources, decreased social participation, and missed school days and may impact a family's ability to take part in usual activities and feel they are able to adequately nurture their child.[9,205,346] Gastroesophageal reflux and aspiration can also occur. Oral-motor programs, proper positioning, and parent education and support are important aspects of comprehensive care. Lack of physical activity can contribute to chronic constipation. In some cases, gastrostomy and antireflux procedures are recommended. Growth curves have been developed for children with complex medical conditions.[9,205,346]

Conversely, increasing rates of obesity in children, including those with CP, are a matter of concern. The overall prevalence of overweight or risk of overweight in children with CP is over 29% and is relatively greater in those who are ambulatory.[172] Concerns associated with obesity, such as muscle loss, pain, pressure sores, and mobility limitations, can be amplified for people with cerebral palsy.[238] Interventions with positive outcomes include encouraging physical activity with techniques such as motivational strategies that allow self-direction of goal setting and activity choice, self-monitoring, positive reinforcement, incremental increases in workload, and engaging in strength training for longer than 15 minutes. Targeting body

weight is more challenging.[238] Child behavior, personality, and family recreational styles predict variation in leisure and recreational participation.[193] Physical therapists can be involved in the early promotion of healthy behaviors including participation in physical activity and healthy eating.

Children with limited mobility or feeding problems may have poor pulmonary function and respiratory muscle weakness.[207] Problems including poor clearance of secretions, aspiration, and susceptibility to pneumonia may necessitate chest physical therapy, suctioning, and other techniques to maintain optimal respiratory function.

Failure to develop an appropriate toileting routine during the preschool years can result in participation restrictions and negative reactions from peers. Development of bladder control in children with CP may be delayed in comparison with typically developing children, but most become continent. Cognitive abilities and a diagnosis of quadriplegia can negatively influence the development of control.[307] Therapists may need to recommend appropriate adaptive equipment.

Mobility

Walking is a preoccupation of parents at the time of diagnosis, a frequent goal of families, a predictor of participation, and a skill that can deteriorate over time. As a result, walking is a major focus of clinical practice and research in children with CP in the preschool years and beyond. Walking is not always a realistic or optimal method of mobility. Alternative means of mobility are essential for some children and are chosen by some children and adults for efficiency in certain environments.[359]

The GMFCS and the Gross Motor Development Curves provide evidence-based information to assist in identifying realistic mobility goals.[314] If the prognosis for walking is good, intervention will include promotion of preparatory ambulation skills, such as effective and well-aligned weight bearing, selective control of movement, and weight shifting needed for gait and balance. Body-weight-support harnesses with treadmill training may provide a learning opportunity for the task of walking.[230] Ambulatory aids, such as walkers, crutches, or canes, may be used, either temporarily while a child is progressing to more advanced gait skills or as long-term aids for independent mobility. The use of posterior walkers has been found to encourage a more upright posture during gait, promote better gait characteristics, and decrease energy expenditure compared with the use of anterior walkers (Fig. 19.9).[289] Children functioning at GMFCS level IV can use wheeled walking devices that support the trunk and pelvis to provide the benefits of upright positioning, the ability to take steps, and a limited degree of mobility. Although there is limited evidence of therapeutic impact, these devices provide opportunities for participation with others and exploration of environments.[276]

Children 3 to 5 years of age are becoming aware of the concept of achievement. Walking may be a coveted skill, but it should not become an all-consuming goal, particularly if it may not be attainable or sustainable at older ages. Adults who are nonambulatory remember walking as the most important goal set for them by their parents and therapists, resulting in feelings of failure from an early age and loss of faith in rehabilitation professionals.[135,190]

The provision of alternative methods of functional, independent mobility is recommended when ambulation is not possible or is inefficient. This need may be met with an adapted tricycle (Fig. 19.10), a manual wheelchair, or a power mobility device,

FIG. 19.9 Child using a posterior walker, reported to promote upright posture and higher walking speeds than an anterior walker. (From Lissauer T, Clayden G. Illustrated textbook of paediatrics, ed 4. St. Louis, 2011, Elsevier.)

FIG. 19.10 An adapted tricycle may meet a child's needs for mobility. (Courtesy Texas Children's Hospital, Houston.)

sometimes with special controls. The University of Delaware's GoBabyGo! program (http://www.udel.edu/gobabygo/program) has developed guidelines to motorize and adapt toy ride-on cars for young children with disabilities.[171] These devices enable children with CP to explore their environment, achieve a sense of independence and competence, and experience increased participation in family, school, and community life. Power mobility may also promote the overall development of self-initiated behaviors and the acquisition of spatial concepts. The lack of self-propelled locomotion can result in apathy, withdrawal, passivity, and dependent behavior that can persist into later life.

Powered mobility is often a sensitive topic for families of young children with CP. Therapists are encouraged to raise the possibility and encourage the family members to share their thoughts. It is important to respect family preferences. Some families may prolong the use of strollers to delay wheelchair use due to acceptance or assumed stigma.[135] Parents initially may be hesitant about introducing power mobility to young children, fearing that it signifies giving up on walking. The topic can be revisited at a later time. Power mobility does not preclude goals for supported walking or walking using a mobility device such as a walker but provides the child with a method of self-mobility for exploration and experiential learning. For children who will continue to be wholly dependent on power mobility for independence, it provides mobility at an appropriate age and gives families an indication of the implications of power mobility for housing, schooling, and transportation needs.

If power mobility is being considered, fine motor control, cognitive skills, visual and auditory abilities, behavior, environmental accessibility, transportation, and financial resources must all be taken into account. Consensus regarding clinical practice suggests that children can begin augmented mobility as early as 8 months of age, when children typically begin to crawl, and can begin to learn how to maneuver a power mobility device before they are 14 months of age. Those able to use a joystick or other steering device can demonstrate control as young as 18 to 24 months of age.[220] Some children with significant cognitive or sensory impairments can learn to use power mobility devices with appropriate practice and environmental support. For more information, see Chapter 33, Assistive Technology.

Play

Play, the primary productive activity of children, should be intrinsically motivating and pleasurable. The benefits of play include helping children discover the effects they can have on objects and people in their environment; development of social skills; and enhanced development of perceptual, conceptual, intellectual, and language skills. Children with CP are often constrained in their playfulness even when they have the capacity to be playful. They receive more support in play at home than in community or school environments.[302] Limitations in the play of children with physical disabilities due to physical impairments, time limitations, and social and environmental barriers may affect the experiential learning derived from play and may result in decreased independence, motivation, imagination, creativity, assertiveness, social skills, and self-esteem.[34] Therapy should provide and demonstrate play opportunities and provide input on dealing with social and environmental barriers to play (Fig. 19.11).

Appropriate toys and play methods should be suggested to parents and caregivers. If children are physically unable to play with regular toys, a variety of adaptations, such as switch access, can make their toys usable.[208] Environmental control equipment also can be introduced to preschoolers.

FIG. 19.11 Therapeutic exercise programs can include highly motivating play activities. Throwing a basketball may be more motivating than trunk extension exercises.

It is important to not overprotect children with CP. Parents should be encouraged to let their children enjoy typical play activities, such as rolling down hills and getting dirty in the mud. Therapists must ensure that therapy and home programs promote, rather than interfere with, normal play experiences. Early integration of children into community recreational activities can introduce a child and family to the benefits of a healthy active lifestyle and social opportunities.

Family Involvement

Planning of interventions should consider the child within the context of the family. Therapists should be sensitive to the family's stresses, dynamics, child-rearing practices, coping mechanisms, privacy, values, and cultural variations and be flexible in their approach and programming. Family–therapist collaboration is crucial for integrating goals into learning opportunities during daily activities and routines. Home programs are important for optimal therapy results because strengthening, extensibility, and motor learning require more input than can be provided in treatment sessions. Parents use the guidance and support that they gain from home programs to build confidence about how to help their child.[267]

Therapists need to be sensitive to the well-being of families and must find a balance between providing home programs that the family cannot realistically be expected to carry out, especially programs that do not promote positive parent–child interactions. Asking a family to spend 15 minutes on a treatment activity means 15 minutes will be lost from another activity.[30] Obstacles may include constraints on time, energy, skills,

or resources, and negative effects on the parent–child relationship. Factors that have a positive influence on the participation of parents in home programs include collaborative decision making regarding the content and intensity of programs, recognition of the needs of individual families, and use of activities that are integrated easily into daily routines and are not stressful for the child or the caregiver.[267] Siblings can have a role in care and play.[103] Their education about CP and ways in which they can help their brother or sister can contribute toward achieving more independence.[74] Sibling well-being must also be considered.

Role of Other Disciplines

Occupational therapists work closely with preschool children to develop independence in activities such as dressing, feeding, toileting, and playing. Speech and language therapists promote use of efficient methods of communication. Psychologists assess cognitive skills and consult with other professionals on the interaction of intellectual abilities with other areas of development. Social workers and behavior therapists provide ongoing support to families because the stresses involved in parenting a child with a disability persist but change. Team assessment and intervention are imperative for addressing issues such as feeding problems, augmentative communication, and transition to school. Orthopedic surgeons monitor musculoskeletal development.

SCHOOL-AGE AND ADOLESCENT PERIOD

During the school-age and adolescent years, children typically participate in school and community life while remaining dependent on their families and living in their parental homes. They refine and maintain the basic functional skills they have learned, develop independence in life skills activities that will enable them to cope effectively with the demands of daily living, interact with peers, and transition to adult life. These years, particularly those spent in high school, can be difficult for children with CP.[255] Youth become increasingly aware of the reality, extent, and impact of their disabilities on themselves, their families, and their relationships with peers. As they strive to contend with the normal stresses of growing up, particularly those of adolescence, they must also cope with being different, acknowledge the potential obstacles to attaining independence, and work to overcome them.

Participation in life activities has been shown to be more challenging as children reach adolescence.[175] Problems encountered during adolescence include mobility limitations, poor endurance in performing routine activities, and continued difficulty and slowness with self-care and hygiene skills at a time when privacy is becoming increasingly important. Adolescents may not have sufficient opportunities to develop socially and sexually or achieve age-appropriate levels of independence from the family. Dating is often delayed and less frequent than for other teenagers.[389] Environmental factors may contribute to reduced access to community and school facilities, limiting opportunities for participation in social, cultural, recreational, and athletic activities.

Parents may be anxious about the effects of their child's disabilities on their participation in age-appropriate endeavors and their future as an adult.[153] They continue to be naturally attentive but have to avoid being hypervigilant or overprotective and must begin to allow their child to take risks and become independent in the outside world.[255] In some cases, financial concerns regarding the need for special equipment, transportation, and home renovations must be addressed. Parents of children who are dependent in activities of daily living (ADLs) and transfers may suffer from physical stresses, such as back problems.

Physical Therapy Examination and Evaluation

Identification of risk for secondary impairment is an important part of the examination. Gross motor assessments may be less frequent as children naturally plateau in this area,[155] but they are still important for monitoring change resulting from interventions such as spasticity management, surgery, the use of orthoses, or periods of intensive therapy or deterioration. Assessment in a child's natural environment may provide valuable information for differentiating between capacity and performance and determining necessary accommodations to allow participation. For example, the walking speed, endurance, and agility necessary for negotiating school hallways with other children, noise, and obstacles may differ from those assessed in a gait laboratory or a structured timed distance test. The mean velocity of typical 7-year-old children leading a line of students in a school hallway is 4 feet/second.[92] Information such as this can provide guidelines for the walking abilities necessary for participation in school mobility and for determination of treatment goals.

Privacy of individuals of all ages should be respected, but this is particularly important during these years, when children are becoming more aware of their bodies and their sexuality. They should be appropriately dressed when attending therapy sessions and clinics, particularly if they will be seen by unfamiliar people or photographed or a video taken. If it is necessary for children to remove their clothing, a reason should be given for doing so and their permission requested.

Physical Therapy Goals, Outcomes, and Interventions

Goals shift during these years to reflect lifestyle and potential for change. Most children with CP achieve their gross motor ceiling capacity at around 5 years of age.[59,155,314] Some children and adolescents may improve their motor function or skills. For example, a systematic review on exercise interventions to improve postural control in children with CP by Dewar et al. (2014) concluded that moderate-level evidence supports the effectiveness of gross motor task training, hippotherapy, treadmill training with no body support, trunk-targeted training, and reactive balance training. However, emphasis tends to focus on prevention of secondary impairments, maintenance of achieved level of motor function, participation in age-appropriate pursuits, and exploration of compensations and environmental accommodations. Potential challenges include contracture, pain, increasing size, puberty, cumulative physical overuse, fatigue, and a more demanding and competitive lifestyle.[23]

School-age children and adolescents should be active participants in conversations regarding goals and programming if they are cognitively able. They should be encouraged to take increasing responsibility for their own health, nutrition, fitness, personal care, finances, and decision making so that they are prepared to assume these responsibilities in adulthood. Therapists should strive to foster self-esteem, self-efficacy, and assertiveness in children and adolescents by emphasizing their abilities, encouraging activities in which they can excel, and helping them to acknowledge their difficulties with a view

toward identifying appropriate compensations such as use of attendant care. In the case of children with more severe involvement, goals may be oriented toward minimizing impairments to facilitate caregiving and comfort. To the extent possible children and adolescents should be knowledgeable of their health condition and learning to self-manage. When motor capacity is limited, self-management involves instruction of others to provide assistance.

Secondary impairments must be anticipated and avoided if possible. Maintenance of muscle extensibility, strength, joint integrity, and fitness is important in preventing secondary impairments. Children and youth need to develop problem-solving strategies to overcome environmental and societal barriers to become as independent and active as possible in home, school, recreational, social, and community life. Education about their disability is an important but often lacking component of assuming self-management.[305] This may occur because the initial education of families occurs when a child is young, and continued provision of age-appropriate information to the child is often inadequate.

Mobility is important for overall health, well-being, and independence. Adolescents may be capable of employing methods of mobility used at younger ages, but environmental and personal factors may influence performance.[312] It is vital to identify underlying causes of excessive energy use, to develop effective strategies to reduce energy-wasteful movements, and to implement physical fitness interventions through community exercise and sport programs. These goals are important for children across the spectrum of GMFCS levels but will be achieved in different ways.[125]

Reducing Primary Impairment and Preventing Secondary Impairment

Progressive resistance training has become a common intervention for children and adolescents with CP, as it has been shown that the effort associated with training is not associated with the exacerbation of spasticity or pain.[136] Elastic bands, free weights, isokinetic equipment, and functional movements have been used, and programs have taken place in home, clinic, or community settings. Many studies have shown that resistance training in the lower limbs of children and adolescents increases isotonic, isokinetic, isometric, and functional strength but has a lesser effect on functional activity and participation.[128,136,353] However, some studies have reported concurrent improvements in activity as measured by gross motor function, gait parameters such as stride length and kinematics, and perception of body image.[128,288,363]

A review of methodologies suggests that protocols may not have implemented evidence-based guidelines for resistance training.[371] Protocol suggestions for school-aged children and adolescents with CP are discussed by Vershuren et al.,[371] Park and Kim,[288] and Gillett et al.[136] and include the following: (1) single-joint training when muscles are very weak or compensations are evident with multijoint muscles; (2) rest intervals greater than 1 minute (perhaps up to 3 minutes); (3) interventions of sufficient length (12 weeks), three times a week, and 40- to 50-minute sessions; and (4) consideration of National Strength and Conditioning Association Guidelines for Children for other parameters.

Youth with CP should exercise in positions that are comfortable and allow optimal selective control of targeted muscle groups. Changes in prepubescent youth are due to neural factors such as improvements in motor skills, increases in motor unit recruitment and firing rate, and changes in coordination more than muscle hypertrophy.[371] Strengthening should be included in regular exercise or physical activity regimens to maintain optimal musculoskeletal function throughout the life span.[125] Strength training is more likely to enhance motor functioning in younger children but may counteract deterioration in youth, thus statistically nonsignificant results may be clinically worthwhile. Protocols involving high-velocity training, plyometric training, or the addition of anaerobic training may be promising.[136,183]

Electrical stimulation, mental imagery, and biofeedback may be helpful for children who have problems contracting their muscles voluntarily.[371] Various methods of neuromuscular electrical stimulation have been used as an adjunct to the treatment of CP in attempts to reduce spasticity, increase strength and muscle extensibility, promote the initial learning of selective control, and improve functional activities such as gait.[68,402] Therapeutic electrical stimulation, low intensities that do not produce a muscle contraction over an extended period of time, has not been shown to have a clinical effect.[79] Functional electrical stimulation, stimulation at high intensities for short durations during practice of an activity, has been shown to have favorable effects on gait parameters when applied to the plantar flexors alone or in combination with dorsiflexors. Protocols should be individualized for patients after careful analysis of movement, and application should be closely monitored. Treatment effects have been observed when stimulation is applied for 30 to 60 minutes per day for at least 6 to 8 weeks.[402] Some studies have shown that functional electrical stimulation is no more effective than activity training alone but might be useful for children who have problems initiating movements due to cognitive or selective control problems.[68]

Spasticity management is still important in this age group. Botulinum toxin continues to be effective and is often combined with serial casting if contractures are present, to provide more marked and long-lasting effects.[99] Contractures are prevalent in this age group, particularly in more severely affected patients.[401] The interventions described in the preschool section are appropriate, but it is important for therapists to ascertain which structures are causing restriction in movement. Joint hypomobility resulting from capsular or ligamentous tightness can be treated with joint mobilization.[46,159]

Continued surveillance of hip joint integrity is necessary even after skeletal maturity for adolescents with risk factors such as scoliosis, leg length discrepancy, or changes in gait or sitting.[403] Although spasticity management and positioning programs may delay or reduce the need for orthopedic surgery, some children benefit from surgical intervention to address progressive contractures or bone deformity and to address problems with gait, posture, hygiene, and pain. Children may become progressively flexed in their gait and may develop a crouch gait pattern, which can be worsened by their pubertal growth spurt. This pattern is characterized by excessive ankle dorsiflexion, knee flexion, and hip flexion and may be accompanied by excessive femoral anteversion, hip subluxation, patella alta, excessive external tibial torsion, calcaneal valgus, and knee pain. Possible surgical procedures include muscle/tendon lengthenings and transfers, tenotomies, osteotomies, and joint stabilization procedures.

Single-event multilevel surgery, including procedures for the hip, knee, and ankle, allows biomechanical alignment and can take place at all joints simultaneously. Children and families

have to deal with only one hospital admission and one period of rehabilitation. Research on the long-term effects of orthopedic surgery is limited due to ethical issues with conducting randomized control trials, a lack of stratification by GMFCS, and inconsistent reporting of the timing of evaluations, procedures, adverse events, postoperative care, and rehabilitation protocols. However, multilevel orthopedic surgery has been shown to improve range of motion, torsion, kinematic and kinetic gait parameters including summary measures, and energy efficiency but only small changes in overall gross motor function and a less predictable effect on quality of life.[235]

More complex surgeries that include procedures such as femoral extension osteotomies and patellar tendon advancements are resulting in promising improvements in knee function and gains in community function.[347] Orthopedic priorities for children functioning at GMFCS level V are the ability to sit comfortably with a stable straight spine over a level pelvis with flexible located hips and plantigrade, braceable feet. The ability to participate in standing transfers is a goal for those functioning at GMFCS level IV. [235]

Physical therapists play important roles in surgical decision making and the management of preoperative and postoperative care. Therapists, surgeons, and families are collaborators in surgical choices based on assessments of gait and other gross motor activities, equipment tolerance, pain, ROM, strength, selective motor control, spasticity, and respiratory function. Child and family goals, resources, motivation, and priorities, as well as surgeon experience, must be considered. As children get older, they should be active participants in making decisions about their care. Their interests, priorities, and concerns about interruptions in their lives as a result of hospitalizations, immobilizations, recovery periods, and commitment to postoperative rehabilitation should be respected.

Preoperatively, therapists can educate the family about postoperative needs such as positioning, lifting, transferring, transportation, respiratory care, feeding, sleeping, and pain management and the potential need for extra help at home. Botox and other forms of spasticity management may be considered to reduce postoperative discomfort.[25] Strengthening and respiratory exercises for preoperative conditioning may be beneficial. Home adaptations and equipment may be put in place in collaboration with occupational therapists, who may provide consultation regarding toileting and bathing needs.

Positioning during the immediate postoperative period is important for comfort and muscle extensibility. Caregiver body mechanics are important when dealing with children who are compromised as the result of casts, movement restrictions, and pain. Postoperative rehabilitation contributes to optimal surgical outcomes, which may continue to improve 12 to 24 months following surgery and may be maintained for many years. Muscle strength, particularly that of the hamstrings, can decrease significantly after surgery.[335] A goal is motor control of lengthened and transferred muscle in the context of functional motor tasks. Specific exercises will vary according to immobilization and weight-bearing and movement restrictions, but extensibility and strengthening exercises to promote functional motor skills will serve as the basis of training programs.[26,335] Hydrotherapy may be beneficial. Re-evaluation of orthotic management, walking aids, and seating may be necessary to maintain alignment, protect surgical correction, and facilitate functional movement.

Spasticity, abnormal extensibility of muscles, muscular imbalance, and weakness can result in scoliosis, which, in turn, can affect positioning, respiratory status, pain, and skin integrity and therefore can be a difficult problem, particularly in the children with spastic quadriplegia.[216] Various types of orthoses can be used in the management of spinal deformity. Evidence does not indicate that bracing prevents the progression of scoliosis in children with CP and may not be tolerated well; however, it may provide benefit by stabilizing trunk posture.[216,249] Surgical correction of severe spinal deformities may be necessary. Despite concerns of morbidity and even mortality, caregivers are satisfied typically with outcomes (see Chapter 8, Spinal Conditions).[216]

Osteopenia with an increased rate of fracture in moderately to severely involved children with CP has been associated with limited ambulation, previous fractures, the use of anticonvulsants, feeding problems, and lower body fat mass.[208] Physical activity that involves weight bearing and bisphosphonate therapy has been shown to have positive effects on bone mineral density in children and adolescents with CP.[115]

Activity and Participation

Attainment of new gross motor skills levels off during these years; however, improvements may be possible, even in children with severe physical and cognitive limitations, if goals are realistic and appropriate behavioral, communication, and motor learning techniques are used.[48] It has been considered that neuroplasticity can continue into the adolescent years or even across the life span but needs to be taken advantage of using optimal types and intensities of treatment.[393] Regardless of the lack of potential for large gains in gross motor skills, therapy programs are necessary to maintain optimal levels of functioning and prevent unnecessary deterioration. Intervention principles such as family-centered service remain the same, but goals, tasks, and motivators may adjust to be age appropriate.

Youth with CP value mobility for independence and participation. Walking in CP is not a dichotomous outcome.[135] As discussed in the section on prognosis for gross motor function, children and youth may have more than one method of mobility depending on varying situations and related to energy expenditure, the activity, the environment, and personal preferences, particularly as children become larger and need to travel greater distances to participate in their social and educational activities.[135,283] Youth who are functioning at GMFCS levels II to IV often choose to use manual or powered wheeled mobility for safety, practicality, or social appropriateness in school or community settings even if they can walk.[283,359] The use of mobility devices may require environmental modifications, such as entrance ramps or washroom renovations, for accessibility. Driver training offers the freedom to travel independently for those capable of driving a car. When driving is not feasible, instruction in the use of public or special transportation should be provided. Dependence on special transportation programs or parents limits the ability to be spontaneous in attending community activities.[283]

Walking may continue to be considered a symbol of normalcy but may become an activity for exercise or to fulfill the expectations of others rather than function.[135] Treadmill training with partial-body-weight-support harnesses can provide safe, task-specific gait training, providing multiple repetitions and active participation for children functioning at GMFCS levels III, IV, and V.[230,257] Studies have small sample sizes but

have demonstrated clinically relevant improvements in walking skills, gait velocity, and endurance, as well as improved standing transfers, in children who do not walk by themselves. To date, the quantity and quality of these studies are insufficient to conclude that partial-body-weight-support treadmill training results in significant improvements for children with CP.[83,257,391] Programs with higher intensities and extended durations have resulted in better outcomes. Robotic-assisted treadmill training using a driven gait orthosis requires less personal effort, allowing high-dose, high-repetition walking practice at increased speeds and longer distances during treatment sessions, and possibly enhancing neural reorganization.[242] This intervention shows promise as a therapeutic option to improve walking velocity and gross motor function in children functioning at GMFCS levels I, II, III, and IV.[241] Treadmills also are useful for increasing endurance and strength and can be used without harnesses in higher-functioning children.

School-age children have usually developed abstract thinking and sufficient cognitive ability to use biofeedback, electronic feedback about muscle activity to teach voluntary control. Research is limited; however, it has been found to improve active ROM, strength, and control of movement such as dorsiflexion in a study of children with CP.[105] Carryover is often limited, generalization to real-life situations is not readily demonstrated, and treatment can be time consuming. Biofeedback has been incorporated into robotic technologies.

Readily available technologies such as smart phones, tablets, and computers and a multitude of games and apps provide youth with disabilities access to the many options of activities and social media typically used by peers. Virtual reality technology has provided opportunities for active, repetitive sensory and motor sensory practice that are relatively low cost, commercially available, enjoyable, motivating, socially acceptable, and safe for children of all GMFCS levels. They can improve balance and enhance visual-perceptual processing, postural control, and functional activities.[114] Active video games that require participants to engage in physical activity can lead to moderate-intensity exercise levels with the potential to promote physical fitness and decrease sedentary behavior and therefore enhance cardiovascular fitness.[114]

Habitual physical activity levels in children and youth with CP have been reported to be 13% to 53% lower than their peers and approximately 30% lower than recommended guidelines.[60] Impairments in strength, muscle tone, balance, coordination, and fatigue can contribute to low levels of participation in physical activity, which can in turn result in obesity, poorer cardiorespiratory fitness, lower physical work capacity, and higher oxygen costs.[125,373] Bidirectional associations can result. Energy expenditure for walking can be up to three times as great as that of typically developing children, with significant differences across GMFCS levels.[184,375]

Physical therapists can play an important role in the promotion of health lifestyle practices. Personal or environmental factors can be facilitators or barriers to physical activity. Therapists need to be aware of and should address contextual factors including self-efficacy, knowledge on why and how to exercise, pain management, family support, availability of time, availability and awareness of appropriate equipment or programs, facility accessibility, transportation, finances, trained recreation staff, and people's conceptions about their abilities and conditions.[185,194,256,373]

Physical activity behaviors in childhood and adolescence are important, as they can establish lifestyle habits that continue into adulthood.[336] Research has shown that exercise interventions can increase habitual physical activity in children and youth with CP, but maintenance can be difficult.[17] Aerobic training studies have shown overall positive effects on children with CP, but few report on the impact on daily activity and participation level.[129] The training intensity may be insufficient or the duration of training is too short to show results in these areas.[129]

Strategies include education about the benefits of fitness activities, goal setting, a mix of structured and unstructured programs, feedback, positive role modeling, and providing support to families to find suitable activities and navigate barriers to participation.[17,317] Physical activity recommendations can be grounded in guidelines for the general population that children and youth participate in an accumulated minimum of 60 minutes of moderate to vigorous physical activity daily including aerobic and muscle and bone strengthening activities and FITTE (frequency, intensity, type, time, and enjoyment) principles.[317] Evidence of the impact of physical activity on body functions (strength, flexibility, aerobic and anaerobic capacity, cognition, daily activity, participation, self-competence, and QOL) is promising.[126,374,375] Qualitative finding such as the ability to play outside longer and walk for longer periods have been reported.[140] Activities can include circuit training; trampoline, running, jumping, treadmill, and cycling activities; and swimming. Physical activity should be incorporated into home, school, and community environments. Programs offered in school settings can contribute to adherence and feasibility. Community fitness programs have been shown to improve muscle strength and perception of physical appearance; participants feel confident and motivated enough to take responsibility for continuing in fitness programs.[91] Online programs have shown success.[17]

Youth with CP have twice the recommended amounts of daily sedentary time.[60] The negative health impacts of sedentary time must be considered; however, the definition of sedentary activity may not be appropriate for people with CP. For example, although long periods of time may be spent in sitting, impairments such as atypical muscle tone, co-contraction, and poor balance may actually lessen the sedentary nature of being seated.[177] Finding ways to limit the total time spent being sedentary and ensuring that prolonged periods of sedentary time are broken up with bursts of movement and light activity, such as sitting exercises or even wiggling in a wheelchair, may lessen the risks of too much sedentary time.[177,373]

Recreational and sports activities provide excellent opportunities for exercise, fun, and social interaction.[345] These include horseback riding,[94] swimming, bicycling,[292] skiing,[345] sailing, canoeing, camping, kayaking, fishing, bungee jumping, yoga, skiing, and tai chi (Fig. 19.12). Adapted games provide exercise, athletic competition, participation in team experiences, and social opportunities (www.medicalhomeinfo.org/health/recreation.html).

All athletes are at risk for sports-related injuries, but relatively minor injuries can incapacitate people with CP. They should be encouraged to be responsible for their bodies during sports activities by completing appropriate conditioning, warm-up, and cool-down routines; following comprehensive injury-prevention programs, which include strengthening, flexibility, and aerobic and anaerobic training activities and protection

FIG. 19.12 Participating in an aquatic class can provide fitness and social opportunities.

of long-term joint integrity; and using appropriate protective and orthotic equipment. Knee injuries commonly involve the patellofemoral joint secondary to spasticity of muscle groups surrounding the joint. Deformities of the ankle and foot, including equinus, equinovarus, and valgus deformities, can lead to an increased risk for injury.[198] Injuries should be taken seriously and treated promptly. For more information, see Chapter 15, Sports Injuries in Children.

School and Community

Tremendous progress has been made in the inclusion of children with physical disabilities into the educational system and community activities. Although many experiences are very successful, some children experience isolation, marginalization, social or physical exclusion, bullying, or constant adult presence.[176] Physical therapists are involved in school-based therapy programs to support student access to and participation in all school activities. These may include positioning, mobility in and between classrooms and during recess, physical education, noncurricular social activities, and field trips. Facilities and resources such as support personnel, equipment, building accessibility, and computer technology may be necessary to meet the educational, physical, and self-care needs of children in the school system. Therapists develop and maintain collaborative partnerships with school personnel. They may interpret the impact of medical conditions; instruct assistants and teachers in positioning, lifting, and transferring children and carrying out exercise programs; and adapt activities through modification and accommodation.[212] Therapists may also be involved in transportation, evacuation, and other safety issues. Therapists working in school settings must be sensitive to the physical and scheduling constraints of the educational environment and must be willing to compromise to meet the educational priorities of students. Therapy may range from consultation and monitoring for students thought to have reached their maximal level of functioning to active therapy for children who have specific goals. When children are seen primarily through the educational system, efforts must be made to keep the family involved in all aspects of care and treatment. Therapists may be involved in the coordination of services among family members, school professionals, health services, and community agencies and influential in empowering students as they become capable of being involved in decision making.[212] See Chapter 31, The Educational Environment, for in-depth information on the role of the physical therapist in the US educational system.

Therapists can also be involved in educating students about cerebral palsy to reduce teasing and bullying and to increase acceptance of children with disabilities. Children with knowledge about and social contact with individuals with disabilities have more positive attitudes toward peers with disabilities and are more likely to have empathy for, and feel less anxious about, interacting with people with disabilities.[7]

Children and adolescents learn about their bodies, their sexuality, and appropriate interactions with other people. Children and adults with disabilities can suffer abuse, including sexual exploitation, which may result in physical, social, emotional, and behavioral consequences.[341] Some abusers have relationships specifically related to the victim's disability. These people may include personal care attendants, transportation providers, residential care staff, and other disabled individuals. Physical therapists must know how to detect the signs of abuse, be sensitive and receptive to clients who may choose to confide in them, and know the proper procedures to follow if they suspect abuse. They must work with other professionals to promote assertiveness and positive self-esteem in their clients.

All people involved with youth with CP must educate them in being streetwise. Their physical and sometimes cognitive limitations can make them particularly vulnerable to crime. They should be taught to avoid unsafe situations and warned about protecting valuables. Purses or knapsacks slung over a wheelchair handle can be easy to grab. Self-defense courses specifically designed for people with disabilities may be available.

Health care professionals must realize that although parents have been coping with their child's needs for a number of years, parent education is still important because the child and the child's needs are constantly changing. Parents of children with CP may experience physical and psychological health problems and need to be encouraged to take good care of themselves. Reported health issues include back problems, stomach/intestinal ulcers, migraine headaches, arthritis, emotional problems, pain, and chronic physical conditions.[43] Continued attention to education in lifting and transferring is necessary to prevent injury to caregivers whose children are growing larger and heavier as they, themselves, are aging.

Role of Other Disciplines

Occupational therapists may be involved in promoting independence in activities of daily living and work closely with physical therapists in managing upper extremity function.[67] Interdisciplinary life skills training can focus on self-care, community living, and interpersonal relationships. Prevocational training and related activities, such as money management and employment searching, may be beneficial. Psychologists or social workers may be involved in various aspects of adolescent life such as social and sexuality issues.

TRANSITION TO ADULTHOOD

Adults strive to be independently functioning and self-sufficient, employed individuals who have satisfying social and emotional lives and contribute to society. They endeavor to live independently in the community, alone or with others.

They have romantic relationships and sexual experiences, enjoy social outings, often marry, and sometimes have children. Adolescents with CP have the same dreams and aspirations for adult life as all young people.[196] The extent to which these goals can be realized depends on factors such as independence in self-care activities and mobility, level of cognition, communication skills, and available resources and support. A review of adults with CP without intellectual disability showed 60% to 80% completed high school, 14% to 25% completed college, up to 61% were living independently in the community, 25% to 55% were competitively employed, and 14% to 28% were involved in long-term relationships with partners or had established families.[121]

Many adults with CP continue to live with their families or in group homes or institutions.[219] At a time when most parents are experiencing freedom from caregiving responsibilities, many parents of youth with CP continue to have these obligations.[153] Their concerns focus on how their child can function as an independent adult, how they can continue to care for their child as they themselves age, and who will care for the child when they are unable to do so. Parents of children who have the potential to live independently must deal with the anxieties of letting go.[142] Many may also be coping with a decrease in the number of relatively organized and available programs and equipment resources that are available for younger children. Continuity of care may be lacking, and it may be difficult to find medical professionals with experience in managing the health care of people with disabilities.

The transition to adult lifestyle and services is complex. Planning and problem solving should take place throughout adolescence. Successful transition has been characterized by self-determination, enhanced knowledge of self and community, problem-solving and decision-making skills, identification of support systems, and supportive environments, including transition clinics.[31] During the transition there should be a gradual shift in responsibilities from parents to the young person, as developmentally appropriate, to develop capacity in self-management.[142] This can start with having adolescents see health care professionals by themselves. Areas of transition to be addressed include vocational or postsecondary education, living arrangements, personal management, leisure time, recreational and social activities, and financial planning. The latter involves education about governmental benefits, guardianship, conservatorship, wills, and trusts. Primary and preventive health care services must be organized. These include provision of therapy when needed, medical consultation, primary care, and equipment needs and maintenance. Internet resources from institutions provide guides to assist adolescents and families in navigating the transition to adulthood. These include Bloorview Kids Rehab (www.bloorview.ca/programsandservices/programserviceaz/growingupready) and Ministry of Children and Family Development in British Columbia (www.mcf.gov.bc.ca/spec_needs/pdf/your_future_now.pdf).

In-depth information is presented in Chapter 32, Transition to Adulthood for Youth with Physical Disabilities.

Role of Physical Therapy

Pediatric physical therapists work together with the individual, the family, and the health care team to provide comprehensive planning to facilitate the transition to managing the challenges of adulthood. Major physical therapy goals during this period of transition are aimed at maximizing the capability to maintain function, prevent deterioration, and achieve optimal independent living. Ideally, the medical, therapeutic, and educational outcomes achieved throughout childhood have prepared youth with CP for success in these areas. Therapists need to encourage problem solving in adolescents who have the potential to live on their own, as they will need to be self-sufficient in managing their health condition.

Adults with CP must deal with the normal effects of aging in addition to their preexisting impairments.[274] They may experience early onset of frailty, chronic pain, fatigue, osteoarthritis, osteoporosis, cardiometabolic disease, sarcopenia, and decreased extensibility and endurance.[291] These can contribute to falls and a decline in mobility and independence and impact employment, social integration, and participation in exercise and other leisure activities.[291] Among adults with CP who are able to walk, 25% are estimated to have reduced abilities compared to when they were younger, more so in those with less capacity to walk, bilateral rather than unilateral motor impairment, older age, and higher levels of pain or fatigue.[246] Gait decline may be characterized by the need for more assistance to walk, greater perceived effort, a reduction in walking distance, speed or environments managed, the ability to climb stairs, or the emergence or increase of features such as onset of pain, breathlessness, or fatigue.[246] Deterioration in function, mobility, and participation in daily life has been attributed to pain, physical fatigue, obesity, and losses of muscle strength, balance, and cardiovascular fitness.[291] Adults with CP who report preservation of mobility accredit this to regular physical activity participation and maintenance of balance, strength, and overall fitness.[291]

Fatigue is a major concern for some youth and adults with CP, particularly with walking long distances, suggesting an association with overuse.[49] Fatigue is associated with pain, lack of physical activity, general health problems, deterioration of physical skills, emotional issues, and low life satisfaction. Physical therapists can encourage youth to be aware of their own bodies, adapt activities to allow continued participation in various aspects of their lives, and counsel regarding the positive and negative effects of activity on pain and fatigue, the use of adaptive equipment, and pacing.[50]

Strength training can improve walking ability and may prevent a decline in mobility.[4] Strength training for adults with CP has been found to increase strength of targeted muscles by 27% compared to a control group but with no improvements in measures of mobility.[353]

Prevention of overuse syndromes, early joint degeneration, progression of contractures, osteoporosis, poor endurance, and pathologic fractures is important. Cervical and back pain, nerve entrapment syndromes, or tendinitis can occur as a result of excessive and repetitive physical stresses.[131] A survey of adults found that 67% reported one or more areas of pain, with lower extremity and back pain most common; 53% had pain of moderate to severe intensity.

Adherence to exercise programs of stretching, strengthening, and aerobics may be poor, and access to therapy programs may decrease in the adult years. Therapists should encourage the use of community and recreational programs that provide the necessary opportunities to promote fitness and focus on healthy lifestyles. Poor exercise habits may start during adolescence, if not earlier, and can result in a cycle of poor fitness and endurance.[131]

Young adults with CP may experience a wide variation in physical problems with intimacy including spasticity, stiffness, movement, fatigue, weakness, and impaired manual ability.[390] Health professionals may be able to provide counseling and necessary information on adaptations for sexual activities.

Overall, adults with CP need to find a balance between alleviating unnecessary energy costs in daily living and staying fit to achieve optimal health and functioning.[81] Preventive strategies that may minimize the long-term effects of neuromuscular dysfunction include choosing exercises that minimize excessive joint stress, using additional mobility aids or devices such as orthoses, and opting for surgery when appropriate. Changes to the environment may be necessary to maintain optimal independence.[274] Technological advances provide many options for adults with CP. These include computers for written communication, artificial speech devices, environmental controls, and power mobility. For more information, see Chapter 33: Assistive Technology.

In many parts of the world, society is becoming more conscious of the rights and needs of individuals with limitations. This recognition has had a positive effect on environmental factors that influence participation. Human rights legislation exists to accommodate people with disabilities and to prevent discrimination in areas such as employment, accessibility, the legal system, and education. Government programs and services are available to people with disabilities. Theaters, restaurants, libraries, museums, government buildings, educational facilities, shopping areas, parks, campground facilities, and parking lots are often accessible through the provision of ramps, appropriate washroom facilities, and other modifications. Air and rail travel are also becoming more available to people with special mobility needs. Some travel organizations cater to people with disabilities. Therapists should be aware of the facilities and resources available to people with physical disabilities. In some situations, funding for assistive devices, living allowances, and housing and tax exemptions helps prevent undue hardship. Therapists also should be cognizant of the political policies and issues affecting the lives of those with disabilities and should advocate for advancement of equal access to community and governmental resources.

GLOBAL ISSUES

Resources and services for children with CP vary throughout the world. Physical therapists use many different approaches or combinations of approaches, depending on the facilities available, the child's and the family's needs, the therapist's training and background, and the diversity of client values, beliefs, and priorities. Many of the interventions and technologies discussed in this chapter are practiced in high-resource countries, where services, although variable in their extent, quality, and funding, are generally available and accessible. However, much of the world's population lives in low-resource, underserved areas, particularly in developing nations or in remote areas of developed nations. In many countries, children with disabilities are not able to realize basic rights and are subject to policies of institutionalization rather than receiving community-based and family-focused care.[299] They may be deprived of opportunities to participate in society, may be denied access to education, and may suffer from stigma. Nevertheless many of the principles and equipment ideas developed elsewhere can be adapted to various situations. Using indigenous materials to fabricate effective and affordable equipment, recycling used equipment, and training local personnel or fostering exchange programs can help to provide resources to underserved areas.

It is important to be sensitive to local customs, cultures, and environmental situations when adapting programs for different settings. Often the direct application of a certain method is impractical or inappropriate because of economic, geographic, or cultural differences. Throughout the world, increasing emphasis is being placed on community-based rehabilitation, which promotes interventions that are practical and functional for specific settings, lifestyles, and cultures.

PROFESSIONAL ISSUES

Many potential facilitators and barriers to the practice of efficacious, effective, and efficient physical therapy are known. Therapists who provide services to children with CP and their families should be aware that the work can be physically and emotionally demanding. They must practice appropriate lifting and handling techniques and should maintain a suitable level of fitness if they are treating patients actively. Working with children and their families can be both fulfilling and emotionally stressful. Therapists may be challenged by ethical issues, unrealistic expectations and demands, limited resources, and the pressures of dealing with families during periods of grieving and times of crisis.

Therapists are encouraged to collaborate with families and focus on family and environment strengths and solutions to challenges. Therapists also have a role in advocating for public policy and resources to enable individuals with CP to have good health and full participation in desired roles throughout life. Professionals must acknowledge their own needs and reactions and feel comfortable seeking assistance and support from others.

The lifelong physical therapy needs of children with CP and their families are often influenced and constrained by service availability, accessibility, costs, and policy. These parameters can affect wait times for services and may have an impact on service frequency. The psychosocial well-being of families may be affected by long wait periods for therapy.[117] Therapists are often faced with the stressful challenges of providing equitable services within their facility or practice while justifying differences in services among facilities or clients. Intensity of services, including decisions regarding how often, how long, and the duration of an episode, varies considerably among families, therapists, administrators, policy makers, and insurers.[280] Family and fiscal resources challenge therapists to create strategies to provide equitable and appropriate services for all children in their care. Alternatives to continuous therapy include consultation, monitoring, or providing blocks of treatment, while taking into consideration periods of readiness for change. Determining whether children are at a stage of acquiring, improving, maintaining, or generalizing skill, and assessing motivation, supports, and environments, can help indicate optimal times to provide services. Small or large group programs and recreation and sports opportunities can provide alternatives to direct individual therapy.[280]

Best practice encompasses the best research evidence available, clinical expertise, and needs and values.[326] These must be considered in the context of a child, the family, and the health care system resources. Physical therapists are encouraged to reflect on these considerations and collaborate with the family

to make individualized decisions for each child. Therapists must critically appraise available and appropriate knowledge, including accessing recent literature, using the Internet, attending educational sessions, and sharing practice-generated knowledge with colleagues and families to promote optimal decision making. Organizations need to support these strategies.[21,188]

SUMMARY

Physical therapists play an important role on the team of professionals who provide services to children with CP and their families. Therapists offer choices and advice and provide interventions to optimize the development of functional abilities, enable participation in all aspects of life, and prevent secondary impairments. The support given during infancy, childhood, and adolescence can have an impact on functioning and quality of life in adulthood. The ICF framework, systems to classify functional abilities, improved prognostic information, psychometrically strong yet clinically feasible tests and measures, established and innovative interventions, progressive advances in assistive technology, and increasing knowledge of the lived experiences, priorities, and preferences of individuals with CP combine to make the practice of physical therapy for children and adolescents with CP challenging but exciting. The "F-words" paper by Rosenbaum and Gorter[308] exemplifies many of these concepts: *fitness, function, family, fun, friends,* and the addition of *future,* suggesting an emphasis on promoting health promotion by enhancing fitness, activities, and accomplishments that are meaningful to the child and family; encouraging friendships while having fun; and aiming for a future that embodies dreams and desires.[308] In our experience, families are particularly interested in planning for the future. The term *anticipatory guidance* refers to collaborating with families to prepare children for new roles and changing environments such as the transition from early intervention to primary school and the transition from secondary education to adulthood.

Case Scenarios on Expert Consult

The case scenarios related to this chapter present two patients (Noelle and Nicole) with accompanying videos. They illustrate some of the management principles discussed in this chapter. Nicole's story recounts her life over the five editions of Physical Therapy for Children, from infancy to adulthood.

ACKNOWLEDGMENTS

Acknowledgments are extended to the children, adolescents, and their families involved in the case studies for their time and valuable perspectives. We also would like to acknowledge the clinical expertise of our colleagues. The literature provides us with research evidence, but best practice would not be possible without our day-to-day learning from each other.

Brachial Plexus Injury

Susan V. Duff, Darl Vander Linden

This chapter focuses on perinatal brachial plexus injury (PBPI), yet the concepts presented apply to resultant impairments, activity limitations, and participation restrictions caused by brachial plexus injury in children at any age. Therapists may work with infants and children with PBPI in a variety of settings, including early intervention programs, acute care hospitals, and specialty clinics. Therapists may also be involved with this population after microsurgical repair to the brachial plexus in infants or after shoulder reconstruction in toddlers and older children. This chapter reviews the etiology and pathophysiology, examination, procedural interventions, family education, and medical management of children with PBPI.

BACKGROUND INFORMATION

ETIOLOGY AND INCIDENCE

A traction injury to the brachial plexus (Fig. 20.1) can occur during a difficult delivery.[28] During a vaginal delivery, forceful traction and rotation of the head during a vertex presentation to deliver the shoulder tends to injure the C5 and C6 roots or the associated nerves. Traction on the newborn's shoulder during delivery of the head in a breech delivery can injure the cervical roots or nerves, fracture the clavicle or humerus, or cause a subluxation of the shoulder. The likelihood of injury to the brachial plexus drops from 0.2% to 0.02% during delivery by cesarean section.[28] Associated damage to the phrenic nerve at C4 is less common but will cause ipsilateral hemiparesis of the diaphragm. Congenital anomalies such as a cervical rib, abnormal thoracic vertebrae, or a shortened scalenus anticus muscle can also cause pressure on the lower plexus.[62]

The incidence of PBPI has been reported to range from 0.38 to 5.1 per 1000.[14,21,34,78] Risk factors that can contribute to PBPI include shoulder dystocia (catching of the shoulder), birth weight greater than the 90th percentile (4500–5000 g), prolonged maternal labor, maternal gestational diabetes, and breech delivery.[1,19,29,51,78] In a prospective study of 62 infants with PBPI of whom 17 had permanent impairment, 16 of the 17 infants had birth weights over 3500 g and only 1 of the 17 had a birth weight less than 3500 g. Twelve of 13 infants (92%) diagnosed with PBPI at birth who weighed less than 3500 g had full recovery of function, but only 67% of infants (33 of 49) who weighed more than 3500 g had full recovery.[78]

PATHOPHYSIOLOGY

Damage to the nerve structure can occur at the level of the nerve rootlets attached to the spinal cord, at the anterior or posterior rootlets (distal to where the rootlets coalesce to form the mixed nerve root that exits the vertebral canal), or in the spinal nerve itself.[79] Roots, trunks, divisions, cords, and peripheral nerves can all suffer neurotmesis (complete rupture), axonotmesis (disruption of axons while the endoneurium remains intact), or neurapraxia (temporary nerve conduction block with intact axons).[65,79] Partial or complete rupture may evolve into a neuroma and a mass of fibrous tissue as disorganized neurons on the proximal end attempt to reach the distal end.

Recovery is usually limited after ruptures and often requires microsurgical repair. Prognosis after axonotmesis is better as the neurons reconnect more successfully through the intact endoneurium. Axon regrowth reportedly proceeds at approximately 1 mm per day.[65] Given this timeline, recovery in most infants with PBPI can take up to 4 to 6 months in the upper arm and 7 to 9 months in the lower arm.[65] Continued recovery can occur for up to 2 years in the upper arm and 4 years in the lower arm.[22] Early recovery after neurapraxia occurs as edema resolves and is usually quick and complete, sometimes within days or weeks.[34] Among infants and children with PBPI, a combination of these types of lesions is common. Furthermore, axon regrowth in young children may be quicker due to neuroplasticity and the shorter growth distance, which may explain the variability of the return of motor function in individual muscles.

NATURAL HISTORY AND PROGNOSIS

The natural history and recovery of PBPI are difficult to determine because few studies have followed children over a long period of time and authors have primarily used outcome measures of impairment and not of activity and participation. In early studies, a recovery rate of 80% to over 90% was reported.[10,50] As a result, a favorable prognosis has been perceived for the majority of infants with PBPI. More recent studies, however, have reported recovery rates of 66% to 73%.[34,54] Thus, close to 35% of infants and children do not fully recover. In a systematic review designed to describe the natural history of PBPI, Pondaag and colleagues[60] examined the literature on PBPI outcomes. The inclusion criteria were (1) a prospective design, (2) all children with PBPI from a demographic area be followed, (3) a minimum follow-up of 3 years with < 10% loss to follow-up, and (4) use of a well-defined outcome measure with a reproducible scoring system and no surgical intervention. Of the 103 identified articles, none met even three of the four criteria defined for the systematic review, but 27 of the 103 met two criteria. Based on the findings, the authors concluded that the excellent prognosis often cited for PBPI was not based on sound scientific evidence.[60]

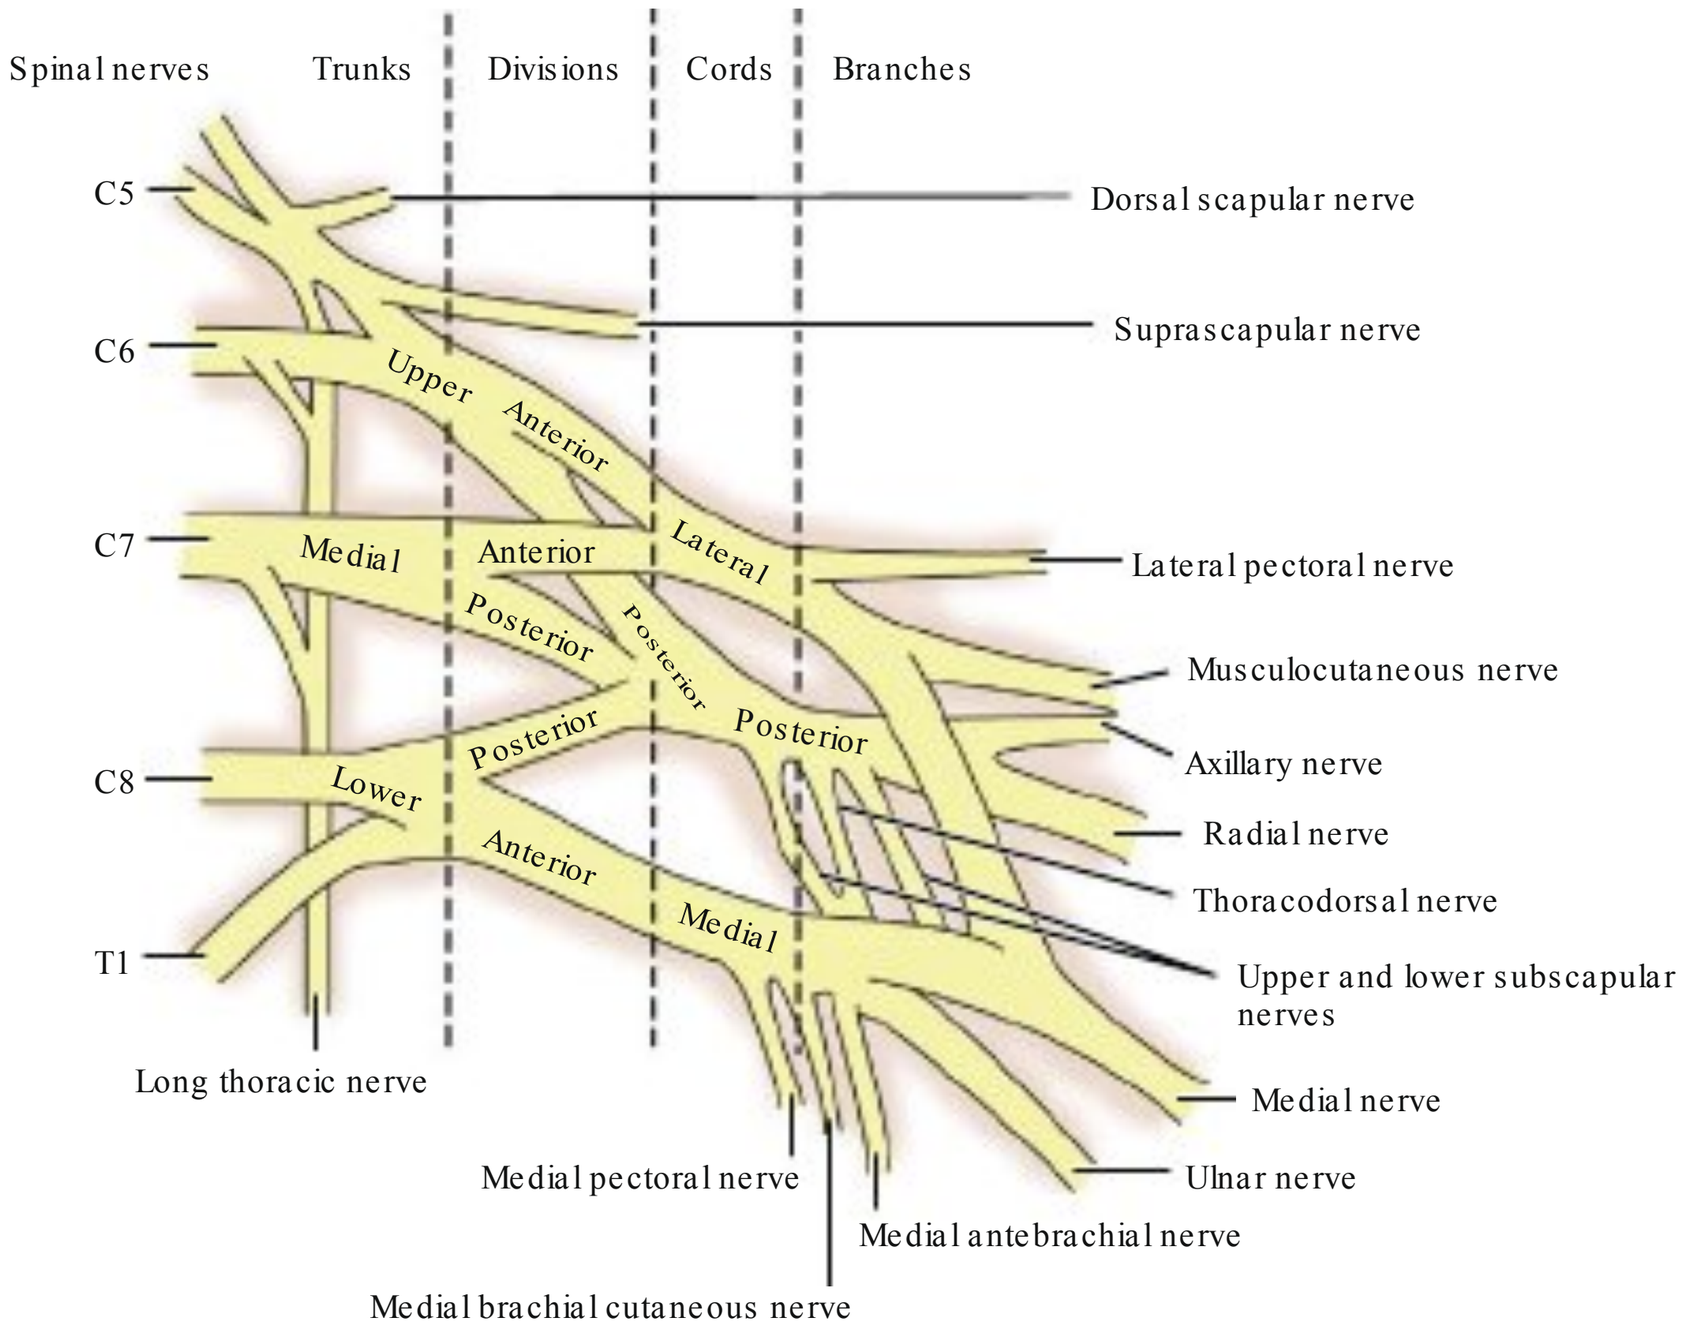

FIG. 20.1 The brachial plexus. Injury can occur at any point along the nerves as they branch off the spinal cord and weave into the brachial plexus. (Redrawn from Waters PM: Obstetric brachial plexus palsy, J Am Acad Orthop Surg 5:205-214, 1997.)

Estimates of spontaneous recovery from PBPI are difficult to establish because many children have neurapraxic lesions that resolve within a few days or weeks so these children are not included in many follow-up studies. Hoeksma and colleagues[34] found, in fact, that 34% of infants (19 of 56) diagnosed with PBPI at birth had full recovery by 3 weeks of age. However, they also found that 32% (18 of 56) had "late" recovery by 1 year of age, and 19 of 56 (34%) did not have full recovery of muscle strength when assessed at a mean age of 3 years. The authors indicated that if the criteria for a "good" outcome as described by Michelow and colleagues[50] of "more than ½ of normal range of shoulder and elbow motion" had been used with their cohort of 56 children, 93% would have had a "good" outcome.[33] DiTaranto and colleagues[13] followed 91 infants in Argentina who did not have access to neurosurgical intervention for at least 2 years. They reported that although 69% had full recovery, 18% of infants had minimal recovery and 13% had global PBPI with flaccid and insensate arms.

The differences reported in the natural history and outcomes for children with PBPI make it difficult for parents and professionals to accurately predict to what extent children will recover postinjury. Studies have begun to use outcome measures standardized for infants and children with PBPI such as the Active Movement Scale[10] and the Modified Mallet Scale.[2] Although more recent reports have specifically defined outcomes based on strength of specific muscle groups,[34,35] few studies report outcomes in terms of activity limitations and participation restrictions in children, adolescents, and adults.

CHANGES IN BODY STRUCTURE AND FUNCTION

Injury Classification and General Impairments

Injury can occur at any level of the brachial plexus, but the most common injury is to the upper plexus (C5 and C6) resulting in a condition referred to as Erb's palsy.[28] Strombeck and colleagues reported that of 247 children followed for PBPI, 52% had C5-C6 involvement and an additional 34% had C5-C7 involvement.[63] As a result of injury to the fibers from the upper plexus, the child's shoulder is usually held in extension, internal rotation, and adduction; the elbow is extended; the forearm is pronated; and the wrist and fingers are flexed in the *waiter's tip* position (Fig. 20.2). Paralysis or decreased activation of the rhomboids, levator scapulae, serratus anterior, subscapularis, deltoid, supraspinatus, infraspinatus, teres minor, biceps, brachialis, brachioradialis, supinator, and long extensors of the wrist, fingers, and thumb can be expected. Grasp is left intact, but sensation may be diminished or lost. Elbow and finger extension are compromised if C7 is also involved and are referred to as an extended Erb's palsy.

Global palsy involves injury to the upper and lower plexus (C5-T1) resulting in paralysis or decreased activation of all muscles of the affected arm with loss of or diminished sensation.[28] Strombeck and colleagues reported that 13% of the children with PBPI in their follow-up study had involvement of the C5-T1 roots.[63] Involvement is usually unilateral but has been reported to be bilateral in a low percentage of children.[71] The pattern of motor loss does not always fit the classic definitions,

FIG. 20.2 Child with Erb's palsy, a C5-C6 brachial plexus injury, resulting in the waiter's tip position of the UE, which is typically observed with this type of injury. (From Shenaq SM, Bullocks JM, Dhillon G: Management of infant brachial plexus injuries, Clin Plast Surg 32:79-98, 2005.)

indicating incomplete or mixed upper and lower types of injury. Horner's syndrome, as a result of T1 root avulsion, or the sympathetic ganglion, can cause deficient sweating, recession of the eyeball, abnormal pupillary contraction, myosis, ptosis, and irises of different colors.[14]

Klumpke's palsy by definition involves only the lower roots or spinal nerves C8-T1.[37] In a 1995 review, Al-Qattan and colleagues found Klumpke's palsy in only 20 of 3508 cases of PBPI reported in the papers they reviewed, for an incidence of only 0.6%.[3] When pure Klumpke's palsy is present, the child's shoulder and elbow movements are not impaired, but the resting position of the forearm is typically in supination with paralysis of the wrist flexor and extensor muscles and the intrinsic muscles of the wrist and hand.

Positional torticollis can develop as a result of the infant's head being habitually positioned away from the affected arm, or it may be present from the same trauma that caused the PBPI.[31] In addition, some infants develop plagiocephaly from prolonged positioning. See Chapter 9 for more information regarding examination of and interventions for torticollis and plagiocephaly.

During the period of neural regeneration following PBPI, infants and toddlers use muscle substitutions that are the most advantageous given the strength of the available innervated muscles. For example, internal rotation at the shoulder, combined with forearm pronation and wrist flexion, is often used to obtain objects. Neglect of the affected extremity may occur due to diminished sensibility or the comparative ease with which the opposite arm and hand can accomplish a task. Some infants also demonstrate self-mutilation of the limb such as biting if there is diminished sensation.[45] Patterns of substitution, neglect, or abuse are reinforced with repetition. The problems that arise from these repetitive patterns include soft tissue and muscle contractures, muscle atrophy, and abnormal bone growth. The contractures most likely to develop are scapular protraction; shoulder extension, adduction, and internal rotation; and elbow flexion. Contractures into forearm pronation as well as wrist and finger flexion may occur in those with severe injury or Klumpke's palsy. These patterns will obviously vary depending on the denervation pattern.

Shoulder Impairment

As the infant develops, persistent muscle imbalance and habitual posturing contribute to common anatomic changes in the shoulder. These changes can include flattening of the humeral head, an abnormally short clavicle, humeral head hypoplasia, posterior subluxation of the humeral head, an irregular glenoid fossa, ligamentous pathology, and muscle tightness.[24,33,39] These deficits correlate with a loss of passive and active shoulder external rotation (ER) along with other changes in shoulder biomechanics.[14,39] The mean glenohumeral-to-scapulothoracic (GH-to-ST) ratio in typically developing children is reportedly 1.3 to 1 in children 6.7 ± 1.5 years[12] and 1.43 to 1 in children 9.12 ± 1.51 years.[27] Duff and colleagues[15] examined the GH-to-ST ratio in children 7.81 ± 2.93 years who sustained PBPI yet had not undergone microsurgery or shoulder reconstruction. During active abduction in the scapular plane, the authors found a mean loss in the GH-to-ST ratio (0.6 to 1) in the affected arm of children with limited arm elevation (< 75°). This first group of children tended to rely on scapular upward rotation versus GH joint elevation to raise the affected arm. Children who could raise the affected arm 75° and above displayed a mean GH-to-ST ratio of 1.7 to 1 during shoulder range of 15° to 75°. Thus, the GH joint of the second group made a greater contribution to arm elevation in the affected arm.

ACTIVITY AND PARTICIPATION LIMITATIONS

Activity limitations will vary greatly, depending on the extent of the initial pathology, neurologic regeneration, and residual impairments. The primary activity limitations in children with PBPI relate to reach-to-grasp skills and the performance of tasks that require bilateral arm use such as catching a large ball or lifting a large object. Activities of daily living (ADLs) that require bilateral upper extremity (UE) use will be compromised. These activities would include donning and removing shirts and pants, tying shoes, and securing fasteners. Studies that examine the nature and extent of activity limitations such as dressing and eating or participation restrictions are emerging.[32]

Typical developmental activities may be compromised as a result of PBPI. Transitions from prone or supine to sitting could habitually be done from one side, thereby asymmetrically strengthening one side of the trunk or delaying development of balance reactions. The developmental milestone of creeping on all fours may not occur or may be adapted because the child may not be able to safely bear weight on the affected arm or may not be able to extend the wrist sufficiently. The child may also scoot around while sitting or progress directly to walking at the appropriate age.

Neglect of the affected limb during activity and self-abusive behavior such as biting can occur because of diminished sensory awareness.[46] Injuries such as burns, insect bites, and abrasions may go unnoticed if sensibility is severely compromised. Shoulder pain and neuritis in adults are complications that can interfere not only with the function of the affected arm but also with other aspects of the individual's social or vocational activities.

FOREGROUND INFORMATION

THERAPEUTIC EXAMINATION

Clinical examination of the neonate with PBPI may be requested before discharge from the hospital. Infants and children may also be referred to therapy in the days, weeks, months, or years after the initial injury. An examination of active and passive range of motion (ROM), posture, pain, sensory status, and visual skills is key in establishing a baseline of early function and capability.[4] Screening the developmental status of the infant or child will ensure that other pathologic conditions are not missed. In the infant, frequent reexamination documents motor and sensory recovery as neural regeneration occurs. These data aid in program planning, whether it be therapeutic exercise, positioning, splinting, determining eligibility for surgery, or establishing readiness for discharge from intervention.

Impairments

Imaging: Electromyography

Neonatally, radiographs are taken to assess for clavicular or humeral fractures.[79] Infants not showing evidence of recovery may initially undergo imaging between 1 and 6 months of age, yet the exact timing of testing varies. Imaging is frequently done to examine the integrity of the nerve roots and neural structure as well as the integrity of the glenohumeral joint. Imaging in the form of magnetic resonance imaging (MRI), electrodiagnostic studies, computed tomography (CT), CT with metrizamide (CT-myelogram), and ultrasound can be used diagnostically and to aid in surgical planning.[2,47,69] CT myelography and MRI are the most frequent modes used to examine nerve structures.[79] Noninvasive ultrasound of the glenohumeral joint[72] between 3 and 6 months of age is reportedly useful to diagnose posterior subluxation of the humeral head.[61] Imaging studies are often repeated in older infants and children to examine glenohumeral joint structure before shoulder reconstruction. However, imaging does not replace the careful physical examination of the clinical and functional consequences of neurologic damage and neural regeneration.

Electromyography (EMG), although of little prognostic value, can determine the extent of involvement and is often recommended as a preoperative baseline.[64,69,70] Repeated EMG testing can alert the clinician to muscles that are undergoing reinnervation before obvious motor changes occur. Findings from diagnostic EMG have been used to assess the extent and severity of the lesion, but they may not correlate well with findings upon surgical exploration.[30] Reinnervation after microsurgery can be identified by EMG immediately after surgery or in the following weeks and months, before clinical signs of motor return are present. This information may alter therapeutic goals and intervention strategies, and it may change a patient's prognosis significantly.

Range of Motion

At any age, passive ROM measurements of the affected arm and cervical area are performed and compared with the contralateral side. Initially, movements should be performed with great care because the child's joints can be unstable[38] and the child may be experiencing pain or diminished/absent sensibility in the affected limb. It is critical to establish baseline passive ROM with goniometry before examining muscle strength. It is also essential that during passive assessment of the GH joint the scapula is stabilized,[16,24] as shown in Fig. 20.3A-C. Gharbaoui and colleagues[24] published a review of the anatomic changes in the GH joint and shoulder in children with perinatal brachial plexus palsy. The authors recommend measuring five shoulder motions: (1) scapulohumeral (SH) angle in abduction, (2) SH angle in adduction, (3) SH angle in horizontal adduction, (4) GH internal rotation (IR) arc of motion in 90° abduction and 90° elbow flexion, and (5) GH ER arc of motion in 90° abduction and 90° elbow flexion. The reader is referred to this article for a full description and photos of the measurement positions and goniometry placement.

Muscle Strength and Motor Function

In the infant, clinicians can observe limb movement or palpate muscle contractions when testing a variety of responses

TABLE 20.1 Active Movement Scale

15 Active Motions*	Grade
Gravity Minimized	
No contraction	0
Isometric contraction, no motion	1
Motion ≤ ½ available passive range	2
Motion > ½ available passive range	3
Full motion	4
Against Gravity	
Motion ≤ ½ available passive range	5
Motion > ½ available passive range	6
Full motion	7

*Shoulder (abduction, adduction, flexion, external rotation, internal rotation), elbow (flexion, extension), forearm (supination, pronation), wrist (flexion, extension), thumb (flexion, extension). Full active range of motion with gravity minimized (grade 4) must be achieved before active range against gravity is scored (grades 5 to 7).

From Clarke HM, Curtis GC: An approach to obstetrical brachial plexus injuries, Hand Clin 11:567, 1995.

and reflexes/reactions such as visual tracking, asymmetrical neck righting reflex, the Moro reflex, the Galant reflex, or the hand-placing reaction.[16] Arm and head movement can be observed during wakeful play periods as a child tries to bring the hand to the mouth or reach for a toy. Care should be taken to document whether movements are made with gravity minimized or against gravity. Asymmetry of abdominal and thoracic movement may indicate phrenic nerve paralysis.

A muscle grading system, titled the Active Movement Scale (AMS) has been developed specifically for infants and children with PBPI to capture subtle but significant changes in active movement of the arm (Table 20.1).[10] This measure has been shown to have adequate interrater reliability and validity to accurately measure motor function of the UE in infants younger than 1 year of age.[11] Curtis and colleagues also provided a review of other measures of impairment that have been used for children with PBPI including the British Medical Research Council (BMRC) system of manual muscle testing and the modified BMRC that uses a 4-point scale (M0 to M3) to measure muscle activity.[11]

Older children can be examined using standard manual muscle tests and dynamometers to obtain an objective measure of muscle strength (see Chapters 2 and 5 for more information on strength testing in children). Patterns of movement, atypical substitution patterns, and posturing of the arm as a result of muscle imbalance and diminished or absent sensation should be documented. The Mallet classification of UE function can be used for children older than 3 to 4 years of age and has been shown to be reliable when used with children with PBPI.[6, 44] The Modified Mallet (Fig. 20.4)[2] expands on the original Mallet scale with the addition of a sixth item, IR with elbow flexion to the abdomen from a position of 90° shoulder abduction.

The impairments present in PBPI do not include spasticity. As a result, any spasticity identified during the examination would suggest an upper motor neuron lesion warranting further diagnostic evaluation by the child's primary physician or neurologist.

Sensation

Narakas[53] developed the Sensory Grading System for children with PBPI. A grade of S0 is regarded as no reaction to painful or other stimuli; S1 is reaction to painful stimuli, none to touch; S2 is reaction to touch, not to light touch; and S3 is regarded as normal sensation. Diminished or absent sensation does not necessarily correspond to the extent of motor impairment;[18] therefore, care should be taken not to ignore this component of the examination in children with milder involvement.

As neural regeneration proceeds, sensory loss may change to hyperesthesia before progressing through diminished or normal sensation.[53] Infants or older children may experience pain or discomfort in reaction to sensory stimulation and touch. This change should be documented and may indicate progression of neural regeneration. More definitive sensory testing to touch pressure, light touch, and two-point discrimination is possible in older children, and specific areas of diminished sensibility can be mapped. Sensation may take as long as 2 years to recover.[53]

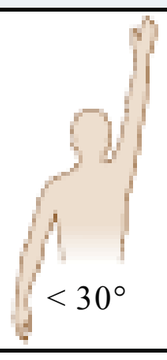
Pain

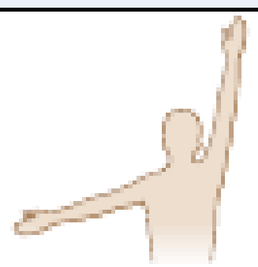
Light palpation to the affected neck and upper shoulder may induce a pain response such as grimacing in an infant or child with PBPI. Active movement as elicited with visual tracking can provide further information on the influence pain may have on neck motion and visual scanning. These behavioral cues can be used to rate pain on the Face, Legs, Activity, Cry, Consolability (FLACC) scale. The FLACC rates pain on a score of 0 to 2 based on behavioral cues from five categories: face, legs, activity, cry, and consolability.[49] Many clinical sites have adopted the resultant 0-to-10 FLACC scale to objectively measure pain in infants. The Wong-Faces pain rating scale[77] is recommend to assess pain in older children.

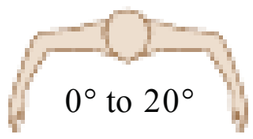
Activity and Participation

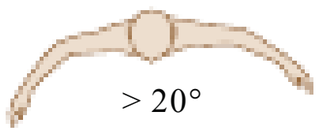
Developmental tests of gross and fine motor performance can be used to establish and track any delays caused by the UE impairment and dysfunction in infants and toddlers. Although no research exists on its use in PBPI, the Test of Infant Motor Performance (TIMP) may be useful for infants younger than 4 months of age postterm to document changes in motor function because it has nine activities that are scored independently for each side of the body.[9] Another useful gross motor assessment standardized for use with children 0 to 18 months of age is the Alberta Infant Motor Scale (AIMS).[59] Gross screens can be conducted to assess the ability the older child has to perform functional activities such as bringing the hand to mouth for eating, bringing the hand to the head for brushing hair, and sufficiently holding select tools (e.g., toothbrush) for their intended use. Taking a video of these activities would allow comparison with follow-up testing.

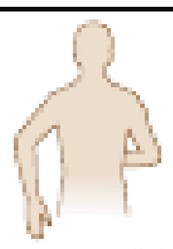
For older children, anecdotal information about activity limitations and participation such as difficulty with ADLs, carrying a tray at school for lunch, or playing a recorder should be documented.[66] Fortunately, specific measures of activity and participation for use with children with PBPI have been developed.[32,41] The Brachial Plexus Outcome Measure (BPOM) and the BPOM Activity Scale were designed for children 4 to 19 years of age. The BPOM tests the quality of UE movement during completion of 11 activities aimed at measuring the key deficient functional movement patterns in children with brachial plexus palsy. Performance is graded on a 5-point ordinal scale based on task completion and visible movement quality. The Assisting Hand Assessment (AHA)[41] and the Mini-AHA[25] assess the bimanual skills of children with unilateral cerebral

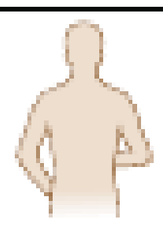


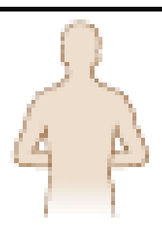


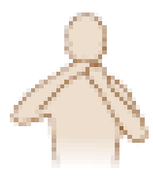


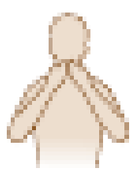


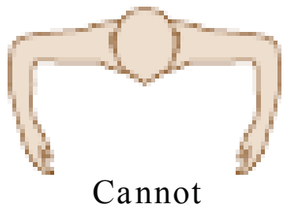


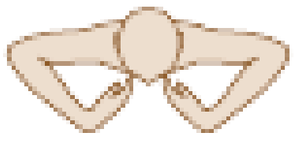


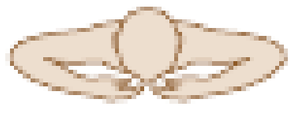












Modified Mallet Classification (grade I = no function, grade V = normal function)						
		Grade I	**Grade II**	**Grade III**	**Grade IV**	**Grade V**
Global abduction	Not testable	No function	 < 30°	 30° to 90°	 > 90°	Normal
Global external rotation	Not testable	No function	 < 0°	 0° to 20°	 > 20°	Normal
Hand to neck	Not testable	No function	 Not possible	 Difficult	 Easy	Normal
Hand on spine	Not testable	No function	 Not possible	 S1	 T12	Normal
Hand to mouth	Not testable	No function	 Marked trumpet sign	 Partial trumpet sign	 < 40° of abduction	Normal
Internal rotation	Not testable	No function	 Cannot touch	 Can touch with wrist flexion	 Palm on belly, no wrist flexion	

FIG. 20.4 Modified Mallet's classification of function in brachial plexus palsy. Grade 0 (not shown) is no movement in the desired plane, and grade V (not shown) is full movement. (From Skirven TM, Osterman AL, Fedorczyk JM, et al.: Rehabilitation of the hand and upper extremity, ed 6, Philadelphia, 2011, Mosby.)

palsy or who sustained brachial plexus injury. The AHA is standardized for children 18 months to 12 years and the Mini-AHA for children 8 to 18 months of age. The AHA, Mini-AHA, and the BPOM are criterion-referenced tools designed to measure how effectively children with unilateral dysfunction actually use the affected hand and arm during bimanual tasks within a play session. These assessment tools could be used to measure change over time or following therapeutic or surgical intervention.

SURGICAL MANAGEMENT

Neurosurgery

For infants who are not displaying sufficient recovery of spontaneous or intentional affected arm motion, microsurgery is recommended. Microsurgical techniques used in the treatment of PBPI include nerve transfers, nerve grafting, neuroma dissection and removal, neurolysis (decompression and removal of scar tissue), and direct end-to-end anastomosis of the nerve ends.[42,68] The technique chosen depends on the anatomic findings and surgical background of the physician.

Indications and Timing of Neurosurgery

It is typically recommended that microsurgical repair of the brachial plexus be done between 3 and 8 months of age for optimal results with select clinical sites opting for surgery at an earlier age (e.g., 3 months).[7,26] For infants who present with complete paralysis and Horner's syndrome, surgery is highly recommended by 3 months of age.[30] Lack of biceps function and elbow flexion are frequently used to determine which infants with incomplete neural recovery are candidates for surgery.[22,23]

Interestingly, Hoeksma and colleagues found that available shoulder ER and forearm supination were more useful determinants of the need for surgical intervention than elbow flexion.[34] Fisher and colleagues[20] also reported that lack of active elbow flexion is not as useful in determining candidates for surgery as total AMS scores are. Hence, diminished or absent active ER and forearm supination as well as total AMS score may be the most useful criteria for determining if an infant should have microsurgical repair secondary to a brachial plexus lesion.

Outcomes of Neurosurgery

The results from brachial plexus microsurgery are far better in infants than in adults due to the reduced distance, better potential for neural regeneration, and the potential for central adaptation.[68]

Interestingly, Terzis and Kokkalis[67] found that a group of infants who underwent microsurgery before 3 months had better shoulder function than those who had surgery between 4 and 6 months and demonstrated less need for secondary reconstruction. However, some authors have demonstrated that late nerve reconstruction can result in improved shoulder function and have recommended this option to extend the window for surgery past 3 to 8 months.[26]

During the immediate postoperative period after microsurgery, the limb is immobilized for about 3 weeks.[42] After this period, the rehabilitation strategies of passive ROM and muscle activation are initiated. It is important to remember that the timing of muscle activation will be variable based on the type of microsurgical procedure that was done. Children who receive nerve transfers should achieve muscle activation months sooner than children who undergo nerve grafting.[43] It is recommended that the therapist communicate closely with the surgeon to determine the best plan of intervention for each child.

Strombeck and colleagues[63] reported that for children with global palsy (C5-T1), those who had microsurgery displayed significant improvements in active shoulder motion when compared to children who did not have microsurgery. In a long-term follow-up of the same group of children who had microsurgery,[64] the integrity of the EMG findings from the deltoid muscle was noted to deteriorate over time, even in those children with full recovery. However, sensibility was less affected. More recently, Lin and colleagues[42] reported that neurosurgical repair that included resection and grafting (n = 92) as opposed to neurolysis only (n = 16) had better movement outcomes based on the AMS. A multicenter retrospective review was conducted to examine the outcome from ulnar or median nerve fascicle transfers to increase elbow flexion and supination.[43] Reportedly, postoperatively 27/31 subjects achieved full elbow flexion and 24/31 achieved elbow flexion against gravity.

In a systematic review of outcomes for children with PBPI who underwent neurosurgery, McNeely and Drake[46] found most studies to be case-series designs without control groups (level III evidence). Although the findings were generally favorable, the authors determined that there was no conclusive evidence of a benefit of microsurgery over conservative management in the medical treatment of children with PBPI. Because most of the studies related to timing and outcomes of microsurgery from a case-series design, it would seem essential that randomized controlled trials (RCTs) examining the outcome of microsurgery in this population be conducted. It would be interesting to compare early versus late surgery, as both have been shown to be beneficial. Ideally, the RCTs should use standardized, reliable, and valid outcome measures in each of the three domains of impairment, activity, and participation.

Orthopedic Surgery

The main goal of orthopedic surgery is to provide the necessary active and passive ROM to enable the patient's hand to reach the head and mouth for meaningful ADLs. Hand and wrist reconstruction may be delayed until spontaneous recovery has plateaued and the child can fully participate in postoperative hand therapy. However, shoulder reconstruction is frequently done much earlier.

Persistent muscle imbalances and soft tissue contractures in children who do not experience complete return after PBPI contribute to progressive GH joint dysplasia.[24,33,75] Prolonged weakness of the shoulder external rotators with overpull of the internal rotators often leads to glenoid retroversion, flattening of the humeral head, and progressive posterior subluxation of the humeral head.[24,75] The GH joint deformity is present in up to 67% of children with PBPI[30,45] and is frequently associated with a shoulder IR contracture. Hoeksma and colleagues found that even mild contractures are strongly associated with shoulder deformity.[33]

Common shoulder surgeries include extraarticular tendon transfers of the latissimus dorsi and teres major to the rotator cuff, musculotendinous lengthenings of the pectoralis major or subscapularis, reductions of GH joint dislocations, and osteotomies.[74,75] In one study, 23 children with GH deformity had transfers of the latissimus dorsi and the teres major tendons to the rotator cuff for weakness in ER, as well as lengthening of the pectoralis major or subscapularis. For these children at a mean follow-up of 31 months, active ER improved significantly on the Mallet[44] (preop score of 2 and postop score of 4) and on the AMS (preop score of 3 and postop score of 6). Tendon transfers reportedly improve shoulder motion,[37] and whereas some studies documented the presence of GH remodeling postoperatively,[75] other postoperative studies did not find a reduction in humeral head subluxation and GH joint alignment.[40] Derotational osteotomies are done to place the arm and hand in more functional positions for use if shoulder impairments persist > 5 to 7 years of age.[76]

Parents pursuing orthopedic surgery for their child should become knowledgeable of the most current research on the technique and outcome of procedures being considered. Transferring a muscle can be expected to result in the loss of one muscle strength grade; therefore, the muscle chosen for transfer should be as strong as possible before surgery. Also, clearly identified functional goals should be established before any surgery. For an excellent review of the evaluation and management of shoulder problems in infants and children with PBPI, parents and therapists are referred to Pearl[58] or Gharbaoui et al.[24]

The rehabilitation goals after shoulder reconstruction resemble those that were outlined previously but also vary depending on the orthopedic procedure. Immediately after most shoulder procedures, stabilization with an orthotic brace or spica cast is employed for 4 to 6 weeks.[76] After the stabilization period the child is often weaned off a brace during the day but may continue to wear one at night, depending on the treatment plan of the surgeon.

Active motion and strengthening can usually begin after the brace or cast is removed.[76] After tendon transfers, place and hold isometric strategies aid the child in activating the tendon/muscle unit in a new functional role. Isotonic exercises can

follow isometrics and when cleared resistive work can begin. Joint releases and muscle-lengthening procedures require diligence with regard to maintenance of the full passive range of motion (PROM) achieved and active motion in the improved range. Strengthening exercises and the performance of functional tasks in the new range are encouraged when tolerated. As the child progresses, rehabilitation strategies that maximize performance and function will be encouraged. Assessment of postsurgical and rehabilitation outcome is ongoing to allow the program to be adjusted as needed.

REHABILITATION GOALS

The ideal outcome for the neonate who sustains a PBPI is complete return of motor control and sensation with no activity limitations or participation restrictions. It is recommended that therapy begin immediately in early infancy, but further research is needed to examine the best modes of treatment to obtain a beneficial effect. The therapy goals during the first few months after diagnosis are to support spontaneous recovery, minimize pain, prevent secondary impairments (e.g., muscle or joint contracture), promote typical movement patterns, and foster overall development. Depending on the extent of the impairment and dysfunction, increasing PROM, strength, and sensory awareness while minimizing pain during functional tasks remains the goal in the first 2 years of life. Neural regeneration and restoration of motor control may be augmented through surgical procedures. Most spontaneous recovery occurs by 9 months of age, but continued recovery may occur up to 2 years after the injury.[22]

Children with PBPI need ongoing monitoring of ROM, sensibility, pain, functional status, and development. At some point in the infant or toddler phase, it may become apparent that significant neural regeneration is no longer occurring, even after microsurgery. Goals would need to be revised for children who lose range or plateau in their recovery over several months. Even with the most diligent implementation of a home program, full PROM can be difficult to maintain when muscle imbalance is present. If GH joint limitations are present, the child may be a candidate for shoulder reconstruction.

The desired outcomes during the toddler-to-childhood phase would be that the child develop age-appropriate self-care skills such as dressing and grooming using either extremity and participate in age-appropriate movement activities and school programs. Goals would include maintaining or increasing PROM and strength in motion critical to specific activities that the child has difficulty with or is invested in performing. For example, the child may need to increase shoulder elevation and elbow extension strength in the affected arm to shoot a basketball.

THERAPEUTIC PROCEDURAL INTERVENTIONS AND FAMILY EDUCATION

During infancy, a therapist may perform a consultation before discharge from the hospital. Once cleared for assessment and treatment, the clinician can perform baseline examinations described earlier in this chapter. A home program is developed for parents featuring passive ROM to the neck and UE joints at risk for contracture. Positioning strategies and therapeutic play activities useful to maintain ROM and activate or strengthen weak muscles are also emphasized. In addition, precautions regarding regions of pain, sensory loss, or diminished sensibility are reviewed. For older children, the provision of DVDs has been shown to improve compliance with the home program.[52] Anecdotally, videos or photos taken with a cell phone have also been used to reinforce home programs for infants and children of any age. Intuitively, therapeutic treatment and home programs seem beneficial for this population whether they progress without surgery or require surgical intervention. However, high-quality evidence in support of various intervention strategies is warranted.

Active Movement

The objective of the rehabilitation program is to facilitate the highest functional outcome possible for the infant or child, particularly in regard to prehensile skills as they relate to meaningful, developmentally appropriate activities. Simple strategies often work best. For example, while being held on a parent's lap, placement of a finger into the palm of a young infant's hand while the elbow/forearm is supported in flexion/neutral supination often encourages activation of the grasp reflex or an intentional grasp. This action can potentially foster activation of weak arm muscles such as the biceps. The use of positioning strategies in clinic and home programs is vital early in rehabilitation.

Strategic positioning in sidelying, prone, and supine positions can aid the activation of weak muscles in young infants. Lying on the affected side (with the head supported in neutral) encourages isolated elbow flexion, whereas lying on the unaffected side encourages shoulder motion. Given the high risk for muscle and GH joint contracture, it is important to prevent sustained shoulder IR of the affected arm (as feasible) when sidelying on the unaffected side. When prone, the infant who does not yet prop on the elbows can stretch the GH joint into ER and horizontal abduction while resting in this position. Alternatively, chest support provided with a rolled-up receiving blanket can allow the infant to prone prop on the elbows when this is developmentally appropriate and tolerated by the affected shoulder. This supported weight-bearing position can encourage activation of the shoulder musculature and neck/trunk extensors. When the infant is placed in the supine position, it is important to place the elbows and hands of the both arms higher than the shoulders to prevent posturing into shoulder extension and to allow greater ease of arm movement against gravity.

During reaching activities, careful attention to the scapula is critical because paralysis of the rhomboids and contracture of muscles that link the humerus to the scapula interfere with the normal 6:1 humeral-scapular rhythm in the first 30° of shoulder movement.[36] The scapula can be manually stabilized as the shoulder is assisted in active elevation while the child reaches for toys. Alternatively, strategically setting up the environment to allow active shoulder movement with gravity minimized can allow for recruitment of weaker muscles and prevent atypical movements from occurring. For young infants the sidelying position allows for shoulder flexion with gravity minimized. For older infants and children, kinesiotaping[73] may be one method to foster scapular stabilization from any position. The published case study by Walsh[73] reported that kinesiotaping and exercise seemed to facilitate muscular support to position the humeral head in the glenoid fossa. Despite the positive outcomes from this case study, further research on the specific benefits of kinesiotaping and exercise for scapular stabilization is warranted.

In clinic and home programs, one must be creative to provide opportunities for activation of weak muscles during prehensile and functional tasks that minimize gravity and prevent substitution patterns. The number of motor behaviors and tasks that need emphasis in this population of children are endless and include hand-to-mouth tasks, hand-to-hand transfer of objects, weight shifting in prone prop and quadruped, tailor sitting with hands propped anteriorly or posteriorly, transitional movements, creeping, and reach-to-grasp behaviors. Simple place and hold isometric exercises are an efficient way to initiate muscle activation in weak musculature. Manual guidance to aid in the accomplishment of tasks is also useful but can be replaced with environmental set-up to ease task completion and encourage self-generated movement as muscle strength improves. Fig. 20.5A illustrates a nonfunctional position that an infant with a classic C5-C6 injury may assume. Fig. 20.5B demonstrates how manually guiding the shoulder into flexion and ER allows the infant to experience a more typical, functional movement pattern and obtain more appropriate sensory information through an open palm. This action can be followed by task practice without manual guidance by setting up the environment to allow the production of self-generated motion and reinforce motor learning. Because active shoulder ER and forearm supination are often weak or absent in children with C5-C6 injuries, toys should be presented strategically in different areas of the workspace to encourage variable muscle activation patterns and different prehensile skills. Intervention strategies designed to augment muscle activation of weak muscles through visual-auditory biofeedback are emerging and showing promise as rehabilitation strategies.[17]

In any position, gravity or toys held in the hand can provide resistance as muscles gain strength for prehensile behaviors. At times, the unaffected arm may need to be gently restrained when encouraging the child to use the affected arm. Tactile stimulation or facilitation of the weak muscles with gentle joint compression in weight bearing, biofeedback, or electrical stimulation can also encourage activation of weak muscles.

Typical posture and developmental activities may be compromised as a result of PBPI. Transitional movement to a seated position may always be done from one (i.e., the unaffected) side, and as a result, posture of the trunk may be asymmetrical and balance reactions may be delayed on the affected side. To address reliance on the unaffected side, movement into sitting and other transitional movements can be practiced from the affected side using manual guidance and facilitation as needed. When sitting is achieved, challenging protective reactions to the affected side can facilitate shoulder abduction.

Typical bilateral UE use will likely be delayed and often needs to be emphasized. Opportunities for the child to experience and practice symmetrical two-handed activities such as tossing and catching large balls can be encouraged as well as the performance of asymmetrical tasks that require stabilization with one hand manipulating the other. Intervention strategies provided in the context of purposeful tasks versus the performance of exercises are also motivating for children. For example, strengthening of the shoulder flexors could be done by asking the child to lift 10 toy people up and into a dollhouse (purposeful) instead of performing 10 repetitions of shoulder flexion (exercise). In the older child who has not experienced full return of motor function, adaptations and devices to assist in ADLs and recreational activities should be made available for the child's consideration. Swimming programs are often recommended at this time because they engage both UEs and are often enjoyable for children.

The use of botulinum toxin has been found to improve active motion in muscles antagonistic to those injected with the toxin.[5] Arad and colleagues[5] examined the short- and long-term outcome after Botox injections to the shoulder internal rotators and triceps musculature to improve shoulder ER and elbow flexion/supination in children who had not undergone microsurgery. The study included children who first received an injection at a mean age of 30 to 36 months of age. Based on AMS scores the authors found that shoulder ER significantly improved after 1 month yet decreased by 1 year of age. Elbow flexion/supination did not initially improve, but after 1 year a significant improvement was noted based on AMS scores. Only the elbow/forearm motions were sustained over time. The authors caution that it is important to determine whether the cause of the muscle imbalance is differential muscle weakness or co-contraction.

Range of Motion

Passive ROM and stretching can be done in isolation, during positioning, or in the context of typical developmental activities

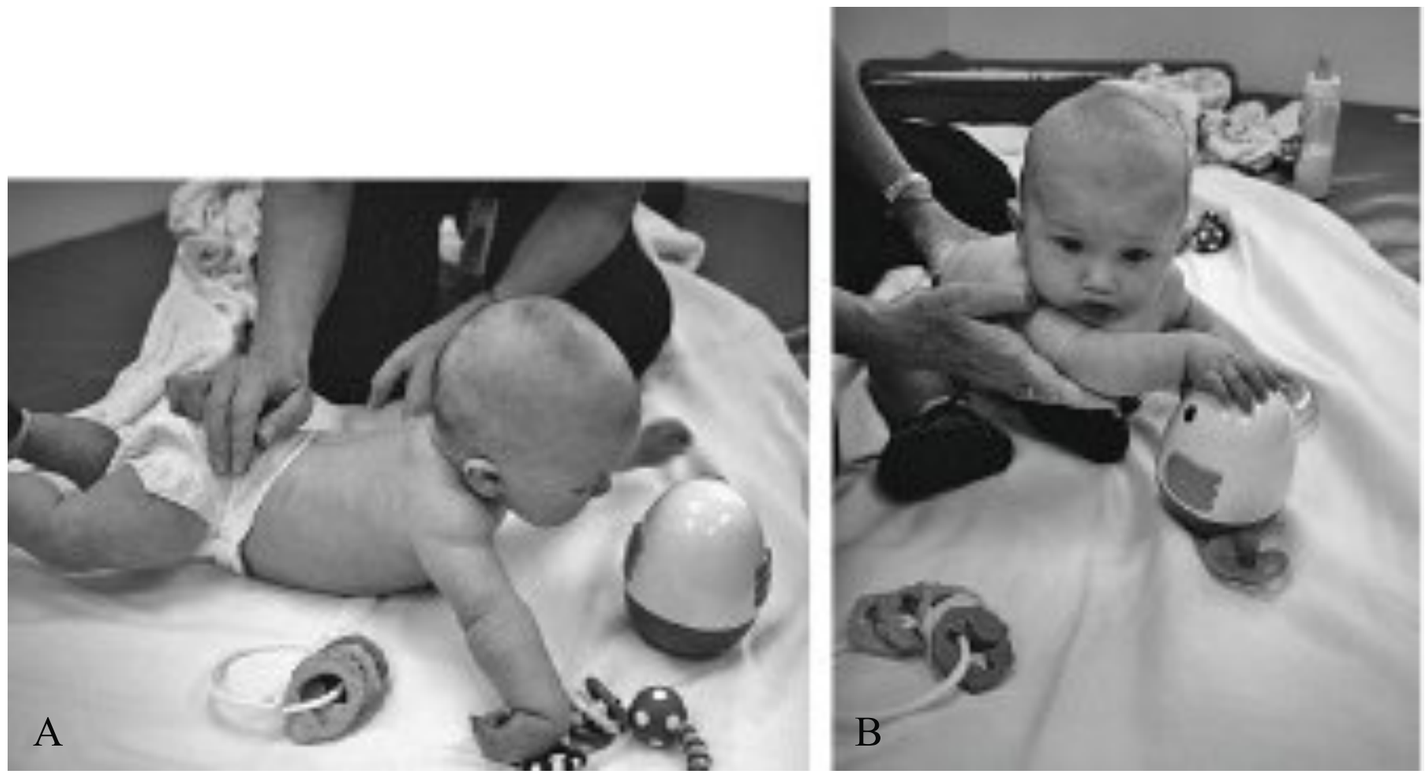


FIG. 20.5 A, Infant with C5-C6 brachial plexus injury trying to prop and reach. B, Infant assisted to reach and grasp with manual guidance.

by parents and clinicians. Goniometric measures of UE PROM should be performed weekly or biweekly and the clinic/home program adjusted based on the findings. Maintaining ROM is important, as up to 65% of children with incomplete recovery of PBPI have been found to have limited ROM at the shoulder.[35] Stretching should never cause pain and should always be gentle. Although passive ROM is encouraged, overstretching can be harmful to joints and joint capsules that are already unstable. Placing the child's arm in optimal positions is a time-efficient way to stretch soft tissue restrictions because this can be done during feeding, carrying, or positioning in a car seat. As the child's arm relaxes during sleep, even more passive range can be attempted.

Prevention of scapulohumeral adhesions is an important goal of therapeutic intervention. The infant or child can do passive shoulder ROM in isolation as tolerated. As mentioned previously, stabilization of the scapula is critical, as shown in Fig. 20.3A-C. Again, the reader is encouraged to review the article by Gharbaoui and colleagues,[24] which introduces five critical stretches that should be used with children to prevent GH joint contractures or encourage an increase in passive ROM.

During reaching tasks, the scapula can be stabilized or restrained to stretch muscles that link the scapula to the humerus during the first 30° of abduction. As mentioned previously, Kinesiotape can be used to foster scapular stabilization during tasks performed at home.[73] Beyond 30°, the scapula must rotate along with humeral ER to avoid harmful impingement of soft tissues on the acromion process, thus, rotation should be encouraged. For a visual demonstration of scapulohumeral rhythm, the reader is encouraged to search for appropriate videos online by using the search term *scapulohumeral rhythm*.

Sensory Awareness

Diminished sensibility can lead to neglect or even self-abuse of the affected arm.[45] Parents must be cautioned about the risk of injury to body areas where sensation is compromised and should watch for any signs of self-mutilation such as biting an insensate area. Enlisting the participation of the affected limb in play activities such as holding a bottle allows the child to perceive the extremity as being a purposeful part of the body. Sensory perception can be enhanced by placing objects of different textures and temperatures in the hand, playing games such as finding toys under sudsy water or in rice with the affected hand, or in the case of older children having them name familiar objects placed in their hand while blindfolded. Parents themselves should be encouraged not to neglect the arm but to caress and play with it as usual while holding or guiding it through movement patterns that need reinforcement.

Orthotics

Intermittent use of orthotics for the wrist and fingers may sometimes be indicated. Wrist orthoses may preserve the integrity of the wrist and finger tendons/muscles until motor function returns. Resting night orthoses can help prevent wrist and finger/thumb contractures by providing a low-load prolonged stretch to the tissues. A dorsal or volar wrist orthotic can maintain the wrist in neutral or partial extension yet free the fingers to grasp and release toys. To prevent shoulder adduction and IR contractures, a "statue of liberty" orthotic or an abduction orthotic has been suggested. However, the child may not tolerate this position for long periods or may not tolerate it at all.

A semi-stretchable strap (e.g., Fabrifoam) that wraps around the hand/forearm and extends from the palm to above the elbow can be used to foster forearm supination. For young infants this strap can be ½-inch wide, and for older infants and children it can be ¾- to 1-inch wide. This type of strap is often worn during waking hours as tolerated with frequent breaks to induce a bias of forearm supination during activities. If the strap does not sufficiently position the forearm, a plastic supination orthotic can be fabricated to use with an additional wide supination strap instead.

Restraining casts, splints, or slings can be used on the unaffected extremity to successfully encourage use of the affected arm and hand as a form of forced use.[8] If shaping activities for the affected arm and hand are employed while the restraint is on the unaffected arm, the approach would be regarded as constraint-induced movement therapy (CIMT). In the case study reported by Berggren and Baker,[8] the child had to use his affected arm to bring a toy to his mouth or self-feed when elbow flexion was restrained on the unaffected side. It is recommended that the restraint be used for brief periods only during the day with frustration levels monitored carefully. It is important to remember that some children will not tolerate any form of restraint, particularly if it is unrealistic that the affected arm can perform functional activities with some independence.

Electrical Stimulation

As introduced previously, Berggren and Baker[8] published a retrospective case report of an infant/toddler who sustained a right global PBPI and presented with Horner's syndrome. At 6 weeks of age he received sensory electrical stimulation (ES) (100 μs pulse duration) at submotor threshold until motor recovery was noted. At 3 months of age he underwent microsurgical repair of the brachial plexus. At 11 months of age, reciprocal ES (150 μs pulse duration with trace [1/5] level of contraction) was initiated to foster efficient motor recruitment and active movement. CIMT was employed over four separate time periods during his first 2 years of life. The outcome based on scores from the AMS, Modified Mallet, and the AHA changed after intervention with significant increases in AHA scores after episodes of CIMT. Okafor and colleagues[55] reported from a small study (eight children per group) that ES paired with conventional physical therapy improved active shoulder abduction and elbow flexion when compared with conventional therapy after 6 weeks. Further research is recommended on the use of ES as an adjunct to increase muscle activation in this population of infants and children.

OUTCOMES

The information available on long-term outcomes in adults with a history of PBPI suggests that disability in daily activities can be lifelong and frequently associated with orthopedic disorders and pain. Strombeck and colleagues[64] evaluated long-term changes in function in a group of 70 participants aged 7 to 20 years. Of this group, 43% had improvements in shoulder function, whereas about 50% had decreased active elbow extension at follow-up. Interestingly, 75% of participants perceived they had no difficulty with ADLs. In another study of 36 adults aged 21 to 72 years with PBPI, Partridge and Edwards[57] found that 60% had painful arthritic joints and 27% had scoliosis. In this group, 80% reported trouble with dressing, 55%

with bathing, and 66% with cooking. Furthermore, 33 of 36 participants surveyed (91%) reported experiencing pain, with 28 of those 33 reporting that their pain was "getting worse." Outcomes research using health-related quality-of-life and participation measures would be extremely helpful for therapists and parents to aid long-term planning for children with PBPI.

PREVENTION

Although the risk factors are known, the positive predictive values for identifying PBPI before birth are lower than 15%.[56] Despite this observation, the goal of prevention continues, thus, risk factors continue to be investigated.[19,47,48] Modified delivery practices such as cesarean section should be considered when there are multiple risk factors for an infant to present with shoulder dystocia during the birth process.

SUMMARY

A unilateral traction injury secondary to shoulder dystocia is the most common cause of PBPI.[29] Infants with PBPI present with impairments of flaccidity or reduced muscle activity that are readily apparent at birth. Therapists and parents can employ strategies to foster early activation of partially denervated muscles and an increase in sensory awareness. It is essential that methods are used to maintain muscle extensibility and joint ROM while reinforcing motor recovery, function, and the acquisition of age-appropriate developmental behaviors. Microsurgery may be considered if substantial spontaneous recovery is not apparent by the age of 3 to 6 months. 28 Shoulder reconstruction can be pursued in a timely manner for cases presenting with GH joint dysplasia. Long-term outcome studies suggest that PBPI affects ADLs and causes disability in adulthood with minimal effects on social participation. As intervention strategies expand, perhaps disability can be reduced and therefore better partner with the positive aspects of social participation.

Case Scenario on Expert Consult

The case related to this chapter presents a child with PBPI, and a video illustrates the outcomes for a child who underwent microsurgical intervention as an infant.

Spinal Cord Injury

Christina Calhoun Thielen, Therese Johnston, Christin Krey

Acquired lesions of the spinal cord occur far less commonly in children than in adults, but the unique aspects of growth and development can make treatment of the child with spinal cord injury (SCI) a challenge for pediatric physical therapists. The rehabilitation process may take years because the young child requires time to achieve adequate strength, adult body proportions, developmental milestones, and cognitive skills for maximal independence. The child who is not skeletally mature may develop orthopedic problems during growth, which may result in altered function. Direct intervention, monitoring skill acquisition, education, and assessing equipment needs are important roles for the physical therapist.

This chapter describes the pathophysiology, resulting neurologic changes, changes in body functions and structures, and their impact on activity and participation of children with SCI. Examination, prognosis, goals, and outcomes and physical therapy intervention for the child with SCI are discussed.

BACKGROUND INFORMATION

Epidemiology

Spinal cord injuries account for a small number of all injuries sustained by children; however, the consequences of SCI can be devastating. The overall incidence of pediatric SCI in the United States is approximately 1.99 cases per 100,000 children and adolescents.[141] Additionally, approximately 5% of the SCIs sustained each year occur in children 15 and younger, although this estimate is likely below the actual percentage due to limited availability of data.[33] From birth to 5 years of age, the ratio of males to females affected by SCI is fairly equal. With increasing age, the ratio of males to females increases to approximately 4:1.[32,33,41,141] Motor vehicle crashes (MVCs), sports, falls, and violence are the leading causes of traumatic SCI; however, this varies as a function of age (Table 21.1).[32-34,41,141,143] MVCs are the most prevalent cause in all age groups, but violence, sports, and falls increase as the cause with increasing age. Injuries sustained due to sports are greatest in the 13- to 15-year-old age group.[14,32,34,41] Child abuse accounts for some cases of SCI, but the frequency of abuse as a cause is unknown.[34]

When an MVC is the cause of injury, a high cervical lesion usually occurs in children younger than 4 years of age, with continued risk for cervical level injuries through age 8.[41,43] Lap belt injuries tend to occur in children between 5 to 8 years of age. Lap belt injuries frequently occur when a child transitions too early from a car seat to sitting in a passenger seat, causing the lap portion of a lap/shoulder seat belt to ride high on the abdomen. Spinal injury from a lap belt in an MVC is typically at the thoracolumbar junction, and significant retroperitoneal injury also occurs.[59,120] Teens injured as a result of an MVC typically sustain cervical level injuries.

Whether a child sustains an injury leading to tetraplegia verses paraplegia and the severity (complete versus incomplete) varies with age.[32,41] If a child is injured prior to the age of 12, about two thirds are paraplegic and a complete injury is sustained. In the adolescent population, approximately half of those injured are paraplegic and slightly more than half sustain a complete injury. It is difficult to classify an injury in a child age 4 or younger due to the reliability of the examination used to classify SCI; therefore, limited data are available for the 0 to 4 age group.[105] This topic will be discussed in more detail later in the chapter.

Nontraumatic causes of SCI in children include tumor (predominantly intramedullary tumors[152]), transverse myelitis, epidural abscess, arteriovenous malformation, multiple sclerosis, and spinal cord infarction due to thromboembolic disorders. Developmental anomalies of the cervical vertebrae can place the spinal cord at increased risk of injury. These anomalies include instability of the atlantoaxial joint, as seen in Down syndrome, juvenile rheumatoid arthritis, os odontoideum (a congenital failure of fusion of the odontoid process to the C2 vertebral body), and dysplasia of the base of the skull or upper cervical vertebrae, as seen in achondroplasia.

The long-term survival rates of children with an SCIs range from 83% of normal life expectancy with an incomplete injury to 50% with a high cervical injury without ventilator dependency,[127] with primary mortality resulting from respiratory complications.[3] Mortality overall seems to follow a different pattern than for individuals with adult-onset SCI as well as the general population of comparable age.[3] A small-scale study suggests that recovery of neurologic function occurs more frequently in pediatric patients than in adults and that recovery can be identified for a longer period of time after injury.[148]

PREVENTION

Proper use of vehicle restraints, water safety instruction, and preparticipation sports physical examinations are important measures for preventing traumatic SCI in children. Lap seat belts must be placed across the pelvis, not across the waist, and shoulder harnesses should cross the clavicle, not the neck, to avoid lumbar or cervical spine injury in the event of a collision. Children should use a booster seat until the lap belt and shoulder harness fit correctly. This typically occurs when the child is about 4 feet 9 inches tall, 8 to 12 years old, or 80 pounds. Once a child is old enough and tall enough to transition to a standard seat, both a lap and shoulder belt should be used and the child restrained in the rear seat until at least 13 years of age. According to the National Highway Transportation and Safety

TABLE 21.1 Causes of Pediatric Spinal Cord Injury Related to Age

Age (years)	Vehicular	Violence	Sports	Falls	Medical/Surgical	Other
0–5	65%	9%	0.2%	6.5%	12%	8%
6–12	52%	22%	11%	6.5%	5%	5%
13–15	41%	19%	28%	8%	3%	1.5%
16–21	49%	22%	18%	8%	0.6%	2%

Adapted from Vogel LC, Betz RR, Mulcahey MJ: Spinal cord injuries in children and adolescents. In Verhaagen J, McDonald JW III, editors: Handbook of clinical neurology, vol 109, Amsterdam, 2012, Elsevier, Chapter 8, pp 131-148.

Administration (NHTSA), American Academy of Pediatrics, and federal law, infants and toddlers should remain in a rear-facing-only seat or rear-facing convertible car seat until at least 2 years of age or until they reach the highest weight or height determined by the car seat manufacturer. Car seat manufacturers have been producing car seats rated to a higher weight in the rear-facing position, as it has been suggested that remaining in the rear-facing position for as long as possible is preferred. Once a child has outgrown a rear-facing weight or height limit, a forward-facing car seat with a harness should be used as long as possible, again to the highest weight and height allowed by the car seat's manufacturer. This again is reflected in the manufacturing of combination car seats with harnesses rated to higher weights. It should also be noted that proper car seat installation as well as proper harness snugness and retainer clip placement is imperative to properly restrain an infant, toddler, or child in an appropriate vehicle safety system (http://www.safercar.gov-/parents/CarSeats/Car-Seat-Safety.htm).

Organizations such as Safe Kids Worldwide (www.safekids.org) and the Center for Childhood Injury Prevention Studies (CChIPS) carry missions to reduce accidental childhood injury through research, public policy, and education and awareness. By determining preventable risks to children, programs are developed to educate adults and children about how and why injuries happen and how they can be prevented. Many health care facilities and schools utilize the programs developed by these organizations to raise awareness and educate the public. Some of these programs include tips on how to prevent injuries and be safe in motor vehicles with restraints, as pedestrians, and during sports, as well as instructions on water safety (https://injury.research.chop.edu/center-child-injury-prevention-studies-cchip).

Because children with Down syndrome have some risk of atlantoaxial instability, the American Academy of Pediatrics[36] recommends screening radiographs to assess cervical spine stability for this population of children between the ages of 3 and 5 years. This radiographic screening is most helpful for children who may participate in sports or who are symptomatic. The Committee on Genetics[135] also recommends that children with achondroplasia be encouraged to participate in activities such as biking or swimming but to avoid gymnastics and contact sports because of the potential for neck or back injury.

ADVANCES IN RECOVERY

Researchers in spinal cord regeneration are focusing on neuroprotection, neuroplasticity, neuroregeneration, and cellular transplant therapy. Many have tried pharmacologic interventions to halt the chain of secondary events producing neural damage and to protect compromised but viable cells. Antioxidants, free radical scavengers, opiate antagonists, vitamins, thyrotropin-releasing hormone, and calcium channel blockers are a few of the agents that have been tested.[119] The only current practice is the administration of methylprednisolone (corticosteroids) in the acute phase to decrease cord edema and limit cell death. High doses, administered within the first 8 hours and continued for 24 to 48 hours, have been shown to slightly enhance motor recovery in humans.[17-19,62,83] Data are lacking on the effects of methylprednisolone in the pediatric population. There have been no pediatric-specific studies, and past studies have had a minimal number of subjects in the 13- to 19-years-of-age category.[19] Currently, the use of the steroid overall is being questioned,[66,67,110,128] and it is even proposed to cause acute myopathy when administered.[119]

After a professional football player was injured while tackling during a game, a treatment of modest hypothermia gained attention.[24] This technique of slowly cooling the body's core temperature to 92°F for a period of time and then slowly rewarming potentially minimizes metabolic demands and edema within an injured spinal cord. Results are promising in terms of safety and have shown improvements in neurologic outcomes.[42] This neuroprotective therapy is still being studied in clinical trials.

A major focus in the SCI community most recently has been on stem cell transplants. Various sources have been used, such as olfactory epithelial cells, bone marrow stromal cells, and, most recently, human embryonic stem cells. Several physicians outside the United States[45,122] have injected humans with these cells, but none of these regimens were conducted through rigorous research, and reported results are mixed. It is a slow process to bring new pharmacotherapies into clinical practice, owing to the necessary steps of animal trials, followed by preliminary and then larger-scale trials in humans. Human trials must be placebo controlled and have a sufficient period of follow-up to assess the efficacy of the treatment. Because SCI is not common, clinical trials usually require collaboration among many medical centers. Approval to move these adult-based studies into the pediatric population is extremely difficult secondary to reluctance to approve studies by human subjects review boards and the Food and Drug Administration (FDA) in an attempt to protect this vulnerable population. It is not clear whether the young, immature spinal cord responds exactly the same way to injury as a mature spinal cord. Therefore, additional studies are being conducted in young animals to evaluate the sequelae of events after injury.

It is important to realize that patients and their families have been and will continue to be tempted by unproved therapies, often at considerable personal financial expense. Therapists can help them to evaluate the evidence regarding potential therapies. Any purported cure should be subjected to randomized clinical trials before being offered to hopeful but vulnerable patients. It is reasonable for patients and therapists to hold out hope for a cure for SCI. It is often just this hope that motivates patients and caregivers to be meticulous about preventing secondary complications.

PATHOPHYSIOLOGY

As mentioned earlier, the site or level at which SCI occurs is often related to the cause of injury and the child's age. Many of the nontraumatic causes (tumors, stenosis) of SCI occur in the thoracic spinal cord and result in incomplete injuries.[98] By contrast, vertebral dysplasias place the upper cervical spinal cord or lower brain stem at risk. Birth trauma as a result of traction and angulation of the spine in a breech delivery most commonly causes SCI at the cervicothoracic junction. In the child younger than 8 to 10 years old, the cervical spine has greater mobility than it does in adults because of ligamentous laxity, shallow angulation of the facets, incomplete ossification of vertebrae, and relative underdevelopment of the neck muscles for the size of the head.[151] Young children are therefore more likely to experience injury at the upper cervical spine than are adults,[15] and SCI may occur without any signs of bone damage by radiography, a finding referred to as SCI without radiographic abnormality, or SCIWORA.[16] Studies have reported the incidence of SCIWORA to be anywhere between 6% and 38% in skeletally immature children.[21,34] In children, 55% of cases of traumatic SCIs result in tetraplegia as a result of injury between the first cervical and first thoracic root levels, and 45% result in paraplegia from injury below the first thoracic level.[112]

Most cases of traumatic SCI are caused by a blunt, nonpenetrating injury to the spinal cord in which the cord is not lacerated or transected, and in the majority of cases, some white matter tracts remain intact across the lesion. The direct effect of the trauma is immediate disruption of neural transmission in the gray and white matter of the spinal cord at and below the injury site, resulting in spinal shock. Reactive physiologic events evolve over a period of hours and induce secondary injury to the spinal cord.[78] The exact sequence of events between transfer of kinetic energy to the cord and subsequent neuronal death is unknown. Animal models have shown that ischemia, hemorrhage, edema, calcium influx into cells, and generation of free radicals contribute to cell membrane degradation and death of neurons.[62] In gray matter, neurons that die are not replaced. In white matter, axonal segments distal to the injury degenerate and synapses no longer function. Although axonal sprouting does occur to a limited degree in the central nervous system (CNS), it appears to be functionally insignificant, and most of the recovery observed in patients with incomplete lesions is probably due to resolution of neurapraxic injury. Case reports of neurologic improvement years after SCI are rare but provide hope that therapies can be developed to enhance function in the remaining spinal cord tissue.[96]

The zone of injury within the spinal cord is usually large enough to cause a transition in neurologic function from normal to abnormal or from normal to absent over several spinal root levels. Soon after SCI, the level of injury may appear to move cephalad as the secondary or indirect injury processes set in. Later, the level of injury may move caudally as these factors resolve, as sprouting develops (either within the spinal cord or peripherally to denervated muscles), or as hypertrophy of weak muscles occurs. The extent of injury may diminish for as long as 1 year, and it is obvious that until the natural history of SCI and recovery is delineated, experimental treatments may be inappropriately credited with enhancing recovery.

There are several distinct patterns of neuroanatomic incomplete syndromes that have distinct clinical representations. *Anterior cord syndrome* is usually due to damage of the anterior spinal artery causing infarction to the spinal cord. This injury produces variable motor paralysis, with reduced sensation of pain and temperature but with preserved dorsal column function. Prognosis for return of function is poor. Hemorrhage in the *central part of the cervical spinal cord* produces flaccid weakness of the arms and strong but spastic legs, with preservation of bladder and bowel function. As a result, ambulation is a potential goal for this population, but hand function may be impaired depending on the level of injury. *Posterior cord lesions* are rare and produce selective loss of proprioception with preserved motor function. Ambulation remains unlikely because of loss of proprioception. A *Brown-Séquard lesion* results in ipsilateral paralysis and proprioceptive loss and contralateral loss of pain and temperature sensation. Brown-Séquard is primarily seen with penetrating trauma to one side of the spinal cord, such as in a stab wound. Prognosis for ambulation as well as bladder and bowel control is good. Injury to the lumbosacral nerve roots results in *cauda equina syndrome,* with lower extremity weakness and areflexia of the legs and bladder. Cauda equina lesions are essentially lesions of the peripheral nerve or lower motoneuron and may show recovery over several years owing to resolution of neurapraxia or to regrowth of damaged axons, as well as to peripheral sprouting.

MEDICAL DIAGNOSIS, ACUTE MANAGEMENT, AND STABILIZATION

Emergent Stabilization (In the Field)

Initial management of a child with SCI is focused on stabilization of the spine to prevent further damage to the intact but injured spinal cord. The spine is immobilized during transport and throughout all assessments and procedures. Modified spine boards should be utilized with infants and toddlers to allow for proper neutral alignment of the cervical spine. Because of their larger head-to-torso ratio, their neck will be flexed on a regular spine board, potentially causing further injury. Modifications include either creating an occipital cutout or elevating the torso on an additional pad (preferred) to allow the cervical spine to be positioned neutrally[12,13,63] (Fig. 21.1).

Diagnostic Studies

At the hospital, a thorough neurologic examination is performed to determine the motor and sensory level of SCI and the completeness of injury. Spinal shock is usually present, although occasionally it has resolved by the time the patient is treated in the emergency department. In spinal shock, the muscles are flaccid below the SCI and all cutaneous and deep tendon reflexes are absent. This state persists for hours to weeks and is said to be over when sacral reflexes, including the bulbocavernous and anal reflexes, are present.

Further evaluation is undertaken with plain radiographs of the whole spine from the first cervical to the sacral vertebrae to identify any fractures, facet subluxations, or dislocations. Full radiographic evaluation is imperative as multiple, noncontiguous fractures occur in 30% of children.[14] Anteroposterior (AP) and lateral radiographs of the entire spine are needed to rule this out.[14] Computed tomography (CT) and magnetic resonance imaging (MRI) are used to diagnose root impingement, the presence of bone fragments in the spinal canal, cord compression, and spinal cord hemorrhage. Because of the high incidence of SCIWORA, particularly in children younger than

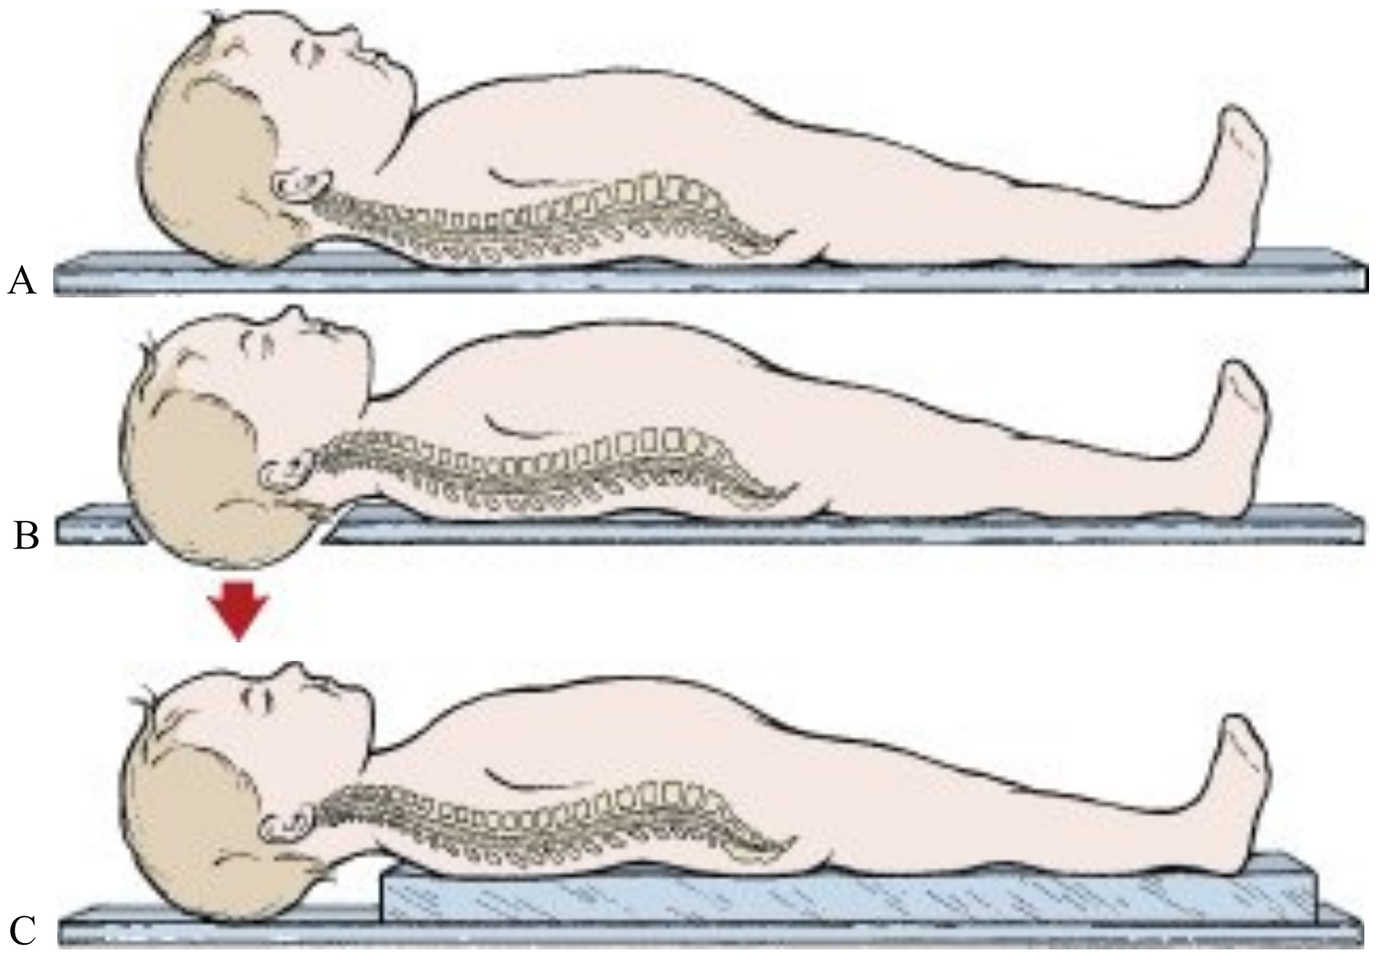

FIG. 21.1 Emergent stabilization. A, the enlarged occiput causes child to flex the head forward. Note improved spinal alignment with pediatric spine board modifications cut out (B) or elevation of torso (C), which is preferred. (From Mencio GA, Swiontkowski MF: Green's skeletal trauma in children, ed 5, Philadelphia, 2015, Elsevier.)

10 years of age, an MRI is indicated for all children who have sustained an SCI and can show problems that are not seen on plain radiographs.[14]

Surgical Stabilization

Whether immediate surgical intervention to correct bone injury and decompress the spinal cord is effective in reducing paralysis is unknown because the numerous surgical procedures have never been subjected to randomized clinical trials. The main goal of surgery is to prevent later deformity, pain, or loss of neurologic function. Surgery may not be necessary if spinal alignment can be achieved with traction and maintained with an orthosis. Tonged cervical traction in children under 12 years of age, however, has increased risks as compared with its use in adults. Therefore, halo traction may be safer and preferred,[12] even in axis (C2) fractures.[88] A variant in the use of halo traction is an increase in the number of pins used, while decreasing the amount of torque on each pin. If a halo cannot be applied, a Minerva-type cervicothoracolumbosacral orthosis (CTLSO) would be an option (Fig. 21.2). External halo orthoses[88] have also traditionally been used in conjunction with internal posterior wiring in children with atlantoaxial and occipital-cervical instability. However, investigation has identified successful rigid internal fixation for children requiring C1-C2 and occipital-cervical stabilization.[6]

Surgery is indicated if there is a penetrating injury, if traction has failed to reduce a dislocation, if nerve root impingement exists, if the spine is highly unstable and at risk of further damaging the cord, or if bone fragments are compressing the cauda equina.[50] Regardless of whether surgery is performed, if bone injury has occurred patients usually wear an external orthosis until bone fusion is complete, often for 3 or more months. There is, however, regional variation in practice among orthopedic surgeons in the use of spinal orthoses after spinal fusion. For some lower lumbar (L4 or L5) injuries, the surgeon may have the child wear an orthosis with a thigh piece, which permits only limited hip flexion (e.g., to only 60°). This is done to reduce torque on the immature fusion mass that could occur from pull of the hamstrings on the pelvis in a position of hip flexion.

FIG. 21.2 Infant wearing CTLSO for acute stabilization secondary to C1-2 injury.

Underlying Injuries and Comorbidities

Traumatic brain injury is one of the most commonly associated comorbidities and has been reported to occur in 38% of patients with SCI.[21] Traumatic brain injury, which can occur with any type of loss of consciousness, is important to recognize at initial examination as it can significantly affect the rehabilitation process and warrant additional therapies such as speech pathology and neuropsychologic testing (see Chapter 22 on acquired brain injuries for further information).

Another comorbidity that can be easily overlooked, particularly in someone with a cervical-level SCI, is injury to the brachial plexus. Brachial plexus injury should be considered if

the mechanism of injury included any type of distraction to the shoulder or impingement or fracture of the clavicle in the presence of asymmetrical weakness in the upper extremities.

MEDICAL COMPLICATIONS, LONG-TERM MEDICAL MANAGEMENT, AND PREVENTION OF SECONDARY IMPAIRMENTS

A child's participation in SCI rehabilitation may be affected by a number of medical complications. Each of the following complications must be addressed by the entire rehabilitation team, physicians, nurses, therapists, and caregivers in order to achieve optimum outcomes.

Autonomic Dysreflexia

Autonomic dysreflexia (AD) is a massive reflex sympathetic discharge that occurs after an SCI of T6 or above in response to noxious stimuli below the level of injury, causing a sudden increase in blood pressure (BP > 15 mm Hg over baseline systolic).[97] If left untreated, the hypertensive crisis can cause stroke, seizures, or even death. Clinical features include headache, flushing, sweating, pilomotor activity, bradycardia or tachycardia, and hypertension. School-age children and adolescents are capable of reporting headaches, but younger children may have difficulty verbalizing symptoms and may have more nonspecific symptoms because of their maturing central and peripheral nervous systems. As a result, autonomic dysreflexia is often overlooked in these youngsters. Infants and children who are unusually sleepy, irritable, or crying may be experiencing an AD episode and should have their vital signs checked. Knowledge of baseline BPs are imperative, as infants, toddlers, and children up to 13 years of age have different normal values for BP.[137] Additionally, patients with SCI typically have lower resting BP (i.e., 90/60).[97]

The primary causes of an AD episode/noxious stimulus below the level of injury are an overdistended bladder and the need for catheterization or a kinked catheter in the instance of an indwelling system; an overdistended bowel and the need to complete a bowel program; and excessive pressure to the skin below the level of injury caused by a wrinkle in clothing, compression hose, or shoes that are too tight/small.

Treatment of AD includes monitoring BP, pulse, and temperature (at least every 5 minutes); elevation of the patient's head (unless contraindicated); removal of compression stockings and abdominal binders; and loosening of tight clothes/shoes. Next the clinician performs bladder management steps and, if BP does not decrease, completes a bowel regimen. It is important to continuously check vital signs for reduction in BP and return to normal as the various management techniques are completed. If none of the above methods resolve the dysreflexic episode, pharmacologic intervention by a physician or nurse practitioner may be warranted.

Respiratory Dysfunction

Respiratory insufficiency may occur with lesions of the cervical and thoracic spinal cord and is a prominent cause of morbidity and mortality in the population with SCI.[3] Dysfunction ranges anywhere from complete diaphragm paralysis and the requirement of mechanical ventilation (C1-C3 and occasionally C4 depending on age/size of child) to diminished vital capacity or weakened forced expiration during coughing as a result of absent/weakened accessory breathing muscles (lower cervical and thoracic level injuries). Respiratory/breathing exercises are all too often overlooked as part of physical therapy rehabilitation but must be included. Respiratory exercises can occur during any part of treatment sessions, including during mat mobility and sitting balance activities. *Quad coughing* techniques are to be taught to the child and caregivers in order to assist with forced expiration when a cough alone is ineffective in clearing secretions. A quad cough is forced compression of the abdomen with a hand in an inward and upward fashion during expiration.

Deep Vein Thrombosis

Paralyzed and dependent lower extremities can develop edema and deep vein thromboses (DVTs). Although common in adults with SCI, deep vein thrombosis occurs less frequently in children with SCI (5%)[136] but does have a significant occurrence rate in 14- to 19-year-old adolescents.[136] A DVT prophylactic protocol of either insertion of an inferior vena cava filter (typically in older adolescents) or pharmacologic treatment is typically initiated during acute care hospitalization and completed during acute inpatient rehabilitation.

Hypercalcemia/Bone Density/Muscle Atrophy

Almost unique to children is the problem of immobilization hypercalcemia.[91] During the first 12 to 18 months after SCI, approximately 40% of bone mineral density is lost via calcium excreted in the urine. Children are more likely to have rapid bone turnover, resulting in a larger load of calcium than the kidneys can excrete. This produces elevated serum calcium level, or hypercalcemia. Nonspecific symptoms include lethargy, nausea, altered mood, and anorexia. Remobilization is an important aspect of treatment in persons without SCI (e.g., the child with a femur fracture), but it is not known if this is effective in reducing hypercalcemia after SCI. The mainstays of treating immobilization hypercalcemia are primarily medical through hydration for improved excretion of the excessive calcium in urine and administration of etidronate (Didronel) and calcitonin (Miacalcin) to avoid excessive calcification in unwanted areas, such as joints (heterotopic ossification) or kidneys (renal stones).

Pathologic fractures, which occur at an increased rate in persons with bone mineral densities below 40% of normal, are a potential complication of osteopenia. Deposition of new bone in periarticular soft tissue can also occur in paralyzed extremities. This heterotopic ossification can be asymptomatic, or it may interfere with range of motion (ROM) around a joint or even cause ankylosis. The most commonly affected joints are hips, knees, shoulders, and elbows. Muscle atrophy begins early and occurs at a rapid rate during acute immobilization through 24 weeks postinjury when it begins to plateau at approximately 15% loss of lean muscle mass below the level of injury.[57]

Orthostatic Hypotension

Orthostatic hypotension, a position-related drop in BP, is a common side effect with SCI. There is a decrease in the venous return of blood from the lower extremities as a result of muscle paralysis, which decreases cardiac output and arterial pressure, causing a quick drop in BP. As a result, the person's BP cannot adjust quickly enough during positional changes such as supine to sit, sit-to-stand, or coming out of a tilted position in a power wheelchair. Treatment for orthostatic hypotension can include gradient compression stockings, an abdominal binder,

utilization of a wheelchair with a reclining back (particularly during acute care mobilization), tilt table, or pharmacologic intervention.

Early physical therapy sessions may address the goal of maintaining a stable BP when transitioning out of bed or while in the wheelchair. The patient's BP should be monitored throughout the treatment session.

Thermoregulatory Dysfunction

Persons with SCIs have an impaired ability to regulate body temperature resulting from the loss of hypothalamic thermoregulatory control and interruption of afferent pathways from peripheral temperature receptors below the level of injury. With injuries above T6, there is the complete loss of shivering and sweating and no peripheral circulatory adjustment below the level of injury. Education provided to children and caregivers must include the increased risk of hypothermia and frostbite in cold weather, as well as heat exhaustion and heat stroke in hot weather. Children with SCI should avoid excessive sun exposure and maintain adequate hydration.

Syringomyelia

Delayed cavitation (syringomyelia) within the damaged spinal cord can occur in patients with complete or incomplete lesions. The occurrence of a cystic cavitation, or syrinx, appears to be common after SCI and it may progressively enlarge, resulting in further loss of neurologic function months to years after SCI.[145] Signs and symptoms that may herald the presence of a syrinx include loss of motor function, ascending sensory level, increased spasticity or sweating, and a new onset of pain or dysesthesia.

Spasticity and Pain

Spasticity is a frequent occurrence after SCI and usually evolves over a period of 1 to 2 years. Although initially the patient is flaccid, hypertonus gradually appears, and in the first 3 to 6 months after SCI hyperreflexia, clonus and flexor spasms develop. Later, extensor spasms usually predominate. Evolution of spasticity after CNS insult is common and is seen in other conditions such as cerebral palsy and stroke. In SCI, the immediate effects of loss of supraspinal inhibition and the later-developing effects of denervation supersensitivity and sprouting by afferent and collateral neurons probably all contribute to the development of spasticity, but the sequence of events behind the evolution of clinical manifestations of spasticity is not known.

Spasticity can be controlled pharmacologically with oral medications, such as baclofen, intramuscular injections, such as Botox, or nerve block injections, such as phenol. Therapeutic interventions to control spasticity include passive ROM, passive and functional electrical stimulation (FES)–assisted cycling, and static standing. Many patients feel a certain amount of spasticity is helpful during transfers, bed mobility, or even some activities of daily living, so pharmacologic or other therapeutic interventions are usually withheld unless the spasticity is severe enough to limit function.

Neurogenic, or neuropathic, pain can occur after SCI at, above, or below the level of injury. Children and adolescents describe neurogenic pain as a burning pain, which anecdotally precedes the return of function or sensation at the dermatologic level(s) where pain is experienced. This type of pain can be unbearable but can be pharmacologically controlled with gabapentin (Neurontin) or pregabalin (Lyrica).

Skin Breakdown and Pressure Ulcers

Pressure ulcers occur as a result of improper positioning, both in bed as well as in a wheelchair, or inadequate pressure relief, which can limit the ability to sit. Pressure ulcers may also occur because of the improper fit of spinal orthoses, upper and lower extremity splints, and braces for ambulation. It is important to remember that skin breakdown is also caused by friction, shear, and moisture. All too often skin breakdown on the buttocks occurs from shearing across the wheel of the wheelchair during transfers and moisture secondary to improper bladder management or continuation of wearing a diaper beyond the age when the child should be dry between catheterizations.

Young children may not exhibit skin breakdown in the typical sense (from poor wheelchair or bed positioning) as seen with adolescents and adults because they are under direct care and guidance of their caregiver; however, young children typically have complete disregard for any body area that is insensate. They often will drag their lower extremities on the ground while crawling, or they may even bite insensate fingertips to the point of self-injury. As children grow older, it is often difficult for them to understand the importance of routine pressure-relief activities, particularly in the adolescent population with their tendency to test boundaries with caregivers. Patients and caregivers must also pay special attention to hot items on insensate skin to avoid burns (e.g., on the thighs from food that has been in the microwave such as popcorn or the heat generated by a laptop computer).

Pressure-relief techniques must also be taught. During acute care hospitalization and rehabilitation, the child/adolescent is turned every 2 hours and frequently is utilizing a specialty low air loss mattress. Children using power mobility can perform pressure-relieving techniques through powered seating, such as tilt and recline. Those using manual wheelchairs can perform wheelchair push-ups or lean laterally and anteriorly. The recommended frequency of pressure-relieving techniques varies between 15 to 30 minutes and should last 1 minute to allow return of blood flow to compressed tissue.[38] Children often utilize a watch with a timer to provide an audio reminder to complete weight-shift/pressure-relief measures at designated times.

Orthopedic Management

Contractures can arise as a result of static positioning, spasticity, or heterotopic bone formation and may interfere with positioning or voluntary movement. As a result, passive ROMs or the prolonged stretches, which an upright stander can provide, are imperative to use as treatments. Tightness is most typically seen in the hip flexor, hamstring, adductor, and ankle plantar flexor muscles. Of note is the fact that children and adolescents with flaccid paralysis may develop "pseudo hip flexion contractures," in which the iliotibial band is actually the tight muscle rather than the iliopsoas and rectus femoris muscles.

Hip subluxation (Fig. 21.3) and dislocation are common in children who have onset of SCI before age 10, with an incidence up to 66% in children under 4 years of age.[93] Management to prevent subluxation/dislocation includes stretching of hip adductor and flexor muscles; proper bed positioning in an abducted position with either a wedge or pillow; and wheelchair seating positioning that encourages proper femoral alignment, such as a medial thigh build-up or pommel. Prevention is important, because although typically nonpainful, hip dislocation can lead to pelvic obliquity and other postural changes that will place the child at greater risk of skin breakdown as well as

FIG. 21.3 Hip instability.

FIG. 21.4 Neuromuscular scoliosis.

exacerbate a neuromuscular scoliosis.[93] Treatment can include surgical plating and pinning to restore joint alignment.

Pathologic fractures can occur to osteopenic extremities as a result of disregard of lower extremities during transfers, falls, or forceful ROM exercises. The osteopenia has been found to be greatest at the hip and knee as compared to children their age without a disability.[84]

Neuromuscular scoliosis occurs in virtually all children with SCI (up to 98% has been reported[13]), particularly in patients injured before their adolescent growth spurt, and can affect the comfort of seating and respiratory function. Sixty-seven percent progress to the point of requiring spinal fusion.[13] Although it is important to provide proper pelvic alignment and trunk support in wheelchairs, external support devices in wheelchairs do not seem to ultimately prevent the development of scoliosis (Fig. 21.4).[14]

Prophylactic bracing is a controversial topic in therapy because the wear of a thoracolumbosacral orthosis (TLSO) will most likely inhibit independent activities, mobility, and reachable workspace while worn.[30,130] The argument, however, is that wearing the brace prophylactically can prevent (curves < 10°) or even delay (curves < 20°) spine fusion. If surgery can be delayed until these children have achieved nearly all of their trunk growth, bracing is considered successful. Once a curve nears or surpasses 20°, however, bracing may be futile.[99] Typical brace prescription can range from "while out of bed" for less significant curves to 23 hours a day, for which aggressive brace wear can delay progression when close to the 20° cutoff, particularly during growth spurts.[99] Brace wear compliance is always a question, as many children and teens tend to return for follow-up and leave the brace at home. Surgery for neuromuscular scoliosis becomes indicated once the degree of curve causes respiratory compromise or significant pelvic obliquity that increases the risk of ischial pressure ulcers.

FOREGROUND INFORMATION

PHYSICAL THERAPY EXAMINATION

The physical therapy examination of the child with spinal cord injury is influenced by many factors, including the age of the child presently as well as age at injury, the development and maturation of the child, any concomitant injuries such as a traumatic brain injury or cognitive delay, and the family's understanding of SCI. Physical therapists examine children with SCI in the acute care, rehabilitation, outpatient, home, and school settings. What is examined in each setting will depend on the age of the child, the child's abilities and needs, and the setting itself.

Key History and Systems Review Information

The physical therapist must have an understanding of the child's history, comorbidities, and restrictions. Children with SCI are at risk for secondary conditions such as skin integrity issues, pain, cardiovascular issues and disease, pulmonary and respiratory issues, and musculoskeletal issues. These issues should be screened for during the examination. Box 21.1 lists questions that should be included in the examination history and systems review. Depending on the child's age, these questions may be answered by the parents/caregiver or the child.

Tests for Impairments of Body Structure and Function

Quantification of changes in body structure and function in the young child is often unreliable because young children are unable to cooperate consistently with formal testing. Passive ROM measurement is possibly an exception, but intrarater and interrater reliability in children with SCI have not been established. In children without SCI and in children with myelodysplasia, manual muscle testing is generally unreliable if the child is younger than 5 years of age.[95,101] In young children, strength testing is often estimated by encouraging and observing movement. Ideally, the therapist places the child in various positions and encourages him or her to reach for toys with a single extremity. This allows examination of gravity-eliminated and antigravity movements, as well as comparison of left and right extremities. Resistance can be provided with small wrap weights (0.25 lb) or the weight of handheld toys. In reality, the best choice may be for the physical therapist to observe

BOX 21.1 History and Systems Review Questions

Date, cause, level, ASIA, AIS classification if known
Concomitant injuries
Current medications
Medical, surgical, and rehabilitative management
Neurologic change
Pain and response to pain
Current functional performance: what the child is capable of doing versus what the child typically does, how function has changed with growth and development
History of orthostatic hypotension and autonomic dysreflexia
Secondary conditions such as scoliosis, hip subluxation, or new medical diagnosis
Current equipment and issues or problems with the equipment
Environmental barriers
Social support
Level of participation at home, school, and in the community
Modes of transportation
Psychological status
Changes since last examination
Current goals
Questions the child or parent may have

spontaneous play and record descriptions of available movements. Ruling out substitutions can be challenging. Muscle strength is recorded as 0 through 5, as with adults (rarely with the finer + or − gradations). Scores of 4 and 5 are subjective measures, particularly in growing children, but with experience the therapist can become an increasingly more accurate evaluator. While examining muscle strength and function, spasticity and spasms should be noted. The physical therapist also facilitates the child's basic postural responses, such as positive support of the lower extremities or protective extension of the upper extremities. Postural alignment should be assessed as well as balance in sitting and standing if applicable.

International Standards for Neurological Classification of Spinal Cord Injury or American Spinal Injury Association Examination

Professionals should use a common terminology when describing the motor or sensory levels of SCI in children or adults. Most widely used are the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI), which are published by the American Spinal Injury Association (ASIA).[2,80] The ISNCSCI standards were developed by consensus of a multidisciplinary group of clinical experts and have been revised periodically since initial publication in 1982. The ISNCSCI standards, more commonly referred to as the ASIA Examination, define right and left motor levels, right and left sensory levels, the neurologic level, the severity of injury (i.e., complete versus incomplete), and a classification called the ASIA Impairment Scale (AIS). The ISNCSCI standards have been used as the primary indicators to predict recovery of neurologic function,[20,89,92,150] and the exams have been used to determine inclusion for entry into drug and device trials that pertain to SCI,[19,60,96,114,125,133,134] including outcomes of activity-based rehabilitation, a program of intensive cycling, assisted treadmill training, and swimming.[96]

Precise description of the motor and sensory loss after SCI is important for two reasons. First, it helps predict the likelihood of further neurologic recovery in both complete and incomplete syndromes. For instance, in motor complete C5 tetraplegia, most if not all patients gain one full motor level, achieving grade 3 wrist extensor movement (a C6 muscle) during the first 8 months after injury.[44] Researchers have also determined that in SCI above T11, preservation of pinprick sensation has predictive value for return of motor function and independent ambulation, probably because of the proximity of the ascending pain fibers and descending motor fibers in the spinal cord.[114] The second reason for the importance of a precise definition of the level of SCI is that it helps predict the ultimate level of independence a patient can expect to achieve in the areas of mobility, self-care, and even communication. Patients with incomplete SCI may exceed the expectations for any given level of injury. Such expectations for independence must also be tempered by consideration of the child's age, which influences developmental expectations. It can take years for preschoolers to reach the expected level of independence, or they may fall short of expectations if complications, particularly orthopedic problems, arise. Environmental and personal factors also play an important role in determining the child's participation in home life, education, community activities, and social relationships.

TABLE 21.2 Key Muscles for Motor Level Classification

C5	Elbow flexors (biceps, brachialis)
C6	Wrist extensors (extensor carpi radialis longus and brevis)
C7	Elbow extensors (triceps)
C8	Finger flexors to the middle finger (flexor digitorum profundus)
T1	Small finger abductors (abductor digiti minimi manus)
L2	Hip flexors (iliopsoas)
L3	Knee extensors (quadriceps)
L4	Ankle dorsiflexors (tibialis anterior)
L5	Long toe extensors (extensor hallucis longus)
S1	Ankle plantar flexors (gastrocnemius, soleus)

From American Spinal Injury Association: International standards for neurological and functional classification of spinal cord injury, Chicago, 2000, revised 2002, American Spinal Injury Association.

Defining the Level of Spinal Cord Injury

The ASIA standards accept the widely used system of muscle grading: 0 = absence, total paralysis; 1 = trace, palpable, or visible contraction; 2 = poor, active movement through full ROM with gravity eliminated; 3 = fair, active movement through full ROM against gravity; 4 = good, active movement through full ROM against moderate resistance; and 5 = normal, active movement through full ROM against full resistance. Motor levels may differ for right and left sides of the body. The key muscles for determining motor level are listed in Table 21.2. Because all muscles have innervation from more than one root level, the presence of innervation by one root level and the absence by the next lower level result in a weakened muscle. The ASIA-defined motor level is the most caudal root level in which muscle strength is grade 3 or more and the next most rostral muscle a grade 5. By convention, if a muscle has grade 3 strength and the next most rostral muscle is grade 5, the grade 3 muscle is considered to have full innervation by the higher root level, for which it is named. For example, for a patient with a grade 2 C8 key muscle, grade 3 C7 key muscle, grade 4 C6 key muscle, and grade 5 C5 key muscle, the motor level as defined by ASIA is C6. One disadvantage to using only the ASIA key muscles to define a level of function is the omission of examination

of hip extensor, hip abductor, and knee flexor muscles. These L5 and S1 muscles play an important role in activities such as transfers, ambulation, and stair climbing. Strength grades of the key muscles can be added together for both sides of the body to create a composite ASIA motor score. This score has been used in research studies assessing the efficacy of pharmacologic treatment of SCI.[7,17-19,45,79,83,122] It can also be used to predict function and need for assistance.[121,123,150]

The sensory level may not correspond exactly to the motor level. Determining the sensory level is especially helpful in injuries above C5 or to the thoracic spinal cord, where there are no key muscles to define the level of SCI. Rather than relying on dermatome charts, which vary from one text to another, the ASIA standards rely on the presence of normal light touch and sharp/dull discrimination (pinprick) sensation at a key point in each of the 28 dermatomes on the right and left sides of the body (Fig. 21.5A, and Table 21.2). Proprioception should also be assessed below the level of injury in patients with incomplete SCI to determine the integrity of dorsal column function.

Classification

A complete injury, or AIS A classification, is defined as the total absence of motor or sensory function in the lowest sacral segments (Fig. 21.5B). There may be some preservation of sensation or motor levels below the level of injury. This is defined as a *zone of partial preservation,* a term used only with complete injuries.

A patient is said to have an incomplete SCI, AIS B, C, or D classification, only if motor or sensory function is present in the lowest sacral segment, implying voluntary control of the external anal sphincter, sensation at the mucocutaneous junction, or both. Further delineation between incomplete classifications occurs based on the extent of preservation of sensory or motor function below the level of injury.

An addition has been the Autonomic Standards Assessment Form (Fig. 21.5C), which highlights autonomic function/dysfunction and can be used to complement the ISNCSCI standards.

Application to the Pediatric Population

Historically, the ISNCSCI standards or ASIA examination has routinely been the clinical tool used for assessing pediatric patients with SCI. It is considered the gold standard assessment for assessing prognosis and outcomes, yet the actual utility in the pediatric population was not assessed until recently. Research suggests that the ISNCSCI exams may have poor utility overall in children under 4 years of age, as they were unable to complete the exam.[105] Additionally, the results suggest poor cooperation of children age 10 and under in terms of anxiety during the pinprick portion of the discrimination exam. Results also showed low precision in confidence intervals for total motor scores in children up to the age of 15, bringing into question the reliability of the motor examination.[105]

Additional questions revolve around the clinical validity of the anorectal exam in classifying children with SCI, particularly children who were injured prior to being potty trained who have never had to conceptualize holding in a bowel movement (which is the verbiage typically used during the anal contraction portion of the exam).[147] Preteens and teenagers may also have difficulty with the anorectal portion of the examination because of privacy concerns.

The WeeSTeP, a complement to InSTeP, is an electronic training module developed to outline pediatric considerations for the current ISNCSCI standards (www.asialearningcenter.org). Some modifications include altering the method of approaching child, conducting sensory testing in a nonthreatening manner, altering vocabulary used to make it more child friendly, and giving the child sense of control during test. Alternatives also include an observational motor assessment or infant motor scale to a certain age. Most important, however, is explaining to the parents/caregivers the current standards, how classification may not be able to be ascertained due to the child's age, and that repeated testing during various points of follow-up will be used in an attempt to identify neurologic change until the child is old enough to reliably complete the ISNCSCI standards (or until a pediatric version becomes available to use as a clinical tool).

Depending on experience and the policy of the facility, a physical therapist may be the clinician completing the ISNCSCI standards examination. In the case of the pediatric patient, it would be the examiner's responsibility to educate the parent and possibly the patient on the purpose of the examination, how it may be modified for the child, as well as the outcome. Based on the age of the child and the examination results, the physical therapist may be able to determine the SCI characteristics such as severity and level of injury.

Tests for Activity and Participation

The physical therapist must establish a thorough baseline report of the child's abilities and activity and determine whether activity limitations and participation restrictions are due to the child's age, primary neurologic changes in body structure and function, secondary conditions such as contractures, pain, decreased endurance, the need to wear a spinal orthosis, or other causes. The Functional Independence Measure (FIM) (for adolescents), Functional Independence Measure for Children (WeeFIM),[1,113] Pediatric Evaluation of Disability Inventory (PEDI),[61,111] Pediatric Quality of Life (PedsQL), and Canadian Occupational Performance Measure (COPM) have all been used to describe function and measure outcomes for children with SCI; however, none fully identifies changes with recovery and rehabilitation in children with SCI.

The FIM and WeeFIM are measures used in acute rehabilitation across many diagnoses to determine the "burden of care." These measures, when used with patients with SCI, may not be sensitive enough to detect change associated with return of function, and some areas tested have ceiling and floor effects. Additionally, a change in FIM or WeeFIM score may be based more on lack of injury severity rather than length of inpatient rehabilitation.[56] For example, in comparing a child with a complete cervical injury to a child with an incomplete thoracic injury, each of whom had a 4-week inpatient rehabilitation stay, the child with the incomplete thoracic injury may show a much larger change in FIM or WeeFIM scores. This change is more related to the fact that, based on level of injury, the amount of functional change is inherently greater as measured by the FIM or WeeFIM, rather than reflecting the effectiveness or amount of rehabilitation received.

Overall, no one measure or test has been deemed the most effective and efficient for children and adolescents with SCIs. One option may be the Spinal Cord Independence Measure (SCIM) III, developed in 1994, which measures performance of daily activities in patients with spinal cord lesions. It has

Muscle Function Grading

0 = total paralysis

1 = palpable or visible contraction

2 = active movement, full range of motion (ROM) with gravity eliminated

3 = active movement, full ROM against gravity

4 = active movement, full ROM against gravity and moderate resistance in a muscle specific position

5 = (normal) active movement, full ROM against gravity and full resistance in a functional muscle position expected from an otherwise unimpaired person

5* = (normal) active movement, full ROM against gravity and sufficient resistance to be considered normal if identified inhibiting factors (i.e. pain, disuse) were not present

NT = not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of > 50% of the normal range of motion)

Sensory Grading

0 = Absent

1 = Altered, either decreased/impaired sensation or hypersensitivity

2 = Normal

NT = Not testable

When to Test Non-Key Muscles:

In a patient with an apparent AIS B classification, non-key muscle functions more than 3 levels below the motor level on each side should be tested to most accurately classify the injury (differentiate between AIS B and C).

Movement	Root level
Shoulder: Flexion, extension, abduction, adduction, internal and external rotation Elbow: Supination	C5
Elbow: Pronation Wrist: Flexion	C6
Finger: Flexion at proximal joint, extension Thumb: Flexion, extension and abduction in plane of thumb	C7
Finger: Flexion at MCP joint Thumb: Opposition, adduction and abduction perpendicular to palm	C8
Finger: Abduction of the index finger	T1
Hip: Adduction	L2
Hip: External rotation	L3
Hip: Extension, abduction, internal rotation Knee: Flexion Ankle: Inversion and eversion Toe: MP and IP extension	L4
Hallux and Toe: DIP and PIP flexion and abduction	L5
Hallux: Adduction	S1

B

ASIA Impairment Scale (AIS)

A = Complete. No sensory or motor function is preserved in the sacral segments S4-5.

B = Sensory Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-5 (light touch or pin prick at S4-5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.

C = Motor Incomplete. Motor function is preserved at the most caudal sacral segments for voluntary and contraction (VAC) OR the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments (S4-S5) by LT, PP or DAP), and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body. (This includes key or non-key muscle functions to determine motor incomplete status.) For AIS C–less than half of key muscle functions below the single NLI have a muscle grade >3.

D = Motor Incomplete. Motor incomplete status as defined above, with at least half (half or more) of key muscle functions below the NLI have a muscle grade ≥ 3.

E = Normal. If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Using ND: To document the sensory, motor and NLI levels, the ASIA Impairment Scale grade, and/or the zone of partial preservation (ZPP) whey the are unable to be determined based on the examination results.

INTERNATIONAL STANDARDS FOR NEUROLOGICAL CLASSIFICATION OF SPINAL CORD INJURY

Steps in Classification

The following order is recommended for determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
The sensory level is the most caudal, intact dermatome for both pin prick and light touch sensation.

2. Determine motor levels for right and left sides.
Defined by the lowest key muscle function that has a grade of at least 3 (on supine testing), providing the key muscle functions represented by segments above that level are judged to be intact (graded as a 5).
Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.

3. Determine the neurological level of injury (NLI).
This refers to the most caudal segment of the cord with intact sensation and antigravity (3 or more) muscle function strength, provided that there is normal (intact) sensory and motor function rostrally respectively.
The NLI is the most cephalad of the sensory and motor levels determined in steps 1 and 2.

4. Determine whether the injury is Complete or Incomplete.
(i.e. absence or presence of sacral sparing)
If voluntary anal contraction = No AND all S4-5 sensory scores = 0 AND deep anal pressure = No, then injury is Complete.
Otherwise, injury is Incomplete.

5. Determine ASIA Impairment Scale (AIS) Grade:
Is injury Complete? If YES, AIS=A and can record ZPP (lowest dermatome or myotome on each side with some preservation)

NO ↓

Is injury Motor Complete? If YES, AIS=B

NO ↓ (No=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

Are at least half (half or more) of the key muscles below the neurological level of injury graded 3 or better?

NO ↓ AIS=C

YES ↓ AIS=D

If sensation and motor function are normal in all segments, AIS=E
Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact; the ASIA Impairment Scale does not apply.

FIG. 21.5 A, Scoring sheet with key sensory testing areas by dermatome for ASIA Examination. Dot in each dermatome indicates exact location within dermatome to complete sensory testing. B, Muscle grading, impairment scale, and steps in classification.

FIG. 21.5, cont'd C, Autonomic standards assessment, newly added assessment sheet to complement muscle and sensory testing of ASIA examination. (Adapted from American Spinal Injury Association: International standards for neurological classification of spinal cord injury, revised 2011, Atlanta, GA, Revised 2011, ASIA., Updated 2015.)

been shown to have strong construct validity (.8–1.4, $p < .05$), interrater reliability (SCIM III kappa .64–.84; ICC > .94), and sensitivity to change (SCIM II, 2001)[26-28] in adults even when compared to the FIM.[27] Evaluating the utility and psychometric properties of the SCIM-III in children with SCI is currently underway. Another option may be Computerized Adaptive Testing (CAT), which employs an algorithm and adapts the number of questions to each specific individual based on previous answers given to achieve the desired precision of scores for all children on a standard metric.[47] Work on development of parent- and child-report CAT specifically for children with SCI has been completed,[22,103,104] and clinical deployment is under way. These SCI-specific CATs, which evaluate general mobility, wheeled mobility, self-care, school, chores, and leisure functions as well as participation, can be used to monitor the child longitudinally or determine change due to an intervention.

It is also critical to systematically test the child's ability to reach in a variety of positions, roll, position in bed, come to sitting, balance in sitting, scoot, crawl, transfer to and from a variety of surfaces, come to kneel, stand, and ambulate. Some or all of these may not be possible, so the type and amount of assistance needed are recorded, or the therapist may simply record the movement as "unable." In general, when assessing function, the dependent, maximal, moderate, and minimal assistance, supervision, and independent scale is used (Table 21.3); however, it is often further qualified based on developmental appropriateness. For example, a child may be able to physically push his or her wheelchair across the street; however, children do not do this independently because the average young child does not move across the street without supervision. Additionally, children may be able to complete a task independently but on a typical basis their parent does it for them (i.e., getting dressed in the morning). Both can be noted and monitored over time.

The examination of the infant, young child, or adolescent with SCI will require modification based on chronologic as well as developmental age. As previously mentioned, determination of motor and sensory levels in infants and young children is challenging and may require multiple examinations to determine what movement is voluntary and what is reflexively mediated. The therapist can determine activity limitations by comparing the infant's motor skills such as head control, rolling, sitting balance, transitional movements, crawling, and standing with expected developmental milestones. Very young children with SCI require careful follow-up over time to ensure that they meet functional goals and are not infantilized by caregivers.

TABLE 21.3 Levels of Assistance for Functional Assessment

Terminology	Definition
Independence	Able to complete the activity safely and timely without assistance of another person and without the use of aids or devices
Modified independence	Able to complete the activity safely without assistance but requires aids or devices or takes extra time to complete
Supervision	Able to complete the activity without physical assistance but another person is present for safety or to provide support if needed
Minimal assistance	A small amount of assistance is required; typically the patient does 75% or more of the task
Moderate assistance	A greater amount of assistance is required, typically the patient does 50%–74% of the task
Maximal assistance	The patient does 25%–49% of the task
Dependent/unable to do	The patient does less than 25% of the task

PHYSICAL THERAPY INTERVENTION

Rehabilitation and Habilitation

Research in the adult population has shown that timely referral of patients with SCI to comprehensive, multidisciplinary SCI centers is more cost effective, with improved patient outcomes, reduced hospital and long-term nursing care charges, and an improved prospect for long-term patient earnings, compared with unspecialized care for SCI patients.[25]

The acute rehabilitation and long-term treatment of children with SCI require a comprehensive interdisciplinary approach involving both hospital and school-based personnel. Team members typically include physical therapists, physicians, nurses, a dietitian, occupational and speech therapists, therapeutic recreation specialists, a social worker, an orthotist, a clinical psychologist, teachers, the child, and the family.

Physical therapists often work alongside a pediatric physiatrist, who typically provides medical management and serves as a team leader. In some centers, however, an orthopedist, a neurologist, or a pediatrician may fill this role. The lead physician may also request consultation by other physicians such as an orthopedic surgeon or neurosurgeon to monitor spine stability and alignment, a urologist to monitor urinary tract function, and a pulmonologist for ventilator management.

Physical therapists develop age-appropriate ROM, strengthening, and SCI education programs. They address functional mobility, including bed mobility, transfers, sitting balance, ambulation, and basic and advanced wheelchair skills. The physical therapist makes recommendations on lower extremity orthoses and plays a primary role in the ordering of a wheelchair. Goals must be set according to usual expectations for age. Greater independence with varying degrees of transfers and mobility will be expected the older the child.

Continuum of Care

Like the physical therapy examination, the interventions may differ in each setting based on the age, abilities, and needs of the child. In general, in the acute care setting, the physical therapy focus is on education, prevention of secondary complications, and discharge planning. During inpatient rehabilitation, physical therapy interventions include trialing, choosing appropriate equipment, and functional activities such as engaging in developmentally appropriate and continued education. With development and increasing age, returning to the inpatient rehabilitation setting for "brush up rehab" is an option. Learning new skills or advancing skills as developmentally appropriate can also occur in the outpatient setting. Home care services may be warranted if the focus is to allow for independence in the home setting, whereas school-based interventions will address the needs of the child while functioning at school.

Education

Physical therapists should include parents as active participants during both the examination and intervention phases. Parent goals often focus on wanting the child "to walk again." However, parents must become experts in all aspects of their

child's mobility and use of adaptive equipment. Parent education and training should be an ongoing process that begins soon after the initial examination and supports success with day or overnight outings. Physical therapy goals for this population focus on education, as the family must be thoroughly trained in all aspects of the child's mobility and care. Children must also be trained to instruct others in their care, including use and maintenance of the wheelchair, mechanical lift, environmental control unit (ECU), computer access, and any other equipment.

Outcomes

The therapist and SCI team must assist the family and child in establishing realistic outcomes. One must consider the child's level of injury (Tables 21.4 and 21.5), the completeness of injury, the age of the child, and the family's expectations for the child. Parents should be included in treatment sessions whenever possible. Although many children work better in therapy sessions in the absence of parents, parents should be regularly included to see the new skills their child can independently accomplish and the emerging skills that require assistance.

Every parent and caregiver want the child with an SCI to walk again. Ambulation is feasible and can be tried with certain portions of this population; however, the goals for ambulation must be realistic.[23] In many cases, ambulation does not replace the use of a wheelchair, especially with braced ambulation, as it is both time and energy consuming. Studies have looked at the relationship between results of the ISNCSCI examination and ambulatory ability.[29,123,150] One pediatric study determined that the total lower extremity motor score can predict ambulatory potential, including the use of ambulation as a primary mode of mobility.[29] Two adult-based studies found that the total lower extremity motor score is directly related to the potential for an individual with SCI to ambulate. If the total lower extremity motor score is less than or equal to 20, an individual's ambulatory ability is typically limited to household situations, in contrast to those with scores greater than or equal to 30, who are often community ambulators.[150] Additionally, the greater the total lower extremity motor score, the greater the individual's walking speed and endurance.[123]

Guidelines have been developed based on developmental level and neurologic impairment to aid in decision making regarding mobility and appropriate clinical goals.[23,37] A stander is recommended for patients with injuries at T1 and higher and either a stander or bracing for injuries below T1. For those with levels of injury at T1 and below, ambulation may be achieved via various types of bracing depending on level of injury and lower extremity muscle strength. With higher-level injuries, ambulation is more of a therapeutic/exercise goal rather than a true functional goal. The cost of bracing and assistive devices must be balanced against the practicality of ambulation and the willingness of the patient and family to follow through with ambulation after discharge/training sessions. The most common reasons for discontinuing use of the braces are the excessive energy costs and the need for assistance to don and remove them for ambulation.[146] Periodic reexamination of the child's physical abilities and outcomes as an outpatient can be used to determine whether ambulation with braces is a reasonable goal. Many patients become less interested over time in ambulation requiring extensive bracing as the permanence of the injury becomes more apparent. Those who remain interested may have specific needs for standing or limited walking that increase the likelihood of long-term use of the orthoses.[146]

TABLE 21.4 Mobility in Complete Tetraplegia, Expected Function, and Necessary Equipment for Level of Injury

Functional Skill	C1-C4	C5	C6	C7-T1

Physical therapy intervention sessions will be structured around the child's motivation for play. Within that framework, the therapist designs activities that encourage strengthening, balance, reaching, rolling, sitting, transitions, and mobility in various combinations.

Sitting balance is often one of the major goals of therapy. Balance is impaired by altered strength and sensation and often by the presence of a spinal orthosis. Conversely, a child with tetraplegia or high paraplegia may benefit from a soft orthosis to facilitate sitting, leaving hands free for other activities (Fig. 21.6). The seated child is encouraged to progress from therapist support to self-support at a tabletop or on a mat and to independent sitting if this is a realistic goal given the level and completeness of injury. These goals may be achieved by engaging the child in play activities.

All innervated musculature must be strengthened, including muscles that have normal grade 5 strength because these will be used to compensate for weakened or paralyzed muscles. Maintaining full ROM, particularly at specific joints, is imperative. For example, full ROM at the shoulders must be maintained for ease of dressing. Historically, patients with tetraplegia who have wrist extension but no hand function were provided with a stretching program that allowed them to develop mild finger flexor tightness to provide for a tenodesis grasp during wrist extension. Current recommendations, however, are to maintain a supple hand and to even splint with metacarpophalangeal flexion and interphalangeal extension ("intrinsic plus" position) to maintain this ROM. The change in practice is due to the evolution of upper extremity reconstructive surgery for the population with tetraplegia, which can augment wrist extension, grasp, lateral pinch, and finger extension.[102] Stretching the hamstrings to allow 100° to 110° of hip flexion is necessary for dressing and self-care. It is important to have excessively flexible hamstrings to prevent overstretching of the low back. Ankle ROM must be maintained at neutral for proper placement on the wheelchair footrest.

A small number of children with tetraplegia have upper cervical injuries (C1-C3) that necessitate mechanical ventilation (see Chapter 25). Physical therapy for these children and for those with C4 tetraplegia has a more narrowed focus because the child is dependent in bed mobility, transfers, and sitting balance (see Table 21.2). Spasticity tends to be more problematic with this population, although daily passive ROM can reduce tone and facilitate positioning.

Bed Mobility and Transfer Techniques

Depending on the level of injury and personal preference for the patient, several strategies can be used when teaching mobility and transfer techniques. It can be challenging for both the physical therapist and patient. The International Network of Spinal Cord Injury Physiotherapists website (www.scipt.org) is a valuable resource, as it contains videos of patients at various levels performing bed mobility, transfers, wheelchair mobility, and gait techniques. Extended detail can also be found in SCI rehabilitation textbooks.[51,131]

Bed mobility and transferring techniques for children and adolescents are similar to those used for adults. Successful mobility focuses on maximizing biomechanics, using momentum, and understanding the head-hips relationship. The head-hips relationship, or the concept of moving your head and upper trunk *opposite* to the direction you are moving and looking away from where you are moving in order to unweight the pelvis for transfers or mat mobility, is not intuitive for a child. Mastery of this concept, however, will open up much more opportunity for mobility.

For children with paraplegia and lower level tetraplegia (C6 and below), transfer training may initially include the use of a transfer (sliding) board. Calling it a transfer board is preferred so that children do not think they can slide on the board, as doing so can shear the skin. Push-up blocks can also be helpful when first learning transfers (Fig. 21.7). As upper extremity strength and balance increase, the child may be able to transfer

FIG. 21.6 A soft orthosis provides external support, improving sitting balance and allowing this child with a high thoracic spinal cord injury to use both hands in play.

FIG. 21.7 Teen wearing a thoracolumbosacral orthosis with a thigh piece that restricts hip flexion uses a sliding board and push-up blocks to begin learning transfers.

without a transfer board. Types of transfers learned should include those for level and nonlevel surfaces, as well as floor to wheelchair and wheelchair to floor. Older children should also learn how to transfer in and out of a vehicle. Young children can be physically capable in transferring themselves; however, they may require a caregiver's assistance from a safety standpoint as they may totally disregard their legs, putting themselves at risk for a lower extremity fracture. Rather than taking a lateral approach to the surface they wish to transfer to, young children may take more of an anterior approach and scoot forward/backward with their legs in either a long or ring-sit position. Children and adolescents with C5 and above tetraplegia are dependent for transfers and require either a caregiver to lift them or the use of a mechanical lift. In either situation, all caregivers must be educated in proper technique, and the child must be able to verbalize the steps that need to be taken for a safe transfer.

Wheeled Mobility

If community ambulation is not an expected outcome, the child needs a wheelchair for mobility. Guidelines for appropriate mobility have been developed for children with SCI to assist the therapist and team.[23] Young children with an SCI at or above C6 need a power wheelchair for independent mobility. Some young children with lower levels of cervical SCI, or even high thoracic injuries, may be able to propel a manual wheelchair for only limited distances on smooth, level surfaces owing to lack of upper body strength and endurance. For these children to be exposed to a broader range of environments, such as preschool playgrounds or uneven or steep terrain around the family home, prescription of a power wheelchair is justifiable to promote age-appropriate functional mobility. A child as young as 18 to 24 months may be trained to use a power wheelchair but requires adult supervision for safety.[82,100,119a] An environmental control unit (ECU) and a complex power wheelchair are needed for independent mobility when a joystick is not appropriate due to a higher level of injury. The joystick is replaced with head, tongue, or sip-and-puff controls and the power tilt must allow for ventilator placement. In addition, a manual tilt-in-space wheelchair is necessary to provide these children with a substitute when the power chair needs repairs. The manual wheelchair is also useful for transport in places where the larger, heavier power chair is impractical. Many families do not have a home with hallways or doors large enough to accommodate a power wheelchair, so power mobility may be used primarily in community and school settings and the manual wheelchair is used in the home.

Power-assist wheels are motorized wheels that can be added onto or are already a part of a manual wheelchair. These allow the user to provide some propulsion forces, and the motors enhance their propulsion to allow them to be functional. This type of wheel is most applicable for patients with C6-T1 level injuries or where upper body endurance is lacking. Power-assist wheels do add weight to the wheelchair, but the trade-off is that there is still a manual wheelchair that can typically be transported in the trunk of a car, rather than a power chair that requires an adapted van or lift. One case series[35] demonstrates positive outcomes of independent propulsion over terrain and ascending ramps in children, ages 7 to 11, with SCI or dysfunction affecting upper extremity strength.

For children/adolescents for whom manual wheelchair propulsion is going to be the primary means of independent mobility, extra attention must be paid to the configuration of the wheelchair in addition to the weight of the chair (Fig. 21.8). Focus is frequently placed on ultra-lightweight materials; however, setup is just as important, if not more so. Proper setup details include overall width and depth of the chair, axle placement, seat-to-floor height, wheel and rim size, caster size, and back type and height. Variances in setup can now be quantified through the use of the SmartWheel (Fig. 21.9), which measures propulsive forces, speed, and cadence.

The Paralyzed Veterans Association (PVA) has also published guidelines on proper wheelchair setup in the adult population[39,82] to preserve the joints of the upper extremity, and because literature is lacking in the pediatric population,[23,82] these may be considered, as best practice is in

FIG. 21.8 A-B, Manual wheelchair setup.

FIG. 21.9 SmartWheel. (Courtesy of Out Front, Mesa, Arizona.)

the pediatric population. Overuse injuries at the shoulder (rotator cuff impingement, capsular injury) and the wrist (carpal tunnel syndrome) are seen in a large percentage of the adult population.[39] It is likely that these same injuries will occur in pediatrics, as they are pushing wheelchairs for more years, and presumably with more force, because the chair can weigh more than the child. Additionally, the tendency is to add backpacks on the back of the chair, only to increase the overall amount of weight the child needs to propel. Finally, oftentimes the wheelchairs provided are larger than needed with the anticipation that the child will grow and the chair needs to "grow" with the child, particularly because insurers will only pay for a new chair approximately every 5 years. Manufacturers have designed chairs that can change seat width and depth, but often proper setup is sacrificed. Other manufacturers have a trade-in program or "growth kit" option to allow for a more appropriately sized and setup frame to be delivered when needed.

The seating components of either a power or manual wheelchair are prescribed with skin protection and spinal alignment in mind (see Chapter 33 for additional information). A level pelvis decreases the amount of pressure placed over individual ischial tuberosities of the sacrum, thereby improving overall pressure distribution. A solid seat and back are preferred to sling upholstery in this age group. Many types of wheelchair cushions are available, but none is universally effective for maintaining skin integrity in all persons with SCI, and individual assessment is required to minimize ulcerative forces (pressure, shear, friction and moisture).

Wheelchair positioning and fit can also limit the development of secondary peripheral neuropathies. Too frequently, peroneal nerve neuropathies are seen as a result of the lateral lower leg, just distal to the head of the fibula, resting against the front end or leg rest of the wheelchair. Additionally, some children and teens use an upper extremity to "hook" around a back cane of a wheelchair for either pressure relief or to assist with balance. Excessive pressure in the antecubital fossa over time may cause median nerve neuropathy.

Wheelchair evaluations can occur in all settings, but often the first time is in the rehabilitation setting. During this time it is best to trial as many wheelchair frames and seating systems as possible to determine what is clinically most appropriate and what the child and parents like best. If no change in neurologic status and function is expected, the wheelchair must be ordered as soon as possible, although because it is unlikely that the new wheelchair will arrive before discharge, a rental wheelchair may be necessary. As the child grows, wheelchair evaluations may occur at the rehabilitation hospital, at an outpatient facility, or in school. All wheelchairs and ECUs should be chosen by the rehabilitation team, child, and family in consultation with a knowledgeable vendor (see Chapter 33). The therapist should be aware of available funding for wheelchairs and other durable medical equipment. There may be limitations in coverage, and the therapist can assist the family in prioritizing equipment needs.

The physical therapist will address a variety of skills. There is no set time to initiate these mobility skills, and the appropriate timing depends on the child's age currently and age at injury, their abilities, and the environments in which they typically interact. Some of these skills include propulsion over even and uneven terrain, negotiation of obstacles, ascending and descending ramps and curbs, assuming a wheelie, falls, and stairs (www.scipt.org).

Ambulation

For those with absent or limited active hip flexion, a hip-knee-ankle-foot orthosis (HKAFO) may be prescribed. The hip joint can be locked for a swing-through gait pattern and unlocked to use active hip flexion for a reciprocal gait. Another option is an reciprocating gait orthose (RGO), which has a cable system that allows for passive reciprocating gait, but the child must be adept at weight shifting and trunk extension. Children who have at least three-fifths strength in the quadriceps muscles or stronger hip flexors can achieve ambulation with KAFOs. The swing-through gait pattern is more efficient than other gait patterns. Many adults who have RGOs or knee-ankle-foot orthoses (KAFOs) prescribed do not use them at all in the long term, and the majority of the remaining patients use them only for standing or exercise. Children with lower-level injuries, L3 and below, and some incomplete injuries may achieve independent ambulation with ankle-foot orthoses (AFOs). Ambulation typically also requires an upper extremity assistive device, particularly for those using H/KAFOs and RGOs. Gait training may be initiated in parallel bars and advance to use of an appropriate assistive device (typically front wheeled walkers or Loftstrand crutches) as the child improves in standing balance. Parastance, where the hips and lower trunk are in excessive extension and balance is achieved by resting on the y-ligaments in the hip, must be achieved in order for those ambulating with H/KAFOs to be successful. Donning and doffing, and general orthoses management, must be taught and practiced with both the child and caregivers. Controlled sit-to-stand transitions must also be practiced.

Preschool-age children (5 years and younger) are more likely to pursue ambulation, perform a higher level of ambulation, and ambulate for a longer number of years as compared to older children and adolescents.[146] Once these younger children enter the preteen and adolescent period, however, ambulation is typically abandoned for wheeled mobility beyond an indoor home or school level in order to keep up with peers.[146]

For children who wish to be upright for physiologic and psychological benefits but do not necessarily wish to ambulate,

FIG. 21.10 A-C, Options for static and mobile standing.

various devices are available. A standing frame (Fig. 21.10B) can be used for static standing, but there are also parapodiums (Fig. 21.10A) or swivel standers, which have a footplate that, in combination with an assistive device, allows a child to swivel the trunk for very short distance mobility. Mobile standers (Fig. 21.10C) are also available in which a child can assume a standing position while propelling with large, wheelchair-like wheels (see the video that accompanying Chapter 21).

Locomotor training (LT) is an activity-based therapy that typically consists of step training via a body-weight-supported (BWS) system, initially on a treadmill often followed by overground gait training. BWS systems are commercially available; some are developed specifically for use overtop a treadmill, whereas others use a track from a ceiling allowing for more movement. The term *activity-based therapy* is used to describe an intervention that results in neuromuscular activation below the level of spinal cord lesion to promote recovery of motor function, thus demonstrating the neuroplasticity of the spinal cord.[8-10] A reported goal of LT is to stimulate the locomotor central pattern generators (CPGs) in the spinal cord.[52] It is believed that reflexive movements of ambulation can be restored by stimulating these CPGs through the repetitive motion.[52] One case study in which LT was performed as part of a young child's acute inpatient rehabilitation demonstrated the return of isolated volitional contractions of lower extremity muscles and significant gains in functional mobility.[117] Research continues in this area, but early results are promising and suggest the potential value of incorporating LT into physical therapy intervention.[10]

Ambulation may also be achieved by using a robotically assisted walking device. These systems allow users to stand and ambulate by wearing an exoskeleton "suit" that provides motorized assistance to leg musculature. There are specific criteria for their use. Most require the user to be able to shift weight in order to activate the motor and therefore take a step. These robotic systems are geared toward adults, as another criterion for use is based on weight and height. There are systems designed for use with a physical therapist in the medical setting as well as devices for personal use.

FIG. 21.11 A 5-year-old child with Spina Bifida using the RT300-SLP FES cycle. (Courtesy Restorative-Therapies, Inc., Baltimore, Maryland.)

Functional Electrical Stimulation for Children

Cycling with FES has gained increased popularity as an activity-based rehabilitation strategy to encourage neuroplasticity and health gains for people with SCI. FES during cycling can be performed at home, and cycles appropriately sized for children are now available (Fig. 21.11). The cycles are FDA approved for children ages 4 years and older; however, the primary limiting factor is the child's size. Typically the bilateral quadriceps, hamstrings, and gluteal muscles are stimulated at the appropriate times during the revolution of the cycle. This intervention has been applied to people with SCI with and without lower extremity sensation. For children with sensation, the FES can be gradually applied and limited in intensity in order to not exceed the child's tolerance. Exercise protocols in the literature commonly involve cycling for 30 to 60 minutes three to five times per week

at cadences of 40 to 50 revolutions per minute (rpm).[54] The ideal protocol, however, is not known, especially for children. The only published literature with children applied FES cycling for 60 minutes, three times per week, at a cadence of 40 to 50 rpm.[77]

Outcomes reported for FES cycling with adults include improvements in bone mineral density,[11,31,40] strength in stimulated muscles,[77] muscle size,[40,55,64] oxygen uptake,[40,65,77] cardiac output,[49,65] stroke volume,[49] and decreased adiposity.[64,124] In children, the literature is more limited with changes reported in bone mineral density,[77] oxygen uptake,[75,77] muscle volume,[77] stimulated muscle strength,[77] as well as decreased resting heart rate.[77] In addition, FES cycling has been shown not to increase the degree of hip subluxation after 6 months of cycling.[75]

Most clinically available applications for FES in pediatric SCI use electrodes placed on the skin surface. For all FES applications, a critical portion of the evaluation is the determination of the ability to stimulate the muscle.[106,134] With a lower motor neuron injury, muscle cannot be adequately stimulated and FES is therefore not appropriate.[72] For example, a child with a C5 SCI is likely to have lower motor neuron damage to C6 due to concomitant damage to the alpha motor neuron or nerve root at C6, and thus stimulation for wrist extension may be problematic. A thorough evaluation using electrical stimulation will provide information as to what muscles are appropriate for FES applications.

FES walking options using surface stimulation for standing and walking are known as neuroprostheses. These systems use the peroneal withdrawal reflex to mimic a step, allowing the leg to advance.[81] The commercially available system is only approved for use when skeletally mature; however, the peroneal withdrawal reflex can be obtained using a portable neuromuscular electrical stimulation (NMES) unit and a trigger if desired for children with incomplete SCI who have some ability to maintain stability during stance. For this technique, an electrode is placed near the fibular head and stimulation intensity is set high enough to cause the leg to withdraw into flexion. Another option during gait for a child with an incomplete SCI is to use a portable NMES unit to create dorsiflexion.[116] For both applications during gait, a switch can be placed into the shoe to control the timing of the FES. Surface systems are commercially available for specific applications such as foot drop or hand function and are available in pediatric sizes. To provide these applications without a commercially available surface system, a more generic neuromuscular electrical stimulation NMES device can be used, and the ability to use a trigger or switch to turn on the stimulation is important for FES applications. Common stimulation parameters for FES include pulse duration sufficient to create a muscle contraction (200 to 400 usec) and a low frequency, measured in pulses per second (pps) (20 to 30 pps) to minimize fatigue. On and off times will be determined by the activity itself, and ramp time can be set for comfort or to minimize spasticity as long as it does not impact the timing of the activity (i.e., during gait when on times are very short).[77]

Implanted devices have been used in pediatric clinical and research applications including facilitation of grasp, standing and walking, bladder and bowel function,[132] and phrenic or diaphragmatic pacing.[48,126] Phrenic and diaphragmatic pacing systems are FDA approved for use in children. With this device, bilateral phrenic nerve electrodes are placed thoracoscopically and after a period of conditioning can provide full-time ventilatory support without a mechanical ventilator.[48] A report of nine children implanted with the phrenic pacemaker showed that eight were able to meet their pacing goals.[126]

Coordination/Communication/Consultation

While hospitalized, the child and adolescent must practice mobility skills outside the structured therapy sessions. For instance, nurses should be updated on progress in mobility skills so that the child can be encouraged to incorporate these abilities into play activities or getting to meals.

Community and school reentry activities are often the combined responsibility of physical therapists, occupational therapists, and therapeutic recreation specialists. Children must become familiar with common architectural barriers such as curbs, heavy doors, and high shelves and learn how to negotiate them or ask for help. Caregivers need to be trained in the type and amount of assistance to provide and cautioned against being overly helpful. Teenagers should be encouraged to problem solve the management of architectural barriers and ask for assistance if safety is jeopardized. Discharge planning and long-term management should address mobility issues in the child's home, school, and community. Whenever possible, a home evaluation should be conducted early in the child's hospital stay. If home modifications are necessary for wheelchair accessibility or safety, the family needs time to gather financial resources and complete modifications. Physical therapists may be asked to consult regarding modifications being made to the home. The US Department of Housing and Urban Development has resources available and has published guidelines on making homes more accessible.[118,139] These modifications can be evaluated during weekend passes. Public schools employ physical therapists and occupational therapists who can provide accessibility information while the child is still hospitalized. Upon school entry, the child can be assisted with accommodations under the provisions of Section 504 of the Vocational Rehabilitation Act of 1973.[140] The therapist plays a major role as a consultant to the school administration, faculty, family, and student regarding accessibility issues and needed modifications to architectural barriers or curriculum. For children living great distances from the hospital, physical therapists in the school can provide a local perspective and become a resource to the family.

Another area of concern in community reentry is safe transportation. The physical therapist can assist the family with evaluating safe transportation for the child. If a van will be used, wheelchair tie-downs will be necessary. If the child has a lower thoracic injury with adequate balance and can sit in a vehicle seat, an appropriate car seat or booster seat may be needed. For teenagers, friends may need to be trained in car transfers so that the patient can stay socially active. The teenager returning to driving needs to be independent with transfers and with loading and unloading the wheelchair.

Exercise and Fitness

Cardiovascular fitness is a major health concern in the SCI population. Adults with tetraplegia have a 16% increased risk of cardiovascular diseases as compared to the general population, whereas those with paraplegia have a 70% greater risk of coronary artery disease (a subset of the cardiovascular diseases).[107]

Greater risk (44%) of cardiovascular diseases is also seen with complete versus incomplete SCI. The prevalence of cardiovascular disease in the SCI population is difficult to estimate because of the presence of silent ischemia that may go undetected, but cardiovascular disease has been reported to be the leading cause of death for people with SCI of greater than 30 years in duration. These data suggest that interventions are desperately needed to decrease the incidence of cardiovascular disease in the SCI population.[107]

People with SCI tend to lead sedentary lifestyles, which further increases their risk for coronary heart disease (CHD).[68] The level of inactivity seen in the SCI population poses a serious health risk because of the accompanying secondary health complications of CHD, obesity, and diabetes.[58,115] Voluntary exercise, however, is difficult for many people with SCI based on the extent of the paralysis, lack of proper exercise equipment, and lack of trained professionals to provide guidance. Although people with paraplegia have more capability to exercise, they are not more fit than people with tetraplegia who have fewer exercise options.[108] In addition, 25% of healthy young people with SCI lack the fitness levels to perform important daily activities.[108] Given the significant impact that SCI has on cardiovascular health, compounded with the lack of availability and need for exercise in this population, there is a dire need for exercise interventions.

Regular exercise can decrease the extent of the metabolic, skeletal, and muscle complications for people with SCI.[73,108,109] Some options for exercise include upper extremity ergometry, FES-assisted activity, swimming, and adapted sports.[68,107] Strong level 1 evidence exists for the ability of upper extremity exercise to improve cardiovascular fitness and oxygen uptake.[149] Central effects (heart and lungs) of exercise reported with people with SCI include increases in peak oxygen uptake up to 65%, as well as improvements in stroke volume of approximately 16%.[115] In addition, regular exercise can have a positive impact on lipid profiles[107,149] and glucose homeostasis.[149] The evidence suggests that more intense exercise than currently being performed may be needed to have an impact on lipids post SCI and that effects are possible with both arm exercise and FES cycling.[149]

Little research has been done on health and fitness in children with SCI, but with the increasing prevalence of obesity among children as a whole, intervening early with children with SCI may help to develop healthy habits that persist into adulthood. Some evidence suggests that 10- to 21-year-old children with SCI have an increased incidence of metabolic syndrome (present in 11 out of 20 children),[109] decreased lean tissue mass compared to overweight and control subjects,[87] increased fat mass (by 22.9% with paraplegia and 25.9% with tetraplegia),[94] and decreased aerobic capacity compared to controls.[149] In addition, children 5 to 13 years of age have been shown to have decreased aerobic capacity.[74] Exercise interventions targeting some of these deficits have been limited.[86] Liusuwal and colleagues[87] studied the outcomes of a 16-week program targeting nutrition, exercise (aerobic and resistance training), and lifestyle change and reported increases in lean body tissue and in power and efficiency during an upper extremity ergometry test. Johnston and colleagues[76] studied the effects of 6 months of FES cycling and reported increases in peak oxygen uptake during an upper extremity ergometry test. These studies suggest that exercise can have a positive impact on the health of children with SCI; however, more research is needed to determine optimal ways to address the health concerns for people with SCI.

Sports and Recreation

Therapists should encourage regular aerobic exercise in children and young adults with SCI to help them develop lifelong habits that promote health, particularly because of their general tendency toward lower-intensity, more sedentary leisure activities.[71] With childhood obesity and type 2 diabetes rates on the rise in the pediatric population, those with SCIs are at greater risk. A majority of children and teens are not involving themselves in organized activities such as sports, clubs, or those offered by youth centers.[71] Therapeutic recreation specialists facilitate participation in an adaptive physical education program, community-based recreational programs for people with disabilities, or competitive wheelchair sports. Offering specific recreation programs during inpatient rehabilitation or camps after discharge can significantly contribute to overall rehabilitation and quality-of-life outcomes.

PSYCHOSOCIAL ASPECTS

A team member skilled in mental health should monitor the child's adaptation to disability and be available to help the child verbally process the injury and rehabilitation. This could be a skilled social worker, but if a behavior management program using reinforcers is needed, a clinical psychologist should be consulted. In rare cases, the child may truly be clinically depressed, and a psychiatrist can be consulted if a medication trial is contemplated. As described by Fordyce,[53] acquisition of an SCI accompanied by pain, medical complications, altered cosmesis, and body image and the new and challenging rehabilitation procedures can be expected to have a significant impact on the patient's affect, self-esteem, and behavior. The child's adjustment to SCI does not necessarily follow predictable stages of crisis response such as shock, denial, depression, and adaptation. Adjustment to SCI probably occurs over several years. The verbal or attitudinal expressions of children with a new SCI are less predictive of outcome than are their behaviors. Physical therapists can facilitate adjustment by actively engaging the child in acquiring the skills needed to maximize independence. Therapists must include parents and caregivers when teaching these skills to children and adolescents, and they must not forget the importance for adolescents of incorporating peers. The psychologist or psychiatrist may also need to confront issues of premorbid risk-taking behavior or even substance abuse. Psychologists, nurses, and pediatric physiatrists collaborate in discussing sexuality and changes in sexual functioning with teenagers who have had SCI. Sexuality is often a difficult topic to approach with teens and their caregivers. If a teen is not ready to verbalize questions or concerns related to sexuality, there are a number of online resources from adult spinal cord injury model systems that may provide additional assistance, such as University of Alabama at Birmingham (www.spinalcord.uab.edu).

A concern commonly expressed by teenagers is that of not being able to trust their bodies. The altered motor and sensory processes and potential changes in bowel and bladder function can make their bodies feel foreign to them. In addition, teenagers are accustomed to privacy and independence in their lives. Both the injury and subsequent reliance on a hospital environment, adaptive equipment, and caregivers can disrupt any sense of control. The rehabilitation team should respect privacy and encourage participation in scheduling therapy, nursing care, and free time.

QUALITY OF LIFE

Physical therapists can have a positive impact on quality-of-life issues a child may face as a result of SCI. Chronic pain has been determined to be one of the most common[69] and limiting factors in terms of quality of life following SCI, resulting in decreased perceived mental and physical health, as well as decreased activity levels[142] (although activity does not seem to decrease as significantly as in the adult population[70]). Musculoskeletal pain is most prevalent in the shoulder, elbow, and wrist. Visceral pain is also frequently identified, particularly originating from the genitourinary tract, as is neuropathic pain.[69]

Depression can hinder quality of life and life satisfaction as it limits community participation and self-inclusion in activities. Adults with pediatric-onset SCI experience depression to varying degrees, which is related to medical complications, perceived mental-health quality of life, occupation, and the severity of their injuries (complete versus incomplete).[5]

By being aware of these potential issues, physical therapists can monitor for them and make referrals to appropriate providers as necessary. By constantly monitoring developmental changes and a child's participation, age-appropriate habilitation and rehabilitation can be addressed as needed.

FOLLOW-UP AND TRANSITION TO ADULTHOOD

The key to ensuring maximal participation in young children with SCI is to provide ongoing examination of impairments and activity and to regularly update expected outcomes that are appropriate. At least two mechanisms are available to accomplish this objective. Children who are discharged from rehabilitation centers are routinely seen in follow-up visits two or more times each year. These reassessments include medical follow-up to reexamine the level and completeness of injury, to evaluate changes in bladder and bowel function and skin integrity, to monitor the spine and hip for development of scoliosis and hip subluxation/dislocation, respectively, to determine the need for medications to treat spasticity or bladder or bowel incontinence, and developmental appropriateness.

Reexamination by the physical therapist is an important part of these follow-up visits. Any changes should be noted, including changes in ROM, strength, sensation, and spasticity. For children, age-appropriate habilitative skills can be taught (i.e., self-catheterization, skin checks, advanced wheelchair skills, and transfers). The wheelchair should be reassessed and adapted as needed to accommodate the child's growth and to ensure that any modifications enhance positioning and propulsion independence.

The physical therapy reexaminations at the rehabilitation facility follow a consultative model. The ongoing progress toward age-appropriate outcomes may occur in a hospital-based outpatient therapy program, but it is more typically accomplished through therapy services offered in the outpatient physical therapy setting, early intervention programs, or in publicly funded schools. Therapists in these programs ideally are in contact with the rehabilitation centers on a regular basis to update progress and goals and to identify new concerns and equipment needs.

Although the majority of young school-age children with SCI receive direct physical therapy and occupational therapy services in school, few adolescents receive such services.[90] The therapist works from a consultative model, using the faculty and student to carry out programs and recommendations. Issues may include supporting the teen to continue with regular pressure releases, stretching and impairment-based home activities, and progressing mobility skills to community distances. The physical therapist and occupational therapist should also consult with the faculty and student regarding an appropriate physical education program; modification of classroom and desk setup; and accessibility to lockers, bathroom, and lunchroom. In reality, many adolescents with SCI have no physical education program, face problems of accessibility at school, and report that breakdown of wheelchairs (both power and manual) contributes to absences at school.[90] Although completion of education is supported by accommodations and modifications, such supports are more often implemented to enhance the child's participation in classroom activities and are not geared toward competitive performance and productivity. Therapists should assist adolescents in achieving independence with assistive technology for mobility, communication, and environmental control. Skills development in directing and managing human assistants may also be needed.[46] Few adolescents with SCI receive educational or vocational counseling beyond the selection of classes each term.[90] Such students may qualify for transition planning under the Individuals with Disabilities Education Act, Public Law 105-17.[138] School physical therapists might participate in a transition program by assessing functional mobility skills in the community or work-study setting. When teenagers with SCI become 18 years of age, they are eligible in the United States for state vocational counseling services. Such services are often important sources of funding for vocation-related education or even equipment. The importance of facilitating education and employment is underscored by research showing that the life satisfaction of adults with pediatric-onset SCI is associated with education, income, satisfaction with employment, and social opportunities but not with level of, age at, or duration of SCI.[144]

For teenagers, follow-up visits should also include discussions related to sexuality and reproduction.[85] Fertility in women is not impaired by SCI, but sexual response and orgasm may be. Pregnant women with SCI should be managed at high-risk medical centers to avoid respiratory and urinary tract complications, detect threatened preterm births, and prevent autonomic dysreflexia during delivery. Although the majority of males with SCI can have erections, these are often fleeting and not adequate for vaginal penetration. Few men with SCI have ejaculations, and sperm quality decreases over time for reasons that are not entirely clear. New techniques for retrieval of sperm and for artificial insemination have helped some men with SCI to father children. In addition to this physiologic information, it is important to include issues of intimacy and relationships in candid discussions of sexuality.

Successful transition to adulthood is a goal of all children/adolescents with SCI. The rehabilitation team plays an important role in fostering success. Transition into a spinal cord injury model system (www.mscisdissemination center.org) is ideal to continue specialized care; however, travel to these facilities may not be feasible. Continued care from a specialized center will not only provide optimum medical care but will also support the services required for seeking education, vocational development, and independent living. Many adults with pediatric-onset SCI do complete an education level equivalent to noninjured peers; however, employment rate, income, rate of independent living, and marital status do not correlate with noninjured peers.[4] See Chapter 32 for more information.

SUMMARY

Physical therapy for the child with SCI can, at first glance, appear straightforward. Preserving ROM and promoting strength and endurance are the cornerstones for the functional achievement predicted by the level of injury. Yet predicting realistic long-term outcomes and attaining them require respect for the broader and more complex picture. The physical therapist must consider the cause of the injury (progressive versus stable), the completeness of the injury (preserved motor function, sensory function), and the potential for, or presence of, secondary complications (scoliosis, skin breakdown, contractures). The therapist must also be sensitive to the child's age, personal and environmental factors, and the child's ability to meet age-appropriate expectations in the home, school, and community. Unlike adults with SCI, who may be very close to expected levels of independence at discharge from inpatient rehabilitation, children often require years of outpatient therapy to achieve optimal outcomes. Thus, it becomes imperative to provide the child and the family with a team approach incorporating multiple disciplines and settings to maximize the child's potential for functional independence and participation in life roles.

Case Scenarios on Expert Consult

The cases related to this chapter present three case scenarios (Stacey, Alex, and Adam) with additional videos. They illustrate some of the management principles discussed in this chapter.

Acquired Brain Injuries: Trauma, Near-Drowning, and Tumors

Michal Katz-Leurer, Hemda Rotem

Acquired brain injury (ABI) in children is a highly stressful event for the child and the family. Damage occurring at a time of development extensively affects the child's abilities to do what children usually do: play, learn, establish friendships, and gradually develop to become independent young adults. The injury commonly causes a variety of physical, emotional, cognitive, and behavioral impairments. Suddenly, the child's expectations from life and the parents' aspirations for their child may be dramatically changed. These unique emotional, social, and developmental needs of the child and family demand a holistic and inclusive approach by a multidisciplinary team, both as a team and by each member of the team as an expert in a unique specialty. This chapter focuses on the role of the physical therapist and the elements of patient/client management: examination, diagnosis, prognosis, and intervention strategies, with emphasis on the child with ABI and the parents and family as they progress through the rehabilitation process.

ABI is a general categorization that describes any injury to the brain that occurs after birth and may be the result of trauma (e.g., head injury after traffic accidents, falls), anoxia (e.g., near-drowning), or a nontraumatic event (e.g., stroke, brain tumor, infection). ABI is the most common cause of morbidity and mortality in children and in young adults.[35] ABI might cause a variety of disorders involving motor dysfunction, cognitive impairment, behavioral disturbance, emotional difficulties, and abnormal function of the autonomic nervous system. Even a mild injury might result in a serious disability that interferes with the child's daily functioning and activities for the rest of his or her life.

Different theories have been put forth regarding the recovery and adaptation processes of brain function following a brain injury. One theory suggests that intact areas of the brain that are anatomically linked to the damaged site might be functionally depressed. Because return of activity occurs in these functionally depressed areas, recovery of function might also occur.[110] Another theory suggests that recovery and adaptation of brain function might occur as the original brain area responsible for that function recovers or through the adaptation of noninjured brain regions that normally contribute indirectly to that function. Furthermore, recovery of function occurs as a result of behavioral substitution in which new strategies are learned to compensate for the behavioral deficit.[110]

These theories serve as the foundation for a variety of interventions physical therapists use for children with ABI, ranging from preventive treatment with the expectation for brain function recovery at one end of the spectrum to a structured motor training program to facilitate compensation processes of brain function at the other. The latter is the source of many innovative treatment strategies for patients with brain damage. Advances in basic science have demonstrated morphologic changes in neural structures within the motor cortex during the process of motor skill acquisition, resulting in behavioral changes in motor performance.[91] The use of functional neuroimaging techniques may help researchers and clinicians to clarify the effect of treatment on neural reorganization and to identify the sequence and timing of interventions that will optimally and efficiently improve function. Although the outcome of the injury depends largely on the nature and severity of the injury itself, appropriate and timely treatment may play a vital role in determining the level of recovery.[73]

The first part of this chapter describes the epidemiology, pathology, and prognosis of ABI among children and adolescents. Examples of three common causes of brain injury among children—trauma, near-drowning as an example of an anoxic event, and brain tumor—are described in detail. The second part focuses on foreground information related to physical therapy examination and intervention throughout the rehabilitation process.

BACKGROUND INFORMATION

TRAUMATIC BRAIN INJURY

Epidemiology

Traumatic brain injury (TBI) is the most common cause of acquired disability in childhood, with an incidence death rate of 4.5, a hospitalization rate for nonfatal TBI of 63, and an emergency department visit rate of 731 cases, all per 100,000 children aged 0 to 14 years per year in the United States.[65] The most frequent causes of injury are motor vehicle accidents and falls, the latter being the primary cause among younger, preschool children; adolescents and young adults are more commonly injured in motor vehicle accidents. The incidence is higher in boys and highest in boys between the ages of 15 and 20 years, followed by children between the ages of 6 and 10 years.[56] Other demographic and socio-environmental factors associated with an increased risk of TBI include poverty, crowded neighborhoods, family instability, history of alcohol or drug abuse, and learning disability.[61] Preexisting behavioral characteristics such as impulsivity and hyperactivity, as well as attention deficit disorder, have been associated with an increased risk of accidental injury[15]; the *shaken baby syndrome* resulting from vigorous shaking of an infant or small child by the shoulders, arms, or legs can also be a cause of brain injury.[12] Preventive efforts are essential and should include educational programs for children, adolescents, and parents. The effectiveness of preventive activities regarding risky behavior and the use of protective equipment have been described. For example, awareness about head injury in children not wearing helmets during bicycle riding arose during the early 1980s, when it was noted that only approximately 15% of riders

younger than 15 years of age wore helmets. Societal interest resulted in the implementation of helmet laws that reduced the incidence of pediatric TBI. The results of a case-control study in Seattle in 1989 indicated that the use of bicycle helmets reduced the risk of bicycle-related head injury by 74% to 85%.[105]

Pathology

Brain damage due to TBI is typically divided into primary and secondary damage. *Primary damage* is related to the forces that occur at the time of initial impact; *secondary* damage occurs as the result of processes evoked in response to the initial trauma.

Primary Brain Damage

Primary brain damage can be classified according to the mechanism of injury, including acceleration-deceleration injury, crush injury, and penetration injury. *Acceleration-deceleration* injuries occur when the force applied is translational (Fig. 22.1) or rotational (Fig. 22.2) and commonly results from motor vehicle accidents; the head hits an immobile object or a mobile object hits the immobile head. Such injuries can lead to lesions that might be microscopic or combined with a focal macroscopic lesion with a predilection for the midbrain, pons, corpus callosum, and white matter of the cerebral hemispheres.[80] Acceleration-deceleration injuries, particularly the rotational component, produce differential displacement of adjacent brain tissue layers. This shearing force has its greatest effect in areas where the density differences of the tissues are greatest. Therefore approximately two thirds of lesions of this type—that is, diffuse axon injury (DAI)—occur at the gray-white matter interface.[92] The child's brain has a higher water content (88%) than the adult brain (77%), meaning that the brain is softer and more prone to acceleration-deceleration injury. *Contusion or crush injuries* are usually frontal or temporal. These injuries result from relatively low-velocity impact such as blows to the head or falls. Skull fractures may be associated, which is significant only when underlying compression of the brain or hemorrhage occurs. Or multiple small intracerebral hemorrhages and occasionally more extensive bleeding may be observed. *Penetration injuries* constitute a minority of pediatric TBI and are classified as nonmissile penetrating injuries and missile penetrating injuries. Children are prone to nonmissile penetrating injuries that result from a fall or from a home or playground accident. These injuries often involve nails, pencils, and sharp sticks, which, in most cases, cause focal damage. Missile injuries caused by gunshots or air pellet rifles lead to substantive intracranial damage.

Secondary Brain Damage

Secondary brain damage usually results from hypoxia or ischemia, which can be caused by *intracranial factors* or *extracranial factors* such as hypoxemia or hypotension (systolic blood pressure <90/mm Hg).[14] The main *intracranial causes* of secondary injuries are hemorrhage and brain swelling. Intracranial hemorrhage is due to laceration of blood vessels within the brain or on its surface, resulting in an epidural, subdural, or subarachnoid hematoma, according to the site. Displacement of the brain can occur as the result of a rise in intracranial pressure due to edema or can be caused by a mass lesion. Diffuse swelling is more common in infants and children than in adults. It has been suggested that the relatively compliant skull and membranous suture properties of the infant skull allow a significant cranial shape change and a more diffuse pattern of brain distortion

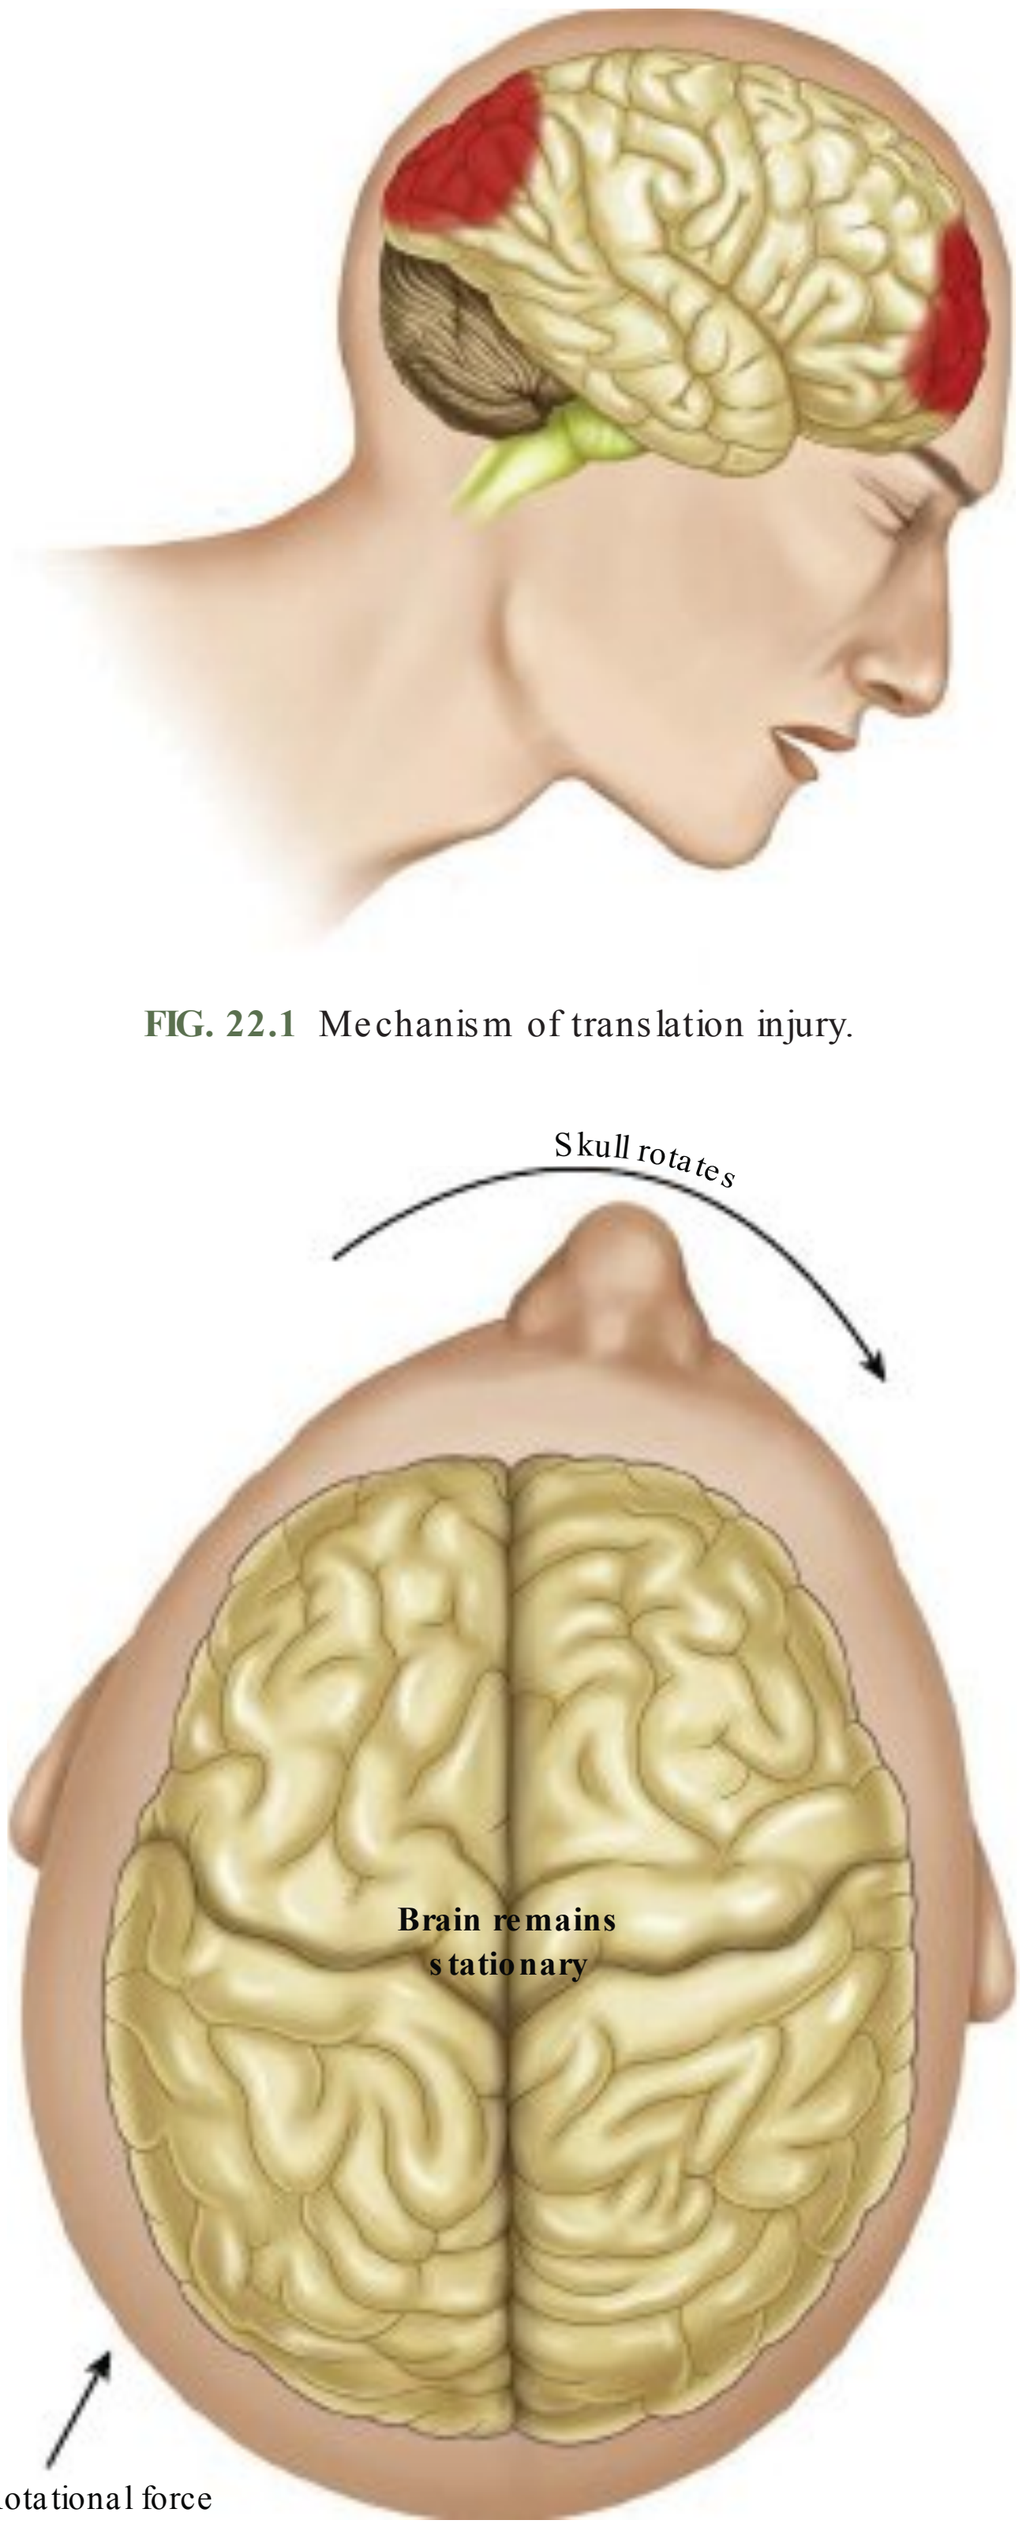

FIG. 22.1 Mechanism of translation injury.

FIG. 22.2 Mechanism of rotational injury.

than is seen in adults after TBI. Experimental studies have suggested that the edema setting in early after injury might be related to enhanced diffusion of excitotoxic neurotransmitters in the immature brain, to an enhanced inflammatory response in the developing brain, or to enhanced blood-brain barrier

permeability after central nervous system (CNS) injury in the immature versus the adult brain.[60]

Further brain damage may occur as the result of complications such as infection, hydrocephalus, hygroma, or convulsions. Infection of the brain may occur after an open fracture or cerebrospinal fluid (CSF) rhinorrhea, or it may be iatrogenic, caused by intracranial monitoring or surgery.[4] A hygroma develops as the result of localized CSF collection or resolution of a hematoma. Posttraumatic seizures typically are divided into three types, depending on their time of onset as related to the trauma. Seizures that occur within minutes are referred to as immediate seizures, early seizures occur within 1 week of the trauma, and late seizures occur beyond the first week of injury. A child who suffers two or more late seizures is diagnosed as having posttraumatic epilepsy.

Prognosis

Studies designed to identify prognostic factors for survival and function after TBI have resulted in an overall conclusion that no single factor adequately predicts outcome from an injury as complex and heterogeneous as TBI. Nevertheless, the severity of the brain injury seems to be directly associated with the outcome.[61]

The most commonly used parameters for determining brain damage severity are the Glasgow Coma Scale, coma duration, and posttraumatic amnesia. The Glasgow Coma Scale (GCS) is a widely accepted method of initially evaluating and characterizing trauma patients with head injuries.[114] The scale has been adapted for infants and young children as the Pediatric Coma Scale.[101] The GCS assesses the level of coma by ranking three aspects of function: motor response, verbal performance, and eye opening. The best response for each is noted on a scale from 1 to 5. The sum of the scores (3 to 15 points) is used as an indication of the depth of the coma and the severity of injury. A GCS score of 13 to 15 points is considered mild, a GCS score of 9 to 12 points is considered moderate, and a GCS score of 3 to 8 points is considered severe. A limitation of the GCS is that it is a time-dependent assessment tool designed to evaluate injury severity within the first 48 hours after the trauma.

Coma duration classifies injury severity as mild (coma lasting less than 20 minutes), moderate (coma lasting 20 minutes to 6 hours), severe (coma lasting 6 to 24 hours), and very severe (coma for longer than 24 hours).[6] Depth and duration of impaired consciousness are negatively associated with functional outcome. Coma duration may be a better predictor of motor and cognitive recovery than coma depth measured with the GCS. The longer the duration of the coma, particularly a duration of coma of longer than 4 weeks, the less likely is a good recovery.[49] Nevertheless it has been noted that coma duration as brief as 1 hour may lead to attention deficits, behavioral disturbances, and irritability.[98]

Posttraumatic amnesia (PTA) is defined as a period of variable length after trauma, during which the patient is confused and disoriented; retrograde amnesia is defined as an inability to remember and recall new information. The longer the duration of PTA, the worse is the outcome. It is unlikely that a person will have an outcome of severe disability if the duration of PTA is less than 2 months. Conversely, it is unlikely that a person will have a good recovery if the duration of PTA extends beyond 3 months.[49]

Of all children who sustain TBI, 95% survive.[61] Among those with severe TBI, that percentage drops to 65%. The highest mortality rate is seen in children younger than 2 years of age, with a decline in mortality rate until age 12 years, and then a second peak at age 15 years.[56] Death is seldom due to the primary damage but is more often the result of secondary intracranial or extracranial complications of brain damage or other related injuries.

NEAR-DROWNING

Hypoxic injury refers to any injury caused by tissue oxygen deficiency and includes drowning and near-drowning, inhalation of a foreign body, hanging and strangulation, suffocation and asphyxia, apnea, and others.[42] Although near-drowning is unique in some aspects, it can serve as a model for understanding many of the pathophysiologic, therapeutic, and prognostic aspects of all types of hypoxic injury in the pediatric population.[118]

Epidemiology

Drowning, defined as death within 24 hours of a submersion incident, and near-drowning, defined as survival for at least 24 hours following a submersion incident, represent significant causes of morbidity and mortality in children.[130] In the United States in 2013, 2% of all deaths were due to drowning among children age 0-14 years. Males were more likely to die of drowning than were females in all age groups; boys 1 to 4 years of age had the highest rate of drowning (2.5 per 100,000), followed by boys 15 to 19 years of age (3.25 per 100,000). http://www.cdc.gov-/nchs/data/nvsr/nvsr64/nvsr64_02.pdf. Efficient preventive procedures include adult supervision of young children in bathtubs and pools and well-maintained four-sided pool fencing that prevents direct entry to the pool from the house or yard.[111]

Pathology

Submersion of a child usually leads to panic and a struggle to surface. In attempting to breathe, the child may aspirate water (wet drowning), or laryngospasm may occur without aspiration (dry drowning).[119] The most significant factors causing morbidity and mortality from near-drowning are hypoxemia and a decrease in oxygen delivery to vital tissues. Sustained hypoxemia causes neuronal injury and finally leads to circulatory collapse, myocardial damage, and dysfunction of multiple organ systems, with further ischemic brain damage. During the first few minutes, the brain is deprived of oxygen (hypoxic injury). As the cardiovascular system fails, cerebral blood flow decreases and ischemic injury occurs. The vulnerability of the brain tissue to hypoxic-ischemic injury varies in the white matter and the gray matter. Areas of greatest susceptibility to ischemic injury are usually in vascular end zones, in the hippocampus, insular cortex, and basal ganglia. Even within the hippocampus itself, vulnerability to hypoxic-ischemic damage varies.[62] More severe hypoxia-ischemia leads to more extensive and global cortical damage.

Prognosis

CNS damage and its outcomes determine survival and long-term morbidity. About one third of all children who survive will have significant neurologic damage caused by hypoxic-ischemic encephalopathy.[21] The prognosis for those who are severely injured may be difficult to determine in the first hours after the hypoxic-ischemic event, although prolonged cardiopulmonary resuscitation, fixed and dilated pupils, and a GCS of 3 suggest a poor outcome.[42] Attention to the adequacy of oxygenation with optimal ventilator strategies to minimize brain and lung injury, provide cardiovascular support, and avoid iatrogenic complications may minimize secondary brain damage.[42]

BRAIN TUMORS

Epidemiology

Brain tumors are the most common form of solid tumors in children and the second most common form of pediatric cancer overall.[36] The annual incidence of brain tumors in the United States is about 38 cases per million children. Brain tumors occasionally are congenital, occur most frequently in children ages 1 to 10 years, and are slightly more common in boys than in girls.[36]

Pathology

Brain tumors may be benign or malignant, primary or metastatic. The term *benign* may imply that a complete cure is possible, but it can be life threatening if it is large or if it results in increased intracranial pressure, cerebral edema, or brain herniation, especially if it is located in a critical area of the brain for maintaining vital functions, such as the pons or medulla. Malignant brain tumors, which make up 80% of brain tumors among children, are life threatening. Primary brain tumors are those that originate directly from cells in the brain and rarely spread outside of the CNS. Metastatic brain tumors originate from tissues outside the brain.

Tumors can cause symptoms directly, by penetration or compression of an area of the brain, or indirectly, by causing an increase in intracranial pressure. Most common symptoms include headache, nausea, vomiting, irritability, balance disturbances, ataxia, seizures, hemiparesis, and visual problems.[67]

Young children have a relatively high incidence of cerebellum and brain stem tumors.[37] The tumors are classified according to their cellular characteristics and location (Fig. 22.3). The most common entities throughout childhood and adolescence are astrocytoma and medulloblastoma, which occur predominantly in the cerebellum. Early signs are those of increased intracranial pressure, as well as cerebellar signs such as ataxia. Metastases may occur throughout the meninges and may involve sites outside the brain. Ependymoma is a primary brain tumor that may occur in the posterior fossa and the cerebral hemispheres. Initial signs and symptoms include those related to increased intracranial pressure in the posterior fossa, seizures, and focal cerebellar deficits.[67] Craniopharyngiomas are histologically benign and occur primarily at the midline of the suprasellar region. Visual disturbances, headaches, and vomiting, as well as endocrine disturbances, are the primary symptoms. Initial signs of brain stem gliomas include progressive cranial nerve dysfunction and gait disorders.

Prognosis

Treatment of brain tumors usually includes surgical resection, radiation therapy, and chemotherapy. Radiation therapy must be used cautiously in young children because of late-onset effects on cognition and learning. Chemotherapy effectiveness is often limited owing to difficulty in crossing the blood-brain barrier. Shunt placement may be necessary to relieve hydrocephalus resulting from blockage of CSF flow by the tumor. The survival rate has been growing continuously, but in general, it depends on the grade of the malignancy and age. The prognosis is better the older the child is at onset and, for example, the prognosis is better for astrocytomas than for medulloblastomas.[100] The astrocytomas arise from astrocytes, cells that play a role in nutrition and various cleanup functions within the central nervous system, and are usually more slow-growing tumors and are therefore considered treatable. However, medulloblastomoas, which are primitive neuroectodermal tumors usually located in the cerebellum, are fast growing and highly malignant.[67] A rough estimate of the 5-year survival rate for malignant brain tumors in children is about 70%.[36] In spite of generally encouraging prognostic data, many long-term survivors continue to have major neuropsychological or cognitive deficits.[83]

ACQUIRED BRAIN INJURY: DIAGNOSTIC TECHNIQUES

Imaging techniques can provide specific and accurate information on the structure of the brain, its metabolic activity, and its functional activity. The techniques assist in making a diagnosis and planning a treatment strategy, and they may provide insight as to the prognosis.

Imaging techniques that provide information about brain structure include magnetic resonance imaging (MRI), x-ray (least informative), computed tomography (CT), and angiography.[57] MRI is based on signals produced by tissue protons when placed in a magnetic field. MRI is sensitive in detecting hemorrhage or hypoxic-ischemic damage, and it can often discriminate between benign and malignant masses and other changes in tissue density. CT illustrates thin slices through the brain based on x-rays. This technique can be used to distinguish among many soft tissues and can indicate the location, density, and the presence of a tumor or edema. CT is particularly effective in identifying foreign bodies and bone abnormalities. MRI has greater tissue contrast resolution than does CT; it does not use ionizing radiation and has not been shown to produce side effects. On the other hand, CT is less expensive, faster, and safer, because an MRI scan requires the child to lie still for an extended period of time, often under sedation. Angiography is used primarily to diagnose and to map vascularization. It is particularly helpful in providing information on blood supply to the brain.[7]

Imaging techniques that provide information about cellular metabolic activity and thereby assist with functional mapping of the brain include functional magnetic resonance imaging (fMRI), positron emission tomography (PET), and magnetic resonance spectroscopy (MRS). The advantage of these techniques is their superior resolution with reference to spatial relationships that define areas of activated brain tissue. fMRI takes a rapid succession of scans that can detect small changes in the level of oxygen consumption and blood flow taking place in areas of the brain that are activated during a test protocol. PET detects the differing levels of glucose uptake that occur in brain tissue. Brain tumors, for example, have a higher level of glucose uptake than normal brain tissue, whereas necrotic tissue has little to no glucose uptake. MRS is another imaging technique that detects metabolic changes; it is noninvasive and does not require contrast agents or labeled tracers.[103]

Techniques that provide information about brain functional activity include electroencephalography (EEG) and evoked potential tests (EPTs)—sensory, motor, or cognitive. Advantages of these techniques are their superior resolution in relation to time. The EEG is a recording of ongoing electrical brain activity, which presents frequency, amplitude, and organization of the waveform at rest and as a response to stimuli. EPT is an electrical potential recorded from the brain after presentation of a stimulus, as opposed to spontaneous potentials as detected by EEG. Sensory EPTs are recorded from the brain after stimulation of sense organs, for example, visual (elicited by a flashing light), auditory (elicited by a click or tone stimulus presented through earphones), or tactile- or somatosensory-evoked potentials (elicited by touch or electrical stimulation of a sensory or mixed nerve in the periphery). In motor-evoked potentials, an area of the brain is stimulated electrically, and the response is recorded in the peripheral musculature.[74] The appropriate choice of tests depends on the suspected pathology, and tests are often repeated to monitor the progress of treatment.

FOREGROUND INFORMATION

PHYSICAL THERAPY MANAGEMENT FOR A CHILD WITH ACQUIRED BRAIN INJURY

Physical therapy for a child with brain injury is a unique and challenging process. The varied clinical presentation and the unpredictable and varied recovery processes obligate the therapist to carry out frequent reevaluation and, as a consequence, modification of the plan of care. Additionally, evaluation and intervention are impacted by the age of the child and the ongoing maturation and refinement of cognitive and functional abilities. In addition, the management of a child with ABI should be based on identifying levels of activity and participation that the child and family wish to assume or reassume after the injury. Only then can the therapist design a plan of care that includes the interventions needed to address the physiologic mechanisms of recovery and adaptation at both impairment and activity skill levels.

Behavioral and Cognitive Disorders

Often the clinical situation is complicated in that not only does neuronal injury directly interfere with motor function, but damage to the cognitive processes *associated* with motor performance and learning has been reported. In the period after the injury, children present with a variety of organic, behavioral, and cognitive disorders, as well as with individual emotional reactions to injury and disability, which might influence their ability to participate in examination and intervention activities. Common situations include the following:

- Low tolerance to frustration, poor social judgment, aggression, and impulsivity are frequent phenomena among children with ABI.[129] Attention deficits might include inability to concentrate, increased distractibility, or even perseveration. Children tend to experience global attention difficulties, which often persist beyond the acute recovery phase and may affect performance and learning capabilities.
- Memory disorders in children with brain injury are varied. Memory is assessed with respect to the child's ability to learn new material. *Explicit* memory, which is memory for facts and events, is mediated by medial temporal cerebral areas that include the hippocampus and the diencephalic nuclei.[109] *Implicit* memory is the ability to develop skills and habits. Motor skill learning is a form of implicit learning in which changes in motor performance with practice can accrue without conscious awareness of all the movement-related abilities that are being learned. Areas associated with implicit learning include the sensory, motor, and prefrontal cerebral cortices, the basal ganglia, and cerebellar areas, which include the neural network for movement.[109] Explicit and implicit learning systems are functionally and neuroanatomically distinct. For example, it is possible that children will present with cognitive deficits that interfere with their ability to have explicit recall but may not interfere with their ability to learn new motor skills.
- Language skill impairment, expressive or receptive, might be due to temporal lobe lesions and can obstruct the child's ability to follow instructions.[129] Expressive disorders impair the child's ability to communicate with others, leading to frustration and aggravation.

TABLE 22.1 Rancho Pediatric Levels of Consciousness

Rancho Pediatric Level	Infants: 6 Months to 2 Years	Preschool: 2 to 5 Years	School Age: 5 Years and Older
I	Interacts with environment Shows active interest in toys; manipulates or examines before mounting or discarding Watches other children at play, may move toward them purposefully Initiates social contact with adults; enjoys socializing Shows active interest in bottle Reaches for or moves toward person or object	Oriented to self and surroundings Provides accurate information about self Knows he or she is away from home Knows where toys, clothes, and the like are kept Actively participates in treatment program Recognizes own room, knows way to bathroom, nursing station, and so on Is potty trained Initiates social contact with adults, enjoys socializing	Oriented to time and place Provides accurate detailed information about self and present situation Knows way to and from daily activities Knows sequence of daily routine Knows way around unit, recognizes own room Finds own bed; knows where personal belongings are kept Is bowel and bladder trained
II	Demonstrates awareness of environment Responds to name Recognizes mother and other family members Enjoys imitative vocal play Giggles or smiles when talked to or played with Fussing is quieted by soft voice or touch	Is responsive to environment Follows simple commands Refuses to follow command by shaking head or saying no Imitates examiner's gestures or facial expressions Response to name Recognizes mother and other family members Enjoys imitative vocal play	Is responsive to environment Follows simple verbal or gestured requests Initiates purposeful activity Actively participates in therapy program Refuses to follow request by shaking head or saying no Imitates examiner's gestures or facial expressions
III	Gives localized response to sensory stimuli Blinks when strong light crosses field of vision Follows moving object passed within visual field Turns toward or away from loud sound Gives localized response to painful stimuli		
IV	Gives generalized response to sensory stimuli Gives generalized startle to loud sound Responds to repeated auditory stimulation with increased or decreased activity Gives generalized reflex response to painful stimuli		
V	No response to stimuli Complete absence of observable change in visual, auditory, or painful stimuli		

Adapted from Professional Staff Association of Rancho Los Amigos Hospital, Inc: Rehabilitation of the head injured child and adult: pediatric levels of consciousness, selected problems, Downey, CA, 1982, Rancho Los Amigos Medical Center, Pediatric Brain Injury Service and Los Amigos Research and Education Institute, Inc.

- Visuospatial and perceptual impairments may affect the child's perception of the environment—for example, the ability to distinguish a given shape from its surroundings.[129] A child may not be able to put on an orthosis and thereby becomes dependent in functional mobility, even though the child is able to ambulate independently once the orthosis is on. Areas associated with these impairments involve the temporal or occipital lobes of the cerebral cortex.

These cognitive and psychological impairments are frequently present to various degrees and often interfere with the child's ability to participate in examination and intervention activities. Although the neuropsychologist formally performs specific testing of these areas, the physical therapist needs to grossly determine the child's level of cognitive ability in order to enhance the effectiveness of the examination and ongoing intervention. The Rancho Levels of Cognitive Functioning (RLCF) is a simple ordinal scale that uses behavioral observation to categorize the child's cognitive functioning level and classifies the level of pediatric consciousness by three age groups: infants (6 months to 2 years), preschool-aged children (2 to 5 years), and school-aged children (5 years and older). The levels of each scale range from V (no response to stimuli) to I (oriented). Behavioral expectations at each level are variable, depending on the age group (Table 22.1). Cognitive function of children 12 years of age and older can be assessed using the RLCF for adults. This scale is reversed in order compared with pediatric forms and delineates adult cognitive functioning into eight levels (Table 22.2).

Table 22.3 provides a basic frame for examination and evaluation that would be appropriate at various stages of cognitive functional recovery of a child with ABI. The next section describes assessments of impairment and functional activity appropriate for the child with ABI.

Physical Therapy Examination

Most children with ABI change their environmental settings during the rehabilitation process from the acute care unit to the inpatient rehabilitation ward, outpatient therapy departments, community services, and educational settings. A systematic examination and evaluation should be performed upon entry into each new setting.

History

The examination process should include a review of the medical record and history. Medical record information may include medical history before the injury, cause of injury, earliest GCS, imaging reports specifying locations and extent of injury, other injuries, procedures and surgeries performed, medications, complications, and previous therapy progress reports. Consultations with other rehabilitation personnel and education professionals enable every team member to have a greater understanding of the child's needs and abilities.

TABLE 22.2 Rancho Levels of Cognitive Functioning

Rancho Adult Level		
I	No response	Completely unresponsive to any stimuli
II	Generalized response	Inconsistent and nonpurposeful response to stimuli
III	Localized response	Specific yet inconsistent response to stimuli; response is related to type of stimuli (turning head toward sound)
IV	Confused–agitated	Heightened state of activity. Demonstrates bizarre and nonpurposeful behaviors relative to the environment
V	Confused–inappropriate	Inconsistently follows simple commands. Shows gross attention to environment but is easily distractible and lacks ability to focus attention on specific task. Memory is severely impaired, new information is difficult to learn
VI	Confused–appropriate	Goal direction behavior appropriate, responds to environment. Can consistently follow simple commands and demonstrates carryover of relearned tasks. Dependent on external cues for direction. Shows little carryover to independent performance of newly learned tasks
VII	Automatic–appropriate	Appears appropriate and oriented to self and environment. Participates in automatic daily routines. Recent memory is impaired, resulting in shallow recall of activities and decreased rate of learning new information
VIII	Purposeful–appropriate	Recalls and integrates past and recent events. Adapts responses to environment. Demonstrates carryover of new learning and does not require supervision once an activity is learned. Deficits remain in the areas of abstract reasoning, tolerance to stress, and judgment in emergencies

Adapted from Malkmus D, Booth B, Kodimer C: Rehabilitation of head injured adult: comprehensive cognitive management, Downey, CA, 1980, Los Amigos Research and Education Institute, Inc.

TABLE 22.3 Examination Strategy Based on Rancho Levels of Cognitive Functioning Categories

Rancho Adult Level	Rancho Pediatric Level	Global Description	Examination Strategies
I–III	V–III	None to early response	Testing should focus on passive manipulation and observation of spontaneous or stimulus-induced movements.
IV–V	II	Agitated, confused	Testing should focus on observation of spontaneous and simple instructed tasks.
VI–VIII	I	Higher-level response	Testing should focus on more complex, two or more staged functional and nonfunctional instructed tasks.

Data to be collected from the family as part of the examination procedure include information regarding developmental history, including learning ability, behavior, and cognitive level. Talking with the parents and family enables the therapist to more fully understand the family's perception of the extent of the injuries and their impact on the previous level of function, and it allows the family to express expectations and goals. During these discussions, the therapist builds up a picture of the child's personality before the injury, the child's favorite music or television programs, specific heroes for the younger children, special hobbies, leisure activities, and information on friends and siblings. This information may enable the therapist to incorporate familiar, attractive, and motivating components into the treatment sessions and to plan for participation in home and community activities.

Systems Review

The physiotherapist should obtain information regarding medical status, medications, cardiac, respiration, musculoskeletal or abdominal status, and injuries prior to performing physical assessments and testing.

Brain injury can cause revealed and concealed dysfunction. An example of more concealed impairment is the neuroendocrine, pituitary dysfunction, which is frequently observed post brain injury. Diabetes insipidus may present with diagnosis in the acute phase post injury; nevertheless the loss of other pituitary hormones may not be diagnosed for months or years. The appearance of the syndrome of growth hormone deficiency, characterized by decreases in strength, aerobic capacity, and the sense of well-being, has to be considered, especially in those with associated facial fractures, cranial nerve injuries, and dysautonomia.[18]

Tests and Measures

In the next stage, the therapist selects appropriate tests and measures in an effort to diagnose impairments, activity limitations, and participation restrictions, and to define appropriate short- and long-term treatment goals in the design of a plan of care. It should be emphasized that many of the described tests have not yet been validated or assessed for reliability in children with ABI. One must consider that children who have experienced trauma or near-drowning might sustain other injuries that impair their ability to perform a test according to its guidelines and that may affect the test's outcomes. Such problems must be noted as limitations when test results are evaluated.

Impairments of body structure and function

Passive range of motion. Limitations to range of motion (ROM) might be associated with one or more factors, such as prolonged bed rest, immobilization, pain, peripheral nerve injury, spasticity, side effects of medical treatment, and skeletal injury due to periarticular new bone formation (PNBF), also known as heterotopic ossification (HO).[22] PNBF is a localized and progressive formation of pathologic bone that develops in the soft tissues adjacent to large joints (hips, elbows, shoulders, and knees). The risk that a child with TBI will develop PNBF is about 20%, and this risk increases with severity of the injury, length of immobilization, duration of coma, and presence of spasticity or fracture, especially if the fracture involves an open reduction with internal fixation or joint dislocation.[41] Assessing the ROM in a child who is unable to follow commands might be problematic, as the child may resist the movement and cry in response to pain. Observations of spontaneous movements and performance of gentle passive ROM exercises will enlighten the therapist regarding joint limitations.

Diagnosis of periarticular new bone formation. Decreased passive range of motion and a painful joint might be the first clinical signs of PNBF. The serum alkaline phosphatase level test, which reflects osteoblastic activity, is useful for obtaining an early diagnosis, especially in patients who cannot report pain. Although radiographs offer a feasible method for recognizing a neurogenic heterotopic ossification, it may take up to 6 weeks for ossification to be evident. Ultrasonography (US) can be used in the early diagnosis of HO, although bone scans such as MRI and CT are considered the most sensitive methods for the early detection of ossification.[112]

Spasticity is characterized by muscles that are perceived as stiff, in which velocity-dependent resistance to passive movement produces increased muscle tone; spasticity is assessed by the Modified Ashworth Scale,[13] which is a simple, quick, but subjective tool with questionable reliability.[23]

Active range of motion/muscle strength. Muscle atrophy and weakness typically result after prolonged bed rest or sedentary behavior. For example, bed rest for 30 days can result in an 18% to 20% reduction in knee extensor peak torque.[11] Peripheral or spinal nerve damage due to trauma or chemotherapy can cause a reduction in muscle strength. Manual muscle testing (MMT) demands careful attention and the ability of the examinee to follow simple commands—not suitable requirements for the confused child. At this stage, the therapist must evaluate strength simply by observation. Movement should be observed in varied situations with gravity eliminated, as well as against gravity in lying, sitting, and standing, statically and dynamically, and with variable task demands. When a child can follow simple commands such as standing from sitting or lifting weights (e.g., plantar flexor muscle strength might be assessed by asking children to raise their heels in standing),[77] then this simple procedure might provide information about the functional strength of the muscle groups. Among children with TBI older than 7 years who can follow simple instructions, lower extremity muscle strength can be reliably tested using a standardized measurement protocol and a handheld dynamometer[55]; hand strength may be measured objectively in children 5 years and older with quantitative analyses of precision-grip forces.[34] See Chapter 2 for more information on strength testing.

Sensory testing. *Sensory testing* in children with ABI is challenging. Children may have cognitive deficits that impair their ability to accurately respond to sensory input. Their young age may also lead to difficulty in perceiving and expressing sensations. Sensory stimuli should be introduced selectively with careful observation to determine the response. Responses are noted as being generalized, with a full-body response, or localized. Localized responses are more appropriate, with the response being specific to the system that is being stimulated.

Activity level tests and measures

Motor performance. Status and change in motor performance might be identified by using a multi-item activity level test of motor performance such as the Gross Motor Function Measure (GMFM), designed and validated to measure change in gross motor function over time in children with cerebral palsy (CP).[107] The maximum performance detectable is that of a typical 5-year-old child (see Chapters 2 and 19 for more information on the GMFM). It is important to note that this measure has not been validated for children with ABI, even though it may provide the therapist with objective information for identifying the child's abilities and may assist in planning intervention and evaluating the child's progress in motor function.

Several norm-referenced, multi-item standardized tests are available to compare a child with ABI to a reference group such as the child's same-aged peers. These tools are used to determine whether the child performs at, below, or above expectations for age on motor skills. These include the Alberta Infant Motor Scale (AIMS) for children from birth to 18 months[96]; the Bayley Scales of Infant Development III, appropriate for children from birth to 42 months of age[9]; the Peabody Developmental Motor Scales (PDMS),[99] appropriate for children from birth to 83 months of age; and the Bruininks-Oseretsky Test of Motor Proficiency (BOTMP), with age standards for children from 4.5 to 21 years of age (see Chapter 2 for further psychometric information on these tests).[27]

Upper limb motor performance can also be compared to age-matched peers using the PDMS fine motor scale or the BOTMP. Fine motor coordination can be evaluated using the Purdue Pegboard Test, in which the child places pegs into board holes in three 30-second test sessions as fast as possible; the numbers of pegs from these trials are then averaged and compared with age standards.[1] The Developmental Hand Function Test measures the time required to complete seven standardized timed subtests: writing, page turning, small object manipulation, simulated feeding with a spoon, stacking checkers, lifting light objects, and lifting heavy objects.[46]

Ataxia is primarily a disorder of balance and control in the timing of coordinated movement. Oscillations during movement, along with an increase in oscillations as the task increases in difficulty, can be detected during functional activities and documented by clinical observation. Ataxia might express itself in the limbs and be observed in tasks such as active reaching or in the trunk, and then it is evident in upright postures with increasing antigravity demands. Common causes of ataxia are injuries to the cerebellum or to sensory structures. Sensory ataxia worsens when the child's eyes are closed.[8]

Postural control and balance. Several studies have reported long-lasting deficits in the motor proficiency of children with TBI, leading to significant balance impairment and functional disability.[54,63] Postural orientation problems may result from sensory impairment such as hemianopsia or impaired proprioception or tactile sensation or may be due to other CNS deficits, including the inability to coordinate sensory inputs from the vestibular, visual, and somatosensory systems. Postural responses may be affected by neurologic impairment or biomechanical constraint. The effect of perceptual deficits on a child's postural control may vary with age and postural development. Younger children have a greater reliance on visual input; the adult-like patterns might be present at the age of 7 years and older.[123] With an increase in active movement and in the use of antigravity positions, impairments in equilibrium and righting reactions may be observed. These reactions can be tested in a variety of positions and activities. Completion, symmetry, and speed of the reactions constitute qualitative information that should be noted when testing. Structured assessment of postural control and balance can be performed only in children who can respond accurately to at least simple instructions. The Pediatric Clinical Test of Sensory Interaction for Balance, for children 4 to 9 years,[102] and the Clinical Test of Sensory Interaction for Balance, for children 8 years and older,[108] require the child to maintain standing balance under six sensory conditions that assist in the identification of impairments in motor responses

in variable sensory environments. Tests that assess balance in relation to gross motor skills include the pediatric balance scale, which contains 14 tasks including sitting and standing unsupported, lifting an object from the floor in standing, and turning 360°.[33] The Functional Reach Test has excellent within-session test-retest reliability for children with TBI,[53,89] The Timed Up and Go[125] exhibits good within-session test-retest reliability values for children with ABI.[53] (See Chapter 2 for more detail about the FRT and TUG for children.) The balance subtest of the Bruininks-Oseretsky Test of Motor Proficiency (BOTMP) is a static and dynamic balance assessment. It focuses primarily on the assessment of the child's anticipatory postural control.[27]

Gait. The walking items of motor assessments can be used as a measure of gait function (see Chapter 2 for further detail on gait tests and measures). For children who ambulate and achieve the highest scores on these items, it is often useful to include an assessment of other gait parameters such as walking speed, distance, and temporal and spatial assessments. Broad-based gait, prolonged time of double limb support, and increased step length variability have been observed in children with TBI.[54] The electronic walkway may provide the therapist with a reliable and valid (i.e., as demonstrated by concurrent assessment with a three-dimensional motion analysis system) measure for assessing walking improvement in children who showed a ceiling effect in the functional gait measures.[122] The timed walking tests and the shuttle walk-run assessment have good test-retest reliability with normative data available; the last has been designed specifically for the patient after TBI.[121]

Cardiorespiratory Status and Fitness. Autonomic instability is common following an ABI, often presenting with signs and symptoms of hyperstimulation of the sympathetic nervous system (including tachycardia, rhythm disturbances, and decreased heart rate variability). The prevalence of these symptoms decreases with neurologic recovery.[58] Respiratory or pulmonary complications noted after ABI include those directly related to the trauma, such as pneumothorax, hemothorax, and flail chest, and those directly related to the drowning event. A number of pulmonary complications may occur that are related, at least in part, to subsequent neurologic dysfunction, including respiratory failure, aspiration pneumonia, neurogenic pulmonary edema, and tracheal-airway complications.[124] Cardiorespiratory status should be screened during the systems review by measuring baseline heart rate, respiratory rate, blood pressure, and oxygen saturation; it is then reevaluated during and after activities. This is particularly important at the initial therapy session in a child with impaired consciousness or after prolonged bed rest, as responses to muscle stretch, pain, or position change may be abnormal. Once the child achieves ambulation, endurance limitations and difficulties in performance may become evident. It has been noted that peak exercise capacity and cardiorespiratory fitness of patients with moderate to severe brain injury are significantly lower compared with the capacity of normal healthy adults of a similar age.[86] Heart rate monitoring as an indicator of exercise intensity is important during endurance training; in addition, a rating of perceived exertion scale such as the OMNI Walk/Run scale can be used. Rossi and Sullivan described a functional fitness battery for children and adolescents with TBI aged 8 to 17 years.[32] The battery includes items assessing flexibility, strength, cardiorespiratory endurance, agility, power, balance, speed, and coordination.[106]

Participation level tests and measures. The Pediatric Evaluation of Disability Inventory (PEDI)[38] and the WeeFIM[117] (see Chapter 2) are standardized criterion-referenced indicators of status and change in functional skills such as mobility and self-care. The PEDI yields normative and scale scores that can be used to compare the child's performance over time. The PEDI focuses on the function of specific tasks and also rates caregiver assistance and modification. It has demonstrated good sensitivity to both global and item-specific changes in children with ABI.[115] About 11 points on a 0 to 100 scaled score is considered to be a minimal clinically important difference for change on any of the PEDI scaled scores.[43] The WeeFIM was designed for use with children 6 months to 7 years of age; the FIM might be used for children 7 years of age and older.[117]

The child and parents can collaborate with health care professionals in setting clear and important functional goals by using individualized outcome measures, which reflect the opinions, preferences, and concerns of child and the child's parents.[26] The Canadian Occupational Performance Measure (COPM) is an individualized child- and family-focused tool that is used to measure a change in goals that are meaningful to the child. The COPM is carried out as an interview and is structured around the areas of self-care, leisure, and productivity. The child and family identify areas of difficulty, prioritize these difficulties, then rate the child's performance and satisfaction in those areas identified as most important to the child. The Goal Attainment Scale (GAS) is a criterion-referenced measure of treatment-induced change. The GAS allows children and their parents to set clear functional goals together with their therapists. It is a 5-point scale, constructed before an intervention period, with 0 representing the expected level of functioning after a predefined period. If a patient achieves more than is expected, a score of 1 or 2 is given, depending on the level of achievement. If the patient's progress is less than expected, a score of 1 or 2 is given.

Two self-report measures of a child's participation in recreation and leisure activities are the Children's Assessment of Participation and Enjoyment (CAPE) and its companion measure, Preferences for Activities of Children (PAC). The CAPE is a 55-item measure of five dimensions of participation: diversity, intensity, with whom, where, and enjoyment, providing three levels of scoring: (1) overall participation scores, (2) domain scores reflecting participation in formal and informal activities, and (3) scores reflecting participation in five types of activities: recreational, active physical, social, skill-based, and self-improvement activities. The PAC is a parallel measure of preference for activities, which can be scored on the same three levels.[5,59]

Outcomes and Intervention Strategies

Based on the data gathered during the examination, and in collaboration with the child, family, and other team members, the physical therapist needs to formulate appropriate discipline-specific outcomes and then decide which intervention strategies are most appropriate for the specific child. The therapist needs to consider all injuries present: the time elapsed since the brain damage event, the rate of recovery, prior interventions, the age of the child, and the child's consciousness and cognitive state. A detailed description of this process is presented in the case scenario found on Expert Consult. General concepts related to global treatment goals

TABLE 22.4 Intervention Strategy Related to Rancho Levels of Cognitive Functioning Level

Rancho Adult Level	Rancho Pediatric Level	Global Description	Global Treatment Goals and Strategies
I–III	V–III	None to early response	Prevent musculoskeletal complications Sensory stimulation Family education
IV–V	II	Agitated, confused	Directed activity Increase child's motivation for activity Family education
VI–VIII	I	Higher-level response	Practice progressively challenging tasks Reduce environmental restrictions Increase physical conditioning

and treatment strategies can be outlined using the child's RLCF grade as a framework (Table 22.4). Next we provide information on some of the typical intervention needs of children at each level of cognitive functioning.

Intervention

Physical therapists employ numerous therapeutic strategies to address issues of motor control. Traditional approaches commonly used to facilitate motor and postural control—such as neuro-developmental Treatment (NDT), proprioceptive neuromuscular facilitation (PNF), and the Brunnstrom approach—were derived from the concept that proprioceptive afferent sensory stimulation can be used to modify abnormal tone and facilitate movement patterns and that recovery from brain damage occurs in a predictable sequence that corresponds to normal development.[72] Another treatment approach may be to target the impairment, as in, for example, muscle strengthening. More contemporary, task-specific training is based on the hypothesis that the most effective form of motor reeducation and learning occurs when performance during practice matches performance during retention and transfer (see Chapter 4 on motor learning).

Unfortunately, clinical trials that specifically examine treatment efficacy in children with ABI are sparse. Evidence from work done on children with cerebral palsy and on adults post stroke might provide a basis for the design of future trials targeting children with ABI to identify the interventions that optimally and efficiently improve function. A systematic review of physical therapy interventions for patients post stroke reveals a greater benefit from task-oriented specific training than from impairment-focused intervention, and almost no evidence suggests improved functional outcome to support the use of traditional approaches.[90,114] Nevertheless, traditional approaches continue to influence practice today. Proximal control and midline alignment, isolated joint movement and selective control as a sign of recovery, and the use of developmental postures to enhance outcome for functional tasks are all components of therapy sessions.

Nonresponse to Early Response Stage

A child with severe cognitive impairment functioning at RLCF adult level I–III, pediatric level V–III is unable to follow commands. The primary focus of physical therapy intervention is to prevent complications associated with prolonged immobilization while creating an environment conducive to recovery. Procedural interventions and patient-related instruction include the following:

- Prevention of musculoskeletal complications
- Multisensory stimulation
- Family education

Prevention of musculoskeletal complications. The main treatment strategies to achieve this goal include positioning in bed, passive movement, splints or serial casting, and assisted sitting and standing.

Positioning. Positioning includes prevention of contractures and minimization of asymmetry. The supine position should be avoided if possible because this position stimulates dystonic posturing or reflex hyperactivity. The child is positioned in a sidelying or semiprone position. A pillow placed between the slightly flexed legs prevents the child from adducting. The upper limb may be positioned on a pillow with the shoulder girdle protracted and the elbow extended. Attention to skin integrity, especially over bony prominence, is important.

The standard practice is to elevate the head above the level of the heart as part of an effort to reduce intracranial pressure by facilitating venous outflow without compromising cerebral perfusion pressure and cardiac output.[88]

Passive range-of-motion exercise. It is unclear whether or not passive ROM exercise has any effect on preventing the development of contractures, unless the muscle at risk is stretched for at least 30 minutes every day.[3,126] In addition, passive ROM exercise may have harmful effects on soft tissue; movements performed too vigorously or in too large a range may cause microtears in muscle, resulting in bleeding into the muscle and subsequent risk for development of PNBF.[79,84] In paralyzed or very weak muscle, exercises performed at the end of the range might overstretch the periarticular connective tissue, and if performed too quickly they may cause an increase in spasticity.[2] Therefore passive ROM exercises should be performed only if no other way of moving the child's joints is known. These exercises should be done slowly, with care taken to avoid overstretching at the end of the range. While doing the exercise, the therapist (or parent) should verbally describe to the child what is being done. An alternative is continuous passive motion (CPM) by an external motorized device, which enables a joint to be moved passively throughout an arc of motion and assists in attaining and increasing ROM. When CPM is used, the range and arc of motion should be carefully determined and reassessed periodically.

Periarticular new bone formation treatment. Prevention should start with early joint mobilization. The role of physical therapy is somewhat controversial. There are those who believe that aggressive ROM may increase bone formation.[62] Nonsteroidal anti-inflammatory drugs (NSAIDs) have demonstrated good results in preventing heterotopic ossification. The role of bisphosphonates in prevention is to inhibit the mineralization of organic osteoid, and they may have long-term effects on the prevention of significant HO years after they are discontinued. It has to be remembered, however, that

post TBI there are frequently other musculoskeletal injuries and, therefore, the use of agents that inhibit new bone may impair fracture healing.[112]

Radiation therapy (RT) is another treatment used in managing patients with HO, and it is thought to work by preventing the differentiation of mesenchymal progenitor cells into HO-forming osteoblasts. The surgical management of HO aims to improve mobility and decrease the complications of immobility such as pressure ulcers, intractable pain, and impingement of important neurovascular structures. In addition, surgery allows the patient or the caretaker to improve mobility and ease of care.[45,112]

Serial casting or positional splints. Serial casting and splints have been found to prevent and correct muscle contractures in the short term[85] and to increase ROM in the elbow and ankle joints in adults with brain injury.[66] Few studies among adults with brain injury reported an improvement in spasticity.[20,40] Whereas splints are used early, mainly for prevention, serial casting is used once a developing contracture is evident. When a two-joint muscle is casted, a lengthened position is easily achieved if the cast is applied while the muscle is not lengthened over both joints (i.e., by first addressing one joint with the other flexed and then extending the cast). Casts should be well padded and particularly well molded. Casts should be changed regularly so that skin status can be assessed and further correction gradually achieved with each change. A little overcorrection is useful to allow for loss of correction and the need to repeat the casting.[70,71]

Although casting and splits are frequently used, there are no well-structured protocols for how long a splint or cast should be applied.[28,68,69,78] In addition, the available literature presents better results for children with CP when splints are combined with other therapy such as goal-directed training, bimanual therapy, constraint-induced movement therapy, or botulinum toxin A injections.[30,64]

Passive sitting and standing. As soon as the vital signs are stable, particularly blood pressure and pulse rate, periods of sitting and standing with external constraints are implemented. The standing position on a tilt table loads bones and cartilage,[24] stretches soft tissues, stimulates internal functions such as bowel movement and bladder emptying, and promotes lung expansion and as a result improves ventilation.[17] The child needs to be stood up slowly while blood pressure changes are monitored. Passive standing for at least 45 to 60 minutes, five times a week, should be part of the daily routine until the child achieves the ability to stand unsupported.[95,116]

Multisensory stimulation. The therapist typically stimulates the five senses directly, and the child's responses are assessed with the intent of advancing the stimulation as the complexity of the response increases. The efficacy of a prolonged sensory stimulation program is controversial. Cochrane's review of sensory stimulation in individuals with TBI in a comatose or vegetative state revealed that most of the literature in this particular area of cognitive-physical rehabilitation is mainly at the level of case studies or case series and as such does not provide strong evidence of its efficacy in raising the level of consciousness.[76]

Family education. Family members are encouraged to participate in intervention sessions as much as possible to facilitate carryover of treatment and practice. In the early stages, the child is dependent in all functional mobility and self-care activities. The parent should therefore be instructed on how to safely and effectively perform all caregiving functions (i.e., dressing, grooming, bathing, and feeding), as well as on how to perform bed mobility activities and transfers into and out of bed to the wheelchair. The caregiver may also contribute to carrying out interventions such as contracture prevention and maintenance of optimal skin integrity.

Vegetative State and Minimal Conscious State

The vegetative state in a child with RLCF adult level I, pediatric level V, is defined as the absence of an adequate response to the outside world and absence of any evidence of reception or projection of information in the presence of a sleep-wake cycle.[47] Children may have periods of restlessness with open eyes and movement, but responsiveness is limited to primitive postural and reflex movements of the limbs. Children in a minimal conscious state have limited self-awareness, but they do feel pain and have sleep-wake cycles. The vegetative and minimal conscious states are directly due to primary brain pathology and are not an extension of coma. Coma is a transient state, characterized by an inability to obey commands, utter recognizable words, or open the eyes with the absence of sleep-wake cycles.[97] The vegetative state and the minimal conscious state may be masked by the state of coma, thus hindering diagnosis.

Spasticity and muscle contractures are two common features associated with the vegetative and minimal conscious states. For a child in these states, maintaining ROM is important for hygiene and nursing. Pharmacologic intervention and neurosurgical procedures to reduce muscle spasticity and improve ROM must be followed by physical therapy. Intervention to maintain passive ROM as described previously was found to be effective in a few studies among adults with TBI.[128] Botulinum toxin type A combined with a cast or splint and intensive physical therapy resulted in improvement on the modified Ashworth scale and in ROM.[120]

Agitation/Confused Stage

A child functioning at RLCF adult levels IV and V, pediatric level II, may follow simple commands but would have impaired judgment and problem-solving ability, thereby necessitating constant supervision to prevent injury. The therapist's aim is to encourage successful performance through adaptive task practice.

The main procedural interventions and patient-related instructional strategies to achieve treatments goals include the following:

- Directed activity
- Increasing the child's motivation for activity
- Family education

Directed activity and *increasing child motivation* may be achieved through the following components of intervention:

- Simple task training
- Modification of tasks to ensure success
- Building a structured environment
- Carrying out many short-interval treatments

Simple task training. Functional activities might be learned using procedural memory and implicit learning through repetition of tasks with appropriate orientation to time, self, and place. At this stage, the child exhibits frequent errors and variable performance. Practice and feedback are two of the more important training variables that can affect motor performance and learning. Children are mainly dependent on

FIG. 22.4 Training facilitated by animal-assisted therapy.

FIG. 22.5 Training facilitated by the "Clown Doctors."

visual and verbal cues to organize their movements. At this early stage of learning, therapists serve as important sources of augmented verbal, visual, or tactile feedback that provides information on outcome and error. Some children with TBI simply fail to act without extensive cueing. A highly structured, consistent, and reinforcing environment is required to ensure active participation in training. Adequate session training time is needed for the child to work on each task and improve performance. When errors decrease, other forms of feedback such as kinesthetic information will be used for error detection and correction.

Modification of the task to ensure success. Often, the physical therapist needs to be creative to keep the child focused on treatment and to increase the child's motivation. The therapist ensures that the activities practiced are relevant to the child's needs but at the same time motivate the child to participate (Figs. 22.4 and 22.5). Too much input or a request for difficult or complex movements may result in frustration and agitation at this stage of recovery.

Building a structured environment. A calm environment with structured stimuli may enhance the child's ability to follow commands for a short time. The therapist should observe the child's behavior in different settings and with different people and should identify the environmental variables that affect the child's behavior either positively or negatively. Negative factors should be eliminated and replaced with those that reinforce desired behavior. This procedure is dynamic, and the therapist needs to reevaluate the effects of environmental modification on progress and modify intervention to facilitate further improvement.

Carrying out many short-interval treatments. At this stage, the child's tolerance of and attention span during treatment is short. Multiple short treatment sessions are preferred to maximize the child's alertness and attention to the demands of therapy.

Family education. At this stage, the caregiver is usually with the child all day long. The child has impaired judgment and a short attention span and as such needs close supervision. A consistent schedule of daily activities and therapy is most effective. Collaborating with the caregiver on how best to implement intervention strategies as part of the daily routine is extremely important. The expectation is that practicing repetitive tasks during this stage will gradually improve motor performance as the child reacquires motor skills that may be independent of any verbal recollection of the task training.

It is often noted that the child may at times become bored and even frustrated during the rehabilitation period. At such times, innovations such as an outing appropriate to the child's condition might be a good solution. A visit to a park with younger children while practicing intervention-related activities in the playground enables children to enjoy themselves while the therapist achieves treatment goals. Observation of the child in a natural environment might lead to the formulation of additional treatment goals. In addition, parents may pick up clues on working toward treatment goals during free-time play activities.

Higher-level response stage. At this level (RLCF pediatric level I or RLCF adult levels VI–VIII), less confusion is noted than in the previous stage, as are an improvement in short-term memory, more appropriate and focused behavior, and increased interaction with others and the environment. Limitations of insight, abstract reasoning, and problem solving, however, can still exist. Although the child is relatively independent at this level, complexities in activities of daily living and therapy may require focus on the tasks and skills needed to facilitate community reintegration. The focus is on helping the child to acquire skills that will lead to meeting self-care, social, and educational goals. Muscle strengthening and endurance activities are implemented if needed. The main procedural intervention strategies to achieve treatment goals include the following:

- Practice progressively challenging tasks.
- Reduce environmental restrictions.
- Increase physical conditioning.

Practice progressively challenging tasks. The therapist should provide opportunities for the child to actively participate and practice meaningful and motivating activities (Figs. 22.6 and 22.7). Functional, relevant, and varied skills should be practiced in an effective manner and in a variety of environmental circumstances. It is common, however, for children to show improvement in the practiced tasks but not be able to transfer the skills to other contexts.[87] Determining the number of repetitions needed to learn a new task, the ability of the child to do the same task the following day, and

FIG. 22.6 Ball exercise.

FIG. 22.7 Riding on a scooter.

FIG. 22.8 Treadmill walking with suspension.

FIG. 22.9 Muscle strengthening exercise—upper extremities.

the ability to do the same task in different contexts provides additional clues to the child's learning capabilities.[81,87]

More recently introduced therapies include the constraint-induced technique and the use of treadmill training with and without body-weight support (Fig. 22.8). These treatment strategies have come about as the result of basic research in neuroplasticity and neurorecovery. The feasibility of such interventions has been assessed in adults with brain damage and in children with CP. The strength of the evidence that exists in relation to the efficacy of treadmill training with body-weight support in children with CP is generally weak,[25] and this approach has not yet been found to be preferable to regular gait therapy in improving functional parameters in adults with ABI.[16] Evidence suggests that children with hemiplegia due to CP may benefit from constraint-induced movement therapy to improve hand function.[113,127] For children with severe ABI, participation in constraint-induced movement therapy may be problematic given the required practice intensity and the frustration that constraint may induce over time. A multiple case study of children with ABI noted that it is possible to implement constraint-induced movement protocols only if the whole team, including parents, totally adhere to the treatment regimen.[48]

Reduce environmental restrictions. The therapist may modify the task or the environment to adjust the difficulty of the functional activity. For example, ambulation can be practiced progressively first indoors and then outdoors and then on different surfaces and so on.

Increase physical conditioning. Weakness is a common impairment in children with ABI.[29] An adolescent might participate in a standard muscle-strengthening program, with repetitions and duration as needed, or perhaps the adolescent would prefer to participate in gym activities with peers (Figs. 22.9 and 22.10). For a younger child, the therapist has to choose appropriate developmental activities that will facilitate muscle strengthening (e.g., play activities combined with stair climbing).

FIG. 22.10 Muscle strengthening exercise—lower extremities.

FIG. 22.11 Aerobic exercise on the treadmill.

Cardiorespiratory fitness may be reduced by impaired motor abilities, due to prolonged bed rest and inactivity, or due to lesions that affect the autonomic nervous system. Among children with TBI, the mean heart rate at rest was found to be significantly higher and heart rate variability significantly lower as compared with healthy controls.[52] Only a few studies have investigated the outcome of challenging the cardiovascular system of the child with ABI, making it difficult for clinicians to make an evidence-based decision concerning the applicability of a fitness program for a child. Responsiveness and tolerance of adult patients at the subacute stage following moderate to severe brain injury to aerobic training have been demonstrated.[10,44] Evidence suggests that this is a safe, well-accepted, and feasible intervention (Fig. 22.11). In the light of insufficient data for children, the therapist must monitor and adhere to acceptable physiologic parameters during endurance therapy sessions.[94]

BACK AT HOME

Once the child is discharged from the rehabilitation setting, outpatient services should continue as necessary to maximize independence at home, at school, and in the community. High cognitive functions of decision making, judgment, and problem solving usually have not fully recovered, and activities that demand these skills usually require close supervision to ensure safety.

At this time, parents, siblings, and the child all try to adapt to a new family constellation. Many aspects of family life, from emotional to financial, might be influenced directly as a result of the injury or its consequences. Siblings frequently experience adverse effects. About half of the families reported that siblings exhibited behavioral problems such as withdrawal from their injured sibling, symptoms such as increased fearfulness, or, on the other hand, became overly involved in family issues.[82] Approximately one third of families reported deterioration in their financial status after the child's injury.[93] Parents need help and guidance to rebuild the family framework, and they need time to reinforce continued development of the child and the child's siblings while getting on with their own lives.

An outpatient treatment program in combination with a home-based program might be proposed to the family because the rehabilitation process might need to continue throughout childhood, and intervention provided in the educational system may be inadequate for addressing medical, as opposed to educational, needs. A home-based program was found to be effective for children with ABI[50,51] and included the advantage of reducing travel time. In adults with TBI, home-based exercise programs were found to improve cardiorespiratory fitness.[39] In addition, home-based activities that educate children to perform exercise as a part of their daily routine might have a long-lasting advantage in preventing secondary impairments such as weight gain, contractures, and pain.[104]

Few studies have examined the effects of repetitive practice of weight-bearing exercises that share similar characteristics to those found in typical functional activities involving the lower limbs (support, balance, and force).[75] For example, sit-to-stand and step-up exercises are mechanically demanding functional activities that children perform many times during their daily routine. Both require muscle strength to raise the body mass, and both require the ability to transfer the center of mass from a larger to a relatively smaller base of support, thereby challenging the muscular system as well as the equilibrium system. As such, these exercises have the potential to train aspects of motor performance such as balance, strength, and endurance. It was found that a short task-oriented exercise program of sit-to-stand and step-up exercises for children with severe ABI carried out at home resulted in increased functional balance performance[50] and walking performance,[51] which were maintained even after the training had ended.

Because adherence to an exercise program is crucial for its success, simple adjustments to increase compliance were found to be effective. For example, a phone call once a week to the child and parent encouraged them to continue with the program, as did providing each child and family with written information about the program, a detailed explanation and practice

run on how to perform each task, and a diary in which the child is requested to keep a record of the number of sets performed each day. All of these tactics have the potential to increase compliance and adherence to the program to well over 50%.[31,50]

For school-aged children, involvement in sports and physical leisure time activities should be encouraged. These have the potential to increase self-esteem and acceptance by peers. Bicycle riding, horseback riding, and other challenging sports activities for children with special needs are recommended and are available in many areas.

ASSISTIVE DEVICES

Nonambulatory children need appropriate assistive technology, and proper use of this technology can be one of the most important aspects of therapeutic intervention. The process of selecting the right equipment requires considerations regarding availability, cost, source of funding, portability, stability, ease of adjustment, ease of modification, construction materials, and aesthetics. Equipment must be reevaluated more frequently than when used by adults because of the functional changes and growth that occur in children.

For preschool children, exploring the environment is crucial for development. For children who cannot ambulate, a device such as a tricycle is a fun alternative to a wheelchair. Many options for adapted equipment are commercially available. When choosing the equipment, one should consider the environment in which the child functions and the needs of caregivers. Another factor to consider is the family's lifestyle and typical activities. For teenagers, who are often greatly concerned about their physical appearance and social acceptance by their peers, the prescribed equipment and devices should be as cosmetic and minimal as possible.

Case Scenario on Expert Consult

The case scenario related to this chapter presents a detailed look at a 6-year-old boy with a severe traumatic brain injury. A video accompanies the case. An additional video is provided that illustrates the course of physical therapy management for a 10-month-old child who was affected by a brain tumor.

Myelodysplasia

Kathleen Hinderer, Steven Hinderer, William O. Walker, Jr., David Shurtleff

Children and adolescents with myelodysplasia, perhaps more than most diagnostic groups of children with disabilities, challenge pediatric physical therapists to use and integrate many facets of their knowledge and skills. The multiple body systems affected by this congenital malformation make intervention for these patients more complex than the congenital spinal cord defect alone might imply. Awareness of the many possible manifestations of this condition, knowledge of methods to examine and detect their presence, and the ability to evaluate the relative contribution of each manifestation to current activity limitations are important. This knowledge, combined with the ability to anticipate future needs and potential problems, empowers the physical therapist to select interventions that will optimize function and prevent the development of secondary impairments. Conversely, lack of awareness of these issues is not without consequences, as significant secondary permanent impairments can result when clinicians are not aware of or do not recognize early signs and symptoms of preventable complications related to myelodysplasia.

The objectives of this chapter are to familiarize the physical therapist with the numerous manifestations of myelodysplasia; describe its impact on body systems and functional skills; provide developmental expectations and prognosis based on the level of involvement; outline the roles of the various disciplines involved in team management; discuss methods of examination, evaluation, and diagnosis; and highlight intervention strategies for specific problems.

BACKGROUND INFORMATION

TYPES OF MYELODYSPLASIA

Dorland's Medical Dictionary defines myelodysplasia as "defective development of any part (especially the lower segments) of the spinal cord." The various types of myelodysplasia are illustrated in Fig. 23.1. Spina bifida is a commonly used term referring to various forms of myelodysplasia. Spina bifida is classified into aperta (visible or open) lesions and occulta (hidden or not visible) lesions.[101] The degree of motor and sensory loss from these lesions can range from no loss to severe impairment. Regardless of initial level of neurologic impairment, individuals with any of these lesions are at risk for further loss of function over time. Paralysis may occur later in life as a complication of abnormal tissue growth (dysplasia) causing pressure on nerves (e.g., lipomatous or dermoid tissue). Lack of proper growth of associated connective tissues around the malformed spinal cord can also cause ischemia and progressive neurologic impairment by tethering of the cord.

Spina bifida aperta is commonly thought of as myelomeningocele (MM), which is an open spinal cord defect that usually protrudes dorsally. MMs are not skin covered and are usually associated with spinal nerve paralysis (see Fig. 23.1C–D). Meninges and nerves can also protrude anteriorly or laterally, making them not visible externally but still associated with nerve paralysis. Some individuals with MM do not have associated paralysis.

Meningoceles are also classified as spina bifida aperta. They are skin covered and are initially associated with no paralysis (see Fig. 23.1B). Meningoceles contain only membranes or nonfunctional nerves that end in the sac wall.[101] Other skin-covered lesions, however, can be associated with paralysis.

The next most common form of myelodysplasia is a lipoma of the spinal cord. Lipomas are classified as spina bifida occulta, but most are visible. They may be large or small and manifest as distinct, subcutaneous masses of fat, frequently associated with abnormal pigmentation of the skin, hirsutism, skin appendages, and dimples above the gluteal cleft. A lipomatous or fibrous tract descends ventrally from the subcutaneous lipoma to varying extents into the subdural space adjacent to the spinal cord. Lipomas of the spinal cord are therefore classified based on the location of the tract. They can be (1) lipomyelomeningocele with paralysis, (2) lipomeningoceles with no paralysis, (3) lipomas of the filum terminale usually with no paralysis, and (4) lipomas of the cauda equina or conus medullaris with or without paralysis at birth. If paralysis is absent at birth, it is acquired over time, and if present at birth, it will worsen with time. Some lipomas involving the spinal cord are not associated with an extension to subcutaneous fat. Lipomas of the spinal cord may or may not be associated with bifid vertebrae (true spina bifida occulta).

Diastematomyelia is a fibrous, cartilaginous, or bony band or spicule separating the spinal cord into hemicords, each surrounded by a dural sac. It can occur as an isolated defect along with vertebral anomalies or in conjunction with either MM or lipomyelomeningocele. Depending on the associated involvement of the spinal cord and meninges, diastematomyelia may be associated with paralysis initially, or progressive weakness can develop later in occulta lesions as a result of cord tethering.

The least common of the myelodysplasias are separate or septated cysts. These myelocystoceles are separate from the central canal of the spinal cord and from the subarachnoid space. They occur in the low lumbar and sacral area and are skin covered. They may or may not be associated with nerve impairment or lipomas of the spinal cord. When a myelocystocele is associated with a primitive gut and an open abdomen, it is classified as an exstrophy of the cloaca. When the bony elements of the sacrum are missing or abnormal, such myelocystic lesions are termed *sacral agenesis*.

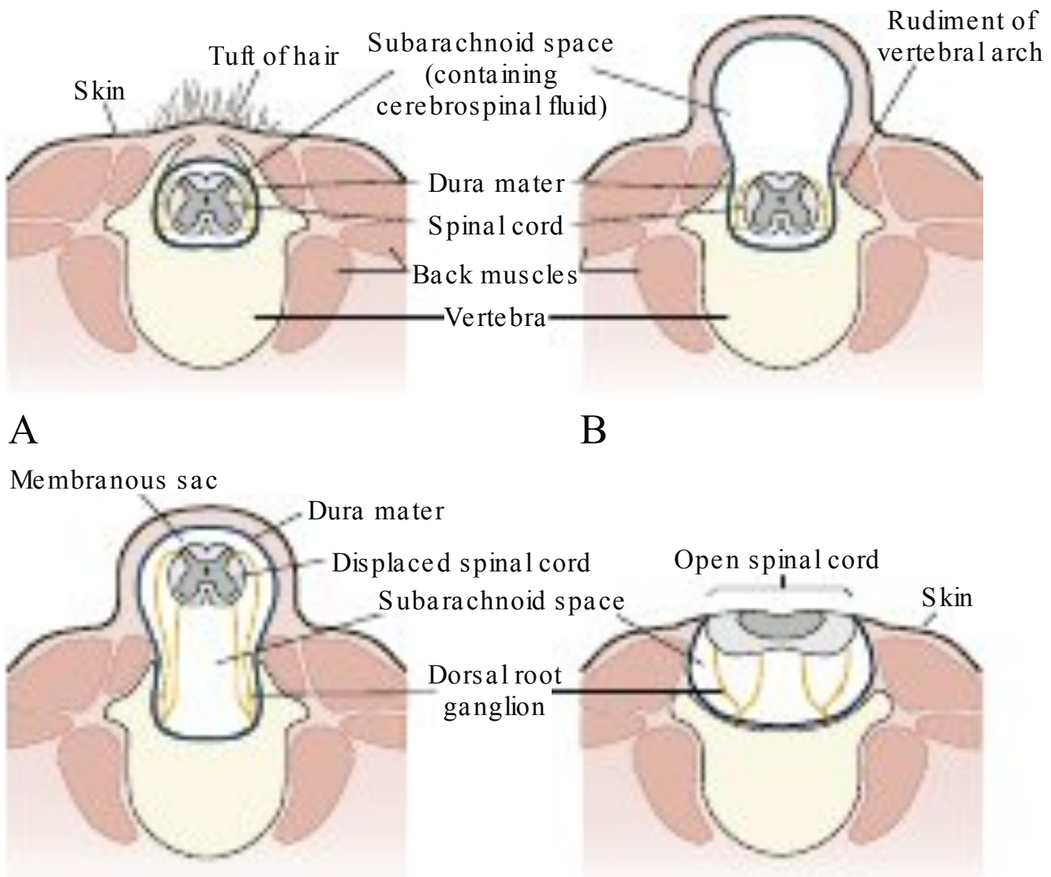

FIG. 23.1 Diagrammatic sketches illustrating various types of spina bifida and commonly associated malformations of the nervous system. (A) Spina bifida occulta. About 10% of people have this vertebral defect in L5 and/or S1. It usually causes no back problems. (B) Spina bifida with meningocele. (C) Spina bifida with meningomyelocele. (D) Spina bifida with myeloschisis. The types illustrated in B through D are often referred to collectively as spina bifida cystica because of the cystic sac that is associated with them. (From Hagen-Ansert SL: Textbook of diagnostic sonography. 7th ed. St Louis: Mosby, 2012.)

PATHOEMBRYOLOGY

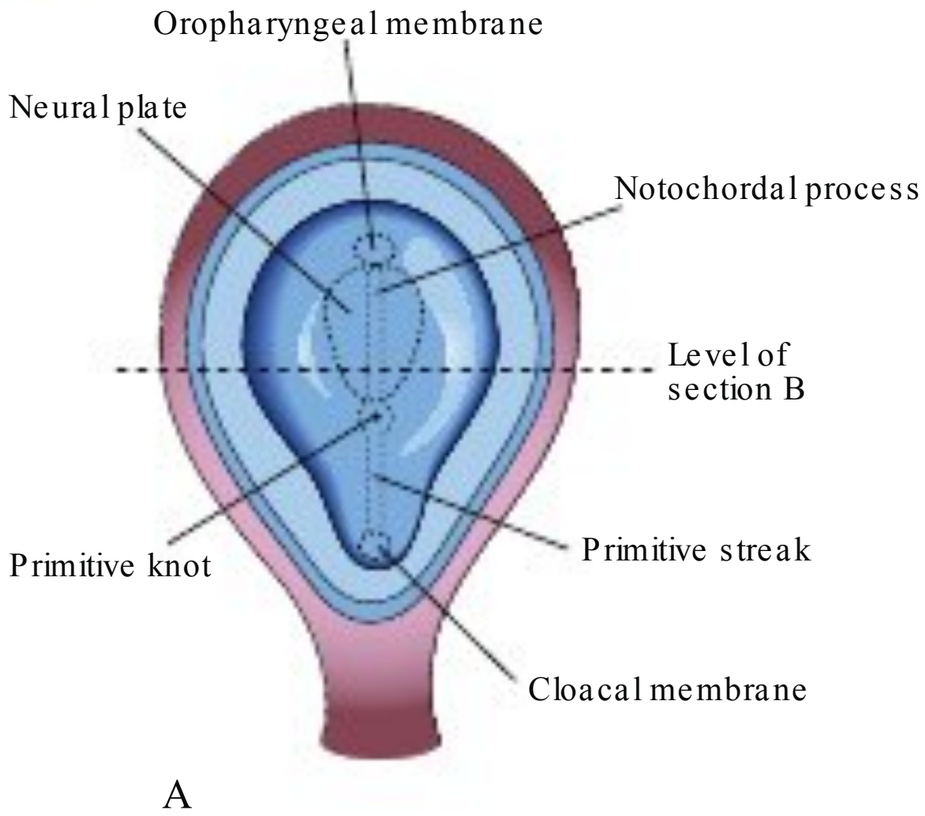
Embryologically, myelodysplastic lesions can be related to two different processes of nervous system formation: abnormal neurulation or canalization. Neurulation is the folding of ectoderm (primitive skin and associated structures) on each side of the notochord (primitive spinal cord) to form a tube that extends from the hindbrain to the second sacral vertebra. Meningoceles can therefore occur both over the skull and along the spinal column. Encephaloceles (containing brain if along the midline of the skull) and MMs, which can occur along the spinal canal from the C1 to S2 vertebrae, result from a failure of complete entubulation with associated abnormal mesodermal (primitive connective tissue, muscle, and nervous tissue) development. Abnormal mesodermal development produces epidermal sinus tracts, lipomas, and diastematomyelia, as well as unfused posterior vertebral laminae (i.e., true spina bifida occulta).[101] Neurulation occurs early in development, before day 28 of gestation.

The spinal cord distal to the S2 vertebra develops by canalization. Groups of cells in the dorsal, central midline of the mesoderm, distal to the S2 vertebra, become nerve cells. These cells clump together into masses, which develop cystic structures that join to form many canals. The canals ultimately fuse into one tubular structure that joins with the distal end of the spinal cord, which was developing from the neurulation process described previously. Failure of proper canalization, with subsequent retrogressive development of this region, embryologically explains the occurrence of skin-covered meningoceles, lipomas of the spinal cord, and MMs, all of which most frequently develop caudal to the L3 vertebra.[101]

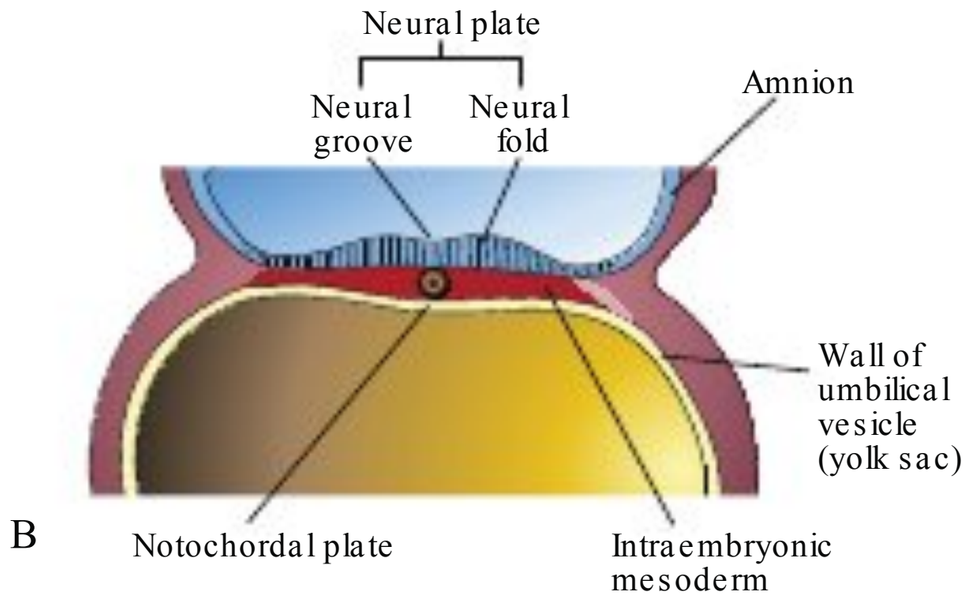
The much better formed, essentially normal, central nervous system (CNS) observed in lesions associated with abnormal canalization and the frequency of CNS malformations (e.g., Arnold-Chiari type II, mental impairment, cranial nerve palsies, and hydrocephalus) associated with neurulation can be explained by the way that neurulation takes place. The neural crests first fuse at approximately the C1 vertebra, and closure of the neural tube progresses simultaneously in cephalad and caudal directions. The same embryologic neurulation processes are simultaneously forming the CNS from the tectal plate to the midlumbar area. It is therefore logical that an influence sufficient to interfere with neurulation along the spinal canal would also interfere with development of the cephalad end, producing CNS malformations above the spinal cord level, which are commonly exhibited in this population.[101] Because canalization occurs by different embryologic processes at a different time period than neurulation, any factor interfering with canalization will not necessarily affect neurulation, so the CNS usually forms normally above the midlumbar area (Fig. 23.2).

ETIOLOGY

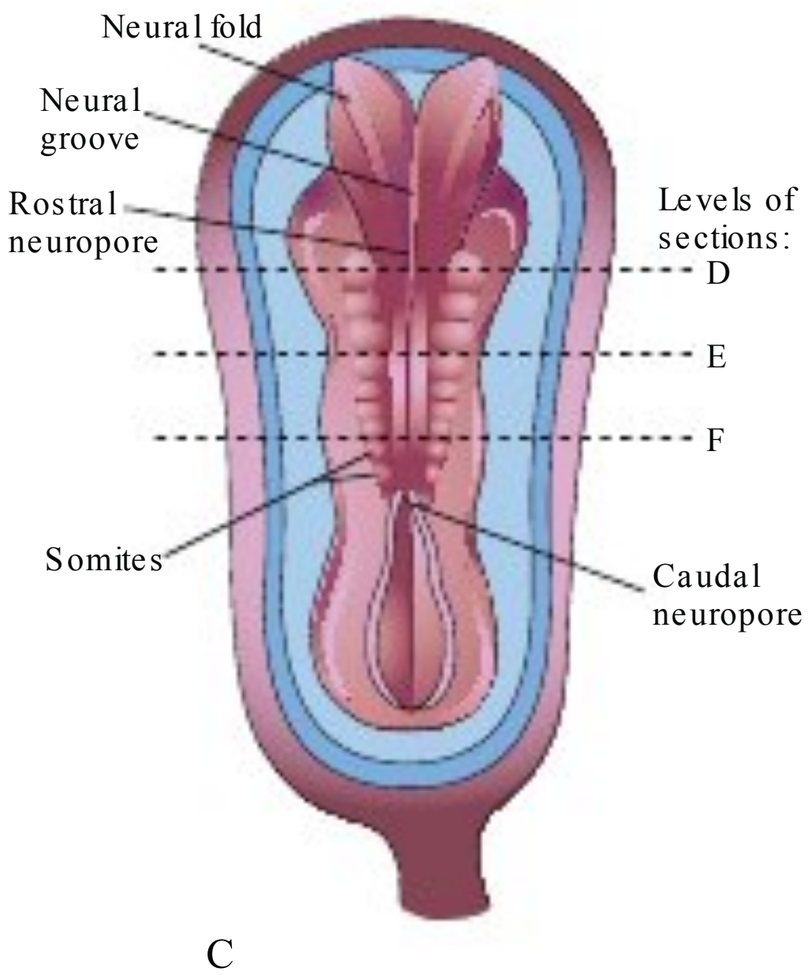
The cause of canalization disorders is unknown. This discussion therefore focuses on disorders of neurulation and, in particular, on MM. These causes may also apply to other MMs that can result from defective neurulation (anencephaly, encephalocele, meningocele, and lipomyelomeningocele, all with or without diastematomyelia). For brevity, we refer to all these lesions throughout this chapter as MM for myelomeningocele and its associated malformations.[181]



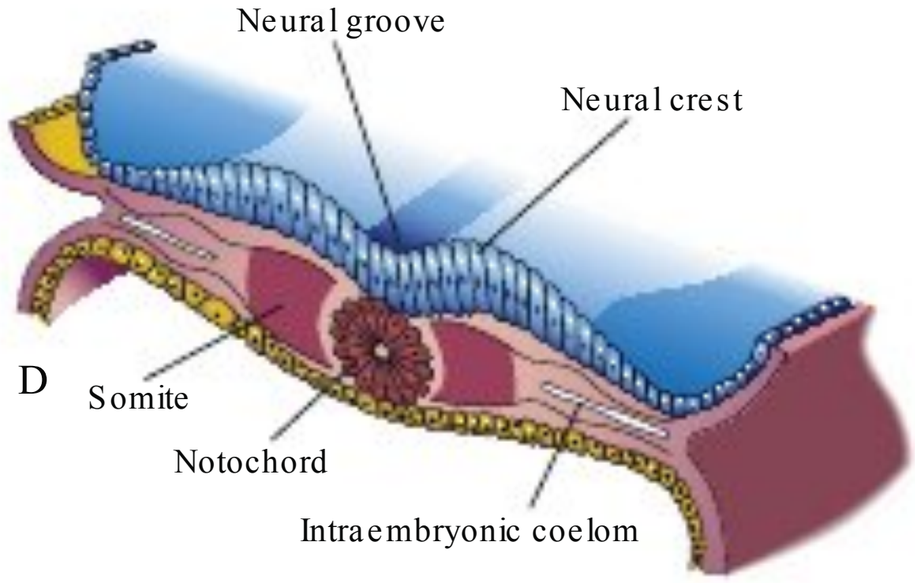
Genetics



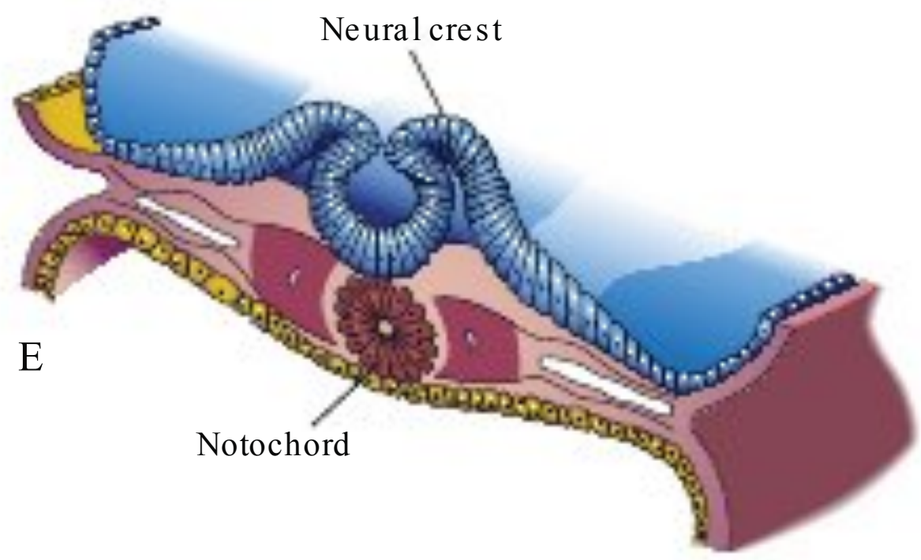
MMs as a group are multifactorial, arising from a complex combination of genetic and environmental factors. MM is often associated with genetic abnormalities, including chromosomal aberrations (Trisomy 13, 18, and 21) and other classic "syndromes"/single gene disorders. Each child born with MM, therefore, warrants a careful physical examination by a pediatrician because the "syndrome" is usually more important than the spinal lesion for defining prognosis. The recurrence risk for siblings in the United States is 2% to 3%.[181]



The prevalence estimates of MM among children and adolescents vary according to region, race/ethnicity, and gender, which suggests possible variations in prevalence at birth or inequities in survival rates.[84] The occurrence of MM varies among races and regions of the world. African blacks have the lowest incidence at 1 in 10,000. Celts (Eastern Irish, Western Scots, and all Welsh) have had a birth incidence recorded as high as 1 in 80. One can conclude from these data that either there are many genetic causes for MM or that there are many genetically determined responses to one or more teratogens.[181] However, with the advent of antenatal diagnosis and elective termination of pregnancy (TOP), the prevalence of MM at birth is no longer reliable as an estimate of incidence.[169]



Teratogens



Teratogens can cause MM. Excess maternal alcohol intake can produce a classic fetal alcohol syndrome with MM. Ingestion of valproic acid or carbamazepine (anticonvulsant medications) during pregnancy are also associated with an increased

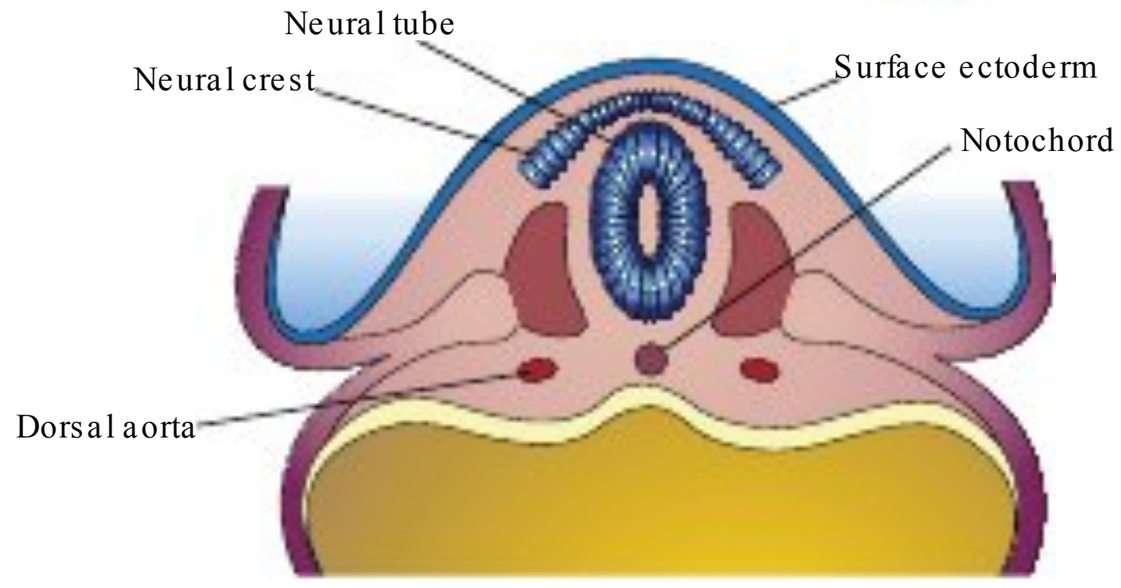


FIG. 23.2 Illustrations of the neural plate and folding of it to form the neural tube. (A) Dorsal view of an embryo of approximately 17 days, exposed by removing the amnion. (B) Transverse section of the embryo showing the neural plate and early development of the neural groove and neural folds. (C) Dorsal view of an embryo of approximately 22 days. The neural folds have fused opposite the fourth to sixth somites but are open at both ends. (D–F) Transverse sections of this embryo at the levels shown in C illustrating formation of the neural tube and its detachment from the surface ectoderm. Note that some neuroectodermal cells are not included in the neural tube but remain between it and the surface ectoderm as the neural crest. (From Moore KL, Persaud TVN, Torchia MG: Before we are born: essentials of embryology and birth defects. 9th ed. Philadelphia: Elsevier, 2016.)

birth incidence of MM. Many other possible teratogens have been studied, but inadequate descriptions of the pathology of the lesions and the relative infrequency of their occurrence have resulted in inconclusive observations. Maternal pregestational insulin-dependent diabetes is associated with a 2- to 10-fold increase, and maternal pregestational obesity (BMI > 29) is associated with a 1.5- to 3.5-fold increase in the occurrence of MM.[132] More studies combining detailed family histories, pathologic anatomy, and detailed physical examinations must be conducted to determine the relative contribution of teratogens to MM formation.[181]

Nutritional Deficiencies

A significant decrease in the incidence of MM births and abortions was observed for MM diagnosed prenatally in the United Kingdom during a placebo-controlled trial of prenatal folic acid administration for women who had given birth to a previous baby with a MM.[134] Other reports suggested that European and United Kingdom studies regarding the benefit of supplementation of folic acid could be applied to other culturally and genetically diverse populations where there are different racial and regional differences in the birth incidence of MM.[16,35,59,150] Early data from the United States did not include pregnancies terminated because of in utero diagnosis of MM and, therefore, led to controversy.[17,128,130,165]

MM stands out as one of the few birth defects for which a primary prevention strategy (folic acid [FA] fortification of food) is available. It has been a highly effective intervention compared with dietary improvement or supplementation because fortification made FA accessible to all women of childbearing age without requiring behavior change. In 1998, the United States was the first country to require mandatory FA fortification of standardized enriched cereal grain products, infant formulas, medical foods, and foods for special dietary use. MM prevalence decreased by 31% after fortification, from 5.04 per 10,000 during 1995 to 1996 to 3.49 at the end of 2006. Unfortunately, this decrease is not uniform across ethnic groups. The reasons for the disparity between declines in the prevalence of MM since FA fortification are unknown. However, no European countries, including the United Kingdom, had implemented mandatory food fortification as of June 2013.[209]

Current Centers for Disease Control recommendations advise women to take folic acid in an effort to reduce both the recurrence in families with[134] and the occurrence in families without a member with MM.[16,33] Women with a first-degree relative with MM or with history of having an open MM in a previous child or fetus should be advised to take 4 mg per day, and women without a positive history should be advised to take 0.4 mg per day. Both should begin the folic acid at least 3 months before conception. Folic acid is believed to be harmless in this age group because the only possible concern is the masking of pernicious anemia resulting from cobalamin deficiency. Both observational and intervention studies, including randomized, controlled trials, showed that adequate consumption of FA periconceptionally can prevent 50% to 70% of MM. Taking folic acid does not eliminate the occurrence of open neural tube defects and has no known effect on the occurrence of closed MM. How FA acts to prevent MM in some individuals and does not appear to have any prevention ability in others remains an important but unanswered question.

INCIDENCE AND PREVALENCE

Superimposed on a general worldwide decrease in the birth incidence of MM are a number of influences to cause both a reduction in birth incidence and increased prevalence resulting from improved survival. Better nutrition applies to many areas of the industrialized world. Wider availability of amniocentesis, maternal serum alpha-fetoprotein screening, and more refined resolution of diagnostic ultrasonography for fetal examination have given parents an option to terminate pregnancies because their fetus has MM.[7,111] Measurement of maternal serum alpha-fetoprotein is now part of the triple test (alpha-fetoprotein, human chorionic gonadotropin, and estradiol) and the quad screen (alpha-fetoprotein, human chorionic gonadotropin, estradiol, inhibin A). Alpha-fetoprotein levels are reported as multiples of the median (MoM); concerning results for an open MM are levels greater than 2.5 MoM.

Diagnosis now occurs frequently at 18 weeks' gestation allowing time for parents to deliberate.[192] It is estimated that internationally approximately 23% of pregnancies where a prenatal diagnosis of a MM is made are voluntarily terminated.[139] TOP is the most common outcome of pregnancy after prenatal diagnosis of anencephaly and MM.[84] One systematic review showed an overall frequency of TOP after prenatal diagnosis to be 83% for anencephaly (range, 59% to 100%) and 63% for MM (range, 31% to 97%). TOP for MM was more common when the prenatal diagnosis occurred at less than 24 weeks' gestation (86 vs. 27%), with defects of greater severity, and in Europe versus North America (66 vs. 50%).[84] Conversely, prenatal diagnosis has allowed other parents to select cesarean section prior to rupture of the amniotic membranes and onset of labor, avoiding trauma to the neural sac from vaginal delivery. The outcome of cesarean delivery compared to vaginal delivery has been children with less paralysis and with minimal risk for CNS infection, both of which were previously a cause for increased morbidity and early death.[182] Improved medical care has resulted in increased survival and, secondarily, an increased prevalence of MM. Incidence at birth in the United States has been reported to range from 0.4 to 0.9 per 1000 births, depending on the reporting source.[181] Prevalence per 1000 births in the United States is reported to be 4.17 for Hispanic, 3.22 for non-Hispanic white, and 2.64 for non-Hispanic black mothers.

PERINATAL MANAGEMENT

Since the late 1980s, the intervention for MM has changed from a postnatal crisis of horrendous magnitude to a prenatal option of either pregnancy termination or improved pregnancy outcome by prelabor cesarean section birth. This advance has been made possible by widespread use of maternal serum alpha-fetoprotein screening as part of the triple screen or quad screen.[111] Unfortunately, this type of screening will not detect skin-covered neural defects such as meningoceles, lipomyelomeningoceles, or other rare lesions covered by skin.

Technical improvements in ultrasonography allow for the identification of anatomic variations/markers to diagnose MM. It is believed that ultrasonography is a reliable method to identify MM by the end of the first trimester of gestation. These markers are more specific for open spinal defects and represent the consequence of the associated Chiari II malformation.

Common cranial ultrasonographic signs described in MM include[34]:

1. The lemon sign (scalloping/overlapping of the frontal bones): the cross-section view of the brain appears lemon shaped rather than oval and is predictive of MM. Seen in 80% of cases.
2. Small cerebellum (transcerebellar diameter < 10th percentile)
3. Effacement of the cisterna magna (width < 2 mm on axial scan of posterior fossa)
4. The banana sign (small cerebellum hemispheres curling anteriorly and obliteration of the cisterna magna as a result of downward displacement of the hindbrain structures). Seen in 93% of cases.
5. Ventriculomegaly (atrial width: severe: > 14 mm; borderline: > 10 mm)
6. Funneling of the posterior fossa (clivus-supraocciput angle < 72 degrees)

Their sequence has not been established; investigators disagree whether cerebellar signs precede cerebral signs or vice versa. These ultrasonographic signs are more accurate in defining the cranial malformations associated with MM than in detecting abnormalities of the spine. As discussed in the section on pathoembryology, these ultrasonographic signs are pertinent to MM cephalad to the S2 vertebra (i.e., neurulation defects) but not to canalization defects, which are usually not associated with cranial malformations responsible for the Arnold-Chiari type II malformation,[176] the cause of the "lemon" and "banana" signs. Some spinal dysraphic states and dorsal lumbosacral masses consistent with canalization defects such as myelocystocele or lipomyelomeningocele can be identified with ultrasonography. Other anomalies consistent with syndromes or organ malformations that are incompatible with survival beyond intrauterine life (e.g., anencephaly) can also be detected.

A third modality for prenatal diagnosis, amniotic fluid analysis, is critical in the evaluation of a fetus with a MM. Up to 10% of fetuses with a MM detected in the first half of the second trimester or before have an associated chromosome error, usually trisomy 13 or 18.[108] Chromosome analysis of amniotic cells is therefore essential to the parental decision-making process regarding abortion of the pregnancy. From the same amniotic fluid specimen obtained for chromosome analysis, the acetylcholinesterase level can be determined. This test is more accurate than determination of the amniotic fluid level of alpha-fetoprotein used previously because the former is positive only in a fetus with an open MM.[111] The presence of a dorsal spine lesion and a negative result of an acetylcholinesterase test suggest a skin-covered meningocele or other skin-covered MM, which is an indication for normal vaginal delivery. A MM lesion containing nerves protruding dorsal to the plane of the back, in the presence of fetal knee or ankle function observed on ultrasonography, warrants prelabor cesarean section, sterile delivery, and closure of the open-back lesion to preserve nerve function.[108]

Prenatal diagnosis also allowed the introduction of repair of the MM sac in utero. While the goal of previous fetal interventions in other conditions was to prevent fetal/neonatal demise, the goal of fetal meningomyelocele (fMMC) repair was to improve long-term outcome in a condition that already had an effective postnatal treatment. Tulipan and associates[197] reported a decreased need for a cerebrospinal fluid shunt and claimed improvement in the Chiari II malformation, as evidenced solely by improved appearance on magnetic resonance imaging (MRI) when intrauterine repairs were performed. Bannister[9] cautioned that the MRI appearance was not as important as function. The claims of Tulipan and associates,[197] however, were not substantiated by the results of cases treated at other centers. Differences in selection criteria and the lack of comparison populations undergoing postnatal repair led the National Institute of Child Health and Human Development to initiate the Management of Myelomeningocele Study (MoMS) (2003–2010) at three centers with prior intrauterine surgery experience. MoMS showed the efficacy of fMMC in a specific homogeneous population under ideal circumstances; these results may not be generalizable outside the eligibility criteria set forth in MoMS. As a result, it is not clear that fMMC is effective in real patients in typical settings. The initial MoMS results were published in 2011,[1] when the majority of the participants were 12–30 months of age. They reported important benefits in children who underwent prenatal closure/repair compared with infants repaired postnatally:

1. Decreased need for postnatal ventriculoperitoneal shunt placement (40% vs. 82%, $P < .001$)
2. Significant reversal of severe hindbrain herniation (22% vs. 6%, $P < .001$)
3. Greater likelihood to walk without devices (42% vs. 21%, $P < .01$)
4. Motor function 2 or more levels better than expected by anatomic level (32% vs. 12%, $P < .005$).

However, MoMS also showed that fMMC surgery increased several risks in children who underwent prenatal closure/repair compared with infants repaired postnatally:

1. Increased risk of spontaneous rupture of membranes (46% vs. 8%, $P < .001$)
2. Increased risk of oligohydramnios (21% vs. 4%, $P < .001$)
3. Increased risk of preterm delivery (79% vs. 15%, $P < .001$); 13% of the fetal surgery group were born before 30 weeks of gestation

Urologic outcomes are a particular area in which the benefits of fMMC repair remain unclear. All of these questions will require further evaluation and extended follow-up. This is a primary goal of the MoMS II study that will evaluate participants between 5 and 8 years of age.

IMPAIRMENTS

The discussions of pathoembryology and diagnosis describe the potential involvement of the brain and brain stem in addition to the spinal cord in individuals with MM. The multifocal involvement of the CNS results in several possible complex problems, making the care of these individuals more challenging than and substantially different from that of children with traumatic spinal cord injuries. The broad spectrum of problems encountered with MM requires a multidisciplinary team approach in a comprehensive care outpatient clinic setting. This section describes the variety of impairments that can occur with MM. In addition, general examination and intervention issues related to each impairment are discussed. Impairment, for the purpose of this discussion, is defined as a change in body structure and function, whereas activity limitation is the inability to perform tasks as a consequence of impairments. Activity limitations and participation restrictions encountered at specific age levels, along with age-specific examination, evaluation, and intervention issues, are discussed in subsequent sections of this chapter.

Musculoskeletal Deformities

Spinal and lower limb deformities and joint contractures occur frequently in children with MM. Orthopedic deformities and joint contractures negatively affect positioning, body image, weight bearing (both in sitting and standing), activities of daily living (ADLs), energy expenditure, and mobility from infancy through adulthood. Several factors contribute to abnormal posture, limb deformity, and joint contractures, including muscle imbalance secondary to neurologic dysfunction, progressive neurologic dysfunction, intrauterine positioning, coexisting congenital malformations, arthrogryposis, habitually assumed postures after birth, reduced or absent active joint motion, and deformities after fractures.[115,175] The upper limbs can also be involved as a result of spasticity or poor postural habits. The upper limb region most likely to have restricted motion is the shoulder girdle due to overuse of the arms for weight bearing and poor postural habits.

Postural stability is essential to effectively perform functional tasks. Symmetric alignment is important to minimize joint stress and deforming forces and to permit muscles to function at their optimal length. Uncorrected postural deficits can result in joint contractures and deformities, stretch weakness, and musculoskeletal pain. Deficits that may appear insignificant during childhood often become magnified once an individual has adult body proportions, resulting in activity limitations and discomfort (e.g., low back pain resulting from an increased lumbar lordosis and hip flexion contractures). Consequently, limb, neck, and trunk range of motion (ROM), muscle extensibility, and joint alignment should be monitored throughout the life span so that appropriate interventions can be implemented as indicated.

Typical postural problems include forward head, rounded shoulders, kyphosis, scoliosis, excessive lordosis, anterior pelvic tilt, rotational deformities of the hip or tibia (in-toeing, out-toeing, or windswept positions), flexed hips and knees, and pronated feet. It is important to observe posture and postural control after a given position has been maintained for a period of time to determine the effects of fatigue. Static and dynamic balance should be observed in sitting, four-point positioning, kneeling, half-kneeling, and standing, as well as during transitions between these positions. Symmetry and weight distribution should also be noted. In addition, typical sleeping and sitting positions should be identified to determine if habitual positioning is contributing to postural or joint deformities (e.g., "frog-leg" position in prone or supine, W-sitting, ring sitting, heel sitting, cross-legged sitting, and crouch standing). These habitual positions should be avoided because they may produce deforming forces and altered musculotendon length that result in the development of secondary impairments such as the progression of orthopedic deformities, joint contractures, and strength deficits. Photographs or videos of sitting and standing postures are often useful to document current status and to provide a visual baseline for future reference.

Postural deviations and contractures that are typical for individual lesion levels are summarized as follows. Individuals with high-level lesions (thoracic to L2) often have hip flexion, abduction, and external rotation contractures; knee flexion contractures; and ankle plantar flexion contractures. The lumbar spine is typically lordotic. Individuals with mid- to low-lumbar (L3–L5) lesion levels often have hip and knee flexion contractures, an increased lumbar lordosis, genu and calcaneal valgus malalignment, and a pronated position of the foot when bearing weight. They often walk with a pronounced crouched gait and bear weight primarily on their calcaneus. Individuals with sacral level lesions often have mild hip and knee flexion contractures and an increased lumbar lordosis, and the ankle and foot can either be in varus or valgus, combined with a pronated or supinated forefoot. They may walk with a mild crouch gait and may bear weight primarily on their calcaneus unless plantar flexor muscles are at least grade 3/5.

Crouch standing is a typical postural deviation that is observed across lesion levels and is characterized by persistent hip and knee flexion and an increased lumbar lordosis. The crouch posture often occurs because of muscle weakness (e.g., insufficient soleus muscle strength to maintain the tibia vertical) and orthopedic deformities (e.g., calcaneal valgus, which results in obligatory tibial internal rotation and knee flexion). Hip and knee flexion contractures often occur secondarily, in response to adaptive shortening of muscles from prolonged positioning in the crouch-standing posture. Altered postures, such as crouch standing, negatively affect both the task requirements (by increasing the muscle torque required to maintain the position) and the torque-generating capacity of the musculoskeletal system.[66] Such increased demands placed on the musculoskeletal system when standing and walking in a crouched posture may negatively impact function and result in secondary impairments.[5,25,66,107,136,137,177,198,206] It is important that appropriate intervention be implemented to ameliorate crouch standing so that the excessive physical demands and stress placed on the musculoskeletal system are reduced and the development of secondary impairments is minimized.

Scoliosis occurs in about 50% of children with MM and can be congenital or acquired; the congenital form is usually related to underlying vertebral anomalies and the curve is often inflexible, whereas the acquired type is usually caused by muscle imbalance and the curve is flexible until skeletal maturity is reached,[115] at which point little further progression is usually observed.[175] Scoliosis is more frequently observed in higher lesion level groups (thoracic 90%; midlumbar 40%; low lumbar 10%) and becomes more prevalent and increasingly severe with age in all groups.[115]

Other spinal deformities that can occur in conjunction with or separate from scoliosis are kyphosis and lordosis deformities (Fig. 23.3). Congenital kyphosis occurs in 10% to 15% of infants with MM.[131,196] Paralytic kyphosis is acquired in approximately one third by early adolescence,[25] progressing at a rate of 7% to 8% per year.[11] Kyphosis can occur in the lumbar spine with reversal of the lumbar lordosis, or the kyphosis can be more diffusely distributed over the entire spine. Hyperlordosis of the lumbar spine is another commonly observed deformity. Like scoliosis, both kyphosis and lordosis are more commonly observed in children with higher spinal lesions and the curves tend to progress with age.[115] Severe kyphosis and scoliosis can limit chest wall expansion with consequent restriction of lung ventilation and frequent respiratory infections. The resulting restrictive lung condition can limit exercise tolerance and can be life threatening in extreme cases.[115] Poor sitting posture, muscle imbalance, and recurrent skin ulcerations are additional problems encountered.[25]

The goal of treatment of spinal deformities is to maintain a balanced trunk and pelvis.[86] Orthotic intervention, usually with a bivalved Silastic thoracolumbosacral orthosis (TLSO), is helpful in maintaining improved trunk position for functional

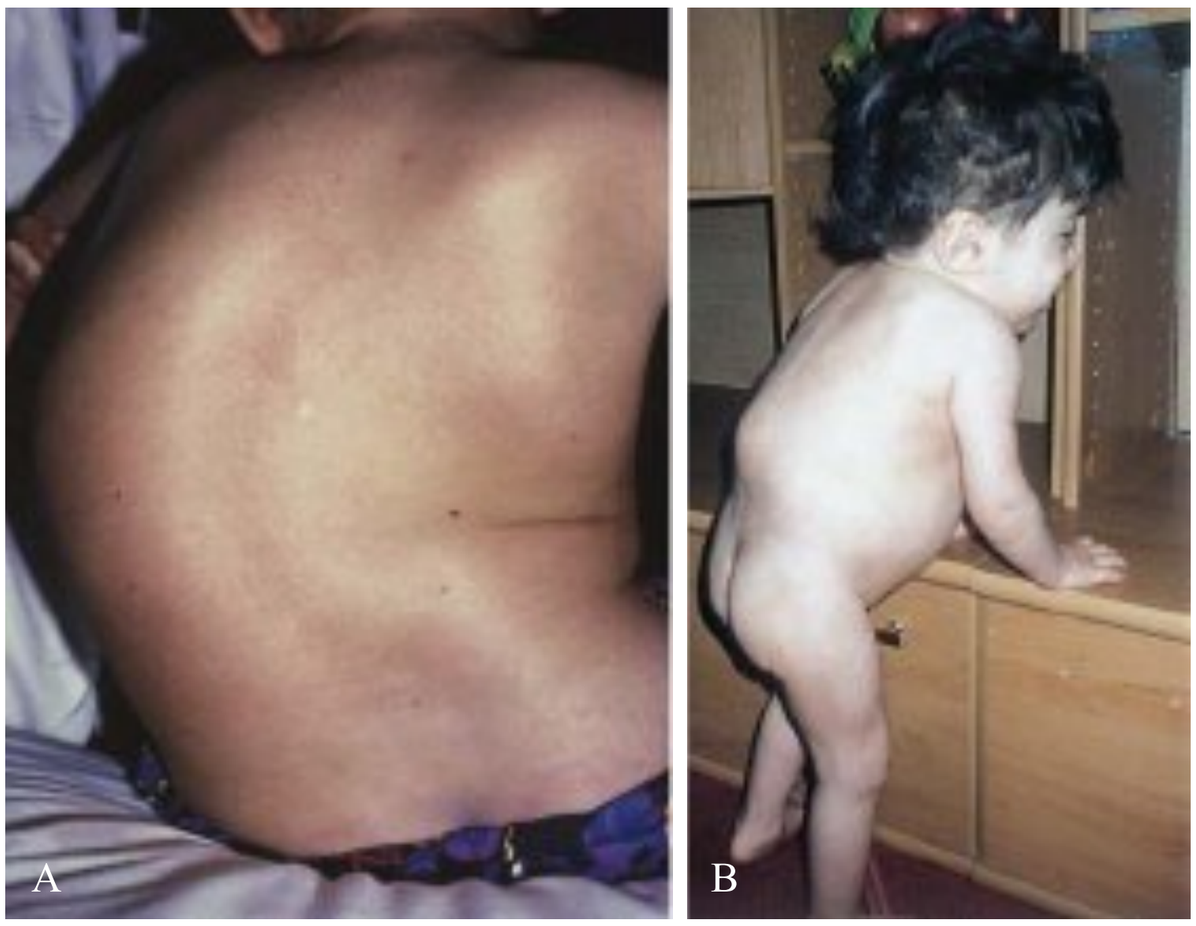

FIG. 23.3 Spinal deformities. (A) Collapsing type of lordoscoliosis. (B) Kyphotic spinal deformity. ([A] From Zitelli BJ, McIntire SC, Nowalk AJ: Zitelli and Davis' atlas of pediatric physical diagnosis. 6th ed. Philadelphia: Saunders, 2016. [B] From Hoyt CS, Taylor D: Pediatric ophthalmology and strabismus. 4th ed. Edinburgh: Saunders, 2013.)

activities but does not prevent progression of acquired spinal deformity.[115] For children with progressive spinal deformities, orthotic intervention is continued until the child reaches a sufficient age to allow surgical fusion of the spine to prevent further progression of these deformities. Long spinal fusions before the skeletal age of 10 result in greater loss of trunk height because of ablation of the growth plates of vertebral bodies included in the fusion mass.[115] In addition, surgery at too young a skeletal age is associated with an increased frequency of instrumentation failure as a result of fragile bones and skin breakdown over the bulky spinal instrumentation.[115] The ideal minimum age for spinal fusion is 10 to 11 years old in girls and 12 to 13 years old in boys.[115] In general, children with MM reach puberty and their growth spurt earlier than their able-bodied peers, so only minimal truncal shortening occurs as a consequence of long spinal fusion when it is performed at the appropriate age. With the introduction of growing constructs such as the vertically expanding prosthetic titanium rib systems and growing rods, children with severe scoliosis at younger ages can undergo a spine stabilization procedure without sacrificing the final truncal height.

It is important to note that a history of recurrent urinary tract infections or poor nutrition increases the risk of perioperative infections with spinal instrumentation procedures for children with MM.[64]

Hip joints also are prone to deformity in children with MM. Fixed flexion deformities often require surgical intervention because they interfere with ambulation and orthotic fit. Correction after surgery should be maintained by encouraging standing and walking.[41,125] Children with high lumbar lesions (L1, L2) have unopposed flexion and adduction forces that gradually push the femoral head superiorly and posteriorly. The resulting contractures and secondary bony deformities of the proximal femur and acetabulum can lead to subluxation or dislocation (Fig. 23.4A and B) in nearly one third to one half of children with MM.[41]

In children with hip subluxation or dislocation, long-term follow-up studies have indicated that reduction of the hips is not a prerequisite for ambulation.[168] Mayfield[115] stated that a level pelvis and good ROM are more important for function than hip reduction. Furthermore, he stated that the presence of the femoral head in the acetabulum does not necessarily improve ROM at the hip or the ability to ambulate. In addition, unlike in children with cerebral palsy, it does not appear to affect the amount of orthotic support required, hip pain, or gait deviation.[159] The indications for hip surgery in children with MM continue to be controversial; however, a basic principle practiced at many centers is to operate only on children with a lesion level at or below L3, when quadriceps muscle function is present, because these children are more likely to be functional ambulators into adulthood.[115,175] Fixed pelvic obliquity caused by unilateral subluxation or dislocation interferes with sitting or standing posture, contributes to scoliosis, and makes skin care unmanageable. It is another indication for surgical relocation of the hip, regardless of lesion level or ambulatory potential, along with painful hip dysplasia in ambulators.[189]

Shurtleff[175] evaluated the frequency of all types of hip contractures in large numbers of children with various spinal lesion levels. He noted that contractures measured in infancy tended to decrease in severity until approximately age 3 to 4 years, then increased to much higher values by adolescence. The initial decrease in severity of hip contractures can potentially be explained as a normal physiologic phenomenon resulting from intrauterine positioning. The increase in severity of contractures by adolescence, however, is of special concern to physical therapists. Mild contractures of minimal functional significance in young children can increase dramatically during later childhood and adolescence, necessitating persistent intervention and follow-up by the therapist to prevent significant functional loss. Consequently, physical therapists should be proactive in preventing the progression of contractures. Thoracic and high lumbar (L1, L2) groups of children have a higher incidence and

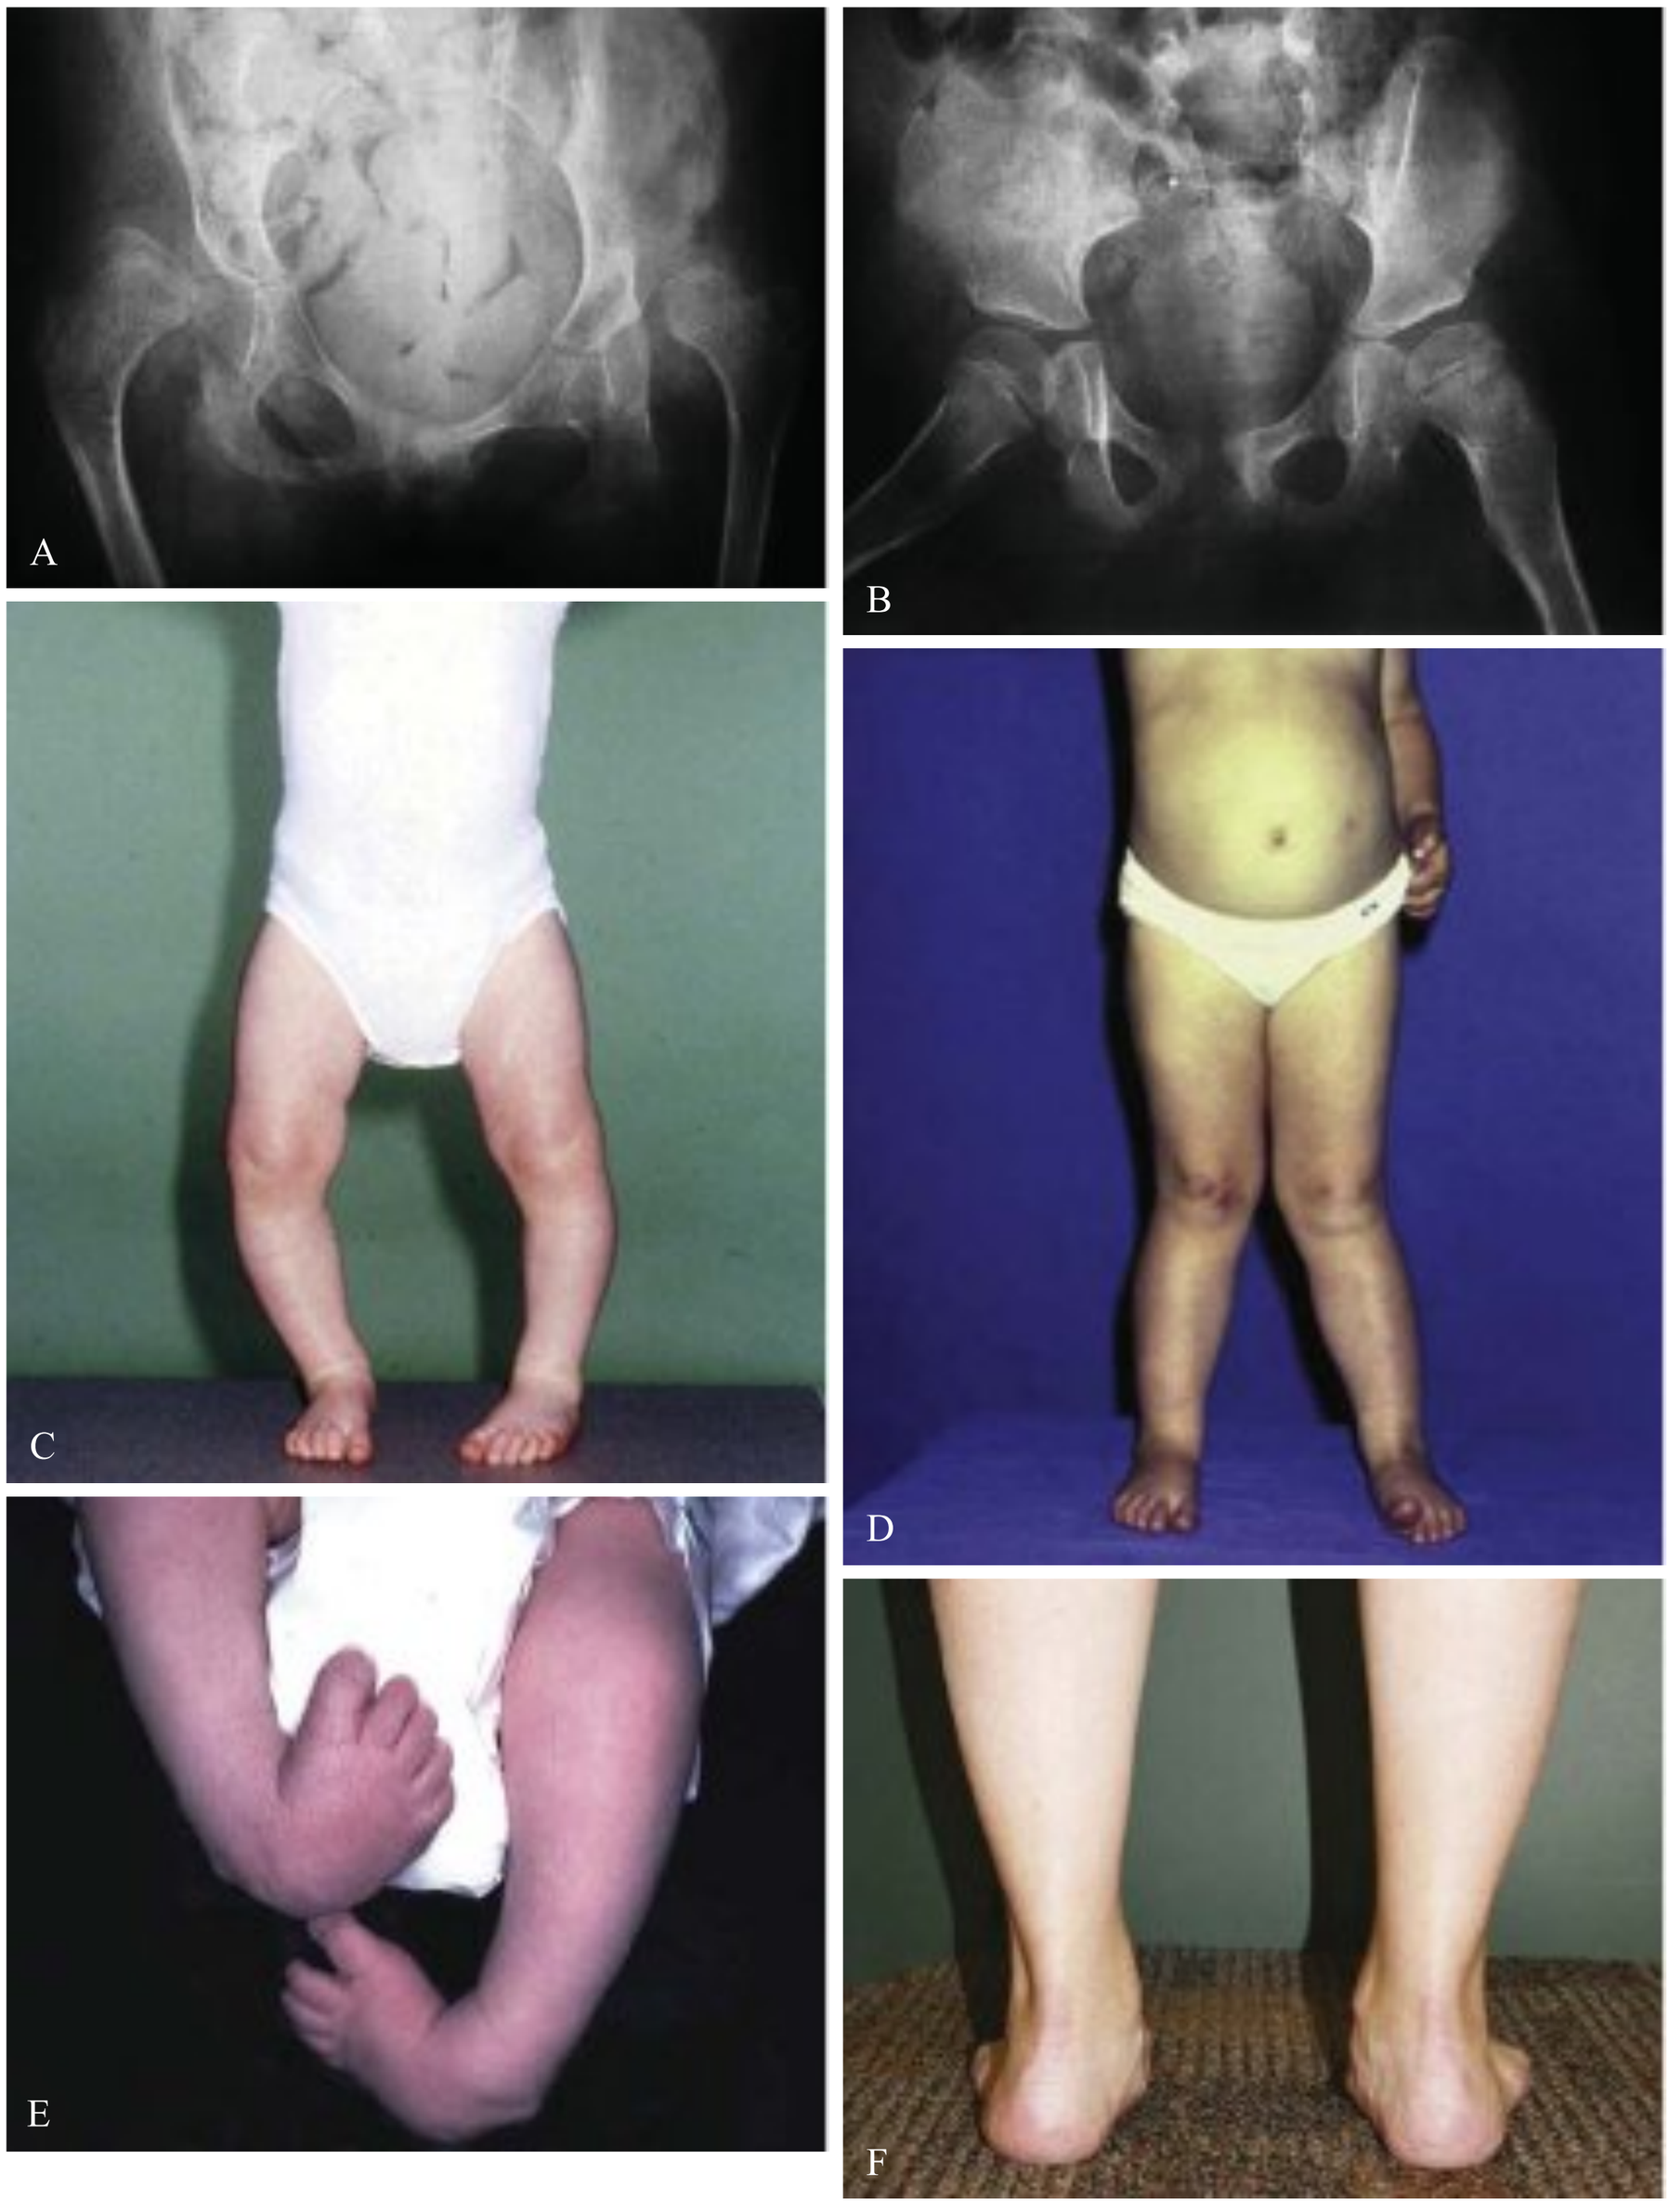

FIG. 23.4 Lower limb deformities. (A) Hip dislocation. (B) Hip dysplasia and subluxation. (C) Genu varus. (D) Genu valgus. (E) Equinovarus. (F) Calcaneal valgus. [F] From Sahrmann S: Movement system impairment syndromes of the extremities, cervical and thoracic spines. St. Louis: Mosby, 2011.)

greater severity of contractures owing to unopposed iliopsoas muscle function, regardless of whether or not they were participating in a standing program.[103] Shurtleff[175] reported progressively declining frequency and severity of contractures in groups of children with lesions at L3, L4 to L5, and sacral levels, respectively. An unexpected finding from Shurtleff's study was that only a certain percentage of children in each lesion level group had hip contractures, subluxation, or both. These relative percentages were not altered by surgical procedures on the hip and stayed constant across age groups. No clear reasons were discerned why certain individuals were susceptible to contractures, whereas others with similar neurologic function were not.

The knee joints of children with MM frequently have contractures or deformities. These include both flexion and extension contractures; the former more commonly occur in children who primarily use a wheelchair for mobility,[103] and the latter often occur after periods of immobility from fractures, decubitus ulcers, or surgical procedures. Varus and valgus deformities (see Fig. 23.4C–D) are also observed. Flexion deformities may make walking difficult or impossible, and extension deformities may complicate sitting. If either flexion or extension deformities are significant, they may need to be ameliorated via surgical release.[189] Wright and associates[208] reported that 60% of individuals with fixed flexion contractures less than 20° and a lesion level higher than L3 were still biped ambulators in late adolescence, as compared to fewer than 5% of individuals with fixed flexion contractures greater than 20°. They also concluded that muscle imbalance and spasticity do not appear to be major causative factors; rather, the lack of normal joint movement may lead to joint stiffness. As described earlier for the hip joints, Shurtleff[175] studied the frequency of knee contractures and deformities in children with different lesion levels. An initial decrease from the contractures measured in infants was also noted at the knees, with the lowest prevalence occurring at age 4 to 5 years for patients with L3 or higher lesions and at age 2 to 3 years for children with lesions below L3. The frequency and severity of contractures increased in all groups from early childhood into adolescence. Knee joint contractures occurred in 65% to 70% of the thoracic and high lumbar groups by age 6 to 8, 20% to 25% of the L4 to L5 group by age 9 to 12, and sporadically among the children with sacral level lesions. Valgus and varus deformities were most frequently observed in the L3 and above groups, with a slight increase during adolescence.

Deformities of the ankles and feet can occur in both ambulatory and nonambulatory children and are most common in children with lesion levels at L5 and above.[175] Partial innervation and consequent muscle imbalance determine the type of deformity that occurs. Even with surgical correction, these deformities will recur unless the deforming forces are removed. Progressive ankle and foot deformities can also be observed in conjunction with the development of spasticity and motor strength loss associated with tethering of the spinal cord. Children with "skip" lesions (see the section on motor paralysis) are particularly prone to progressive foot deformities.[175]

A variety of foot and ankle deformities can occur (see Fig. 23.4E–F), including ankle equinovarus (clubfeet), forefoot varus or valgus, forefoot supination or pronation, calcaneal varus or valgus, pes cavus and planus, and claw-toe deformities. The most frequent contracture observed is of the ankle plantar flexor muscles. The frequency of foot deformities has been reported to vary from 20% to 50% between lesion level groups[175] and has been reported to be as high as 90% for high-level paralysis and 60% to 70% for lower-level paralysis.[24,52,189] Although some deformities are more frequently associated with certain neurosegmental levels (e.g., clubfeet in thoracic and high lumbar lesions, claw-toes in sacral lesions), all types of ankle and foot deformities are observed in children at every lesion level. Congenital clubfeet are common, and surgery is indicated once the child is developmentally ready to stand.[25] Other foot deformities may develop over time as a result of muscle imbalance. Dias[40] noted that ankle valgus occurs in the presence of fibular shortening, the latter being highly correlated with paralysis of the soleus muscle. Surgical treatment of a valgus ankle is indicated when the deformity cannot be functionally alleviated with orthotics. The presence of ankle and foot deformities can greatly affect sitting and standing posture, balance, mobility, foot ulcerations, and shoe fit, regardless of lesion level. Weight-bearing forces often result in ankle and foot deformities. Even partial weight bearing on wheelchair footrests in poor alignment over time can result in deformities and foot ulcerations. Consequently, achieving a plantigrade position of the feet is a priority, regardless of ambulatory status. Surgical procedures are often necessary and are effective.[189] Orthoses and assistive devices should be adjusted properly to maintain neutral subtalar alignment and a plantigrade foot position.

Torsional deformities are common. Excessive foot progression angles and windswept positions of the lower limbs are often present (Fig. 23.5) as a result of hip anteversion, hip retroversion, or tibial torsion. These torsional deformities negatively affect sitting and standing balance, weight distribution, and walking. See Cusick and Stuberg[32] for factors that contribute to torsional deformities in individuals with developmental disabilities, examination procedures, normative values, and intervention suggestions.

Joint alignment and evidence of abnormal joint stress are often most apparent during dynamic activities such as walking or wheelchair propulsion. Joint stresses are often magnified when walking on uneven surfaces, stairs, or curbs. Observing wear patterns on shoes and orthoses can provide additional clues to abnormal stress and malalignment. If joint deformities are supple, they may respond to stretching, combined with orthoses or positioning splints to maintain alignment. Fixed deformities may respond to serial casting (e.g., foot deformities) but will often require surgical intervention (e.g., scoliosis, unilateral hip dislocation, or tibial torsion). If muscle imbalance is severe and the deforming forces are not effectively counteracted by stretching, strengthening, or positioning, muscle transfers may be indicated (e.g., partial transfer of the anterior tibialis muscle to the calcaneus to achieve a plantigrade foot position by balancing the unopposed dorsiflexion force in a child with L5 motor function).

There are several reasons for maintaining joint ROM. Limited ROM can interfere with ADLs, bed mobility, and transfers. Bed mobility is more efficient and self-care is easier for individuals who have maintained their flexibility.[68] Restricted ROM, combined with muscle weakness, can result in poor postural habits and gait deviations. Adequate ROM must be maintained to perform ADLs such as bathing and toileting. Restricted joint motion can result in overlengthening of weak muscles, not permitting them to function in the optimal range of the length-tension curve. Limited ROM may result in discomfort, especially when lying down (e.g., tight hip flexors pulling on the lumbar spine). Severe contractures also can negatively affect body image. Contractures that may seem insignificant

during childhood may become functionally limiting once the individual has adult-sized body proportions (e.g., knee extension contractures can interfere with the ability to maneuver in a wheelchair). In extreme cases, difficulty in managing paralyzed limbs because of joint contractures can put individuals at risk for skin breakdown and possibly amputations because of the increased incidence of injury.[68] The impact of limited ROM on functional performance should be considered before deciding whether intervention is indicated.

ROM and positioning of paralytic limbs should be done carefully, without excessive force, to avoid fractures.[163] Caution should also be exercised when adducting the hips to avoid hip dislocation. The prone hip extension test[188] for measuring hip extension is the method of choice in this population because of interference of spinal and pelvic deformities and lower limb spasticity with the traditional Thomas test method.[13] Ankle ROM should always be measured with the ankle joint in subtalar neutral so that measurements are comparable across time and therapists.

The long-term effects of surgical interventions and weight bearing on insensate joints are becoming evident as individuals with MM reach adulthood.[25] Secondary impairments of knee joint deterioration and arthritis occur with increased frequency in older individuals.[107] Nagankatti and associates[137] reported a prevalence of 1 per 100 cases of Charcot arthroplasty in the MM population.

There are several ways to minimize musculoskeletal stress and reduce the incidence of acquired orthopedic deformities. Improving traction of the hands by providing biking gloves for community wheelchair mobility reduces the grip forces required for wheelchair propulsion. Wheelchair seat positions influence propulsion effectiveness and the amount of stress on upper

limb joints and muscles.[114] For ambulators, shoes with nonskid soles improve foot traction. Symmetric neutral joint alignment should be maintained in both sitting and standing via appropriate orthotics or seating devices. It is important to avoid shifting weight to one leg when standing and to avoid crossing the legs when sitting. Extreme ROM should be avoided, especially when bearing weight. Crutch and walker handgrips should be angled to avoid hyperextension of the wrists, and weight should be distributed across a broad, cushioned area. Orthoses should provide total contact to minimize the risk of development of pressure areas. Excessive pressure on tendons and the palms of the hand should be avoided to reduce the risk of developing carpal tunnel syndrome. Overhead reaching and work activities should be minimized by adapting the home, school, and work environments. In addition, long-distance mobility options should be provided to reduce joint stresses. When sitting, weight bearing should be symmetric, pelvic tilt should be neutral with a slight lumbar lordosis, the hips and knees should be at 90°, and the feet should be flat on the floor. Good lumbar support should be provided. Inclining the seat backward 15° minimizes stress on the lumbar spine and helps keep the pelvis seated back in the chair.[28] Tilting the desk or tabletop upward improves the position of the upper trunk, head, and shoulders.

Osteoporosis

The incidence of fractures is reported to be 11% to 30% in children with MM.[44,113,193] This high rate of fractures is believed to be secondary to reduced bone mineral density from limited ambulation and muscle weakness caused by the MM.[112]

Decreased bone mineral density, thought to be secondary to hypotonic or flaccid musculature combined with decreased loading of long bones from altered mobility, is frequently observed in children with MM and often results in osteoporotic fractures. In a comprehensive review of studies evaluating pediatric supported standing programs, Paleg[148] concluded: "Standing programs 5 days per week positively affect bone mineral density (60 to 90 min/d); hip stability (60 min/d in 30° to 60° of total bilateral hip abduction); range of motion of hip, knee, and ankle (45 to 60 min/d); and spasticity (30 to 45 min/d)." These issues must be studied further in the MM population, however. Bone responses in children with flaccid paralysis may be quite different. Rosenstein and associates[157] examined this issue in the MM population and reported that bone mineral density was 38% to 44% higher in household or community ambulators compared with nonfunctional ambulators (exercise-only ambulators or nonambulators). Salvaggio and associates[160] reported that walking ability was a highly significant determinant of bone density in prepubertal children with MM. Because the effects of lesion level were not controlled in either of these studies, however, the potential contribution of muscle activity versus weight-bearing status to the differences in bone mineral density cannot be determined. In addition, neither study addressed the issue of reduction of the incidence of osteoporotic fractures.

Studying the frequency of fractures is a more direct and clinically significant method of examining the benefits of standing programs. Shurtleff[175] asked the question, "Are fractures less common among those patients in standing or ambulatory programs than among similarly paralyzed sedentary peers?" Asher and Olson[6] showed no correlation between fractures and the use of wheelchairs. DeSouza and Carroll[39] reported no fractures in 7 nonambulators and 38 fractures in 16 ambulators. Their data implied that exposure to forces that can produce fractures (i.e., upright mobility) is the important risk factor for fractures, rather than the level of flaccid paralysis, as would be expected. Liptak and associates[103] found no difference in the frequency of fractures between a group of children who were wheelchair users and a comparable group of children who ambulated with orthoses. Clinically, the use of standing frames, parapodiums, or hip-knee-ankle-foot orthoses (HKAFOs) in children with high lumbar and thoracic lesions does not appear warranted for the purpose of fracture prevention. For children with lower lumbar and sacral lesion levels, for whom upright positioning and mobility are important functional skills, undue restriction of physical activity for fear of a fracture is not indicated. The fact that passive weight bearing does not decrease the risk of fractures in these children makes sense if one considers that bone density is more likely maintained by torque generated from volitional muscle activity. Active muscle contraction generates forces through the long bones that are several times greater than the forces from passive weight bearing.

Fractures often present subacutely because of lack of sensation, with swelling and warmth at the fracture site and a low-grade fever often being the only symptoms. Fractures frequently occur after surgery, immobilization in a cast, or as a sequela to foot arthrodesis. Because of the correlation between the duration of casting and the incidence of fracturing, immobilization in a cast is kept to a minimum and fractures are contained in soft immobilization for alignment.[25] Weight bearing is resumed as soon as possible to avoid the risk of additional fractures.[86]

Motor Paralysis

The inherently obvious manifestation of MM is the paraplegia resulting from the spinal cord malformation. Upper limb weakness can also occur in this population, regardless of lesion level, and is often a sign of progressive neurologic dysfunction. Knowledge of the motor lesion level is useful for predicting associated abnormalities and for prognostication of functional outcome. A detailed discussion regarding developmental and functional expectations for each motor lesion level is provided later in the section on outcomes and their determinants. Strategies for assessing strength and planning intervention programs to enhance motor function are provided in the section on age-specific examination and physical therapy intervention strategies.

The motor level is defined as the lowest intact, functional neuromuscular segment. For example, an L4 level indicates that the fourth lumbar nerve and the myotome it innervates are functioning, whereas segments below L4 are not intact. Table 23.1 provides the International Myelodysplasia Study Group (IMSG) criteria for assigning motor levels from manual muscle strength test results.[80] The IMSG criteria have been shown to best reflect the innervation patterns of individuals with MM as opposed to other spinal segment classification systems. MM spinal lesions can be asymmetric when motor or sensory functions of the right and left sides of the body are compared. Consequently, motor function should be classified individually for the right and left sides.

Neuromuscular involvement of individuals with MM may manifest in one of three ways: (1) lesions resembling complete cord transection, (2) incomplete lesions, and (3) skip lesions.[175] Lesions resembling complete cord transection manifest as normal function down to a particular level, below which there is flaccid paralysis, loss of sensation, and absent reflexes.

Incomplete lesions have a mixed manifestation of spasticity and volitional control. Skip lesions are also observed, where more caudal segments are functioning despite the presence of one or more nonfunctional segments interposed between the intact more cephalad spinal segments. Individual skip motor lesions manifest either with isolated function of muscles noted below the last functional level of the lesion or with inadequate strength of muscle groups that have innervation higher than the lowest functioning group.[149] Consequently, it is important to evaluate muscles with lower innervation than the last functional level to determine whether a skip lesion exists. The presence of spasticity and reflexes should also be carefully documented.

McDonald and associates[119] demonstrated that muscle strength grades for the gluteus medius and medial hamstring muscles correlate more highly with strength grades of the hip adductors, hip flexors, and knee extensors than lower limb anterior compartment muscles that have been previously described as being innervated by the L4, L5, and sacral nerve roots. These data potentially explain the clinical observation that individuals with MM often have functional strength in the gluteus medius and medial hamstrings despite having weak or nonactive lower limb anterior compartment muscles. It was concluded from this study that it is more useful clinically to group individuals with MM by the strength of specific muscle groups, as outlined in Table 23.1, rather than by traditional neurosegmental levels.

TABLE 23.1 International Myelodysplasia Study Group Criteria for Assigning Motor Levels

Motor Level	Criteria for Assigning Motor Levels
T10 or above T11	Determined by sensory level or palpation of abdominal muscles.
T12	Some pelvic control is present in sitting or supine (this may come from the abdominals or paraspinal muscles). Hip hiking from the quadratus lumborum may also be present.
L1	Weak iliopsoas muscle function is present (grade 2).
L1-L2	Exceeds criteria for L1 but does not meet L2 criteria.[a]
L2	Iliopsoas, sartorius, and the hip adductors all must be grade 3 or better.
L3	Meets or exceeds the criteria for L2 plus the quadriceps are grade 3 or better.
L3-L4	Exceeds criteria for L3 but does not meet L4 criteria.
L4	Meets or exceeds the criteria for L3 and the medial hamstrings or the tibialis anterior is grade 3 or better. A weak peroneus tertius may also be seen.
-	Exceeds criteria for L4 but does not meet L5 criteria.
L5	Meets or exceeds the criteria for L4 and has lateral hamstring strength of grade 3 or better plus one of the following: gluteus medius grade 2 or better, peroneus tertius grade 4 or better, or tibialis posterior grade 3 or better.
L5-S1	Exceeds criteria for L5 but does not meet S1 criteria.
S1	Meets or exceeds the criteria for L5 plus at least two of the following: gastrocnemius/soleus grade 2 or better, gluteus medius grade 3 or better, or gluteus maximus grade 2 or better (can pucker the buttocks).
S1-S2	Exceeds criteria for S1 but does not meet S2 criteria.
S2	Meets or exceeds the criteria for S1, the gastrocnemius/soleus must be grade 3 or better, and gluteus medius and maximus are grade 4 or better.
S2-S3	All of the lower limb muscle groups are of normal strength (may be grade 4 in one or two groups). Also includes normal-appearing infants who are too young to be bowel and bladder trained (see "no loss").
"No loss"	Meets all of the criteria for S2-S3 and has no bowel or bladder dysfunction.

[a]When description states "meets criteria …," strength of muscles listed for preceding levels should be increasing respectively.

Sensory Deficits

Sensory deficits are not clear-cut in this population because sensory levels often do not correlate with motor levels and there may be skip areas that lack sensation. Because skip areas can occur within a given dermatome, it is important to test all dermatomes and multiple sites within a given dermatome to have an accurate baseline examination. Deficits should be recorded on a dermatome chart with areas of absent and decreased sensation color-coded for the various sensory modalities (e.g., light touch, pinprick, vibration, and thermal). Proprioception and kinesthetic sense should also be evaluated in both the upper and lower extremities.

Based on the results of a study conducted on 30 adults with MM, testing with both light touch and pinprick stimuli is not necessary in this population because there is little discriminating value for detecting insensate areas.[70] In contrast, vibratory stimuli could be felt one dermatome below light touch and pinprick sensation. Based on these results, vibration sensation should be evaluated in addition to either light touch or pinprick sensation.

It is important for individuals with MM to be aware of their sensory deficits and to be taught techniques to compensate by substituting other sensory modalities (e.g., vision). The impact of decreased sensation on safety should be emphasized, especially when checking temperature (e.g., bath water or when sitting near a fireplace) and when barefoot. Skin inspection and pressure relief techniques should be taught early so that they are incorporated into the daily routine. The importance of pressure relief cushions and sitting push-ups for pressure relief should be emphasized. Proper intervention of lower limbs and joint protection techniques should be taught when learning how to perform ADLs such as transfers.

The impact of sensory deficits on functional performance should be kept in mind when teaching functional tasks. Individuals with MM may rely heavily on vision to compensate for sensory deficits.[166] They may lack the kinesthetic acuity that permits subconscious completion of many repetitive motor tasks. Consequently, visual attention may not be available to be directed at other factors in the environment.[4] Adding small amounts of weight to the ankles or a walker may enhance proprioceptive awareness and facilitate gait training. Use of patellar tendon-bearing orthoses (Fig. 23.6) instead of traditional ankle-foot orthoses (AFOs) may also facilitate foot placement for individuals with innervation through L3 because the orthosis contacts the skin in an area of intact sensation.

Hydrocephalus

Hydrocephalus is excessive accumulation of cerebrospinal fluid (CSF) in the ventricles of the brain. Approximately 25% or more of children with MM are born with hydrocephalus. An additional 60% develop it after surgical closure of their back lesion.[153] If left untreated, the continued expansion of the ventricles can cause loss of cerebral cortex with additional cognitive

FIG. 23.6 Ground-reaction ankle-foot orthosis. Polypropylene patellar tendon-bearing ground-reaction ankle-foot orthoses molded with the foot in a subtalar neutral position. Note the zero heel posts and posts under the first metatarsal heads.

BOX 23.1 Early Warning Signs and Symptoms of Shunt Dysfunction

Changes in speech
Fever and malaise
Recurring headache
Decreased activity level
Decreased school performance
Onset of or increased strabismus
Changes in appetite and weight
Incontinence begins or worsens
Onset or worsening of scoliosis
Onset of or increased spasticity
Personality change (irritability)
Decreased or static grip strength
Difficult to arouse in the morning
Decreased visuomotor coordination
Decreased visual acuity or diplopia
Decreased visuoperceptual coordination
Onset or increased frequency of seizures

Adapted with permission from Shurtleff DB, Stuntz JT, Hayden P: Hydrocephalus. In Shurtleff DB, editor: Myelodysplasias and exstrophies: significance, prevention, and treatment. Orlando, FL: Grune & Stratton, 1986.

and functional impairment. Cerebellar hypoplasia with caudal displacement of the hindbrain through the foramen magnum, known as the Arnold-Chiari type II malformation, is usually associated with hydrocephalus.

The hydrocephalus will occasionally arrest spontaneously; however, 80% to 90% of children with hydrocephalus will require a CSF shunt.[181] A ventriculoperitoneal catheter shunts excess CSF from the lateral ventricles of the brain to the peritoneal space, where the CSF is resorbed. Because a shunt is a foreign body, it can be a nidus for infection or can become obstructed, requiring neurosurgical intervention. Repeated or prolonged shunt dysfunction and infections often lead to additional functional and cognitive decline of the child. Shunt dysfunction is often gradual, with subtle symptoms. Therapists should be familiar with these symptoms to facilitate early detection and appropriate referral to a physician for further evaluation. Box 23.1 provides a list of early symptoms and signs of shunt obstruction. Of particular interest are the findings of Kilburn and associates,[90] which suggest that static or declining grip strength measurements are potentially an early indicator of neurologic dysfunction such as shunt malfunction or symptomatic Arnold-Chiari malformation. Hydrocephalus persists throughout life with consequent need of ongoing follow-up by a physician who is familiar with the medical complications associated with MM.

Cognitive Dysfunction

Early closure of spinal lesions with antibiotic intervention to prevent meningitis and improved CSF shunt intervention have increased the expected cognitive function of children born with MM. However, an increasing body of work supports the concept that specific intellectual deficiencies in individuals with MM can be attributed to structural brain defects. A higher level of spinal lesion has been used as a marker for more severe anomalous brain development. Intelligence scores have traditionally been reported as higher in lumbar and sacral lesion level groups than in thoracic lesion level groups.[166] However, recent studies comparing lesion level and measures of intelligence, academic skills, and adaptive behavior are not consistent in their findings.

Dise and Lohr[43] demonstrated the need for individual analysis of "higher-order" cognitive functions, including conceptual reasoning, problem solving, mental flexibility, and efficiency of thinking for individuals with MM, regardless of lesion level or general intelligence level. They argued that such neuropsychological deficits likely underlie the "motivational" and academic difficulties observed in this population, especially for those with an average IQ. The impairments in areas such as language, mathematics, and executive functioning persist throughout life.

The current neuropsychological focus is on a MM phenotype that is the product of multiple complex processes rather than a dichotomous (visual vs. auditory perception; verbal vs. nonverbal learning disability) approach. The result of these multiple complex processes is the recognition of a more variable cognitive phenotype. Particularly important are deficits in assembled processing (the ability to assemble, construct, and integrate information across various content domains) and relatively intact associative processing (the ability to activate or categorize information; data driven).[38] About 25% of school-aged children with spina bifida have a mathematical learning disability; children with spina bifida have difficulties with specific aspects of executive functioning: problem solving, planning and goal-directed behavior, focused attention, ability to shift attention, response inhibition, and working memory.[87]

Structural brain abnormalities in MM are important determinants of the neuropsychological profile. Three core deficits have been described in the neuropsychological assessment of individuals with MM and have been associated with specific brain structural anomalies:

- deficits in timing related to the volume of the cerebellum;
- deficits in attention related to the status of the midbrain, posterior cortex, and corpus callosum;
- deficits in movement related to spinal cord dysfunction and cerebellar dysmorphologies that affect sensory motor timing and motor regulation.

The majority of children without hydrocephalus or with uncomplicated hydrocephalus (no infections or cerebral hemorrhage) will have intellect falling within the broad range of normal scores on intelligence testing. The distribution of scores tends to be skewed toward the upper and lower ends of normal, however, with fewer children scoring in the middle of the curve and a greater proportion scoring at the lower end of the range.[166] The intellectual performance of children who have had significant CNS infections is lower than those who have not had infection.[173] Verbal subtest scores usually exceed performance subtest scores.[166] The poorer scores on performance subtests, however, may not represent true differences in verbal versus nonverbal reasoning skills. Instead, these differences can potentially be explained by upper limb dyscoordination (discussed later) and by memory deficits.[166] Dyscoordination and memory deficits are manifested as distractibility on subtests assessing acquired knowledge (e.g., arithmetic), integrated right-left hemisphere function (e.g., picture arrangement, block design, and coding), speed of motor response (e.g., coding), and memory (e.g., digit span, coding, and arithmetic). Further controlled studies must be conducted to determine the source or sources of discrepant verbal versus performance intelligence scores observed in individuals with MM.

The "cocktail party personality" is a cognitively associated behavioral disorder that occurs in some individuals with hydrocephalus, regardless of age or intelligence level.[78] These individuals are articulate and verbose, superficially appearing to have high verbal skills. Close examination of the content of their speech, however, shows frequent and inappropriate use of clichés and jargon. Individual words are often misused. Despite the initial appearance of being capable, these individuals are often impaired, their performance in daily life is below what they superficially appear capable of,[78] and they lack social skills.[183] They often have difficulties with behavioral regulation. Difficulties include identifying the rules, maintaining goal-directed activities during play, performance in unstructured social situations, and a failure to benefit from feedback or instruction about their behavior. Children with spina bifida have a higher incidence of attention deficit/hyperactivity disorder (ADHD) than the general population and typically show problems with inattention rather than with impulsivity and hyperactivity on objective and subjective measures of attention, even when controlling for differences in intellectual functioning. It is important for the physical therapist to directly observe skills that these children report that they can perform and to confirm regular performance of the task at home with parents and care providers to determine if information provided by the patient is accurate.

Language Dysfunction

Although language was once viewed as an asset, children with MM and hydrocephalus demonstrate a profile of both intact and impaired language skills. Their strengths are in the formal, fixed structures of grammar and single words or phrases (vocabulary) and "stored" meanings. Their weaknesses include deficits in discourse, characterized by a high frequency of irrelevant utterances and poorer performance with abstract rather than concrete language. Their communication can be difficult to process and is uneconomic and unclear. These language weaknesses adversely affect their success in social discourse settings. Culatta and Young[31] administered the Preschool Language Assessment Instrument (PLAI) at four levels of abstraction to children with MM and comparable language-age control children. Children with MM performed comparably to control subjects on concrete tasks of the PLAI, but they produced more "no response" and irrelevant responses than control participants on abstract tasks.

Latex Allergy

A range of up to 73% of children with MM have been reported to have latex allergies[167,210] compared to 1% to 5% of control groups. Unfortunately, 2% of latex consists of major IgE-sensitizing proteins that are ubiquitous in our culture, and some children with MM have life-threatening anaphylaxis when exposed to them. Latex-containing materials are almost never present in operating rooms or in products used elsewhere in the hospital; however, latex is still present throughout the general community. The IgE proteins in latex may be present in wheelchair seats and tires, foam rubber lining on splints and braces, elastic on diapers and clothes, pacifiers, balls, examination gloves used for bladder and bowel programs, and many other everyday objects. While almost all children's hospitals have latex precaution policies, it is important for therapists in schools and clinics in the community to be aware of the need for children with MM to avoid exposure to latex products.

Upper Limb Dyscoordination

Children with MM frequently display upper limb dyscoordination, especially those with hydrocephalus.[166] The dyscoordination can potentially be explained by three possible causes: (1) cerebellar ataxia most likely related to the Arnold-Chiari type II malformation; (2) motor cortex or pyramidal tract damage secondary to hydrocephalus; or (3) motor learning deficits resulting from the use of upper limbs for balance and support rather than manipulation and exploration. These children perform poorly on timed fine motor skill tasks.[166] Their movements can be described as halting and deliberate, rather than the expected smooth, continuous motion of able-bodied children. It often appears that there is a heavy reliance on visual feedback instead of kinesthetic sense. Consequently, even with extensive training, these children often have difficulty integrating frequently used fine motor movements at a subconscious level.[166] Practicing fine motor tasks has been found to be beneficial, however, and often carries over into functional tasks.[49] These coordination deficits have been described by some authors as apparent motor apraxias or motor learning deficits.[26,97] Given the frequent occurrence of upper limb dyscoordination in these children, true apraxias are probably less common than these studies indicate.

An additional factor that may contribute to upper limb dyscoordination is delayed development of hand dominance.[166] A large number of children with MM have mixed hand dominance or are left-handed, suggestive of possible left hemisphere damage.[166] Brunt[26] indicated that delayed hand dominance may contribute to deficits in bilateral upper limb function integration, resulting in further difficulty with fine motor tasks.

Visuoperceptual Deficits

Studies assessing visual perception have not clearly determined whether deficits in children with MM are common, as has been described in the literature.[126,161,195] Tests that require good hand-eye coordination, such as the Frostig Developmental

Test of Visual Perception, may artificially lower scores of children with MM as a result of the upper limb dyscoordination described earlier. When upper limb motor function has been removed as a factor in testing by using the Motor Free Visual Perception Test, children with MM have performed at age-appropriate levels.[166] Consequently, results of visuoperceptual tests must be interpreted carefully, in conjunction with other examinations, before a diagnosis of a visuoperception deficit is made.

Cranial Nerve Palsies

The Arnold-Chiari malformation, along with hydrocephalus or dysplasia of the brain stem, may result in cranial nerve deficits. Ocular muscle palsies can occur,[176] such as involvement of cranial nerve VI (abducens) with consequent lateral rectus eye muscle weakness and esotropia on the involved side. Correction with patching of the eye, prescription lenses, or minor outpatient surgery is necessary to prevent amblyopia and for cosmesis.[153] Gaston[55] studied 322 children with MM for 6 years to monitor them for ophthalmic complications. Forty-two percent of these children had a manifest squint, 29% had an oculomotor nerve palsy or musculoparetic nystagmus, 14% had papilledema, and 17% had optic nerve atrophy. Only 27% of those surveyed had definite normal vision. Seventy percent of proven episodes of raised intracranial pressure (ICP) from CSF shunt malfunction had positive ophthalmologic evidence of the ICP. Shunt surgery is the first priority but may not restore normal ocular motility and visual function, requiring further compensatory interventions.

Cranial nerves IX (glossopharyngeal) and X (vagus) can also be affected with pharyngeal and laryngeal dysfunction (croupy, hoarse cry) and swallowing difficulties.[176] Apneic episodes and bradycardia may occur with a severely symptomatic Arnold-Chiari type II malformation and can potentially be life threatening. These severe symptoms usually appear within the first few weeks of life but can occur at any time.[153] The survival rate is only about 40% in these severe cases.[174] Those infants who do survive, however, have been noted to have gradual improvement in cranial nerve function. Neurosurgical posterior fossa decompression and high cervical laminectomies do not seem to substantially improve the outcome.[57,174] In contrast, surgical decompression of the Arnold-Chiari malformation has been shown to be beneficial for the intervention of progressive upper and lower limb spasticity.[57]

Spasticity

The muscle tone of infants and children with MM can range from flaccid to normal to spastic. Stack and Baber[187] found that some upper motoneuron signs were present in approximately two thirds of children with MM whom they examined; however, only about 9% had true spastic paraparesis. The remainder of this group had predominantly a lower motor neuron presentation with scattered upper motor neuron signs (e.g., flexor withdrawal reflex). In the group of children without upper motor neuron signs, most had totally flaccid paralysis below the segmental level of their spinal lesion, but a small percentage had normal tone. In contrast, Mazur and Menelaus[117] stated that approximately 25% of individuals with MM exhibit lower extremity spasticity because of associated CNS abnormalities. As with other CNS conditions, spasticity and abnormal reflexes can affect function, positioning, or comfort in individuals with MM.

Progressive Neurologic Dysfunction

Minor improvements in strength or development of sensation, although rare, can occur even as late as the fourth decade of life. More important, however, is the deterioration from neurologic changes that are due to treatable complications. These changes that can occur in the upper or lower extremities or trunk include loss of sensation, loss of strength, pain at the site of the sac repair, pain radiating along a dermatome, initial onset or worsening of spasticity, development or rapid progression of scoliosis, development of a lower limb deformity not explained by previously documented muscle imbalance, or change in bowel or bladder sphincter control. Such changes can be due to CSF shunt obstruction, hydromyelia (syringohydromyelia, syrinx), growth of a dermoid or lipoma at the site of repair, subarachnoid cysts of the cord, or spinal cord tethering and can be detected via MRI. Cord tethering occurs from scarring of the neural placode or spinal cord to the overlying dura or skin with resultant traction on neural structures.[180] One third of children with MM will require surgery for a tethered spinal cord. The tethered cord syndrome may also result from other congenital anomalies, including thickening of the filum terminale and diastematomyelia.[154] An acquired cause of progressive spinal cord dysfunction that has been reported is severe herniation of intervertebral disks into the spinal canal, causing compression of the cord.[177] Lais and associates[96] stated that slow deterioration of neurologic function is not uncommon.

Progressive deterioration of spinal cord function resulting from any of these causes can be arrested by neurosurgical interventions. Deterioration of the gait pattern is frequently the first complaint by patients or their parents. Because physical therapists see these patients more frequently than physicians or surgeons, the therapist is often the first to observe these changes and should be alert to the need for immediate referral to a neurosurgeon. Owing to this risk of progressive loss of function, it is essential that individuals with MM be closely monitored throughout their life span.

Seizures

Seizures have been reported to occur in 10% to 30% of children and adolescents with MM.[168] The etiologies of seizure activity include associated brain malformation, CSF shunt malfunction or infection, and residual brain damage from shunt infection or malfunction. Anticonvulsant medications, which are necessary for prophylaxis against seizures, unfortunately can also accentuate any cognitive deficits or dyscoordination already present.[54,155] Untreated seizures, however, can lead to permanent cognitive or neurologic functional loss, or even death.

Neurogenic Bowel

Fewer than 5% of children with MM develop voluntary control of their urinary or anal sphincter.[153] Abnormal or absent function of spinal segments S2 through S4, which provide the innervation to these organs, is the primary reason for the incontinence. The anal sphincter can be flaccid, hypotonic, or spastic, causing different manifestations of dysfunction during defecation. Anorectal sensation is also often impaired, preventing the individual from receiving sensory input of an imminent bowel movement so that he or she can take appropriate action. In addition to incontinence, constipation and impaction can also occur. Fortunately, conscientious attention to individually designed bowel programs can have effective results, minimizing problems of incontinence and constipation.[92,153,201,202] The

presence of a bulbocavernosus or anal cutaneous reflex (indicating that lower motor neuron innervation of the sphincter is present) is highly predictive of success with a bowel training program.[92] King and associates[92] also reported that instituting bowel training before age 7 years correlates with improved outcomes by means of better compliance. When stool incontinence is interfering with a child's school and social activities, the physical therapist may want to become involved to help address the problem. Incontinence often affects feelings of self-image and competence, which in turn can affect performance in other activities pertinent to the therapist's intervention program.

Neurogenic Bladder

Just as the nerves to control defecation are impaired, so are the nerves that produce bladder control. Eighty-five percent of patients with MM have an underlying neurogenic bladder.[53] A variety of different types of dysfunctions can occur, depending on the relative tonicity of the detrusor muscle in the bladder wall and the outlet sphincters of the bladder. Bladder intervention strategies are directed toward the point or points of dysfunction. The goal is infection-free social continence with preservation of renal function. Retrograde flow of urine from the bladder up the ureters to the kidneys, termed *vesicoureteral reflux,* can occur without symptoms or signs being evident until the later stages of irreversible renal failure. Inadequate emptying of the bladder with residual urine retention within the bladder provides an optimal culture medium for bacteria, causing recurrent urinary tract infections and possible generalized sepsis. Adequate bladder intervention is therefore an essential component of health maintenance and normal longevity of people with MM, in addition to being an important social issue.

The bladder dysfunction can begin in utero (5% to 10% of newborns with MM show evidence of hydronephrosis and reflux). This is typically due to dyssynergy between the detrusor muscle of the bladder and the external urethral sphincter (i.e., the bladder contracts but the sphincter does not relax to allow the flow of urine out of the urethra). This results in high bladder pressures and vesicoureteral reflux. It is now standard practice for all newborns with MM to undergo an extensive urologic workup in the neonatal period. Early implementation of intermittent catheterization in infancy helps to prevent later problems with detrusor muscle function from overstretching the bladder wall.[14]

For most individuals, effective bladder intervention is achieved with clean intermittent catheterization on a regularly timed schedule for voiding. A small catheter is inserted into the bladder through the urethra until urine begins to flow. After the bladder is empty or urine stops flowing, the catheter is withdrawn, cleansed with soap and water, and stored for future use. It has been shown that the clean method of catheterization, as opposed to sterile technique, is sufficient for prevention of urinary tract infections.[153] The risk of injury to the urethra or bladder from clean intermittent catheterization is sufficiently low to allow young children to be taught to catheterize themselves. Mastery of the technique is usually achieved by age 6 to 8 years depending on the severity of the involvement.[179] Supplementation of clean intermittent catheterization with medication is frequently recommended to decrease bladder storage pressure and improve urinary continence and achieve intervention goals by altering spastic detrusor muscle function (e.g., oxybutynin [Ditropan], tolterodine [Detrol]), spastic sphincter function (phenoxybenzamine), or hypotonic sphincter function (ephedrine, pseudoephedrine, phenylpropanolamine). Medications may be delivered orally, transdermally, and via intravesicular injection. Botulinum toxin A is a relatively new addition to the therapeutic armamentarium for these patients, and onabotulinumtoxinA (Botox) has recently received US Food and Drug Administration approval for use in patients with neurogenic bladder conditions. Overnight catheter drainage has also been effectively used in a select group of patients with small, poorly compliant neurogenic bladders to decrease the risk of upper urinary tract deterioration. It is recommended that individuals with MM have regular follow-up with a urologist every 6 months until age 2, and yearly thereafter, throughout the life span.[91]

The physical therapist must be aware of the method used for urine drainage as it relates to wheelchair positioning, transfer techniques, and orthoses so that assistive devices do not interfere with effective performance of urine drainage techniques. It is important to allow adequate time for patients with MM to attend to bowel and bladder needs before and after examination and therapy sessions so that they are comfortable and continent during physical activities. Discomfort from a distended bladder or rectum may impair performance. Patients are often not assertive in requesting necessary time for personal care, and therapists should encourage them to do so to avoid embarrassing accidents.

Sexual function is also impacted, especially by diminished or absent sensation of the genitalia. For males, a transposition of the ilioinguinal nerve to the dorsal nerve of the penis can provide sensation for sexual activity.[144] The procedure has helped to contribute to the quality of life and overall adjustment to adulthood for adolescents and young men who have undergone the procedure.

Skin Breakdown

Decubitus ulcers and other types of skin breakdown have previously been shown to occur in 85% to 95% of all children with MM by the time they reach young adulthood.[172] Okamoto and associates[141] performed an extensive study of skin breakdown on 524 patients with MM who were 1 to 20 years old. Perineal decubiti and breakdown over the apex of the spinal kyphotic curve (gibbus) occurred in 82% of children with thoracic level lesions, 62% of those with high lumbar level lesions, and 50% to 53% of those with lower level lesions. Lower limb skin breakdown was approximately equivalent in all lesion level groups (30% to 46%). Although the sites and causes of skin breakdown varied among lesion level groups, the overall frequency was the same. The prevalence of skin breakdown at any one time was 20% to 25% for the population sampled. Several etiologies for skin breakdown were ascertained. In 42% of the children, tissue ischemia from excessive pressure was the cause. In 23% a cast or orthotic device produced the breakdown. In another 23% urine and stool soiling produced skin maceration. Friction and shear accounted for another 10%; burns accounted for 1%; and 1% of causes were not recorded or were unknown. Other authors have described additional causes of skin breakdown.[172] These include excessive weight bearing over bony prominences of the pelvis as a result of spinal deformity, obesity, lower limb autonomic dysfunction with vascular insufficiency or venous stasis, and tenuous tissue postoperatively over bony prominences. One might expect at least modest improvement in the prevalence of skin breakdown for children with MM owing to improved wheelchair cushion technologies and seating options;

however, no recent studies have been performed to assess the breadth or severity of this problem.

Age is an important factor in the etiology of skin breakdown. Shurtleff[172] showed that young children who are not toilet trained have the greatest problem with breakdown from skin soiling (ammonia burns). Young active children with MM have the greatest frequency of friction burns on knees and feet from scooting along rugs, hot water scalds, and pressure ulcers from orthoses or casts. Older children, adolescents, and young adults develop skin breakdown over lower limb bony prominences (even if they did not have ulcers when they were younger) from the increased pressure of a larger body habitus, asymmetric weight bearing resulting from deformities, abrasions of the buttocks or lower limbs resulting from poor transfer skills, improperly fitted orthoses, and lower limb vascular problems. Strategies for prevention taught by the physical therapist therefore should be directed to the likely causes of skin breakdown for the age of the individual. Helping the child develop an awareness of his insensate extremities is important during the early years in order to later develop independence with personal care. Mobley and associates[133] found that preschoolers with MM exhibited altered self-perception as evidenced by their drawing fewer trunks, legs, and feet on self-portraits than their able-bodied peers.

Pressure sores can result in a delay or loss of ambulation.[42] Skin breakdown of the insensate foot is often a cause of decreased ability to ambulate. Predictors of skin breakdown resulting from excessive pressure during ambulation or while resting feet on wheelchair footrests are foot rigidity, nonplantigrade position, and surgical arthrodesis.[116] Clawing of the toes may be another contributing factor that also affects shoe wear. To avoid foot ulcerations, physical therapists should examine and document foot deformity, level of sensation, and pressure areas. The insensate foot can be protected with appropriate footwear, orthotics, or surgery. Total contact casting can be useful in healing ulcers.[25]

Obesity

Obesity is a common and difficult multifactorial problem occurring in children with MM that complicates orthotic and wheelchair fitting and can affect independence and proficiency with transfers, mobility, and self-care activities. For children who are ambulatory, a greater expenditure of energy is required to participate in physical play activities, so it is likely that less time will be spent engaged in physical play and that more sedentary activities (e.g., watching television) will be adopted. Children with mobility limitations, whether they are ambulatory or wheelchair mobile, may not be well accepted by able-bodied peers when they attempt to participate in physically challenging play, or they may feel conspicuous because they have difficulty keeping up. The likelihood of participation under these circumstances is diminished. As obesity develops, this further complicates participation and negatively affects self-image, creating an undesirable cycle perpetuating weight gain. In addition, children with MM probably are at a disadvantage physiologically. Studies evaluating the caloric intake required for children with MM[173] have shown that the intake should be lower than for able-bodied obese peers. This is probably not just a function of the decreased activity level of children with MM. Decreased muscle mass of large lower limb muscle groups diminishes the ability to burn calories (i.e., the basal metabolic rate of children with MM is probably lower than normal). This is consistent with the observation that children with high lumbar and thoracic lesions have greater problems with obesity. Decreased muscle mass coupled with lower extremity inactivity reduces the daily caloric needs such that a young adult who uses a wheelchair as his primary means of mobility will need fewer than 1500 calories a day to maintain his current weight.[109] Liusuwan and associates[105] showed that in a population of children ages 11 to 21, children with MM, when compared to a control group, have significantly less lean body mass measured using dual energy x-ray absorptiometry as well as significantly lower resting energy expenditure measured with an open-circuit indirect calorimeter.

An easy and readily available mechanism to screen for obesity in the general population is height-weight ratios; however, arm span–weight ratios are more appropriate for monitoring individuals with MM. Shurtleff[173] noted that height-weight ratios are not useful in children with MM because of their short stature, decreased linear length secondary to spine or lower limb deformities, and decreased growth of paretic limbs. He recommended monitoring individuals with MM by measuring serial subscapular skinfold thickness, linear length measured along the axis of long bones to take into consideration hip and knee joint contractures, arm span measured with a spanner, and weight measured on a platform scale (subtracting the weight of the wheelchair or adaptive aids). Results should be recorded on National Center for Health Statistics percentile charts.[61] Arm span measurements should be adjusted using correction factors to avoid underestimating body fat content: 0.9 arm span for children with no leg muscle mass (thoracic and high-lumbar levels), 0.95 arm span for those with partial loss of muscle mass (mid- and low-lumbar lesions), and 1.0 arm span for children with minimal or no muscle mass loss. Del Gado and associates[37] reported that in comparison to a control group, 32 children with MM had significantly lower stature, higher weights, and greater subcutaneous fat deposits in their trunks, the latter being associated with cardiovascular disease risk factors.

Weight control is not just a function of decreased caloric intake for children with MM, however, and must involve a regular exercise program. The challenge of the physical therapist is to find age-appropriate physical activities for their clients that are fun and at which they can succeed; in this way, physical activity is positively reinforced and a lifelong pattern of engaging in such activities is developed. Liusuwan and associates[104] piloted a program combining behavioral intervention, exercise, and nutrition education that showed promise as a method for improving health and fitness of adolescents with spinal cord dysfunction.

FOREGROUND INFORMATION

AGE-SPECIFIC EXAMINATION AND PHYSICAL THERAPY INTERVENTION

There are issues of particular importance for specific age groups with MM. Intervention should be provided to keep pace with the normal timing of development.[18,171] Throughout the life span, it is important to keep in mind the overall picture of the needs of the patient and family. The medical problems and the number of health care professionals involved in the care of individuals with MM can be overwhelming. Many members of other disciplines, in addition to the physical therapist, may also be making requests of the family's time. Each professional should prioritize his or her goals relative to those of other disciplines and coordinate

planning so that the demands placed on the patient and the family are realistic. It is best to work as a team with the family and other disciplines to integrate appropriate intervention programs into the patient's daily routine. In addition, if conflicting information is provided to parents, they often become confused and may lack appropriate information to set realistic goals for their children and adolescents (e.g., goals for mobility, self-care, employment, and independent living). Consequently, multidisciplinary team collaboration with the family is important to establish appropriate goals and expectations.

The following sections focus on special considerations throughout the life span. Four age groups are discussed: infancy, preschool age, school age, and adolescence. Participation restrictions that are typically present, as well as the causes and impact of activity limitations on expected life roles, are discussed for each of the four age groups. Examination and evaluation of body structure and function, activity limitations, and participation restrictions, along with recommendations for ongoing monitoring, typical physical therapy goals, intervention, and strategies to prevent secondary impairments and activity limitations, are also discussed. In addition, typical secondary participation restrictions and activity limitations encountered during adolescence and their impact on the transition to adulthood are discussed in the section on adolescence and transition to adulthood. The information presented in this latter section has important implications for preventive intervention during childhood and adolescence to minimize the incidence of acquired impairments and activity limitations that often surface later in life.

It is important to keep in mind that the interaction of a multitude of impairments may affect an individual's functional performance, yet only a few key impairments are discussed for each age group. The reader is referred to the previous section on impairments for a more thorough discussion of other factors. Similarly, only key examination and intervention strategies that are specific to a given age category are discussed in each section. Common goals across the life span are to prevent joint contractures, correct existing deformities, prevent or minimize the effects of sensory and motor deficiency, and optimize mobility within natural environments.[117]

Infancy

Typical Participation Restrictions: Causes and Implications

The multiple impairments and overwhelming medical needs of a newborn with MM may interfere with parent-infant interaction. Parents are often afraid to handle their infant with MM, and the opportunities for handling and interacting with their child may be further limited by medical complications. Parents and extended family members may be cautious in handling the infant, resulting in decreased stimulation. Naturally occurring opportunities for early environmental stimulation, observation, exploration, and social interaction also may be limited as a result of somatosensory and motor deficits, hypotonia, and visual deficits. Family and infant interaction may be further impeded by the additional parental duties required (e.g., bowel and bladder intervention), frequent medical visits, and hospitalizations for complications.

The achievement of fine motor and gross motor developmental milestones is usually delayed during infancy because of multiple impairments, including joint contractures and deformities, motor and sensory deficits, hypotonia, upper limb dyscoordination, CNS dysfunction, visual and perceptual disorders, and cognitive deficits. The lack of normal infant movements, combined with impaired sensation, decreases kinesthetic awareness and inhibits perceptuomotor development. Independence with early ADLs such as holding a bottle or finger feeding is also negatively affected by impairments resulting from MM, especially swallowing disorders, upper limb dyscoordination, and visuoperceptual deficits.

Examination of Impairments

As discussed in Chapter 5, therapists must be aware of normal physiologic flexion of the hips and knees when assessing newborns. Limitations of up to 35° are present in normal newborns. These contractures may be more pronounced at birth in the infant with MM after prolonged intrauterine positioning of the relatively inactive fetus. Physiologic flexion spontaneously reduces in able-bodied infants from the effects of gravity and spontaneous lower limb movements. Physiologic flexion of infants with MM typically does not spontaneously reduce because of decreased or absent spontaneous lower limb activity secondary to muscle weakness. Consequently, contractures may develop even in children with sacral level function if they lack full strength of the gluteal muscles.

Two primary orthopedic concerns during this period are to identify and manage dislocated hips and foot deformities. Early orthopedic intervention of these deformities results in improved potential for standing balance and more timely achievement of motor milestones such as sitting and walking.[115,124] Achieving a plantigrade foot position is important regardless of ambulatory prognosis. Plantigrade alignment is optimal for shoe fit, positioning and weight distribution in sitting, and stability when bearing weight for standing pivot transfers or ambulation.

When assessing muscle tone in infants, either the Harris Infant Neuromotor Test[63] (HINT) or the Movement Assessment of Infants[29] is a useful tool. Hypotonia is typical in infants with MM, even if sacral level function is present.[207] Poor head control, delayed neck and trunk righting, automatic reactions, and low trunk and lower limb muscle tone are typical. A mixture of hypotonia and spasticity may be present in the limbs. It is important to distinguish between voluntary and reflexive movements when assessing muscle function.

One of the key physical therapy considerations in managing the newborn with MM is to establish a reliable baseline of muscle function. This baseline is important for predicting future function and for monitoring status. In addition, it is important to identify muscle imbalance around joints and existing joint contractures that are unlikely to reduce spontaneously.

In the newborn, muscle function is assessed before and after surgical closure of the back to determine the extent of motor paralysis. Sidelying is usually the position of choice for testing the newborn to avoid injury to the exposed neural tissue.[163] The state of alertness must be considered and documented when testing newborns or infants. Repeated examinations may need to be conducted at different times of the day to observe the infant's muscle activity in various behavioral states. Optimal performance cannot be elicited if the infant is in a sleepy state. Muscle activity is best observed when the infant is alert, hungry, or crying. Several techniques can be used to arouse the drowsy infant, including assessing limb ROM, rocking vertically to stimulate the vestibular system, and providing tactile and auditory stimulation.[69,163] Ideally, the infant's spontaneous activity should be observed in supine, prone, and sidelying positions

before the examiner starts handling the infant. Handling the infant may suppress spontaneous activity. Movement can often be elicited through sounds, visual tracking, reaching for toys, tickling, placing limbs in antigravity positions to elicit holding responses, and moving limbs to end-range positions to see if the infant will move out of the position.[69] For older infants, muscle activity can be observed, palpated, and resisted in developmental positions. If leg movements in myotomes caudal to the MM occur concurrently with performance of general movements in infants, functional neural conduction through the MM is implicated.[184]

Therapists often do not record specific strength grades for infants and young children. Instead, either a dichotomous scale (present or absent) or a 3-point ordinal scale (apparently normal, weak, or absent) is often advocated.[135,146,163] This 3-point scale, however, lacks sensitivity and predictive validity.[135] In contrast, specific manual muscle test strength scores (grades 0 to 5) have been found to provide useful information for infants and young children with MM and are predictive of later function.[120] Consequently, when strength is assessed manually, we recommend using the full manual muscle testing scale, regardless of age. The estimated quality of the examination should also be recorded, indicating the examiner's degree of confidence in the results based on the child's level of cooperation. Neck and trunk musculature should be graded as "normal for age" if the child is able to perform developmentally appropriate activities.[88]

Testing sensation in infants and young children presents special challenges. Complete testing of multiple sensory modalities is not possible until the child has acquired sufficient cognitive and language abilities to accurately respond to testing.[163] Parents can often provide useful information to help focus on probable insensate areas. It is best to test the child in a quiet state. Testing with a pin or other sharp object should begin at the lowest level of sacral innervation and progress to more proximally innervated dermatomes until a noxious response is noted (e.g., crying or facial grimace).

Teulier and associates[194] used a motorized treadmill to evaluate stepping responses of infants with MM from 1 to 12 months of age. Treadmill practice elicited steps and increased motor activity. Holding infants with MM on a moving treadmill resulted in 17% more motor activity of their entire body during the year than holding them on a nonmoving treadmill. Infants with MM stepped less than typically developing infants (14.4 versus 40.8 steps/minute), however, and they were less likely to produce alternating steps than typically developing infants at any age level. Responses were affected by lesion level but varied markedly among infants because of other confounding factors such as shunt revisions, medications, joint and ligament structures, and family support resources. Infants with the highest lesion levels (L1–3) exhibited a very low step rate over time, which the authors proposed was due to marked delays in muscle strength and limb control, rather than an innate lack of capacity as three of four infants in this group developed the ability to walk with walkers by 44 months of age. In contrast to interlimb stepping patterns, the within-limb step parameters of infants with MM were quite similar to typically developing infants. The authors plan to study the potential for treadmill practice to produce positive outcomes for infants with MM such as increasing muscle and cardiovascular strength, bone density, and neuromotor control required for upright locomotion.

Ongoing Monitoring

During the first year of life, it is important to monitor joint alignment, muscle imbalance, and the development of contractures. Typical lower limb contractures that develop are hip and knee flexion contractures combined with external rotation at the hips. Children with weak or absent hip musculature often lie in a "frog-legged" position with the hips flexed and externally rotated and the knees flexed. Consequently, these muscle groups are typically in a shortened position. It is important to closely monitor ROM and muscle extensibility during periods of rapid growth. Soft tissue growth typically lags behind skeletal changes, resulting in decreased extensibility. Stretching exercises should be initiated early on, if indicated, when contractures are relatively flexible and respond well to intervention. If orthoses or night-positioning splints are used to correct orthopedic deformities, the fit of these devices should be monitored to prevent skin breakdown.

Changes in muscle tone and muscle function are observed with progressive neurologic dysfunction. Baseline measurements, therefore, are essential, and these parameters should be closely monitored. Therapists should also watch for behavioral changes, decreases in performance, and other subtle signs of shunt malfunction (see Box 23.1) or seizure disorders. Motor development must also be observed to determine whether an infant is keeping pace with normal developmental expectations. Abnormalities in any of these areas should be reported to the child's primary care physician.

Typical Physical Therapy Goals and Strategies

During the newborn period, physical therapists must be sensitive to the feelings and needs of parents and other extended family members who are learning to cope with the overwhelming problems of a child with MM. Parents go through a period of tremendous adjustment. They are required to meet the demands of a normal infant, plus deal with the extensive medical and surgical needs of their newborn and adjust to the long-term implications of their child's multiple impairments. Not all instructions may be assimilated at any one time given the large amount of information to which parents are asked to attend. Often instructions must be reviewed and reinforced during subsequent visits. Written instructions should be provided to augment verbal explanations.

If ROM is limited, parents should be instructed in positioning techniques. It is optimal to maintain ROM by means of positioning because little additional time is required of the family. If contractures do not resolve with positioning, or if contractures are not supple, parents should also be instructed in stretching exercises and soft tissue mobilization techniques. It is usually most efficient to perform stretching exercises and soft tissue mobilization techniques in conjunction with diaper changes.

For infants who exhibit hypotonia, parents should be instructed in handling techniques to facilitate head and trunk control. Techniques advocated for children with hypotonic cerebral palsy[21] are often beneficial. Parents should be encouraged to provide sitting opportunities for the infant to facilitate the development of head and trunk control. Additional head and trunk support are often required in high chairs, strollers, and car seats. If motor development is significantly delayed and requires intervention, optimal handling techniques and treatment methods to improve posture and motor control discussed in the Infancy section in Chapter 19 in this text are potentially

applicable to this population as well. Therapeutic interventions and adaptive equipment should ideally be planned to keep pace with the normal timing of development so that the child is provided with typical developmental experiences. During the latter half of the first year, preparatory activities for mobility are indicated. Emphasis should be placed on balance, trunk control, and facilitating an upright posture as the child progresses through the developmental sequence.

Prevention of Secondary Impairments and Activity Limitations

Parents should be instructed in proper positioning, ROM, and handling techniques with the lower limbs in neutral alignment to prevent the development of contractures. If the hips are dislocated or subluxed, parents should be instructed in proper positioning, double diapering, and the use of a night-positioning orthosis, if indicated.[158,162] If surgery is indicated to relocate hip dislocations (see previous section on orthopedic deformities), it is generally performed after 6 months of age. Foot deformities are generally treated through serial casting or positioning splints.

Parents should also be instructed to inspect insensate skin areas during diaper changes and dressing for signs of pressure or injury. Parents need to understand the importance of skin inspection and that insensate areas should be inspected on a daily basis throughout the life span.

Toddler and Preschool Years

Typical Participation Restrictions: Causes and Implications

The achievement of fine motor and gross motor developmental milestones continues to be delayed. Mobility is typically impaired in this population owing to orthopedic, motor, and sensory deficits. As the child nears the end of the first year of life, it is important to provide opportunities for environmental exploration. If the child does not have an efficient, effective mode of independent mobility by the end of the first year, provision of a mobility device is indicated.

Environmental exploration is essential for the development of initiative and independence. Limited early mobility may result in a lack of curiosity and initiative and may negatively affect other aspects of development.[15,27,175] If a toddler does not have an effective means of independently exploring and interacting with the environment, he or she may learn to be passively dependent. The negative influence of limited early mobility on personality and behavior development can persist throughout life. Passive-dependent behavior is a commonly observed personality trait of adolescents and adults with MM.

Limited mobility also negatively affects socialization, especially interaction with other children. If a stroller is used as the primary mode of community mobility beyond the normal age of weaning a child from a stroller, other children will view the child with MM as a "baby." Play opportunities are also limited if a child does not have an effective means of mobility.

Independence with ADLs is often impaired in this population because of fine and gross motor impairments, upper limb dyscoordination, and CNS dysfunction. Children who are not independent with ADLs may miss out on normal childhood experiences (e.g., play time) while waiting for others to assist them with basic skills. Their self-esteem may also be negatively affected if other children tease them regarding their dependency.

It is important that parents, child care personnel, and preschool teachers be aware of other motor deficits that are often exhibited in this population, such as poor eye-hand coordination. The potential impact of these deficits on functional performance in handwriting and the acquisition of ADL skills such as feeding and dressing should be realized so that reasonable goals can be established and the use of appropriate adaptive equipment implemented.

Examination and Evaluation of Impairments and Activity Limitations

By the end of the first year, ROM is expected to be within normal limits. If limited ROM persists, it is important to distinguish between fixed and supple contractures, determine muscle extensibility, and evaluate orthopedic deformities to determine whether they are fixed or flexible.

To assess strength, functional muscle testing techniques are advocated for children 2 to 5 years old because they may not cooperate with traditional test procedures.[69,146] Functional activities that are helpful in determining the strength of key lower limb muscle groups include gait observations, heel- and toe-walking, climbing up and down a step, one-legged stand, toe touching, squat to stand, bridging, bicycling while supine, the Landau position, prone kicking, the wheelbarrow position, sit-ups, pull to sit, and sitting and standing push-ups. It is often possible for young children to cooperate with isolated muscle actions by having them push against a puppet to show how strong they are. To elicit the cooperation of older preschoolers (3- to 4-year-olds), it is often helpful to name the muscle and describe its "job" (the muscle action). The children think that the muscle names are humorous, maintaining their attention. Asking children to have the muscle do its "job" makes strength testing more understandable.[65] We have found it possible to obtain objective, reliable measures of strength from children as young as 4 years of age using handheld myometry techniques.[69] The degree of confidence regarding whether the child's optimal performance was elicited should be recorded.

Once the child is 2 years of age, light touch and position sense can usually be assessed by eliciting tickling responses or having the child respond to the touch of a puppet. Other sensory modalities can ordinarily be accurately tested once the child is 5 to 7 years old. The accuracy of responses often must be double-checked because of short attention span and response perseveration. Two sensory testing techniques minimize perseveration of responses. The first is to randomly alternate between testing light touch and pinprick and have the child identify the type of sensation. The second is to have the child point to the spot that was touched and correctly state when no area was touched.

Fine and gross motor development should be measured using appropriate standardized tests such as those discussed in Chapter 2 of this text. Examination of ADLs should focus on what the individual actually does on a daily basis, in addition to what she or he is capable of doing. If independence with ADLs is limited, appropriate adaptations and interventions should be implemented to foster independence. The Functional Activities Assessment[142,185,186] provides specific ADL performance data for MM (Fig. 23.7). Items may be scored by direct observation or by parent report. Assistive devices required to perform a given task are also documented. The "Can" and "Does" scoring format permits the examiner to record what the child can do versus what the child actually does on a regular basis. In addition, if the child is directly observed performing the task, the degree of independence and the time to complete the task are recorded.

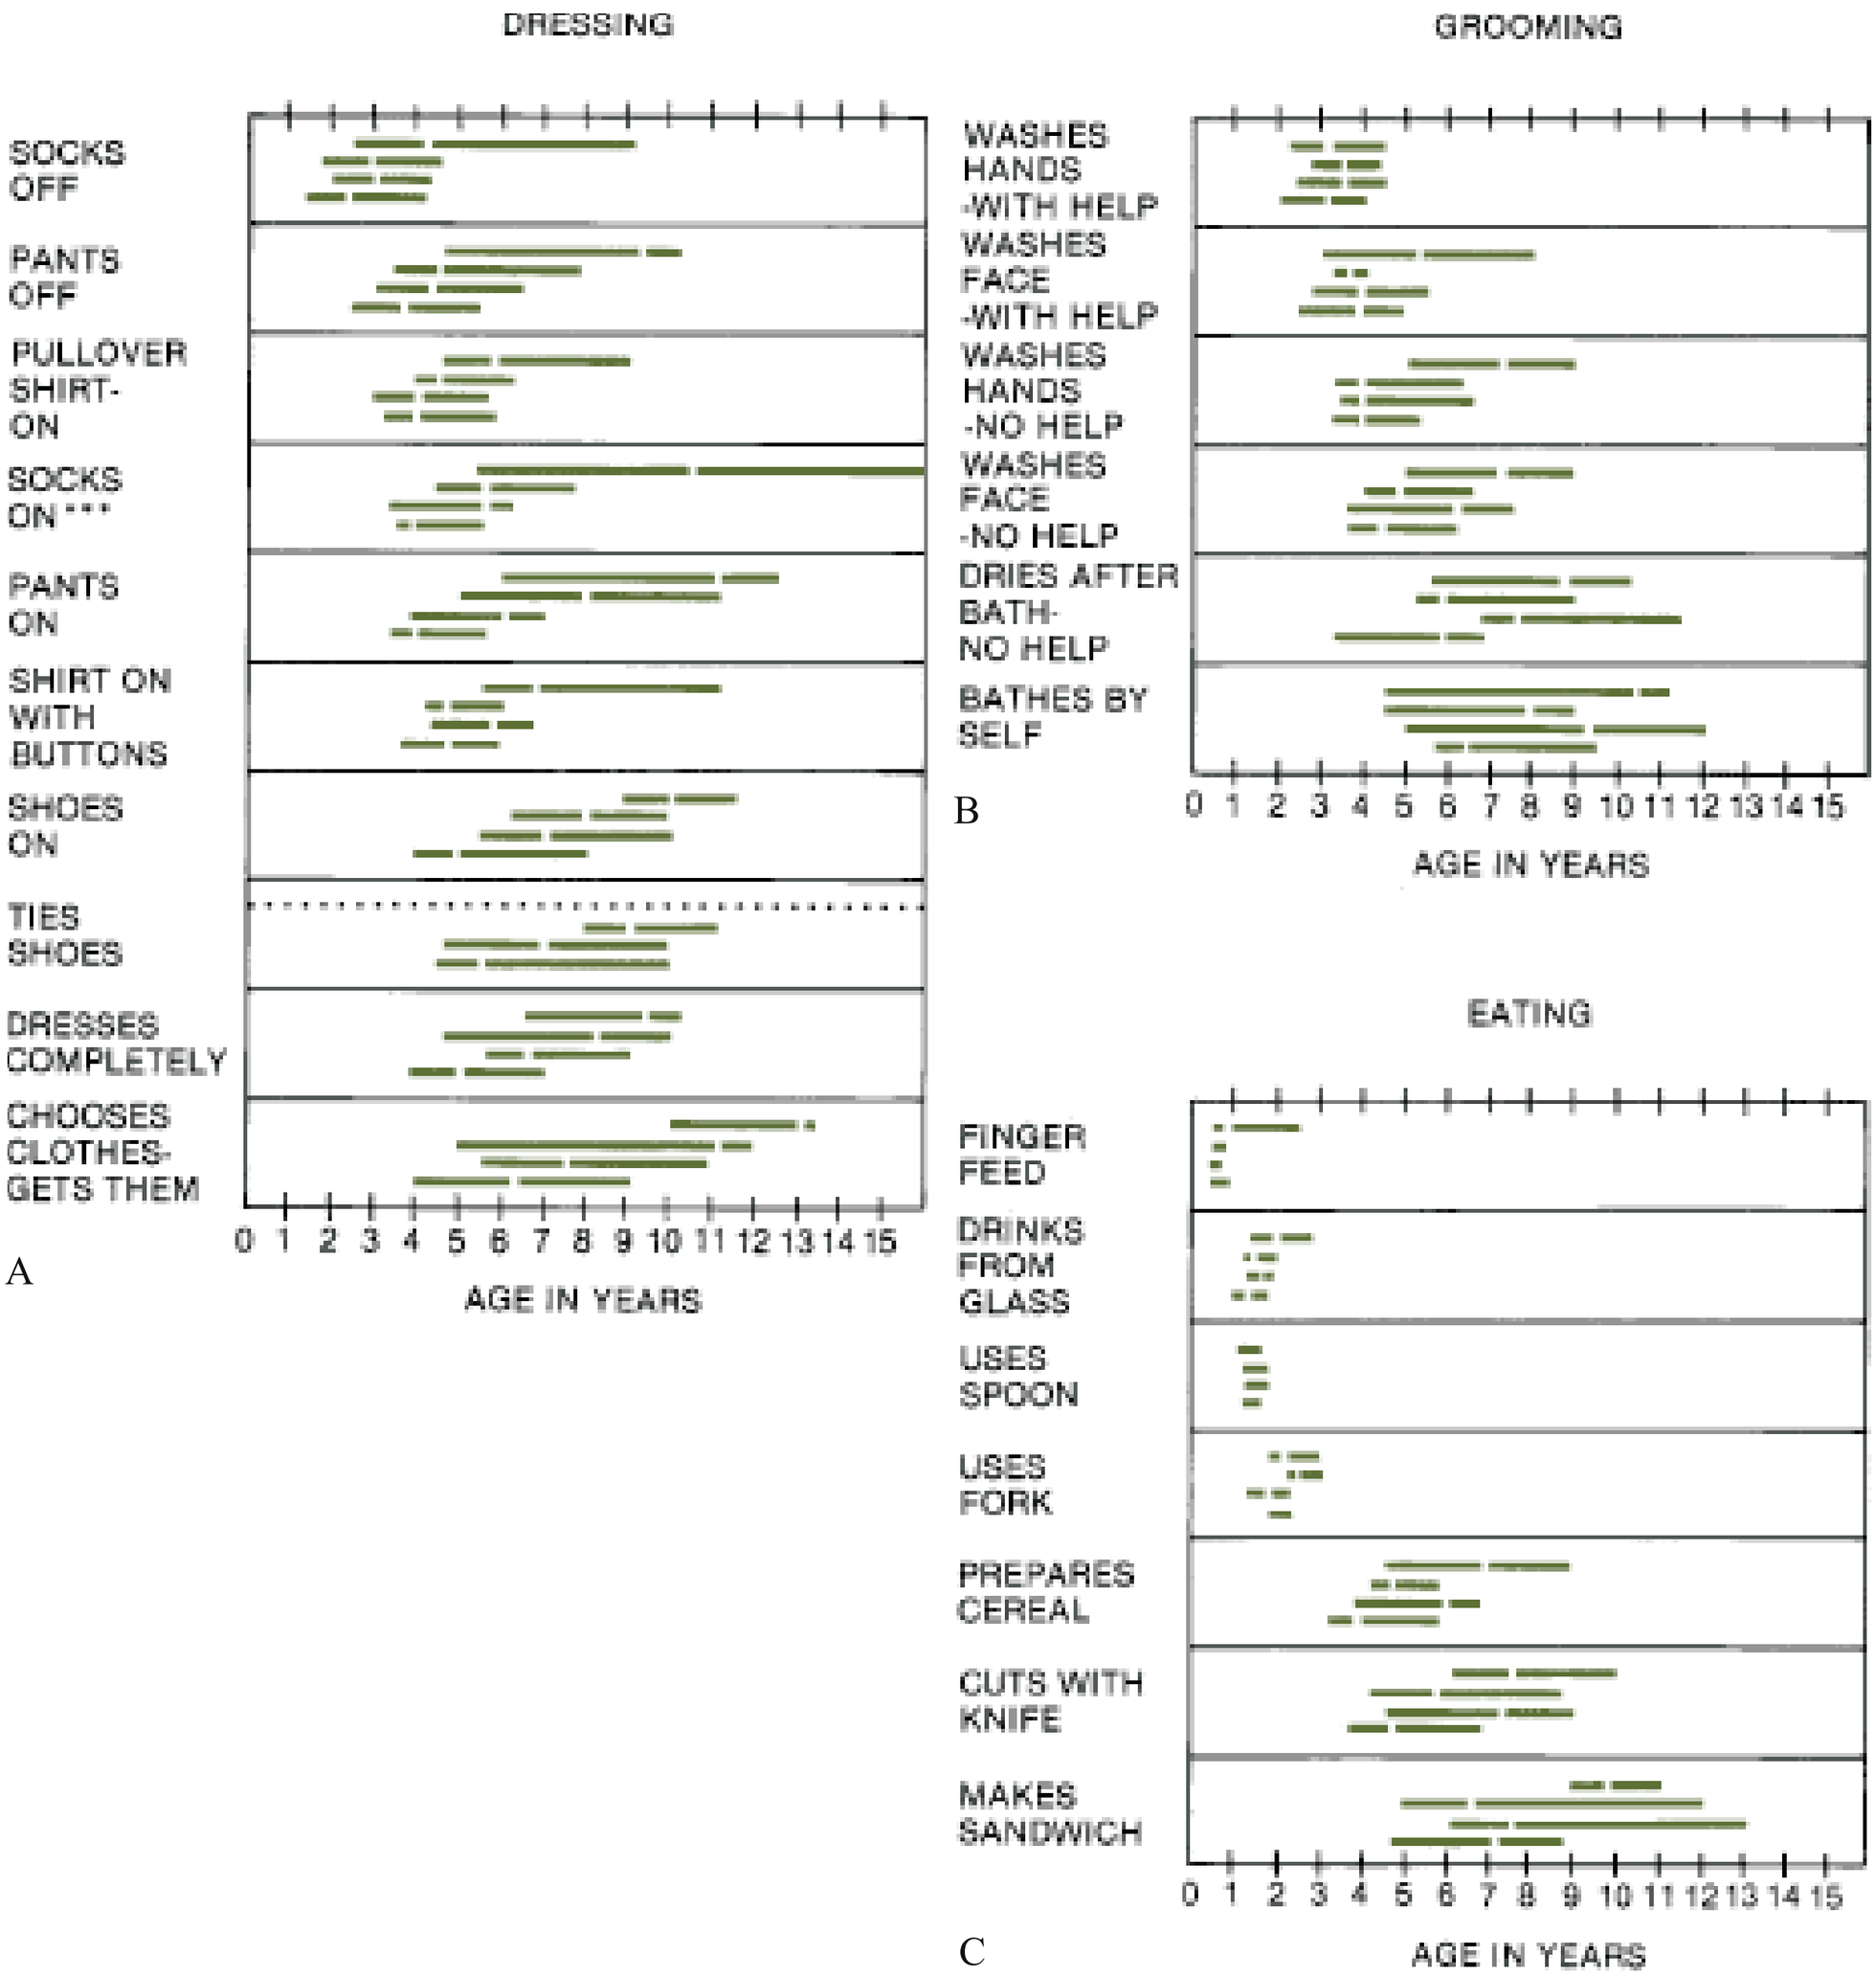

FIG. 23.7 Functional activities assessment. The age at which 20%, 50%, and 80% of a group of 173 children with MM learned dressing (A), grooming (B), and eating (C) skills is indicated by the beginning of, space between (white space), and end of the black bars, respectively. Triple asterisks indicate that this group never achieved an 80% learning proportion. Dotted line indicates activity was attempted with this group. The bars in each category represent, from top to bottom, (1) thoracic and L1–L2; (2) L3 and mixed lesions, L2–L4; (3) L4–L5; and (4) sacral-level groups. All data were recorded as the child achieved the skill during the 2.5-year period of the study, within 4 months of entering the study, or when the caretaker entered a specific date of achievement in the child's diary. These charts were created from data published by Okamoto and associates[142] and Sousa and associates.[186] (From Shurtleff DB, editor: Myelodysplasias and exstrophies: significance, prevention, and treatment. Orlando, FL: Grune & Stratton, 1986.)

Ongoing Monitoring

Joint alignment, muscle imbalance, contractures, posture, and signs of progressive neurologic dysfunction should continue to be monitored. Contractures that seem insignificant during childhood may become functionally limiting once the individual has adult-sized body proportions. For example, knee extension contractures can interfere with the ability to maneuver in a wheelchair.

Typical Physical Therapy Goals and Strategies

Joint alignment, contractures, muscle strength, and postural alignment should continue to be treated as necessary. Proper positioning in sleeping and sitting should continue. If stretching or strengthening exercises are indicated, it is often helpful to involve other family members in the exercise program so that the child does not feel singled out. For ambulatory candidates with weak hip and knee musculature, strengthening activities may be beneficial if the child is cooperative. In addition to traditional posture exercises,[88] many play activities promote strengthening and the development of good posture.[48] The use of therapy ball techniques to strengthen postural muscles is also beneficial. Muscle reeducation techniques, such as functional electrical stimulation and biofeedback, are useful to teach muscles to function in new ROM after stretching exercises. Electrical stimulation has also been found to be beneficial in increasing strength and enhancing functional performance in this population.[85]

During the preschool years, the focus is on improving the independence, efficiency, and effectiveness of ADLs and mobility. Development of independence with dressing and feeding should be encouraged. Appropriate guidance should be provided so that parents have age-appropriate expectations. It is important for young children to actively participate in skin inspection, bowel and bladder intervention, donning and removing orthoses, wheelchair intervention, and other ADL tasks. Teaching these skills early on and actively involving the child facilitates independence and incorporation of these activities into the daily routine. As a result, these extra responsibilities required of the child with MM become as natural as other ADLs such as brushing teeth. Waiting to introduce tasks until the child is older often is met with resistance, especially when the child observes that siblings do not have the same requirements.

By kindergarten age, children without disabilities are able to dress and toilet themselves (with the exception of some fasteners), eat independently, and be mobile.[49] These skills must be emphasized at an early age in children with MM so that they achieve independence by the time they begin school. A wide range of age of achievement of independence with ADLs is evident in this population when examining the normative data provided on the Functional Activities Assessment (see Fig. 23.7). This wide variability in age of achieving skills within a given motor level suggests that a significant percentage of children are delayed in ADL skill acquisition because of attitudes and expectations. Fay and associates[49] suggested that these delays may be partially caused by low parental expectations and protective attitudes, perceptions that it is faster for the parent to perform the task, and parental difficulty accepting the reality of the child's activity limitations. Showing parents the ADL normative data for children with MM and promoting positive parental expectations of independence are beneficial. It is important for parents to positively reinforce the child's attempts to be independent so that she or he is motivated to achieve. It is also important to help the parents understand how incontinence retards their child's normal sexual exploration, learning, and social inhibitions that normal preschool children learn. Alternative opportunities should be offered to children with MM.[22]

Skin inspection and pressure relief techniques should be taught early so that they are incorporated into the daily routine. Proper intervention of lower limbs and joint protection techniques should be taught to avoid injury of insensate areas when learning how to perform ADLs such as transfers. The impact of sensory deficits on functional performance should be kept in mind during gait training and when teaching other functional tasks.

Provision of an effective means of independent mobility is essential for young children. Consequently, if a child does not begin maneuvering effectively within the environment by 1 year of age, alternative means of mobility must be considered to achieve independent home and short-distance community mobility.[27,175] Mobility options should be explored and implemented as frequently as is needed so that the child is able to actively participate in normal childhood activities. Various mobility options are available from manual devices such as a caster cart to electric wheelchairs. Electric wheelchair use has been found to be feasible and beneficial for children as young as 24 months of age.[27] If a wheelchair is indicated, it is important to present this option to the parents in a positive way. Based on our clinical experience, the use of a wheelchair does not preclude walking. In fact, children who use wheelchairs at an early age generally are more interested in mobility, independence, and environmental exploration. Consequently, they tend to be more independent in all forms of mobility later in life. For example, Ryan and associates[159] recommended introducing a wheelchair as early as 18 months to enable children to keep up with their peers, boost self-confidence, facilitate independence, and increase activity levels. A more recent case report[110] suggests that it is potentially feasible to train infants as young as 7 months old to safely operate a power mobility device.

Preparatory activities for mobility are indicated for 1- to 2-year-olds. Emphasis should be placed on balance, trunk control, and facilitating an upright posture. For ambulatory candidates, once the child begins to pull to stand, the need for orthoses to improve weight-bearing alignment should be considered. It is important to anticipate future ambulatory needs when recommending orthoses to maximize their utility.

For children with high-level lesions (thoracic to L3), preparatory activities for wheelchair mobility should be emphasized (e.g., sitting balance, arm strengthening, transfer training, wheelchair propulsion, and electrical switch operation if indicated). The focus of wheelchair training for toddlers and preschoolers with high-level lesions should include mobility, environmental exploration, safety, and transfer skills. Household distance ambulation using a parapodium, HKAFO, knee-ankle-foot orthosis (KAFO), or reciprocating gait orthosis (RGO) may be attempted, but energy expenditure is very high. Consequently, wheelchairs are generally used for community mobility of children with thoracic to L3 motor function, particularly once body proportions increase.

Effective biped ambulation is feasible for toddlers and preschoolers with L4 and below motor function. They will require wheelchair skills as older children, however, to participate in sports and prolonged activities. It is essential to maintain adequate ROM and to emphasize an upright posture so that

weight-bearing forces are properly distributed and muscles can function at their optimal length. Therapeutic activities that promote trunk control and balance are beneficial. Children with lumbar level lesions will require upper limb support for walking. In general, a reverse-facing walker is best when the child is learning to walk because it allows the child to be upright and minimizes upper limb weight bearing. Reverse-facing walkers have been found to promote better postural alignment than anterior-facing walkers.[106] At the point an upright gait is established, the child can be advanced to forearm crutches.

If children with sacral level motor function require upper limb support to begin walking, a reverse-facing walker is also usually best to minimize upper limb weight bearing. Alternatively, forearm crutches can be used if the child is able to walk upright while manipulating the crutches. Children with L5 and S1 level lesions often abandon their upper limb aids when they are young and their center of mass is low to the ground. Upper limb aids may still be indicated for endurance and to decrease trunk sway when walking long distances, for balance when walking on rough terrain, or to minimize the stress on weight-bearing lower limb joints. The need for upper limb aids should be reevaluated when the child is older and body proportions and environmental demands have changed.

The use of positive reinforcement is often recommended for this population to enhance cooperation with examination procedures and intervention programs. In general, food is not an appropriate form of reinforcement because obesity is often a concern. Verbal reinforcement is preferred at this age.

Prevention of Secondary Impairments and Activity Limitations

Individuals are at risk for joint contractures when there is muscle imbalance around joints, when a substantial portion of the day is spent sitting, when there is a prolonged period of immobilization or bed rest, following surgery, and during periods of rapid growth when soft tissue growth may lag behind skeletal changes. It is important to closely monitor individuals with MM during these periods so that intervention can be initiated early on, if needed, when contractures are still flexible and respond well to intervention. Early detection and intervention of contractures can prevent fixed deformities and stretch weakness of overlengthened muscles. Similarly, the importance of skin inspection of insensate areas, use of pressure relief cushions, and sitting push-ups for pressure relief should be emphasized at an early age so that these preventive measures become routine. Daily monitoring of insensate areas can be taught at an early age by jointly inspecting the skin and verbalizing that there are no red areas. Body image can be promoted by playing games that involve touching and finding body parts.

Habitual postural positions that contribute to deforming forces should be discouraged. It is essential to emphasize an upright posture when a child is learning to walk. If children are permitted to stand and walk in a crouched posture, habits become established and it is difficult to teach a more upright posture because of the development of secondary impairments (e.g., joint contractures and stretch weakness of excessively lengthened muscles). Therapists should closely observe joint alignment and posture when a child is standing. Postural deviations that look insignificant when a child is young are often magnified once body proportions increase.

School Age

Typical Participation Restrictions: Causes and Implications

Independence with ADLs often continues to be impaired in this age group. Children who are not independent with ADLs may miss out on normal childhood experiences (e.g., playtime or recess) while waiting for parents or teachers to assist them with basic skills. Their self-esteem may continue to be negatively affected if other children tease them regarding their dependency.

Mobility limitations are magnified once a child begins school because of the increased community mobility distances and skills required. Advanced mobility skills are needed because of environmental barriers such as curbs, ramps, uneven terrain, and steps. Ineffective or inefficient community mobility can further reinforce dependent behaviors if other children carry his or her schoolbooks and lunch tray or push the wheelchair.

The negative effects of limited mobility and physical limitations on socialization become more apparent at this age. Play and recreational opportunities are restricted if a child does not have an effective method of mobility. Often children with MM are excluded from recess or physical education class. Consequently, they miss out on opportunities for social interaction. Even if they are included in these activities, often their involvement is peripheral (e.g., serving as the score keeper during physical education class). Mobility limitations, dependency with ADLs, difficulties with toileting, and the difficulty of managing adaptive equipment often interfere with other aspects of peer interaction, such as going over to friends' houses to play or spending the night with friends.

Finally, it is important that parents and teachers be aware of perceptuomotor, visuoperceptual, and sensory deficits. The potential impact of these deficits on writing speed, legibility, and accuracy; the efficiency and effectiveness of performing ADL skills; problem solving; and cognitive abilities should be realized so that reasonable goals can be established and the use of appropriate adaptive equipment can be implemented. Multiple hospitalizations or medical complications can also negatively affect school performance.

Examination and Evaluation of Impairments and Activity Limitations

As with younger children, joint alignment, strength, muscle imbalance, contractures, muscle extensibility, and posture should continue to be monitored. Other parameters that should be assessed include sensation, coordination, fine motor skills, ADLs, mobility, gait, body awareness, and functional skills.

Reliable, sensitive, objective measures of strength can be obtained in school-age children.[65] We recommend that objective methods of strength examination, such as handheld myometry, be used to serially monitor strength of individuals with MM who are old enough to cooperate (typically age 4 or older). Stationary isokinetic or strain gauge devices can also provide objective measures of strength, but these devices are not available in the typical clinic or school setting.

Independence with ADLs should be assessed. In addition to the basic ADL skills evaluated in the Functional Activities Assessment, the school-age child's ability to carry items and assist with basic household chores should be evaluated. The physical therapist also assesses the adequacy of clearance, duration, frequency, and reliability of performance of wheelchair push-ups. A nurse usually evaluates bowel and bladder function and the degree of continence. It is important that the

physical therapist understand these and degree of independence with bowel and bladder function, however, because positioning, adaptive equipment, and mobility issues can often restrict independence with bowel and bladder intervention programs.

The home, school, and community environments should be accessible so that individuals with MM can participate fully in all activities. The Americans with Disabilities Act of 1990 mandates access to all buildings, programs, and services used by the general public in the United States. Even partial exclusion from a school program can have lasting negative effects on a student's social and emotional development.[8] Providing accessibility to the entirety of school, home, and community activities lets individuals with MM know that they have the same opportunities and rights of access as everyone else. Limited access broadcasts a message of exclusion and estrangement. Both physical and social barriers to participation must be addressed. For a more thorough discussion of evaluating environmental accessibility in the school setting, see Baker and Rogosky-Grassi.[8] Community accessibility should also be evaluated. Ideally, the patient should have access to the community school, church, grocery and drug stores, post office, bank, cleaners, stores and shopping malls, library, restaurants, theaters, sports arenas, hospital, physician's office, work environment, and public transportation. Streets, sidewalks, crosswalks, and parking lots should also be accessible.

Ongoing Monitoring

Joint alignment, muscle imbalance, contractures, posture, and signs of progressive neurologic dysfunction should continue to be monitored. As school-age children mature, they should become more responsible for daily inspection of insensate skin areas when they are bathing and dressing. Appropriate performance of pressure relief strategies should also be monitored. Areas of skin breakdown should be noted so that appropriate adjustments in equipment and preventive behaviors can be implemented or reviewed.

School-age children should be observed closely during periods of rapid growth because they are at risk for loss of function as a result of cord tethering. Parents and teachers should be made aware of signs of progressive CNS complications so that they know when to refer the child to a primary care physician.

Typical Physical Therapy Goals and Strategies

The stretching and strengthening strategies discussed for the two previous age groups also apply to the school-age child. Improving the flexibility of low back extensor, hip flexor, hamstring, and shoulder girdle musculature should be emphasized. When possible, stretching and strengthening exercises should also be incorporated into the physical education program. It is important that children with MM participate in physical education classes and sports activities in a meaningful way. As noted earlier, if children dependent on braces and crutches learn wheelchair skills and use at an early age, they will not be depressed and perceive wheelchair use as a failure when they arrive at adolescence.

Proper positioning while sleeping and sitting should continue. In the classroom, seating should provide stability and symmetric alignment. Feet should be flat on the floor or on wheelchair footrests. The seat and desk height should be adjusted to fit the child's body proportions. The desktop should be tilted up to improve neck and upper trunk alignment. Appropriate cushioning should be provided. The child's chair should be positioned in the room so that the teacher and blackboard can easily be viewed while maintaining neutral alignment, without having to turn in the chair.

If a child has not achieved independence with a given ADL task by the age at which 50% of the normative group achieved independence on the Functional Activities Assessment, the child's performance should be assessed to determine if adaptive equipment is required or if further interventions are indicated. Goals for ADL performance should include efficiency in addition to independence. If the child is not as efficient as the primary caretaker, the caretaker will most likely perform the task. The target goal, therefore, is for the child to be able to perform the task as efficiently as the primary caretaker. Showing parents the ADL normative data for children with MM and promoting positive parental expectations of independence are beneficial (see Fig. 23.7). It is important for parents to positively reinforce the child's attempts to be independent so that he or she is motivated to achieve. Pressure relief techniques should be incorporated into the daily routine. Joint protection measures should also be implemented early on to prevent the development of future degenerative changes.

Once children with MM begin school, it is important that they have an independent, efficient, and effective means of mobility for home and long community distances. Alternative means of mobility may need to be considered for long distances to ensure that children with MM are able to keep up with their peers and still have energy left to attend to classroom activities. Various mobility options should be evaluated according to the criteria outlined in Box 23.2 to determine the most effective means of mobility for a given environment. Community-level wheelchair and ambulation skills should be taught, emphasizing efficiency and safety. Community, home, and school environments should be assessed to determine if there are architectural barriers that interfere with daily activities. It is essential for normal social development to permit accessibility to all school, home, and community activities, including recess, physical education, and field trips.[8]

A functional environment should be created at home and school by removing obstacles and adapting the environment to facilitate efficient and independent function. Adaptive equipment and effective mobility devices should be provided to maximize function. Community mobility skills may need to be practiced to facilitate independent function. Endurance training may also be indicated to ensure that the individual has sufficient endurance and efficiency to function effectively in all activities.

Recreation and physical fitness are important for physical, psychological, and social reasons. Psychosocial benefits of participation in recreational activities include enhancing confidence and self-esteem, increasing socialization, improving group participation skills, providing a means of exercising in a more normal way, and increasing interest and motivation in maintaining flexibility, strengthening, and endurance. In contrast, perceived physical restrictions result in a sedentary lifestyle, potentially predisposing these individuals to problems with obesity and degenerative diseases. It is important to stimulate a lifelong interest in fitness and recreation. In addition, community resources, feasibility of transportation, and the family's lifestyle must be taken into account.

Recreation activities must be carefully selected to ensure that they are beneficial and feasible yet enjoyable so they will be continued on a regular basis. Ideally, recreation activities should

BOX 23.2 Feasibility of Wheelchair and Biped Ambulation: Criteria for Evaluation

Household Distances

Endurance

Adequate to go between rooms in house?
Adequate to get to yard and car?

Efficiency

Record heart rate and calculate energy expenditure.
Record normal and fast household walking speeds.
Is fast pace adequate for emergency situations?
Is normal pace practical for everyday activities?

Effectiveness

Independent with all transfers?
Able to carry, reach, lift, and climb?
Able to perform activities of daily living?
Able to go forward, backward, sideways, and turn?

Safety

Has good stability and balance?
Observes joint and skin protection?
Able to maneuver around obstacles?
Safe on smooth surfaces and rugs?
Safe when turning?

Accessibility

Maneuvers in and out of house independently?
Necessary household rooms accessible?
Emergency exit routes accessible?

Community Distances

Endurance

Sufficient at a functional speed for average community distances (e.g., going to school, store, medical appointments, and social activities)?
Adequate for play and recreational activities (e.g., playground, park, beach, theater, sports arenas, sports participation)?
Adequate for long-distance community distances (e.g., shopping mall, zoo, concert, sporting events, hiking)?

Efficiency

Record heart rate and calculate energy expenditure.
Record normal and fast walking paces.
Adequate speed to cross intersections?
Is typical pace practical for community distances?

Effectiveness

Independent with all transfers?
Able to maneuver in all directions?
Able to climb and step over obstacles?
Able to carry packages and groceries?
Able to reach and lift items from shelves?

Safety

Has good stability and balance?
Observes joint and skin protection?
Safe on wet or slippery surfaces?
Able to maneuver around obstacles?
Able to maneuver in congested areas?
Safe on uneven terrain, curbs, inclines, and steps?

Accessibility

Maneuvers in and out of car and bus independently?
Necessary community buildings accessible?

incorporate forms of aerobic exercise along with socialization. It is important for individuals with MM to be involved in regular aerobic exercise to maintain their physical fitness and effectively control their weight. Recreational and physical fitness goals include maintaining and improving flexibility, strength, endurance, aerobic capacity, cardiovascular fitness, and coordination and controlling weight. Low-impact aerobics are preferred to minimize stress on joints. Aerobic exercise videos have been developed for individuals with disabilities. Swimming is an ideal sport for this population because they are often able to be competitive with their able-bodied peers and there is minimal stress on joints (www.brighthub.com/education/special/articles/44574.aspx). Other low-impact activities include cycling, rowing, cross-country skiing, roller and ice skating, and aerobic dance (www.cureourchildren.org/sports.htm).

Verbal reinforcement or implementation of a token economy system to earn special privileges is preferred at this age to enhance cooperation with examination procedures and intervention programs. As mentioned above, food is not an appropriate form of reinforcement.

Prevention of Secondary Impairments and Activity Limitations

Deficits that may appear insignificant during childhood often become magnified once an individual has adult body proportions, resulting in activity limitations and discomfort (e.g., low back pain resulting from an increased lumbar lordosis and hip flexion contractures). Joint protection is also important, beginning in early childhood. Joint trauma from excessive stress is cumulative over the life span. Children do not typically complain of pain, and children with MM may not be able to reliably detect pain in insensate areas. Consequently, sources of excess joint stress must be identified by carefully observing children while they perform ADLs and transfers, walk, and propel their wheelchair. Permitting school-age children to assume responsibility for daily skin inspection checks with supervision prepares them for independence in adolescence.[151] One method of teaching careful skin inspection involves letting the child locate a small colored adhesive dot that is placed randomly on insensate skin.

Children and their parents should be involved as much as possible in the decision-making process and intervention for their disability. The rationale for assistive devices and therapeutic interventions should be explained so that they agree with intervention plans and become knowledgeable regarding acquisition of medical care and services, rather than being passive recipients.

Adolescence and Transition to Adulthood

Typical Participation Restrictions: Causes and Implications

If normal stages for early childhood development have not been successfully accomplished, adolescence can present a crisis. The preparation of individuals with MM for a successful transition into adult life must be based on developmental concerns and timely issues from infancy through all stages of development to young-adult life.[151] Adolescence brings expanded domains of travel for individuals with MM. School buildings become larger, with more

environmental barriers for people with physical disabilities. To keep up with peers, community mobility must include mobility skills to travel long distances quickly and efficiently between classrooms, out to athletic fields as a participant or spectator, around shopping malls, and into crowded movie theaters, dances, and nightclubs. Independent adult living also requires mobility and balance skills that permit completion of advanced ADL tasks such as cooking, cleaning, clothes washing, shopping, yard work, house and equipment maintenance, driving, riding on public transportation, and going to work. Children who have gotten by with slow, inefficient ambulation skills using cumbersome adaptive equipment or who have had basic wheelchair mobility on level surfaces but suddenly cannot handle ramps, hills, curbs, and uneven ground find themselves lagging behind their peers. Nearly all of the adults in a study of 30 individuals with MM[72] required referral to a physical therapist to address advanced mobility or equipment issues. It has been the observation of the authors that many adolescents and young adults do not have sufficient mobility skills to succeed independently in the community and must play catch-up to achieve their functional potential. The price paid for this delayed development of functional community mobility and lack of independence is social incompetence, dependence for advanced living skills, and unemployability, all of which must subsequently be addressed once mobility skills are improved. It is also important to train for competence and self-reliance. Blum and associates[18] reported that young people with MM who perceived that they were overprotected had less happiness, lower self-esteem, higher anxiety, lower self-perceived popularity, and greater self-consciousness.

Changes in functional mobility skills often occur concurrently with the rapid changes of adolescence. Individuals who have previously been ambulatory often become more reliant on a wheelchair. Dudgeon and associates[45] reported that adolescents with MM often exhibit changes in ambulation that are not explained by progressive complications. They suggested that these changes reflect adaptation of mobility to new environmental and social demands that require different speed, accessibility, and energy demands than those encountered in childhood. If orthotic stabilization of the hip, knee, or both is required, it is unlikely that adolescents with MM will maintain community ambulation; instead, most become nonambulators.[45] Brinker and associates[23] reported a decline in the ability to walk in 11 of 35 adults with sacral level MM (19 to 51 years old). Of the 34 adults who were initially community ambulators, 5 had become household ambulators, 2 were nonfunctional ambulators, and 4 were nonambulators. The one adult who had been a household ambulator became a nonambulator. The most common reasons for their declining ambulatory status were foot ulcerations, infections, and amputations. Wheelchair transfer skills have also been observed to decline during the transition from adolescence to adulthood. In a study of 30 adults with MM who had thoracic through sacral level motor function, the mobility status for 43% had declined since previous examinations performed during adolescence.[72] Several potential factors can play a role in this decreased function.

Changes in body proportions and body composition occur throughout the growing years, but the rate of these changes is accelerated dramatically during adolescence.[69] Increases in limb length affect the torque generated by muscles because of altered muscle length and resistance force moment arms. In addition, increases in height raise the location of the center of mass higher off the ground, making upright balance more difficult and energy expenditure greater to perform mobility tasks. Changes in body composition also alter the biomechanics of movement and affect performance. The relative percentage of force-generating muscle to fat and bone tissue changes the ratio of force-producing tissue to the load of the limbs. The development of obesity often occurs during adolescence and can further accentuate these changes. Banta[10] stated that body mass increases by the cube or volume whereas strength increases only by the square or cross-sectional area. The inevitable result during the adolescent growth spurt is that walking efficiency declines as the energy demands increase. Furthermore, during the adolescent growth spurt, the rate of skeletal growth exceeds the increase in muscle mass; the latter catches up after skeletal growth slows in late adolescence. Decreased flexibility of the trunk and two-joint limb muscles is often observed as part of this process. Normal adolescents frequently become clumsy during this period of adjustment while learning how to coordinate their longer limb lengths and increased muscle mass. Adolescents with MM already have a mechanical disadvantage and are consequently more susceptible to dyscoordination and decreased flexibility. It is likely that these developmental changes contribute to the decline in mobility that often occurs in adolescents with MM.

Progression of the neurologic deficit is another potential cause for decline in mobility function, and adolescents are particularly at risk during rapid periods of growth. Forty percent of the participants in our adult follow-up study[72] had lower limb strength loss compared with previous strength examinations as adolescents. Twenty-seven percent had a reduction in lower limb sensory perception. The greatest motor and sensory losses occurred in the group with lesions at L5 and below—the individuals with the most function to lose. In addition, 10% of study participants demonstrated upper limb strength loss. Progressive neurologic loss, therefore, appears to be an important factor in the changes in mobility status of many individuals during the transition from adolescence to adulthood.

Immobilization for intervention of secondary complications of MM can also contribute to decreased mobility skills. Decubiti, fractures, and orthopedic surgeries such as spinal fusions often require extended periods of immobilization with consequent disuse weakness, decreased endurance, and contracture development, all of which can decrease performance of mobility and transfer tasks.

Prolonged periods of bed rest are often necessary to heal decubitus ulcers to avoid bearing weight on pressure areas. Adolescents often have an increased incidence of decubiti compared with younger children. This is due to their increased body mass causing greater pressure over bony prominences around the buttocks and because of the development of adult sweat patterns in these areas. Fifty-six percent of the adults evaluated in our study[72] had a history of skin breakdown since their last examination as adolescents; nearly 17% had breakdown present at the time of the examination. An alarming number of these people had little insight into the causes or methods for preventing skin breakdown despite their previous care in a large multidisciplinary pediatric clinic. Even more disturbing was the fact that three individuals (10%) had sustained lower limb amputations since adolescence (two bilateral, one unilateral) as a result of nonhealing ulcers that had progressed to osteomyelitis. Clearly, functional mobility is affected by decubitus ulcers and especially by limb loss.

Musculoskeletal problems can also affect the mobility of adolescents. Progression of spinal deformities often occurs

during the growth spurt or in conjunction with one of the neurologic complications previously discussed. Sitting and standing balance can be affected by these spinal changes, leading to decreased mobility and transfer skills. Spinal orthoses prescribed to maintain optimal postural alignment also limit trunk ROM and hip flexion, interfering with wheelchair transfers and moving from sitting to standing. Surgical fusion of the spine to correct deformity and prevent its further progression can lead to immobilization with its consequent effects on mobility described earlier. Lower limb fractures secondary to osteoporosis can also necessitate immobilization with increased risk of functional loss.

Adolescents often begin to develop degenerative changes of weight-bearing joints and overuse syndromes as a result of the excessive loading of these joints necessitated by their neurologic deficit. Joint pain, ligamentous instability, or tendinitis can further limit mobility capabilities. Fifty percent of the adult study participants[72] complained of joint pain, and 100% had joint or spinal deformities noted at the time of their examination.

Several other issues become important for the physical therapist to be cognizant of during adolescence. Independence with self-care and other daily activities is essential for normal socialization and for preparing individuals to lead normal adult lives. Bowel and bladder continence and independent intervention of bowel and bladder emptying are essential for social acceptance by peers and are even more critical at this stage because of the impact on dating, sexuality, higher education, employment, and independent living. Design and fit of wheelchair equipment, mobility aids, and orthoses affect independence with these tasks. Cosmesis is also a consideration with regard to equipment selection because body image and appearance become increasingly important issues during adolescence. Improper design or fit of equipment can significantly limit normal development in these areas.

Examination and Evaluation of Impairments and Activity Limitations

Based on the discussion of participation restrictions and their causes, the physical therapist should assess several impairments. Emphasis of specific impairments should be based on the known or suspected concurrent medical problems.

Joint ROM and muscle extensibility of two-joint muscles (especially hip and knee flexors) and trunk muscles should be assessed. Neck and low back motions are often restricted, particularly in adolescents and adults, because of muscle imbalance and poor postural habits. Joint swelling, ligamentous instability, crepitus, and pain with or without joint motion should be documented. If these conditions are progressive or severe enough to interfere with function, the patient should be referred to a physician for further evaluation and intervention. The distribution of degenerative joint changes should be noted with regard to performance of mobility tasks and obesity to determine the contribution of abnormal joint stresses to joint pain and dysfunction.

Muscle strength should continue to be monitored for all major upper and lower limb muscle groups. When progressive neurologic dysfunction is suspected, coordination testing and serial grip strength measurements can also be helpful. Posture and trunk balance in sitting and standing (for ambulators) should be assessed. Real or apparent leg length discrepancy may be present in individuals with foot and ankle deformities, lower limb contractures, unilateral or bilateral hip dislocation, or pelvic obliquity related to spinal curves.

Thorough examination of bed mobility, floor mobility, wheelchair mobility and transfers, and appropriateness and fit of wheelchair equipment is essential for wheelchair users. Endurance and effectiveness of mobility should be assessed to determine whether the individual's current mode of mobility is practical for community-level function. Box 23.2 provides further detail regarding important areas to assess. When orthoses are needed to maintain proper alignment or to facilitate efficient ambulation, the physical therapist must assess their appropriateness and fit. Boxes 23.3 and 23.4 provide further information regarding lower limb orthoses used in this population.

Ongoing Monitoring

Given the multitude of potential problems that can occur during adolescence and adulthood, comprehensive examinations should continue on at least a yearly basis, and potentially more frequently when problems are suspected or known to be present. Without regular reexamination, these individuals often fall through the cracks and endure permanent loss of

BOX 23.3 Indicators for Lower Limb Orthoses

Foot Orthoses and Supramalleolar Orthoses

Advantages

Permits full active dorsiflexion and plantar flexion
Maintains the subtalar joint in neutral alignment
Provides medial and lateral ankle stability

Motor Function

S1 to "no loss"
Must have adequate toe clearance and sufficient gastrocnemius/soleus strength to provide adequate push-off and decelerate forward movement of tibia

Indications

Unequal weight distribution, resulting in skin breakdown, foot deformities, or abnormal shoe wear
Medial and lateral ankle instability, resulting in balance problems, especially difficulty traversing uneven terrain
Poor alignment of the subtalar joint, forefoot, or rearfoot

Ankle-Foot Orthoses (Standard AFOs and Ground-Reaction Force AFOs)

Advantages

In general, the ground-reaction force (see Fig. 23.6) is advantageous for this population. The proximal trim line can be extended medially to control genu valgus. The ground-reaction force AFO also facilitates push-off and knee extension during the stance phase and improves static standing balance. The ground-reaction force AFO has a patellar tendon-bearing design. This design distributes pressure across a broad area, preventing skin breakdown and lower leg deformities, which are common when traditional AFO anterior straps have been worn for an extended period of time. If traditional AFOs are used in this population, the anterior straps must be well padded.

Motor Function

L4 to S1
Weak or absent ankle musculature
Knee extensors at least grade 4

BOX 23.3 Indicators for Lower Limb Orthoses—cont'd

Indications

Medial and lateral instability of knee or ankle
Insufficient knee extension moment (ground-reaction force AFO)
Lack of or ineffective push-off
Inadequate toe clearance
Crouched gait pattern

Knee-Ankle-Foot Orthoses

Advantages

If unable to maintain upright posture because of joint contractures or muscle weakness, or if the knee joints are unstable, KAFOs are indicated.
If the knee joint is primarily required for medial and lateral stability so the knee joint is unlocked, or if there is potential to progress to ambulation with the knee joints unlocked, it is best to incorporate the ground-reaction force AFO component into the KAFO design to provide the advantages listed earlier in the AFO section.

Motor Function

L3 to L4
Weak knee musculature
Absent ankle musculature

Indications

Medial and lateral instability of knee
Weak quadriceps (grade 4 or less)

Reciprocating Gait Orthoses or Hip-Knee-Ankle-Foot Orthoses

Advantages

The reciprocating gait orthosis (RGO) cable system facilitates hip extension during stance phase and hip flexion during swing phase by coupling flexion of one hip with extension of the opposite hip.
Release of both cables permits hip flexion when sitting.
The RGO reduces the energy required for ambulation compared with walking with traditional KAFOs.

Motor Function

L1 to L3 (some centers also advocate for thoracic level)
Weak hip flexion is required to effectively operate the cables.

Indications

Unable to maintain an upright posture with the hip joints extended
RGO is indicated to facilitate hip extension and swing phase.

Thoracic-Hip-Knee-Ankle-Foot Orthoses, Parapodiums, or Verlos

Advantages

Upright positioning for high-level lesions
Generally for exercise walking only

Motor Function

Thoracic to L2. Walking is usually nonfunctional for these high-level lesions because of the high energy expenditure required and the slow, cumbersome walking pace.

Indications

Limited distance mobility
Upright positioning
"Exercise" walking

BOX 23.4 Lower Limb Orthotic Specifications, Objectives, and Examination Criteria

Orthotic Specifications

Shoe Heel Height

A low heel (¼ to ½ inch) may improve balance by shifting the center of gravity forward in a person with a calcaneal weight-bearing position.
A low heel (¼ to ½ inch) may decrease knee hyperextension by shifting the center of gravity forward.
A high heel shifts the center of gravity too far forward and causes balance problems in a person with weak plantar flexors.
A high heel may result in increased hip and knee flexion, combined with an increased lordosis or swayback posture.

Ankle Angle

Ideally molded or set in 5° plantar flexion with a rigid anterior and posterior stop to reduce energy requirements and to increase the knee extension moment as long as toe clearance is adequate and the knee does not hyperextend. If foot clearance is a problem, set angle more acutely, no higher than neutral, at the minimum angle required to clear the foot during swing phase. Plastic orthoses must enclose the malleoli to effectively resist dorsiflexion and provide a rigid anterior stop.[100]
Do not set ankle angle more acutely than a neutral angle unless trying to control a knee hyperextension problem because the energy expenditure will increase.

Keel

Generally, keel should be rigid to the distal aspect of the metatarsal heads (to decrease energy expenditure by providing a longer lever). The plastic should extend to the end of the toes to maintain proper toe alignment, but it must be pulled thin distal to the metatarsal heads to provide a flexible toe break. If a flexible toe break is not provided, the knee extension moment may be excessive, resulting in knee hyperextension. The alternative is to trim the plastic at the metatarsal heads, but the toes are not adequately supported in this latter case.
Extending a rigid keel out to the end of the toes may be indicated to increase the extension moment at the knee. Do not extend the rigid lever arm to the end of the toes if it results in knee hyperextension or difficulty with balance (especially on stairs).

Plantar Aspect

Posting may be required to accommodate the hindfoot and rearfoot position so that the subtalar joint is maintained in a neutral position, yet a plantigrade position is achieved.[200]
Posting helps distribute the weight across the plantar aspect and prevents varus or valgus.

Straps

All straps should be well padded.
An instep strap angled at 45° helps hold the heel in place and prevents pistoning and friction.
KAFOs should have a three-point pressure distribution.
A combined suprapatellar and infrapatellar strap distributes the pressure best. A spider kneecap pad can also be used but results in greater shear forces through the knee joint.
An infrapatellar strap often deforms the lower leg when worn for a prolonged period of time because the pressure is not well distributed. The patellar tendon-bearing orthotic trim line is preferred in this population because the pressure is better distributed.

Orthotic Fabrication Objectives

Increase Medial and Lateral Stability

Mold in subtalar neutral position.[93,200]

Continued

BOX 23.4 Lower Limb Orthotic Specifications, Objectives, and Examination Criteria—cont'd

Proximal trim line should be sufficiently proximal and anterior to provide adequate leverage to control the ankle and to distribute pressure evenly.
Increase base of support and equalize weight-bearing forces by means of external posting.

Valgus or Pronated Foot

Post medially under first metatarsal head and medial aspect of calcaneus.
Flare posting medially to increase the base of support and to prevent deviation into valgus.

Varus or Supinated Foot

Post medially under first metatarsal head to accommodate supinated position of forefoot and equalize pressure distribution.
Zero posting under calcaneus (with lateral flare if needed) to prevent deviation into supination at heel strike.
Orthoses must sit level in shoes, and the shoes should be fastened securely so they do not slide on orthoses.

Decrease Energy Expenditure

Ankle angle ideally molded or set at 5° plantar flexion with rigid anterior stop (see ankle angle, earlier).
Distal trim line at metatarsal heads to provide a long rigid lever arm.
Provide adequate toe clearance and simulate push-off.
Plantar flexion stop, ideally set at 5° of plantar flexion if able to adequately clear toe without increasing knee flexion during swing phase (see ankle angle, earlier).
Generally a rigid dorsiflexion stop is required unless the patient has sufficient plantar flexor strength to control forward movement of tibia during stance phase.

Increase Knee Extension Moment

Ground-reaction force, patellar tendon-bearing orthosis.
Solid ankle, cushioned heel, or wedge heel anteriorly to move ground-reaction force forward at heel strike.
Rigid dorsiflexion stop set in 5° plantar flexion (see ankle angle, earlier).
Keel rigid to distal aspect of metatarsal heads to provide a long rigid lever and yet still permit a flexible toe break (see keel, earlier). An even greater extension moment can be provided by extending the rigid lever to the end of the toes. This is usually contraindicated, however, because it results in difficulties with balance (especially on stairs).

Prevent Knee Hyperextension

Prevent knee hyperextension by increasing knee flexion moment.
Flare heel posteriorly to move ground-reaction force behind knee joint axis at heel strike to produce a flexion moment.
Ankle set at neutral angle with rigid dorsiflexion and plantar flexion stop (if this does not adequately prevent knee hyperextension, the angle may need to be set more acutely, into dorsiflexion). The more acute the angle, however, the greater the energy expenditure.[93]
A low heel (¼ to ½ inch) may decrease knee hyperextension by shifting the center of gravity forward.
Keel rigid to the distal aspect of the metatarsal heads to provide a long rigid lever to decrease energy expenditure. Plastic must be pulled thin beyond this point, however, to provide a flexible toe break (do not extend the rigid keel to the end of the toes because this will increase the knee extension moment at push-off).
If knee hyperextension cannot be adequately controlled with previously described modifications, use KAFOs with knee extension stops.

Improve Pressure Distribution

Use total contact orthoses.
All straps should be well padded.
Bony prominences should be padded (e.g., malleoli, prominent naviculi, patellar tendon region).
Posting to equalize pressure distribution on foot and minimize pressure on malleoli and naviculi.
Patellar tendon-bearing orthosis distributes pressure better than a proximal strap.
KAFOs: the combination of a suprapatellar and infrapatellar strap distributes pressure most effectively.

Improve Balance

Adding a low heel (¼ to ½ inch) may improve balance by shifting the center of gravity forward in a person with a calcaneal weight-bearing position.
A high heel shifts the center of gravity too far forward and causes balance problems, particularly in a person with weak or absent plantar flexors.

Orthotic Examination Criteria

Check for pressure areas.
Heel must seat well in orthosis.
Check for rigid keel and flexible toe break.
Check knee alignment and congruency of knee joint axis.
All straps and bony prominences should be well padded.
Check medial and lateral alignment, and make sure the orthosis is posted properly with subtalar joint in neutral.
Check angle at ankle (anterior/posterior and medial/lateral).
Check anterior and posterior stops to make sure they adequately control motion, facilitate push-off, and permit toe clearance during swing phase.
Insert orthosis in shoe to check alignment. If molded properly, the orthosis should be able to balance and stand without support on a flat surface.

function that was avoidable. An unfortunate example was one of the adult study participants with a diagnosis of lipomeningocele and a neurosegmental classification of "no loss" as an adolescent. His lesion level was reclassified at an L5 level at the time of our study. His loss of neurologic function was caused by a recurrent lipoma on his spine that went undetected and was not surgically removed until permanent neurologic loss had occurred. This individual thought that because his original lesion was removed as an infant with preservation of his spinal cord function, he had no risk of future problems; therefore he did not seek medical care until neurologic loss was irreversible. Early detection of progressive muscle strength loss, scoliosis, progression of spasticity, or contractures by the physical therapist with timely referral to a physician familiar with the potential complications associated with MM, along with aggressive physical therapy to reverse lost function (see section on prevention of secondary impairments and activity limitations), can prevent this scenario. This patient's story underscores the need for all individuals with MM to be followed throughout life, even if there are seemingly no current problems or their lesion has been classified as "no loss" after surgical closure.

Typical Physical Therapy Goals and Strategies

Functional goals for adolescents and adults are based on a number of factors that have been discussed in preceding sections of this chapter. The section on outcomes and their determinants provides guidelines for outcome expectations based on neurologic system function. In general, the goal for all but the most severely involved patients is to achieve independent basic and community mobility skills. The physical therapist must,

therefore, be aware of all environments, distances, and barriers the individual is required to negotiate to adequately prepare the patient for all eventualities. Instruction in advanced community skills, along with endurance training, is often indicated. Physical and occupational therapists often need to be involved with driver's education programs and with the provision of adaptive equipment required for driving.

Goodwyn[56] expanded the Functional Activities Assessment format to include adolescent skills required for independent living. The items were selected from existing adult-oriented skill achievement tests, and normative data were studied in this population. The Assessment of Motor and Process Skills (AMPS) was also studied in a group of individuals ranging in age from 6 to 73 years old (mean = 21.3 years) and was found to be a valid assessment of ADL performance.[94] The AMPS assesses motor and process skills in terms of efficiency, effort, safety, and level of independence. The Kohlman Evaluation of Living Skills[122] is also a useful screening tool for determining independence with adult living skills such as self-care, safety, health maintenance, money management, transportation, telephone use, and work and leisure activities. For adolescents and adults, the ability to lift and carry items such as a hot dish, grocery bags, a laundry basket, and heavy household items is also important to assess. It is particularly important to observe safety issues and the use of proper body mechanics for advanced living skills. In addition, the maximum carrying distance should be determined and contrasted with functional demands. If independence and effectiveness with ADLs are limited, appropriate adaptations and interventions should be made to foster independence. Environmental adaptations or assistive devices required to perform functional tasks should be determined and specifically selected for application to social, educational, vocational, and work capacity requirements of the adolescent and adult. Vocational counseling and planning should begin early during the high school years. A social worker may need to assist the family with the transition to independent living because a mutually dependent relationship is often fostered by the intense lifelong involvement of parents and siblings in assisting the individual with MM. Recreation therapy may be used to assist with shopping for and purchasing personal items, use of public transportation, and developing appropriate adult leisure activities. Occupational therapy is useful to address advanced living skills such as cooking, cleaning, laundry, money management, and driver's training for appropriate candidates. A social worker can assist with locating accessible housing and obtaining appropriate support services for physical tasks that are too difficult for the patient. Depending on the practice setting, however, it may be necessary for the physical therapist to manage these areas. The expectation for individuals with MM who have intelligence in the normal range and sufficient motor function to care for themselves is the ability to thrive as an independent adult in our society. See Chapter 32 for more information on transition to adulthood.

Prevention of Secondary Impairments and Activity Limitations

The physical therapist plays an important role in anticipating the potential for functional loss when one of the medical complications of MM previously described increases the risk of secondary impairments. For example, when an adolescent undergoes a surgical procedure that requires extended bed rest, maintenance of muscle extensibility, joint ROM, and strength at the bedside followed by resumption of physical mobility tasks as soon as possible postoperatively can prevent long-term or permanent decline in mobility skills. Unfortunately, care providers are often not aware of these issues, and intervention is not instituted until it is too late to recover lost function. The physical therapist must serve as an advocate for the patient under these circumstances. Regular skin inspection continues to be important to monitor skin integrity. Another mechanism for preventing secondary impairments is education of patients and their parents regarding the fit, specifications, condition, and maintenance of their adaptive equipment. They should know how to monitor skin tolerance and the fit of adaptive equipment. They should also understand the rationale for equipment and design features that are recommended. Knowledgeable consumers can detect and report potential problems before they result in complications such as decubiti. They need to be aware of the potential consequences of poorly fitted equipment so that they can advocate for quality equipment. The majority of adults in our follow-up study had improperly fitted equipment or lacked equipment that was essential for optimal function. These adults were also unaware of proper equipment maintenance techniques.[72] As a result, many of them were functioning well below their capabilities and had skin breakdown, back pain, or joint pain as a result of poorly fitted orthoses or improper wheelchair design and seating.

OUTCOMES AND THEIR DETERMINANTS

Survival, disability, health, and lifestyles were investigated in a complete cohort of adults with MM in Cambridge, England.[77,138] Outcomes were investigated at age 35 for 117 individuals who were born between 1963 and 1971. Sixty-three (54%) had died, primarily the most severely affected. The mean age of the survivors was 35 years (range 32 to 38), and 39 of the 54 survivors had an IQ above 80. Sixteen could walk for community distances (50 meters or more) with or without aids. These 16 individuals all had a sensory lesion level at or below L3. Thirty had pressure sores, 30 were overweight, and only 11 were fully continent. In terms of independent living status, 22 survivors lived independently in the community, 12 lived in sheltered accommodations where help was available if required, and 20 needed daily assistance. Twenty of the survivors drove cars and another nine had given up driving. Thirteen were employed, with five of them being in wheelchairs. Seven females and two males had had a total of 13 children (none with visible MM). Hunt and colleagues[76] also reported that shunt revisions, particularly after the age of 2, were associated with poor long-term achievement in this same group of adult survivors with MM. Achievement was operationally defined according to their independent living status, employment, and use of a car. McDonnell and McCann[121] in a commentary to Hunt and associates' article reported more optimistic outcomes in terms of mobility and employment for shunt-treated survivors of MM in Belfast, Northern Ireland. Hunt[75] reported that only 50% of adults were capable of living independently based on a sample of 69, of whom 68% had normal intelligence. In a sample of 18 patients 16 to 47 years old in Japan, Oi and associates[140] reported that patients with spina bifida occulta (spinal lipoma) have a risk of neurologic deterioration whether or not they have undergone radical preventive surgery in infancy. This deterioration is primarily related to lower spinal functions, such as ambulation and bowel and bladder control, that likely result from tethered cord, reexpansion of the residual lipoma, or syringomyelia. In contrast, these

authors reported psychological problems in patients with spina bifida aperta. Padua and associates[147] reported that adolescents with MM who have relatively mild activity limitations (i.e., they are able to walk and run) but who have urologic problems need psychological support to a greater extent than adolescents with severe activity limitations and limited independence. There are many factors that contribute to the observed outcomes.

The motor function present is an important factor for predicting outcomes. Common characteristics of each lesion level are described in this section. The functional motor level does not always correspond to the anatomic lesion level because of individual variations in nerve root innervation of muscles. The information presented here is intended to serve as general guidelines for expectations at a given level of motor function. Many factors besides muscle strength influence an individual's functional potential and result in variations of performance within a given lesion level group. These factors include age, body proportions, weight, sensation, orthopedic deformities, joint contractures, spasticity, upper limb function, and cognition. The relative contribution of these factors is highly individual, and a thorough examination and follow-up of each child is necessary to maximize potential capabilities.

Thoracic Level

Individuals with thoracic level muscle function have innervation of neck, upper limb, shoulder girdle, and trunk musculature, but no volitional lower limb movements are present. Banta[10] stated that at the thoracic level the orthopedic goals are to maintain a straight spine, level pelvis, and symmetric lower limbs. Neck, upper limb, and shoulder girdle muscle groups are innervated by the C1 to T4 spinal nerves; back extensors by the C2 to L4 spinal nerves; intercostals by the thoracic nerves; and abdominals by T5 to L1. Consequently, individuals with motor function at or above T10 have strong upper limbs and upper thoracic and neck motions, but their lower trunk musculature is weak. They have difficulty with unsupported sitting balance and may have decreased respiratory function. Sliding boards may be required to perform wheelchair transfers because of the combination of poor trunk control and upper limb dyscoordination.

Individuals with motor function at T12 have strong trunk musculature and good sitting balance and may have weak hip hiking by means of the quadratus lumborum (innervated by T12 to L3). Ambulation may be attempted for exercise at this level using a parapodium; however, it is generally not an effective means of mobility.[103] A wheelchair is required for functional household and community mobility.

Children with thoracic level lesions also tend to have greater involvement of other areas of the CNS, with corresponding cognitive deficits. Consequently, even though many of these people achieve independence with basic self-care skills and mobility by late childhood, they often require a supervised living situation throughout life. They are rarely competitively employed but often participate in sheltered workshop settings or perform volunteer work.[72]

High Lumbar (L1–L2) Level

Individuals with high lumbar motor function have weak hip movements. The iliopsoas muscle is supplied by nerve roots L1 through L4, with its primary innervation at L2 and L3. The sartorius muscle is supplied by L2 and L3 and the adductors by L2 through L4. With L1 motor function, weak hip flexion may be present, and with L2 motor function the hip flexors, adductors, and rotators are grade 3 or better. According to Schafer and Dias,[162] unopposed hip flexion and adduction contractures are often present at the L2 motor level, and this muscle imbalance often results in dislocated hips. Short-distance household ambulation is possible with high lumbar innervation (L1 and L2) when body proportions are small, using KAFOs or RGOs and upper limb support. These children generally use a wheelchair for community distances. By the second decade of life, a wheelchair is typically the sole means of mobility commensurate with increased energy requirements and enlarged body proportions.[72,175]

The prognosis of children with high lumbar lesions for function and independent living as adults is similar to that of the thoracic group described earlier.[72] More individuals in this group, however, achieve independent living status (approximately 50%), but they are rarely able to maintain competitive employment as adults.

L3 Level

Individuals with L3 muscle function have strong hip flexion and adduction, weak hip rotation, and at least antigravity knee extension. The quadriceps muscle group is innervated by nerve roots L2 through L4. Children with grade 3 quadriceps strength usually require KAFOs and forearm crutches to ambulate for household and short community distances and a wheelchair for long community distances. By adulthood, most individuals with L3 level lesions are primarily wheelchair mobile.[72,178,190]

Approximately 60% of individuals with lesions at this level achieve independent living status as adults.[68] Despite their higher level of independence, only a small percentage (about 20%) actively participate in full-time competitive employment.[72]

L4 Level

At the L4 motor level, antigravity knee flexion and grade 4 ankle dorsiflexion with inversion may be present. The medial hamstrings are innervated by nerve roots L4 through S2, and the anterior tibialis is innervated primarily by L4 and L5, with some innervation from S1. An individual is considered to have L4 motor function if the medial hamstrings or anterior tibialis is at least grade 3. Calcaneal foot deformities are common at this motor level as a result of the unopposed action of the tibialis anterior muscle.[162] Knee extension is usually strong, and these individuals are generally functional ambulators with AFOs and forearm crutches. When first learning to walk, however, KAFOs, a walker, or both may be required. A wheelchair is often needed for long distances.

In the adult follow-up study that we conducted, only 20% of individuals with L4 motor function continued to ambulate as adults.[72] Many individuals stopped ambulation after their adolescent growth spurt. Others were unable to maintain ambulation because of ankle and knee valgus joint deformities and elbow and wrist pain resulting from years of weight bearing in poor alignment. To increase the likelihood of maintaining biped ambulation for individuals with L4 motor function throughout adulthood, upright posture should be emphasized when ambulating to minimize the weight-bearing stress on upper limb joints. Orthoses must be aligned properly and posted to support the ankle in a subtalar neutral position. If the ankle joint is malaligned, the knee joint position is adversely affected. It is essential to maintain the knee and ankle in neutral alignment when weight bearing. A flexed and valgus position should not be permitted. Ounpuu and associates[143] demonstrated that 30%

of the mechanical work occurs at the ankle during normal gait, underscoring the importance of controlling the ankle in order to provide proper alignment of the body to the ground reaction force. Often a patellar tendon-bearing, ground-reaction force orthotic design is optimal to protect the knee and increase the knee extension moment. The proximal medial trim line can be extended higher to provide additional medial knee support, if needed, to reduce a genu valgus deformity (see Fig. 23.4). Knee musculature should be strengthened to help maintain the knee in neutral alignment when weight bearing. Every effort should be made to progress ambulation to using AFOs and forearm crutches to allow short-distance ambulation to easily be combined with long-distance wheelchair mobility. Crutches can be transported on the wheelchair, and AFOs are optimal because, unlike KAFOs, they do not interfere with dressing or toileting and do not cause skin breakdown when sitting. The prognosis for independent living and employment is similar to that for the group with L3 lesions.

L5 Level

According to the IMSG criteria, classification of an L5 motor level is based on the presence of lateral hamstring muscles with at least grade 3 strength, and either grade 2 gluteus minimus and medius muscles (L4–S1), grade 3 posterior tibialis muscles (L5–S1), or grade 4 peroneus tertius muscles (L4–S1). Therefore an individual with an L5 motor level has at least antigravity knee flexion and weak hip extension using the hamstrings and may have weak hip abduction, as well as weak plantar flexion with inversion, strong dorsiflexion with eversion, or both. Weak toe movements may also be present. Hindfoot valgus deformities or calcaneal foot deformities are common as a result of muscle imbalance. Individuals with motor function through L5 are able to ambulate without orthoses yet require them to correct foot alignment and substitute for lack of push-off. A gluteal lurch is typically evident unless upper limb support is used. Bilateral upper limb support is usually recommended for community distances to decrease energy expenditure, decrease gluteal lurch and trunk sway, maintain symmetric alignment, protect lower limb joints, and improve safety. The need for upper limb support often becomes more apparent with increased height following growth spurts. Traversing uneven terrain is often difficult. A wheelchair may be required when there is a rapid change in body proportions (e.g., pregnancy) or for long distances on rough terrain. A bike is also useful for long community distances.

Approximately 80% of individuals with lesions at L5 and below achieve independent living status as adults.[72] About 30% are employed full time and an additional 20% part time, well below the average employment rate of the general adult population.

S1 Level

With muscle function present through S1, at least two of the following additional muscle actions are present: gastrocnemius/soleus (grade 2), gluteus medius (grade 3), or gluteus maximus (grade 2). Individuals with S1 motor function have improved hip stability and can walk without orthoses or upper limb support. A weak push-off is evident when running or climbing stairs. A mild to moderate gluteal lurch is often present. Vankoski and associates[199] documented the benefits of crutch use for this lesion level, which resulted in improved pelvis and hip kinematics during gait. Gait deviations and activity limitations are often more pronounced after the adolescent growth spurt. The toe musculature is generally strong. Foot deformities are less common at this level, but foot orthoses or AFOs may be required to improve lower limb alignment and permit muscle groups to function at a more optimal length. Medial and lateral stability at the ankle are required for adequate function of the plantar flexor muscles during push-off.[98]

S2, S2–S3, and "No Loss" Levels

Motor function is classified at the S2 level if the plantar flexor muscles are at least grade 3 and the gluteals grade 4. The only obvious gait abnormality present at this level is generally a decreased push-off and stride length when walking rapidly or running as a result of the decreased strength of the plantar flexor muscles. If all lower limb muscle groups have grade 5 strength except for one or two groups with grade 4 strength, the motor level is classified as S2–S3 according to the IMSG criteria. The term "no loss" is used if the bowel and bladder function normally and lower limb strength is judged to be normal through manual muscle testing. Functional deficits may be present, however, for individuals classified as having no loss. Foot orthoses are often used to maintain the ankle in the subtalar neutral position and optimize ankle muscle function by maintaining optimal muscle length.

EXAMINATION, EVALUATION, AND DIRECT INTERVENTIONS FOR MUSCULOSKELETAL ISSUES, MOBILITY, AND FUNCTIONAL SKILLS

There are three primary reasons for evaluating the individual with MM: (1) to define an individual's current status so that appropriate program planning can occur, (2) to identify the potential for developing secondary impairments so that preventive measures can be implemented, and (3) to monitor changes in status that could indicate progressive neurologic dysfunction. Because of the complexity of problems associated with MM, numerous dimensions of disability must be assessed by various disciplines. The physical therapist provides essential information to other team members for program planning and to monitor status. Careful documentation is important for communication among team members and for serial comparisons over time. General examination and intervention strategies will be discussed in this section. Considerations that are specific to certain age categories are discussed in the section on age-specific examination and physical therapy interventions.

Examination Strategies

The tests and measures typically used by physical therapists include ROM, muscle extensibility, joint alignment or orthopedic deformities, muscle tone, muscle strength and endurance, sensation, posture, motor development, ADLs, mobility skills, equipment needs, and environmental accessibility. It is important to follow standardized procedures, when available, that have good reliability and validity to permit comparison within and between individuals.[71,185,186] (Refer to Fig. 23.7 Functional Activities Assessment for ADL performance ranges of children with MM). If more than one measurement method exists (e.g., hip extension ROM), the specific method employed should be documented and used consistently. Comprehensive examinations should be conducted at regular intervals throughout the life span on all individuals with MM. In addition, to avoid potential biases it is recommended

that therapists remain blind to previous results of the more subjective measures (e.g., manual muscle testing scores or gait deviations) until the examination is complete. Videos and photographs are often useful adjuncts to clinical examination of gait, joint deformities, and posture. These visual records provide an excellent baseline for comparison purposes if deterioration in status is suspected. It is beneficial to conduct examination of activities that are influenced by environmental or endurance factors (e.g., wheelchair mobility, gait, or ADLs) in more natural settings.

The IMSG recommends a comprehensive, multidisciplinary assessment for all individuals with MM, regardless of functional level, because they all are at risk for progressive neurologic dysfunction, as discussed earlier. The following examination intervals are recommended: newborn preoperatively, newborn postoperatively, 6 months, 12 months, 18 months, 24 months, and annually thereafter, continuing through adulthood.[174] Annual examinations are suggested to occur around an individual's birth date so that they are not forgotten. ROM, muscle extensibility, strength, endurance, coordination, and functional parameters should be monitored more closely during periods of rapid growth, when individuals with MM are at increased risk for loss of function. Family members and caregivers should be educated regarding symptoms of neurologic loss to help with monitoring. Preintervention and postintervention measurements should be obtained for individuals undergoing surgery or other therapeutic procedures. More frequent evaluation of specific goal attainment is indicated for individuals receiving ongoing therapeutic intervention. Mobility and independence with ADLs should be assessed when body proportions or environmental demands change to determine if the individual has the strength, endurance, coordination, and adaptive equipment required to function effectively.

Individuals with MM should be examined on at least a yearly basis by multiple disciplines at a comprehensive care center. It is important, however, for comprehensive care centers and local school and intervention settings to coordinate their examinations, goals, and intervention programs to avoid duplication of effort and to ensure appropriate prioritization of intervention goals. The use of the PDMS facilitates communication and coordination of services between team members. The School Needs Identification and Action Forms[158] also provide a useful format for identifying impairments, academic and activity limitations, and the remedial action recommended. The areas assessed by the school needs forms include health-related services required, physical intervention instructions, accessibility, safety and fire drills, preparation for school entry, educational rights and related services, academic difficulties, psychological evaluation, perceptuomotor deficits, visuoperceptual deficits, self-help skills, social acceptance, social and emotional issues, parent and school relationships, transitional services, and other needs. The School Function Assessment (SFA) measures needs and abilities during school-related functional tasks for kindergarten through sixth-grade students.[30] The SFA consists of three sections: (1) participation in a variety of school activity settings, (2) task supports required (physical and cognitive/behavioral assistance and adaptations), and (3) activity performance in school-related functional activities (e.g., using materials, following rules, and communicating needs). The School Function Assessment Technical Report available at www.pearsonassessments.com/NR/rdonlyres/D50E4125-86EE-43BE-8001-2A4001B603DF/0/SFA_TR_Web.pdf describes the standardization sample of 676 students, including 363 students with special needs from 112 sites in 40 US states and Puerto Rico.

Intervention Strategies

Once primary and secondary impairments, activity limitations, and participation restrictions are identified through a comprehensive examination and evaluation, the functional significance must be determined to plan appropriate intervention strategies. Intervention of an impairment is indicated if it currently interferes with function or if the deficit can progress to a point where it may negatively affect future function. Intervention is also indicated if the efficiency, effectiveness, or safety of performance can be improved. Strength, endurance, and efficiency of performing tasks should be emphasized. Weight-bearing joints must be protected to prevent early onset of osteoarthritis and pain and to prolong mobility. In addition, the most efficient and effective means of mobility for a given environment should be determined. Goal setting for intervention must consider the impact of the multiple impairments discussed earlier on functional performance expectations. The cognitive, social, and behavioral issues discussed in the impairments section should also be considered.

Fay and associates[49] recommended three specific intervention approaches for developmental delays in this population. The first is developmental programming in which children are encouraged by parents, teachers, and therapists with a "high dose" of normal developmental activities in "at-risk" areas. The philosophy behind this approach is that supplemental early emphasis and practice in potential problem areas will minimize later deficits. These early intervention programs are often initiated for children with MM before measurable delays are identified. The second approach, remediation, is implemented once problem areas are clearly identified. This approach consists of repeating a set of graded tasks in the domain of concern. Improved performance through practice theoretically carries over into functional activities. The third approach is teaching compensatory skills. Compensation is often implemented when the other two approaches have not produced sufficient results or when the child is older or more severely impaired. This intervention approach involves identifying and developing strategies to help the child become as independent as possible or providing adaptive equipment to compensate for underlying problems and minimize disability in daily life.

Specific Examination and Intervention Strategies

Specific examination and intervention strategies as they pertain to strength, mobility, gait, and equipment issues are highlighted in this section because of the magnitude of the impact of these factors on function in this population, regardless of age or lesion level. Suggestions for impairment-specific parameters (e.g., ROM, orthopedic deformities, and sensation) were discussed in the section on impairments. Developmental issues were discussed in the section on age-specific examination and physical therapy interventions.

Strength

Upper limb, neck, and trunk musculature should be screened for weakness. If evidence of weakness exists, a more specific examination of strength should be conducted. For individuals with thoracic or high lumbar level involvement, it is important

to palpate trunk musculature to determine which portions of muscle groups are functioning. Dynamometer values of grip and pinch strength should also be obtained. Kilburn and associates[90] suggested that grip strength measurement can be a sensitive gauge of progressive neurologic dysfunction. Level[102] provided a standardized protocol for obtaining grip strength measurements and normative values for children.

Specific testing of isolated motions of lower limb muscles is essential to determine if individual muscles are functioning. Standardized test protocols should be used.[73,82,88] It is essential to detect changes in strength in this population as soon as possible because loss of strength can be a sign of progressive neurologic dysfunction. As a result, we recommend using quantitative strength measurements in conjunction with traditional manual muscle testing techniques. It is also important to distinguish between reflexive and voluntary movements. Reflexive movements should be documented, but they should not be considered when determining motor lesion levels.

Manual muscle testing is the most common method used to assess strength in this population because of its adaptability in a typical clinic setting. Manual muscle testing is the method of choice for screening muscle strength to determine the presence of volitional activity in specific muscles and to determine whether an individual muscle's function varies throughout the ROM. There are several limitations to relying only on manual muscle testing scores for serially monitoring strength, as discussed in Chapter 5.

Manual muscle testing has limited interrater and test-retest reliability.[65] Manual muscle test scores must change more than one full grade to reliably indicate that a true change in strength has occurred.[62] In addition, manual muscle testing has poor concurrent validity compared with more quantitative measures. Several studies have demonstrated that deficits in strength exceeding 50% are not detected by manual muscle testing.[2,3,20,58,127] Agre and colleagues[2] examined this issue in 33 adolescents with MM. Individuals who had been classified as having "no motor deficits" by means of manual muscle testing actually had strength deficits compared with normative data. These deficits were 40% for the hip extensor and 60% for the knee extensor muscles. The lack of concurrent validity of manual muscle testing compared with quantitative measurements demonstrates that the sensitivity of manual muscle testing in detecting weakness is limited and is inadequate for detecting early strength loss in individuals with MM.

The predictive validity of manual muscle testing has been examined in two studies on children with MM. Murdoch[135] examined the predictive validity of neonatal manual muscle testing examinations using a truncated 3-point scale. The correlation between muscle power of the newborn and subsequent mobility of the child at age 3 to 8 years was "very poor." In contrast, McDonald and associates[119] examined the predictive validity of manual muscle testing for individual muscle groups on 825 children with MM using the complete 0- to 5-point grading scale. Predictive validity of manual muscle testing generally increased from birth to age 5. The probability that a given manual muscle test score precisely predicted future scores varied with age and the particular muscle group tested. These probabilities ranged from 23% to 68% for newborns and from 54% to 87% for older children. The probability that a single test score predicted future strength within ±1 manual muscle test grade, however, was considerably higher, ranging from 70% to 86% for newborns and from 87% to 97% for older children. These results indicate that manual muscle testing is useful for predicting future muscle function within one manual muscle test grade. Strength test results obtained in infancy using the complete manual muscle test scale, therefore, appear to provide useful information for prognosis and for planning the course of intervention.

The limited reliability and concurrent validity of manual muscle testing indicates that it is not the method of choice for monitoring changes in strength over time. In contrast, strength testing using handheld instruments has been found to be a reliable and sensitive method for assessing strength in children and adolescents with MM. Intraclass interrater and test-retest correlation coefficients using this technique ranged from 0.73 to 0.99.[47,65] Other authors report good to high levels of reliability when testing the strength of other populations of children and adolescents with handheld instrumentation.[51,67,69,74,79,123,191] Several portable, handheld instruments are available for use in conjunction with manual muscle testing.[69] The advantages of these tools over nonportable instruments are that they are easily applied in typical clinic settings and can be used with standard manual muscle testing techniques to obtain objective force readings from most muscle groups.

It is best to obtain three myometry trials and report the average score because the mean is more stable over time and between raters.[60,65] Torque values should be reported (force times lever arm length) to permit comparison over time, regardless of changing body proportions, at least until skeletal maturity has been attained. Torque values also permit direct comparison of force production capabilities between individuals with different body proportions. Standardized testing techniques must be implemented when assessing strength with handheld instruments to ensure the consistency of measurements. Many factors influence test results and must be controlled for when testing, including test positions, instructions and commands provided, use of reinforcement and feedback, application of resistance, the type of contraction, and the examiner's body mechanics. For more information regarding techniques used in testing with handheld instruments, see Hinderer and Hinderer.[69]

Several factors should be considered when testing the muscle strength of children with MM, including age, developmental level, cognitive level, ability to follow directions, attention span, motivation, motor planning skills, sensation, and proprioception. The examiner must carefully watch for muscle substitutions. This is particularly challenging in the MM population because of altered angles of pull from orthopedic deformities. It is often difficult for multijoint muscles such as the hamstrings to initiate motions. Any differences in function between end-range and midrange positions should be noted. Special considerations when testing infants and young children are discussed in the section on age-specific examination and physical therapy interventions.

As discussed in the impairments section, several CNS complications can account for loss of muscle function in this population, necessitating serial strength testing for early detection. There are many factors that can result in normal variations in strength, however, that should also be considered when interpreting test results. These factors include changes in body proportions, hormonal influences, motor learning, illness, injury, surgery, immobilization, physical or psychological fatigue, the prior state of activity, seasonal variations, temporal factors, motivation, cooperation, and comprehension. Discussion of

the specific influences of these factors is beyond the scope of this chapter. For further information regarding the impact of these factors on force production, see Hinderer and Hinderer.[69] Because of the multiple factors that can influence force production, it is important to repeat the testing at more frequent intervals, if strength loss is suspected, to determine whether consistent test results are obtained. Several variables should be considered when interpreting muscle test results, including the reliability and standard error of measurement of the testing method used, the concurrent and predictive validity of test results, and factors that can account for fluctuations in strength.[69]

Static strength measurements should be correlated with functional measures to observe the effects of fatigue and to determine the effect of reduced strength and limited endurance on function. Individuals with neurogenic muscle weakness may have a higher degree of variability in force production as a result of the lower threshold of fatigue and slower rate of recovery of weak musculature. Local muscle endurance appears to be deficient in some neuromuscular diseases.[12,129] Although this issue has not been specifically tested in the MM population, these results suggest that force production may be more variable in weak muscle groups of individuals with MM.

If function is present but weakness exists in muscle groups that are important for postural stability, ADLs, mobility, or balance of muscle forces around joints, strengthening exercises are indicated. The specific muscle groups to emphasize vary depending on the lesion level and functional requirements. In general, strong upper limb muscle groups are required for performing transfers, for wheelchair propulsion, and when using assistive devices to walk. Increasing the strength of trunk musculature improves sitting balance and postural stability. Increasing the strength of key lower limb muscle groups that are critical for ambulation can improve gait and can possibly minimize the need for orthoses and assistive devices. For example, increasing the quadriceps and hamstrings strength in an individual with L4 motor function may enable progression of ambulation from using KAFOs to using AFOs (see the case scenario found on Expert Consult).

Muscle groups should be strengthened within functional ROM. In addition to traditional strengthening exercises, many play activities promote strengthening.[48] Muscle reeducation techniques such as functional electrical stimulation and biofeedback are useful to teach muscles to function in new parts of the ROM. Electrical stimulation has also been found to be beneficial to increase strength and enhance functional performance in this population.[85] Strengthening programs should be implemented during periods when an individual is at risk for loss of muscle strength and endurance (e.g., after recent surgery, immobilization, illness, or bed rest) and during periods of rapid growth when individuals often lose function as a result of changes in body proportions.

Endurance activities are also important for weight control and to enhance aerobic capacity. Individuals with MM must have adequate endurance to meet the challenges of community mobility. Low-impact aerobic activities to minimize joint stress are preferable. In general, jumping activities should be avoided because joint stress is increased as a result of the inadequate deceleration provided by weak lower limb muscles. Indications for endurance training and instruction in energy conservation techniques include decreased aerobic capacity, high energy cost of mobility, and limited endurance.

Mobility

Ineffective mobility is a hallmark of MM. Effective mobility is defined as any efficient and effective means of moving about in space that enables the individual to easily traverse and explore the environment, grow and develop, and independently pursue an education, vocation, or avocation.[175] Mobility options provided should meet these criteria for all environments encountered by the individual so that lifestyle is not limited by endurance and difficulty traversing uneven terrain.

Changes in body proportions can significantly affect mobility. Mobility options, orthoses, and assistive device requirements that are ideal at one time may not be effective once body proportions, environmental demands, or both change. Consequently, the appropriateness of adaptive equipment and mobility options must be reevaluated throughout the life span. Health care providers should emphasize this point to patients to help prevent the feeling of failure if alternative mobility options are required in the future. Too often, individuals with MM grow up being praised for walking instead of using a wheelchair or for walking without assistive devices, depending on their lesion level. This emphasis gives the impression that normal biped ambulation is the only socially acceptable form of mobility. Several of the adults in our follow-up study reported that it was difficult to accept the use of a wheelchair or other assistive devices as they grew up because they felt that they were a failure or that they would disappoint their parents and health care providers.[72] It is important to emphasize that wheelchairs and other assistive devices are aids for effective mobility and that their use does not represent a failure of biped ambulation.

Bed mobility, floor mobility, wheelchair mobility, ambulation, and transfers should be assessed and compared with the requirements for independent function. Criteria for assessing mobility parameters are endurance, efficiency, effectiveness, safety, degree of independence, and accessibility. Objective information regarding these parameters is often helpful to convince children and their parents that alternative methods of mobility should be considered. Efficiency can be estimated by measuring the time required to complete a task. Energy expenditure can be estimated by measuring heart rate (HR). Regression equations have been determined for this population to equate heart rate with the energy expenditure required for a given task.[205] The regression equations for energy expenditure and efficiency of this population are as follows:

$$\text{Energy cost } (\text{ml } O_2/\text{kg min}) = 0.073\ (\text{HR}) + 6.119$$

$$\text{Energy efficiency } (\text{ml } O_2/\text{kg meter}) = 0.006\ (\text{HR}) - 0.313$$

Criteria for determining the most practical and effective mode of mobility for household and community distances are provided in Box 23.2. Standardized tests that are useful for assessing mobility in the population with lower level lesions are discussed in Chapter 2. In addition, the Timed Test of Patient Mobility[83] is beneficial for assessing the efficiency of mobility because the time required to perform bed mobility, transfers, wheelchair mobility, and gait mobility tasks is documented. Normative data are available for comparison purposes.[83] We suggest augmenting the efficiency time score of the Timed Test of Patient Mobility with a rating scale for the level of independence, safety, practicality, and assistive devices required for each task.[72] Other tests that are

specific to function in wheelchairs include the Functional Task Performance Wheelchair Assessment of positioning, reaching, and driving tasks[36] and the Seated Postural Control Measure for sitting posture and functional movements.[50]

Gait

Delays in achieving ambulation can be expected for all children with MM, including those with sacral level lesions, and children with high level lesions may cease walking after a period of 3 to 4 years of biped ambulation.[203] Thorough examination and documentation of gait status are essential to monitor functional motor status and to watch for signs of progressive neurologic dysfunction. Patients or their parents typically notice changes in gait patterns and walking endurance before they notice increased muscle weakness. Careful gait observation is also needed to determine the most appropriate orthoses and assistive devices. Examination of orthoses and assistive devices for wear patterns helps determine if they are being used on a regular basis or just to perform in the clinic setting. Gait should be assessed in a natural environment on a variety of walking surfaces. Patients should be observed walking for typical household and community distances to determine the effects of fatigue. The 10-meter walk test for gait velocity and the 6-minute walk test for endurance are standardized tests that are useful for assessing upright mobility in clients with MM. More information about these tests is provided in Chapter 2 of this text-book.

All too often, decisions regarding gait problems and the need for orthoses and assistive devices are made by observing short-distance ambulation on a smooth clinic floor. Performance in the home or community environment may be vastly different from in a clinic situation, especially when walking around a number of obstacles, when in congested areas, when traversing uneven terrain, or with inclement weather. The impact of these factors must be considered when making recommendations.

Requirements for orthoses and ambulatory aids should be documented. Gait deviations should be closely observed and recorded. If possible, gait deviations and efficiency parameters both with and without orthoses and assistive devices should be observed. Typical gait parameters assessed include arm swing, trunk position and sway, pelvic tilt and rotations, compensated or uncompensated Trendelenburg position, excessive hip flexion and rotation, excessive knee flexion or hyperextension, toe clearance, foot position, push-off effectiveness, and foot progression angle.

Observational gait analysis is the technique used most commonly to assess gait in clinical settings.[95] Video analysis augments clinical observations by allowing the evaluator to observe gait multiple times at slow speeds and by providing a permanent record that is invaluable for comparison purposes if deterioration of functional status is suspected. The interrater reliability of observational analysis through videos, however, has been reported to be low to moderate.[46,95] Footprint analysis is a low-cost method of obtaining objective information regarding velocity, cadence, foot progression angle, base of support, toe clearance, stride length, and step length.[170] More sophisticated methods of objective gait analysis are described by Stout in Chapter 34, Development and Analysis of Gait (on Expert Consult).

Criteria for the effectiveness, efficiency, and safety of household and community ambulation are provided in Box 23.2. Efficiency and practicality of ambulation can be estimated by monitoring heart rate, normal and fast walking velocity, and maximum walking distance. Other time-distance variables (e.g., step and stride length, cadence, and cycle time) provide useful information regarding symmetry, stability, and function. These variables can be used for comparison purposes if they are normalized (adjusted) for stature.[156]

Time-distance variables provide information about gait symmetry by comparing right-left differences in step lengths and stance-to-swing phase ratios. Examining cadence and the percentage of time spent in the stance phase versus the swing phase provides information regarding the stability of gait. For instance, a high cadence or an imbalance in the stance versus swing phase duration may indicate instability. Parameters such as walking velocity and cadence provide information regarding the functional practicality of gait. If the velocity is too low or step rate is too high, the individual may not be able to meet environmental demands.

It is essential to normalize time-distance variables for stature to compare these parameters serially over time for a given individual or to compare between individuals of different stature (e.g., comparing with normative data). These parameters are normalized by dividing by leg length. An alternative but less precise method of normalizing time-distance parameters is to divide by height because overall height is closely correlated to individual limb lengths. If these parameters are not normalized for stature, conclusions regarding differences in function may be confounded by changes in body proportions over time.

Indications for lower limb orthoses are provided in Box 23.3. Specifications and their effect on gait are outlined in Box 23.4. Indications for gait training include when a child is first learning to walk; when there is potential for progression to a new type of orthosis or upper limb aid; for progression to a more efficient gait pattern (e.g., from a four-point to a two-point alternative gait); when there is potential for improving gait (e.g., crouched gait pattern, excessive foot progression angle); to improve safety and confidence with advanced walking activities (e.g., walking on inclines, rough terrain, steps; learning to fall safely and stand up independently from floor; carrying and lifting objects); and to improve the efficiency and safety of gait, transfers, and intervention of aids.

Strength of the quadriceps muscles has been suggested by some authors to be the best predictor of ambulatory potential in children with MM[164,205]; others indicate that iliopsoas muscle strength is better.[118] McDonald and associates[118] examined the relationship between the patterns of strength and mobility in 291 children with MM who had received at least three serial standardized strength examinations after age 5 and who were classified for their mobility status as community ambulators, partial (household) ambulators, and nonambulators. Iliopsoas muscle strength was found to be the best predictor of ambulation. The quadriceps, anterior tibialis, and gluteal muscles also were determined to have significant importance for ambulation in these children. Grade 0 to 3 iliopsoas strength was always associated with partial or complete reliance on a wheelchair. Patients with grade 4 to 5 iliopsoas and quadriceps muscle strength were almost all community ambulators, and no members of this group were completely wheelchair dependent. Children with grade 4 to 5 gluteal and anterior tibialis muscle strength were all classified as community ambulators and did not require the use of an assistive device or orthosis.

Key muscle groups for community ambulation, listed in order of importance, are the iliopsoas, gluteus medius and maximus,

quadriceps, anterior tibialis, and hamstring muscles.[12] Specific strength of these muscles accounted for 86% of the variance in mobility status. Gluteus medius muscle strength was found to be the best predictor of requirements for aids or orthoses. In individuals with gluteus medius strength grade 2 to 3, 72.2% required aids, orthoses, or both. If activity in this muscle was absent or trace, 95.7% required aids, orthoses, or both. In contrast, if gluteus medius strength was grade 4 to 5, only 11.2% required aids, orthoses, or both. Mazur and Menelaus[117] reported that 98% of all individuals with quadriceps strength of grade 4 to 5 were at least household ambulators, with 82% being community ambulators. In contrast, for individuals with quadriceps strength of grade 3 or less, 88% were exclusive wheelchair users.

Agre and associates[2] reported that maximum walking velocity was correlated with hip and knee extensor muscle strength. They compared the energy expenditure and efficiency of ambulation in children with MM versus able-bodied peers and found that children with MM used almost twice as much energy when walking and had a 41% lower ambulation velocity. They also reported that mobility in a wheelchair was considerably more efficient than walking, approximating normal gait in terms of energy requirements. In addition, individuals classified as having "no loss" by means of manual muscle testing had a decreased walking velocity and increased energy expenditure compared with able-bodied peers.

Equipment

A wide variety of adaptive equipment typically is required for individuals with MM. Equipment needs vary considerably with level of lesion and age. Therapists must be aware of the available options and be able to select the most appropriate type of equipment for a given situation. In addition, it is important to educate parents and patients regarding the fit and appropriateness of adaptive equipment so that they can be knowledgeable consumers. It is beyond the scope of this chapter to discuss specific equipment items. See Baker and Rogosky-Grassi,[8] Knutson and Clark,[93] and Pomatto[152] for further information regarding adaptive equipment and orthoses for this population. Indications for lower limb orthotics are provided in Box 23.3. Design specifications, objectives, and considerations when assessing the components and fit of orthoses are included in Box 23.4.

Examinations of adaptive equipment and orthotics should be conducted on at least a yearly basis. Examinations should occur more often during periods of rapid growth; when environmental demands change (e.g., changing school or work settings); when there are changes in lifestyle, goals, or vocation; or when there is a change in status that may affect motor control or mobility.

SUMMARY

Few populations challenge the skill and knowledge domains of the physical therapist as extensively as individuals with MM. This discussion has highlighted the multitude and complexity of problems encountered by children and adolescents with MM. Each lesion level group has general functional expectations that help direct physical therapy goals from an early age. Although MM is a congenital-onset problem requiring intervention by the physical therapist during infancy and childhood, most of the impairments and functional deficits described in this chapter occur throughout the life span. Individuals with MM should be followed on a regular basis, even as adults, in multidisciplinary specialty clinics by care providers familiar with this population. Because the physical therapist has extended contact with these individuals from infancy through adolescence, the therapist plays an important role in screening and triaging for potential problems, in addition to more traditional physical therapy roles. The challenges and rewards of working with this population are therefore extraordinary.

Case Scenarios on Expert Consult

The cases related to this chapter present two case scenarios (Sally and Megan), along with an additional case scenario presented on video (Megan). Each of the cases illustrates several of the management principles discussed in this chapter.

Children With Autism Spectrum Disorder

Toby Long, Jamie M. Holloway

INTRODUCTION

Autism spectrum disorder (ASD) is a developmental disability that results in significant social, communication, and behavioral challenges. Data from the Centers for Disease Control and Prevention (CDC) suggest that, although an experienced professional can identify ASD by the time a child is age 2, ASD is often not diagnosed until a child is age 4 or later.[23] The cause of ASD is unknown, but suspected genetic and environmental risk factors are associated with the diagnosis. The CDC currently estimates that 1 in 68 children are diagnosed with autism.[23] Blumberg et al.,[17] however, surveyed parents regarding the ASD diagnosis, and their results indicate that the prevalence may be as high as 1 in 50. Boys are four times more likely to be diagnosed with ASD than girls.[6,22]

This chapter describes the characteristics of ASD, the diagnostic process, program planning, and evidence-based decision making for children with ASD. The chapter also emphasizes the role of the physical therapist in a comprehensive interdisciplinary team–based approach to the intervention of children and youth with ASD.

BACKGROUND INFORMATION

ETIOLOGY AND PATHOPHYSIOLOGY OF AUTISM SPECTRUM DISORDER

There is no one etiology for autism. Autism is considered a neurologically based condition, probably due to a genetic predisposition and environmental interactions. In addition to the increased incidence of children in families being diagnosed with ASD, there are also several genetic disorders associated with ASD. These include tuberous sclerosis, fragile X syndrome, chromosome 15 deletion syndromes such as Prader-Willi syndrome and Angelman syndrome, Down syndrome, moebius, and CHARGE syndrome (of the eye, heart defects, atresia of the choanae, retardation of growth and development, and ear abnormalities and deafness).[56]

Family studies have also provided information on the genetic basis for ASD. Hallmayer et al.[53] found that in a sample of 192 sets of twins in California, 77% of the identical twin boys and 31% of the fraternal twin boys had ASD. Chawarska and colleagues from the Baby Siblings Research Consortium (BSRC)[24] found that as young as 18 months of age, siblings of children diagnosed with ASD have distinct patterns of behavior that may predict the diagnosis of autism at 36 months of age. The BSRC study indicates that siblings of children with autism are 14.7 times more likely than siblings of children without autism to be diagnosed with autism at 36 months of age. The study found patterns of behavior at 18 months of age that identified the amount of risk to be diagnosed with ASD at age 36 months. Children at 18 months of age who showed poorly modulated eye contact to initiate, terminate, or regulate social interactions; the absence of giving objects to others to share; and limited use of emotional or descriptive communicative gestures other than pointing were three times more likely to be diagnosed with ASD at 36 months. Other children who showed impaired eye contact and the inability to spontaneously engage in pretend play were almost two times more likely to be diagnosed with ASD. A third group of siblings in this study demonstrated repetitive and stereotyped behaviors and rarely or never engaged in sharing behaviors, typical eye contact, and other appropriate communication behaviors. Despite being what the authors considered to be borderline at 18 months, children in this group were three times more likely to be diagnosed with ASD at 36 months than were peers who did not have siblings with ASD.

Evidence of a variety of neurologic abnormalities has been found in people with ASD. Studies suggest that *underconnectivity* in the brain leads to decreased communication between brain regions and resultant impairments.[49,61,86] Libero[71] also found significantly decreased cortical thickness, white matter connectivity, and neurochemical concentrations in the brains of adults with ASD. Evidence of inflammation in the glia of the brains of people with ASD has also been found.[52] These brain abnormalities may be associated with the motor deficits seen in children with ASD. For example, Bailey et al.[8] showed a decrease in the number of Purkinje cells in the vermis and hemispheres in the cerebellum. This may contribute to the poor coordination seen in children with ASD.[44]

Other neurologic evidence suggests that the function of mirror neurons might be altered in children with ASD. Mirror neurons are activated when people perform a task as well as when they observe a task.[41] Mirror neurons are thought to be involved in the recognition of motor tasks. Studies have suggested that the dysfunction in this system might also explain the social and cognitive impairments observed in children with ASD.[97]

Although environmental factors may interact with genes to contribute to the expression of autistic symptoms, there is little indication of what these specific environmental factors may be.[56]

DIAGNOSTIC CRITERIA ACROSS AUTISM SPECTRUM DISORDER

A diagnosis of ASD is made based on criteria listed in the *Diagnostic and Statistical Manual,* Fifth Edition (DSM-5).[34] The DSM-5 combines the criteria for autistic disorder, Asperger disorder, childhood disintegrative disorder, and pervasive developmental disorder not otherwise specified (PDD-NOS) under

the umbrella of autism. The diagnosis is based on symptoms that do the following:

- Cause functional impairment
- Are present in early childhood
- Are not better described by another condition

The criteria define the severity of ASD based on the level of support the child needs to communicate, problem solve, use movement, and use behavior above what would be expected for his or her age. The severity also reflects the impact of co-occurring conditions such as an intellectual disability or attention deficit disorder.

There are three categories of symptoms:

- Social reciprocity
- Communication intent
- Repetitive behaviors

These three categories of symptoms fall under two types of ASD:

- Social communication/interaction
- Restricted and repetitive behaviors

For a child to be diagnosed with the *social communication/interaction* type of ASD, three behaviors must be present. The child must have difficulty establishing/maintaining back and forth interactions, maintaining relationships, and communicating nonverbally. For a child to be diagnosed with the *restricted/repetitive behaviors* type of ASD, two of four behaviors must be present. The child must display stereotyped, repetitive speech, movements, or object play; excessive adherence to routines or rituals; highly restrictive, abnormal interests; or hyper/hyporeactivity to sensory input or unusual interest in sensory input. Box 24.1 delineates the criteria as defined by the DSM-5.

Several additional features associated with ASD have been identified.[6] These include the following:

- Motor deficits such as unusual gait, clumsiness, or toe-walking
- Self-injurious behavior such as head banging or biting
- Anxiety or depression

BOX 24.1 DSM-5 Criteria for the Diagnosis of Autism Spectrum Disorder

- Deficits in social communication and social interaction across multiple contexts
  - Deficits may be in social-emotional reciprocity
  - Deficits in nonverbal communication
  - Deficits in developing, maintaining, and understanding relationships
- Restricted repetitive patterns of behavior, interest, or activities; the individual must demonstrate two of the following four criteria
  - Stereotyped or repetitive motor movement, use of objects, or speech (lining up toys, echolalia, etc.)
  - Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (difficulties with transitions, greeting rituals, etc.)
  - Highly restricted, fixated interests that are abnormal in intensity or focus (perseverative interests, strong attachment to or preoccupation with unusual objects, etc.)
  - Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (adverse responses to sounds or textures, apparent indifference to pain/temperature, etc.)
- Symptoms must be present from early developmental period
- Symptoms must cause clinically significant impairment in social, occupational, or other important areas of current functioning
- Disturbances are not better explained by intellectual disability or global developmental delay

From Autism spectrum disorder. In American Psychiatric Association: Diagnostic and statistical manual of mental disorders, ed 5, Washington, DC, 2013, American Psychiatric Association.

- A large gap between intellectual ability and adaptive/self-care skills
- Significant delays or impairments in performing routine daily caregiving tasks, even if the child does not have an intellectual disability

Motor skill performance has previously been thought of as a strength for children with autism. Research, however, indicates that this area may be a strength only in comparison to other areas of difficulty or deficits. Several studies synthesized by Downey and Rapport[33] have found that children with ASD score lower on tests of fine and gross motor skill development when compared to children without autism. Current literature also shows difficulties with coordination and postural control in children with ASD.[33] Green et al.[50] found that 79% of their sample of children with ASD had motor impairments based on the *Movement Assessment Battery of Children–2,* and the scores of 10% more of their sample were in the borderline range. More recently, children with ASD demonstrated greater overall motor impairment in comparison to children who are typically developing or have a diagnosis of attention deficient disorder (ADHD).[2] Children with ASD are also likely to have more difficulty maintaining balance and catching a ball, findings that are consistent with previous reports.[2,50]

Associated Conditions

Children with autism may also have a variety of related conditions. ASD commonly co-occurs with other developmental, psychiatric, neurologic, chromosomal, and genetic diagnoses (Table 24.1). The co-occurrence of one or more non-ASD developmental diagnoses such as intellectual disability, learning disabilities, or sensory processing disorders is 83%.[70] The co-occurrence of one or more psychiatric diagnoses such as anxiety or depression is 10%.[70] It is critical for the interdisciplinary team determining the diagnosis of ASD to differentiate autism from other possible diagnoses and share with families all conditions that may be contributing to a child's behavior and characteristics. Table 24.1 describes associated conditions often seen in children with ASD.

GENERAL/MEDICAL DIAGNOSTIC PROCESS

Screening

Early identification and intervention are critical for children with autism.[128] Research indicates that early intervention positively effects developmental and functional outcome of children with ASD.[100] Screening tools are helpful to determine if a family should explore further evaluation. Studies show that routine screening increases the rates of referral to appropriate intervention services and supports.[31,51] Several tools have been developed to screen for ASD in young children. Caution should be taken when using these tools because they were developed using previous diagnostic criteria and may not accurately screen for ASD under current DSM-5 criteria. There has been little research assessing the accuracy of these screening tools against the DSM-5 criteria. However, as clinical tools to determine if referral for further testing is necessary, they still are useful. General developmental screening tools, such as the *Ages and Stages Questionnaires–3*[113] or the *Denver Developmental Screening Tool,*[48] are also used to determine if a child has generalized developmental delays. Table 24.2 describes commonly used tools developed specifically for screening children for ASD. The American Academy of Pediatrics[60] recommends screening for autism during well child checks at 18 and 24 months of age for all children, with earlier screening recommended if a specific

TABLE 24.1 Co-occurring Conditions Associated With Autism Spectrum Disorder

Condition	Characteristics/Prevalence
Attention deficit hyperactivity disorder	Children with developmentally inappropriate inattention, impulsiveness, and hyperactivity 41%–95%[4]
Communication disorders	Difficulty making intentions known through talking or other forms of expression (gestures, signs, assistive technology) or understanding the spoken or written word[3] Speech disorders: Difficulty formulating sounds Language disorders: Difficulty understanding Pragmatics: Functional and socially appropriate communication Processing disorders: Deficit of CNS processing information Production disorder: Inability to produce sounds. Includes fluency disorders such as stuttering 63.4%[70]
Epilepsy	The occurrence of two unprovoked seizures of any type 16%–44%[69]
Gastrointestinal disorders	The most common gastrointestinal symptoms reported are constipation, diarrhea, reflux, food regurgitation, food selectivity, food intolerance, or allergy 42%[129]
Intellectual disability	Children with below average intelligence (< 70) and adaptive skills 18.3%[70]
Learning disabilities	Children with at least average intelligence who have difficulty or an inability to acquire and use the academic skills of oral language, reading, written language, and math (DSM-5) 6.3%[70]
Motor planning disorders or dyspraxia	Difficulty planning, coordinating, initiating movements and actions Praxis or motor planning requires: —Ideation (generating the idea of a movement), —Motor planning (organizing the action), and —Execution (actually performing the movement) Etiology may be due to underlying sensory processing disorders or CNS inefficiency or injury Evidence indicates that dyspraxia may be a core component of autism spectrum disorder (ASD) Characteristics Difficulties with eye movements, walking, hopping, skipping Tend to bump into objects Difficulty with fine motor skills May be sensitive to touch In older children dyspraxia may contribute to: —Difficulty coordinating more sophisticated motor skills needed to play sports —Speech difficulties —Writing difficulties —Difficulty developing social relationships 34%[134]
Obesity	Body mass index > 95th% 31.8% of adolescents[93]
Psychiatric disorders (mood disorders, anxiety, depression, obsessive-compulsive disorder, schizophrenia)	Patterns of psychological or behavioral symptoms that interfere with the way a person behaves, interacts with others, and functions in daily life; anxiety is the most common and schizophrenia the least in children with ASD 10%[70]
Sensory processing disorders	Inability to organize, process sensory input from the body (visual, auditory, taste, olfactory, tactile, vestibular) and environment Three categories have been described[9,10,84,123] —Under-responsive —Over-responsive —Sensation seeking 15.7%[70]
Sleep disorders	Difficulty with sleep initiation or maintenance 50%–80%[64]
Tic disorders	0.5%[70]
Toe-walking	20.6%[12]

concern arises from the parent or pediatrician or if the child has a sibling with ASD. Physical therapists working with young children may also be involved in screening for ASD to make appropriate referral to an interdisciplinary team for diagnostic evaluation if concerns are noted. Based on screening results, recommendations for a comprehensive diagnostic examination will be made to determine eligibility and to develop a comprehensive program plan if necessary.

Diagnostic Evaluation

A diagnostic evaluation should be completed to determine an appropriate diagnosis if a screening indicates that a child may have ASD. Research shows that an accurate diagnosis can be made by 24 months of age.[31] Best practice guidelines recommend diagnostic evaluations be conducted by an interdisciplinary team. Team members may include a psychologist, psychiatrist, developmental pediatrician, neurologist, physical therapist, occupational therapist,

[a]Based on reported research.

speech-language pathologist, and sometimes a special educator. Physical therapists who are involved in the diagnostic evaluation process will conduct a comprehensive physical therapy examination of a child's sensory-motor abilities and behaviors and make recommendations for services. Physical therapists may also be involved in the administration of specific tools used to aid in the diagnosis of ASD if they have received specialized training in these tools.

The comprehensive interdisciplinary evaluation examines all areas of development including communication, speech, language, fine, gross, and perceptual motor skills, self-help skills, social-emotional, and cognitive skills. A diagnosis is made based on criteria in the DSM-5 described previously. Some tools also exist to help clinicians gather information specific to the diagnosis of ASD based on salient characteristics. As indicated under screening, these diagnostic tools were also developed prior to the publication of the DSM-5, thus caution should be used when interpreting the information in relationship to the DSM-5 diagnostic criteria. Table 24.3 provides salient information on the three most popular diagnostic tools administered by trained members of interdisciplinary teams that evaluate and serve individuals with ASD and their families. Box 24.2 delineates specific information about the *Childhood Autism Rating Scale,* Second Edition,[106] a commonly used tool to differentiate children with ASD from those with severe cognitive disabilities. All members of the team are eligible to be trained in the use of these tools, including physical therapists.

FOREGROUND INFORMATION

PHYSICAL THERAPY EXAMINATION

History

A comprehensive physical therapy examination includes obtaining a thorough history through chart review, family interviews, and interviews with other caregivers such as child care providers or teachers. Critical medical history may include history of seizures, allergies, medications, immunizations, and any significant hospitalization. Specific to children with ASD, information such as involvement in and outcomes of past therapeutic history, early intervention services, and community-based activities should be obtained. Children with ASD often participate in alternative programs such as special diets. Documenting these programs and what effects these may have had is important.

Systems Review

The physical therapy examination begins with an anatomic and physiologic review of systems. Any issues or concerns identified during systems review warrant further testing during examination of body structures and function, activity, and participation. Children with ASD often have co-occurring conditions in a variety of physiologic and psychological systems (see Table 24.1). Because ASD is a complex, multisystem condition, the physical therapy examination is most often one component of a multidisciplinary evaluation. Information specific to cognition, communication, social skills, and the like will be examined by other team members; however, the physical therapist should be aware of the child's communication and interaction style and skill level to interact effectively with him or her, thus the physical therapist should review current information in these areas. The physical therapy examination will include specific examination of the musculoskeletal, neuromuscular, and sensory-motor systems, but a brief assessment of these systems should begin during the systems review to identify initial concerns related to these systems. Older children with physical activity limitations or who are obese may identify issues in these areas that warrant further cardiovascular/pulmonary system examination assessing endurance and speed for example. A brief assessment of the integumentary system is also important

TABLE 24.3 Tools Used for the Diagnosis of Autism Spectrum Disorder

Tool	Description	Population	Format	Availability	References
Autism Diagnostic Interview-Revised (ADI-R)	Gathers information in three domains: language/communication, reciprocal social interactions, and restricted, repetitive, and stereotyped behaviors and interests	Children and adults with mental age above 2.0 years	Parent interview format that takes about 1.5 to 2.5 hours to complete	http://www.wpspublish.com/	Rutter, Le Couteur, and Lord 2003
Autism Diagnostic Observation Schedule-Revised (ADOS-2)	Consists of five modules Select module based on expressive language level and chronologic age Modules 1 through 4 provide cutoff scores that fall into classifications of autism spectrum disorder, or nonspectrum Module 1: Children 31 months and older who do not consistently use phrase speech Module 2: Children of any age who use phrase speech, but are not verbally fluent Module 3: Children who are verbally fluent and young adolescents Module 4: Older adolescents and adults who are verbally fluent The Toddler module provides "ranges of concern" to help inform clinical impressions but avoid formal classification. Children between 12 and 30 months of age who do not consistently use three or more word phrases to communicate (phrase speech)	People aged 12 months through adulthood	Direct observation of child taking about 40–60 minutes to administer	www.pearsonclinical.com	Lord, Rutter, and DiLavore et al., 2012
Childhood Autism Rating Scale 2nd Ed (CARS-2)	Rates behaviors of children to determine severity of symptoms 4-point response scale based on the frequency, intensity, peculiarity, and duration of the behavior Discriminates between children with ASD and those with severe cognitive disabilities Standard Version Rating Scale (ST) and a High-Functioning Rating Scale (HF) each contain 15 items (see Table 24.5) The test also includes a questionnaire for parents and caregivers to assess early development; social, emotional, and communication skills; repetitive behaviors; play and routines; and unusual sensory interests (see Table 24.5)	People 2 years of age through adulthood	Direct observation	http://www.wpspublish.com/	Schopler et al., 2010

BOX 24.2 CARS-2 Functional Areas of Assessment

- Relating to people
- Imitation (ST); social-emotional understanding (HF)
- Emotional response (ST); emotional expression and regulation of emotions (HF)
- Body use
- Object use (ST); object use in play (HF)
- Adaptation to change (ST); adaptation to change/restricted interests (HF)
- Visual response
- Listening response
- Taste, smell, and touch response and use
- Fear or nervousness (ST); fear or anxiety (HF)
- Verbal communication
- Nonverbal communication
- Activity level (ST); thinking/cognitive integration skills (HF)
- Level and consistency of intellectual response
- General impressions

HF, High-Functioning Rating Scale (HF); ST, Standard Version Rating Scale.

to evaluate the integrity of the child's skin and inquire about the child's history of self-injurious behavior or falls. Important findings from the review of systems will determine specific tests and measures to be performed during the physical therapy examination. Physical therapists should review, through family interview or chart review, systems such as the gastrointestinal, hearing, and vision.

Tests and Measures

Impairment

Impairments in body structure and function may impact a child's activities and participation. Measures of strength, range of motion, muscle tone, and balance described elsewhere in this text can also be used with children with ASD.

Measurement of sensory processing is an important factor in the physical therapy examination for children with autism. Sensory processing differences have been well documented in people with ASD. Prevalence rates range from 40% to > 90%.[101] Tomchek, Huebner, and Dunn[123] have provided background information on these differences documented in the basic science literature, clinical literature, and in first-person accounts. Sensory processing difficulties have been associated with social communication challenges,[130] social participation,[96] and social adaptive behaviors.[14]

The *Sensory Profile 2 (SP-2)*[36] is one of a family of tools developed to determine how people process sensory information in everyday situations. The SP-2 is a parent-report tool on children from birth through 14 years 11 months that measures sensory processing through six sensory systems: auditory, visual,

touch, movement, body position, and oral. Scores are used to develop a sensory pattern for the child. The tool also includes a planning report to link findings to participation in a variety of settings such as home and school.

Research using the Sensory Profile[35,36] has identified sensory processing dysfunction in children with autism and differentiating patterns of sensory processing in children with ASD in comparison to typically developing peers.[123] Tomchek, Huebner, and Dunn[124] conducted a large-scale study (n = 400) identifying six sensory processing factors using a short form of the Sensory Profile, which may impact development, learning, and social interaction. These include low energy/weak, tactile/movement sensitivity, taste/smell sensitivity, auditory/visual sensitivity, sensory seeking/distractibility, and hyporesponsitivity. These factors are consistent with findings from smaller-scale studies conducted since the 1990s[35,81,82] indicating that deficits in these areas limit a child's attention, contribute to distractibility, and influence arousal, all necessary components for learning. Physical therapists' knowledge in the sensory processing area and their expertise in evaluating this area are unique contributions to the team's ability to describe the child comprehensively, explain performance, and develop comprehensive, responsive, functional program plans.

Activity and Participation

Examination of a child's strengths and limitations in activities and participation during daily routines is an important part of physical therapy examination. When possible, the examination should occur during the child's natural routines to obtain a true picture of the child's abilities. The examination should focus on activities most relevant to the child and family's needs.

Tools are available to assist the physical therapist (PT) in determining developmental skill level.[13,19,46] There are also tools that assess underlying components of movement or motor skills that may be helpful for children with dyspraxia, a characteristic seen in many children with ASD.[101] Tools such as the *Test of Gross Motor Development–3;*[125] the *Movement Assessment Battery for Children–2;*[54] and the *Miller Function and Participation Scales*[83] may be helpful for children with less severe forms of ASD. As discussed earlier, Ament et al.[2] demonstrated that findings from the *Movement Assessment Battery for Children–2 (MABC-2)* differentiated children with ASD from those with ADHD and typically developing children, thus the MABC-2 may be a particularly helpful tool for physical therapists. The MABC-2 is designed to differentiate skills that require visual, temporal, and spatial characteristics of an action such as ball catching.

Emphasis on examining a child's participation has become increasingly important, and tools have become available to guide this component of a comprehensive physical therapy exam. The *Children's Assessment of Participation and Enjoyment (CAPE)* and the *Preferences for Activities of Children (PAC)*[63] are designed to measure the participation of children ages 6 to 21. These tools are self-report measures of the child's participation in recreation and leisure activities outside of required school activities. The *CAPE* measures formal and informal activities of recreational, active physical, social, skill-based, and self-improvement domains. The *PAC* has an additional dimension to examine the child's preferences. The *Preschool Activity Card Sort (PACS)*[15] was developed to examine participation for children between the ages of 3 and 6 years old. The PACS is administered through parent interview. Domains of the PACS include domestic life, self-care, mobility, education, interpersonal interactions and relationships, and community, social, and civic measurements.

McWilliam and colleagues[80] have developed a family of routines-based tools that help providers determine a young child's engagement and independence in participating in a variety of functional activities. These routines-based interviews are especially helpful for team-based decision making and outcome determination in early intervention or early childhood programming. The *School Function Assessment (SFA)*[28] is another tool that teams find helpful for determining a child's activity limitations and participation. The SFA helps school-based teams determine how participatory early elementary-aged children are in completing nonacademic skills required in classrooms and school wide. Skills include classroom activities such as computer use, mobility around the school environment, and participation in the cafeteria. See Chapter 2 for a full description of these and other tools that therapists may find helpful for assessing activity limitations and participation. Also, *Selected Assessment Tools for the Evaluation of Children with Autism Spectrum Disorder in School Based Practice,* developed by the Academy of Pediatric Physical Therapy of the American Physical Therapy Association, describes a variety of tools across domains that the PT may find helpful.

Assessment of gait is another important component of the examination, as toe-walking and other gait abnormalities are common in children with ASD. Over 20% of children with ASD walk on their tiptoes.[12] A study by Esposito et al.[42] found that toddlers with ASD showed more asymmetry in gait compared to toddlers with developmental delay and toddlers who were typically developing. Gait abnormalities such as toe-walking can lead to decreased range of motion in the ankle joint, thus, it is important to address this issue as early as possible.

Determining the child's level of independence and participation in adaptive skills such as self-care is also important. Research suggests that higher adaptive functioning is associated with positive outcomes in adults with ASD.[43] The *Pediatric Evaluation of Disability Inventory-Computer Adapted Test (PEDI-CAT)* as described in Chapter 2 is commonly used to measure capability and performance of skills in the self-care, mobility, and social function in children from birth to 21 years of age. The authors have adapted the PEDI-CAT to meet the unique characteristics of children with autism.[65] Research indicates that the PEDI-CAT (ASD) is a reliable tool that parents find easy to use. The *Vineland Adaptive Behavior Scales, Second Edition (VABS-II)*[111] measures adaptive behavior from birth through adulthood. Domains on the VABS-II include communication, daily living skills, socialization, motor skills, and an optional maladaptive behaviors index. The VABS-II is administered via parent or teacher interview. Using the daily activities, social/cognitive and responsibility domains of the PEDI-CAT (ASD), Kramer, Lilenquist, and Coster[65] found that those constructs are similar to the VABS-II in children with autism, providing validity for its use with this population. The authors also found that parents preferred the PEDI-CAT (ASD) to the VABS-II as they found the computer version easier to use, quicker, more efficient, and more strength based.

Environmental Considerations

The International Classification of Functioning, Disability and Health (ICF) model views disability and functioning as the

outcome of the interaction between the health condition and contextual factors.[133] Contextual factors include external environmental factors and internal personal factors. Environmental factors include limiting and enabling factors that are external to the individual such as social attitudes, legal policies, and architectural characteristics. The physical therapist may not be able to directly control or change the environmental factors; however, understanding the child's functioning within the context of the environment is important for establishing appropriate intervention strategies. Consideration of the environmental stimuli that are present is important when working with children with ASD. For example, a child with ASD might prefer an environment with low noise and minimal visual distractions, whereas another child may prefer a loud, busy environment. Personal factors are those that are internal to the individual, including age, coping style, and past experience. An understanding of personal factors that motivate an individual can provide an important context for meaningful interventions for the child. This is especially important when working with children with ASD who have very narrow interests. The Sensory Profile 2 is a helpful tool for linking environmental factors to a child's behavior. Although it may be challenging to achieve change in certain characteristics of a child with ASD (for example, tactile sensitivity), removing tags from clothing or avoiding certain materials may decrease the child's negative behaviors that are a preferred response to tactile stimulation.

Evaluation/Interpretation–Clinical Decision Making Regarding Need for Physical Therapy Services

Using the examination information and that obtained from team members, the physical therapist, in collaboration with the team, will design an appropriate, meaningful, functional intervention plan. The evidence-informed decision-making process considers the strengths and needs of the child and family, research evidence on intervention strategies and procedures, clinical expertise, and the home and community environment. Current practice indicates that children should be served in the natural environment by those practitioners with the skills and knowledge to best help the child and family meet their outcomes.[38,120]

Determining Outcomes and Goals

The comprehensive physical therapy examination process includes collecting information specifically to help the program planning process. Program planning includes determining outcomes and goals that promote a child's functional activity and participation, limit impairments, or prevent further disability. Depending on the physical therapy practice environment (early intervention, school based, inpatient, outpatient, etc.) these outcomes may be developed within a team process or independently. In addition to tools described previously such as the routines-based interviews, the CAPE/PAC, SFA, and so on, the *Canadian Occupational Performance Measure,*[68] goal attainment scaling,[105] and the top-down approach are useful for program planning.

The top-down approach described in Chapter 18 is very helpful for identifying possible barriers to the accomplishment of specific tasks for children with complex diagnoses such as ASD. This approach is consistent with a family-centered, team-based practice that is supported for children with disabilities, especially those being served by the part B and part C components of the Individuals with Disabilities Education Act (IDEA). The approach helps providers to link specific impairments or activity limitations to a desired outcome, easing the measurement and documentation of change toward reaching functional outcomes.

As discussed previously, decisions regarding which professionals will provide intervention to the child and how often are based on the outcomes determined by the team.

PHYSICAL THERAPY INTERVENTION

Coordination, Communication, Documentation

Physical therapists must coordinate their services with other service providers to ensure that children with ASD are receiving comprehensive services delivered in a manner that reinforces goals and outcomes across providers, builds on the child's strengths, and assists the child to bypass barriers in performing functional and meaningful skills and activities. PTs are responsible for communicating their examination findings to other team members, explaining perspective and findings, and developing with the team a comprehensive integrated service plan. Physical therapists may be required to document their services in a variety of ways depending on the payment and regulatory systems. For example, under the Infants and Toddlers Program of IDEA, physical therapists will need to document their services through the Individualized Family Service Plan (IFSP) process. They may also have to document their services as required by a third-party payment system such as Medicaid. Physical therapists often voice concern about inefficiency, duplication of documentation, and the changing requirements for documentation as children age due to the variety of regulatory and payment systems serving children with complex developmental disorders such as autism spectrum disorder.

Patient/Caregiver Instruction

Pediatric physical therapy requires ongoing collaboration with family members and other caregivers. Evidence indicates that children develop new skills, learn tasks, and participate effectively when intervention is intensive and embedded into the context of daily routines and activities. Parent and caregiver instruction should focus on strategies to promote a child's participation in daily routines and activities.

Procedural Interventions

Contemporary practice supports a team-based approach to intervention planning and service delivery that promotes active participation of children with ASD in the community. As with all children with disabilities or developmental delays, intervention for children with ASD should be evidence based and represent contemporary best practices. These practices include those that are (1) team based, in which the family is an equal, contributing member of the team; (2) delivered in what is considered the natural context for learning the skills desired; (3) based on the interests of the child; and (4) lead to mastery.[25] Information about interventions for children with ASD can be found readily in professional literature as well as in popular media.

Families receive a variety of mixed messages in regard to intervention effectiveness. Professionals should be aware that parents, who ultimately choose interventions for their children, more often base those decisions from nonmedical professionals and lay publications.[85] It is critical that professionals present intervention choices to families based on

objective, evidence-based information and help families sort through the plethora of information presented. This is particularly relevant for interventions considered complementary and alternative medicine (CAM). It is estimated that between 52% and 95% of children with ASD have used CAM.[1] Physical therapists should discuss nonjudgmentally with families the evidence for the effects of various types of CAM. A thorough summary of common CAM used by families with children with ASD has been provided by Akins, Anguskustsiri, and Hansen.[1] A unique aspect to this review, which may be particularly helpful for physical therapists, is categorization of each intervention as being safe or unsafe, and it provides an evidence-based recommendation to discourage or monitor its use.

Guiding Principles of Effective Intervention

Many interventions and programs exist for children with autism. The appendix describes a variety of programs commonly used for children with ASD. Although research is emerging to support some approaches, it is apparent that no single approach works for every child with ASD. A 2003 review of the literature on ASD-specific interventions, however, revealed six common characteristics or threads among programs that have been deemed effective for children with ASD.[57] The literature continues to support these characteristics[62,89]:

- *Early intervention*. Research supports the importance of earliest possible intervention. Children who receive intervention early tend to make changes across all domains.[128]
- *Family involvement*. Because families are the consistent and stable influence in a child's life, it is imperative that families are involved in the intervention. Family involvement includes teaching parents strategies to promote development or desired behaviors. Family involvement during an individualized family support plan (IFSP) and individualized education program (IEP) development is mandated by the Individuals with Disabilities Education Act (IDEA) and research indicates that children whose families are a part of the intervention program meet outcomes faster.[37]
- *Individualized programming*. Given that no single approach appears to benefit all children with ASD, it is recommended that interventions are individualized to meet the needs of the child with ASD and his or her family and team. Individualized programming involves consideration of the family's preferences and child expectations (for example, classroom expectations) when determining the intervention methods used and outcomes to be met. Incorporating the child's preferences and interests into the program and focusing on the child's strengths are also important factors for individualized programming.
- *Systematic intervention*. Systematic intervention refers to the systematic collection of data to identify developmental outcomes and carefully outline intervention procedures for serving children as well as evaluating the effectiveness of the procedures. Systematic intervention targets the promotion of meaningful skills and the collection of specific data to determine change over time.[55,104]
- *Structured/predictable environments*. Environments are considered structured when the activities, schedule, and environment are clear to the child, teacher, therapist, and family. Young children, including those with ASD, have been shown to prefer and thrive in structured, predictable environments.[27]
- *Functional approach to behavior*. Current research recommends using positive behavior support to identify the function of a problem behavior and teach new skills to replace the challenging behavior with a new socially appropriate skill or communication method.[30]

Evidence of Effectiveness

Two major research studies have examined the effectiveness of interventions for children with ASD. The National Standards Project,[87] in an update of its 2009 systematic review of the effectiveness research, categorized and described interventions used for children with ASD that were found to be effective for improving behavior, communication, social skills, and other skills (i.e., motor) important for participation. Teams providing services to children with ASD should be aware of these reviews to assist families in making intervention decisions. Many intervention components are described in these reviews that, although not considered traditional physical therapy techniques, are certainly strategies used within a comprehensive treatment session—for example, modeling, practice, prompting, schedules, parent training, and natural environments. Additionally, a strategy often used by physical therapists serving children with ASD, sensory integration, is categorized as an unestablished treatment. The following categories are used for describing levels of evidence:

- *Established:* These interventions have sufficient evidence to confidently determine that they produce beneficial treatment effects.
- *Emerging:* One or more studies have suggested that these interventions will produce beneficial treatment effects, but further study on effectiveness is needed.
- *Unestablished:* There is little or no evidence to support the use of these intervention strategies (Table 24.4).

The National Professional Development Center on ASD[29] reviewed the literature and found 27 intervention strategies met its criteria for evidence-based practice. This review also described strategies that are effectively incorporated into a physical therapy session. For example, in addition to the strategies described by the National Standards Project, the National Professional Development Center on ASD described task analysis, extinction, visual supports, and reinforcement as evidence based.

It is clear from these reviews that service providers should focus their attention on the components of the models rather than the model in its entirety. Physical therapists incorporate these interventions within a comprehensive physical therapy session. For example, within a preschool program a PT may lead a small motor group intervention session that promotes the acquisition of developmental motor skills. To be most effective, the PT would incorporate strategies such as modeling, extinction, peer teaching, prompting, and time delay, thereby supporting what Bhat, Landa, and Galloway[16] described as multisystem physical therapy intervention for children with ASD. Research, however, has examined the effects of specific motor interventions used to improve developmental and functional skills as well as behavior. The next section discusses two types of motor-based interventions often used by physical therapists in a comprehensive intervention approach for children with autism.

TABLE 24.4 Interventions for Children Under 22 Years of Age With Autism Spectrum Disorder (National Standards Project, 2015)

Established (n = 14)	Emerging (n = 18)	Unestablished (n = 13)
• Behavioral interventions (discrete trial training, joint attention training, reinforcement, practice, modeling, etc.) • Cognitive-behavioral intervention package • Comprehensive behavioral treatment for young children: intensive services based on principles of applied behavioral analysis • Language production training • Modeling (live or video) • Naturalistic teaching strategies: natural environment, context specific • Peer training • Parent training • Pivotal response training • Schedules • Scripting • Self-management • Social skills package: turn-taking, recognizing facial expressions, initiating interactions, etc. • Story-based intervention	• Augmentative/alternative communication devices • Developmental relationship-based treatment • Exercise • Exposure package • Functional communication training • Imitation-based intervention • Initiation training • Language training (production and understanding) • Massage therapy • Multicomponent package • Music therapy • Picture exchange communication system • Reductive package • Sign instruction • Social communication intervention • Structured teaching • Technology-based intervention • Theory of mind training	• Animal-assisted therapy • Auditory integration training • Concept mapping • Developmental, individual difference, relationship based/floor time • Facilitated communication • Gluten-free/casein-free diet • Movement-based intervention • SENSE Theatre intervention • Sensory intervention package • Shock therapy • Social behavioral learning strategy • Social cognition intervention • Social thinking intervention

Motor Specific Interventions

Exercise and physical activity. Children with autism demonstrate delays in motor skill development, impairments in motor skill performance, and recent reports indicate increasing rates of obesity[114] in addition to sensory processing difficulties, poor social skills, difficulty communicating, and behavioral challenges. Like children with other types of developmental disabilities, children with ASD participate in more sedentary activities or individual physical activities (i.e., swimming), limiting the social components of group or team-based activities.[110] Research on the effectiveness of exercise and physical activity is limited and has focused primarily on changes in behavioral or social interactions. Lang et al.[67] conducted a systematic review of 18 research studies that incorporated exercise as a treatment for children with ASD (ages 4 to 20 years). Findings indicate that exercise was effective in decreasing stereotypic behaviors, aggression, off-task behavior, and elopement and an increase in on-task behavior and improvement in motor skill acquisition. Various exercise programs were used such as weight training, aerobic exercise, bike riding, and jogging. Although promising, these results must be interpreted with caution as the number of participants across the 18 studies was low (n = 64), most of the research designs were single-subject or within-subject designs, and the programs combined exercise with other behavioral interventions such as reinforcement, prompting, and modeling, all which have been shown to be effective practices. Sowa and Meulenbroek's meta-analysis of the effects of exercise for children and adults indicated similar findings.[110] Additionally, they found that individual rather than group interventions were more successful. Again, in a one-to-one situation, other behavioral strategies may have affected the outcomes.

Because of the lack of information on the effect of exercise on cardiovascular and musculoskeletal fitness and weight management, Srinivasan, Pescatello, and Bhat[114] recommended that this is a rich opportunity for physical therapists to increase involvement. As exercise specialists, physical therapists are in the ideal position to ensure that exercise and physical activity are included in a comprehensive intervention program. It is necessary to systematically collect data and use specific measures to assess physical fitness.

One exercise that shows promise for children with autism is swimming. Physical therapists have used aquatics as a therapeutic strategy for many years, thus they are in an ideal position to design programs and determine the effectiveness of aquatic programs for children with ASD.

Although limited, research on the effectiveness of swimming on children with ASD appears promising. Pan conducted a series of experiments testing the effectiveness of swimming on improving aquatic skills,[92] physical fitness,[91,92] and social behaviors[91] in young children with ASD. The findings from his most recent study, which involved 23 children with ASD and their typically developing siblings, indicate that children with ASD and their siblings without ASD improved on a variety of parameters following a 14-week aquatic program. As compared to other studies that incorporated swimming into the methodology, this program focused on the principles of motor learning and physical fitness. All groups demonstrated improvement in swimming skills as well as physical fitness as tested by strength, flexibility, and endurance. There was no positive effect on body composition as assessed by body mass index nor were the results long lasting, however. As previously recommended, this study incorporated a goal-directed, structured curriculum that taught skills in a progressive fashion. Additionally, the program's dosage was at a level from which change was more likely to occur: frequent (twice weekly), intense (60-minute sessions), and long duration (14-week time period.) Because the positive changes were not sustained, it is recommended that providers help children adopt a healthy active lifestyle rather than only providing limited program-specific interventions. Physical therapists are ideally positioned to support families in adopting lifestyle changes and advocating for a variety of community-based

opportunities to help families and children maintain active lifestyles throughout the life span.

Sensory processing intervention. As discussed previously, many children with ASD demonstrate sensitivity to sensory input and have been identified with sensory processing dysfunction,[123] dyspraxia,[76] and incoordination.[47] A variety of strategies have been used with the intention of improving sensory-based impairments with limited, if any, effectiveness.[21,99] These ineffective strategies include (1) weighted vests and other compression garments used to provide proprioceptive input and calming to increase attention, concentration, and focus; (2) brushing and sensory diets[131] to increase tolerance to tactile input, increase focus, and improve organization; (3) fidget and fiddle toys to help sustain attention and concentration; and (4) Auditory Integration and Therapeutic Listening programs.[108]

Although sensory impairment remediation focused interventions have not been shown to be effective, Dunn and colleagues[37] have indicated that sensory-based symptomatology that prevents functional behaviors can be effectively addressed through management strategies such as adapting tasks, environments, and routines. Based on Dunn's model of sensory processing,[35] Dunn and colleagues improved parental competence and child outcomes through contextually based interventions that focused on managing the detrimental effects of sensory processing symptoms in young children with ASD.[37] Parents were provided coaching within the naturally occurring context that they identified as problematic. Contexts were primarily the home and the community. Therapists used the findings from the family-completed Sensory Profile 2[36] to determine sensory strengths or barriers to accomplishment of the functional skill desired. The therapists coached families to identify strengths-based solutions to promote outcome attainment rather than telling the family what to do. This study illustrates that using information from tools like the Sensory Profile 2 to help families identify solutions to family-identified outcomes may be an effective strategy to produce functional change.

Outcome Measures and Clinical Decision Making Regarding Response to Physical Therapy Intervention

After intervention strategies are selected and implemented, providers must continue to collect data and monitor the child's progress toward achieving the outcomes. Physical therapists conduct ongoing assessment to determine if any changes or modifications need to be made to their intervention plan. Data collection plans should consider the following:

- Use data to monitor progress and troubleshoot intervention approaches.
- Link assessment results to intervention by using them to guide and plan what skills to promote.
- Consider several intervention methods while remembering that no single approach will be right for every child. Some children may benefit from a combination of methods.
- Provide data indicating the effectiveness of the interventions used.
- Observe and record data consistently. Consider different approaches when the data indicate that the child is not progressing or succeeding.
- Collect information regarding the family's perspective on the child's success. Ask the family members how they see the child progressing.

Measuring effectiveness of intervention using goal attainment scaling (as described in Chapter 2) may be helpful when working with children who have complex needs. Schaaf, Benevides, Kelly, and Mailloux-Maggio[105] found that goal attainment scaling was useful for linking changes in function/participation to changes in sensory processing as a result of a sensory integration–based therapeutic program for children with ASD. Using goal attainment scaling, the Canadian Occupational Performance Measure, and the Parent Sense of Competence as outcome measures, Dunn and colleagues[37] found that a sensory processing–based family coaching intervention improved parent competence and children's participation in everyday activities.

Determining Intervention Dosage: Type, Intensity, and Frequency

Providers and families often have questions and concerns about the type, frequency, and intensity of services delivered. The type, frequency, and intensity of intervention should be individualized to meet the needs of the child and family. Five evidence-based factors have been identified to assist providers and families as they determine services for children with ASD[26]:

1. *Intensity.* Intensity refers to the amount of service provided and is often conceptualized by families and providers as number of hours of direct service. Research suggests that true intensity may be better measured by the child's level of *engagement* in everyday routines and activities as engagement is a powerful predictor of developmental growth.[80,116] Rather than thinking about the number of hours on a program plan (IFSP, IEP, PT Plan of Care) the team should consider whether or not the strategies and services are sufficient to influence the child's engagement across all daily routines and meet the outcomes or goals established.
2. *Fidelity of intervention delivery.* When selecting an evidence-based intervention, the team should examine what experience the provider has with the approach and whether or not the provider has a method to determine if the intervention is being correctly implemented and a plan if the outcomes are not achieved. Providers may need additional training, support, and supervision to reach the fidelity of a specific method.
3. *Social validity of outcomes.* Social validity refers to the degree in which there is an impact on the child's social participation in life when a particular outcome has been met. For example, teaching a toddler to walk up three steps in the clinic only to turn around at the top to come back down would have low social validity compared to teaching the same toddler to walk up the carpeted stairs at home to get to a playroom. In the latter case, the child's new knowledge can directly control the environment and meet immediate needs. Therefore, this activity would have high social validity.[7,88]
4. *Comprehensiveness of intervention.* Research on intervention for children with ASD suggests that progress in one developmental domain has minimal impact on other domains.[75,118] These findings have been widely replicated and strongly support a comprehensive program plan design that addresses all relevant domains of performance for the child and family.[77]

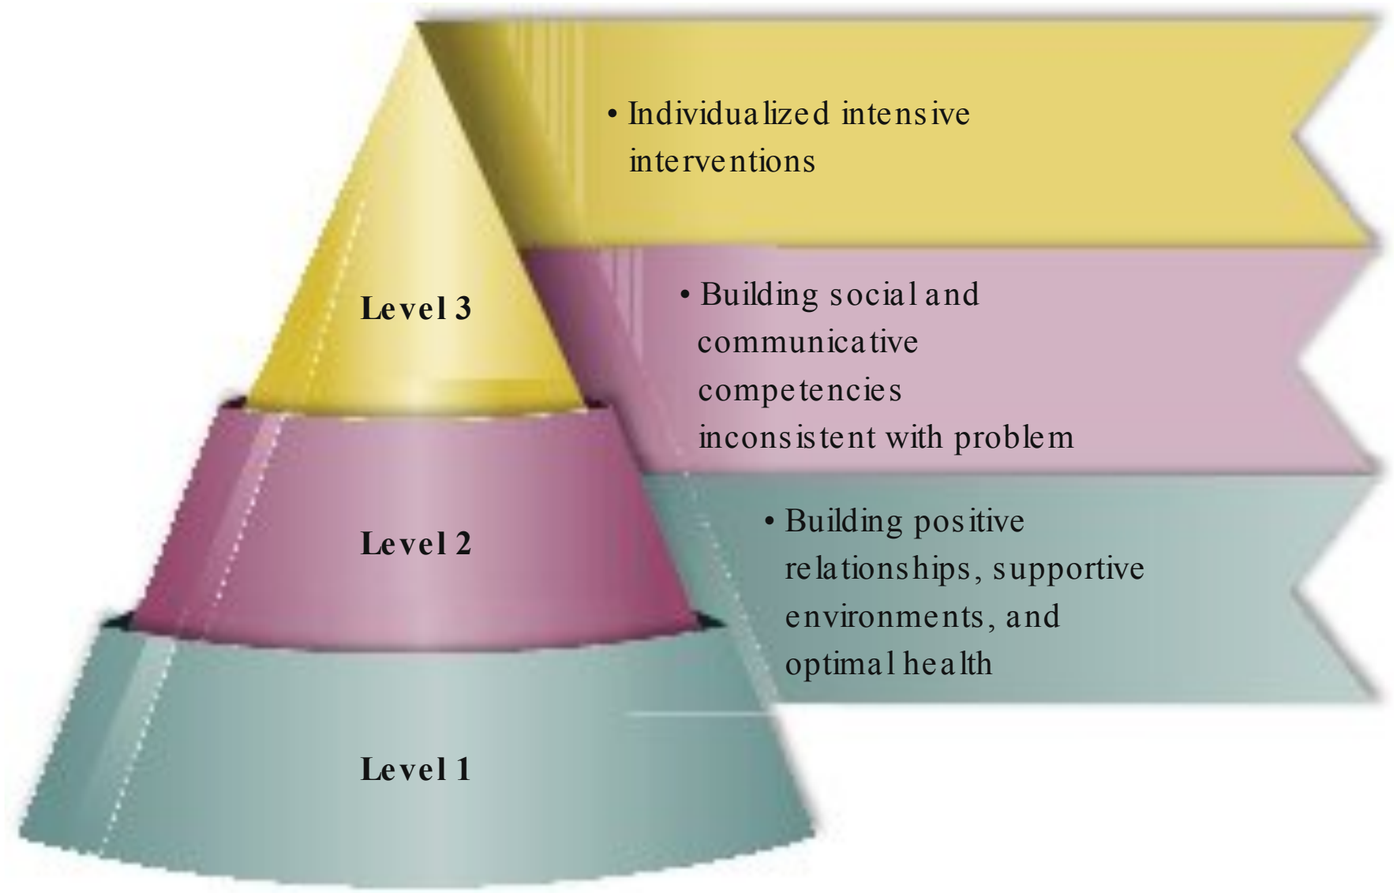

FIG. 24.1 Three-tiered intervention model.

5. *Data-based decision making.* An important component to effective intervention is to collect and monitor data to inform decision-making strategies and optimize the delivery of effective services.[59]

In addition to considering the preceding five factors, there are further considerations that impact the decisions regarding type, frequency, and intensity of services, which include the following:

- Outcomes identified by the team
- Child's age
- Total hours of engagement the family currently implements
- Developmental profile of the child
- Learning characteristics of the child
- Child's previous involvement in intervention
- Family's availability for level of service including daily routines of the child and family
- Quality and quantity of concerning behaviors

Members of the team collaborating with the family decide the type of service and the frequency and intensity of the service necessary to meet the team-developed outcomes. The team will include a variety of people depending on the age of the child and the system delivering the services, but no matter the system, the family is a team member and the family's opinions are equal to those of other team members. Team decision making requires that all members share information, and decisions are reached through consensus based on what will best meet the outcomes and expectations deemed beneficial to the child, not based on any one member's opinions, desires, or administrative constraints. The roles of team members may vary depending on the system. Ultimately, the decision regarding frequency and intensity should be based on whatever is necessary to help the child achieve the identified outcomes. It is imperative that teams identify relevant outcomes and objectively monitor the progress.

The Academy of Pediatric Physical Therapy of the American Physical Therapy Association has three key documents that may be helpful in determining the dosage of physical therapy across a variety of intervention environments school-based services, acute care, outpatient; (Academy of Pediatric Physical Therapy, 2014, 2013, 2012). Although these documents are not written specifically for children with ASD, therapists may find them helpful for decision making. Physical therapists collaborating with family members and other team members use these documents, the five evidence-based factors, and the individual family and child characteristics to design program plans and implement therapeutic strategies at a level of intensity, frequency, and duration to influence the attainment of outcomes. The dosage of therapeutic input will change over time due to the changing capacities of the child, the child and family's involvement in services and support in addition to physical therapy, and the family's constraints. Outcome-driven, family-centered physical therapy balances the shifting needs, concerns, and priorities of the family and child.

Tiered Levels of Intervention

A tiered intervention model (Fig. 24.1) for children with ASD to support developmental, functional, and social skill acquisition and to limit the impact of atypical or problematic behaviors is promoted[26,104]:

- Level 1 describes general experiences and supports that are reasonable for any child with ASD, regardless of the child's abilities.
- Level 2 involves strategies designed to enhance a child's behavioral competences and prevent problem behaviors. Level 2 is used when strategies from level 1 are insufficient to meet the child's needs.
- Level 3 strategies are used when problem behaviors have developed to the point that they have become obstacles to learning and healthy social emotional development. Level 3 consists of procedures that are most readily associated with problem behavior interventions. Table 24.5 provides a detailed explanation of the three tiers as depicted in Fig. 24.1.

The three-tiered model shows that an early emphasis on prevention has the potential to influence a child's development of more positive social behaviors and prevent the occurrence of severe problem behaviors. Additionally, the model implies that a strong foundation of level 1 and level 2 strategies will reduce the need for more labor-intensive interventions at level 3.

TABLE 24.5 Description of Tiered Levels of Intervention

Level	Description	Examples
1	• Development of positive relationships between caregivers and child • Provision of a safe, comprehensive, stimulating, and responsive environment • Procedures to ensure that the child's physical health is sound • Activities that promote the acquisition of functional movement skills	• An engaging game is initiated by adult with child and then stopped to allow the child to look or gesture to indicate the game should continue • Creating opportunities for children to walk on a variety of surfaces, play with a variety of sizes or textures of balls, or play games that require a child to start and stop quickly, hold postures, etc.
2	• Procedures designed to enhance a young child's behavioral competencies and help prevent display of problem behaviors	• Appropriate engagement strategy such as incorporating motor activities into the intervention strategies used to promote communication and language or building on the child's strengths in the motor area to promote social skills • Pivotal response training (PRT) • Incidental teaching
3	• Procedures used to improve impairments, bypass activity limitations, or to eliminate problematic behaviors	• Positive behavior support • Specific teaching of motor skills using individualized behavior management strategies • Providing sensory-motor intervention to diminish negative effects of sensory input

Lifelong Implications and the Role of Physical Therapy

Transition to Adulthood

The transition from adolescence to adulthood can be difficult for people with ASD. Unlike early intervention or school system services, adult systems often do not utilize a service coordination model, making it difficult for families to become aware of available programs and to synchronize services between programs. Young adults with ASD were 3 to 14 times more likely to be socially isolated than young adults with an intellectual disability, emotional disturbance, or learning disability.[90] Physical therapists working with adolescents with ASD should talk with the teenager and family about plans for education or employment after high school graduation and refer them to appropriate resources to help achieve their goals. Early involvement with transition and employment programs is key to a successful transition.[78]

SUMMARY

Many opportunities exist for physical therapists to help children with ASD achieve optimal outcomes throughout the life span. Physical therapists should be aware of the signs of ASD and refer the family for diagnostic evaluation as necessary. In addition, incorporating appropriate behavior strategies and current evidence-based interventions for children with ASD into physical therapy interventions is imperative to meet outcomes.

Case Scenario on Expert Consult

The case related to this chapter presents Micah, a 30-month-old child, and illustrates some of the management principles discussed in this chapter.

Behavioral

Applied Behavior Analysis (ABA)

ABA-based interventions have been shown to improve a wide variety of skills across all areas of development. Tasks are broken down into discrete trials and then coupled with reinforcement to build positive behaviors. ABA is usually administered with low adult–child ratios and can be done at home, in a classroom, or in the community. Intervention is usually intense (25–40 hours a week) and consists of individualized targeting of skills. Parents are trained to become active co-teachers. Strong evidence exists to support the use of ABA-based interventions in children over the age of 3.[112,127]

Differential Reinforcement

A form of ABA, this approach is used to increase the occurrence of desired, functional behaviors using rewards. Interfering behaviors decrease because they are not reinforced. Evidence exists to support the use of differential reinforcement in children over 4 years of age.[66]

Discrete Trial Training (DTT)

DTT is a one-on-one approach that is used to teach skills that are best taught in steps. Positive praise or rewards are used to reinforce the behavior or desired skill. Practitioners collect data to determine progress and challenges, skill acquisition, and generalization of skills. Evidence suggests that DTT is beneficial for children between 2 to 9 years of age.[45]

Schedules

Schedules can assist with managing challenging behavior by providing a visual learning strategy as well as making a routine more predictable. Schedules may consist of photographs, line drawings, three-dimensional objects, or icons. This method is flexible and may consist of a schedule for an entire day or for a specific event. They may also be used in a single place such as the classroom or may travel with a child between places within the community. Schedules are an established intervention for children ages 3 to 14.[87]

Self-Management

Self-management interventions teach children with ASD to regulate their behavior by recording when the target behavior does or does not occur. The child with ASD independently seeks or delivers reinforcers. Self-management may involve the use of checklists, visual prompts, tokens, or wrist counters. Self-management is an established intervention for children 3 to 18 years old. Studies have shown improvements in interpersonal skills and self-regulation.[87]

Communication

Augmentative and Alternative Communication (AAC)

A variety of AAC approaches are used to improve the social and communication skills of individuals with autism. Approaches such as the use of gestures, sign language, and facial expressions are classified as unaided AAC. The use of pictures, symbols, or written cues and the use of tools such as speech-generating devices are classified as aided AAC. Research suggests that speech-generating devices have been used to teach requesting skills.[126] AAC is considered an emerging intervention for children 3 to 9 years of age with ASD.[87]

Continued

Communication–cont'd

Hanen Program

The Hanen Program for Parents of Children with Autism Spectrum Disorders, also known as More Than Words, is a program for families of children with ASD who are under the age of 5. The program focuses on teaching families to become the primary facilitator of their child's communication and language development. Families using this approach maximize the child's opportunities to develop communication skills through everyday situations. Preliminary studies have shown that the More Than Words program may enhance early language skills, positively impact parent–child interactions, and increase social interaction.[119]

Picture Exchange System (PECS)

The PECS is one type of unaided AAC. This approach consists of using pictures as a means for individuals with autism to communicate. PECS is considered an emerging intervention for children 0 to 9 years of age.[87]

Educational

Learning Experiences and Alternative Program for Preschoolers and Their Parents (LEAP)

LEAP is an inclusive educational program where children with autism are included with peers who are typically developing. The model teaches the child's peers to facilitate the social and communicative behaviors of children with autism. ABA, peer-mediated instruction, incidental teaching, self-maintenance training, and parent training strategies are all incorporated into the LEAP model.[117]

Naturalistic Teaching Strategies

Naturalistic teaching strategies teach functional skills in the environment using child-directed interactions. Interventions may include modeling how to play, providing choices, encouraging conversation, or providing a stimulating environment. Naturalistic teaching is an established intervention for ASD. It has been shown to improve communication, interpersonal skills, learning readiness, and play skills.[87]

Pivotal Response Training (PRT)

PRT is an educational intervention designed to target "pivotal" behavioral areas. These areas include motivation to engage in social communication, self-management, and responsiveness to multiple cues. PRT also focuses on family involvement and intervention in the natural environment. PRT is an established intervention for children with ASD ages 3 to 9. It has been shown to improve communication, interpersonal skills, and play skills.[87]

Social Communication Emotional Regulation Transactional Supports (SCERTS)

SCERTS is a multidisciplinary, comprehensive educational model used to improve function in children with ASD. The model is used to increase participation in developmentally appropriate activities within a variety of settings by achieving "authentic progress." Authentic progress is defined as "the ability to learn and spontaneously apply functional and relevant skills in a variety of settings and with a variety of partners." The SCERTS model can be also combined with other approaches.[94]

Treatment and Education of Autistic and Related Communication-Handicapped Children (TEACCH)

TEACCH is a comprehensive educational program designed to help children develop key life skills used for independent living. TEACCH is based on the idea that all individuals with ASD have similar neuropsychological deficits as well as strengths. The model uses "structured teaching," based on understanding the learning characteristics of children with ASD and the use of visual supports to promote independence. TEACCH can be done in all settings, including the home and classroom.[121]

Relationship Based

Developmental, Individual Difference, Relationship-Based Model (DIR)

The DIRFloortime model focuses on building healthy foundations for social, emotional, and intellectual capacities rather than focusing on skills and isolated behaviors. Parents, educators, and clinicians work together to conduct a comprehensive assessment and to develop an intervention program specific to the strengths and challenges of the child with ASD. The developmental part of the model focuses on six developmental milestones (self-regulation and interest in the world; intimacy, engagement, and falling in love; two-way communication; complex communication; emotional ideas; and emotional and logical thinking) that are necessary for healthy emotional and intellectual growth. The individual differences section examines the biologic challenges that are unique to the child. These may include processing issues that are interfering with the child's ability to learn. The relationship part of the DIR model refers to learning how to develop relationships with caregivers, peers, educators, and therapists whose affect-based interactions are tailored to the child's individual differences and developmental capacities.[32]

Early Start Denver Model (ESDM)

The Early Start Denver Model focuses on increasing the child's social-emotional, cognitive, and language skills. This approach combines behavioral and relationship-based intervention with a developmental, play-based approach that is individualized and standardized. Intervention is provided in the home by trained therapists and takes place within naturally occurring routines. Parents and caregivers are involved in all aspects of this treatment approach.[40]

Joint Attention Intervention

Joint attention interventions teach a child to respond to the nonverbal social communication of others or to initiate joint attention interactions. This may include showing items to another person, following eye gaze, or pointing to objects. Joint attention intervention is an established treatment approach to ASD for children 0 to 5 years of age. Studies have shown benefits in the areas of communication and interpersonal skills.[87]

Modeling

Modeling is a type of intervention in which an adult or peer demonstrates a target behavior for an individual with ASD and encourages the individual to imitate it. This approach is often combined with other strategies such as prompting and reinforcement. This intervention may involve live or video modeling. Modeling is an established intervention for children 3 to 18 years of age with ASD. Studies have shown improvements in communication, cognitive skills, interpersonal skills, self-regulation, and personal responsibility. Decreases in problem behaviors have also been noted in research.[87]

Play and Language for Autistic Youngsters (PLAY Project)

The PLAY project is based on the principles of the DIR model and aims to help parents become their child's best PLAY partner. The program is designed to be used with children 18 months or older. PLAY is administered at least 25 hours per week and uses a one-on-one approach.[122]

Relationship Development Intervention (RDI)

RDI is a cognitive-developmental approach in which the parents or caregivers are trained to provide daily opportunities for successful functioning. The approach is taught to families by trained consultants, beginning with 6 days of intensive training and followed by weekly or biweekly meetings with reevaluation at 6 months. RDI is most appropriate for children younger than 9 years of age without intellectual disabilities.[95]

Sensory-Motor

Alert

The Alert program focuses on teaching children to recognize their body's state of alertness and how it can be regulated to be appropriate for the current situation and environment. Children learn how to self-regulate their state of arousal while parents and teachers learn how to promote these behaviors. The Alert program can be used for children of all ages with sensory processing disorders and is often done in conjunction with sensory diet.[132]

Sensory Diet

A sensory diet is an individualized activity plan designed to provide the specific sensory input a child needs during the day. The goal of a sensory diet is to help children to tolerate different sensations, regulate their alertness, increase attention span, limit sensory seeking behaviors, and handle transitions with less stress by reorganizing the nervous system.[11]

Sensory Integration

Sensory integration intervention focuses on creating an environment that challenges children to use all of their senses effectively. The goal of sensory integration therapy is to address overstimulation or understimulation from the environment. Some studies suggest sensory integration intervention may improve play performance, enhance social interaction, and decrease sensitivity.[11] Sensory integration is considered an unestablished intervention because research findings have been inconsistent or do not apply to children with ASD.[87]

Pharmacologic Interventions

These interventions are generally used in children with ASD to control or improve attention, obsessive-compulsive behaviors, tantrums, irritability, self-injury, or aggression. There are varying levels of evidence for the use and effectiveness of medications for children with ASD. Decisions to use medications are made by the family in consultation with the primary care provider, and they may be used in combination with other interventions. Interventions include the following categories of medications: anticonvulsants, antidepressants, antipsychotics, and stimulants.

Dietary Interventions

Dietary interventions for ASD include the Defeat Autism Now (DAN) protocol gluten- and casein-free diets, and omega-3 fatty acids. There is little evidence that these dietary interventions are effective in promoting skills or positively impacting behavior or symptoms for children with ASD. Families may ask questions about or have an interest in trying these interventions. It is important to have an open discussion about the use of these interventions, the minimal evidence to support them, and the benefits, risks, and costs that may be associated with their use for their individual child. Families should consult their health care providers before beginning any dietary intervention.

Children Requiring Long-Term Mechanical Ventilation

Helene M. Dumas, M. Kathleen Kelly

Advances in medicine and biomedical technologies have improved the survival of children with complex health care needs, in particular those who require prolonged mechanical ventilation. Mechanical ventilation (MV) is a life-sustaining form of medical technology that either substitutes for or assists a child's respiratory efforts. Children require MV as a treatment modality because of underlying disease processes resulting in respiratory insufficiency. By definition, an individual is considered to be a *long-term* ventilator user if MV is required for more than 21 days.[90] Although the degree of support and care varies from child to child, each child dependent on long-term MV requires high-cost care that demands sophisticated equipment and round-the-clock monitoring.

The child with ventilator dependence represents a unique challenge for all health care professionals, as providers have moved beyond the goal of increasing survival rates and are now identifying evidence-informed practices that result in optimal quality-of-life outcomes. For the child dependent on long-term MV, goals include minimizing impairments, reducing the incidence of activity limitations, and maximizing participation in home, school, and the community.[52] The role of the pediatric physical therapist is an important one in addressing these aims. Children dependent on MV may be seen by physical therapists in a hospital-based setting such as a neonatal or pediatric intensive care unit (NICU or PICU), in a tertiary care hospital, or in a postacute care rehabilitation facility. Children dependent on MV may also be seen by a physical therapist in the community in a public or private school, a medical day care, a home- or center-based early intervention program, or at home.

This chapter presents a framework for physical therapist examination, intervention, and outcomes for children dependent on long-term MV. The pathophysiologic processes associated with chronic respiratory failure are described, as are the common modes of ventilatory support.

INCIDENCE

Although children dependent on long-term MV are a small percentage of the overall group of children with medical complexity, the number continues to increase as a result of continuing advances in medical care and improved technology.[49,60,88] From 2000 to 2006, there was a 55% increase in the number of hospital discharges for children dependent on mechanical ventilation.[4] Estimates indicate that in the state of Utah, the number of children using MV at home increased by 33% from 1996 to 2004.[26] In Indiana, the incidence of children with chronic respiratory failure secondary to bronchopulmonary dysplasia (BPD) and dependent on MV at home was 1.23 per 100,000 live births in1984 and increased to 4.77 per 100,000 live births in 2010. In Massachusetts, the number of children dependent on MV has increased nearly threefold from an estimated 70 children in 1990 to 197 in 2005.[27] In 2012, it was estimated that 8000 children in the United States are dependent on MV and live at home.[8] This steadily growing prevalence has also been established outside the United States.[31,49,60,70,88]

The introduction of safe and portable respiratory equipment for home care use and the presumption of an overall reduced cost of care have added to the positive expectations of care for children at home on a ventilator in various geographic regions.[15,20] Geographic differences in the prevalence of children with ventilator dependence may exist, however, as a result of differing medical practices, parental expectations of long-term survival, and the expectation of being able to care for a child on a ventilator at home.[3,13,15,26,27,88] Unfortunately, no central tracking system exists for documenting ventilator use, outcomes of care, or care settings for children dependent on long-term MV.[27]

The highest percentage of children requiring MV is no longer due to the chronic lung disease associated with premature birth but rather is the result of congenital and neurologic disorders and neuromuscular diseases.[13,27,31,69] This shift is of particular importance to physical therapists because children with congenital, neurologic, and neuromuscular diagnoses are common diagnostic groups referred to physical therapists, and it is thus increasingly more likely that physical therapists will encounter a child who is dependent on MV. In a study of children requiring MV and admitted to one of six inpatient postacute hospitals in the northeastern United States, 83% received rehabilitation services during their hospitalization, and 50% of those children discharged using ventilators required rehabilitation services following discharge from the hospital.[59]

CHRONIC RESPIRATORY FAILURE

The need for long-term MV is due to ongoing impaired respiratory function. Adequate respiratory function requires the effective exchange of oxygen and carbon dioxide with an organ for gas exchange (the lungs), a "pump" mechanism (the rib cage, diaphragm, and external intercostals for inspiration and the rectus abdominis, internal intercostals, and accessory muscles for nonpassive expiration), and the neural control centers for breathing (involuntary-medulla and pons and voluntary-cerebral cortex). Under normal conditions, an individual's respiratory function adapts to satisfy the increased metabolic needs that occur during exercise, hyperthermia, or other demands, but when these systems are unable to deliver oxygen and remove carbon dioxide from the pulmonary circulation, respiratory failure ensues and gas exchange is impaired.[55,66,85]

Chronic respiratory failure and dependence on technology characterize the health condition of children requiring long-term ventilator assistance rather than the medical or rehabilitation diagnosis. Acute respiratory failure may develop in minutes or hours, whereas chronic respiratory failure develops over several days or weeks (Box 25.1). Chronic respiratory failure is the result of an uncorrectable imbalance in the respiratory system in which a failure of the exchange of oxygen and carbon dioxide occurs within the alveoli, along with failure of the muscles required to expand the lungs or failure of the brain centers controlling respiration. In this situation, ventilatory muscle power and central respiratory drive are inadequate to overcome the respiratory load. Regardless of the etiology, there is a need to balance the medical, developmental, and psychological needs of these children.[66,67,85]

Generally, the causes of chronic respiratory insufficiency in children have been grouped into the following categories: (1) conditions that cause *central dysregulation of breathing* (e.g., ischemic encephalopathy, traumatic brain injury, spinal cord injury), (2) conditions that affect the *lungs, lung parenchyma, and airway* (e.g., BPD, tracheobronchomalacia), and (3) diseases/disorders of the chest wall and thorax that affect the *respiratory pump* (e.g., spinal muscular atrophy, scoliosis).[55,56,74,85] See Table 25.1.

Central Dysregulation of Breathing

Central dysregulation of breathing is characterized by disorders affecting the central respiratory centers (i.e., brain stem or cervical spinal cord) that control the depth and frequency of involuntary breathing. Appropriate rhythmic depth and frequency of breathing maintain homeostatic levels of oxygen, carbon dioxide, and hydrogen ions in arterial blood. Voluntary control of breathing is under control from the cerebral cortex (i.e., speaking, breath holding); these voluntary pathways bypass the respiratory centers in the medulla and directly affect the respiratory motor neurons that are located in the spinal cord.

BOX 25.1 Signs of Chronic Respiratory Failure

Clinical Signs

Decreased inspiratory breath sounds
Use of accessory muscles/chest wall retractions
Altered depth and pattern of respiration (deep, shallow, apnea, irregular)
Weak cough
Nasal flaring
Wheezing/expiratory grunting/prolonged expiration
Retained airway secretions/incompetent swallowing/weak or absent gag reflex (neurologic, neuromuscular, and skeletal conditions)
Cyanosis
Tachycardia
Hypertension
Bradycardia
Hypotension
Cardiac arrest
Fatigue/decreased level of activity
Poor weight gain
Excessive sweating
Changes in mental status
Retained airway secretions
Restlessness/irritability
Headache
Papilledema
Seizures
Coma

Physiologic/Laboratory Findings

Hypoxemia (acute or chronic): $PaO_2 < 65$ mm Hg
Hypercapnia (acute or chronic): $PaCO_2 > 45$ mm Hg
O_2 saturation <95% breathing room air (metabolic or respiratory)

TABLE 25.1 Common Pathophysiologic Mechanisms Leading to Chronic Respiratory Failure

Lungs, Lung Parenchyma, and Airway	Central Dysregulation of Breathing	Diseases/Disorders of the Chest Wall and Thorax (Pump Failure)
Bronchopulmonary dysplasia	Congenital central hypoventilation syndrome	Congenital myopathies
Respiratory distress syndrome	Infectious disease of the brain/brain stem	Muscular dystrophies
Chronic lung disease of infancy	Brain tumor	Phrenic nerve trauma
Tracheobronchomalacia	Arnold-Chiari malformation	Diaphragmatic dysfunction
Tracheomegaly	Traumatic brain injury	Botulism
Tracheoesophageal fistula	Spinal cord injury	Dwarfism
Subglottic stenosis	Intracranial hemorrhage	Scoliosis
Laryngeal atresia	Hypoxic encephalopathy	Guillain-Barré syndrome
Bronchial atresia		

Congenital central hypoventilation syndrome (CCHS) (previously known as Ondine's curse) is a rare disorder that presents shortly after birth or early in infancy. CCHS is characterized by failure of the central autonomic control of ventilation in the absence of primary pulmonary or neuromuscular disease or in the absence of a brain stem lesion. CCHS is due to a defect in the *PHOX2B* homeobox gene, the product of which is a transcription factor important for regulation of neural crest cell migration.[5,42] Symptoms of this disorder are generally noted in the neonatal period when the infant experiences hypoventilation and apneic episodes during sleep. CCHS is known to be associated with genetic or oncologic conditions such as Hirschsprung's disease[41] and neuroblastoma. Although the incidence of CCHS is low, this group of patients faces a lifelong dependence on MV, almost exclusively with positive-pressure ventilators or diaphragmatic pacemakers. Early treatment is essential to minimize the neurologic effects of hypoxia.[42] CCHS is fatal if untreated.[78]

Disorders of the brain stem that affect respiration typically result from trauma, infectious disease processes, brain stem tumors, or complications of Chiari malformations.[82] In these instances, chronic respiratory failure may be transient or long term and may present as apnea or other forms of sleep-disordered breathing. Traumatic injuries or acquired disorders of the spinal cord can also result in chronic respiratory failure, leading to dependence on MV. The prognosis for dependence on MV depends on the level of the lesion, the extent of nerve damage, and the nature of the lesion.[14] Following injuries involving the upper cervical or cervicothoracic area, respiration is often compromised because of phrenic and intercostal nerve root damage affecting the function of the diaphragmatic and accessory muscles of respiration. Patients with cervical-level injuries usually require MV throughout the day and night or, occasionally, only at night. The rate and extent of recovery of respiratory sufficiency and motor function after a spinal cord injury are contributing factors to quality-of-life outcomes.[75]

Lungs, Lung Parenchyma, and Airway

A common cause of primary lung failure is respiratory distress syndrome (RDS), in which primary lung or airway disease compromises pulmonary gas exchange. Respiratory distress syndrome, associated with preterm birth, pulmonary immaturity, and deficiency of surfactant, is a common cause of ventilator dependence in infants, as well as a major cause of neonatal death. Because of anatomic and physiologic immaturities, infants are predisposed to respiratory dysfunction such as atelectasis, airway obstruction, increased pulmonary vascular resistance, and pulmonary edema. As well, they are predisposed to diaphragmatic fatigue and instability in the neural control of breathing. Treatment of neonatal respiratory distress includes antenatal steroids, surfactant replacement therapy, oxygen therapy, and high-frequency ventilators used in the early neonatal period.[7,47,62,86,91]

Smaller and more immature infants requiring prolonged MV are at risk for ventilator-induced lung injury resulting in BPD and chronic lung disease of infancy (CLDI). BPD, first described by Northway et al. in 1967, is diagnosed when an infant is 28 days of chronologic age, continues to require supplemental oxygen, and has an abnormal clinical examination and chest radiograph. CLDI is diagnosed at 36 weeks of postmenstrual age if the clinical examination and chest radiographs continue to be abnormal and the need for oxygen is still present; BPD accounts for the majority of cases of CLDI.

A newer and milder form of BPD has emerged as a result of surfactant administration and improved critical care practices that are more lung protective.[68] The classification of BPD is based on several factors, and disease severity is categorized as *mild, moderate,* or *severe* based on the need for supplemental oxygen or positive-pressure ventilation at 36 weeks of postmenstrual age for infants born before 32 weeks or 56 days of postnatal age for infants born at 32 weeks or after. This new phenotype is characterized by impaired/disrupted alveolar development, rather than the airway damage and fibrosis seen in the classical form of BPD.[47] Although no breakthroughs have occurred in the prevention of BPD, long-term outcomes have improved, and disease severity has been reduced as a result of improvements in medical and pharmacologic treatment, including the use of surfactant and lung protective ventilatory strategies such as high flow oxygen and noninvasive positive-pressure ventilation.[62,6] Although many infants "recover" from BPD and eventually achieve respiratory function independent of assisted ventilation or supplemental oxygen therapy, a small proportion require long-term ventilation. The reader is referred to Chapter 29 for information on early management of RDS, BPD, and CLDI.

Chronic respiratory failure may also result from congenital or acquired airway anomalies. These can include tracheal anomalies such as tracheomalacia, tracheomegaly, and tracheal atresia; abnormalities of the bronchi such as bronchial atresia, bronchial stenosis, and bronchomalacia; laryngeal atresia; tracheal and esophageal fistulas; and subglottic stenosis. All of these conditions can prevent alveolar ventilation and increase the respiratory workload, necessitating the need for MV support.[66]

Respiratory Pump Failure

Respiratory compromise can also occur with failure of the respiratory pump. Inadequate pump output can result from decreased respiratory muscle capacity due to weakened or fatigued respiratory muscles or from a workload that exceeds the capabilities of the pump. In either case the imbalance results in an inadequate generation of force and an inability to sustain ventilator requirements.

Congenital muscle disorders that affect respiratory muscles are a common cause of respiratory pump failure. Children with congenital myopathies typically manifest symptoms of respiratory failure early in the course of the disease, whereas those with muscular dystrophies typically do not present with respiratory compromise until late childhood or early adolescence. The degree of muscle weakness varies based on the type and nature of the disorder. In either case, MV may be warranted to compensate for the significantly reduced respiratory muscle function.[2,22,66] Muscular dystrophy and spinal muscular atrophy are presented in Chapter 12.

Pump failure can also result from congenital anomalies of the thorax and rib cage. In these conditions, reduced chest wall compliance or structural abnormalities restrict lung and chest expansion. Thoracic abnormalities are often associated with a variety of syndromes such as asphyxiating thoracic dystrophy, arthrogryposis (Chapter 10), osteogenesis imperfecta (Chapter 11), and dwarfism, as well as scoliosis (Chapter 8).[38,48,84]

MECHANICAL VENTILATION

Although the underlying disease processes and severity of respiratory failure differ considerably among individuals, MV is the final common treatment approach for individuals with chronic respiratory failure. MV is designed to assist with or substitute for respiratory function (i.e., moving air into and out of the

lungs) in order to give the respiratory muscles a rest until the disease process resolves or lessens.

The decision to institute MV is often made as a lifesaving measure, and MV is increasingly used to preserve physiologic function and improve quality of life. In many instances involving infants and children, the clinical decision is to take advantage of the growth and maturational potential of the lungs and to maximize the child's overall developmental potential. Thus, the desired outcome for many children is medical stability with adequate growth and healing of the lungs and then the eventual withdrawal of assisted ventilation.[66,84,90]

Decisions on the type and parameters of MV are individualized and based on limited research evidence and, to some extent, on the experience of the medical team. The optimal ventilator settings for each patient are determined by the patient's metabolic requirements, respiratory drive, and pulmonary mechanics. The type of MV and the various parameters chosen depend on the child's age, the underlying disease process that precipitated ventilatory failure, available equipment, available research evidence, provider experience with specific types of machines, and site of care (e.g., PICU, home environment) (Table 25.2). In general, ventilators are adjusted to maintain an oxygen saturation > 95% and a CO_2 tension within the range of 35 to 45 mm Hg while the child is awake or asleep.[66,67,85]

TABLE 25.2 Selection Criteria for Mechanical Ventilation

Parameter	Findings
Clinical	
Respiratory[a]	Apnea; decreased breath sounds; rigorous chest wall movement; weakening ventilatory effort
Cardiac	Asystole; peripheral collapse; severe bradycardia or tachycardia
Cerebral	Coma; lack of response to physical stimuli; uncontrolled restlessness; anxious facial expression
General	Limpness; loss of ability to cry
Laboratory[b]	
$PaCO_2$	Newborn: > 60–65 mm Hg Older child: > 55–60 mm Hg Rapidly rising > 5 mm Hg
PaO_2	Newborn: < 40–50 mm Hg Older child: < 50–60 mm Hg

[a]More than one episode of apnea with bradycardia or an episode of cardiac arrest is an adequate indication for initiating mechanical ventilation (MV), even in the absence of blood gas data.
[b]Laboratory values less extreme than those indicated must be supplemented by clinical evidence of severity to warrant initiating MV.

Tobin, editor: Principles and practice of mechanical ventilation, ed 2, New York: McGraw Hill, 2006; Venkataraman ST: Mechanical ventilation and respiratory care. In Fuhrman BP, Zimmerman JJ, editors: Pediatric critical care, ed 4, Philadelphia: Saunders, 2011.

Since the beginning of the modern era of MV in the 1950s, ventilators have continued to undergo significant technologic advances. Specifically, pediatric MV has undergone continual changes that reflect increased knowledge, understanding, and appreciation of the developing cardiorespiratory system. Currently, ventilation approaches utilize protective strategies to avoid atelectrauma and lung overdistention through the use of maximal alveolar pressures, minimal positive end-expiratory pressure, and permissive hypercapnia. Contemporary knowledge of respiratory physiology and a more detailed understanding of the pathophysiologic mechanisms underlying diseases of the respiratory system continue to drive research and development in this area. Although it is beyond the scope and intent of this chapter to detail available technical information on MV, a brief overview of MV will be provided.

Positive-pressure ventilation (PPV) is the most commonly used assisted ventilation strategy and can be delivered using noninvasive approaches as well as invasive methods. Most often, PPV is delivered invasively via an endotracheal (for the short term in the tertiary care hospital) or tracheostomy tube (for long-term management) with pressurized gas delivered into the airways and ventilator circuit during inspiration until the ventilator breath is terminated. As the airway pressure drops to zero, elastic recoil of the chest accomplishes passive exhalation by pushing the tidal volume out. Positive-pressure ventilators can be broadly classified as pressure limited or volume limited, the description indicating the method used to switch from the inspiratory phase to the expiratory phase. For a volume-cycled ventilator, the signal to terminate the inspiratory activity of the ventilator is a preset *volume*. For pressure-cycled ventilators, a preset *pressure* limit is used. The modes within each of those classes are categorized according to the type of inspiratory support (Box 25.2).

There has been an increasing use of partial ventilator assistance strategies to avoid the complications related to controlled MV.[73] Ideally, the desirable mode of ventilation is one with optimal synchrony and patient-ventilator interface, along with the use of lung-protective strategies. With the advent of microprocessor technology, newer models of ventilators are able to offer greater flexibility with respect to modes of oxygen delivery.

Although long-term MV has decreased mortality rates for infants and children, complications can impact overall health, growth and development, and quality of life. Long-term invasive PPV requires a tracheostomy, which increases the complexities of care (Fig. 25.1).[35,64] Complications due to tracheotomy such as tracheitis, accidental decannulation, tracheal ulceration, or granuloma development are common. Tracheostomy placement or complications require routine surgical surveillance or surgical intervention (bronchoscopy).[36] An artificial airway also interferes with speech and nutrition. Secondary illnesses that have been reported include ventilator-associated pneumonia[79] and respiratory syncytial virus infection.[87]

Despite the benefits of PPV, there is risk of secondary lung injury. Numerous complications can occur with invasive PPV (Box 25.3), making it essential that individuals who work with children requiring long-term MV understand normal and pathologic respiratory physiology, anatomic and physiologic changes of the developing respiratory system, and how the machine interfaces with the patient's physiology.

Positive-pressure ventilatory support may also be accomplished noninvasively. Positive pressure via facemask can be accomplished using continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP). CPAP applies continuous distending pressure to the alveoli throughout the respiratory cycle, keeping the alveoli partially inflated so that they may expand more easily with each cycle. CPAP may be delivered nasally, thus minimizing discomfort. BiPAP uses

BOX 25.2 Types of Positive-Pressure Ventilations

Noninvasive Positive-Pressure Ventilation

Modes of Application

- CPAP: single level of airway pressure applied throughout the respiratory cycle
- BiPAP: provides airway pressure during inspiration and an expiratory pressure to maintain lung expansion during expiration

Invasive Positive-Pressure Ventilation

Types of Ventilation

Pressure limited ventilation: inspiration ends after delivery of a set inspiratory pressure; tidal volume variable

Modes

- Pressure-controlled MV: minute ventilation determined by set respiratory rate and inspiratory pressure; patient does not initiate additional minute ventilation
- Pressure-limited assist-controlled MV: minimum minute ventilation set and patient can trigger additional pressure-limited breaths
- Pressure-limited synchronized intermittent MV (SIMV): ventilator breaths are synchronized with patient's spontaneous inspiratory efforts
- Pressure-support ventilation: patient-triggered breath with preset positive pressure, thus uses patient's own inspiratory timing and tidal volume; often used in weaning
- Volume limited ventilation: inspiration ends after delivery of a set tidal volume

Modes

- Controlled MV: preset tidal volume and respiratory rate delivered; patient does not initiate any ventilation
- Assist-controlled MV: preset minute ventilation; patient can trigger additional breaths, which have a set tidal volume
- Intermittent mandatory ventilation (IMV): allows patient to breathe in between mandatory ventilator breaths
- Synchronized intermittent MV (SIMV): allows the mandatory breaths to be triggered by the patient's spontaneous breaths

cycling variations between two CPAP levels, allowing spontaneous breathing during every ventilatory phase and has been used effectively to wean children from long-term MV.

In addition to the obvious advantage of avoiding a tracheostomy, noninvasive forms of PPV reduce the risk of acquired infection and allow patients to be more mobile.[37] Difficulties with noninvasive ventilation in children, however, such as poor mask fit, inadequate ventilation because of leaks, and eye irritation and nasal dryness due to high flow, have been reported. In addition, the use of noninvasive ventilation is limited in patients with congenital facial anomalies, which may preclude a tight-fitting mask, and with conditions that have the potential for infection, such as facial trauma or burns.[37]

Another strategy for noninvasive MV is the use of negative-pressure ventilation (NPV). NPV provides a pressure gradient, which is established by creating a negative pressure around the person's entire body (from the neck down) during inspiration, causing air to enter the lungs. The typical interface used with this type of ventilation is a customized chest shell, a wrap/poncho, or a tank ventilator (Fig. 25.2). A major advantage of NPV is that it avoids or delays the need for a tracheostomy, thereby reducing the risk of infection. Another advantage of NPV is that ventilation is not interrupted when secretions are suctioned. NPV has been used most successfully for patients with normal lung mechanics and hypoventilation, as seen in patients with neuromuscular disease and pulmonary disease requiring periodic or nocturnal ventilatory support. There are limitations in use of NPV with infants and young children. Airway occlusion may occur during sleep. The chest shell or wrap is not effective for children who require high respiratory rates, tidal volumes, or distending pressures; thus NPV is not commonly used.[49,66,88]

Weaning From a Ventilator

The transition from mechanical ventilation to unassisted breathing is a complex process. Weaning a child from the support of a mechanical ventilator is highly individualized, is accomplished in response to recovery from respiratory insufficiency, and may not be a goal for some children. The primary consideration is whether a child is capable of maintaining adequate alveolar ventilation while breathing spontaneously. This requires adequate central nervous system regulation, respiratory muscle capacity to support the work required for breathing, and that the lungs and airway are not severely compromised by disease. Although weaning from MV may be a goal for many children, no standard protocol exists for the discontinuation of long-term ventilator support.

BOX 25.3 Complications Associated With Mechanical Ventilation

Respiratory

Tracheal lesions (erosion, edema, stenosis, granuloma, obstruction, perforation)
Accidental endotracheal tube displacement or actual extubation
Air leaks (pneumothorax, pneumomediastinum, interstitial emphysema)
Infection (tracheitis, pneumonitis)
Trapping of gas (hyperinflation)
Excessive secretions (atelectasis)
Oxygen hazards (depression of ventilation, bronchopulmonary dysplasia)
Pulmonary hemorrhage

Circulatory

Impairment of venous return (decreased cardiac output and systemic hypotension)
Oxygen toxicity (retinopathy of prematurity, cerebral vasoconstriction)
Septicemia
Intracranial hemorrhage
Hyperventilation (decreased cerebral blood flow)

Gastrointestinal

Gastrointestinal hypomotility
Stress ulcer

Metabolic

Increased work of breathing ("fighting the ventilator")
Alkalosis (potassium depletion, excessive bicarbonate therapy)

Renal and Fluid Balance

Antidiuresis
Excess water in inspired gas

Equipment Malfunction

Power source failure
Improper humidification (overheating of inspired gas, inspiratory line condensation)
Improper tubing connections (kinked line, disconnection)
Ventilation malfunction (leaks, valve dysfunction)

From Zielinska MS, et al: Mechanical ventilation in children: problems and issues. Adv Clin Exp Med 23:843–848, 2014; Slutsky AS, Ranieri VM: Ventilator-induced lung injury. N Engl J Med 369:2126–2136, 2013; Venkataraman ST: Mechanical ventilation and respiratory care. In Fuhrman BP, Zimmerman JJ, editors: Pediatric critical care, ed 4, Saunders, 2012.

In critical care, the process of endotracheal tube extubation and ventilator weaning is often done by trial and error, whereby time off the ventilator is variable, dependent on when hypercapnia and hypoxia develop. In addition to the increased length of time for the weaning process, weaning strategies for children in a postacute setting are inherently different from those used in the neonatal or pediatric ICU because of differences between the use of a short-term endotracheal tube and a more permanent stable airway with a tracheostomy. Proposed criteria for weaning readiness in the postacute pediatric hospital setting include the following: (1) no escalation in ventilator support within 2 days before weaning; (2) stable chest radiograph; (3) blood $PaCO_2$ level not more than 10% above baseline; (4) blood pH within normal range; (5) supplemental FiO_2 of 0.6 or lower; (6) stable blood pressure over the previous 5 to 7 days; (7) heart rate no greater than 95% maximal normal for age; (8) tolerance of adequate nutrition; (9) absence of active infection, acute pain, or

FIG. 25.2 Cuirass negative pressure ventilation device. (From McDonald CM, Joyce NC: Neuromuscular disease management and rehabilitation, part II: specialty care and therapeutics. Phys Med Rehabil Clin N Am 23:xiii-xvii, 2012.)

other medical problems that might negatively affect the weaning process; and (10) reported understanding by the family/guardian and all health care providers of the desirability of weaning. In pediatric pulmonary rehabilitation, children may be weaned completely off MV, advanced to portable equipment, progressed to milder levels of ventilation (i.e., reduced pressure support), or weaned to a less invasive mode of support (i.e., CPAP).[58]

Despite the expected financial, clinical, and psychosocial advantages of weaning children with ventilator dependency in a postacute inpatient setting, only a few studies have reported outcomes on cohorts of children with long-term NV dependence undergoing weaning programs. In a single-site study, successful ventilator weaning was achieved during 30% of admission-discharge episodes, with diagnosis (prematurity with BPD) and age (younger) being the strongest predictors of weaning success. Nearly half of children admitted to a prospective multisite study over a 1-year enrollment period who were dependent on MV 24 hours per day at admission no longer required MV at discharge from inpatient rehabilitation. In addition, four children required only 12 or fewer hours per day of ventilator support at discharge.[59] Even though respiratory function is not monitored as closely, reports have described children's dependence on MV being minimized while they are cared for at home. Programs report that up to 57% of children are weaned from MV while at home.[26,57]

Weaning can be an arduous task, both physiologically and psychologically, and must be done with caution. The weaning prognosis can be enhanced by improvements in cardiorespiratory strength and endurance, adequate nutrition, and overall health; however, both muscular and respiratory fatigue should be avoided during this time. The timing and prognosis for weaning are important for physical therapists to understand so that physical therapist management may be directed appropriately. It is imperative for the physical therapist to coordinate and communicate with the medical team as to the amount of physical exertion that can be tolerated safely. During a time of weaning, the child's schedule of activities may need to be altered. In addition, the observations and ongoing clinical assessments made by the physical therapist may be influential in ventilator

weaning. Ventilator settings are often influenced by the child's physical capacity such as strength, endurance, and developmental/functional skills. When these findings are communicated to the medical care team, weaning may be progressed, halted, or interrupted. Conversely, unpublished clinical observations by the authors indicate that when children are being actively weaned from the ventilator, physical therapy participation may be limited. Infants may sleep more, and older children often do not tolerate the same level of physical activity, until they accommodate to the increased demands of reduced ventilator settings on their respiratory system.

CONTINUUM OF CARE

Children who require mechanical ventilation may be seen by a physical therapist anywhere along the health care continuum. Infants in a neonatal intensive care unit may be placed on MV because of lung or airway anomalies, neurologic disorders affecting respiration, or disorders of the respiratory pump.[83] Children in a pediatric ICU may be placed on MV for postsurgical indications; as the result of recent trauma, illness, or organ failure; or because of a history of chronic respiratory failure. Only a small percentage of these children, however, will require long-term MV.[81]

For children who require MV for an extended period, the locus of inpatient care has shifted from acute care hospital neonatal and pediatric ICUs to postacute rehabilitation units or hospitals, where children can spend longer periods of time at a lower financial cost. In the rehabilitation unit or hospital, children may be weaned from their oxygen or ventilators or weaned to a less invasive mode of ventilation.[31,59] The more developmentally appropriate environment and rehabilitation services are intended to optimize weaning from a ventilator to a less restrictive mode of respiratory support for safe discharge home. Parent–child interaction, parent education, and growth and development can be promoted along with medical stability.[59] This is an important consideration for referring children to rehabilitation programs and for setting realistic expectations for referral sources, children and families, clinical staff, and payers. Whether fully weaned, weaned to fewer hours per day of MV, or weaned to a less invasive mode of ventilation, the ultimate goal is to discharge children home.

Children dependent on MV can be cared for at home and can participate in community activities when medically stable on a ventilator suitable for nonhospital use and with appropriate caregiver support.[57] Technological advances in design, efficiency, and portability have contributed to an increase in the use of MV outside the hospital environment. This option is dependent on many factors but primarily on a stable airway, an oxygen requirement typically less than 40%, a $PaCO_2$ level not more than 10% above baseline, and an adequate nutritional intake to maintain growth and development.[58] Home ventilation minimizes nosocomial infections and improves children's psychosocial development, social integration, and quality of life.[13,15,63,67,69]

Barriers to discharge from the hospital include the inability to recruit qualified home nursing staff inadequate or delayed funding of home care resources, unsuitable housing, delays in obtaining the appropriate equipment, and a limited number of capable family caregivers. It is imperative that the family or designated caregivers be involved in, and capable of learning, all aspects of the child's care. This care includes not only managing the ventilator and other monitoring equipment but also being able to recognize signs of medical distress and provide emergency medical procedures. The high degree of medical and technological expertise required by parents or caregivers can be a tremendous drain on a family.[19,67,116]

The transition to home carries with it other circumstances that can increase stress such as financial burden and significant changes in a family's routine, lifestyle, and relationships. The shift in responsibility for medical care from health care professionals to a family results in a myriad of issues that require psychological, social, ethical, financial, and policy solutions.[12,13,19,46,116] In many cases, the primary caregiver has to leave the workforce to care for the child at home.[51] Also, for children using MV at home, hospital readmissions are common.[11,34,87] Burdens of a hospital readmission for the child and family may include separation from family, coping with the illness itself, and financial concerns such as loss of income and the cost of the hospital admission. Children and families also face the possibility of a breakdown in their established network of community service providers caused by the interruption in service.[19] Although these added burdens do not necessarily outweigh the tremendous benefits of children being raised at home and integrated into their communities, they can be overwhelming and can have an impact on the quality of life of the child and family.[12,19,46,67]

As the degree and complexity of impairment, activity limitations, and participation restrictions increase, quality of life usually decreases—especially when financial, psychosocial, and emotional supports dwindle. With this in mind, one of the most important roles of health care providers is to work closely with family members as a child is being considered for discharge from the hospital and while at home. Physical therapists are encouraged to collaborate with families to identify their information needs and share intervention options in ways that enable informed decision making about caring for their children at home.[30,43,67] It is essential that the child's therapy program be integrated into the family's daily routine and not be the focus of a family's daily schedule.[43,51]

PHYSICAL THERAPIST MANAGEMENT

Physical therapy may be provided for children dependent on long-term MV who have or may develop impairments, activity limitations, and participation restrictions related to congenital or acquired conditions of the musculoskeletal, neuromuscular, cardiovascular, pulmonary, or integumentary systems. As noted previously, children who require long-term mechanical ventilation are a diverse and heterogeneous group. Despite differences in the underlying cause of respiratory insufficiency, children may have similar activity limitations and participation restrictions. The video accompanying this chapter illustrates some of the physical therapist interventions used with a 22-month-old girl with a diagnosis of Moebius syndrome, central respiratory dysfunction, and long-term mechanical ventilator dependence.

Children dependent on long-term MV may have limitations in self-care, mobility, cognitive, communication,[32] or oral feeding activities. Limitations in self-care and mobility activities may increase with fatigue, due to reduced cardiorespiratory endurance or limited access to environmental surroundings because of tubing length and the ventilator itself. The lack of frequent and variable practice opportunities makes skill acquisition particularly difficult, and thus the repertoire of skills in a

variety of developmental domains is limited (see Chapter 4 for additional details on motor learning). As a point of illustration, the acquisition of independent mobility in children who are typically developing allows them to acquire information about their world and develop perceptions upon which they can act. Thus, development of cognitive skills such as object permanence is facilitated through motoric competencies. This interweaving of developmental domains and their interdependence is a well-known phenomenon, so the impact of limitations in the amount and type of mobility and lack of environmental affordances can be substantial.

A case report described the achievement of independent ambulation while a child was using CPAP.[16] An 18-month-old child with chronic lung disease of infancy and tracheobronchomalacia was provided with a CPAP device that allowed compressed air to be delivered via tracheostomy tube with extended tubing. It was hypothesized that the shorter, heavier tubing of the traditional CPAP device had severely restricted the child's mobility, but the application of the new CPAP device afforded the child the space to move up to 10 meters, and thus, psychomotor development was stimulated. Unfortunately, no studies documenting the relationship of physical therapist intervention, ventilator weaning, and motor/mobility outcomes are available for children dependent on long-term MV.

In addition to the aforementioned impairments and activity limitations, the additive effects of secondary complications such as recurrent hypoxic episodes, recurrent infections, poor weight gain, and poor physical growth can directly result in any number of secondary impairments and subsequent activity limitations. For example, because of the often prolonged periods of immobility or restricted activity early in the course of their disease, children may demonstrate impairments such as sensory defensiveness, generalized weakness, and soft tissue or muscular tightness. Likewise, if the child has hypoxic or ischemic episodes, neurologic damage may additionally limit motor skill acquisition and fluency. Infants with BPD and extremely low birth weight with a history of MV have an increased risk of being diagnosed with cerebral palsy, attention deficit disorder, and developmental coordination disorder (DCD).[92]

Due to children's impairments, reliance on external equipment requiring a power source and back-up safety materials (e.g., Ambu bag, extra tracheostomy tube), and the need for a trained adult caregiver, participation in activities outside the home may be difficult and appropriate recreation and leisure activities may be hard to find. Reports of participation in an ice skating program[23] and in a hospital-based fitness program are available.[24] Summer outdoor overnight camps for children dependent on MV are offered in multiple states throughout the United States.[39]

A multidisciplinary team approach is essential in the management of children with long-term MV and should be the standard of practice, regardless of the physical therapist's practice setting. For optimal patient management, the physical therapist who works with infants, children, and adolescents dependent on MV should have a thorough understanding of cardiorespiratory physiology and the implications of a compromise to that system in addition to an understanding of typical and atypical motor skill development. Physical therapists should be aware of the pathophysiology of chronic respiratory failure, the physiologic conditions requiring MV, the parameters of ventilator machinery, the varied types of MV, and the use of physiologic monitoring devices (Table 25.3). Types and settings of ventilators will vary according to the child's age and diagnosis, site of care, availability of equipment, and providers' knowledge and experience with specific types of ventilators. Although the infant or child may be medically stable, the presence of an artificial airway creates a critical situation because it may become dislodged or occluded. In addition, the infant or young child may not communicate well; thus it is up to the therapist to interpret any signs of impending or actual distress.

TABLE 25.3 Commonly Encountered Noninvasive Monitoring Devices[a]

Equipment	Physiologic Parameters Monitored
Cardiorespiratory monitors	Heart rate and respiratory rate
Pulse oximeter[b]	Transcutaneous arterial oxygen saturation to monitor hypoxemia
Ventilator alarms	Various modes chosen for the individual case, as well as airway pressures, gas concentrations, and expiratory tidal volumes
Transcutaneous PaO_2 and $PaCO_2$	Partial pressure of oxygen and carbon dioxide in the arterial blood
Oxygen analyzers on the ventilator	Oxygen supply in the ventilator circuit
Sphygmomanometer	Blood pressure

[a]These are some noninvasive devices that one may use to monitor response to activity and general status. Before any examination or treatment session, the therapist should be familiar with all of the equipment used for the child.
[b]Pulse oximeters are not useful for discriminating hyperoxia because the blood is fully saturated at PaO_2 of 150 mm Hg.

Examination

Before any examination or intervention session, the therapist should confer with the child's primary caregiver to determine the child's current medical status, in addition to his or her baseline physiologic parameters. Depending on the nature and severity of the predisposing condition, cardiorespiratory parameters may vary from what is considered to be typical for the child's age (Table 25.4). It is always prudent to establish safe physiologic parameters within which to work. Typically, heart rate, respiratory rate, and oxygen saturation are monitored electronically while the child is on the ventilator.

Physical therapists should familiarize themselves with the type of mechanical ventilator being used by the child. The therapist should understand whether the ventilator is doing all the work of breathing for the child or whether it is assisting the child with the number or depth of breaths. Physical therapists should be knowledgeable of the clinical signs that indicate that the child needs respiratory assistance and the alarm systems of the ventilator, monitors that record oxygen saturation levels, heart and respiratory rates, and the emergency response procedures of the care setting. Therapists should be competent observing the child for signs of respiratory distress, skin color changes indicative of hypoxia, and changes in respiratory rate, breathing pattern, symmetry of chest expansion, posture, and general comfort. Signs of respiratory distress such as retractions, nasal flaring, expiratory grunting, and stridor may not be evident when a child is on a mechanical ventilator. For more information specific to the assessment of the cardiorespiratory system, the reader is referred elsewhere.[53]

As with any child referred for physical therapy services, the therapist must first complete a comprehensive examination that includes a history, a systems review, and specific tests

TABLE 25.4 Normal Ranges of Physiologic Values[a]

Parameter	Newborn/Infant (< 1 year)	Older Infant and Child (> 1 year)
Respiratory rate (breaths/minute)	24–40 40–70 (preterm infant)	20–30 (1–3 years) 20–24 (4–9 years) 14–20 (> 10 years)
Heart rate (beats/minute)	100–160 120–170 (preterm infant)	70–120 (1–10 years) 60–100 (> 10 years)
Blood pressure-systolic (mm Hg)	60–90 55–75 (preterm infant)	80–130 (1–3 years) 90–140 (> 3 years)
Blood pressure-diastolic (mm Hg)	30–60 35–45 (preterm infant)	45–90 (< 3 years) 50–80 (> 3 years)
PaO_2 (mm Hg)	60–90	80–100
$PaCO_2$ (mm Hg)	30–35	30–35 (< 2 years) 35–45 (> 2 years)
Arterial oxygen saturation (%)	87–89 (low) 94–95 (high) 90–95 (preterm infant)	95–100

[a]These measures represent "normal" physiologic values; in the case of infants and children with varying pathophysiologic processes, the "normal" values may be different.
From Bernstein D: History and physical examination. In Kliegman RM, Stanton BMD, St. Geme J, et al., editors: Nelson textbook of pediatrics, ed 20, Philadelphia: Elsevier 2016; Marx J, Hockberger R, editors: Rosen's emergency medicine: concepts and clinical practice, ed 8, Philadelphia: Saunders, 2014.

and measures. Because of varying ages, diagnoses, prognoses, and intervention settings for children dependent on MV, tests and measures must be aimed at quantifying a child's aerobic capacity and endurance, motor function, musculoskeletal performance (flexibility, strength, posture), and general adaptive behaviors that are age appropriate and most relevant to the child and family goals and the clinical setting.

The neuromuscular/musculoskeletal examination should provide information about the child's general neurologic and musculoskeletal status and includes assessment of active control of movement and strength, flexibility, sensation, and posture. Examination procedures will vary, depending on the age and cognitive level of the child, and areas of emphasis may be different, depending on the diagnosis, the care setting, and child and family goals. An important component is the measurement of neuromotor development and motor control as children on long-term MV are at great risk for global developmental delays that may or may not have a pathophysiologic component.

An examination of the child's functional activity level should include age-appropriate activities of daily living, general mobility skills, communication skills, and an assessment of the child's role within the family and within the relevant environment. The functional assessment provides an indication of how well the child is integrated into his environment, family, and, if applicable, community. A performance-based assessment or a patient-reported measure may be appropriate. A performance-based standardized developmental assessment or functional assessment tool can be used to quantify achievement of motor milestones or changes in functional mobility skills. No specific tool has been recommended for children dependent on ventilators, and only a few of the currently available tools have been reported to be used in populations in which children were ventilator dependent. When choosing an assessment, therapists should consider the child's age, as well as the care setting, prognosis, diagnosis, and intended outcomes (e.g., developmental milestones such as rolling, functional skills such as transfers, factors influencing quality of life such as accessing transportation to school), while remembering that standardized developmental assessments seldom take into account factors related to endurance for exercise. See Chapter 2 for information on physical therapy tests and measures.

A reexamination will include performing selected tests and measures to evaluate progress in response to parent/caregiver questions or concerns, physical therapist intervention, growth and development, and medical recovery. Reexamination is indicated at times of new clinical findings or failure to respond to physical therapist intervention, or as dictated by the care setting.[29] For children dependent on MV, a change in type of ventilator or ventilator settings, or a decrease in the number of hours of ventilator support per day, may warrant a reexamination of aerobic capacity and endurance for motor tasks or the appropriateness of adaptive equipment.

Evaluation and Diagnosis

Information gathered during the physical therapy examination should be used for the therapist's evaluation and determination of a physical therapy diagnosis. Results of the examination should be synthesized to determine the child's impairments, activity limitations, and participation restrictions, as well as to identify strengths and resources available to minimize disability. Ideally, a multidimensional approach to the use of tests and measures should be employed and the results correlated to relevant activity limitations and participation restrictions interfering with the child's quality of life. For example, the child with chronic lung disease and mechanical ventilator dependence secondary to BPD may have coexisting neurologic impairments, gastrointestinal abnormalities, and growth disturbance. The physical therapy diagnosis therefore might include developmental delay, aerobic capacity and endurance limitations, and a decreased repertoire of movement patterns. On the other hand, children with the neurologic diagnosis of congenital central hypoventilation syndrome may be otherwise medically stable and at risk for developmental delay only if they are hospitalized for a prolonged time. Thus, at this stage of clinical decision making, diagnostic determinations will vary depending on the age of the child, the severity and chronicity of the lung disease, and the coexisting diagnoses.

Prognosis and Plan of Care

The physical therapy prognosis for a child who is dependent on long-term MV may be difficult to establish. The prognosis is the determination of the predicted maximal level of improvement and the estimate of how long it will take the child to achieve that improvement. As this population of children is diverse in its medical diagnoses and age range, the literature base on which to base a prognosis for the reduction of impairments, improvement of function, and facilitation of participation in home and community life is limited.

Decisions regarding the mode, intensity, and frequency of activity need to be made in conjunction with other members of the child's medical team and modified as the disease process changes. The physical therapist must recognize the potential for adverse physiologic stress when implementing any intervention and the potential impact on the child's prognosis. The amount and type of motor activities must be individualized and

graded to the child's level of tolerance so that risks associated with the physiologically immature or unstable systems are not magnified.

One of the ultimate goals for pediatric physical therapists, however, should be to promote the concept of lifelong health and fitness. Barring any medical contraindication, physical activity in children who are dependent on a ventilator should be encouraged and incorporated into the plan of care. The long-term benefits of physical activity and lifelong fitness include mental health benefits such as improved self-esteem and confidence.[61]

Physical Therapist Intervention

The multiple medical, emotional, educational, and rehabilitative needs of the child with ventilator dependence are beyond the expertise of a single provider and thus require the care and coordination of an interdisciplinary team. This team will include a primary care physician and multiple specialty physicians. Therapists working with a child dependent on long-term MV should routinely communicate with the child, family, other daily caregivers (e.g., nurse, home health aide), and the child's primary physician. Therapists should also communicate with other medical specialists such as the pulmonologist, physiatrist, orthopedist, and neurologist about the child's therapy goals and physical response to intervention.

Members of the child's team in the home setting may expand to include a case manager, a respiratory equipment provider, and a durable medical equipment vendor. Additionally, team members in a school setting may include teachers, classroom aides, the school nurse, and transportation personnel (bus driver and monitor[s]). In many states, it is typical for a child with a tracheostomy on a ventilator outside the hospital to have a nurse with him or her at all times. Sharing of successful strategies for communication and motivation, as well as carryover of all rehabilitation goals among physical, occupational, and speech therapists, can facilitate a successful therapist–client relationship and can enhance a consistent approach to the needs of the child and family. Short-term and long-term goals developed by the team should be formulated in conjunction with the family, while the ultimate goal of maximizing function from a physical, cognitive, social-emotional, and family dynamics perspective is kept in mind.

No one intervention strategy or intensity is unanimously embraced by physical therapists for any diagnostic group. Similarly, in the case of children with long-term ventilator dependence, physical therapy varies widely because of differing philosophies of management and the wide range of problem areas that might be identified. Thus, the intent of this section is not to recommend specific interventions but to present a conceptual framework from which one can organize an appropriate plan of care and to emphasize considerations unique to this group of children. Specific interventions are listed and detailed in the Guide to Physical Therapist Practice.[29] Table 25.5 summarizes key consideration for physical therapy intervention for children dependent on MV. Before continuing, readers unfamiliar with children requiring long-term mechanical ventilation might want to first view the video accompanying this chapter on Expert Consult that illustrates physical therapist intervention with a 22-month-old girl who is ventilator dependent.

Infants and children who are typically developing are capable of using a variable repertoire of motor skills to explore and learn. Motor development in childhood presumes a smooth interaction of the cardiopulmonary and musculoskeletal systems, as well as the necessary cognitive requirements. In the case of a child with chronic respiratory insufficiency, compromised physiologic stability may limit the seemingly endless exploration and practice in which children typically engage. In children with a chronic illness, a reduced capacity for activity or exercise can be a direct or indirect result of their underlying pathophysiologic process. For example, Smith et al.[78] reported on a large cohort of school-aged children born very preterm and noted significant impairment in exercise capacity despite evidence of only mild small-airway obstruction and gas trapping. Regardless of the cause, a vicious circle of

TABLE 25.5 Considerations for Physical Therapy Interventions

Type of Intervention	Procedures
Airway clearance techniques	Breathing strategies for airway clearance Manual/mechanical techniques for airway clearance Positioning Postural drainage
Assistive technology	Splints, casts, prosthetics, and orthotics Activity of daily living and bathroom technologies (e.g., adaptive commodes, shower benches) Mobility technologies: strollers, standers, and wheelchairs Seating and positioning equipment Transfer technologies (e.g., mechanical lifts)
Biophysical agents	Biofeedback Taping Electrical stimulation Hydrotherapy
Integumentary repair and protection techniques	Debridement Dressing selection Orthotic, protective, and supportive device recommendations and modifications Topical agents
Manual therapy techniques	Manual traction Massage Mobilization/manipulation Passive range of motion
Motor function training	Balance training Gait training Manual and power wheelchair training Perceptual training Postural stabilization and training Task-specific performance training Vestibular training
Therapeutic exercise	Aerobic capacity/endurance conditioning or reconditioning Aquatic therapy Developmental activities Flexibility exercises Gait and locomotor training Relaxation techniques Training for strength, power, and endurance
Patient or client instruction	Activity tolerance, vital sign monitoring, and clinical signs indicating the need for emergency intervention Diagnosis/prognosis Indications for ventilator use and impact of ventilator on motor and mobility skills Positioning, orthotic and equipment use Mobility strategies-home, school, and community transportation options Resources for leisure and recreation activities

inactivity may ensue—inactivity with reluctance to move and explore resulting in decreased endurance and fitness and further inactivity.

Another consideration is that children with long-term MV may associate movement with negative experiences such as fatigue, hypoxia, and pain, which limits their motivation to be active. A major goal of the physical therapist in the management of children who are dependent on ventilators should be secondary prevention—that is, to prevent deprivation of sensory and motor experiences because of inactivity and the various sequelae that result from that deprivation. Regardless of the child's medical diagnosis, intervention should be aimed at providing a variety of opportunities for movement challenges and for exploration, as well as increasing their function and capacity for exercise. Depending on whether the child has a specific motor impairment, these goals may be accomplished with or without the use of assistive devices. For example, in the case of a child with BPD who also had an intraventricular hemorrhage, adaptive equipment may be needed for positioning because of poor antigravity trunk control or for ambulation because of lower extremity weakness and spasticity. Alternatively, the child with congenital central hypoventilation syndrome and no impairments in motor control may be independent in all motor skills but may exhibit exercise intolerance.

Patient or Client Instruction

The pediatric health care environment embraces family-centered care,[40] recognizing that family members are the most important people in a child's life. The role of the family in shaping the child's environment to be the most conducive for growth and development is crucial. Importantly, from a practical point of view, the child's life depends on parents' knowledge of the intensive care needed to maintain the child's health and safety when dependent on long-term MV.

Physical therapists can provide the child, family, and other team members with information about the child's diagnosis, indications for ventilator use, and the functional abilities of the child. Therapists can also provide consultation on positioning, orthotic and equipment use, activity tolerance, vital sign monitoring, clinical signs indicating the need for emergency intervention, mobility strategies within the home and school environments, transportation options, resources for leisure and recreation activities, and psychosocial factors affecting intervention.

Airway Clearance Techniques

Although therapists often focus on strengthening the muscles of respiration and core trunk muscles, maintaining mobility of the rib cage, spine, and shoulder girdle is important to promote any nonassisted ventilation. Physical therapists select, prescribe, and implement airway clearance techniques that may include breathing strategies for airway clearance, manual/mechanical techniques for airway clearance, positioning, and pulmonary postural drainage. Although the goals of physical therapists are to enhance exercise performance; reduce risk factors and complications; enhance or maintain physical performance; improve cough; improve oxygenation and ventilation; or prevent or remediate impairments in body functions and structures, activity limitations, or participation restrictions, they may also teach a child and family airway clearance techniques and positioning for pulmonary drainage.

Assistive Technology

Appropriate assistive technology can minimize caregiver dependence and help children to attain functional skills and mobility unattainable on their own. Assistive technology may also be used to decrease pain, minimize the chance of secondary impairments due to the underlying disease process or immobility, and promote function and participation. Examples of assistive technologies to improve safety, function, and independence include splints, casts, prosthetics, and orthotics; transfer technologies (e.g., transfer boards, mechanical lifts/hoists); activity of daily living and bathroom technologies (e.g., adaptive commodes, shower benches); and strollers, standers, and wheelchairs.

Orthoses may be needed to manage joint contractures, maintain joint flexibility, or provide proper alignment of the trunk, feet, legs, and hands or arms. Of particular importance for children who require a trunk orthosis in order to maintain an upright posture or manage a scoliosis is an orthosis that is fabricated to allow the rib cage to expand fully and accommodate a gastrostomy tube.

Seating, positioning, and mobility equipment options are extensive (e.g., custom-molded seating, upper extremity support trays for wheelchairs, prone standers, manual or power wheelchairs). Young children may require specialized adapted strollers with ventilator-carrying capability. Older children may require manual or power wheelchairs adequately outfitted to transport a ventilator. The ventilator and other equipment must be safely secured to the seating system (Fig. 25.3). If the child is ambulatory, a portable ventilator may be transported in a backpack that the child or the care provider can carry.

All systems of transport should meet the Federal Motor Vehicle Safety Standard for car seats and bus transport. This includes securing the ventilator on the seat next to the child. In addition, when transporting a ventilator, in the authors' experience it is common for the child to have a spare tracheostomy tube, Ambu bag, oxygen tank, or portable suction unit with sterile catheters, as well as an external battery for the ventilator.

FIG. 25.3 Portable ventilator is placed on the back of the wheelchair. (From Panitch HB: Diurnal hypercapnia in patients with neuromuscular disease, Paediatr Respir Rev 11:3-8, 2010.)

Although physical therapists are not the ones who prescribe assistive technology to promote communication for children without speech and those with learning challenges, they may be consulted regarding the design and access of these devices.

Biophysical Agents

Biophysical agents—modalities that use various forms of energy primarily to increase muscle force, tissue perfusion, healing or tissue extensibility, or decrease pain or inflammation—may be used in conjunction with other physical therapist interventions.[29] There is, however, no evidence supporting or refuting the efficacy of such agents with children dependent on long-term MV. Examples of biophysical agents used with children with neuromuscular diagnoses that may also be applicable for a child with a neuromuscular diagnosis and long-term MV dependence include biofeedback, taping, electrical stimulation, hydrotherapy, and mechanical devices (e.g., standing frame).

Integumentary Repair and Protection Techniques

Methods and techniques may include debridement, dressing selection, orthotic selection, protective and supportive device recommendations and modifications, biophysical agents, and topical agents.[29] Often because of the multiple medical providers involved with a child who has ventilator dependence, another member of the health care team may be the one to employ several of these techniques. Of particular concern for children with long-term MV is the skin around the tracheostomy, which is at high risk for breakdown due to the moisture and tubing and requires vigilant monitoring.

Manual Therapy Techniques

Manual therapy techniques include skilled movements of joints and soft tissue intended to improve tissue extensibility; increase range of motion; induce relaxation; mobilize joints; and reduce pain, swelling, inflammation.[29] Techniques may include manual traction, massage, mobilization/manipulation, and passive range of motion. The child's dependence on a ventilator does not in itself prohibit the use of these techniques if indicated.

Motor Function Training

Motor function training is the systematic performance or execution of planned physical movements, postures, or activities. Motor function training may include balance training, both static and dynamic; gait training; manual and power wheelchair training; perceptual training; task-specific performance training; vestibular training; and postural stabilization and training.[29] Physical therapists commonly use motor function training activities for children with neuromuscular diagnoses; thus, these methods may be applicable for the plan of care for children with long-term MV dependence.

Therapeutic Exercise

Therapeutic exercise may include the following: aerobic capacity/endurance conditioning or reconditioning; developmental activities training; aquatic therapy; flexibility exercises; gait and locomotor training; relaxation techniques; and training for strength, power, and endurance for head, neck, limb, pelvic-floor, trunk, and ventilator muscles (active, active-assistive, and resistive exercises). This broad group of activities is intended to improve strength, flexibility, muscular and cardiorespiratory endurance, balance, coordination, posture, and motor function or development.

Simply stated, the "normal" response to exercise is an increase in heart rate, followed by a return to baseline. Ventilation also increases linearly with the metabolic rate until approximately 60% of oxygen consumption, at which time it increases more rapidly (see Chapter 6 for a summary of the cardiorespiratory and musculoskeletal components of exercise and fitness). These relationships, as well as the other physiologic processes that support adequate ventilation and perfusion during exercise, are altered in conditions of lung disease. Whereas exercise is normally cardiac limited, in individuals with chronic lung disease, exercise may be ventilator limited as a result of deficient exercise capacity and gas exchange or poor pulmonary mechanics. The optimal level of physical activity for children with chronic lung disease, however, is not related to disease severity.[80] Response to exercise and capacity for improvement, therefore, are evaluated for each child.

The beneficial effects of exercise have been documented in certain populations with respiratory conditions such as individuals with cystic fibrosis[50] (see Chapter 26) and asthma (see Chapter 27).[21] No group design study has examined active exercise and strength training for children who require MV. Strength training has been found to be useful for children with neurologic and neuromuscular disorders.[25] As with any health condition, exercise limitations and restrictions should be determined before the start of an exercise program, and with all exercise, children should be supervised closely to avoid musculoskeletal injury, excessive heart and respiratory rate, and dislodgement of tubing.

In infants and children dependent on MV, physical activity can be viewed as exercise and a means of improving endurance and tolerance for movement. There is a paucity of research on the effect of developmental interventions on cardiopulmonary function and exercise tolerance. In one study investigating physical therapist intervention activities and cardiorespiratory response for young children with chronic respiratory insufficiency, sitting activities were the most frequently applied and prone activities were used the least.[18] Ventilator dependence often dictates limited movement and mobility if the child must remain close to a nonmobile ventilator. For example, time spent in a prone position is often limited and may occur only during physical therapy. Exercise and activity in a prone position are useful for strengthening the neck and shoulder girdle musculature and for developing righting reactions. Rotational movements and crossing the midline of the body are important for many functional activities but are often constrained by the child's ventilator tubing. For children of all ages, upright positioning in sitting or standing is important for physiologic function and bone density and should be encouraged when developmentally and medically appropriate. Activities such as pulling to stand and cruising may occur in a crib if a young child is in the hospital with limited opportunities for playtime on the floor.[17]

SUMMARY

Children dependent on long-term MV have complex medical conditions including prematurity and chronic lung disease, cardiac conditions, congenital anomalies, and, most commonly, neuromuscular and neurologic conditions. The prevalence of infants and children dependent on MV continues to increase due to medical and technological advancements. Children requiring long-term MV are at high risk for secondary illness, recurring hospitalizations, global developmental delays, tracheostomy-related complications, and equipment failure.

Minimizing a child's dependence on MV has important benefits for the quality of life of both the child and the family. This includes a reduction in hospital stays, improved physical and mental health, and more opportunities for social participation. There is limited evidence on how often successful weaning from a ventilator is achieved.

Physical therapists have an important role in fostering the health and development of infants, children, and youth with chronic respiratory failure and supporting families. Once the decision is made to begin artificial ventilation, prevention and treatment of associated complications are primary goals of medical and rehabilitation management. Although the type and intensity of intervention varies, desired outcomes of physical therapy include maximizing children's mobility, self-care, and participation. Some physical therapist interventions are medically related, such as percussion and postural drainage. A major focus of physical therapist interventions is to integrate goals into everyday activities and support the family in managing the child's health and developmental needs. The ecologic validity of intervention increases if goals are made a part of daily activities and routines.

Physical therapists are encouraged to participate in clinical research to contribute to the evidence supporting management of children who require long-term ventilation. Research is needed to determine effective program planning, program improvements, and appropriate resource utilization, and to set outcome expectations for infants, toddlers, and children dependent on long-term MV. Additional research questions may involve the impact of rehabilitation interventions on the weaning process and the impact of rehabilitation interventions on quality-of-life outcomes for children and their families.

Case Scenario on Expert Consult

Two case scenarios on the Expert Consult website illustrate the physical therapy management of children who require long-term mechanical ventilation. The first case is a video of a 22-month-old child with Mobius syndrome and central respiratory dysfunction. The second case describes a 24-month-old child with chronic lung disease using the Guide to Physical Therapist Practice and the International Classification of Functioning, Disability and Health as frameworks.

The case scenario related to this chapter illustrates the physical therapy management of a child requiring long-term MV who has several comorbidities.

Cystic Fibrosis

Jennifer L. Agnew, Blythe Owen

The increasing life expectancy of individuals with cystic fibrosis (CF) and continuing advances in treatment have contributed to an expanded role of the physical therapist as a member of a multidisciplinary health care team. In this chapter, background information is presented on pathophysiology, etiology, diagnosis, and medical management of CF that is critical for setting goals, developing, and modifying the physical therapy plan of care. The role of the physical therapist in promoting self-management of respiratory function and physical activity beginning at a young age and progressing through childhood, adolescence, and adulthood is discussed. Supporting families and children's self-efficacy are essential components of intervention to promote well-being and quality of life.

BACKGROUND INFORMATION

CF was identified in 1928, when Andersen published a paper describing the clinical course of a number of children who had died of pulmonary and digestive problems. She labeled the disorder "cystic fibrosis of the pancreas."[5] This disease thereafter was classified as a disorder of exocrine gland function, influencing the respiratory system, pancreas, reproductive organs, and sweat glands. At times the first presenting sign has been the subjective report, "My child tastes salty to kiss"; the "sweat test" often confirms the diagnosis. Subsequent study and interest led to a clearer understanding of the disease and a coordinated approach to treating the associated impairments. Over time the disorder that had so intrigued Andersen has come to be known as cystic fibrosis, and research has continued, yielding vast knowledge about this chronic illness.

Classified as a hereditary disease, CF is inherited through an autosomal recessive pattern in which two copies of the gene responsible for CF are passed on to an affected individual. Both parents of a child diagnosed with CF must be carriers of at least one copy of a mutation at the gene locus responsible for CF. Those persons with one copy of the CF gene are termed *heterozygote carriers* and are not diagnostically positive for CF. In 1989 a major scientific breakthrough occurred with discovery of the precise locus on chromosome 7 of the gene responsible for CF.[169] The pathology of the physical manifestations of CF has since been determined.

Although cystic fibrosis was once referred to the most commonly inherited life-shortening illness in the Caucasian population, advances in its management have improved the quality of life and prognosis for life expectancy.[55] In the United States, 45% of the approximately 30,000 individuals diagnosed with CF are over the age of 18; therefore CF is no longer thought of as exclusively a childhood disease. The median predicted age of survival for individuals with CF is currently 41.1 years in the United States.[151,198] An increasing number of people with CF are reaching the fifth decade of life; the median age of survival in Canada is 50.9 years.[46] Surgical advances in lung transplantation offer hope of prolonging life for people with chronic pulmonary disabilities.

CF is diagnosed in 1 in 3500 children born to white American parents, and statistical analysis of this incidence yields a best estimate of the rate of heterozygote carriers as about 5% of the population in areas of the world where significant white populations have settled.[19,147] The incidence of CF in black and Asian peoples is considerably lower than that in whites: approximately 1 in 17,000 births in the black population and an estimated 1 in 90,000 births in Asian societies.[19] Several reports have documented the incidence of CF in the South Asian population, estimated to be 1 in 10,000 to 1 in 40,750.[125] Recent research and carrier screening are producing more precise statistical estimates of the incidence of individuals who are heterozygote CF carriers, suggesting that previous rates were underestimated.[210] Prenatal diagnosis of CF is now possible, as is screening for carrier status, which is discussed in detail later in this chapter.

The gene responsible for CF was identified in 1989 by an international team of researchers led by Drs. Tsui, Collins, and Riordan.[93] This discovery was an extraordinary achievement in molecular genetics and has led to subsequent research advances in the understanding of genetic and pathologic components of CF worldwide. Approximately 2000 distinct mutations within the CF gene have been identified in many ethnic groups, although fewer than 10 mutations occur with a frequency greater than 1%.[182] The trinucleotide deletion, delta-F508, is the most common mutation associated with clinical CF, occurring in 66% of patients worldwide.[166] This mutation results in loss of the amino acid phenylalanine from the product protein, which ultimately affects its production, regulation, and/or function. The specific genetic mutation can now be used to predict the severity of lung disease and the prognosis in terms of survival.[43,124]

Specialized health care is most often provided through regional CF centers. Comprehensive treatment programs for CF were established over 55 years ago[59] and are the primary mode of delivery of specialized health care. CF centers changed the practice of focusing on the treatment of ongoing disease to taking a proactive approach of early intervention, maintenance of health, and preservation of lung function.[198] CF centers can offer their clients the services of respirologists, gastroenterologists, physical therapists, respiratory therapists, pharmacists, dietitians, genetic counselors, social workers, psychologists, exercise physiologists, and specialty care nursing personnel. The multidisciplinary team is dedicated to the delivery of the most effective and palatable treatments and promoting the optimal level of well-being

for patients with CF and their families. CF centers worldwide work collaboratively in sharing their clinical expertise and their knowledge base to develop new treatment possibilities and to renew hopes for an ultimate cure for CF. Definitions of key terms used in the chapter are provided in Box 26.1.

PATHOPHYSIOLOGY

The CF gene defect leads to absent or malfunctioning of the cystic fibrosis transmembrane conductance regulator (CFTR) protein, which results in abnormal chloride conductance on the epithelial cell. The main organ systems affected are the respiratory system and the gastrointestinal system, although the reproductive system, sinuses, and sweat glands are also impaired. Blockage of exocrine glands prevents the delivery of their product to target tissues and organs and creates clinical abnormalities in these body systems.

In the lung, abnormal CFTR protein leads to depletion of the airway surface liquid layer (ASL) due to obstruction of mucus secreting exocrine glands and hyperviscous secretions, which can lead to ciliary collapse and decreased mucociliary transport. The accumulation of hyperviscous secretions leads to progressive airway obstruction, secondary infection by opportunistic bacteria, inflammation, and subsequent bronchiectasis and irreversible airway damage. This vicious cycle can be complicated by bronchoconstriction of the airways and chronic lung hyperinflation. Deconditioning of the respiratory muscles and malnutrition also affect the functional limitations of the respiratory system.[166]

Obstruction of the small airways in CF and subsequent air trapping and atelectasis result in ventilation and perfusion mismatch, which leads to hypoxemia. Long-standing hypoxemia may result in pulmonary artery hypertension and cor pulmonale or right ventricular failure. Large airway bronchiectasis combined with small airway obstruction reduces vital capacity and tidal volume and results in decreased volumes of airflow at the alveolar level. Consequently, progressively increasing arterial carbon dioxide concentration ($PaCO_2$) occurs, which may lead to hypercapnic respiratory failure. Respiratory failure accounts for 95% of the mortality rate in CF.[143]

In the gastrointestinal tract, viscous secretions begin to obstruct the pancreatic duct in utero, and periductal inflammation and fibrosis cause the loss of pancreatic exocrine function. The resulting maldigestion of fats and proteins results in steatorrhea and the excretion of excessive quantities of fat in the stools.[60] The stools are described as bulky, frequent, and "greasy" and as having a strongly offensive odor. Infants with CF can display evidence of protein-calorie malnutrition with a protruding abdomen, muscle wasting, and initial diagnosis of failure to thrive despite reports from parents of hearty appetites.[111] Compensating for loss of pancreatic function remains a critical feature of management throughout the life span.

Another pathologic finding that presents in 10% to 20% of individuals with CF is meconium ileus, which is demonstrated in neonates.[133] The combination of abnormal pancreatic function and hyperviscous secretions of the intestinal glands creates an altered viscosity of the meconium, which causes an obstruction at the distal ileum, thus preventing passage of meconium in the first neonatal days.[111] Distal intestinal obstruction syndrome (DIOS) is seen in some older patients, associated with abnormal intestinal secretions and increased adherence of mucus in the intestines.[35]

Hepatobiliary disease has been reported with greater frequency among patients with pancreatic insufficiency. CF-related liver disease occurs in up to 30% of people with CF, but it is a significant clinical problem only in the minority of individuals (cirrhosis, portal hypertension). Patients with CF and pancreatic sufficiency have an increased risk of developing acute pancreatitis.[62] CF-related diabetes mellitus (CFRD) is a systemic complication whose prevalence increases with age. CFRD occurs in 2% of children, 19% of adolescents, and 40% to 50% of adults. Incidence and prevalence are higher in females age 30 to 39, but otherwise, no gender difference is noted.[128]

In the reproductive system, obstruction of the vas deferens causes infertility in 98% of males with CF.[35] Older studies reported that the fertility rate for females with CF was 20% to 30% of normal, but more recent data have suggested that the reproductive tract is normal in most women with CF. Therefore females with CF who have good weight and lung function can expect to have normal hormone levels that contribute to regular ovulation and menstruation. The only mechanical barrier present in females with CF is the cervical mucous plug.[61]

In the upper respiratory tract, chronic pansinusitis occurs in 99% of individuals with CF and contributes to the infection of the lower respiratory tract by acting as a reservoir of infection. Sinusitis may cause persistent headache and nasal polyps occur in 6% to 40% of patients and can recur after initial resection.[35] Hypertrophic pulmonary osteoarthropathy is often associated with advanced severity of pulmonary disease and is most noticeable in the clinical finding of "clubbing," or rounded hypertrophic changes in the terminal phalanges of the fingers and toes.[110] Osteopenia is present in up to 85% of adult patients, and osteoporosis in 10% to 34%. In children, the reported prevalence is not consistent because of comparisons with different control populations and corrections for bone size in growing children.[180]

BOX 26.1 Definitions of Key Terms

Airway Clearance: Cardiopulmonary techniques used to open up the airways and to loosen, unstick, collect, and mobilize secretions from the peripheral airways to the central airway to promote mucus transport in the lungs.

Cystic Fibrosis: Autosomal recessive disorder that results from the 2 CFTR mutations.

Cystic Fibrosis Transmembrane Conductance Regulator (CFTR): A protein channel that transports negatively charged chloride ions across the membrane of exocrine cells, resulting in the movement of water and other ions across the epithelial cell membrane. In the lung the balance of ions and water hydrate the airway surface liquid layer to support ciliary stability and functioning and ultimately to promote mucociliary transport.

Exercise Testing: An objective exercise assessment used to evaluate physical limitations and aerobic capacity, in which the results can be used to make recommendations for an individualized exercise program.

Forced Expiratory Volume in 1 sec (FEV_1): The amount of air that is forcefully expired in 1 second during spirometry.

Inhalation Therapy: The administration of aerosolized medications with proper breathing technique.

Pulmonary Function Tests: A group of tests that assess how well the lungs are working; determine how much air the lungs can hold, how well air moves in and out of the lungs, and how efficient gas exchange is.

Sweat Chloride Test: Clinical diagnostic test used to detect elevated chloride levels in sweat and help make a diagnosis of cystic fibrosis.

ETIOLOGY

The cause of CF is traced to the abnormal gene product, CFTR protein, which seems to be most abundantly expressed in the apical membrane surface of epithelial cells of the respiratory, gastrointestinal, and reproductive systems and in the sweat glands. Normal epithelial cells secrete fluid by allowing chloride ions (negatively charged) to pass through the luminal membrane of the cell. Because this membrane is permeable to sodium ions (positively charged), they passively follow; increased levels of sodium chloride then stimulate fluid secretion. Fluid levels in the airways must be maintained at a sufficient level to provide for normal mucociliary transport. There are 6 different classes of CFTR mutations: i) defective synthesis of the protein; ii) defective protein processing and trafficking; iii) defective CFTR channel gating; iv) defective protein channel conductance; v) reduced synthesis of CFTR; vi) high CFTR protein turnover at the cell surface.[22,53] The consequence is an electrolyte abnormality (chloride impermeability and sodium hyperpermeability) that leads to excessive amounts of fluid being removed from the airway lumen, resulting in reduced airway surface liquid (ASL) volume and underhydrated mucus. These impairments, in turn, lead to impaired mucociliary clearance and retention of mucus in the lower airways.[21,111] Abnormal expression or regulation of the CFTR protein in airway epithelial cells is the primary cause of the respiratory manifestations of CF.

DIAGNOSIS

Early diagnosis, including prenatal determination of the presence of the CF gene mutation, has enabled researchers to follow the expression and progression of the disease from birth in many patients. Impairment of the respiratory system may not manifest immediately, and at birth the lungs often appear normal on radiologic examination. A history of respiratory illness such as repeated respiratory tract infections, recurrent bronchiolitis, or even pneumonia is often reported, but in 80% of newly diagnosed cases, no family history of CF is known.[111] Chest CT scans can detect infection and inflammation that are present in a significant proportion of infants with CF at 3 months of age, and it has been shown that these early structural changes are progressive. Dilation and hypertrophy of mucus-secreting goblet cells begin early in life, leading to subsequent impaired mucociliary clearance, obstructive mucous plugs, air trapping, atelectasis, and bronchiectasis, which all reflect abnormal ventilation and perfusion. Data from CT scans have been correlated with survival and health-related quality of life; it can also be used to identify children at risk for worse pulmonary outcomes and may help to guide treatment.[192]

A diagnosis of CF is made if the patient has one or more clinical features of the disease, a history of CF in a sibling, or a positive newborn screening test, plus laboratory evidence of an abnormality in the CFTR gene or protein. Acceptable evidence of a CFTR abnormality includes biologic evidence of channel dysfunction (i.e., abnormal sweat chloride concentration or nasal potential difference) or identification of a CF disease-causing mutation in each copy of the CFTR gene (i.e., on each chromosome).[64] An elevated level of sodium chloride in the sweat has been the principal diagnostic indicator for CF for more than 50 years.[70] A positive sweat test occurs if the chloride concentration is greater than 60 mmol/L or is within the intermediate range (30–59 mmol/L for infants younger than 6 months of age and 40–59 mmol/L for older individuals).[147]

In a few centers with specialized laboratory and trained personnel, another diagnostic test, nasal potential difference (PD), is possible. This test measures the electrical charge (potential difference) across the epithelial surface (mucous membrane) of the nose. In normal subjects, a small charge of −5 to −30 mV is present, whereas subjects with CF demonstrate values between −40 and −80 mV.[143] The degree of CFTR dysfunction as measured by the nasal PD correlates with the number and severity of CFTR gene mutations.[192]

Screening tests for prospective parents who are known carriers (with prior offspring with CF or with CF themselves) are now possible and raise a number of ethical issues when CF is suggested prenatally. Genetic counseling therefore is available at CF centers. Analysis of the blood of known heterozygote parents and of tissue from the fetus obtained through amniocentesis or chorionic villus sampling can determine the presence of the CF gene mutation common to the family history.

Newborn screening is being performed increasingly in many states and provinces within North America and around the world. A sample of blood is taken, and the IRT/DNA test is a two-stage test that is used to screen for CF. The first stage of the test looks for high levels of an enzyme called IRT (immunoreactive trypsinogen) in the blood sample from the baby's foot. If the amount of IRT is above a certain level, a DNA test is performed on the same blood sample. The DNA test looks for the most common genetic mutations associated with CF. A positive finding indicates that the child is at increased risk of CF and a sweat test must be performed to confirm the diagnosis. Without the onset of newborn screening, children with CF were not diagnosed with the disease until they became symptomatic with respiratory signs or failure to thrive. Several studies have shown that newborn screening for CF leads to improved nutritional outcomes, which in turn lead to improved pulmonary outcomes later in life.[147]

The diagnosis of CF may even be discovered in adulthood because these patients usually present with milder lung disease and pancreatic sufficiency. Their diagnosis is often delayed because of the belief that CF is a pediatric disease and the finding that some adults have normal to borderline sweat test results. The criteria for making a diagnosis are the same for adults and children.[213]

MEDICAL MANAGEMENT

Individuals with CF should be followed periodically at CF clinics (usually every 3–4 months, although this can vary) by a multidisciplinary team; this practice has contributed to increasing life expectancy.[55] To determine the plan of care for each individual, the clinical team evaluates the radiologic assessment, pulmonary function testing (PFT), sputum cultures, nutritional status and patterns of weight loss, blood analysis, exercise testing, and subjective reports of treatment adherence. All of these findings help the team address the changing therapeutic needs of patients with CF and initiate treatment regimens with the aim of preventing or slowing development of functional limitations. Increased frequency of monitoring and increased use of appropriate medications have been associated with an improvement in forced expired volume in 1 second (FEV_1: see section on measuring pulmonary function) in CF centers.[89]

Morbidity in individuals with CF is primarily related to deteriorating pulmonary status. The treatment of CF lung disease aims to decrease airway obstruction due to chronic bronchorrhea (abnormal mucous secretions) and the progressive inflammation that occurs secondary to chronic bacterial infection.[112] Irreversible airway damage is caused by bacteria that infect the respiratory tract at an early age (which may be difficult to eradicate) and the associated aggressive host inflammatory response. The development of antibiotic resistance after multiple antibiotic courses leads to chronic persistent infection. In infants and younger children, *Staphylococcus aureus* and *Haemophilus influenzae* predominate, although the most common CF pathogen is *Pseudomonas aeruginosa*. It has been suggested that inhaled *P. aeruginosa* has a high affinity for CF airways, which may explain the high prevalence of this organism in patients with CF. Some bacteria such as *P. aeruginosa* and *Burkholderia cepacia* complex can also produce biofilms that protect themselves, explaining the persistence of bacterial infection in the majority of CF patients despite attempts at eradication.[52] Chronic *Pseudomonas* infection is associated with a reduction in lung function and a poorer prognosis.[134]

Antibiotic therapy appears to have significantly influenced the effects of the chronic endobronchial infection that typifies CF and has been a mainstay of treatment regimens for over 60 years.[55] Optimally, the choice of antibiotics should be based on the results of sputum culture and sensitivity tests.[19] Sputum cultures show infection by a number of organisms in a common pattern that changes with severity of disease and with the age of the patient. Opportunistic bacteria, such as *P. aeruginosa, S. aureus, H. influenzae, B. cepacia* complex, *Stenotrophomonas maltophilia,* and *Achromobacter xylosoxidans,* are the organisms most frequently seen. Combinations of infectious organisms are common, particularly when disease severity and age of the patient advance. Some evidence suggests that early and vigorous use of antibiotics produce better results than delaying their administration until symptoms are well developed or advanced.[19]

Inhaled antibiotics, such as tobramycin and colistin, are beneficial in suppressing bacterial pulmonary infection because aerosolized medications can be delivered in higher doses directly to the airways while minimizing systemic exposure and toxicity. Ramsey and colleagues showed that inhaled preservative-free tobramycin twice a day resulted in a significant increase in FEV_1 and a 36% reduction in the use of intravenous antibiotics for pulmonary exacerbations.[4,164] In the Early Intervention TOBI Eradication (ELITE) trial, a 1-month course of inhaled TOBI (preservative-free tobramycin solution) monotherapy achieved an eradication rate > 90%. Approximately 70% of patients remained culture-negative for > 800 days after the short-course eradication protocol. Inhaled antipseudomonal antibiotics have been associated with improved quality of life, decreased risk of pulmonary exacerbation, improved pulmonary function, and decreased mortality.[65]

Delaying the onset of chronic *P. aeruginosa* and the development of a mucoid strain may help to preserve lung function over the longer term.[167] Intravenous antibiotics such as ceftazidime and other aminoglycosides are used to target *Pseudomonas* infections in hospitalized patients when oral or inhaled antibiotics do not improve their respiratory symptoms related to a pulmonary exacerbation. The combination of IV antibiotics with intensified airway clearance was shown to improve lung function more than with IV antibiotics alone.[17] Nebulized aztreonam (Cayston) is a relatively new inhaled antibiotic that has been shown to improve lung function and respiratory symptoms such as decreased cough, sputum, and wheezing in patients with CF. The drug is prescribed three times daily and must be taken with a special nebulizer system, the e-flow device that is a type of vibrating mesh technology.[2]

B. cepacia complex is made of 9 different species (e.g., *B. cenocepacia, B. multivorans*) and is an opportunistic pathogen in individuals with CF and other compromised hosts.[111] *B. cepacia* complex is recognized as a particularly virulent pathogen because of its high level of intrinsic antibiotic resistance, its tenacity to persist in the lungs, and its association with more advanced pulmonary disease. Synergy studies combining antibiotics may help identify a more effective antimicrobial therapy.[24] *B. cepacia* complex is highly transmissible from person to person, which has led to initiation of segregation practices and attempts to control cross-contamination of equipment in many centers. Infection with *B. cepacia* complex can cause a rapid decline in pulmonary function and can increase mortality fourfold in individuals with CF, due to the possibility of a sepsislike condition.[35]

An organism that can be present in the airways without causing infection is *Aspergillus fumigatus,* though an intense allergic response to this fungus, allergic bronchopulmonary aspergillosis (ABPA), is seen in up to 15% of patients with CF. Clinical manifestations of ABPA include wheezing, pulmonary infiltrates, and central bronchiectasis.[147] Non-tuberculous mycobacterium, such as *Mycobacterium abscessus* complex and *Mycobacterium avium* complex, is the most emerging threat to individuals with CF. It was previously regarded as a relatively benign environmental bacteria and now has been recognized as an opportunistic pathogen that can affect morbidity and mortality in CF.[162]

Although several of the virulent products of bacterial infection cause airway inflammation and progressive epithelial destruction and therefore contribute significantly to the severity of the pulmonary impairment in CF,[111] it has also been reported that inflammation can precede infection, as was observed in bronchoalveolar lavage (BAL) studies in infants.[96] Anti-inflammatory corticosteroids may slow progressive pulmonary deterioration but are associated with numerous side effects when used on a long-term basis and require careful consideration before use.[111] They may be used in a small percentage of patients for specific indications such as fungal infection and ABPA.[19]

Influenza, rubella, and pertussis infections are particularly harmful to individuals with CF and can trigger a downward spiral of lung function. Early immunization is highly recommended, and a routine yearly influenza vaccine should be addressed in the regular clinic routine.[19]

The use of inhaled hypertonic saline has been suggested as an inexpensive treatment option to improve mucociliary clearance and pulmonary function in patients with CF. Hypertonic saline is associated with bronchospasm, so patients should be pretreated with bronchodilators. Recent studies suggest that hypertonic saline (7%) may increase the airway surface layer (ASL) to facilitate mucociliary clearance, thereby producing a short-term improvement in lung function in older children and adults.[202] Most studies have included patients with moderate to severe lung disease. In children with CF under the age of 6, there was no difference in the rate of pulmonary exacerbations between inhaled hypertonic and isotonic saline, although it has been shown to be tolerated in this age group.[63,170]

Another mucolytic agent, recombinant human DNase (dornase alfa), thins mucus by cleaving the DNA released by dead neutrophils that are responsible for the tenacity of the mucus in the airways. Daily inhalation of aerosolized DNase can reverse early air trapping and ventilation inhomogeneity, decrease markers of inflammation in sputum, reduce pulmonary exacerbation risk, and improve or slow down the decline of pulmonary function.[65]

Malnutrition is a key feature of CF because defective CFTR in the pancreatic epithelium results in obstruction of the pancreatic duct. CF patients become pancreatic insufficient when more than 95% of total pancreatic exocrine function is lost. These patients develop nutrient malabsorption and are at risk for vitamin and mineral deficiencies.[4] Nutrition and lung function are linked such that poor nutritional status and poor somatic growth affect the ability to repair lung disease. Similarly, pulmonary disease affects growth through appetite suppression and increased energy expenditure. Special attention to a properly balanced, high-calorie diet with supplementary pancreatic enzymes and vitamins requires acceptance and compliance in patients. During acute episodes of respiratory exacerbations, the anorexia that accompanies the frequent racking cough, the increase in mucus production, and the increased work of breathing pose a challenge to provision of adequate nutritional intake. Levels of resting energy expenditure have been shown to be in excess of 150% of normal in patients with CF with more progressive pulmonary disease or malnutrition.[111] Oral nutritional supplements are available, but if patients fail to improve their weight, a gastrostomy feeding tube may be inserted for additional nutritional supplementation.[4]

Cystic fibrosis–related diabetes (CFRD) can develop in CF patients, with the average age of onset between 18 and 21 years. Annual screening for CFRD with an oral glucose tolerance test starts at age 10. Hyperglycemia during times of stress, such as pulmonary exacerbations or while on steroids, can occur.[4] Female patients with CFRD have a poorer survival than male patients.[147] Intermittent CFRD can be treated with insulin, with the goal of normalizing glucose levels.

In patients with CF the airway lumen is compromised not only by secretions but also by airway edema, smooth muscle hypertrophy, and bronchoconstriction. Inhaled steroids, although never proven effective in CF in controlled clinical trials, may reduce airway edema. Bronchodilators such as β-adrenergic agonists or theophylline, intended to relax airway smooth muscle, are routinely administered, although not all patients respond to them in direct testing. Some patients may have paradoxical decreases in pulmonary function likely due to extensively damaged airways, which normally are held open by muscle tone.[55] When used immediately before exercise or pulmonary physical therapy, bronchodilators may help prevent induced bronchospasm in some people and therefore are often prescribed as an important adjunct to physical therapy.[111]

Many medications employed in the treatment of CF require nebulization. As a result, the performance characteristics of the nebulizer must be considered when a method of delivery for inhaled medications is selected. Studies comparing the efficiency of different aerosol delivery systems found a significant difference among systems in terms of particle size, total delivery of fluid, and time taken to deliver the medication.[38,107] Less drug wastage, reduced treatment time, and more specific matching of the delivery system to the breathing pattern of the individual are possible.[38]

Effective clearance of mucus-obstructed airways benefits the pulmonary system by allowing for improved ventilation and gas exchange and by limiting the tissue damage associated with recurrent infection. Today's airway clearance techniques are based on the physiologic strategy of opening up the airways and getting air behind the secretions, mobilizing and collecting secretions from the peripheral airways, transporting them toward the central airways, and finally evacuating the secretions.[102] Physical therapy techniques to promote airway clearance include postural drainage and percussion, positioning, expiratory vibrations, positive expiratory pressure (PEP) therapy, oscillating PEP therapy, high-frequency chest wall oscillations (HFCWO), directed breathing techniques such as the active cycle of breathing technique (ACBT), and autogenic drainage and are all combined with huffing and coughing. Exercise, thoracic mobility, and postural realignment exercises are often prescribed to maximize pulmonary fitness.

More research is needed to scientifically support the efficacy of the use of pulmonary physical therapy modalities in CF. Most studies assess only short-term effects on airway clearance by measuring qualities of sputum (i.e., volume, weight, and viscosity) or rates of clearance of radiolabeled aerosol from the lung. Although some modalities yield short-term improvements in these markers, few measure long-term and clinically important end points like health-related quality of life or rates of exacerbation, hospitalization, and mortality. Cochrane reviews demonstrate the need for more adequate controls, randomized design and sampling, larger sample sizes, and use of valid outcome measures.[119,131] The ethics of performing long-term randomized trials that withhold airway clearance from patients with CF is problematic because this treatment is considered to be the standard of care and has an established short-term benefit in increasing expectorated sputum volume and enhancing mucus clearance. In addition to airway clearance, exercise should be included in the management of CF. In a study at the Hospital for Sick Children in Toronto that evaluated the effects of a 3-year home exercise program, it was found that pulmonary function declined more slowly in the exercise group than in the control group, suggesting a benefit for patients with CF participating in regular aerobic exercise.[175]

Increased understanding of how CFTR dysfunction causes lung disease has resulted in new therapies that target the basic defect. CFTR replacement therapy involves the use of gene transfer therapy. This approach has been limited by the selection of an appropriate vector because of adverse side effects, transfection efficiency, and short-lived gene expression. Another treatment alternative is CFTR pharmacotherapy, which affects the trafficking, expression, or functioning of CFTR, depending on the class mutation. Most recently, a tremendous breakthrough in the disease-modifying therapy ivacaftor (Kalydeco), an oral pharmacologic potentiator that restores the function of defective CFTR at the cell surface caused by the class III mutation G551D, demonstrated improvements in lung function, weight, quality of life, and sweat chloride levels and a reduction in the frequency of pulmonary exacerbations in randomized placebo-controlled trials. This drug is approved in Canada and the United States in children older than 2 years old with the specific CFTR mutation. Moreover, ivacaftor is currently being investigated in phase 3 trials as a combination therapy with lumacaftor in patients older than 12 years of age with two F508 CFTR mutations. This novel approach involves a two-step strategy: lumacaftor brings the defective CFTR to the cell surface,

FIG. 26.1 A teenager is performing inhalation therapy via a reusable breath-enhanced nebulizer with a mouthpiece.

and ivacaftor supports the activity of the protein to restore salt and water balance for less viscous secretions.[53] Inhaled osmotic agents are being developed because they are thought to increase the airway fluid layer (Fig. 26.1). These exciting therapies are being developed to treat the early and root causes of CF, which will improve outcomes and potentially reduce the burden of care.[166] The unprecedented volume of current research and the emergence of new, successful therapies for CF dictate a need for conscientious practitioners to remain educated and receptive to adjusting their management plans and critical pathways for care of patients with CF.

LUNG TRANSPLANTATION

Organ transplantation is now a treatment option in many different terminal illnesses, including CF. Advances in surgical technique and postoperative care with improved immunosuppressive therapies have given some patients with CF a new lease on life. (See Chapter 28 for a more detailed discussion of the involvement of physical therapy in postsurgical care.)

In North America, both heart-lung and double-lung transplants have been performed on patients with CF with end-stage pulmonary disease. The Toronto Lung Transplant Group performed the world's first successful double-lung transplant in 1987.[155] Cystic fibrosis has gradually become a leading indication for lung transplantation and accounts for 54% of pediatric lung recipients in North America and 73% in Europe[14] while in adults, 17% of international lung recipients are due to CF.[216] Survival rates in pediatric lung transplantation are similar to those reported in adults, with a median survival of 4.9 years versus 5.4 years, respectively, in recipients undergoing transplantation between January 1990 and June 2011.[14]

Living-donor lobar lung transplantation has been performed since 1993, but because it involves recruitment of two donors and the surgical procedure carries inherent risks to the donors, it is not without its problems. The impact of this technique on survival statistics appears comparable with that of other approaches, but long-term analysis is needed.[184] Complications most often arise from infections or graft rejection in the early post-transplant period. In children, development of bronchiolitis obliterans syndrome is an indicator of chronic rejection and a leading cause of death after lung transplantation.[14] The problem with malabsorption in patients with CF dictates difficulties with the therapeutic regimen for adequate immunosuppression after transplantation. Individual transplant centers should direct and monitor the immunosuppressive regimen because close monitoring of serum levels and adjustment of doses are vital to successful post-transplant management.[212]

Guidelines for listing a patient with CF for lung transplantation include FEV_1 30% of predicted or rapidly declining lung function (increased frequency and duration of hospitalizations for pulmonary exacerbations, increasing antibiotic resistance of infectious bacteria, and increasing oxygen requirements, hypercapnia, and pulmonary hypertension). Patients also should have a history of compliance with medical treatment, an acceptable psychosocial profile, and functional vital organs.[99,212] A referral for transplant (and acceptance onto the waiting list) must be made early enough to allow for a substantial wait for a suitable donor and creates a need for the development of a preoperative program of physical conditioning for these patients, which is a component of the lung transplantation program in many centers. These conditioning programs are designed to optimize the patient's functional ability and exercise tolerance and to help maintain emotional well-being during the long wait for a transplant.[45] Recently, a study found that pediatric lung transplant candidates that are ambulatory prior to transplant and able to walk greater than 229–305 m during a 6-MWT have better outcomes postoperatively.[215] The inclusion of a home-based or hospital-attended semiindividualized exercise program following lung transplantation in children demonstrated improved health-related fitness.[57] Physical therapists play a primary role in the development and implementation of both preoperative and postoperative exercise programs.

Double-lung transplantation is now most often performed by bilateral anterolateral thoracotomies using bilateral submammary incisions, as first described in 1990.[149] The lungs are transplanted as sequential single-lung grafts. The lung with the worst pulmonary function is replaced first, while oxygenation and ventilation are maintained by the native lung. Replacement of the second lung can then proceed with the newly implanted lung supporting the patient. Use of this technique has reduced to 30% to 35% the number of patients requiring anticoagulation and cardiopulmonary bypass during surgery. This surgical innovation has also reduced the degree of complications from perioperative bleeding, which can be a significant problem for patients with CF because of the presence of inflammatory adhesions within the pleural space.[209]

Single-lung transplants are not performed on patients with CF because the remaining native lung continues to be ventilated after transplantation, and its overexpansion will compress the transplanted lung.[110] Contamination of the native lung could also spread infection to the transplanted lung.

Impairments in Pulmonary Function and Digestive Absorption

Mucous plugging and bronchiolitis in the patient's airways cause ventilation-perfusion abnormalities, and the subsequent

hypoxemia worsens as severity of the obstruction increases.[110] Further declines in arterial oxygenation can occur during sleep, so blood gases may have to be monitored throughout the night to assess the need for nocturnal supplementary oxygen.[132] Increased oxygen demands during exercise can be a contributing factor to hypoxemia in individuals with CF. Although arterial blood gas measures are considered the "gold standard" in blood gas analysis,[218] they are not commonly used in patients with CF because of their invasive nature. Other noninvasive techniques are preferred, such as pulse oximetry, which measures the level of oxygen saturation in the blood. This assessment tool can be used to evaluate the suitability of supplemental oxygen during exercise performance.

Other changes in blood gas readings forewarn of serious advanced pathology. Hypercapnia in CF indicates advanced pulmonary disease and carries a poor prognosis. In a study of survival patterns of patients with CF who demonstrated hypercapnia, it was found that death usually occurred within 1 year of the development of chronic hypercapnia[201] without interventions such as noninvasive ventilation or lung transplantation.

Chest radiographs can provide detailed evidence of the progressive nature of pulmonary disease in CF (Fig. 26.2). In the initial stages of pulmonary involvement, the chest radiograph may reveal signs of hyperinflation and peribronchial thickening. As the disease progresses, bronchiectasis can become apparent, particularly in the upper lobes, and pulmonary infiltrates appear as nodular shadows on radiographs. With severe pulmonary disease the hyperexpanded lungs can precipitate flattening of the diaphragm, thoracic kyphosis, and bowing of the sternum—all detectable on radiography.[110] Confirmation of the development of a pneumothorax can also be provided by examining the chest radiographs. When pulmonary disease is advanced, pulmonary artery hypertrophy may be noticed on radiography as a sign of the pulmonary hypertension associated with cor pulmonale.[110]

Cultures from sputum of a patient with CF identify the variety of bacteria that have infected the lower respiratory tract. Sensitivity studies can then be performed to identify effective antibiotic therapies.[143] CF centers perform regular sputum bacteriologic tests to ensure adequate antibiotic coverage for their patients and to help monitor the state of bacterial infection.[112]

The physical examination provides valuable information on pulmonary function. Examination of the chest includes inspection, palpation, percussion, and auscultation. Inspection can reveal postural abnormalities (Fig. 26.3), modifications of breathing pattern (Fig. 26.4), or signs of respiratory distress. Evidence of a chronic productive cough is desirable. Examination of the comparative dimensions of the chest in the anterior-posterior and transverse planes is important because barrel chest deformity is common to obstructive lung diseases.[86] Inspection of the fingers and toes may reveal bluish nail beds and clubbing of the digits, which reflect a change in the amount of soft tissue at the nail bed associated with lung disease. Palpation of the chest wall for excursion and for tactile fremitus may reveal atelectasis, pneumothorax, or large airway secretions. The resonance pattern of the chest is examined by percussion. Audible changes in the resonance pattern are an indication of abnormally dense areas of the lungs.[86] Age of the patient may limit the reliability and clinical usefulness of components of the physical examination. In infants, measurement of chest wall expansion may be difficult and percussion may not be appropriate.[44]

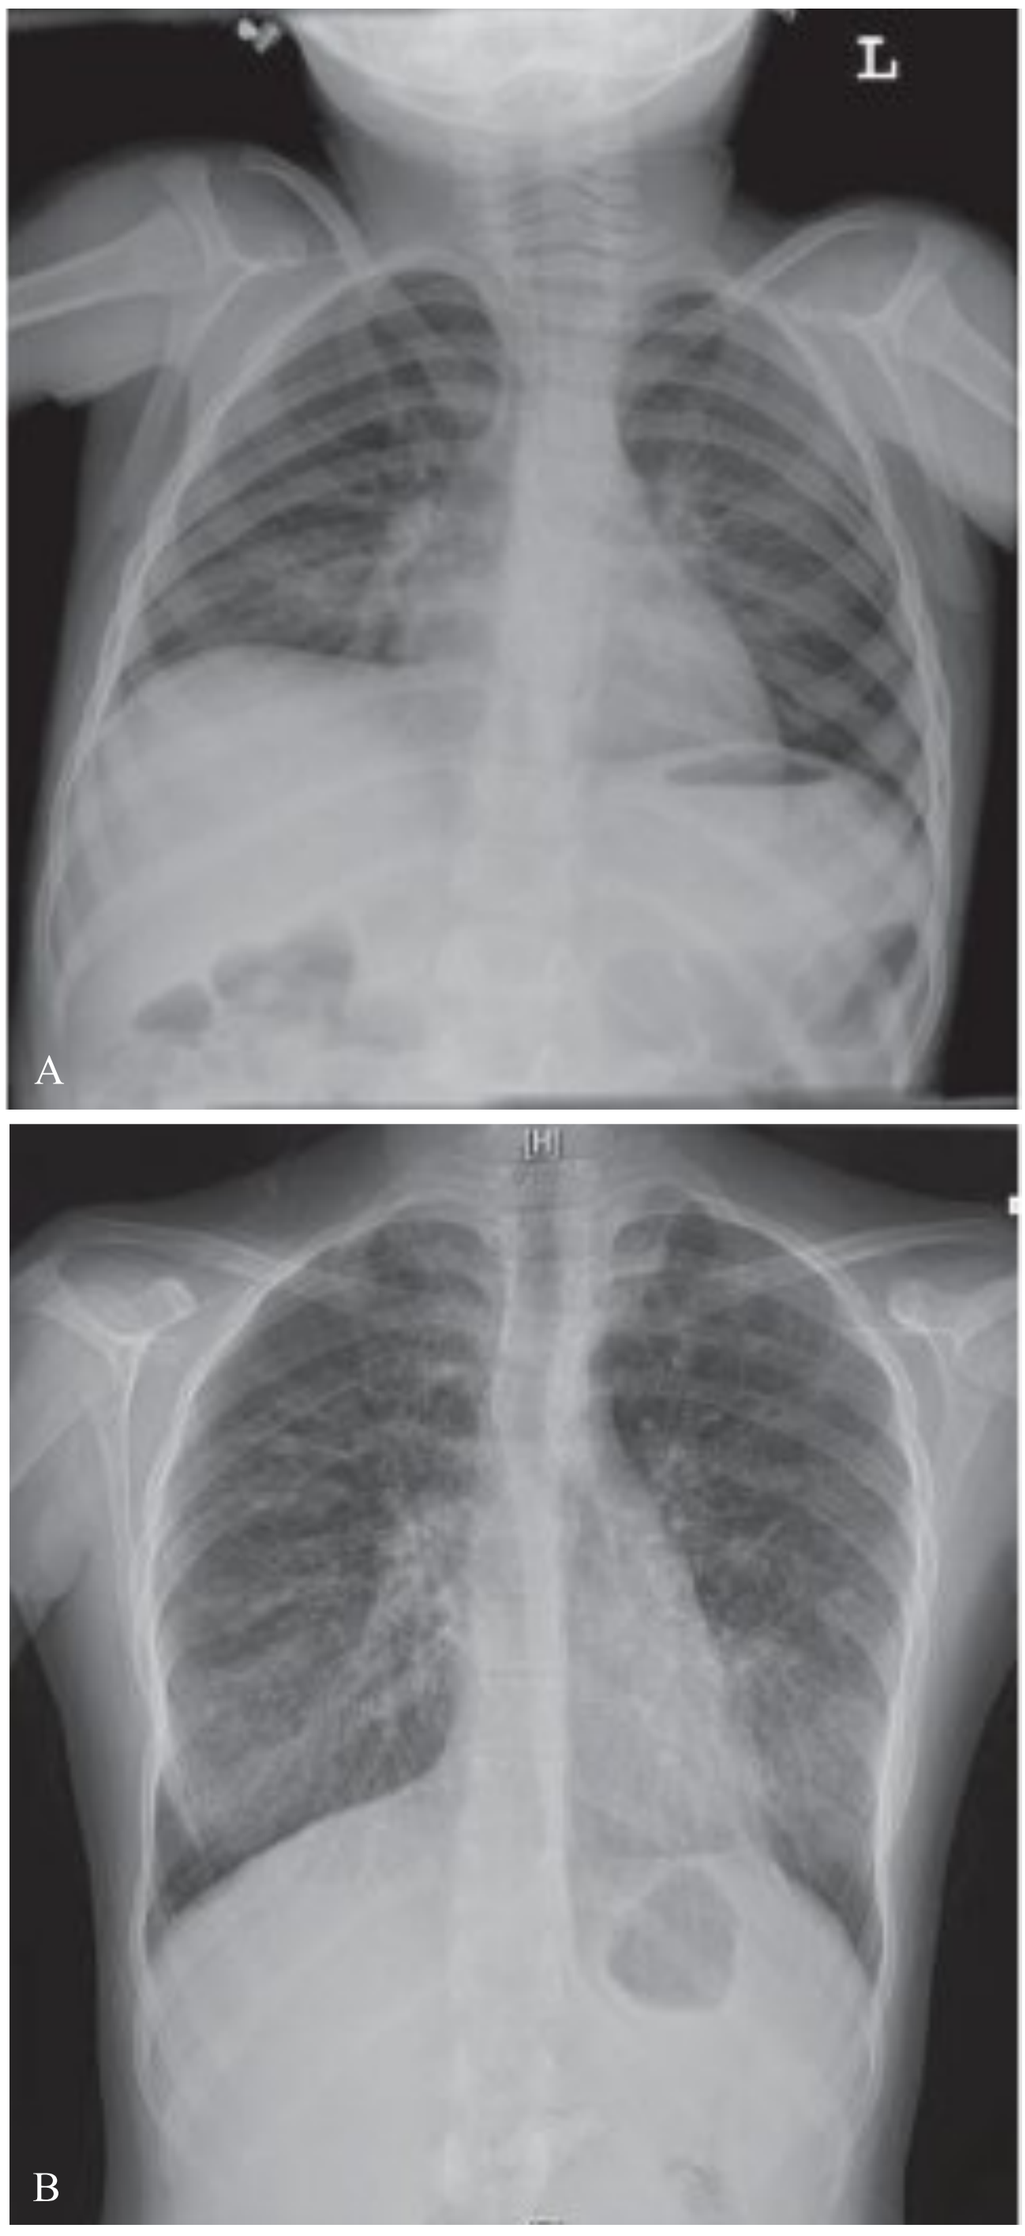

FIG. 26.2 Two chest radiographs of the same individual showing marked deterioration over the course of 10 years. (A) At age 4, there is already evidence of bilateral perihilar peribronchial thickening and patchy infiltrates in the right middle lobe, suggestive of mucous plugging. (B) Diffuse bilateral bronchiectasis associated with cystic fibrosis with hyperinflation and bilateral areas of consolidation.

Auscultation of the chest contributes information on the quality of airflow and evidence of obstruction in different areas of the lungs. Reduced ventilation is suggested by decreased breath sounds or the presence of inspiratory crackles (also called *rales*). If crackles are heard throughout the ventilation

FIG. 26.3 An example of postural changes in an individual: elevation of the shoulders, protracted scapulae, and increased anterior-posterior diameter of the chest. Note the intercostal indrawing.

FIG. 26.4 Use of accessory muscles of respiration, tracheal tug, and supraclavicular indrawing is apparent on physical inspection. Note the gastrostomy tube and the port-a-catheter line.

cycle, this suggests impaired secretion clearance. Diffuse airway obstruction may cause polyphonic wheezing. The examiner must be aware that chronically hyperinflated lungs tend to mask or make it difficult to hear adventitious sounds on auscultation.[86] Familiarization with a patient's lung sounds is important because a change may signal a change in pulmonary function that might otherwise have gone undetected.

Individuals with CF must make a concerted effort to consume adequate calories to meet the increased work of breathing and altered digestive absorption. Individuals with CF who are pancreatic insufficient require oral supplementary enzymes to absorb adequate nutrients from their diet. Pancreatic function is determined by a number of methods including fecal fat assessment, pancreatic substrate assays, and direct collection of pancreatic secretions by duodenal intubation.[111] Individuals with CF whose pancreatic function is sufficient are able to maintain fat absorption and have less pulmonary dysfunction than individuals who have pancreatic insufficiency.[42] Because pulmonary function is strongly associated with adequate nutrition and weight gain, the goal of treatment is prevention of the cascade of wasting precipitated by reduced lung function, increased energy expenditure, decreased intake due to poor appetite, and increased losses due to malabsorption.

Other factors that are associated with a preferred prognosis include single-organ involvement at diagnosis, absent or single-organism sputum colonization, and a normal chest radiograph 1 year after diagnosis. Multiple organ involvement, abnormal chest radiographs at diagnosis, colonization of multiple organisms in the sputum, a falloff from typical growth, and recurrent hemoptysis are all factors associated with a poor prognosis. There also appears to be a gender bias in severity of disease expression, with males having a better prognosis than females.[112]

Pulmonary Function Testing

Pulmonary function tests (PFTs) are used to evaluate lung function and are administered by pulmonary function technicians. PFTs are indicated to determine the presence or absence of lung disease, to quantify the effects of a known lung disease on lung function, and to determine the beneficial or negative effects of various types of therapy.

PFTs consist of a number of different tests, and the type of test ordered depends on the question to be answered. The most common question for patients with CF is, "What is the degree of obstruction?" This parameter is easily measured with spirometry, which measures forced vital capacity (FVC), FEV_1, and airflow rates (forced expired flow between 25% and 75% of the vital capacity) during different phases of expiration, yielding an indication of the amount of bronchial obstruction present. The measure of FEV_1 chronicles the early portion of expiration and is often reported as a ratio of FVC. In a healthy individual, FEV_1/FVC is 0.70 to 0.80 indicating that 70% to 80% of the FVC is expired in the first seconds of a forced exhalation.[78] A decrease in this ratio reflects an obstructed expiratory airflow.

Early detection of abnormalities in lung function in CF is critical because these initial changes involve the small airways. Miller suggests that forced expiratory flow (FEF) 25%–75% is more sensitive than FEV_1 or FEV_1/FVC in detecting changes in small airway obstruction.[127] Timed volumes at high lung volumes (e.g., FEV_1) may remain within typical limits because the contribution of the small airways to overall resistance is low.[91] FEV_1 therefore is not a sensitive test in early lung disease but indicates obstruction of the central bronchi and becomes markedly abnormal as disease progresses.[111] (A video demonstrating administration of pulmonary function testing is included on Expert Consult.)

Another form of PFTs is plethysmography, in which the patient breathes through a mouthpiece to measure changes in air pressure within a sealed chamber (body box) while the volume of air remains constant. The volumes that can be measured include functional residual capacity (FRC), total lung capacity (TLC), and residual volume (RV), which can also be assessed by gas dilution methods.[172] Both of these techniques can further

evaluate severity of lung disease by determining the degree of gas trapping that occurs in an obstructive disease such as CF.

The US National Institutes of Health's comparative review of 307 cases of CF reported that PFT scores showed a common pattern: progressive decline in flow rates and vital capacity (VC) and an increase in the RV/TLC ratio, correlating with clinically gauged worsening of disease.[58] As pulmonary disease becomes progressively more severe, deteriorating PFT scores can be used to help predict life expectancy. In one study, patients with poor arterial gases and an FEV_1 of less than 30% of predicted value had 2-year mortality rates of greater than 50%.[94] Individuals with CF demonstrate a characteristic decline in mid-expiratory flow rate ($FEF_{25\%–75\%}$); noting the rate of this decline becomes an important prognostic indicator.[77] Steadily worsening PFT scores correlate with declining clinical conditions and are used as an indicator in assessment for lung transplantation.[95] FEV_1 has been shown to be the strongest predictor of mortality in CF and has been the primary outcome measure in many clinical trials[206]; however, it may not be sensitive enough to detect changes in lung function because most patients with CF have normal FEV_1 until adolescence.

Although PFTs are informative and invaluable for early detection in advance of lung disease, these tests are not always easily performed. Patients must be cooperative, must be able to follow specific instructions, and must give maximum effort. Children younger than age 6 years usually cannot perform the standard test of forced expiration in 1 second in a reliable manner. Recent reports document that children between 3 and 6 years can successfully undergo spirometry[139]; however, there is a large learning curve and extra time may have to be scheduled into their clinic appointment. Another study examining children age 2 to 5 years found that modifying the FEV_1 test to $FEV_{0.75}$ gave a reliable measure of pulmonary function for young children.[10] Various techniques are being developed to measure pulmonary function in infants, such as the raised-volume rapid thoracoabdominal compression (RVRTC) technique and fractional lung volumes. Revised techniques of rapid thoracic compression following increasing lung volumes near TLC and multiple breath washouts have also been investigated. Infant PFTs require sedation, special equipment, and trained personnel, which currently are available in only a few centers.[206]

In older children and adults, many other factors, such as sputum retention, poor nutrition, and fatigue, can influence the individual's performance during spirometry. Notably, many children with CF show performance scores on repeat tests that have a significantly greater range of variability than scores of typical test subjects.[41] The body plethysmography test can help to more accurately assess lung function by measuring the patient's lung volumes (FRC, TLC, and RV). Some claustrophobia may be experienced by patients undergoing testing in the "body box," and plethysmography may not be appropriate for all young children.

The lung-clearance index (LCI) is a more sensitive test than spirometry at the early stages of disease because it correlates with structural changes on computed tomography imaging and has been shown to be predictive of later lung function abnormalities.[186] The test consists of multiple-breath washout of a nonabsorbable gas (sulfur hexafluoride, nitrogen gas) to measure ventilation inhomogeneity caused by airways narrowing from inflammation or partial obstruction by mucus. The technique is easy to perform, requiring only tidal breathing; no additional coordination or forced maneuvers are needed, making it possible to use the technique in infancy and during preschool ages to generate repeatable and reproducible results. A small study demonstrated that abnormal LCI values could be present in younger children with CF who have apparently normal FEV_1.[196] One disadvantage is that the inhaled gas does not reach regions of the lung that are completely obstructed and therefore may underestimate disease severity.[51] Recently, the measurement technique was standardized and was shown to provide good short- and medium-term repeatability as well as being responsive to interventions such as intravenous antibiotics, hypertonic saline, and DNase.[192]

TABLE 26.1 Selected Tests and Measures Used and/or Interpreted by Physical Therapists

Test/Measure	Performed by
Exercise testing: cycle ergometer, stationary bike, treadmill	Exercise physiologist
Pulmonary function test (PFT): Spirometry, LCI	PFT technician
Exercise field tests (6 MWT, 12 MWT, shuttle test, 3 MST)	Physical therapist
15-Count breathlessness score	Physical therapist
RPE (rate of perceived exertion) using modified Borg scale	
Radiologic tests	Technician
Pulse oximetry	Physical therapist
Heart rate	Physical therapist
Respiratory rate	Physical therapist
Sputum: quantity, color, viscosity, odor	Physical therapist
Manual muscle testing	Physical therapist
Postural screening and range of motion (ROM)	Physical therapist
Breathing patterns	Physical therapist

LCI, lung clearance index; MST, Minute Shuttle Test; MWT, Minute Walk Test.

FOREGROUND INFORMATION

PHYSICAL THERAPY EXAMINATION, EVALUATION, AND INTERVENTION

The role of the physical therapist in serving children and families is described during infancy, preschool and school age, adolescence, and transition to adulthood. Readers are encouraged to navigate the website of the Cystic Fibrosis Foundation (http://www.cff.org) to become familiar with the available resources. Selected tests and measures and interventions for children with CF are provided in Tables 26.1 and 26.2.

Infancy

Newborn screening for CF is currently carried out in many countries around the world, including the United States and in most provinces of Canada. The current method of screening suggests that many but not all newborns with CF can be identified. Studies have suggested that through newborn screening, nutritional deficits are detected and that early intervention may be useful to protect against loss of lung function.[19] A shorter prediagnostic period is associated with less negative feelings and increased confidence in the medical profession among parents of children with CF.[126]

A diagnosis of CF for their child can mean many things to parents. At the most basic level, it means they have a child with

TABLE 26.2 Summary of Physical Therapy Interventions for Children With Cystic Fibrosis

Intervention	Example
Airway clearance techniques	Modified postural drainage and percussions, positive expiratory pressure, oscillating positive expiratory pressure, active cycle of breathing technique, autogenic drainage
Postural exercises	Chin and shoulder retraction
Mobility exercises	Side trunk flexion, chest expansion
Stretches	Pectoral stretch over ball
Strengthening	Core muscles, large muscle groups
Aerobic training	Swimming, running
Inhalation therapies	Compressor, nebulizer education on administering medications
Energy conservation	Positioning for shortness of breath, pacing, timing of activities
Efficient breathing pattern training	Diaphragmatic pursed lip breathing
Urinary incontinence training	Core and pelvic floor muscle strengthening The Knack (contraction of the pelvic floor muscles before and during events that increase pressure on the pelvic floor)

"special needs," and those needs can be seen to influence the family dynamics.[106] The child's family members are forced to familiarize themselves with CF and with the psychological and practical demands inherent in this diagnosis. Addressing family information needs including what to expect for their child is critical. Intervention often must be implemented immediately upon diagnosis, and the family needs assistance in making the necessary adjustments and provisions to ensure adherence with the recommended therapeutic regimen.

Supporting Families

Sensitivity and equanimity while interacting with families of infants diagnosed with CF are important for effective communication because this is a very stressful time for all involved. Active listening, asking for feedback after information is shared, and clarification are strategies used by physical therapists to minimize miscommunication; what the family or professional may "hear" can differ from what is actually said.[26] Families seem to want information that acknowledges the seriousness of the disease while emphasizing the likelihood of a happy and fulfilling family life. Flexibility promotes better integration of the child's treatment into the family's routines. Parents may have many concerns and a host of questions and can be especially confused by all the uncertainty that typifies the disease. Because the progression of CF is so variable from case to case, ongoing examination of the child is the only way to ensure that treatments are individualized to meet child and family needs. This means that family members must have continued association with the CF center and appreciate their role as integral members of the caregiving team.

Children with a chronic condition have been shown to have increased risk of psychosocial dysfunction with low self-esteem, poor school attendance, and family factors all playing a significant role in their ability to adjust.[193] Because parental overprotection is strongly linked to the existence of psychosocial maladjustment in children,[85] the parents of a child with CF must be alerted to the dangers of unnecessarily shielding their child from aspects of normal life. In infancy, this may take the form of overdressing the child to guard against drafts or neglecting to allow the child to participate in exploratory play. Physical therapists should reassure parents that infants with CF have the same interests and learn through social interactions, movement, and play similar to other infants. Parents are encouraged to position and play with their infant following developmental milestones to encourage chest mobility, leg strengthening, and endurance training.

In a large study across nine countries, 17% of patients with CF reported depression, which was two times that reported in community populations; 37% of mothers and 31% of fathers reported clinically elevated depression, which were three times the rate in the community samples. The authors conclude that assessing and treating mental health issues in patients and families coping with a serious, chronic illness should be performed.[161] The physical therapist can help to identify individuals with CF and their families who appear to be struggling and refer them to the psychologist or psychiatrist on the team so issues can be addressed early. Excellent reference materials are available in most CF centers. Teaching manuals designed to supplement the information imparted by the CF center staff are often distributed to families and can be made available to other interested caregivers such as child care workers or school teachers.

Management of Impairments in Pulmonary Function

In the neonate the most common symptoms of CF are meconium ileus, malabsorption of nutrients, and failure to thrive, all of which are associated with involvement of the gastrointestinal tract.[171] Overt pulmonary involvement is not apparent in the neonatal period because the lungs are morphologically normal at birth.[80,110] Within a few months, however, some infants with CF develop signs of impaired respiratory function, manifesting symptoms suggesting bronchiolitis. Pronounced wheeze, an indication of hyperactive airways, is sometimes apparent, and chest radiographs can reveal evidence of hyperinflation. Obstruction of airflow may be related to airway inflammation, mucosal edema, copious mucus secretion retention, and increased airway tone.[189] The bronchioles are the main site of airflow obstruction in infancy. Studies using bronchoalveolar lavage revealed that every infant with CF, whether symptomatic or not, has small airway obstruction in the form of bronchial mucous casts.[211] Pulmonary function cannot be measured in the conventional way (e.g., spirometry) in infants; therefore researchers have had to modify standard methods by using the raised-volume rapid thoracoabdominal compression technique (RVRTC). $FEV_{0.5}$ was measured and was found to be significantly lower in infants with CF shortly after diagnosis (median age of 28 weeks) and 6 months later on retest.[165]

Infants with CF demonstrate decreased lung compliance and a less homogeneous distribution of ventilation when compared with typical control subjects.[191] Tepper and colleagues found these changes in both symptomatic and asymptomatic infants.[190] Abnormalities in flow-volume curves[71] and low values of maximal expiratory flow[83] indicate that limitations to airflow in infancy are associated with bronchoconstriction.[80] Infants with CF have indeed displayed altered bronchial tone after the administration of a bronchodilator, as revealed by the fact that airflow rates showed significant increases not seen in a control group.[83] Methacholine challenge testing also revealed heightened airway responsiveness.[1]

The PFTs used for infants in research are not feasible or practical in most clinics or CF centers. Examination of pulmonary involvement in infancy is usually limited to observation of

chest and breathing patterns, history of respiratory symptoms, and chest radiographs. Carefully observing for signs of respiratory distress, such as nasal flaring, expiratory grunting, retractions of the chest wall, tachypnea, pallor, or cyanosis, produces an indication of respiratory status. Interpretation of auscultation of an infant or young child is more challenging because of easily transmitted sounds from close structures underlying the thin chest wall,[44] but careful auscultation is necessary to ascertain if there is any evidence of wheezing. Changes visible on radiography are the most reliable indication of early pulmonary involvement because it has been demonstrated that airflow obstruction may precede the presence of overt respiratory symptoms. Historical accounts of respiratory illness must also be carefully considered.

The rate of deterioration of pulmonary function in individuals with CF may be slowed by early initiation of treatment. Bronchoalveolar lavage findings in infants with CF show the presence of infection and inflammation within the airways as early as 4 weeks postpartum even before clinical manifestations, which can damage the respiratory epithelium resulting in an impairment of mucociliary transport and secretion retention. The airways of infants with CF have also been shown to be morphologically abnormal with greater diameter and thicker walls.[108] The change in respiratory patterns and mechanics suggests that early therapeutic intervention might actually delay the onset of overt symptoms of respiratory impairment, but the value of initiating pulmonary treatment before development of symptoms remains controversial, although various theoretical arguments for initiating therapy as soon as possible can be presented. The time before onset of structural changes provides an opportunity for intervention and prevention of onset of progressive airway damage.[23] Adherence may be improved if airway clearance therapy is incorporated into the child's daily routine; prevention of respiratory impairment should be emphasized early in the treatment plan.[211] Parents of infants with CF can also develop sensitive observational skills needed to detect changes in their infant's status and to liaise with the team appropriately.[102]

A study was conducted to evaluate the combined effects of a bronchodilator and cardiopulmonary physical therapy on infants newly diagnosed with CF, addressing the controversy surrounding treatment for asymptomatic children.[80] Baseline, preintervention measurements of the mechanics and energetics of breathing were obtained for all subjects. Twenty minutes after the inhalation of a bronchodilator, cardiopulmonary physical therapy was given to the subjects, consisting of 20 minutes of chest percussions and vibrations applied in five different postural drainage positions. Immediately after the physical therapy session, repeat pulmonary function measurements were taken. Most of the infants (10 of 13) demonstrated decreases from baseline values in pulmonary resistance, with subsequent decreases in the work of breathing, after administration of the bronchodilator and physical therapy.[80] The investigators postulated that the bronchodilator relieved subclinical bronchospasm and aided the reduction of mucosal edema, and physical therapy assisted the mucociliary system by effectively mobilizing secretions and improving the patency of the airways.[80] When serial PFTs are possible, objective measures of the progression of impairment and the effects of specific treatments may provide evidence of the effects of early intervention.[80]

Prevention of obstructive mucous plugging is the initial goal of pulmonary physical therapy. Historically, in infants with CF the primary modalities used in airway clearance were postural drainage, percussion, and vibration, which all use gravity-assisted positions to drain secretions while using a cupped hand to percuss. More recently, assisted autogenic drainage, baby PEP mask, and mobility exercises have been recognized as alternatives to airway clearance in infants.[87]

FIG. 26.5 Modified postural drainage and percussion on an infant performed by a parent using a palm cup.

In obstructive airway diseases such as CF, the effectiveness of the antireflux mechanism at the esophagogastric junction is reduced.[145] Increases in intraabdominal pressure associated with coughing also promote gastroesophageal reflux.[176] The effectiveness of the antireflux barrier is further reduced in infants because of the anatomy of their chest. Their chests are more cylindrically shaped with a more cartilaginous rib cage, making the ribs more horizontally aligned while flattening the diaphragm and increasing the sternocostal angle.[102] Of newly diagnosed infants with CF, 35% had symptomatic gastroesophageal reflux in one study,[197] and 24-hour esophageal monitoring revealed abnormalities in 10 successive infants newly diagnosed with CF in another.[48] There are suggestions that reflux can worsen lung disease in CF and cause upper respiratory symptoms.[214] A 5-year comparative study by Button and colleagues compared the standard 30° head-down tilt position versus the modified position (no tip) in 20 infants with CF who were asymptomatic.[29] The investigators found that infants positioned in the modified position had significantly fewer days with upper respiratory tract symptom, shorter courses of antibiotics during the first year of life, better chest x-ray scores at 2.5 years of age, and better pulmonary function at 5 years compared with children who received postural drainage with their heads-down tilt. Therefore it is recommended that the modified postural drainage position be used for postural drainage.

Timing physical therapy around feeding schedules may also be necessary to reduce the risk of gastroesophageal reflux. Postural drainage positions are easily achieved by placing the infant in the desired position on the caregiver's lap. Holding the small child in this way also seems to offer the child an extra measure of security. Adapting hand position (by "tenting" the middle finger) or using a rubber palm cup suits the application of percussion on a tiny chest wall (Fig. 26.5). The applied force of percussion should vary with the size and condition of the infant, and conscientious monitoring of the infant's response guides the amount of vigor used in percussion. Timing of manual vibrations to coincide with the expirations of an infant is difficult because of the infant's rapid respiratory rate, and this technique may be very challenging to teach to parents. (A video

demonstrating modified postural drainage and percussion is included on Expert Consult.)

Use of a PEP mask has been compared with postural drainage in infants with CF. Constantini and colleagues studied 26 newborns with CF over 12 months using PEP and postural drainage as airway clearance techniques.[39] The use of PEP was associated with less severe gastroesophageal reflux when compared with postural drainage. No significant difference in the effectiveness of airway clearance was noted; however, patients and parents preferred PEP. Assisted autogenic drainage is an alternative airway clearance technique for infants or individuals who are unable to cooperate.[195] The goal of this technique is to prolong expiration toward residual volume and increase the expiratory flow, which can enhance mucus transport toward the larger airways. The placement of the therapist's hands on the individual chest wall provides pressure and gradually restricts the inspiratory level.[87] Ongoing communication, education, and instruction with the family are important. Periodically asking the parent or caregiver to demonstrate treatment positions and manual technique allows the therapist to reinforce proper technique and identify problems with proper application. Instructing parents to play breathing games with their infants and toddlers is a first step in learning to perform diaphragmatic breathing and huffing. Breathing exercises can promote use of collateral ventilation and can introduce concepts of techniques that will be used at older ages. In some CF centers, the physical therapist is also responsible for ordering, demonstrating, and arranging equipment necessary for the aerosol delivery of medications. Instruction on the care and use of these nebulizers is vitally important to ensure correct delivery of prescribed medications.

Adherence to a therapeutic regimen requires commitment on the part of the caregiver. The demands of caring for a child with CF can seem extreme when considering the extra attention to nutritional issues, medications, and physical therapy. Signs of excessive stress or evidence that the family is having difficulty in coping with the caregiving requirements may become obvious. Referral to a social worker or a psychologist might help identify the family in crisis and aid the family in developing strategies to enable adjustment to the various challenges that lie ahead of them as they nurture their child with CF.

Preschool and School Age

More than 75% of children with CF are now diagnosed before their second birthday.[151] When there is a positive family history of CF, parents are familiar with the disease, but in many cases, there is no prior knowledge of the disorder and the diagnosis can be startling. Initial shock may be followed by disbelief, anger, or grief.[106] The age of the child when diagnosed affects parental reaction to some extent. The older the child, the greater the likelihood that the parents may experience extreme shock at the time of diagnosis.[25] Sensitivity to the anguish experienced by the family must be shown.

The clinical status of children with CF is highly variable. Some toddlers may have already experienced pulmonary complications and been hospitalized repeatedly, whereas others exhibit little or no detrimental impact on their respiratory function. The effects of protein-calorie deficits due to malabsorption may be manifest in stunted development such as small stature or a lower than average weight-to-height ratio; therefore a difference in appearance from their healthy siblings or friends may be perceptible.

Self-Efficacy and Participation

Young children need to develop the ability to function socially outside the family circle. Demands of school and new friendships dictate a lessening of parental attachments and a capacity for some measure of independence.[106] This type of autonomy may be difficult to achieve for the child with CF. If parents perceive that their child is fragile with exceptionally vulnerable health, they may become overprotective. Cappelli and colleagues found a strong correlation between parental overprotection and psychological maladjustment in the child.[31] Encouraging children with CF to participate in a variety of social and physical activities could prove beneficial for their physical and emotional health. The physical therapist should stress the importance of incorporating an active lifestyle into the family dynamic.

Assisting children to gain a sense of self-efficacy is an important goal. A key factor of lifelong adherence to necessary treatment is incorporating a sense of self-efficacy (the confidence that one has the ability to perform a behavior). Adherence is promoted through interaction with a credible role model, encouragement to perform tasks of self-management, and development of competency. Individual care plans are developed with each child, and a self-care manual is provided to the families to act as a guide. Initiating teaching when the child is young and regularly reinforcing education with both parents and children may counteract the negative correlation between adherence and aging.[7] Better adherence to CF therapies is more likely in children whose parents strongly believe that the treatments are necessary.[72] In a study evaluating the association between adherence to pulmonary medications and health care use, low adherence was a significant predicator of subsequent health care use and costs.[160]

Examination and Evaluation

Examination and evaluation in the young child include history, physical examination, chest radiographs, blood gases, oximetry, and sputum bacteriology. The pulmonary function of younger children can be assessed by the lung clearance index (LCI) if the equipment is available and in children who are able to execute the necessary voluntary maneuver spirometry.

Examination by the physical therapist should include thorough history taking, a physical examination including posture when applicable, and some type of exercise tolerance testing. A minority of young children with CF may have chronic cough, hypoxemia, and decreased compliance of the lungs,[191] leading to restrictions in maximal oxygen consumption, an increase in the work of breathing, and an increase in resting energy expenditure.[181] These factors all compromise exercise tolerance.

Exercise testing is an objective method by which the physical therapist can quantify the patient's disease severity and functional ability.[163] Individuals with CF often will not be aware of the extent of their physical limitations owing to the slow progression of their disease.[33] An exercise test can detect mild pulmonary dysfunction, which may go undetected during investigations at rest, and will also help reveal how individuals cope with work despite their disability. (A video demonstrating exercising testing is included on Expert Consult.)

When an exercise test protocol is chosen, the purpose of the test and the age and disease severity of the subject should be carefully considered. Choosing the appropriate exercise test depends on the specific question being asked. For example, to assess activity limitations in aerobic performance, the exercise

test should be progressive and should stress the subject's cardiorespiratory system to a symptom-limited maximum. The test should also be reproducible and capable of providing meaningful results.[81]

Cycle ergometers are often used for testing exercise capacity in children with pulmonary disease.[34,138] An accurate prediction of oxygen consumption can be obtained because the mechanical efficiency for pedaling a cycle is independent of body weight and therefore is almost identical for all individuals.[33] Although the treadmill test generally yields higher oxygen consumption values, the cycle ergometer offers the advantages of being relatively inexpensive, portable, and safe. Because cycling is a familiar exercise for many people, it is less likely to cause apprehension. As with the treadmill test, cycle ergometry is reproducible. In addition, the subject is relatively stationary, and therefore vital signs are more easily monitored. Most ergometers have adjustable seat heights suitable for children, and it is important to be able to adjust handlebars and pedal crank length.

Several progressive exercise protocols are used on the cycle ergometer to determine maximum oxygen consumption or individual peak work capacity (Fig. 26.6; see Chapter 6). Cerny and colleagues examined subjects with CF matched to a control group without CF to monitor cardiopulmonary response to incrementally increased workloads with cycle ergometry.[34] Workloads were increased every 2 minutes until the subject could not continue. The study demonstrated that subjects with typical development needed an increased workload of 0.32 W/kg on average for an increase in heart rate of 10 beats per minute. Subjects with CF required workload increases ranging from 0.15 to 0.35 W/kg, depending on the severity of their disease, to demonstrate the same change in heart rate. Cerny and colleagues concluded that the limiting factor in exercise tolerance was severity of pulmonary involvement and not cardiovascular limitation.[34]

If the child is too small to successfully use a cycle ergometer, a treadmill can be used because only the ability to walk is required. The child should be monitored closely to maintain a sense of confidence during the test. Elevation and speed are adjusted according to the size and skill of the subject and should be selected to allow even the subject with severe dysfunction to exercise at two to three levels of difficulty.[33] Two protocols frequently used for children with CF are the Godfrey protocol for cycle tests and the Bruce protocol for treadmill testing.[163]

FIG. 26.6 Exercise testing with a young patient on oxygen.

For individuals with severe lung disease, field walking tests such as 6- or 12-minute walks[27] or the shuttle walking test[177] may be preferred. The reliability and validity of the 6-minute walk test[76] and the shuttle test[179] with children with CF have been demonstrated, and normative values for children who are healthy have been published.[163] Walking tests are simple, inexpensive, and can be performed by individuals of all ages and abilities with little risk of injury.[156] Because they are highly reproducible, walking tests correspond closely to the demands of everyday activity. Another quick and portable test that may prove useful in a clinical setting is the 3-minute step test, which showed similar results as the 6-minute walk test when outcome measures were oxygen saturation, maximum pulse rate, and the Modified Borg Dyspnea Scale.[11] Narang and colleagues, however, found that when the 3-minute step test was compared with the cycle ergometer, the 3-minute step test provided limited information related to exercise performance in a group with mild lung disease.[135] They suggest that a more suitable test for this group must be given at a higher intensity and must equate better to typical levels of physical activity.

Subjects performing an exercise test must be closely monitored and special attention must be given to signs of increased work of breathing that are disproportionate to what is expected.[33] Subjective measures of the perceived level of respiratory labor with a dyspnea scale such as Borg's Scale of Ratings of Perceived Exertion[16] can be taken before, during, and after the exercise test. Borg's scale is a good indicator of physiologic and psychological strain and allows individuals to interpret the intensity of their exercise according to subjective impressions.[148] For more information on quantifying increased work of breathing, a 15-count breathlessness scale is an objective measure that can be used with the Borg scale or a visual analog scale.[157]

Maximal work capacity is limited by ventilation in individuals with pulmonary disease.[33] Deficiencies in gas exchange and poor pulmonary mechanics compound the effects of decreased exercise capacity.[34] The limitation to exercise caused by pulmonary restrictions is further evidenced by failure to reach predicted peak heart rates in exercise test subjects with CF, suggesting that exercise capacity is not limited by cardiovascular factors.[30]

A complete physical examination should assist in revealing the individual's level of fitness, thus aiding the physical therapist in choosing the most appropriate exercise testing protocol. By assessing an individual's response to exercise, physical limitations, exercise-related symptoms, and aerobic capacity can be measured. The results of an exercise test can be used to design an individualized exercise program to improve one's exercise capacity and fitness level while encouraging individuals with CF to be physically active throughout their lives.

Management of Impairments in Respiratory Function

Individuals with CF demonstrate wide variance in the severity of illness because the disease progresses in individuals at different rates, but some amount of chronic airflow obstruction is often already present in childhood. The small peripheral airways are the site of most of these early pulmonary changes, and patchy atelectasis and ventilation-perfusion abnormalities lead to increases in functional dead space and discernible hypoxemia.[110]

The goals of physical therapy for the young child encompass improvement of exercise tolerance with continued attention to secretion clearance techniques. Correction and maintenance of proper postural alignment are also stressed. Goals of intervention are determined with the child and his or her family and take into account the developmental stage of the child and the family's priorities and concerns. The intervention plan must accommodate the child's learning style and avoid prescriptive tasks that are beyond the child's capabilities to promote self-efficacy and adherence. Collaboration with caregivers is essential when planning the home program. Children with a chronic illness should be encouraged to assume a degree of responsibility for their own treatment. Feeling some level of control over one's own health fosters self-esteem and helps subdue anxiety.[92]

Although the practice of postural drainage and percussion has long been used in the treatment of CF, it has been criticized as being too time consuming and difficult to perform independently. Adherence to a daily physical therapy regimen is reported as lower than with all other aspects of treatment.[150] Evidence of effectiveness might promote adherence, but research that has examined the effects of postural drainage and percussion is difficult to interpret because of the wide variety of outcome measures, including different PFTs, volume of secretions produced, and participants' subjective impressions.[185] It is also problematic to compare studies done on children at different stages of the disease and/or characteristics. Identifying the independent variable is sometimes troublesome because of the diverse combinations of techniques used; for example, percussion is rarely performed independently of postural drainage and coughing, making it difficult to determine the effect of each procedure. Recent reviews suggest the need for studies comparing treatment versus no treatment, but the ethical considerations of withholding treatment have prevented researchers from conducting this type of research.[82]

In a study by Lorin and Denning, the short-term effect of postural drainage and percussion physical therapy for patients with CF, compared with cough alone, was production of more sputum.[109] Other studies support the effectiveness of postural drainage and percussion in increasing amounts of sputum expectorated by subjects when excess secretion production is already a feature of the patient's condition.[13,114] The amount of sputum produced may be quantified by volume or weight, but caution must be used when interpreting the findings from this type of measurement. Because many individuals may swallow a portion of their sputum, the output can underestimate the true volume produced. The amount of saliva that contaminates the product is difficult to determine, and this has resulted in measurement of the dry weight of sputum in some studies. Measurement of dry weight is not practical in most clinical settings. In addition, the amount of sputum produced does not indicate where it originated.

Alternative methods for mobilizing secretions and stimulating cough have been suggested, usually involving directed breathing techniques. These include huffing, PEP, oscillating PEP (Flutter and Acapella), autogenic drainage, and active cycle of breathing (formerly known as forced expiratory technique, or FET). The rationale for use of huffing, a type of forced expiration with a similar mechanism to coughing, was suggested by a study that bronchoscopically demonstrated that maintenance of an open glottis throughout the maneuver stabilized the collapsible airway walls of subjects with chronic airflow obstruction.[84] The glottis normally closes in the compression phase of a cough, translating high compressive pressures on the tracheobronchial tree that may cause bronchiolar collapse.[185] Uncontrolled coughing is often nonproductive and exhausting.

The concept of the equal pressure point (EPP) in which the intraluminal pressure and the extraluminal pressure are equal, helps to explain how huffing is effective in clearing secretions. During a huff, the intraluminal pressure decreases from the peripheral airways toward the mouth thereby manipulating the position of the EPP to control the degree of compression of the airway. To perform huffing, the subject is asked to take either a low-, mid-, or large-volume (depending on the location of the secretions) inspiration and then, without allowing the glottis to close, to render a strong contraction of the abdominal muscles to aid in forceful expiration. Maintaining an open glottis can be compared with vocalizing "ha" or "ho."[185] Huffing is an uncomplicated breathing technique that can be easily taught to young children, and performing huffs can introduce the child to the concept of controlled or directed breathing techniques. (A video demonstrating huffing is included on Expert Consult.)

Forced expiratory technique (FET) employs forceful expirations combined with an open glottis as in huffing, interspersed with controlled breathing at mid to low lung volumes. A 3-year study conducted by Reisman et al. compared the treatment effects of FETs versus postural drainage and percussion physical therapy in subjects with mild to moderate pulmonary involvement and found that subjects who performed only FETs had significantly greater rates of decline in measures of FEV_1, midexpiratory flow rates ($FEF_{25\%–75\%}$), and lower Shwachmann CXR scores compared to subjects performing postural drainage and percussion.[168]

To clarify how to properly use FET, which always includes finer breathing control techniques and thoracic expansion exercises, Pryor and associates reclassified it as an active cycle of breathing techniques.[158] The three components are combined in a set cycle: relaxation and breathing control and three to four thoracic expansion exercises repeated twice, then relaxation and breathing control followed by one or two forced expirations. The number of breaths within a cycle can be modified to suit the individual's need. When secretions reach the larger, proximal airways, they may be cleared by a huff or a cough at high lung volume. Postural drainage positions may augment the effect, but the sitting position may be used if a gravity-assisted position is contraindicated.[205]

PEP (Fig. 26.7) as a means of secretion mobilization for individuals with CF has been proposed. Introduced for use in this

FIG. 26.7 An adolescent doing his routine PEP therapy technique with the physiotherapist.

population in the 1980s in Denmark, PEP has been shown to be as effective as traditional cardiopulmonary physical therapy both for chronic (baseline) stages of CF[69,118,140] and during an acute exacerbation of pulmonary complications.[119,141] This flow-regulated technique aims to temporarily increase functional residual capacity (FRC) to allow the tidal volume to be above the opening volume of obstructed alveoli.[28] The transmural pressure generated by maintaining positive pressure throughout the expiration phase is thought to allow airflow to reach some obstructed alveoli through use of collateral airway channels. Airways are "splinted open" through the maintenance of PEP, thereby facilitating movement of peripheral secretions toward central airways.[103] The PEP technique usually consists of diaphragmatic and pursed lipped breathing followed by 10–15 slightly larger than tidal volume breaths into the mouthpiece or mask after which huffing and coughing are performed. These steps are repeated 5–6 times, for a total of 15–20 minutes of airway clearance. (A video demonstrating a cycle of PEP therapy is included on Expert Consult.)

A 1-year randomized study that compared postural drainage and percussion with PEP in children and adolescents showed an improvement in lung function in the PEP group, while the postural drainage and percussion group deteriorated.[118] A 2-year study of[66] subjects found that PEP therapy is a valid alternative to postural drainage and percussions.[69] In another long-term study, pulmonary function scores improved in subjects using PEP versus postural drainage and percussions, which indicated that PEP was preferred by subjects, thereby increasing adherence.[118] The physiologic basis for the efficacy of low PEP and high PEP was shown to improve gas mixing in individuals with CF, and these improvements are associated with increased lung function, sputum expectoration, and arterial blood oxyhemoglobin saturation.[49] Contraindications for PEP include undrained pneumothorax and frank hemoptysis.[28]

Oscillating PEP is another effective alternative to other forms of airway clearance techniques.[131] Oscillating PEP (Flutter device, Acapella, RC Cornet) was developed to generate a controlled oscillating positive pressure and interruptions to airflow during expiration through a handheld device (Fig. 26.8). The Flutter was developed in Europe in the late 1980s, and the device consists of a steel ball in a plastic cone with perforated cover and a plastic mouthpiece. The effect of this device is angle dependent and the position of the ball determines the frequency of vibrations (range: 6–26 Hz). The range of PEP generated with the Flutter is 18–35 cm H_2O. The Acapella, developed in the United States in the 21st century, uses a counterweighted plug and magnet to create airflow oscillation.[28] Compared to the Flutter, the Acapella is not angle dependent and has an adjustable dial to modify the amount of PEP and oscillations provided depending on the individual. Oscillating PEP has been shown to be as effective as other commonly practiced airway clearance techniques.[131] A long-term comparative study in children found that using Flutter in isolation from other airway clearance techniques did not prove as effective as PEP in maintaining pulmonary function and that it was more costly because of the increased number of hospitalizations and antibiotic use.[123] The Flutter technique has been altered since this study. Newbold and colleagues reported no significant difference between PEP and Flutter in terms of pulmonary function and health-related quality of life in adult patients using the now-recommended technique.[136] One study comparing Acapella versus Flutter found that they had similar performance

FIG. 26.8 A child performing his daily airway clearance using the Flutter device. (From Hockenberry MJ, Wilson D: Wong's nursing care of infants and children. 10th ed. St. Louis: Mosby, 2015.)

characteristics. Investigators suggested that Acapella may have some advantages over Flutter because it is not position dependent and can be used at very low expiratory flows.[199] Main and colleagues compared the RC Cornet, a type of oscillatory PEP, to the use of PEP alone and showed that neither PEP nor Cornet was associated with significant changes in lung function over a 6- or 12-month period.[113]

BubblePEP is another form of oscillating PEP that can be used in young children. It can be made at home using a container of water with a height of 5–10 cm of water and 5-mm diameter tubing to create 10- to 20-cm H_2O pressure. The bubbles created in the water by expiring through the tubing create oscillations into the airways. Food coloring or bubble solution can be added to make the activity fun for younger children. This apparatus is not a closed system and will cause only transient increases in FRC. Appropriate cleaning of devices or BubblePEP apparatuses should be performed routinely to prevent growth of microorganisms. Contraindications to oscillating PEP are frank hemoptysis and an undrained pneumothorax, and precautions should be taken in individuals with increased intracranial pressure, hemodynamic instability, recent facial or oral surgery, acute sinusitis, or middle ear pathology.[28]

High-frequency chest wall oscillation (HFCWO) consists of an inflatable fitted vest attached to a pump that generates high-frequency oscillations applied to the external chest wall. It is proposed that HFCWO enhances mucociliary transport in three ways: by altering the rheologic properties of mucus, by creating a coughlike expiratory flow bias that shears mucus from the airway walls and encourages its movement upward, and by enhancing ciliary beat frequency.[79] Short-term studies have found that HFCWO and postural drainage and percussion are comparable for airway clearance,[73,188,203] but caution must be used when comparing these studies because a number of manufacturers producing this device use different protocols.[153] Recently, a 12-month long-term multicenter randomized controlled study of HFCWO versus PEP mask in 107 children

and adults older than 6 years old with CF across Canada was conducted. The study found that the number of pulmonary exacerbations (PE) requiring antibiotics and the time to the first pulmonary exacerbation were significantly higher in the HFCWO group than the PEP group.[120] The number of PEs and the time to PEs have been associated with greater lung function decline and higher morbidity and mortality and have been shown to be a more sensitive measure of improvement in studies.[204] McIlwaine et al. report that the results of their study do not support the use of HFCWO as the primary means of airway clearance in patients with CF.

Intrapulmonary percussive vibration (IPV) is a form of physiotherapy that is administered through the mouth to the airways to mobilize secretions centrally while increasing resting lung volumes. The goal of IPV is to integrate percussion and oscillatory vibration to mobilize retained secretions, high-density aerosol delivery to hydrate mucus, and PEP to recruit alveolar lung units.[28] IPV has been compared with other airway clearance techniques in individuals with CF though more long-term studies are warranted.

Physical Activity

Physical activity is an integral part of managing cystic fibrosis from a musculoskeletal point of view as well as cardiorespiratory perspective. Exercise is known to stimulate the respiratory system by changing breathing patterns, expiratory flows, and ventilation distribution while mobilizing secretions at the same time. A 30-month study of the effects of discontinuing other airway clearance modalities in favor of participation in aerobic exercise activities demonstrated no significant declines in clinical status, radiographic results, or PFT outcomes.[6] In an acute exacerbation, exercise proved as effective as postural drainage and percussion for the study subjects when pulmonary function was reviewed. The group assigned to "exercise" continued to receive one bronchial hygiene treatment session by a physical therapist daily, whereas the postural drainage and percussion physical therapy group received three of these sessions per day. Cerny concluded that hospitalized patients could substitute exercise for part of the standard in-hospital care.[32] It has also been shown that nasal epithelial sodium channels are inhibited during exercise in patients with CF, which may help to hydrate mucus and improve mucociliary clearance.[194]

Benefits of an exercise program extend beyond increases in peak oxygen consumption, increased maximal work capacity, improved mucus expectoration, and improved expiratory flow rates.[144,217] Exercise also improves general fitness, self-esteem, and measures of quality of life. Exercise is socially acceptable and helps to normalize the patient's life rather than adding a therapy that accentuates differences from peers. Fitness level also has implications as a prognostic indicator. An improved survival rate is found in individuals with CF who demonstrate higher levels of aerobic fitness. Although this may simply reflect less severe illness, the ability to maintain aerobic fitness appears to have value in improving longevity.[138] In a habitual physical activity study of 187 (99 females) patients age 7 to 25 years, subjects were divided into high- and low-activity groups and were followed over a 6-year period. Those in the low activity group had a significantly steeper rate of decline in FEV_1 compared with those in the high-activity group. The authors conclude that higher activity levels are clearly associated with a slower rate of decline of FEV_1.[208] Selvadurai and colleagues discovered that prepubescent activity levels were similar between genders in patients with CF and between patients with CF and controls.[178] After puberty, girls with similar severity of CF were significantly less active than boys. In another habitual physical activity study, Nixon found that children with CF engage in less vigorous physical activities than their non-CF peers despite having good lung function. Therefore it was concluded that individuals with CF should be encouraged to engage in more vigorous activities to promote aerobic fitness that may ultimately have an impact on survival.[137]

Low activity levels are also related to low bone mineral density and vice versa. It is important to encourage children with CF to optimize nutrition and to participate in regular physical activity to maximize the potential to acquire bone mass in childhood.[207] Prevention and treatment of CF-related bone disease must address the myriad of risk factors. These factors include decreased absorption of fat-soluble vitamins and poor nutritional status due to pancreatic insufficiency, altered sex hormone production, chronic lung infection with increased levels of bone active cytokines, physical inactivity, and glucocorticoid therapy. Chronic pulmonary inflammation leads to increased serum cytokine levels, which are thought to increase bone resorption and decrease bone formation. Decreased quantity and quality of bone mineral density can lead to pathologic fractures and kyphosis in late childhood. Kyphosis contributes to diminished stature, pain and debilitation, rib and vertebral fractures, and chest wall deformities that reduce lung function, inhibit effective cough, hinder airways clearance, and ultimately accelerate the course of CF. The prevalence of bone disease appears to increase with the severity of lung disease and malnutrition. Cross-sectional studies have reported a higher incidence of fractures in individuals with CF.[8] Postural exercises aimed at preserving good mobility of the thorax, back, and shoulders are recommended to prevent thoracic kyphosis while maintaining the functionality of bodily structures and improving self-image and body awareness. It is helpful to teach individuals how to distinguish between acceptable shortness of breath and abnormal dyspnea and how to modify exercise intensity in response to symptoms.[104]

Young children with CF should be encouraged to use the treatments that best suit their requirements for adequate secretion clearance and prevention of deterioration of clinical status. Attitudes toward adherence with treatment can greatly influence the effectiveness of any therapeutic regimen, and the challenge for the physical therapist is to design an intervention strategy that is useful for both efficacy and practicality. Factors that should be considered in designing a therapy program include disease presentation and severity; patient's age; motivation and ability to concentrate; physician, caregiver, and child goals; research evidence; training considerations; work required; need for assistance or equipment; and costs. Children who learn to adopt their physical therapy as an aspect of daily living, as opposed to a burden or punishment, are more likely to adhere with the intervention plan.

Adolescence

Adolescence is a time of rapid transformation in many areas of development. Sexual maturation comes about as a result of major changes in circulating hormones occurring around the time of maturity of the skeletal system, typically when the child is about 11 or 12 years old. These hormonal secretions cause a "growth spurt" in the adolescent.[74] "Delay of maturity" occurs when there has been slowed or prolonged skeletal maturation.

This is often the cause of delayed puberty in adolescents with CF.[58] Arrested sexual development, combined with a smaller than average physical build, can intensify feelings of isolation from healthy peers. Osteopenia (low bone mass) is a possible complication of CF that may be linked to nutritional factors, delayed puberty, reduced exercise or weight-bearing activities, treatment with corticosteroids, and chronic infection.[40] The prevention of osteoporosis and the risk of fracture in patients with signs of osteopenia must be considered when developing a therapy program. The need for increasing independence can conflict with the demands of daily medical care, making adherence with the routine seem arduous. Adolescents with CF who look and feel different from the perceived "norm" may rebel against continuation of time-consuming treatments that reinforce their sense of being dissimilar or abnormal.[20]

Management of Impairments in Respiratory Function

Adherence with the routine of daily postural drainage and percussion sessions is poor in the adolescent population.[150] One challenge with this population is to promote self-efficacy with alternative methods of treatment. The use of PEP, active cycle of breathing technique, or a program of regular exercise may help to promote independence and has already been discussed. Autogenic drainage (AD) is another treatment modality involving self-controlled breathing techniques.

Autogenic drainage requires no equipment or special environment to execute and relies on the user's ability to control both inspiratory and expiratory airflow to generate maximum airflow within the different generations of bronchi.[36] Three separate phases of the technique are believed to "unstick" mucus in the peripheral airways, "collect" the mucus in the middle airways, and "evacuate" it from the central airways according to the volume level of controlled breaths.[117] Mobilization of airway secretions by autogenic drainage does not rely on the gravity assistance needed for postural drainage and can be performed in a sitting position.

Research on the effectiveness of AD is scarce.[130] A study comparing AD with postural drainage and percussion physical therapy and PEP in patients with CF[122] and a 2-year comparison trial of AD and postural drainage and percussion physical therapy found no significant differences between treatment groups when clinical status and PFT scores were used as outcome measures.[50] Learning the technique of AD poses difficulties for both the adolescent and the instructor. The technique requires concentration and the ability to use proprioceptive and sensory cues to localize secretions in the various levels of bronchi. A hands-on approach is essential, with a minimum of environmental distractions. Frequent training sessions and reviews are necessary. This type of concentrated self-directed activity usually is not achievable by children younger than age 12.

Maintenance of proper posture is important for individuals with CF to provide efficient breathing mechanics. Changes in the length-tension relationships of the respiratory musculature may occur with increases in FRC creating a mechanical disadvantage that contributes to increased work of breathing and muscle fatigue.[33] Several postural changes are found in adolescents with CF to varying degrees, associated with chronically hyperinflated lungs, including increased anterior-posterior diameter of the chest, shoulder elevation, and forward protraction and abdominal flexion. Thoracic kyphosis predisposes individuals to back pain with up to 94% of adults with CF reporting chronic back pain.[105]

The physical therapist examines posture and evaluates whether deviations are reversible or amenable to treatment. Exercises to promote improved posture include a strengthening program for the supporting muscles of the back and spine, stretching of shortened musculature, and increasing awareness of postural alignment. Weight-bearing exercises should be included to promote bone formation. An innovative way to keep adolescents active that can address the above issues is "ball therapy" (Fig. 26.9). Ball therapy can also be used to promote aerobic fitness, balance, coordination, and relaxation.[183] Projecting a good appearance is usually very important to adolescents, and informing the teenager with CF of the benefits of a good postural maintenance and weight-bearing program may provide the incentive necessary to ensure adherence to recommendations for exercises.

More recently, Schneidermann and colleagues found that despite natural progression of CF lung disease, increased habitual physical activity of 17 min/day is feasible and is associated with a slower rate of decline in FEV_1 at 1.63% per year, which is lower than the documented average decline in lung function. This study highlights the opportunity to have a positive impact on lung function decline, by promoting a physically active lifestyle throughout childhood, to encourage the maintenance of activity and enhance the carryover into adulthood.[174] A retrospective pilot study in the United Kingdom analyzed data for a 5-year period and compared 24 CF patients identified as partaking in an exercise group or no record of exercise. Despite no difference in FEV_1 between the two groups, the exercise group required significantly shorter days of IV antibiotics, suggesting that more intensive treatment was required to maintain lung function in the group that did not exercise regularly.[115]

A secondary effect of strength training with weights may be an improvement in self-confidence in the adolescent because training has been shown to be beneficial in promoting weight gain.[187] As pulmonary function declines, nutritional status is a consideration that requires a great deal of focus. Reduced anaerobic performance in individuals with CF is predominantly due to poor nutritional status.[97] The dietitian can identify situations in which intervention is necessary and may be a valuable ally in reinforcing the message that exercise can promote weight gain when appropriately managed. A liaison with the dietitian can ensure coordination of dietary and physical therapy recommendations.

Urinary incontinence is an underreported problem in individuals with CF due to embarrassment,[129,146] although it occurs in 5% to 16% of males and in 30% to 68% of females. Girls with CF as young as 9–11 years of age may experience urinary incontinence, which is exacerbated by the repeated physical strain of coughing, airway clearance, worsening lung disease, and various types of physical exercise.[2] Addressing this issue should become part of routine management and should be followed up regularly. Strategies that focus on the contraction of the pelvic floor muscles ("the Knack"), strengthening and endurance training of the lower abdominal core muscles, and optimal positioning during airway clearance all help to decrease stress on the pelvic floor muscles.

Transition to Adulthood

When CF was first described in 1938, fewer than half of the patients survived their first year,[54] but CF is no longer a purely pediatric disease. The currently reported median age of survival is 41.1 years, although many patients live well into their fifth

FIG. 26.9 (A–B) Therapy ball stretches to promote proper posture and thoracic mobility. (C) Using modern forms of technology, Nintendo Wii Fit System, for exercise.

decade of life.[198] Although many of the issues physical therapists are concerned with in the pediatric patient are similar for adults, some special differences should be considered. Standard programs of transition from a pediatric to an adult center should include all team members to ensure continuity of the patient's care.[64] Continuity of care enhances the effectiveness of care and minimizes uncertainty and distress for young individuals and their families. Transition from the pediatric to the adult CF team is an important milestone for patients and must be handled sensitively. Transfer is more easily achieved when the pediatric and adult clinics work closely together.[101]

The psychosocial issues in adulthood are distinct because the normal progression of psychological maturation brings new concerns with each developmental stage.[54] Greater clinical awareness, early treatment, and more effective management of CF have all contributed to improvement in prognosis.[154] Choices regarding education, employment (medical insurance), marriage, and family will have to be made. These choices are more complex than usual for the adult with CF, who not only has to consider present health status but also must attempt to predict and prepare for future health status.

Consideration should be given to medical insurance coverage, flexible work hours, and sick time when choosing employment.[213] Physically demanding occupations may not be appropriate for the adult with CF with pulmonary limitations; therefore careful consideration of the physical demands of any task must be undertaken. Jobs involving constant exposure to dust, chemical fumes, or smoke should be avoided.[54,143] Adults with CF will face few restrictions on choice of employment; however, infection control issues should be well thought out when choosing a career in health care.[213] Treatment complexity and high treatment burden are highest among adults and pose a challenge to patient self-management and adherence.[173] Physical therapists should help to accommodate the adult's busy lifestyle and incorporate strategies for fitting treatment into work schedules. Methods that are more convenient and promote independence, such as the PEP mask, Flutter, or AD, may be more agreeable to the adult at work or school.

Because many adults with CF witness death among their peers, deterioration of their own health may have heightened significance for them. The adult who as an adolescent chose to be nonadherent with a physical therapy regimen may decide to initiate one again. Generally, individuals with CF have a strong positive outlook and are able to fully enjoy many of the typical pleasures of adulthood despite having to contend with unusual difficulties.[143] Patients' attitudes and outlook on life can have a tremendous influence on the medical progression of CF and are considered in prognostic scores.[54]

In general, cardiac status is related to severity of pulmonary involvement: the more severe the pulmonary adaptation to

hypoxemia, the worse the pulmonary hypertension and right-sided heart strain. With comparable degrees of pulmonary disease, adults, especially those with mild lung disease, have more severe echocardiographic abnormalities than children. This may reflect the accumulative effects of episodes of mild hypoxemia and nocturnal oxygen desaturation that occur in even minimally affected individuals.[54]

Management of Impairments in Pulmonary Function

The progressive nature of CF may predispose many adults to have more symptoms and activity limitations than they had as children[143]; thus it is essential that the physical therapist works closely with the individual to adapt the intervention plan accordingly. Minor hemoptysis or blood streaking occurs in up to 60% of adults with CF[58]; in most cases, the cause is an increase in bronchial infection that has irritated a blood vessel.[142,144] Bleeding within the lungs can worsen infection by providing a more hospitable environment for bacteria; thus routine airway clearance can be continued if increased hemoptysis does not occur. Webber and Pryor believe that physical therapy should be continued with blood streaking.[205] Strategies that emphasize huffing and breathing control may be less likely to increase the amount of bleeding than the frequent uncontrolled coughing that may occur with completely stopping airway clearance.

Massive hemoptysis, which is also strongly related to advancing age,[54] is defined as rupture of a bronchial blood vessel into the airways, producing greater than 240 ml of blood in 24 hours or recurrent bleeding greater than 100 ml/d over several days. The average incidence of massive hemoptysis is 1 in 115 patients per year, and approximately 4.1% of all patients with CF will suffer this complication during their lifetime, with a median age of 23 years.[66] This complication warrants hospitalization and possible blood transfusion.[106] The CF Foundation Pulmonary Therapies Committee recommends that an individual's usual airway clearance technique can be continued in the presence of scant hemoptysis but that with massive hemoptysis airway clearance therapies should be ceased until the active bleeding stops.[67]

Spontaneous pneumothorax occurs 1 in 167 patients with CF per year, and approximately 3.4% of all patients will suffer from this complication during their lifetime with a median onset age of 21 years.[66] A common cause of pneumothorax is the spontaneous rupture of apical bullae, which develop as the result of increased air trapping and microabscess formation in the diseased lung.[110] Cardiopulmonary physical therapy is contraindicated in the presence of an untreated, progressing, or tension pneumothorax; however, treatment can continue with a small, stable pneumothorax and with a pneumothorax that has resolved through treatment with a thoracotomy and insertion of a chest tube for vacuum drainage of air.[56] Percussion must not be performed directly over the chest tube site owing to the danger of displacement, but percussion may be safely performed elsewhere on the thorax as tolerated. The PEP mask is a relative contraindication because theoretically it could make the pneumothorax worse as a result of repetitive increased pressure generated in the airways. In the event of a large or unstable pneumothorax, it is recommended that certain airway clearance therapies be stopped, including PEP, oscillating PEP, and IPV.[67] In summary, if a particular technique appears to make the situation worse, it should be discontinued and other modalities using breathing techniques may be beneficial at this time.

FIG. 26.10 (A–B) Positioning for energy conservation, promoting relaxation and ease of breathing.

Episodes of hypertrophic pulmonary osteoarthropathy also increase in prevalence with advancing age.[54] Digital clubbing can become more noticeable in people whose pulmonary disease is severe.[143] Standard anti-inflammatory agents are used to treat the joint pain associated with hypertrophic pulmonary osteoarthropathy.[152] Physical therapists have a role in helping to relieve pain while maintaining joint range of motion (ROM). A home treatment program consisting of stretching, muscle strengthening, and ROM exercises for the specific joints involved can be easily added to the individual's existing exercise program.

When pulmonary disease becomes so disabling that the individual is having difficulty performing activities of daily living, physical therapy goals should encompass these needs. The patient may have to be instructed on energy conservation techniques such as diaphragmatic pursed-lip breathing and assuming positions that relieve breathlessness. These positions should promote comfort and relaxation and should encourage mobility of the thorax and support of the spinal column. They should also include hip flexion to relax the abdominal musculature and aid in increasing intraabdominal pressure for coughing.[56] Examples of energy conservation positions are shown in Fig. 26.10. Retraining of the respiratory pattern using pursed-lip breathing in conjunction with diaphragmatic excursion has shown temporary benefits in increased tidal volume, decreased respiratory rate, reduction in $PaCO_2$ levels, and improved PaO_2 levels, as well as subjective benefits reported by patients. It may be that pursed-lip breathing improves confidence and decreases anxiety by providing some temporary control over oxygenation.[37]

Oxygen needs with exercise may have to be assessed at this time. Continuation of an active lifestyle should be promoted for all individuals with CF to optimize physical condition and maintain an optimistic outlook. If the individual is considering lung transplantation as an option, physical therapists must involve the individual in a formalized exercise program. The Toronto Lung Transplant Program at the Toronto General Hospital has a well-established rehabilitation program. Exercise capacity is determined by using a 6-minute walk test and ear

oximetry, or the Modified Bruce Protocol on the treadmill.[45] The purpose of assessing a patient's exercise capacity is to determine if the severity of disability warrants consideration for transplant. A 6-minute walk test result of less than 400 meters was found to be a significant indicator for a patient to be listed for transplantation.[90] Individuals can also be monitored at regular intervals with these tests to gauge potential deterioration in their functional status. Once accepted into the lung transplantation program, most centers require attendance at a formal rehabilitation program[75] featuring aerobics, muscle strengthening, stretching, and light calisthenics.

Expected physical therapy outcomes for the adult with CF include optimizing functional ability, physical exercise tolerance, and emotional well-being. For individuals awaiting a lung transplant, improvement in overall function should enable them to handle the surgery and immediate postoperative period with less difficulty.[45] Arnold and associates found that 13 patients with end-stage CF showed improvement in their functional exercise capacity by participating in pulmonary rehabilitation while awaiting double-lung transplantation.[9] Pulmonary rehabilitation entailed treadmill walking and lower extremity ergometry three to five times per week, initiated at the time of listing for double-lung transplant. Six-minute walks were performed biweekly to assess changes in functional exercise capacity and workload on the treadmill and bicycle ergometer was recorded. Six-minute walk distances and treadmill and bicycle workloads all increased significantly. Conclusions from this data confirm the possibility of improving functional exercise capacity in patients with end-stage CF awaiting double-lung transplantation, despite severe limitations in pulmonary function.

Noninvasive ventilation, most commonly biphasic positive airway pressure (BiPAP), may benefit CF patients who are experiencing respiratory failure and awaiting lung transplantation. Although nocturnal oxygen therapy has not been shown to improve long-term prognosis, nighttime BiPAP reduces hypoxia, hypercarbia, and work of breathing and may enhance airway clearance and reduce pulmonary hypertension.[200]

Physical therapists have a role in serving individuals in the terminal stages of their disease. Intervention at this stage includes the provision of comfort measures and must be directed by the patient's wishes. Treatment sessions may have to decrease in duration and be offered with increased frequency throughout the day. Adaptations to postural drainage positions may have to be adopted so treatment can be tolerated. As the work of coughing becomes too tiring or painful, other modalities such as splinting and huffing can be reviewed. Pain control measures and relaxation and anxiety-reducing techniques, such as massage, may be the primary need of the dying patient. Simply listening to the concerns of these patients can be therapeutic. The value of a compassionate ear should not be underestimated. Physical therapists treating patients who are terminally ill should be careful to incorporate the families' needs, respecting the fact that this is an emotionally volatile time for all involved.

SUMMARY

Physical therapists have an important role in promoting self-management of respiratory function and physical activity of children and youth with CF beginning at a young age. Supporting families and children's self-efficacy are important to promote well-being and quality of life. The multisystem involvement and chronicity of CF requires physical therapists to keep abreast of medical management and continually interact with a team of professionals to communicate and coordinate care. Collaboration with a multidisciplinary health care team is stimulating and fosters creative and fulfilling practice of physical therapy. New advances suggest exciting possibilities for the future care of people with CF. Physical therapists serving children and youth with CF are encouraged to continually adapt their interventions based on current knowledge and research.

Case Scenario on Expert Consult

The case scenario related to this chapter follows a child with cystic fibrosis from diagnosis at 2 months of age to 16 years of age. Changes in his health condition and the role of the physical therapist at different ages are described.

Asthma: Multisystem Implications

Mary Massery

Asthma is a common childhood health condition that can result in activity limitations and participation restrictions that impact quality of life. Asthma is characterized by airway inflammation, airway obstruction, and bronchial hyperresponsiveness to stimuli. The pathophysiology is complex with multiple system interactions making each child's presentation of asthma unique. The purpose of this chapter is to: (1) describe pathophysiology from infancy to adulthood, (2) discuss the primary and secondary impairments of asthma and their impact on children's long-term health and development, and (3) present medical and physical therapy management. The physical therapist needs to be knowledgeable of pathophysiology, primary and secondary impairments, and pharmacologic management to understand how asthma affects a child's ability to participate in physical activities and what role the therapist can play in optimizing the child's health, motor development, and physical activity. An extensive longitudinal case scenario on Expert Consult illustrates physical therapy management.

BACKGROUND INFORMATION

PREVALENCE

According to the Centers for Disease Control (CDC), nearly one in 10 children in the United States has a diagnosis of asthma.[2,11] The percentage nearly doubles among children born preterm.[5] A full listing of national asthma facts and figures can be found on the CDC website (http://www.cdc.gov/asthma/faqs.htm).

PATHOPHYSIOLOGY

According to the National Institutes of Health (NIH), asthma is defined as a pulmonary disease with recurring symptoms that are variable in presentation and show three significant characteristics: (1) airway inflammation, (2) airway obstruction that is often reversible either spontaneously or with pharmacologic intervention, and (3) bronchial hyperresponsiveness to stimuli.[40] Asthma is a disease of both the large and the small airways with recurrent episodes of shortness of breath, wheezing, chest tightness, and coughing.[40] Extrinsic or allergic (atopic) stimuli include but are not limited to pollen, mold, animal dander, cigarette smoke, foods, drugs, dust, and other environmental factors. Intrinsic or nonallergenic stimuli include but are not limited to viral infections, inhalation of irritating substances, exercise, and emotional stress (Fig. 27.1). An individual may be sensitive to either type of stimuli or to both types. The hyperresponsiveness to stimuli in turn causes an inflammatory response. Inflammation has been identified as a central component of asthma and is likely the primary contributor to airway remodeling leading to chronic inflammation.[40] This structural change may make the airways less responsive over time to medications.

Genetics plays a role but does not account for all types and severities of asthma. The physical, environmental, neurogenic, chemical, and pharmacologic factors that are associated with asthma vary among individuals. They stimulate or trigger the immune system (i.e., mast cells, eosinophils, neutrophils, T lymphocytes, macrophages, epithelial cells) to release chemical mediators, which in turn cause constriction of the bronchial muscles, increased mucus production, and swelling of the mucous membranes. The most recent NIH guidelines, developed by a panel of asthma experts, point to two major environmental factors that significantly increase the risk of developing asthma: airborne allergens and respiratory viral infections (especially respiratory syncytial virus [RSV]).[40] Recent findings confirm and explain the increased risk of developing asthma when exposed to RSV in infancy.[6] Other environmental factors such as secondhand smoke increase the risk of asthma and influence the severity of the disease. For example, 6- to 11-year-old children with asthma who were exposed regularly to secondhand smoke showed greater adverse health and participation outcomes than their asthma peers not exposed to smoke.[1]

PRIMARY IMPAIRMENT

Diagnosis

The diagnosis of asthma is made on the basis of history, physical examination, auscultation and palpation, and pulmonary function tests (PFTs), especially in response to a methacholine challenge.[4] Wheezing and rhonchi may be detected by auscultation even when the child does not show difficulty breathing. Breathing is often reported as being worse at night or early in the morning. Hyperexpansion of the thorax, increased accessory muscle breathing, postural changes, increased nasal secretions, mucosal swelling, nasal polyps, "allergic shiners" (darkened areas under the eyes), and evidence of an allergic skin condition may be noted on physical examination.

During an acute asthma attack, the child may show an increased respiratory rate, expiratory grunting, intercostal muscle retractions and nasal flaring, an alteration in the inspiration-expiration ratio, and coughing. In severe cases, a bluish color of the lips and nails may be noted (oxygen desaturation). Other conditions mimic asthmatic symptoms, such as vocal cord dysfunction, airway hyperreactivity, other small airway diseases, dysfunctional breathing, nonobstructive dyspnea, and hyperventilation condition. These "copy-cat" conditions

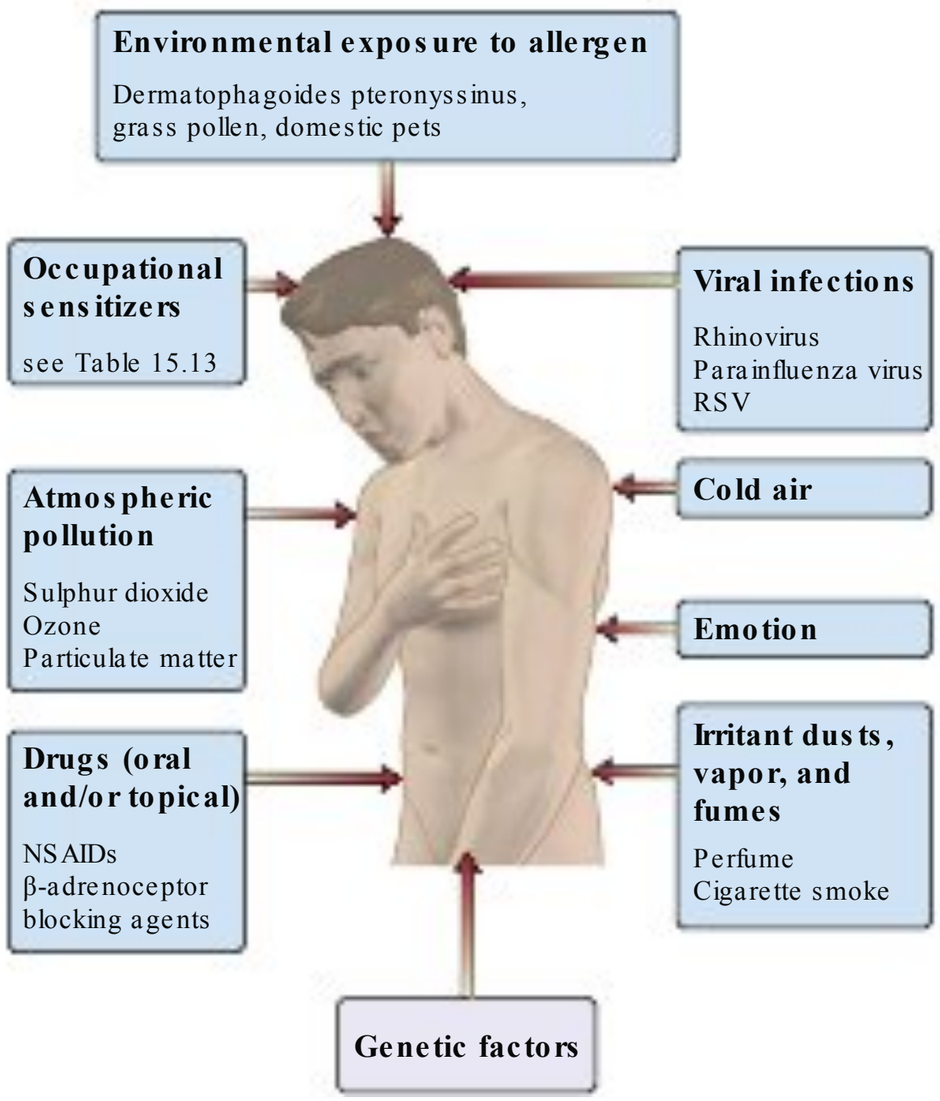

FIG. 27.1 Causes and triggers of asthma. (From Kumar P, Clarke ML: Kumar and Clark's clinical medicine. 8th ed. Edinburgh: Saunders, 2012.)

should be ruled out during a differential diagnosis process to avoid making the wrong diagnosis.[3,27,33]

Classification and Guidelines for Treatment

A classification system and guidelines for stepwise treatment of asthma were developed by an expert panel to streamline communication among medical professionals and researchers and were published by the NIH in 2007.[40] The classification system lists childhood asthma by age (0–4 years old, 5–11 years old, 12 years old and older) and by clinical symptoms. The disease is classified as (1) intermittent, or persistent; (2) mild persistent; (3) moderate persistent; or (4) severe persistent. The summary of the report and recommendations for each age range can be found online at: http://www.nhlbi.nih.gov/health-pro/guidelines/current/asthma-guidelines/summary-report-2007. The severity classification table for children 12 years old and older is presented as an example of this classification system (Table 27.1). The classification system facilitates more consistent communication between practitioners and researchers. Desired goals of classification include improved treatment choices and more accurate documentation of patient outcomes by disease severity. Taken together, it is hoped that a national classification and treatment guideline will lead to better management of this chronic condition. New panels of experts are organized to report and compile the latest findings in the management of asthma approximately every 10 years.[32]

Pulmonary Function Tests (PFTs)

PFTs are a group of tests that measure lung function. Test values are compared with predicted values based on age, sex, and height.[12] PFTs are performed for patients with asthma to determine the location and degree of the respiratory impairment as well as the reversibility of bronchoconstriction following

FIG. 27.2 A spirogram (pulmonary function testing). (From Frownfelter DL, Dean E: Cardiovascular and pulmonary physical therapy: evidence to practice. St. Louis: Mosby, 2012.)

administration of a bronchodilator (methacholine challenge) (Fig. 27.2).[29] PFT measurements are typically used to reveal one or more of the following: (1) decreased forced vital capacity (FVC), (2) decreased forced expiration during the first second of FVC (FEV_1), (3) decreased forced expiratory volume compared with forced vital capacity (FEV/FVC), (4) decreased peak expiratory flow rate (PEFR) because of airway obstruction in large or small airways, (5) forced expiratory flow (FEF) during 25% to 75% of FVC (FEF 25% to 75%) because of airway obstruction in the small airways, (6) increased residual volume (RV), and (7) increased functional residual capacity (FRC) because of air trapping.[40] Asthma is an obstructive lung disease, meaning the inflamed airways trap the air in the distal segments making it hard for the patient to exhale; thus his or her expiratory flows such as FEV_1 and PEFR are likely to be low. However, the swelling and mucus may also restrict the patient's ability to inhale (restrictive lung condition); thus FVC may be low as well. The physician will determine which tests are the most sensitive measures to indicate sickness/wellness for each individual patient.

School-age children and youth with asthma often monitor their pulmonary status at home by daily or weekly testing of their PEFR with a peak flow meter to assist the physician in adjusting medication. A peak flow meter is not a substitute for a formal PFT, but it can help to monitor the child's condition at home.[40] PFTs are generally not reliable for children under the age of 5 years old because they require cooperation and consistent maximal effort.[40] Children under the age of 5–6 years old are monitored on the basis of clinical signs and symptoms.[10] Asthma guidelines for pediatricians are constantly being updated.[26,57] Check the current literature for updates.

Impairments in Body Functions and Structures

Asthma is a pulmonary disease with recurring symptoms; thus the diagnosis is not typically made until the child is 3 to 5 years of age when numerous episodes of pulmonary problems have been demonstrated and are consistent with symptoms of asthma.[40] Initially, a child may be diagnosed with "reactive airway disease."[30] Over time, the physician will determine if the diagnosis of asthma is appropriate. The young child diagnosed with asthma may present with a multiple of risk factors that interact to cause asthma and influence disease severity: family history of asthma or atopic (allergy) predispositions, prematurity, lung abnormalities, exposure to secondhand smoke or other environmental pollutants, history of episodes of wheezy bronchitis, croup, recurrent upper respiratory tract infections, chronic bronchitis, recurrent pneumonia, respiratory distress syndrome, difficulty sleeping, bronchopulmonary dysplasia,

TABLE 27.1 NIH Classification of Asthma Severity

Pediatric asthma severity is classified according to 3 age groups: 0 to 4 years, 5 to 11 years, and 12 years and older. This example is for the older child: youths 12 years old or older.

Assessing severity and initiating treatment for patients who are not currently taking long-term control medications

Components of Severity		Classification of Asthma Severity ≥12 years of age			
		Intermittent	Persistent		
			Mild	Moderate	Severe
Impairment Normal FEV_1/FVC: 8–19 yr 85% 20–39 yr 80% 40–59 yr 75% 60–80 yr 70%	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2x/month	3–4x/month	>1x/week but not nightly	Often 7x/week
	Short-acting $beta_2$-agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily, and not more than 1x on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	• Normal FEV_1 between exacerbations • FEV_1 >80% predicted • FEV_1/FVC normal	• FEV_1 >80% predicted • FEV_1/FVC normal	• FEV_1 >60% but <80% predicted • FEV_1/FVC reduced 5%	• FEV_1 <60% predicted • FEV_1/FVC reduced >5%
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/year (see note)	≥2/year (see note) →		
		← Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV_1.			
Recommended Step for Initiating Treatment (See "Stepwise Approach for Managing Asthma" for treatment steps.)		Step 1	Step 2	Step 3	Step 4 or 5
		In 2–6 weeks, evaluate level of asthma control that is achieved and adjust therapy accordingly.		and consider short course of oral systemic corticosteroids	

Key: EIB, exercise-induced bronchospasm, FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; ICU, intensive care unit

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.
- Level of severity is determined by assessment of both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2–4 weeks and spirometry. Assign severity to the most severe category in which any feature occurs.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

From NIH: Expert panel report 3: guidelines for the diagnosis and management of asthma: National Institutes of Health: National Heart, Lung, and Blood Institute. Expert Panel Report 3, p. 43.

respiratory syncytial virus (RSV) infection, gastroesophageal reflux (GERD), sleep dysfunction, rapid weight gain in infancy, obesity later in childhood, chronic dehydration, and low vitamin D levels.[16,31,41,42,45,48,51,55,58] Research has recently focused on early life events and exposures that appear to increase the risk of asthma or the risk of disease severity. Significant co-morbidities that contribute to a higher risk of asthma and are easily screened for by pediatric physical therapists are highlighted.

Gastroesophageal reflux disease: GERD occurs when stomach acid is involuntarily refluxed up into the esophagus and sometimes into the upper airway, causing chemically induced damage to the tissues.[7,13] Reflux can cause hyperirritation to the upper airway, triggering the onset of asthma or contributing to the severity of asthma. Children with asthma work harder to breathe at rest and with exertion. They pull the air in (inhalation) with greater muscular effort to overcome airway restrictions, and some have to push their air out with abdominal muscles (exhalation) to overcome obstructed airways. This increases the pressure differential across the lower esophageal sphincter, increasing risk for developing reflux. There are conflicting results on whether GERD causes asthma or whether it just contributes to disease severity.[15,30,52,54] There is agreement that children with suspected asthma should be screened for GERD.[42]

Sleep: Disrupted or poor sleep patterns are common symptoms of asthma[41,51] that have been linked to GERD as well.[13] What is not understood is which came first: the GERD, the disrupted sleep, or the asthma? Sleep-disordered breathing was found to be significantly more prevalent in individuals with asthma (26%) than age-matched controls (11%), as was habitual snoring (36%, 16%, respectively).[20] Sleep dysfunction is an important part of the child's asthma profile and should be ruled out as a significant contributor to disease severity.[9,36,45,51] In children, chronic sleep-disordered breathing is positively correlated with problems in neuropsychological development and adverse brain development, which makes it absolutely critical to rule out a sleep disorder for this high-risk population.[24,35] Because of relationships between the quality of sleep and the increased risk for poor health (such as asthma) and impaired cognitive performance, physical therapists should routinely inquire about a child's sleep pattern to screen for a possible sleep disorder.

Infant rapid weight gain: It is known children born preterm are at increased risk of developing asthma,[30,55] but there is mounting evidence that rapid weight gain by infants born preterm, especially in the first 3–4 months, is also associated with higher risk of asthma as a school-aged child.[48] In a study of > 800 preterm infants, rapid body weight gain in the first year of life was independently associated with an increased risk of developing asthma, whereas increased longitudinal growth in the same period was not associated with an increased risk of asthma.[5] The higher risk for asthma with fast weight gain as an infant was also noted in a large study of more than 25,000 infants born full-term who were followed to school age.[58] With the current preponderance of evidence on the adverse pulmonary health outcomes of early weight gain, practitioners should be compelled to instruct parents about this modifiable risk factor for asthma. Physical therapists need to be aware of this risk as well.

Viral infections: Viral infections, especially severe RSV infection in infancy, is highly associated with a later diagnosis of asthma.[55] Two recent studies found inflammatory markers that begin to explain this increased risk.[6,46] It is hoped that understanding the physiology of the inflammatory response will lead to improved treatments that lower the risk of developing asthma later in childhood. In the meantime, physical therapists should carefully watch children with a history of infant RSV infections for signs of asthma.

Prognosis

By adolescence, asthmatic symptoms often decrease. However, even if adolescents are symptom free, they often have impairments in respiratory growth and development. Their lungs are smaller compared with healthy peers, and they are more likely to demonstrate decreased lung function.[25,50] Infants born preterm with respiratory problems are even more likely to have lung and airway restrictions later in childhood and young adulthood.[6,22,25,38] It is speculated that children born preterm who develop asthma are at higher risk for developing emphysema-like conditions in middle age.[4,21,50] This remains an hypothesis, however, because survivors of extreme prematurity have not yet reached middle age. For these reasons, pediatric physical therapists are encouraged to screen and educate children and families about the ongoing risk of developing asthma and other chronic lung diseases all the way into adulthood.

Medical Management

Asthma is not a curable disease, so the medical treatment plan is focused on short-term relief and long-term management to control or prevent symptoms as best as possible.[40] The NIH has been the leader in developing and disseminating national guidelines on asthma based on the best available evidence and a consensus of asthma experts.[40] To see the full, current guidelines go to: http://www.nhlbi.nih.gov/health-pro/guidelines/current/asthma-guidelines/summary-report-2007. Short-term goals focus on managing acute airway obstruction (bronchoconstriction). Long-term management addresses the triggers that cause the bronchial hyperresponsiveness and the underlying inflammatory response.

Short term: The frequency, duration, and severity of asthma attacks can be highly variable even for the same individual. Symptoms are usually reversible and can be prevented or modified to some degree when individual-specific triggers are identified. Acute treatment is aimed at reversing the bronchoconstriction; thus bronchodilator medications are the drugs of choice. Bronchodilators, such as the generic albuterol, are short-acting beta2-agonists (SABAs).[40] Bronchodilators relax the smooth muscles of the airway, providing immediate relief of the constriction, usually within 5 minutes. Relief may last for 3–6 hours. SABAs are inhaled via a metered dose inhaler (MDI) or through a nebulizer treatment (Fig. 27.3). SABAs do not control asthma, but they are typically used to manage acute asthma attacks or purposely taken before a known trigger such as exercise (exercise-induced asthma). The most common adverse side effects are rapid heart rate, headaches, nausea, and anxiety. The physician takes the child's individual response to SABAs into account when developing an asthma plan of care. Typically, when SABAs are used more than 2×/week, the plan of care is adjusted to focus on long-term control rather than quick acute relief.[40]

If an asthma attack is severe and does not respond to bronchodilator medications, the child may develop status asthmaticus.[40] This is a life-threatening emergency. Physical therapists should stop treatment immediately and seek medical attention

FIG. 27.3 Nebulized aerosol treatment with a mouthpiece. (Courtesy Texas Children's Hospital, Houston. From Hockenberry MJ, Wilson D: Wong's nursing care of infants and children. 10th ed. St, Louis: Mosby, 2015.)

by the hospital emergency team (in-patient setting) or by calling for an ambulance (community setting).

Long term: The goals of long-term asthma management are to prevent chronic and troublesome symptoms, to maintain pulmonary function and physical activity level, to prevent recurrent exacerbations, to minimize the need for emergency room visits or hospitalizations, to provide optimal pharmacotherapy, and to meet the patient's and family's expectations and satisfaction.[40] To achieve all of the goals, no two medical care plans will be exactly the same. Each written action plan should address disease severity, disease control, and responsiveness to treatment and should be considered a fluid document that changes with the child over time.[40]

NIH guidelines have specific treatment plan suggestions based on the disease severity: intermittent asthma, or persistent asthma (mild, moderate, or severe) (see Table 27.1). In addition to managing asthma itself, it is critical to manage the co-morbidities that influence disease severity such as allergens, environmental factors (e.g., smoke, pollutants), exercise response (exercise-induced asthma), GERD, sleep dysfunction, rhinitis, sinusitis, obesity, stress, depression, nutrition, etc.[40] Factors that can be easily modified such as allergies, secondhand smoke, initiating exercise safely to avoid EIA response, and weight gain should be addressed immediately. After assessing the child's response to the initial program and assessing the risk of exacerbations, the action plan should be appropriately modified. This plan should be shared with school and other personnel who are involved with the child on a regular basis. The child's or family's knowledge, understanding, and willingness to follow through (adherence) with the program are essential for successful long-term management of asthma.[18,40] Researchers have repeatedly found poorer health outcomes for children with poor adherence to their asthma treatment plans and are continually looking for methods to improve adherence.[44,49]

Medications: The current NIH Publication on the Guidelines for Asthma describes a terraced approach to pharmacologic management for long-term control of asthma.[40] Recommendations for dosing medication are based on severity and age (0 to 4 years, 5 to 11 years, and 12 years and older) because evidence indicates that children respond differently to asthma medications than adults. Long-term control starts with managing the inflammatory component of asthma. Inhaled corticosteroids continue to be the drug of choice across all age groups for long-term management of inflammation.[40] Cromolyn sodium and nedocromil medications are used to stabilize the mast cell response and may be useful in managing exercise-induced asthma symptoms and allergen triggers.[40] Other medications include immunomodulators, leukotriene modifiers, long-acting beta2-agonists, and methylxanthines. These medications are more likely to be prescribed if the child's symptoms are not well controlled using an inhaled corticosteroid. Most children take a combination of medications, each adjusted to meet their asthma management goals. Physical therapists need to understand the pharmacologic management of their patients with asthma.

Although the medications used in the management of asthma are necessary, the side effects may have an unintended impact on daily life. For example, oral corticosteroids may cause an increased appetite and weight gain, fluid retention, increased bruising, and mild elevation of blood pressure.[40] Other side effects reported from asthma medications include nervousness, headache, trembling, heart palpitations, dizziness or light-headedness, dryness or irritation of the mouth and throat, heartburn, nausea, bad taste in the mouth, restlessness, difficulty concentrating, and insomnia.[40] Thus for children with asthma, adverse motor, cognitive, or emotional behaviors could be related to their medication and should be ruled out as a factor for such behaviors. For example, concentration difficulties could be misdiagnosed as a primary attention deficit disorder; anxiety consequences could be misdiagnosed as primary psychological disorder; overeating could be misdiagnosed as a primary eating disorder; and dizziness and trembling consequences could be misdiagnosed as primary motor impairments to balance and fine motor performance and ultimately to the child's participation level.

New drugs are constantly being researched and developed; thus, any listing of medications is relevant only within a limited time frame. The overall goal of long-term asthma management is to find the medication or combination of medications that will stop the inflammatory process at an earlier point or prevent the presentation of asthma altogether. As the understanding of the pathophysiology and genetics of asthma increases, new medications with more specific but fewer side effects will likely be developed. Medications to address coexisting conditions such as allergies and GERD will also contribute to the effective management asthma. Physical therapists should communicate with the child's physician about current medications and the implications for optimal physical activity and endurance.

SECONDARY IMPAIRMENTS

Quality of Life

Asthma is a chronic condition that is managed, not cured. Thus the diagnosis of asthma affects the life of the entire family and not just the child.[57] Numerous quality-of-life studies show extensive effects on family life.[8,14,56] For example, adolescents with asthma don't thrive as well as their nonasthmatic peers.[39]

This poor outcome is exacerbated when parents aren't coping well with the child's asthma.[39] Other family decisions reflect the parents' concerns for their child's health. For example, parents may restrict their child's participation in normal childhood activities out of fear of asthma exacerbations or social retributions.[56] In fact, it is not only the child who suffers from restricted participation. Parents are forced to miss days of work just like the child is forced to miss days of school; taken together they reduce the quality of life for the entire family.[47]

Growing up with this chronic childhood disease undoubtedly influences quality of life and choices made by individuals with asthma across the life span.[17] In fact, a recent study shows that 88% of adults with moderate to severe asthma report that their asthma is not well controlled, which negatively affects their burden of care and life choices.[59] When developing a plan of care for children with asthma, physical therapists are encouraged to engage the child and family in conversation about health and wellness, suggesting how the child can safely participate in his or her preferred physical and social activities. The therapist's recommendations should support the importance of adherence to medical management and encourage the child's self-management.

FIG. 27.4 Seven-year-old boy with asthma playing baseball. This is representative of an exercise that the child enjoys doing.

Growth and Development

Children with asthma are often shorter than their peers. Prolonged use of high-dose inhaled corticosteroids has been shown to reduce height compared to peers without asthma.[53] Recognition of the potential for reduced height as an adult is taken into consideration when developing a plan of care, but control of the child's asthma is paramount. Some modifications include recognition that bone mineral density (BMD) levels were better maintained with inhaled corticosteroids rather than with frequent bursts of oral corticosteroids.[19] Thus physicians may alter their choice of medication or delivery to control asthma while trying to minimize adverse secondary effects. Current recommendations call for the lowest dose of inhaled corticosteroids that will control the asthma symptoms but minimize the adverse effect on the child's musculoskeletal development to optimize adult lung growth and height growth and to maximize BMD.[19] Vitamin D is being explored as an asthma supplement to counteract the adverse effects of inhaled corticosteroids on height and BMD. Early results are promising, but more long-term studies are needed.[16]

Financial Impact on the Family and Society

According to the CDC, asthma is associated with the high related costs of care, reportedly topping $56 billion a year: http://www.cdc.gov/asthma/impacts_nation/asthmafactsheet.pdf. Children with moderate to severe asthma had higher costs, and those with exacerbations had the highest care costs.[28] Thus having a child with asthma not only increases the family's focus on the child's medical needs but also consumes the family's and the community's financial resources.

FOREGROUND INFORMATION

PHYSICAL THERAPY MANAGEMENT

Physical therapists are traditionally involved in exercise programs for children with asthma, and studies have shown the efficacy of such programs in improving endurance and decreasing asthmatic symptoms.[43] The specifics of exercise testing and the development of a fitness program are covered in Chapter 6 and will not be covered here. Endurance programs such as treadmill training, which are also common, will not be covered either because this author prefers to find ways to improve fitness and endurance through participation in typical childhood activities rather than in contrived activities, circumstances permitting. If physical fitness is seen as an "exercise duty," it is this author's experience that the child and family are less likely to follow through, seeing physical exercise as a chore rather than an opportunity for growth. Interventions that improve adherence to the child's asthma program are associated with improved health outcomes; thus finding exercises or activities that a child likes to do is well matched with those desired outcomes (Fig. 27.4).[44]

The child with asthma may need more than a nudge and emotional support to engage in age-appropriate physical activities. Few studies address possible secondary physical restrictions due to asthma (or other childhood chronic pulmonary diseases), such as adverse musculoskeletal changes/alignments and neuromotor strategies for breathing or trunk control that could limit the child's functional potential.[34,37] In the *Guide to Physical Therapist Practice,* physical therapy is defined as a "profession with … widespread clinical applications in the restoration, maintenance and promotion of optimal physical function."[23] Thus if physical function and activity limitations are identified as occurring secondary to asthma, physical therapy would be the appropriate service to restore, maintain, and promote optimal physical functioning and address activity limitations.

Physical therapy examination and evaluation and considerations for physical therapy interventions will be discussed in an in-depth case longitudinal scenario presented on Expert Consult. The case involves "Jonathan," who was referred to physical therapy at age 9 because his exercise-induced asthma limited his ability to participate in competitive soccer. In addition, a congenital chest wall deformity (pectus excavatum) was exacerbated by his asthma and further limited his inspiratory capacity and posture. The case scenario is intended to: (1) inform the physical therapist of the process of a differential

diagnosis for the potential physical and activity limitations that may occur in children with asthma and (2) present intervention strategies and procedures to enable children with asthma to play and participate in age-appropriate physical activities with peers, rather than participating in adult-supervised exercise programs. This is an especially important consideration for children with exercise-induced asthma because it is a common reason for decreased participation in school-age activities. Long-term outcomes from these interventions are presented.

SUMMARY

This chapter presented the pathophysiology and current medical management strategies associated with childhood asthma. Asthma has three primary traits: airway inflammation, airway obstruction, and bronchial hyperresponsiveness to stimuli. The pathophysiology is complex and interactive; thus physical therapy and medical plans of care must be developed specific to each patient. The child and family's adherence to the medical management of asthma is critical to positive long-term outcomes. A detailed longitudinal case scenario on Expert Consult illustrates physical therapist diagnosis and management from a multisystem and multidiscipline perspective. Therapists are encouraged to screen for impairments in cardiopulmonary, neuromuscular, musculoskeletal, integumentary, and gastrointestinal systems that contribute to activity limitations and participation restrictions that cannot be fully explained by asthma alone. The individualized physical therapy program presented in the case scenario along with the short-term and long-term outcomes serve as a template for setting goals and planning interventions for children with asthma.

Case Scenario on Expert Consult

The case scenario related to this chapter demonstrates the process of a differential physical therapy diagnosis for potential physical and activity limitations secondary to asthma. There is a special focus on the potential long-term outcomes of physical therapy procedural interventions on the maturation and physical performance of a child with asthma.
