Congenital Heart Conditions

Betsy Howell, Chris D. Tapley

Approximately 6 to 10 in 1000 children are born each year with moderate and severe forms of congenital heart defects.[88] Early detection, often prenatal, and improved medical and surgical management combine with the type of defect and the individual child characteristics to determine the impact. For example, two children, each diagnosed with a ventricular septal defect, may have entirely different histories. One child may go undiagnosed for several years, whereas the other child may require surgery in infancy. Many children are now diagnosed in utero—an especially important development for children with hypoplastic left heart syndrome (HLHS). In the past, most congenital heart defects were repaired when the child was at least 1 year old, often older. These surgeries are now being performed during the first days and months of life, which is likely to affect how children with congenital heart defects grow and develop. The likelihood of a physical therapist treating a child who has previously had open-heart surgery is greater now that more children survive open-heart surgery. The number of adults who have survived surgery in childhood for congenital heart defects continues to increase.

Physical therapists serving children with congenital heart conditions are encouraged to closely monitor and document the nature and extent of developmental differences that may result from surgical repair, as well as potential neurologic impairments related to the cardiac defect itself or to postoperative complications. To prepare therapists for this task, this chapter describes congenital heart defects; surgical repairs, including heart transplantation and mechanical assistive devices; acute and chronic physical impairments secondary to heart defects and surgery; and profound cyanosis or neurologic implications and complications. Physical therapy management following cardiac surgery and ongoing management of infants, children, and adolescents with congenital cardiac defects is presented.

BACKGROUND INFORMATION

Although embryologists can identify at what point during fetal development certain defects occur and what risk factors may contribute to their development, the cause of congenital heart defects remains largely unknown. The presence of more than one child with congenital heart defect in the same family or in the family history suggests a possible genetic component. Heart defects may be associated with Down syndrome, Turner syndrome, Williams syndrome, Marfan syndrome, Costello syndrome, DiGeorge syndrome, and the VATERL association, an acronym for the following characteristics: vertebrae, imperforate anus, cardiac anomalies, tracheoesophageal fistula, renal anomalies, and limb anomalies. The American Heart Association published a lengthy statement on current knowledge of the genetic basis for congenital heart defects[167] that describes in detail many of the above syndromes and their chromosomal disorders and associated cardiac defects. The American Heart Association has also published a lengthy statement on noninherited risk factors linked to congenital heart defects.[98]

Infants of diabetic mothers also have an increased incidence of congenital heart disease (CHD). Other noninherited risk factors found to be associated with congenital heart defects are maternal phenylketonuria, rubella, maternal obesity, and many different medications.[98] Women who used a multivitamin supplement before or just after conception were reported to have a significant reduction in the incidence of cardiac defects in their children.[29]

Diagnosis of cardiac impairments may occur during prenatal life or at birth. Some congenital heart defects require immediate attention, and others may be followed by further evaluation. Even with improved diagnostic techniques, some infants with severe cyanotic disease are not diagnosed before they are discharged to home, but several weeks later they may be diagnosed with a heart defect when they develop symptoms of septic shock. Prenatal diagnosis is essential for some diagnoses, especially hypoplastic left heart syndrome. In a review of mortality rates and the number of cardiac cases performed each year by different institutions, those with smaller surgical programs had increased mortality rates when outcomes of the more severe defects were compared.[223] Other cardiac defects may not be diagnosed until much later, even as late as adolescence. For example, coarctation of the aorta is occasionally diagnosed during a sports physical examination when a large difference between upper and lower extremity blood pressures or an abnormally high upper extremity blood pressure is observed.

The infant with a congenital heart defect often has abnormal respiratory signs, including a labored breathing pattern and an increased respiratory rate. The infant may be diaphoretic and tachycardic. Symptoms may include edema around the eyes and decreased urine output (evidenced by dry diapers). Eating problems result from difficulty in coordinating sucking and swallowing with breathing at an increased rate. Irritability that is difficult to assuage may be noted. These symptoms of congestive heart failure can lead to the diagnosis of a cardiac defect or can provide evidence of worsening of a known defect.

Congenital heart defects are usually classified as acyanotic or cyanotic. With acyanotic conditions, the child is pink and has normal oxygen saturation. If mixing or shunting of blood occurs within the heart, the blood shunts from the left side of the heart to the right side, so oxygenated blood goes to the lungs

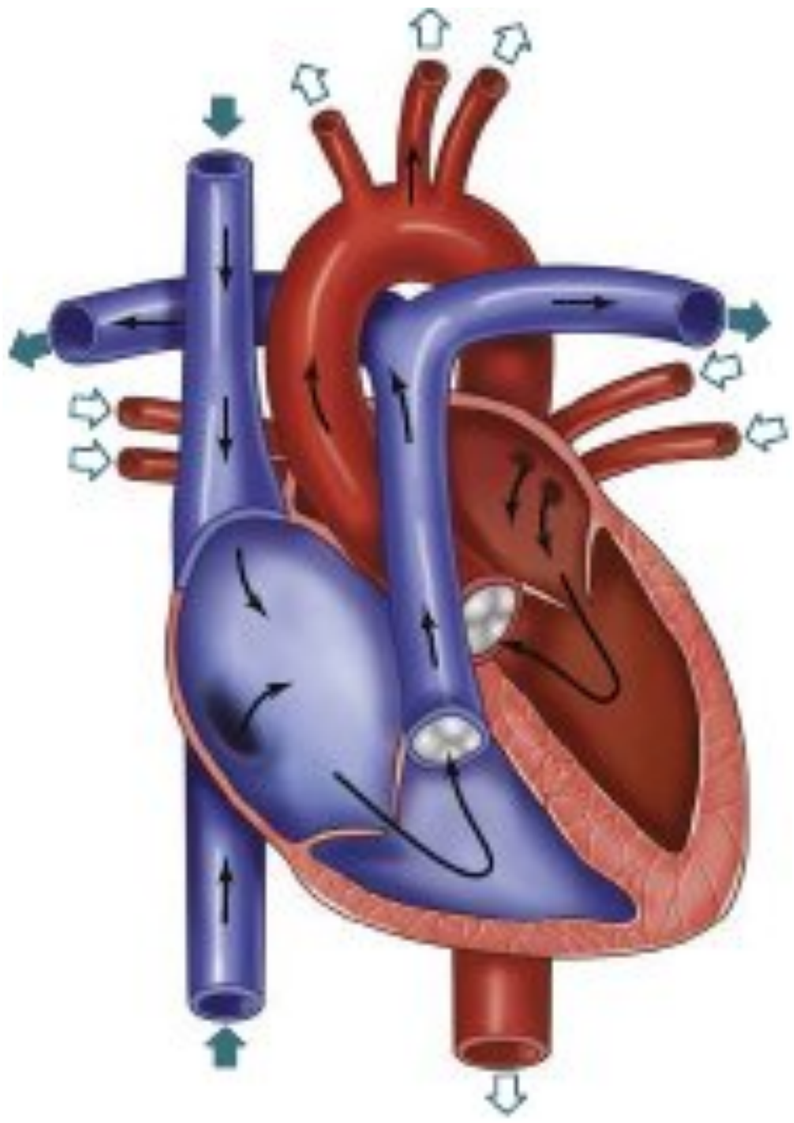

FIG. 28.1 Anatomy of the heart.

as well as to the body. Common acyanotic lesions include atrial septal defects (ASDs), ventricular septal defects (VSDs), patent ductus arteriosus (PDA), coarctation of the aorta, pulmonary stenosis, and aortic stenosis.

In cyanotic heart conditions, blood is typically shunted from the right side of the heart to the left side. Unoxygenated blood is then returned to the body, resulting in arterial oxygen saturation levels 15% to 30% below normal values. Common cyanotic lesions include tetralogy of Fallot, transposition of the great arteries, tricuspid atresia, pulmonary atresia, truncus arteriosus, total anomalous pulmonary venous return, and hypoplastic left heart syndrome.

Type and timing of intervention depend on the defect and the child's age. Some defects are repaired immediately, whereas others require a staged procedure, with the first of several surgeries being palliative rather than corrective. Some acyanotic defects are not repaired until the child is several years old.[140] Concerns regarding neurologic complications following surgery and their impact on long-term functional and cognitive development continue to be examined as an increasing number of infants survive earlier and more complex surgeries.[120] Acyanotic and cyanotic defects are further described in the next two sections and may be compared with normal anatomy of the heart (Fig. 28.1). Table 28.1 summarizes the common types of congenital heart defects, their typical surgical repair, and associated impairments and functional limitations described in the following sections.

TABLE 28.1 Summary of Congenital Heart Defects, Surgical Repair, and Associated Issues

Type of Defect	Surgical Repair	Associated Issues	Physical Therapy Issues
Atrial septal defect	Suture or patch closure/device closure		
Ventricular septal defect (VSD)	Dacron patch closure/device closure	Failure to thrive; pulmonary hypertension	Failure to thrive
Atrial ventricular septal defect/ endocardial cushion defect	Pericardial patch	Down syndrome; failure to thrive	Developmental delay
Coarctation of the aorta	Stent or subclavian patch/end-to-end anastomosis	Hypertension	Upper extremity range of motion
Pulmonary stenosis	Valvotomy		
Aortic stenosis	Valvotomy; aortic valve replacement; conduit		
Tetralogy of Fallot	VSD closed; right ventricular outflow tract resected	"Tet" spells	
Transposition of the great arteries (dextro)	Arterial switch operation	Edema; poor left ventricle function	Decreasing exercise tolerance with age
Pulmonary atresia (PA) with a VSD	Blalock-Taussig shunt (BT); VSD closed; right ventricle–to–pulmonary artery conduit	Developmental delay; poor oral intake	Developmental delay; feeding issues
Pulmonary atresia without a VSD	Valvotomy/BT shunt; right ventricular outflow tract patch, ASD closed, Fontan procedure	Very sick postoperatively, low oxygen saturations	Developmental delay
Total anomalous pulmonary venous return	Anomalous veins connected to left atrium; ASD closed	Failure to thrive	Failure to thrive
Tricuspid atresia	Atrial septostomy, BT shunt Bidirectional Glenn or hemi-Fontan procedure Fontan procedure	Low oxygen saturations	Failure to thrive
Truncus arteriosus	VSD closure, right ventricle–to–pulmonary artery conduit	Pulmonary hypertensive crisis	Developmental delay; failure to thrive
Hypoplastic left heart syndrome	Division of the main pulmonary artery; suture PA to the aorta; BT shunt and patent ductus arteriosus ligation; bidirectional Glenn or hemi-Fontan procedure; fenestrated Fontan procedure	Low oxygen saturations	Poor oral feeders; developmental delay; may not crawl; neurologic and behavioral issues; decreased exercise tolerance, especially with right-to-left shunt

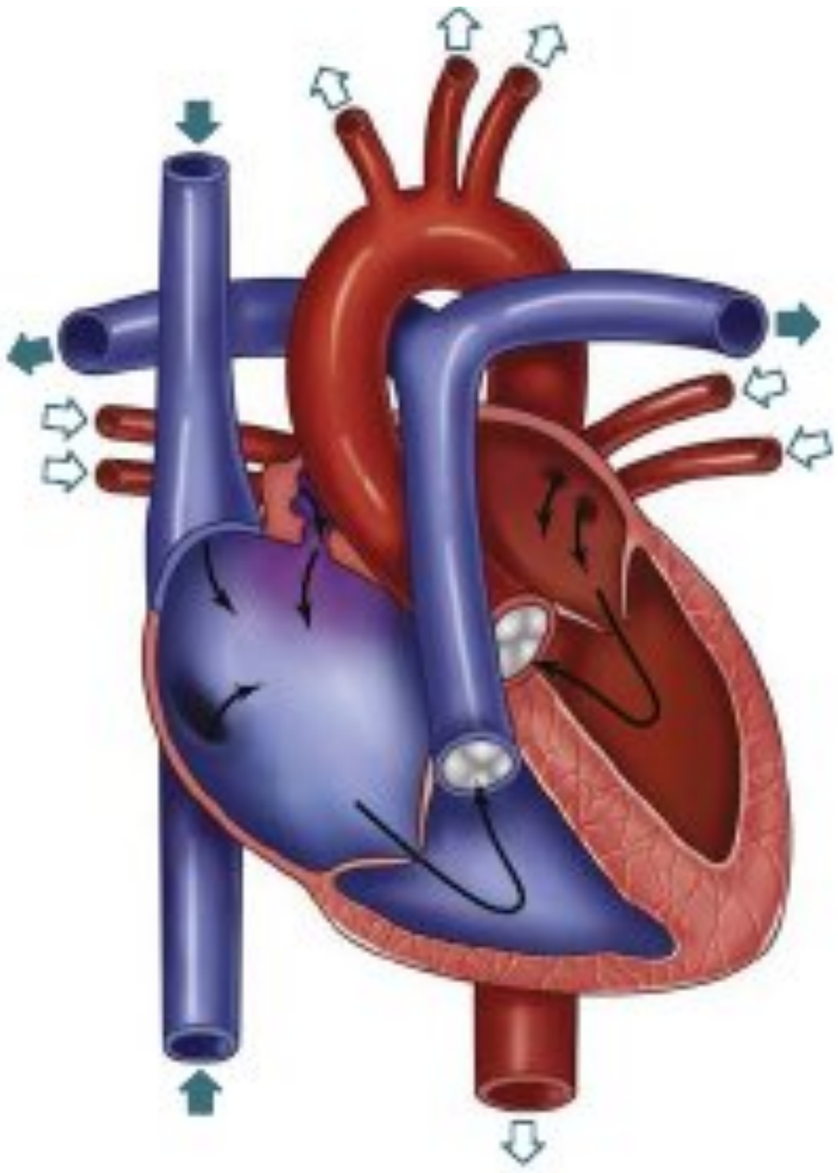

FIG. 28.2 Atrial septal defect.

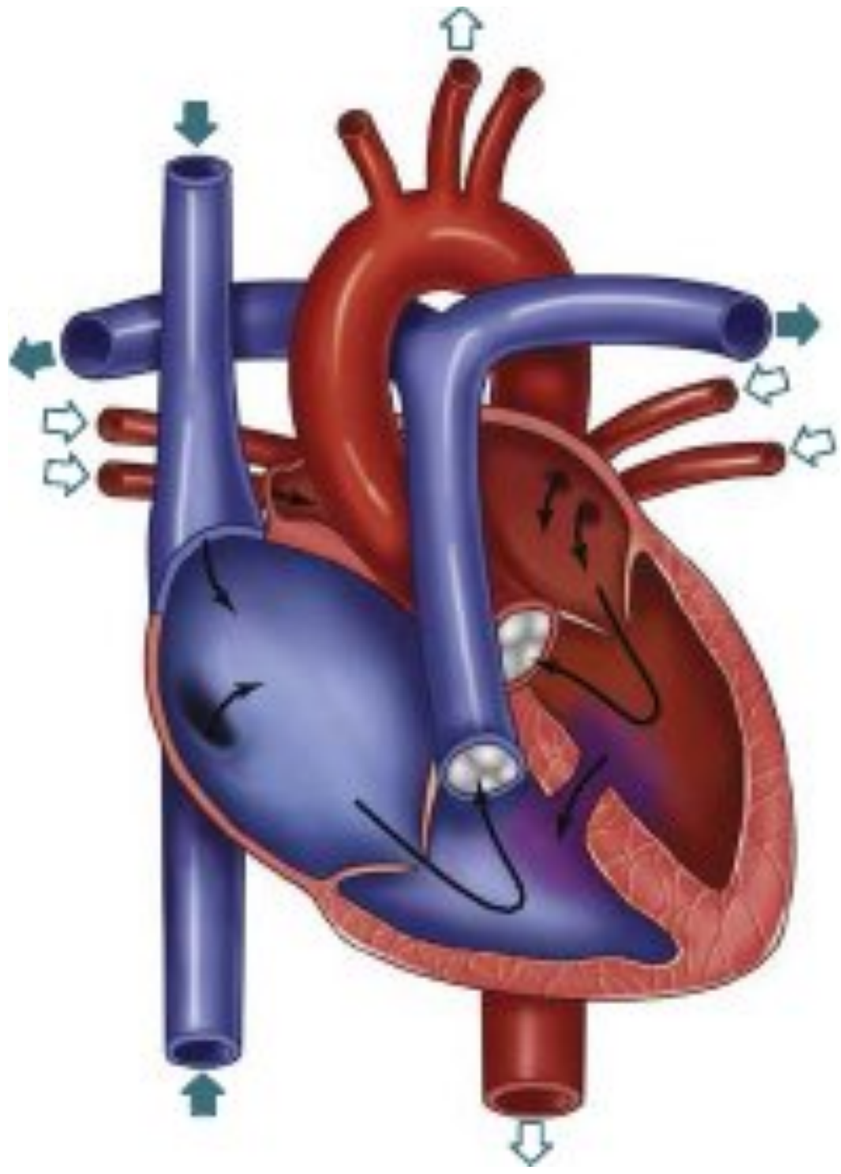

FIG. 28.3 Ventricular septal defect.

ACYANOTIC DEFECTS

Atrial Septal Defect

Atrial septal defect, one of the most common congenital heart defects, is an abnormal communication between left and right atria (Fig. 28.2). The defect is classified by its location on the septum. Blood is generally shunted from the left atrium to the right atrium. This defect generally does not require immediate repair because of slow progression of damage to the heart and lungs. The timing of surgery depends on the age of the child, when the diagnosis is confirmed, and how symptomatic the child is, but it typically occurs during the first 5 years of life. If a child has more severe symptoms, the defect is repaired sooner.[10] Some adults with signs of heart failure have a previously undiagnosed ASD. As medical technology advances, late diagnoses should become rare.

Closure of an ASD is usually done by placing a septal occluder or synthetic material to close the hole that is inserted via cardiac catheterization. Surgical repair may still occur if the ASD is in an unusual position, making it difficult to close via cardiac catheterization, or if the patient has other cardiac defects requiring repair. Surgery may be done through a median sternotomy incision; however, minimal-access techniques can be used, which can entail a smaller incision of approximately 4 cm.[10,103] Suture closure or, for larger defects, a patch closure is usually used to close the defect when surgery is necessary.[10,103] A longitudinal study of patients undergoing closure of an ASD during childhood reported excellent survival and low morbidity rates.[182]

Ventricular Septal Defect

VSD is the most common congenital heart defect, accounting for up to 40% of cardiac anomalies.[28] VSD can be present alone or in association with other defects such as tetralogy of Fallot and transposition of the great arteries. VSD alone is discussed here.

A VSD is a communication between the ventricles that allows blood to be shunted between them, generally from left to right (Fig. 28.3). The increase in blood flow through the right ventricle to the lungs may lead to pulmonary hypertension. In severe cases, in which pulmonary pressures exceed systemic pressures, shunting switches from right to left, which is often termed *Eisenmenger syndrome*.[142] A large defect may lead to early left ventricular failure. An infant with a large VSD has signs of severe respiratory distress, diaphoresis, and fatigability, especially during feeding, when the infant's endurance is stressed.[28] The infant's weight is dramatically affected in this situation. A child severely affected requires a much earlier surgical repair than a child who is asymptomatic.

Small defects may close spontaneously. Defects that compromise the clinical status of the patient must be surgically closed. The timing of surgery varies, depending on the child's tolerance of the defect. A child with a larger defect undergoes surgery earlier to diminish the negative effects on growth and the pulmonary system.

Surgical intervention is provided through a mediastinal approach and usually requires a synthetic patch closure.[28,142] Transcatheter devices are now being used with regularity and good success to close muscular VSDs but not as successfully as with perimembranous VSDs.[142]

Patent Ductus Arteriosus

The ductus arteriosus is a large vessel that connects the main pulmonary artery to the descending aorta (Fig. 28.4). It usually closes soon after birth but will dilate (remains patent) in response to hypoxia or prostaglandins E1 and E2. The ability to maintain patency of the ductus arteriosus becomes important in certain cyanotic heart defects (to be discussed later). Spontaneous closing of the ductus arteriosus can create a critical situation in the infant with an undiagnosed heart defect.[64] In some cases spontaneous closure does not occur. Reasons for

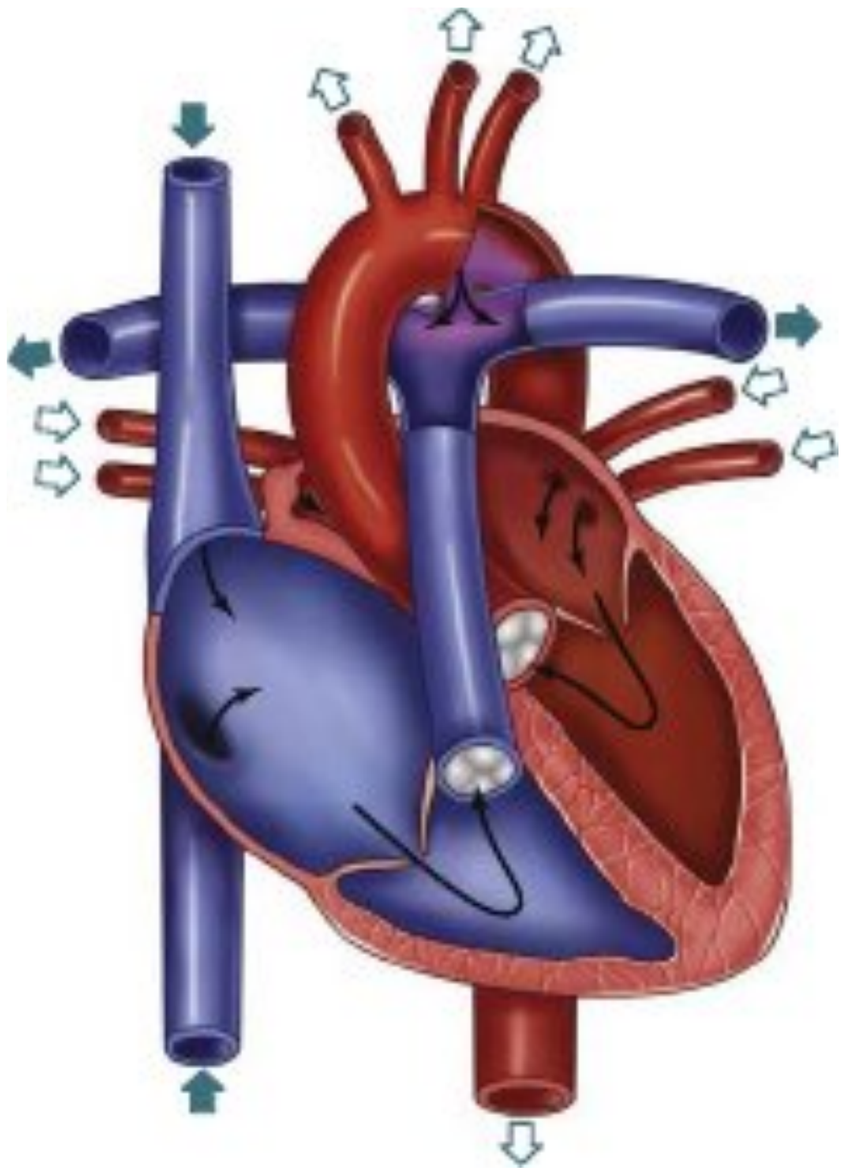

FIG. 28.4 Patent ductus arteriosus.

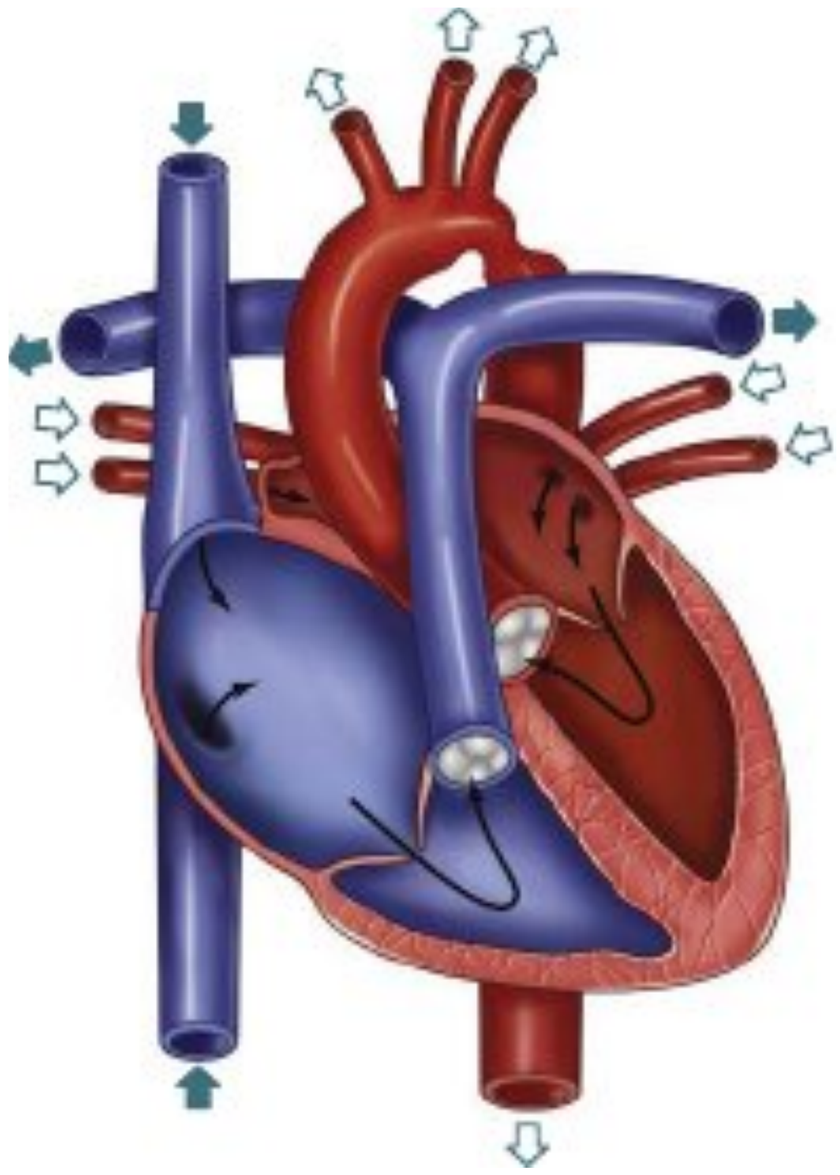

FIG. 28.5 Coarctation of the aorta.

nonclosure in the term infant are unclear but are thought to be due to ductal abnormalities, genetic factors, and some congenital infections. A high incidence of patency is found in premature infants because of respiratory distress syndrome and the resulting hypoxia.[152]

Several options are available if the PDA fails to close spontaneously or with medication. One option is video-assisted thoracoscopic surgery, which involves several small thoracostomies and results in no chest wall muscles being cut and no rib retraction.[152] Another option is transcatheter coil occlusion performed by cardiac catheterization, which can be an outpatient procedure. This is the preferred method of closure with all but the youngest children. Video-assisted and coil occlusion techniques are less traumatic, can reduce hospital stay,[64] and may decrease the risk of scoliosis, which is associated with thoracotomy. A left thoracotomy incision is the standard operative approach if video-assisted and coil occlusion cannot be performed. The ductus is ligated and sutured.

Coarctation of the Aorta

Coarctation of the aorta is defined as a narrowing or closing of a section of the aorta (Fig. 28.5). It may occur in isolation or in conjunction with other defects including bicuspid aortic valve, VSD, and in the neonatal population PDA.[116] Infants with a severe narrowing may develop cardiovascular collapse following closure of the ductus arteriosus. Early repair is necessary when a child is severely symptomatic.[9] The child or adult without symptoms may go undiagnosed until a routine physical examination reveals a hypertension.[9]

Surgical intervention is generally the method of treating coarctation of the aorta. Access to the aorta is gained through a left thoracotomy, after which the aorta is repaired with an end-to-end anastomosis, a subclavian flap, or a patch aortoplasty. The coarctation can also be treated via cardiac catheterization using a balloon that is inflated in the constricted area, although this has been shown to have higher complications.[9]

Pulmonary Stenosis

Pulmonary stenosis, a narrowing of the right ventricular outflow tract, is classified by the location of the narrowing relative to the pulmonary valve. It often occurs in association with other heart defects. Timing of intervention depends on the severity of the narrowing and the degree of functional compromise, as well as on when pressure in the right ventricle becomes too high. Intervention is generally a balloon valvotomy that is performed via cardiac catheterization. Surgery when necessary is performed through a median sternotomy; the type of surgical procedure depends on the site of narrowing. A valvotomy may be performed, or, in severe cases, the valve may need to be replaced.[95]

Aortic Stenosis

Aortic stenosis, a narrowing of the left ventricular outflow tract, is classified by its relation to the aortic valve (supravalvular, valvular, or subvalvular) (Fig. 28.6). The narrowing will cause the left ventricle to work harder to pump blood through the narrowing. Depending on location and severity of obstruction surgical correction is indicated. Surgical technique will vary dependent on type and location of stenosis.[31]

CYANOTIC DEFECTS

Tetralogy of Fallot

Tetralogy of Fallot is the most common complex cardiac defect with an estimated incidence of 3.3 per 10,000 live births. The primary abnormalities that occur in the tetralogy of Fallot are a VSD, right ventricular outflow tract obstruction, an aorta that overrides the right ventricle, and hypertrophy of the right ventricle (Fig. 28.7).[155] Clinical manifestations depend on the

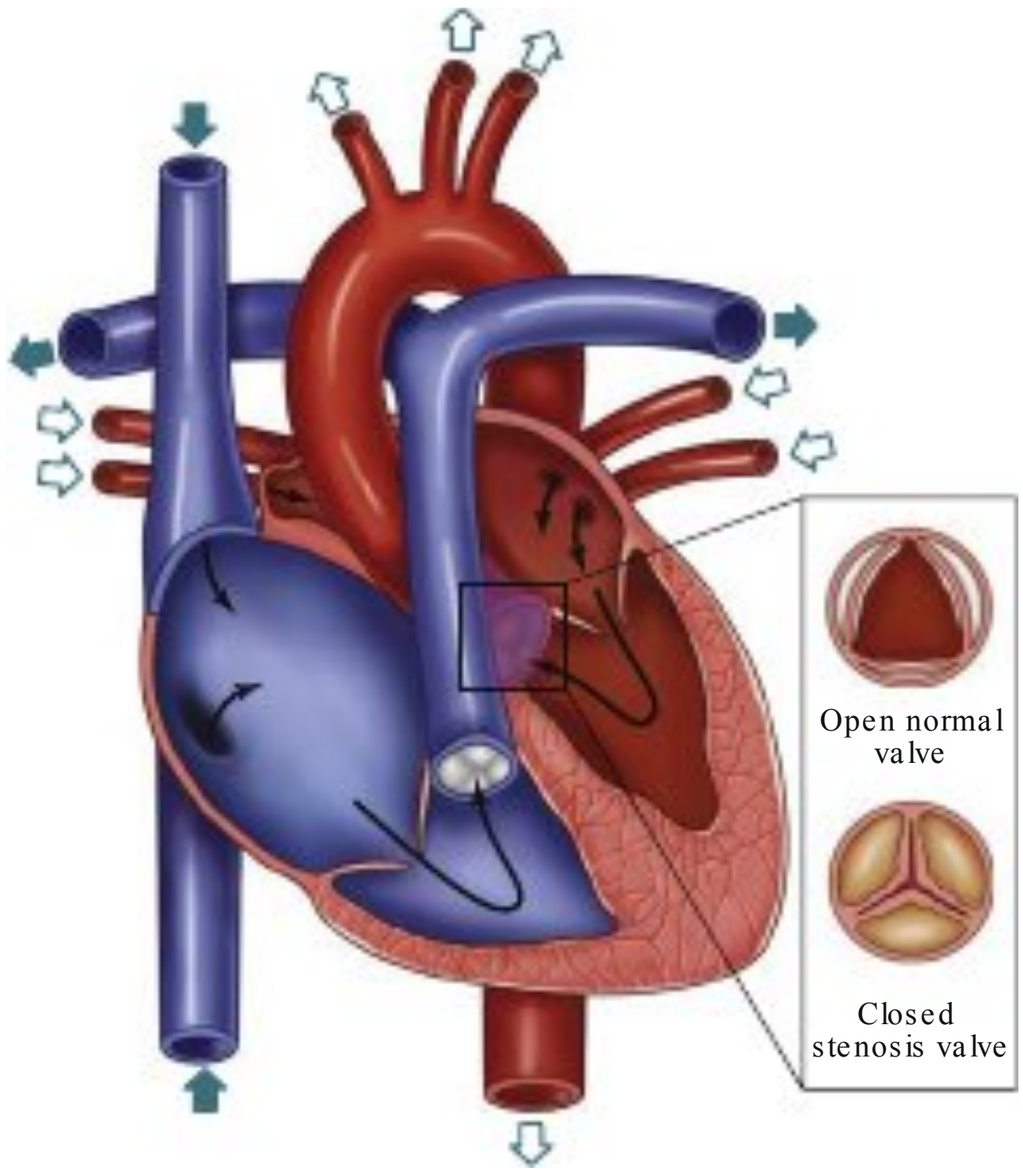

FIG. 28.6 Aortic stenosis.

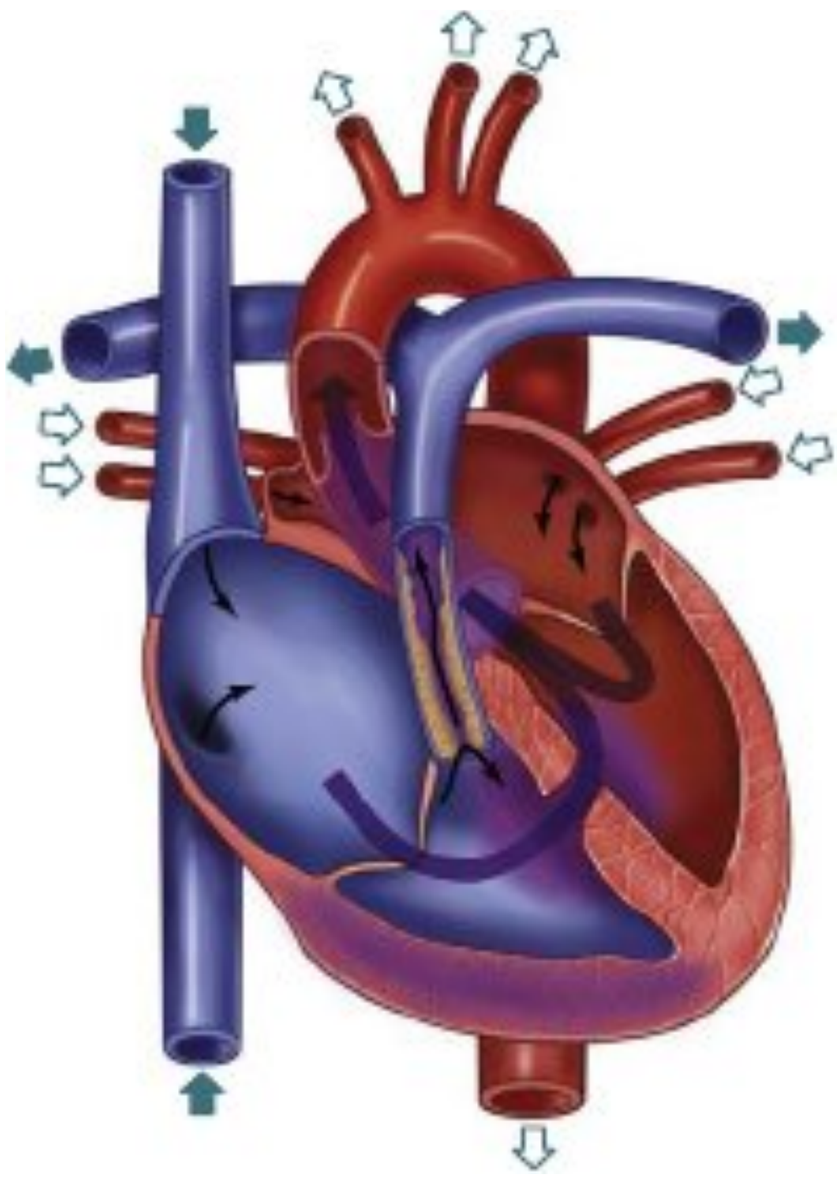

FIG. 28.7 Tetralogy of Fallot.

severity of obstruction of the right ventricular outflow tract. With increasing obstruction, an increase in cyanosis is observed over the first 6–12 months of life. Some children will develop hypercyanosis, or "tet spells," which are periods of profound systemic hypoxemia typically occurring in the context of crying, eating, or defecation. These spells are characterized by a marked

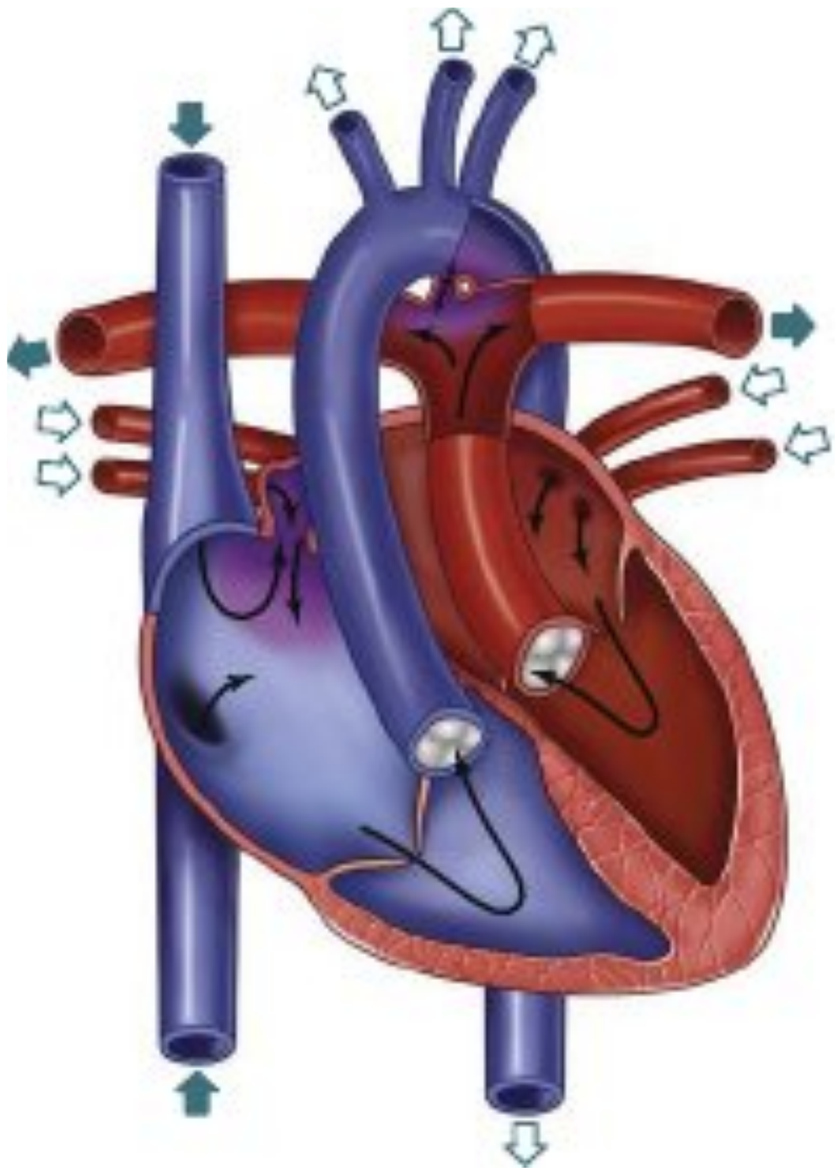

FIG. 28.8 Transposition of the great arteries.

decrease in pulmonary blood flow and an increase in the right-to-left shunt across the VSD into the left ventricle and out the aorta and are characterized by dyspnea, syncope, and deepening cyanosis.[155] Cyanotic episodes can be relieved by squatting or by bringing the knees to the chest. These maneuvers are believed to increase systemic vascular resistance and ultimately to increase pulmonary blood flow. Medical management including increasing blood volume with fluid administration or transfusion, treating acidosis with bicarbonate, sedation, and use of medication to increase systemic vascular resistance may be necessary.[155]

Surgical intervention depends on the patient's symptoms and overall clinical picture. If possible, a complete repair is usually done early in life. Early palliation may be necessary if an infant is severely involved and would probably not survive corrective surgery. The palliative procedure used most often is a modified Blalock-Taussig (BT) shunt performed through a median sternotomy. The modified BT shunt involves a 3.5- or 4-mm Gore-Tex shunt being anastomosed end to side to the innominate artery and to the ipsilateral branch pulmonary artery, providing increased pulmonary blood flow while the infant gains more time to grow before undergoing corrective surgery.[205] Infants who receive early palliation continue to have cyanosis until complete repair is performed.

Corrective surgery involves closing the VSD and relieving the right outflow tract obstruction. After surgical repair a high incidence of ventricular and atrial arrhythmias has been seen and should be considered as activity is progressed.[205] Early (hospital) mortality rate following repair is reported to be between 1% and 5%.[155]

Transposition of the Great Arteries

In transposition of the great arteries, the pulmonary artery arises from the morphologic left ventricle, and the aorta arises from the right ventricle (Fig. 28.8).[50] In the absence of other defects,

systemic blood returns to the body unoxygenated and pulmonary blood returns to the lungs fully oxygenated. This situation is not compatible with life unless the ductus arteriosus remains patent. Immediate intervention, usually with infusion of prostaglandin E1, is necessary to keep the ductus arteriosus open. An atrial septostomy is performed by a cardiac catheterization to keep the child alive until surgical intervention occurs.[141]

The preferred surgical technique for correction of transposition of the great arteries is the arterial switch procedure. Surgery during the first 2 to 4 weeks of life is desirable so that the left ventricle meets the systemic demands. Surgical repair occurs through a median sternotomy and involves transecting the aorta and pulmonary artery. The coronary arteries are excised with a wide button of aortic tissue and reimplanted in the old pulmonary arterial vessel; the great vessels are then switched and anastomosed so that the aorta connects to the left ventricle and the pulmonary artery connects to the right ventricle. The arterial switch procedure produces results that are free of the dysrhythmias and right ventricular failure associated with Mustard or Senning techniques.[141] Previously the Mustard or Senning techniques were used to redirect the venous return to the atria by baffles or flaps of atrial wall, respectively. These techniques leave the right ventricle as the pumping chamber for the system creating a physiologic but not anatomic correction.[141] The Mustard or Senning techniques are generally not used anymore due to complications including superior vena caval obstruction, baffle leak, atrial and ventricular arrhythmias, tricuspid valve insufficiency, and right ventricular failure.[141] Therapists may see teenage or young adult patients who have had this repair.

The Rastelli procedure is a surgical technique used when a severe left ventricular outflow tract obstruction and a VSD coexist. Repair usually occurs when the child is between 6 and 12 months old. A conduit diverts blood from the left ventricle through the VSD and the right ventricle to the aorta, a right ventricle–to–pulmonary artery conduit is formed, and any previous shunts are eliminated.[141]

Tricuspid Atresia

Tricuspid atresia is failure of development of the tricuspid valve, resulting in lack of communication between the right atrium and the right ventricle. Usually, an ASD or a VSD or both exist to allow pulmonary blood flow (Fig. 28.9). Right-to-left shunt allows mixing of unoxygenated and oxygenated blood, causing the child to be cyanotic. The right ventricle is frequently underdeveloped.[172]

Surgical repair is staged, with the initial operation shunting blood from the body to the lungs with a modified BT shunt. If the VSD is large and too much blood is going to the lungs, however, a band may be placed around the pulmonary artery to decrease blood flow to the lungs.[141] The child will remain cyanotic for several years. The next stage of surgical repair is often the Fontan procedure (or a modification thereof), performed through a median sternotomy in which the right atrium is attached to the pulmonary artery or directly to the right ventricle, using a conduit or baffle. The VSD may be surgically closed. In some institutions, a bidirectional Glenn procedure performed before the Fontan procedure leads to an improved outcome. In the Glenn procedure the superior vena cava is anastomosed to the right pulmonary artery. The child remains cyanotic but gains time for growth before undergoing the Fontan operation.[141]

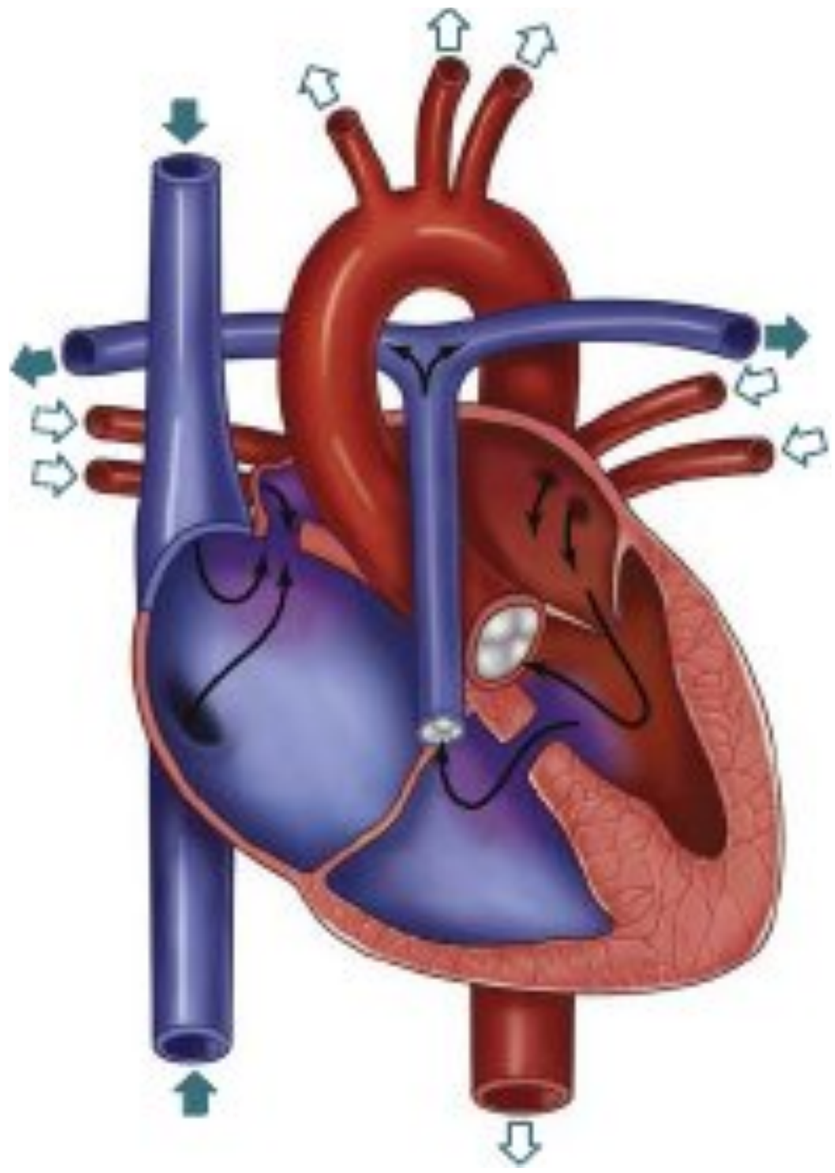

FIG. 28.9 Tricuspid atresia.

Pulmonary Atresia

Pulmonary atresia occurs when the pulmonary valve fails to develop, resulting in obstruction of blood flow from the right side of the heart to the lungs. Blood flow to the lungs is initially maintained by a PDA. An ASD or a VSD may also be present, allowing shunting of blood from the right to the left side of the heart and ultimately back to the body. The size of the right ventricle may vary, affecting later surgical decisions. Early intervention involves maintaining patency of the ductus arteriosus to increase blood flow to the lungs until surgery can be performed. Surgical repair will vary significantly depending on extent of right ventricle development and other malformations present.[83]

Truncus Arteriosus

Truncus arteriosus occurs when the aorta and the pulmonary artery fail to separate in utero and form a common trunk arising from both ventricles (Fig. 28.10). Four grades of the condition are differentiated, depending on the location of the pulmonary arteries. Early surgical intervention is necessary. Surgical repair is provided through a median sternotomy and involves removing the pulmonary arteries from the truncus, closing the VSD, and connecting the pulmonary arteries to the right ventricle by an extracardiac baffle. Hospital mortality rates range from 4.3% to 17% with most deaths occurring in the most complex forms.[24]

Total Anomalous Pulmonary Venous Return

Total anomalous pulmonary venous return (TAPVR) occurs when the pulmonary veins fail to communicate with the left atrium and instead connect to the coronary sinus of the right atrium or to one of the systemic veins. The ductus arteriosus often remains patent (Fig. 28.11). The increase in flow through the right side of the heart and into the lungs may lead to congestive heart failure. Anastomosis of the pulmonary veins to the

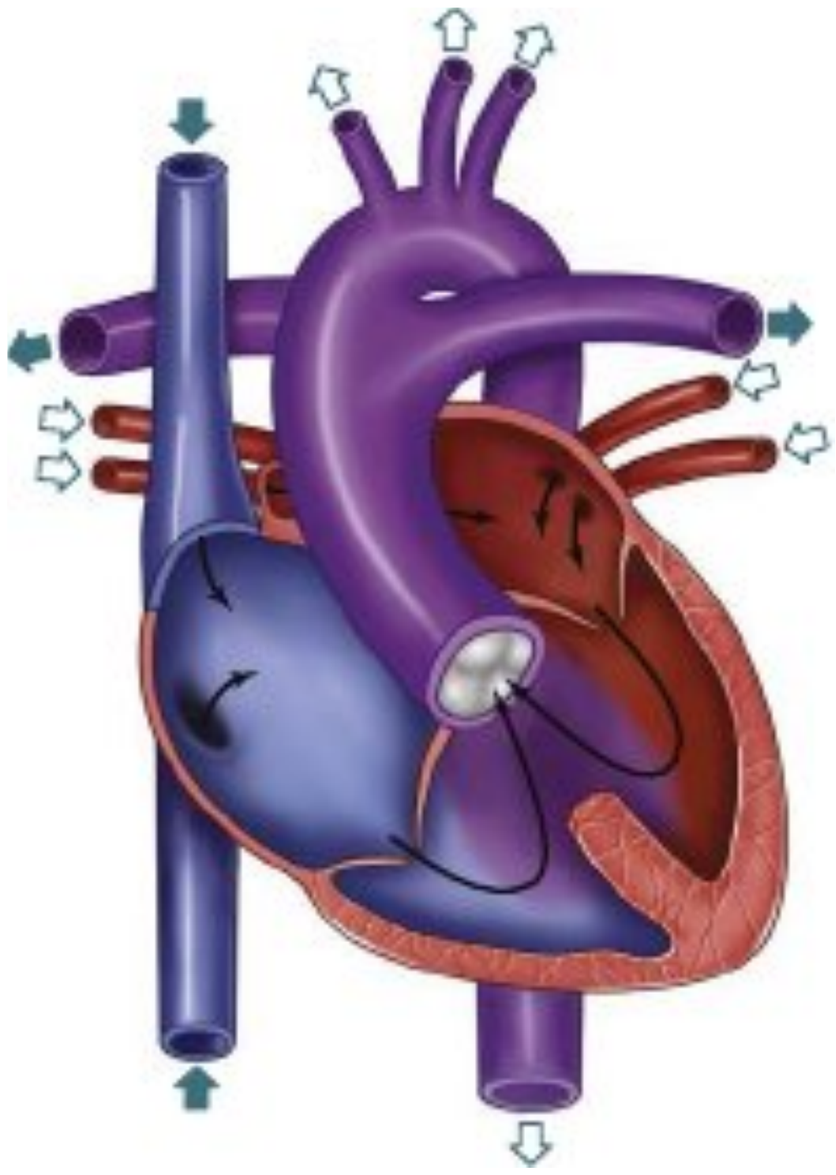

FIG. 28.10 Truncus arteriosus.

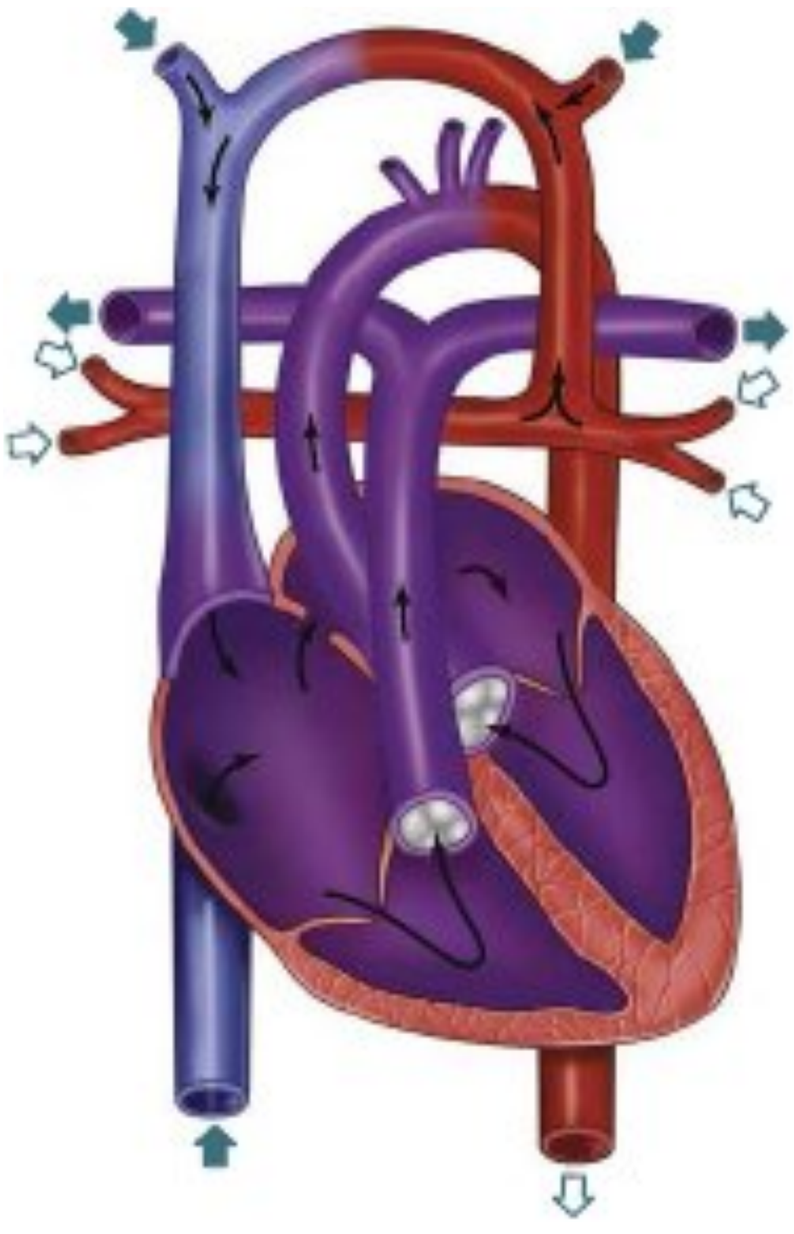

FIG. 28.11 Total anomalous pulmonary venous return.

left atrium through a median sternotomy is usually performed as soon as possible. Postoperative ventilation may be difficult because of stiffness and wetness of the lungs from the previous excessive blood flow. Mortality rates continue to improve with early and late mortality for simple TAPVR being 10% and 4%, respectively.[164,216] There is one reported case of a 48-year-old patient who is 47 years postrepair for total anomalous pulmonary venous return.[42]

Hypoplastic Left Heart Syndrome

Hypoplasia (incomplete development or underdevelopment) or absence of the left ventricle and hypoplasia of the ascending aorta make hypoplastic left heart syndrome (HLHS) the most common form of a univentricular heart, often coexisting with severe aortic valve hypoplasia. A PDA provides systemic circulation until surgical intervention. Without surgical intervention, death is certain. Hospital survival rate (the percentage of children who leave the hospital alive after surgery for HLHS) still lags behind the rate for other congenital heart surgeries, but the surgical survival rate is now 90%.[168] Bove reported that the survival rate after second-stage palliation is now 97%, and the survival rate is 81% after the Fontan operation.[30] Five-year survival rates are between 69% and 71%, depending on the patient's anatomy,[30] and 10-year survival rates were observed to be at 55%.[16]

Prenatal diagnosis and care are essential for the parents to prepare for and to be counseled about prognosis and surgical options. They also enable the parents and medical staff to plan for delivery and the immediate postpartum period.[16] Tibballs observed that prenatal diagnosis led to termination of pregnancy at a rate of 44% to 71% in Europe and 18% to 45% in the United States.[210] It was observed by Mahle and colleagues that prenatal diagnosis was found to possibly decrease postoperative neurologic events when compared with those diagnosed postnatally.[128]

Three options are available to parents of infants diagnosed as having HLHS. One option is no surgical intervention. As a second option, the child's name may be placed on a waiting list for a heart transplant; as a third, the child may undergo a series of palliative procedures.[36]

The initial surgical procedure (Norwood I[30]) involves enlarging the ASD, transecting the main pulmonary artery and anastomosing it to the aorta, and reconstructing the aortic root. A BT or central shunt is placed to allow pulmonary blood flow. Some centers use a right ventricle (RV)–to–pulmonary artery (PA) conduit as the first stage.[16,127,168,193] This procedure may require the second stage to be performed sooner, and the potential long-term consequences of cutting into the right ventricle are not known.[30] A third technique for the child who is medically fragile is a hybrid technique that combines interventional cardiac catheterization with surgery. This involves an atrial septostomy and placing a pulmonary artery band to restrict pulmonary blood flow and a stent in the arterial duct to hold it open. The child does not need to go on cardiopulmonary bypass.[16] Before the second stage the child's oxygen saturation and activity level may start to decrease. Children may have more difficulty eating, especially with taking a bottle or nursing, which requires more energy. The second stage, generally completed between 4 and 10 months, is a hemi-Fontan or bidirectional Glenn procedure in which the superior vena cava is anastomosed to the pulmonary arteries and the BT shunt is ligated. The Fontan procedure is then performed between 18 and 24 months. This procedure provides continuity between the right atrium and the pulmonary artery, and pulmonary venous return is separated from the systemic system. As a result, the right ventricle pumps fully oxygenated blood to the body.[86]

HEART FAILURE

Pediatric heart failure can result from congenital heart defects, dilated cardiomyopathy, cardiomyositis, metabolic disorders, or from eventual failure of previous repairs or palliation.[184] The number of children with single-ventricle palliation is increasing with likely future increases in heart failure either as an older adolescent or young adult.[46] Management of these patients can be accomplished via pharmaceutical methods, surgical management including placement of mechanical assist devices, and in the worst cases orthotopic heart transplantation. This population tends to have frequent and often lengthy hospitalizations as well as ongoing functional deficits requiring acute and chronic rehabilitation efforts.[184] In this section we will present options for management and implications for the pediatric physical therapist.

Inotropic Support

Intravenous inotropic support is commonly used for end-stage congestive heart failure in the pediatric population.[23] Inotropic agents are drugs that increase or decrease the contractility of the heart during preload and afterload. These drugs include digoxin, dopamine, norepinephrine, epinephrine, isoproterenol, dobutamine, amrinone, and milrinone. Previously, these drugs have often been limited to in-hospital use because of the need for close monitoring and supervision.[23] There has been a trend to complete outpatient inotropic support with medications such as milrinone as a bridge to transplantation. Berg and colleagues reported the use of home inotropic support in 14 children with end-stage congestive heart failure and found minimal complications as well as substantial cost savings and improved family dynamics.[23] Birnbaum and colleagues[25] recently reported comparable results with a much larger study including 106 patients being supported at home with milrinone as a bridge to transplant: 85% of patients underwent transplantation, 8% of patients successfully weaned from support as outpatients, whereas 6% died.[25] McBride and associates also reported on the safety of a monitored exercise program for pediatric heart transplant candidates on multiple inotropic support.[143] They found that patients were able to engage in an aerobic and musculoskeletal conditioning program three times per week with no adverse episodes of hypotension or significant complex arrhythmias. Physical therapists need to be aware of the increased use of these medications in the home setting. As noted, studies are showing safety with activity while on inotropic support. Patients, however, still need to be carefully monitored when engaging in therapeutic activities while on inotropic support.

Technological Support

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) may be used for cardiovascular and respiratory support in children after open-heart surgery. ECMO consists of an external circuit that moves venous blood through an artificial gas exchanger, which provides blood oxygenation and decarboxylation. ECMO support can be provided either in a veno-venous (VV) or veno-arterial (VA) setup. VV ECMO provides only respiratory support, bypassing the patient's lungs, while VA ECMO provides both respiratory and circulatory support, bypassing both heart and lungs.[195] The ECMO circuit takes over oxygenation and perfusion of the child's body while the heart and lungs are "rested." Indications for biventricular support by ECMO in the early postoperative period include progressive hypotension, increased ventricular filling pressures, poor peripheral perfusion, decreased urine output, and decreased mixed venous oxygen saturation.[57,107] ECMO is also used as a bridge to surgery or transplant in the severely compromised patient who is too ill to undergo repair immediately. Bautista-Hernandez and associates observed that 62% of their patients survived to discharge from the hospital—patients who probably would not have survived their initial surgery without EMCO first to stabilize them.[18] ECMO is capable of providing support for several days to at most a few weeks[11] and is associated with severe complications such as cerebral infarction, brain hemorrhage, renal failure, and multiorgan system failure.[93] Historically, patients on ECMO must remain intubated and sedated and therefore are unable to be mobilized while on support.[93] More recently, there is a push for early mobilization of patients on ECMO when medically appropriate. This has been used primarily in cases of VV ECMO and predominantly in settings of respiratory failure only.[115,169,212,231] As technology advances, early mobilization of children receiving other forms of ECMO may become possible. Early rehabilitation might improve outcomes. Therapists providing services to children with cardiac conditions in acute and outpatient settings should be aware of a history of ECMO due the high incidence of neurologic impairment and possible impact on developmental and functional outcomes.

Ventricular Assistive Devices

As previously noted, young children with the most severe heart failure are most often supported with ECMO.[93] An alternate approach uses ventricular assistive devices (VADs). VADs, circulatory pumps that supplement or completely replace the pumping function of one or both ventricles, have been used extensively in the adult population as a bridge to a transplant device or to a recovery device for many years. Their use in the pediatric population, however, has been limited because of limited availability of devices that meet pediatric physiology and cardiac flow needs.[11,180,208] Bastardi and colleagues and others have suggested that despite the lack of pediatric-specific devices, VADs are a viable option to be used as a bridge to transplant therapy or in some cases to recovery in the pediatric population.[17,35,84,180] In addition, Adachi et al. and Zafar et al. each showed significant decreases in heart transplant wait list mortality since more widespread use of pediatric VADs.[2,230]

Currently, a limited number of VADs are available for use in the pediatric population, especially in the infant and young pediatric population. The primary device used in the United States for this population is the Berlin Heart Excor (Berlin Heart AG, Berlin, Germany). This pneumatically driven, pulsatile VAD may be used as a left ventricular assistive device (LVAD) or as a biventricular assistive device (BiVAD). The Berlin Heart Excor supports a variety of blood pumps capable of delivering stroke volumes from 10 to 80 ml, making it suitable for use in children as small as 3 kg through full-size adults.[84,136,147,180,208] The Berlin Heart Excor is the only pediatric-specific device approved for use by the Food and Drug Administration (FDA).

Morales and associates[151] have reported their experience with use of the Berlin Heart Excor in a multicenter North American experience. Between June of 2000 and May of 2007, 73 patients underwent implantation at 17 different institutions with the Berlin Heart Excor system. Fifty-one patients (70%)

were successfully bridged to transplant, five patients (7%) were bridged to recovery, and 17 patients (23%) died.[151] Rockett and associates also reported their experience with the Berlin Heart Excor. Between April of 2005 and May of 2008, 17 patients underwent implantation with the Berlin Heart Excor System. Eleven of those patients went on to transplant, two patients underwent explantation due to recovery, three died while on support, and one patient remained on support at the time of publication of the study.[180] Malarisrie and colleagues reported similar findings with eight patients with the Berlin Heart Excor implanted.[134] Five patients survived until transplant, and three died while on support. Of note, in both reports a high incidence of neurologic complications was noted, with seven of 11 patients reported by Rockett[180] and five of eight patients reported by Malarisrie.[134] Despite the high level of neurologic complications in both studies, many children survived to transplant who would likely have died otherwise without use of a VAD system.

In addition to the Berlin Heart Excor there has been a recent increased use of VADs originally designed for use in adults in the older pediatric population. Most of these are continuous flow devices allowing smaller size and easier implantation. The HeartWare HVAD (HeartWare, Inc, Framingham, MA) has been implanted successfully in individuals with a body Surface Area (BSA) of > 0.7 m^2.[125,147] The HeartMate II (Thoratec Corp, Pleasanton, CA) has been successfully implanted in patients with a BSA of > 1.2 m^2.[125,148] Both devices have increased portability with the ability to discharge home as compared to the Berlin Heart Excor, which to date has not been amenable to discharge home.

Use of a VAD or other mechanical support system offers additional benefits as well. Most notably for physical therapists is the ability to mobilize and engage in aggressive physical therapy soon after implantation of a VAD in children of all ages.[178,180] Experience at multiple centers has shown the benefits and safety of mobilizing patients after VAD implantation.[63,91,178,180,163,198,203] During the immediate postoperative period, while patients remain intubated, the focus of physical therapy is positioning and prevention of contractures. After extubation, progression will depend on the age and medical status of the patient.

An important consideration is providing families education and support for handling and positioning their infants and toddlers for caregiving and development.[91,178] Many times, families are very hesitant to handle and care for their children after implantation of a VAD. Through education and support, parents and other family members gain comfort with handling and transferring the child as medically appropriate. All care needs to be provided in coordination with the medical and nursing team.

As the infant or toddler becomes more stable, it is essential to provide as much of a normalized routine as possible, incorporating physical therapy, occupational therapy, speech therapy, and school and activity staff as appropriate. Consideration must be given to device limitations, but, as able, children should be progressed through activities to facilitate achievement of developmental milestones. Each different device will present its own unique challenges, and collaboration and training among team members of all disciplines are required to provide the most comprehensive and appropriate care.[63,91,178]

For the older child and adolescent, many of the same considerations as noted for the infant and the toddler apply. A team approach should be implemented to normalize the daily schedule as much as possible. Physical therapy should focus on increasing the child's independence with activities of daily living (ADLs), transfers, and mobility in early therapy sessions, with progression to higher-level functional activities and strengthening and endurance activities as the child's condition allows. The goal is to have the child at peak conditioning and level of fitness at the time of transplantation. It is also important to discuss device safety and limitations as appropriate.[91,178,203] If possible, children should be provided opportunities for physical activity and socialization off of the medical unit with appropriately trained staff and family. Continuous flow devices have enabled children return to school, community, and home settings.[163,198] Pediatric physical therapists in a variety of settings have a role in promoting and monitoring physical activity of children with VADs.

Children with a VAD have a high rate of neurologic complications.[17,35] The physical therapist may be the first member of the team to observe signs and symptoms of neurologic impairment, such as onset of muscle weakness, changes in level of arousal, balance impairments, and changes in speech. These "red flags" should be immediately shared with the medical team and addressed in treatment. Children have demonstrated significant functional recovery after neurologic complications, and their ability to participate in therapy plays a large role in that recovery.[180]

Because of the integral role that mechanical assistive devices have as a bridge to transplant in children, a focus of research is to create devices that can be used by children at various stages of development.[11,208] Pediatric therapists are likely to see increased numbers of children with a mechanical assistive device. Comprehensive rehabilitation programs and therapy management plans will be integral to participation of children with mechanical assistive devices in home, school, and community activities.

Heart Transplantation

Cardiac transplantation is a viable option for children with end-stage heart failure secondary to congenital malformations or for children with cardiomyopathy. Advances in surgical technique, immunosuppressive medications, and treatment for rejection have increased the median survival posttransplant to 20.6 years for infant transplant recipients, 17.3 years for children transplanted between the ages of 1 and 5 years, 14.6 years for children transplanted between the ages of 6 and 10 years, and 12.9 years for adolescents.[51,209]

In the past, the indication for transplantation in children was largely cardiomyopathy (62%). In recent years the number of transplants for congenital heart defects has surpassed that of cardiomyopathy. In infants, 55% of transplants are completed due to congenital heart disease while cardiomyopathy accounts for 41%. In other age groups percentages are similar with approximately 66% and 23% of the 11- to 17-year-old, 59% and 32% of the 6- to 10-year-old, and 54% and 40% of the 1- to 5-year old recipients having had transplant for cardiomyopathy and congenital heart disease, respectively.[51]

Lamour and colleagues conducted a review of the impact of age, diagnosis, and previous surgery on children undergoing heart transplantation, using data from the Pediatric Heart Transplantation Study and the Cardiac Transplant Research Database.[112] They found that morbidity was higher post–heart transplant in patients with CHD (86%) than in those with cardiomyopathy (94%). The 5-year survival rate was approximately 80% among children who received heart transplants between 1990 and 2002. Other variables related to increased morbidity

included long ischemic times, history of Fontan pretransplant, and older recipient age. The mortality rate was less for those undergoing a cardiac transplantation after a Glenn procedure than after a Fontan.[97] Griffiths evaluated patients with failing Fontan physiology and their response to heart transplantation.[77] They found that patients who were transplanted because of impaired ventricular function had a lower mortality rate than those with preserved ventricular function but with secondary problems such as protein-losing enteropathy, plastic bronchitis, ascites, and edema. Overall, more than 50% of patients who underwent heart transplantation as a teenager were still alive 15 years later. This number is even higher for those who received heart transplantation as infants.[104]

Surgery is performed through a median sternotomy and involves removal of the recipient heart with residual atrial cuffs remaining. The atria are reanastomosed with the donor heart, and then the great arteries are connected.[185] Severing of the vagus nerve and the cervical and thoracic sympathetic cardiac nerves leaves the heart denervated.[160] The heart has an intrinsic control system, so it is not dependent on innervation for function. Cardiac impulse formation occurs because of spontaneous depolarization of the sinoatrial node. This results in a higher than normal resting heart rate and a decreased heart rate response.[160]

Primary control of increased heart rate with exercise occurs due to catecholamine release from the adrenal gland. Hormonal release takes several minutes to have an effect on heart rate and contractility. As a result, during the acute phase of rehabilitation it is generally advised that children perform several minutes of warm-up exercises before vigorous exercise. It also takes several minutes for the body to reduce the hormones to normal levels, so a cool-down period at the end of exercise is also advised. The resting heart rate is higher than usual in transplant recipients, and the peak heart rate is lower; both should be taken into account when transplant patients are exercising.[160] There is an ongoing debate on the most effective rehabilitation approach for children following heart transplantation. With evidence suggesting some level of reinervation,[160] some have suggested higher levels of exercise and possible interval training may be possible. The potential benefit of moderate or higher intensity exercise is unclear, and further research is needed.[160]

Antirejection treatment begins with triple drug immunosuppression with corticosteroids, a calcineurin inhibitor (e.g., cyclosporine or tacrolimus), and an antiproliferative agent (e.g., azathioprine or mycophenolate mofetil).[185] All serve to combat rejection of the donor heart. Rejection is an immune response to the donor heart. The resulting inflammation occurs through T-cell and humoral immune mechanism. Failure to control the inflammation can result in necrosis of the cardiac tissue and death. Rejection is the number one cause of death posttransplant.[4] Transplant recipients are often weaned from the use of steroids as soon as possible to minimize the detrimental effects of long-term steroid use.[4] Antirejection medicines can lead to bone loss, photosensitivity, thickening of the gums, muscle and bone weakness, headaches, increased potassium levels, nausea, and increased cholesterol levels.

Rejection is a concern for all children who receive heart transplantation. Signs and symptoms of rejection include: fever, malaise, poor appetite, weight gain, tachycardia, tachypnea, low urine output, complete heart block, pulmonary edema, and shock.[4,150] Symptoms associated with severe rejection have been observed in several adolescent transplant recipients after missing just one dose of immunosuppressive medicine.

Several complications from heart transplantation are common in children. Hypertension immediately posttransplant occurs frequently, and the cause may be multifactorial including persistent elevation in systemic vascular resistance, use of oversized donor organs, and corticosteroid treatment.[150] Other early posttransplant complications include impaired renal function due to nephrotoxic qualities of many of the immunosuppressive medications, infection due to immunosuppression, and severe muscular deconditioning due to pretransplant medical status.[150] Long-term complications include continued rejection with symptoms of weakness, fatigue, malaise, fever, and flulike symptoms. We have used the dyspnea index previously described to help patients know there may be a change in their cardiac status and they should call their cardiologists. A patient who has received heart transplantation can exercise and achieve normal endurance with a baseline dyspnea index of 1 breath to count out loud to 15. If he or she suddenly requires 2 breaths or more to count out loud to 15 he or she should contact his or her cardiologist. Other complications that can occur are: coronary allograft vasculopathy, chronic infections, continued renal dysfunction, hypertension, hyperlipemia, and development of posttransplant lymphoproliferative disease (PTLD). PTLD can present as a wide range of malignancies from benign tonsillar hyperplasia to life-threatening monoclonal lymphoma.[4,150] Therapists working with children with heart transplantation need to be aware of these potential complications as well as their signs and symptoms. Often therapists are the first to notice symptoms and bring this to the attention of the medical team. As more children survive successful initial cardiac transplant, the potential need for retransplantation increases. Availability of donors, long-term survival, and functional outcomes are factors that continue to be investigated.

FOREGROUND INFORMATION

MANAGEMENT FOLLOWING CARDIAC SURGERY

Most acute impairments after thoracic surgical procedures occur in the immediate or early postoperative period. Physical therapists play an important role in minimizing and helping to address these impairments. In this section management of pulmonary complications, pain, sedation, decreased mobility, and initiation of developmental care will be described. Considerations for physical therapy management following cardiac surgery are summarized in Box 28.1.

Pulmonary Management

One of the primary areas to be addressed after heart repair is the pulmonary status of the patient. Mechanical ventilation is common after open-heart surgery in the pediatric patient. Recent improvements in cardiopulmonary bypass, decreased operating time, and improved postoperative fluid management have allowed early extubation, often immediately after or within 4–6 hours of surgery.[206] This has led to decreased costs, early patient mobility, and fewer respiratory complications.

Following extubation, some patients are transitioned to noninvasive ventilation such as CPAP and BiPAP. Noninvasive ventilation has been shown to improve gas exchange, reduce work of breathing, and help to avoid intubation in children. It can be provided via a variety of interfaces including nasal prongs, nasal mask, or nasal mask, full facial mask, or helmet.

As well current noninvasive ventilators provide a wide range of settings.[206] In addition to CPAP and BiPAP, a nasal cannula may be used to deliver heated humidified high-flow nasal oxygen. High-flow oxygen delivery provides continuous positive airway pressure.[206] Inhaled nitric oxide can also be used with patients who have pulmonary hypertension postoperatively.

BOX 28.1 Considerations for Physical Therapist Management of Children with Congenital Cardiac Conditions

Postsurgical Management

Positioning and respiratory techniques (e.g., percussion, vibration, assisted cough) to mobilize secretions and increase aeration
Early mobilization including range of motion exercises and walking
Screening for neurologic impairments
Supporting the family to interact and care for their child
Facilitating age-appropriate activities and developmental play

Infancy and Early Childhood

Screening for and monitoring neurologic impairments
Screening and intervention for developmental and sensorimotor delays
Facilitating mutually enjoyable parent–child interactions
Assessing and educating on feeding difficulties and providing support as necessary
Encouraging the family to allow their child to self-limit activity and play, rather than parent-limited activity and play
Providing the family information to help them anticipate how the child's cardiac condition might influence development (e.g., crawling is often limited in infants with a cyanotic defect)

Childhood and Adolescence

Screening for and monitoring neurologic impairments
Assessing endurance as well as visual-perceptual, visual-motor, motor planning, and fine motor skills and adapting recommendations for physical activity including instruction and education as necessary
Establishing an exercise program to improve the child's endurance, strength, self-esteem, and to decrease parental anxiety
Supporting the child to engage in regular exercise including participation in desired recreational activities and addressing parental concerns

Although physical therapist intervention varies with the age of the child, the primary goals are to mobilize secretions, increase aeration, and increase general mobility (Fig. 28.12).

The child's position should be changed regularly to assist with effective ventilation and oxygenation. The full upright position is considered most beneficial and should be achieved as soon as possible. The supine position has been shown to cause diminished alveolar volume, functional residual capacity (FRC), and lung compliance; it thus interferes with the distribution of ventilation, respiratory muscle efficiency, and gas exchange; and promotes airway closure. Sidelying has been observed to be a better position than supine for improving oxygenation. In adults, oxygenation improved when the "good" lung was in the dependent position.[222] In children, however, the opposite was observed: namely, gas exchange improved with the good lung uppermost.[222] Sidelying with the best lung dependent may improve ventilation and perfusion matching but should be closely monitored for signs of distress or improvement.[222] Prone position has been associated with an improved ventilation and decreased work of breathing.[222] Positioning in prone may be beneficial in preventing respiratory difficulty in a child who is extubated.

Mucous transport is slowed after surgery, which can lead to atelectasis. Atelectasis also occurs secondary to an altered breathing pattern, prolonged positioning in supine, and possible diaphragmatic dysfunction in the early postoperative period.[222] Incentive spirometry is an effective tool for reducing the occurrence of atelectasis in the pediatric population. The primary emphasis with incentive spirometry or any other respiratory intervention should be prolonged slow inspiration to facilitate end-expiratory lung volume helping to decrease atelectasis.[206] Bubble blowing or blowing on a windmill can be used with young children (Fig. 28.13).[206] When performing these activities, children often take in a large inspiration before exhaling. Other respiratory techniques such as percussion and postural drainage, vibration, segmental expansion, and assisted cough techniques (Fig. 28.14) can be performed to mobilize secretions and increase aeration.[222]

Segmental lung expansion techniques may be performed to reduce postoperative complications and are used to

FIG. 28.12 Two examples of children 24 hours after open-heart surgery.

preferentially augment localized lung expansion. The goals are to increase and redistribute ventilation, improve gas exchange, aid in reexpansion of air spaces, mobilize the thoracic cage, and increase the strength, endurance, and efficiency of the respiratory muscles.[222]

Lung expansion techniques are performed by placing a hand over a particular segment and allowing it to move with the ventilator or respiratory cycle. Gentle pressure may be applied to the chest wall during exhalation at the end of the expiratory phase, just before the inspiratory phase. This facilitates airflow to the specific segment. When a specific lobe or segment has decreased aeration, this technique, used in conjunction with gentle sustained pressure on the opposite upper lobe, may increase aeration to the affected area.[222] This technique is particularly effective when the child is upset or does not tolerate percussion or other treatment techniques. It may decrease the respiratory rate and is especially useful with infants who cannot respond to the therapist's verbal cues for relaxation. We have used this technique with lung transplant recipients who are unable to cooperate or follow commands for deep breathing and coughing and found it effective in decreasing atelectasis and increasing oxygen saturation. Segmental expansion techniques performed before other respiratory techniques also may be beneficial.

FIG. 28.13 Child blowing bubbles 24 hours after open-heart surgery.

FIG. 28.14 Child receiving percussion after open-heart surgery.

Percussion may need to be performed to assist in removal of excess secretions. Percussion is defined as rhythmic clapping with cupped hands over the involved lung segment performed throughout the respiratory cycle, with the goal of mechanically dislodging pulmonary secretions.[222] Vibration also assists in mobilization of secretions. It is performed by creating a fine oscillating movement of the hand on the chest wall just before expiration and continuing until the beginning of inspiration.[222]

Both percussion and vibration techniques can be performed in conjunction with postural drainage. Optimal positions are described by Crane and are pictured in Frownfelter's text on chest physical therapy.[43] Positioning must be used with caution in the postoperative period. For example, the Trendelenburg position is often contraindicated after open-heart surgery. It is important to confirm with the nurse or the physician whether it is even suitable for the child to be flat in bed. Despite limitations, percussion and vibration can be performed in the positions available. It has been the authors' experience that children respond well to both percussion and vibration, even on the first postoperative day. Encouraging the child to tell you if the treatment hurts—because it should not be painful—often facilitates cooperation. It may also be helpful to coordinate the treatment with administration of pain medications. Percussion may be contraindicated when platelets are low, pulmonary artery pressures are too high, or the child becomes too agitated with treatment. Vibration can generally be safely used instead. Blood pressure and intracardiac pressures should be closely monitored throughout treatment because they are indicators of intolerance to treatment. The physician usually establishes parameters, set on an individual basis.

Massery described a counter rotation technique for altering respiratory rate in the neurologically impaired patient that has been safely used in children after open-heart surgery through a median sternotomy only.[222] The counter rotation technique has been used by the authors to slow the respiratory rate and increase expansion of the lateral segment. It generally relaxes children and increases their tidal volume. When the technique is used postoperatively following cardiac surgery, the therapist must take extreme caution to avoid disturbing chest tubes and other intravenous lines. This treatment is recommended only after intracardiac lines have been removed. The sternal incision has not been a problem: because it is stable, it does not undergo any mobilization during application of this technique. The counter rotation technique is performed with the child in sidelying and the therapist standing behind, near the child's buttocks. One hand is placed on the anterior iliac spine and the other hand is placed on the child's posterior shoulder. On inspiration the hand on the buttocks pulls down and posteriorly, while the hand on the shoulder gently pushes up and anteriorly. On expiration the therapist's hands and the child's body return to neutral. This is repeated several times in cycle with the child's breathing. It should be very relaxing and comfortable for the child.

The techniques described not only facilitate increased lung expansion but also mobilize secretions. Once mobilized, secretions act as an irritant in the airway when the child takes a deep breath, and a spontaneous cough usually occurs.[222] The child may require assistance to remove excess secretions, owing to

TABLE 28.2 FLACC Scale

	SCORING		
Categories	**0**	**1**	**2**
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant quivering chin, clenched jaw
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers; occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or being talked to; distractible	Difficult to console or comfort

Merkel S: The FLACC: A behavioral scale for scoring postoperative pain in young children. Pediatr Nurs 23:293-297, 1997. Copyright 1997 by Jannetti Company, University of Michigan Medical Center.

lack of cooperation or to inability to cooperate secondary to age. This may be accomplished by coughing or airway suctioning.

Pain and Sedation Management

Pain management and level of sedation are extremely important for mobilization of children following cardiac surgery. Most institutions that perform cardiac surgery on children have pain management teams that assist the surgical team in monitoring and managing the child's postoperative pain because uncontrolled pain can be detrimental to the child's recovery. Monitoring and assessment of pain and level of sedation are critical components to an effective pain and sedation management regimen. The FLACC scale is often used to determine if the child is in pain (Table 28.2).

Opioids such as morphine and fentanyl are the primary medications employed for effective analgesia or pain relief. As with most medications they carry adverse side effects including respiratory depression and nausea and vomiting that must be monitored and balanced with appropriate pain relief.[175] In addition to pain relief, sedation management must also be considered. Sedation is often required to increase compliance and tolerance of treatment. In addition, it may be required to allow effective ventilation or support of cardiac function. Goals for sedation goals vary from mild calming to near anesthesia.[175] Several medications are used to achieve sedation; the two most common are dexmedetomidine and midazolam. Both medications provide appropriate levels of sedation without respiratory depression, though midazolam is not as well tolerated in the cardiac population.[175] Other techniques used to manage postoperative pain include regional anesthetic techniques and patient-controlled analgesia.[175]

Early Mobilization

Early mobilization and ambulation after surgery reduce both pulmonary and circulatory complications as well as demonstrate increases in functional outcomes and quality of life.[90,101,226] Early mobilization and physical therapy involvement in the adult ICU setting have been shown to have beneficial effects on muscle strength, physical function, health-related quality of life, ventilator-free days, and lengths of stay in the ICU and hospital.[101] Studies in the pediatric population are more limited but have shown similar results.[91,226] Postoperative immobility can lead to a variety of problems, including reduced ventilation and perfusion distribution, shallow breathing, fever, retention of secretions, fluid shifts, decreased muscle strength, and generalized discomfort from immobility.[219,222] The following section reviews the importance of early mobilization and positioning and how to safely initiate both.

FIG. 28.15 A child walking 1 day after open-heart surgery.

Range-of-motion (ROM) exercises should begin as soon as possible. Initially it may not be possible to attain full ROM because of discomfort or intravenous or arterial lines, but movement helps to mobilize the patient. ROM exercises are extremely important for the child with a thoracotomy incision because the incision tends to produce more guarding than is produced by a median sternotomy. Passive to active-assisted shoulder ROM to 90 degrees of flexion is usually tolerable. Discomfort often occurs when the arm is returned to a neutral position. The therapist may apply gentle resistance to the arm as the child attempts to return the arm to a neutral position because contraction of the arm muscles tends to minimize discomfort.

At our center, children are mobilized including ambulation as soon as atrial lines and groin lines are removed. Intubation with mechanical ventilation is not considered a reason not to initiate physical therapy intervention, though it may limit mobility. Children often ambulate for the first time with any or all of the following: central venous pressure line, peripheral intravenous line, arterial line, chest tubes, temporary pacemakers, and oxygen (Fig. 28.15). The first walk is often only for 5 to 10 feet and may be difficult for the child. Anxiety often plays as big role in the perceived difficulty as does the discomfort. It may be beneficial for the child to receive pain medication before the first walk. Children are often anxious, so the benefits of early

TABLE 28.3 Potential Limitations in Early Motor Development in Children With Congenital Heart Conditions

Age	Age-Expected Skills	Potential Limitations
0–3 months	Prone: lift head to 45 degrees, turn head to clear airway	Prone: lack of time and stimulation in prone
	Supine: reciprocal kicking, chin tuck, random upper extremity movement	Supine: prolonged period in supine, neck in hyperextension, arms restrained for IVs
	Sitting: head control 2–5 seconds, hands to surface for support	Sitting: limited time in upright/ being held and carried; arms not placed in flexion or weight-bearing position
	Standing: bear weight on lower extremities, hips not in line with trunk	Standing: limited to no time in supported standing
3–6 months	Prone: come up on extended upper extremities, arms beginning to be under shoulders	Prone: not encouraged to push with arms onto hands; lack of trunk strength due to not be carried
	Supine: bringing hands to mouth; starting to bring feet and knees to hands, rolling supine to prone	Supine: anterior incisions and prolonged supine weakens abdominal muscles so may have difficulty bringing hands to midline; feet to face and hands not encouraged; reaching across midline toward stimulation to roll is not encouraged or done
	Sitting: prop by 3–4 months with head steady, approaching independent by 6 months	Sitting: often not able to due to lack of opportunity, too much support, not carried on caregiver's hip
	Standing: in supported standing stands with hips in line with trunk	Standing: IV lines in groin may limit early lower extremity weight bearing; lack of time in prone limits time to strengthen hip extension against gravity
6–12 months	Prone: pivoting, coming up to 4-point, rocking in 4-point, creeping; rolling in and out of this position	Prone: Lack of prone time, upper extremity weight bearing and core stability; crawling and creeping may be too energy consuming, will move by rolling or scooting on back just not in 4-point, may desaturate if pushed
	Supine: fully function in and out of position	Supine: may have difficulty with segmental rolling due to lack of core strength
	Sitting: independent getting in and out of sitting, no support needed	Sitting: not willing to go into flexion to transition in and out of sitting to stand
	Standing: pulling to stand at surface, cruising, independent standing and early stepping	Standing: limited use of uppers and limited above head use of arms; toys brought to child instead of weight shifting and rotating to get toys
1–2 years	Independent walking progressing to low guard upper extremity position, running, throwing a ball underhand, weight shift to kick a ball	Delay in milestones, weak core and extremity proximal strength, lacks experience in standing, poor standing balance and trunk rotation
2–3 years	Climbing over objects and onto furniture; mature walking and running with arms down and reciprocal swing of arms; mature gait on stairs with reciprocal gait with one hand held; jumping with both feet off the ground; walking on heels and toes; kicking with some accuracy; throwing a ball overhand	Upper body weakness, lacks core strength, weakness of hip extensors and posture muscles; poor standing balance reactions; lack of experience with activity

ambulation should be explained to them with emphasis on the problems that can occur by remaining in bed.

Potential Effects of Cardiac Surgery on Early Motor Development

The potential effects of cardiac surgery on early motor development are summarized in Table 28.3. The infant who undergoes surgery within the first few days after birth experiences immediate disruption of all aspects of typical newborn life. The infant is often sedated, restrained, and intubated, all of which interfere with being held, bundled, and fed. The physical therapist provides the family information about sensory-motor activities the infant is unable to experience and instruction in ways to compensate for this deprivation. Encouraging parents, as well as nursing staff, to hold their child as soon as possible is recommended. Holding the infant prone on the parent's chest is beneficial to early development and bonding. The fact that their child is born with a congenital anomaly may impede the attachment process.[123] The therapist promotes parent-infant interaction by providing parents suggestions for engaging and calming their baby as well as positioning to minimize postoperative complications. We encourage therapists to involve parents in treatment as soon as possible.

Toddlers who have cardiac surgery often recover very quickly with little impairment. Anxiety over being left alone during the hospitalization may be the biggest problem interfering with function in this age group.[123] The child may feel abandoned and may react by becoming passive and apathetic or, conversely, by becoming aggressive. These behaviors are more commonly observed in the child who is in the hospital for the first time, such as the child with an ASD.

Toddlers are often limited more by restrictions imposed by their parents than by their own physical limitations.[40,123] Activity guidelines should be reviewed with parents on an ongoing basis; showing them by example may be even more helpful. Although it is beneficial to explain to the parents ahead of time what their child will experience, it may be helpful to wait to tell the toddler what is happening as it is happening. Connolly and colleagues evaluated children who underwent cardiac surgery at 5 to 12 years of age both preoperatively and postoperatively for posttraumatic stress disorder (PTSD) symptoms.[41] They found PTSD symptoms in 23% of the children, and 12% met criteria for PTSD. They also observed an increased number of symptoms correlated with an intensive care unit stay longer than 48 hours. The therapist can add "fun" to the postoperative activities to make it less threatening and ultimately more beneficial.

Adolescents who have cardiac surgery may need to be encouraged to move and may need to be assisted to become active. The parents are often more reluctant than the adolescent about early mobilization, including ambulation. They should be reassured that it is beneficial for their child to move as soon as possible. Adolescents may choose to assert their independence and try to do everything for themselves, or they may choose to become totally dependent on their parents and hospital staff. Whichever situation occurs, young people benefit from early education about how to move and what they should be doing. This helps them to realize what is expected of them. They should be informed of what they need to do and should not be given a choice when the task is not optional.[215]

Medical Complications

Several medical complications can affect postoperative function. Secondary to phrenic nerve palsy, some children may have a paralyzed diaphragm after surgery that affects their early postoperative course, as well as their long-term respiratory status and endurance.[206] Infants have horizontal ribs and lack the normal bucket handle movement, relying primarily on use of the diaphragm for respiration. Paralysis of the diaphragm by unilateral or bilateral phrenic nerve palsy can cause further respiratory problems, including difficulty in weaning from the ventilator.[206] Noninvasive positive-pressure ventilation has been successfully used for bilateral diaphragm paralysis until diaphragm function has returned.[109] In a study by Ross Russell and associates, phrenic nerve palsy was observed in as many as 20% of infants who underwent cardiac surgery, mechanical ventilation was at least an average of 72 hours in this group, and the risk of death before discharge from the hospital was greater than 10%.[188] The incidence was greater for those younger than 18 months of age, but two thirds of those with phrenic nerve palsy had fully recovered by 3 months postoperatively.

Prolonged mechanical ventilation is required for some children, especially infants, after surgery for congenital heart defects. Mechanical ventilation has been associated with nosocomial pneumonia, higher surgical risk, increased postoperative fluid, and low cardiac output.[201] Instances of children requiring a tracheostomy and/or gastrostomy after congenital heart surgery have been reported. Performing these procedures sooner may allow for earlier discharge from the hospital. The incidence of tracheostomy after surgery is fairly low at 1% or less,[186] but Kelleher and colleagues reported that 28% of their patients undergoing a Norwood operation required nasogastric tubes for feeding or placement of a gastrostomy tube at discharge from the hospital.[102] Guillemaud and associates found that at least 3% of all children with cardiac defects who underwent surgery had some type of airway problem, the most common being vocal cord paralysis.[79] This should be taken into account when an infant is having difficulty coming off the ventilator or when treating an infant with difficulty with oral feedings.

Neurologic Implications and Complications

Postoperative neurologic impairments were long thought to be largely due to prolonged surgical time, usually related to length of hypothermic arrest, low cardiac output, or arrhythmias after surgery.[58,224] Research on infants with congenital heart defects, however, has indicated that preoperatively brain maturation is delayed,[118] cerebral blood flow is diminished,[119] brain volumes are smaller,[121] and there is some incidence of mild ischemic lesions associated with periventricular leukomalacia.[119,130] Miller, et al.[149] observed that newborns with CHD had widespread brain abnormalities before cardiac surgery. Lynch et al.[126] studied neonates with HLHS and observed that earlier Norwood palliation may decrease acquired white matter injury. Neurodevelopment has also been noted to be affected postoperatively in children with repaired congenital heart defects possibly for several reasons, including how a child is rewarmed after surgery,[191] genetic factors,[68,232] seizures,[66] type of circulatory arrest,[20] and length of stay after surgery.[157] Seizures during the initial postoperative period are associated with a significant increase in abnormal neuromuscular findings. The mean Mental Developmental Index score on the Bayley Scales of Infant Development II was significantly lower for children with frontal lobe seizures compared to children with seizures in other areas of the brain.[66]

Hemodynamic instability and coagulation disturbances are risk factors for postoperative neurologic problems in infants as well. Thirty-five percent of premature infants weighing less than 2 kg who had open-heart surgery developed neurologic complications.[187] Neurologic consequences may be the result of an air embolus, a prolonged hypotensive period,[215] or complications of long-term cyanosis[5] as well as cerebral hypoxic-ischemic conditions.[87] Cerebral development may be deterred due to aortic-to-pulmonary collaterals that may develop in single-ventricle children and that can result in cerebral blood flow diminishing.[59] Choreoathetosis has been observed in some children after they have been on cardiopulmonary bypass. When a basal ganglia lesion is also seen, the prognosis is poor.[89] It is encouraging to note that of almost 700 children who underwent a Fontan operation, fewer than 3% had a stroke.[54]

In an attempt to reduce the risk of neurologic injury during surgery, some centers are using continuous regional cerebral perfusion, especially during aortic arch reconstruction.[30] Many centers are using near-infrared spectroscopy to monitor cerebral oxygenation in the perioperative period, but in a review of the literature on this topic, Hirsch and colleagues found little substantial evidence to support that the use of perioperative near-infrared spectroscopy has an impact on neurologic outcomes.[85] Multiple cardiac surgeries, longer hospital stays, poorer linear growth, and tube feeding were associated with worse neurologic outcomes in 131 children with CHD but without a known genetic defect.[153] Low regional cerebral oxygen saturation in the first 48 hours after the Norwood procedure was significantly correlated with an adverse outcome.[166]

Physical therapists are encouraged to seek opportunities to be involved in research to determine forms of cardiac monitoring that are associated with favorable postoperative neurologic outcomes. The child who has sustained a neurologic insult requires both early intervention and physical therapy following hospital discharge. A child with severe extensor tone may benefit from inhibitive casts on the lower extremities and hand splints to decrease the effects of increased tone and to maintain ROM. Parent education concerning the impact of a neurologic insult, including information on handling and positioning the child with increased muscle tone, appropriate stimulation, use of adaptive equipment, and long-term follow-up, should begin as soon as the diagnosis is confirmed. Box 28.2 summarizes characteristics of children with congenital cardiac conditions who are at highest risk for neurodevelopmental impairment

BOX 28.2 Children at Highest Risk for Neurodevelopmental Impairments

1. Neonates or infants requiring open-heart surgery
2. Children with other cyanotic heart lesion not requiring infant heart surgery
3. Congenital heart disease combined with any of the following:
   a. Prematurity < 37 weeks
   b. Developmental delay
   c. Suspected genetic abnormality or syndrome associated with developmental delay
   d. History of mechanical support (ECMO or VAD)
   e. Heart transplantation
   f. CPR
   g. Hospital stay > 2 weeks after surgery
   h. Perioperative seizures
   i. Abnormal findings on brain imaging or small head circumference

MANAGEMENT OF CHILDREN WITH CHRONIC ACTIVITY LIMITATIONS

Chronic Disabilities and Activity Limitations

Various disabilities and activity limitations occur as a result of primary impairments incurred by children with congenital heart defects (see Table 28.1). Considerations for physical therapy management are summarized in Box 28.1. The disabling process may start very early secondary to poor attachment between parent and infant.[75] Infants who had cardiac surgery showed less positive affect and engagement than typical babies, making it even more stressful for mothers who are already distressed.[65] Poor attachment can lead to poor social development.

The overprotection and excessive activity restrictions imposed by some parents may compound activity limitations. Parents have shared that they were afraid to permit physical activity in their child with CHD.[78] An important role of the physical therapist is to provide the family guidance in identifying physical activities that the child enjoys and has the physiologic capacity to safely perform. Maternal perceptions of their children's disease severity were a stronger predictor of emotional adjustment than was disease severity.[49] Emotional maladjustment may contribute to the poor self-esteem that is often noted in children with congenital heart defects. Limitations resulting from decreased activity, delayed development, poor self-esteem, overprotection by parents, and physical illness may lead to poor peer interactions and social participation. Concerns should be shared with parents and the child as early as possible to limit the potential effects on development.

Infancy

Recent research has been important in establishing the preoperative status of the brain, its development, and subsequent neurologic impairment in the infant with a congenital heart defect. Licht and associates assessed infants preoperatively with hypoplastic left heart syndrome and transposition of the great arteries.[118] Infants were found to have head circumferences that were smaller by a whole standard deviation, as well as brain development that lagged a full month behind their gestational age, thus indicating that in utero brain development is affected by the cardiac defect. This group of researchers also found that preoperative cerebral blood is diminished, which was sometimes associated with periventricular leukomalacia.[119] Thus children with congenital heart defects start off at a disadvantage neurologically and developmentally.

Infants with dextro-transposition of the great arteries who underwent a preoperative balloon atrial septostomy had an increased rate of embolic stroke compared with those who did not undergo balloon atrial septostomy.[113,157] Surveillance for this risk should be conducted when these infants are seen in the immediate postoperative period, or even later.

In children with CHD, several other contributing factors can lead to impairment and activity limitations in infancy. Common problems include poor feeding, poor growth, and developmental lag.[153] Owen et al.[162] found that infants with CHD showed poor behavioral state regulation leading them to become easily overwhelmed. This can add to parental anxiety. Parents must constantly watch for signs and symptoms of congestive heart failure in their infant at rest and while feeding. These signs include the onset of rapid breathing, changes in behavior, edema, excessive sweating, fatigue, vomiting, and poor feeding.[40] Parental frustration and stress can affect early attachment to the infant. It has been observed during the first year of life that securely attached infants showed greater improvements in health than did insecurely attached infants.[74] Gardner and associates observed infants with cardiac defects to be consistently less engaging with their mothers when compared with infants without defects.[65,67]

When compared with healthy infants and infants with cystic fibrosis, infants with CHD were the least attached to their mothers, and their parents were the most stressed.[75] Normal attachment may be difficult, particularly with the very sick infant who is frequently hospitalized. The health care team should begin working with the parents as early as possible on how they can interact with their infant to facilitate attachment and avoid overstimulating their infant. Positive gains were noted in feeding practices, parental anxiety, and worry as well as infant mental state when interventions were done to bolster mother–infant interaction, therapy, and parent skills training with infants with severe CHD and their mothers.[145]

It is not uncommon for infants with CHD to be poor feeders, which further increases parental stress. Infants with corrected cyanotic heart defects had a significantly delayed first feed when compared with those infants who had undergone correction for an acyanotic defect. They also had a longer duration from first feed to discharge.[94] The delay in being able to feed their infant followed by possible difficulty with feeding may add stress to the parents.

Many of the major centers that perform surgical repair for complex cardiac defects treat children from all over the world. It is important to be aware of the family's diet and foods that are available in their country, the size of the child's parents, and the issues surrounding the surgery when a child's nutritional state is evaluated. Vaidyanathan and colleagues studied the nutritional status of children in South India after surgical repair for congenital heart defects and found that persistent malnutrition was predicted by birth weight and initial nutritional status as well as by parental anthropometry.[214]

Infants expend most of their energy during eating. In normal infants, decreased ventilation is observed during feeding, creating a decrease in the partial pressure of oxygen and an increase

in the partial pressure of carbon dioxide.[137,138] This decrease in ventilation may seriously compromise the child with CHD and is compounded by the increase in metabolic rate. Not only does the child not eat well, but he or she also requires more calories to thrive.[71] When studying infants with CHD after surgery, Nydegger and colleagues found that an increased resting energy expenditure before surgery persisted in infants repaired after 10 days of life; by 6 months of age, it was comparable to that in infants without CHD.[159] Abnormalities in mesenteric perfusion are documented in several studies, with mesenteric hypoperfusion noted after the Norwood operation.[47,82] This may lead to feeding intolerance in addition to difficulty in getting enough calories into the child's body.

Watching their child failing to thrive can be devastating to parents and increase their anxiety about feeding their child and trying to encourage adequate caloric intake.[71] The prolonged time the child needs to feed can be frustrating to parents and make them feel inadequate.[32,123] Dysphagia has been observed in 24% of infants with CHD who were studied postoperatively with 63% of those infants exhibiting aspiration on a videofluoroscopic swallow study.[228] If alternative feeding methods are used, such as nasogastric or gastrostomy tube feedings, parents should be educated not only on how to administer the feeding but also on how to hold and nurture their child during the feeding.[123] It may be helpful to tell parents that providing time for nonstressful interaction may improve the parent-infant attachment and ultimately may improve the health of their infant. It is helpful to inform parents that the overall time that supplemental feedings are necessary varies with each child. Some parents have stated that they were able to remove supplemental feedings within 1 week of leaving the hospital; others have stated that it took months for their child to take enough by mouth to be able to discontinue supplemental feedings. Many parents have stated to these authors that their infant ate better at home, where it was possible to eat on demand and to have a more routine day.

Physical therapy assessment is sometimes indicated to observe the infant feeding and parental interaction. Other problems unrelated to poor endurance may be exhibited by the infant with CHD. If oral-motor dysfunction exists, it should be addressed with parents as soon as possible. Some parents need assistance in how best to handle and support their child during feeding. It can be beneficial for parents to observe that their child does not feed well for anyone.

Poor growth is closely associated with poor feeding. It has been observed that infants with cyanotic heart disease have poor growth in height and weight, whereas infants with acyanotic heart disease, specifically those with a large left-to-right shunt, are severely underweight secondary to the marked increase in metabolism.[71] Growth improves after surgery, but the child may not achieve typical parameters. This lack of catch-up growth is especially remarkable in children with cyanotic defects with a right-to-left shunt.[71,183] Poor growth in height was associated with worse neurodevelopmental outcomes in infants with single ventricles.[174]

Functional and activity limitations, especially delayed achievement of basic motor skills, can be observed in the infant with cardiac disease. Schultz and associates assessed the development of infants with CHD who had undergone repair before 6 months of age and compared them with their twin siblings without CHD.[197] They found that infants with CHD had lower scores on the Psychomotor Developmental Index of the Bayley Scales of Infant Development II compared with the Mental Developmental Index and both indices were lower than those of their siblings without CHD. Infants with a univentricular heart were evaluated using the Alberta Infant Motor Scale and scored significantly lower than healthy infants especially in the prone and standing subscales; the infants with hypoplastic left heart syndrome were delayed in all subsets.[171] Many of the infants did not walk until almost 18 months. This is not that surprising considering most of these infants spent several months of their life in an ICU and experienced some level of hypoxia during this developing period.

Decreased nutrition and cardiac function may leave the infant too weak to expend the energy required for typical motor activity.[123] Some children with cyanotic heart defects preferentially scoot around on their buttocks and, even after extensive intervention at home, do not crawl. They often go on to walking without ever crawling,[99] probably because of the increased energy expenditure associated with use of both upper and lower extremities in crawling. Children with cyanotic heart defects tend to have an internal mechanism that permits them to do only what they are physically capable of doing, given their oxygen saturation.[40] They often rest without cueing and can rarely be pushed beyond what they are willing to do. Intervention may or may not improve the child's functional abilities; however, it may help relieve parental anxiety. The focus is on quality and efficiency of movement for exploration and play, instead of developmental delay. Therapists are encouraged to collaborate with parents to address concerns regarding physical activity and identify motor activities that promote positive parent–child interactions and can be incorporated into the family's daily routines, rather than one block of time.

The presence of congestive heart failure is associated with mental and motor developmental delay. Infants with congestive heart failure scored less well than expected on the Bayley Scales of Infant Development I as early as 2 months of age.[3] Haneda and associates observed a significant decrease in developmental quotient on the Gesell Developmental Schedules in infants and children who had circulatory arrest time greater than 50 minutes.[81] This information is useful when working with parents to help them understand that their child is demonstrating typical developmental skills for a child with CHD. This does not mean that intervention is not indicated. Resolution of neuromotor impairments by 15 months of age was reported for infants with CHD who had abnormal findings at 4–6 months of age and subsequently received physical therapy.[37] Therapists are encouraged to collaborate with families to promote motor development. If impairments in body functions and structures and activity limitations are minimized, the effects of reparative surgery may be dramatic.

Neurologic impairment and activity limitations may also occur from physiologic factors related to the surgical repair. Discrepancy exists regarding the effects of deep hypothermia and circulatory arrest on the psychomotor and intellectual development of infants.[26,80,146,187,200] Messmer and associates observed no delay in psychomotor and intellectual development in infants after deep hypothermia.[146] Kaltman and associates evaluated neurodevelopmental outcome in infants after an early repair for a VSD.[100] Mean mental and psychomotor indices were within the normal range for children who did not have a suspected or confirmed genetic syndrome. In another study, infants did not have neurologic impairments after surgery but did demonstrate mild developmental delays, most pronounced in infants with cyanotic heart defects.[80] Bellinger and associates

observed that infants who had total circulatory arrest during the arterial switch operation scored lower on the Bayley Scales of Infant Development at 1 year of age than infants who had low-flow bypass.[21] These children were also observed to have expressive language difficulties at 2.5 years of age and exhibited more behavior problems.[21]

Deep hypothermic circulatory arrest greater than 40 minutes correlated with a greater occurrence of seizures postoperatively.[68] Clancy and associates observed seizures postoperatively in greater than 11% of infants in the immediate postoperative period.[39] All of the infants had undergone cardiopulmonary bypass during surgery.[39] The presence of a genetic syndrome was a strong predictor of lower scores on the Bayley Scales of Infant Development.[156] Gessler and associates performed neurologic examinations on infants preoperatively and postoperatively and reported mild asymmetries in muscle tone in one third of the infants preoperatively and in almost two thirds postoperatively.[69] They also found that the inflammatory response to cardiopulmonary bypass has an adverse effect on neuromotor outcome. Research by Sahu and associates indicates that weaning the infant off bypass at lower temperatures lowers the risk for postoperative neurophysiologic dysfunction more than weaning at slightly higher temperatures.[191] Parental report of their children's health-related quality of life at 1 year and 4 years after open-heart surgery was lower in the physical and cognitive dimensions especially if there was an underlying genetic defect or the infant was tube fed.[225]

There is a need for research to identify factors that are predictive of risk for neurologic impairments in young children after cardiac surgery.[211] In light of conflicting evidence, therapists should realize there is some uncertainty. Parents should be advised that their child might take longer than usual to accomplish developmental milestones. In a comprehensive review of the literature from the mid 1970s to the late 1990s, the overall long-term development of children after repair or palliation for CHD as infants was within the expected range for most standardized tests.[131]

Early Childhood

The young child (3–5 years of age) with chronic disabilities related to CHD has spent a lot of time in a medical environment. This familiarity with the environment may help to alleviate some of the child's and the parents' anxieties when surgery is imminent. Parental anxieties can be exacerbated during this period, however, as they begin to realize the impact that their child's cardiac disease has on growth and development. The child's symptoms could be worsening, and another surgery may soon be needed. Parent responses and interactions during this period are important; it should be recognized that parents already have the tendency to be overprotective of their child, and this may increase during the preschool period.

The emotional adjustment of the child has been observed to be affected by the mother's perception of the severity of the child's illness more than by its actual severity.[49] Among children with repaired CHD, increased parental stress was associated with behavior problems at 4 years of age.[218] In children with acyanotic heart defects, lower intelligence quotient was associated with poorer adjustment, greater dependence, and greater maternal pampering and anxiety.[173] These findings suggest that if a mother perceives her child's health challenges to be more severe than they are and limits the child accordingly, the child's physical development and social participation may be affected. If this is a concern, we recommend that the therapist and parents discuss activities the child is capable of performing and observe whether the child self-limits physical activity when necessary.

Atallah and associates evaluated the mental and psychomotor developmental indices of children after the Norwood procedure and compared the traditional modified Blalock-Taussig shunt era with the newer right ventricle–to–pulmonary artery shunt era.[7] The mental development index did not differ between the two groups. Children who received the right ventricle–to–pulmonary artery shunt, however, had a psychomotor development index and more frequent sensorineural hearing loss.

Children with CHD have been reported to have developmental delays, especially those children with cyanotic disease.[21,56,135,173] Children with cyanosis scored significantly lower than children who were acyanotic and children without a cardiac condition on all subscales of the Gesell Developmental Schedules[81] and on Stanford-Binet and Cattell intelligence tests.[173] Children with cyanotic heart defects were observed to sit and walk later than children with acyanotic heart defects and children with typical development and were slower in speaking phrases than were children without disabilities.[56,173,202] Curtailment of physical activity in the child with severe cardiac dysfunction interferes with manipulation of objects, which facilitates sensorimotor processes.[173,202] When toddlers at 24 months of age (who had undergone open-heart surgery before 3 months of age) were assessed using the Peabody Developmental Motor Scale, gross motor quotients improved but fine motor quotients decreased significantly. All scores were less than average; fine motor quotients were greater than 1 standard deviation below the mean.[192] Despite concerns about the impact of limitations in amount of movement and manipulation of objects, intelligence and behavior are often within age expectations.[73] Activities of daily living are another area of development to consider.[120]

Educating parents about what their child is able to do is as important as teaching precautions. Children made significant improvement in gross motor advances during their second year of life when parental warmth was combined with a decrease in parental restrictions. It was also observed that children with CHD performed better on intelligence tests when their parents attempted to accelerate their children's development.[173] Parents should be informed that children with cardiac disease, particularly cyanotic disease, limit their own activity and stop and rest when needed.[40] Physical therapists can support the family in becoming more comfortable encouraging the child to initiate and sustain play within the limits of physical endurance. Children with Down syndrome and a cardiac defect were observed to score higher on developmental tests and achieve feeding milestones earlier if parents implemented therapy recommendations.[44]

Childhood

Cognitive function was not found to be affected in children who underwent an ASD repair between ages 3 and 17 years while on cardiopulmonary bypass.[204] However, children may be at risk for learning problems and academic issues independent of surgical closure or transcatheter closure.[194] This is an important finding because it has long been believed that this was a primary factor in neurologic problems after surgery for congenital heart defects. Children with an ASD, however, do not have the

same associated risk factors, such as unstable hemodynamics, chronic hypoxemia, and metabolic acidosis, that children with other congenital heart defects have, particularly those with cyanotic heart defects. When comparing children who had an ASD closed surgically (using cardiac bypass) and children who had interventional closure by cardiac catheterization, Visconti and associates found that scores on the Wechsler Intelligence Scale for Children were significantly lower in the surgical closure group.[217] This was largely due to impairments in visual-motor and visual-spatial functions. Children who had interventional closure by cardiac catheterization, however, had significantly lower scores for sustained attention.

Bellinger and associates compared development and neurologic status of children who received hypothermic circulatory arrest during surgery compared with children who received low-flow cardiopulmonary bypass.[22] The two groups did not differ in IQ or overall neurologic status, but both groups had scores below age expectations for visual-spatial and visual-motor integration skills. Children with hypothermic circulatory arrest had lower scores on balance, nonlocomotor ability, and manual dexterity and more difficulty with speech, particularly with imitating oral movements and speech sounds. Bellinger and associates confirmed visual-perceptual motor deficits in another group of children who had undergone cardiac surgical repair as infants.[19] The findings were not associated with operative methods, but nevertheless the literature supports that all children undergoing surgical repair for a cardiac defect should be considered at risk for neurodevelopmental problems, especially visual-perceptual problems. Mahle and associates performed a similar study but did not find differences in verbal or performance IQ regardless of whether or not the child underwent cardiac bypass.[129] Along with congenital heart defects and subsequent surgery, children are at risk for lower IQ scores if they have other defects or a lower socioeconomic status.[60] Physical and psychosocial functioning were influenced negatively by lower family income.[144] Special attention should be given to children with congenital heart defects and a lower socioeconomic status.

School adjustment and peer interaction have been observed to be altered in children with CHD. In a study by Youssef, school absenteeism was high and proportionate to the severity of disability.[229] It has been observed that a child's adjustment to school is affected more by strain on the family than by the child's physical limitations related to the CHD.[34] Teachers have noted that children with CHD had more school problems; especially boys. Children with more behavior problems had lower self-esteem and more depression.[229] Some of the inability to focus and sustain attention on a task may be related to the surgery, the cardiac defect in and of itself, and frustration with the difficulty associated with visual-motor skills and completing fine motor tasks.[19,105] After surgical intervention, some of the behavioral problems may be alleviated; both missing school and diminished activity level should improve postoperatively.[122] Children may need rehabilitation after surgical repair, however, to learn how much they are capable of doing, to address limitations in visual-perceptual and fine motor tasks, and to help them manage activity limitations or inability to perform a task. This is critical due to the association between behavioral abnormalities and motor problems in children with CHD.[117]

Surgery to correct a cyanotic defect has a positive impact on the child's development. Improvement in IQ following surgery has been reported[122,161] and intellectual development was found to be essentially normal in children after the Fontan operation.[213] Mahle and associates observed, however, that school-age children with hypoplastic left heart syndrome who had a seizure before their initial surgery scored lower on all IQ subsets.[132] Children with hypoplastic left heart syndrome were observed to have reduced exercise tolerance and more frequent education and behavioral concerns.[45] Self-confidence, social confidence, and general adjustment have been reported to improve after surgery.[122] Significant improvement in self-perception was observed in children after they had their heart defect repaired.[227] To the extent decreased experiences are a factor in developmental delay, a child whose activity is no longer limited by a cardiac defect should demonstrate an increased rate of development.

Parental overprotectiveness can continue to prove more limiting to a child's development than the defect itself. Parents were found to underestimate their child's exercise tolerance in 80% of the cases studied by Casey and associates.[33] Parents were also found to rate their child lower cognitively than the child scored on standardized neurologic testing administered by a professional.[129] Parental restriction generally begins with the advice of the physician and proceeds from there,[40,108] but parent perception of the physician's advice can be unclear. Longmuir and McCrindle evaluated the physical activity restrictions of children after the Fontan operation.[124] Twenty percent of children were being unnecessarily restricted in physical exertion by their parents. Yet only 40% of parents knew that their child should not participate in competitive sports, and 50% of parents did not understand that their child had body contact restrictions as a result taking anticoagulation medication.

Social and emotional maladjustment in children with cardiac disease can be due to maternal maladjustment and guilt.[108] Parental stress has been found to be correlated with IQ scores and with receptive language abilities, behavior scores, and socialization skills.[133] Psychosocial or family therapy interventions by professionals are sometimes recommended to facilitate positive parent–child interactions. Some improvement in maternal interaction and attitude was noted after surgical correction of the child's cardiac defect.[161] Interestingly, a study by Laane and associates found that children with congenital heart defects reported a higher quality of life than healthy children.[111] It was also observed that parents of children with hypoplastic left heart syndrome described their children's health, physical ability, and school performance as average or above.[132] When compared with healthy children, children with repaired pulmonary atresia had an overall equal quality of life.[55] It is important for therapists to keep these findings in mind when interacting with children with congenital heart defects and their families.

Adolescence

Adolescents who have CHD and physical limitations may have feelings of anxiety and impulsiveness.[110,154] Early professional intervention to assist the parents and child to cope best with the child's physical limitations may be helpful. It is also important to continue to monitor adolescents with CHD who underwent surgery as an infant. Studies are now finding diminished white matter, which may contribute to cognitive issues as well as decreased cortical grey matter.[181,220] Executive functions, perceptual reasoning, memory, visual perception, and visuomotor integration were found to be lower in adolescents with repaired CHD when compared to peers without CHD.[196, 220]

A delay in the onset of puberty may further complicate social development and participation of adolescents with CHD. Body structure of adolescents with CHD was found to be different

from adolescents with typical development.[6] Height and weight were significantly reduced in adolescents with CHD. Head, neck, and shoulder measurements were similar to those of healthy adolescents, but the thorax, trunk, pelvis, and lower extremities were significantly smaller. The anterior-posterior diameter of the pelvis was so reduced that it appeared almost flat. Physical differences of this magnitude can contribute to adolescents with CHD feeling different and low self-esteem.

Participation in physical activities, including guidelines on how to participate, may improve peer interaction and ultimately self-esteem of adolescents with CHD. Children who participated in an exercise program were observed to have improvement in their self-esteem as well as in their strength. Parents were found to be less restrictive and had less anxiety about their child after a formal exercise program.[52]

Exercise prescription for children with CHD should account for the type of cardiac defect and surgical intervention, as well as possible alterations in the child's response to exercise. The American Heart Association has published an extensive review of exercise testing in children, including recommendations for children with congenital heart defects.[96] Exercise testing performed on children 5 to 18 years after their operation for a Fontan revealed significantly lower maximal workload, maximal oxygen uptake, and maximal heart rate compared with peers without CHD. Children post Fontan surgery were also observed to have less efficient oxygen uptake during submaximal exercise.[179] Children post Fontan surgery who had a persistent right-to-left shunt were found to have decreased oxygen saturation levels during exercise.[207] This needs to be taken into account when any kind of therapy is provided to children who have a history of the Fontan procedure.

Children who participated in cardiac rehabilitation programs have made significant and beneficial changes in hemodynamics and improvement in exercise endurance and tolerance.[12,15,72,106,139,165,189] Following physical training, adolescents with CHD had near typical activity levels.[72] Children tested 10 years after an arterial switch procedure demonstrated excellent exercise capacity.[92] Psychological improvements may be noticeable and as important as physical improvements.[52,106,134]

Adolescents who have undergone heart transplantation are able to achieve an increase in cardiac output in response to exercise; however, they do not achieve the same peak workloads or maximal oxygen consumption as do adolescents without cardiac conditions.[38] During the early phase of rehabilitation, many children with transplanted hearts, lungs, or heart-lungs are so debilitated that they are unable to perform at an intensity that would raise their heart rate. The dyspnea index used as part of the Stanford heart transplant protocol is helpful in monitoring the child's physical tolerance during activity.[190] The child counts out loud to 15. The goal initially is to attempt to do this on one breath. At first, it may take three breaths to count to 15 while at rest. Exercise should increase the number of breaths to reach the count of 15 by only one or two breaths and should not be resumed until a return to resting baseline. Most children progress quickly, usually reaching 15 on one breath within 1 week of beginning exercise. The dyspnea index is an easily used measure for self-monitoring of exercise tolerance at home.[99] Children who underwent heart transplantation in infancy were found to have exercise capacities that were not different from those of children without cardiac conditions.[1] They did have a slightly lower peak heart rate, peak oxygen consumption, and a lower anaerobic threshold, but the respiratory exchange ratio was equal and the oxygen pulse index did not differ significantly.

Following heart, heart-lung, and lung transplants, children and youth often experience marked improvements after rehabilitation.[27] Following heart-lung transplantation, children have an increased ventilator response to exercise.[13,14,199] The dyspnea index is useful in monitoring physical tolerance to activity. The authors have found the dyspnea index highly beneficial for adolescents after transplant to change their lifestyle, as well as increase physical endurance. Quality of life often improves dramatically following heart transplantation with most children reported to be functioning at an age-appropriate level without developmental delays.[53,114,158]

In a systematic review of long-term survival and morbidity in the presence of CHD, Verheught and associates reported that survival is decreased in individuals with CHD when compared with the normal survival rate. Morbidity increased with more complex CHD. The review also concluded that supraventricular arrhythmias were prevalent in patients with ASD, transposition of the great arteries (TGA), and tetralogy of Fallot (TOF); ventricular arrhythmias were more prevalent in TOF, and CVAs were more common with TGA, ASD, and coarctation of the aorta. Heart failure, cyanosis, and complexity of lesions are predictors of increased mortality in adults with CHD. Increased ventilatory response or poor exercise capacity in adults 25 years after a Mustard or Senning operation for transposition of the great arteries increased risk for cardiac emergency or death.[70] Fredriksen and associates[61] found that patients who underwent surgical correction for TGA demonstrated a gradual decline in exercise performance with age and a significantly lower exercise capacity than healthy peers.[61] The International Society for Adult Congenital Heart Disease published an extensive report on the guidelines and management of adults with CHD.[221] Readers are referred to this resource for information on management of adults with repaired congenital heart defects.

SUMMARY

The physical therapist has an integral role in the habilitation and rehabilitation of children with congenital heart conditions. This chapter provided foundation knowledge for physical therapists on congenital heart conditions, surgical and medical management, and implications for physical activity and development. Because medical procedures and surgical interventions are occurring earlier, it has become increasingly important for physical therapists to monitor motor development and support parent–child interaction to promote socioemotional development. A major role of the physical therapist involves education and instruction to address parental concerns about physical activity. Knowledge of the physical capacity of children with congenital heart conditions is essential to promote motor development and for leisure and recreational activities.

Case Scenarios on Expert Consult

The case scenarios related to this chapter involve the following two topics: cardiomyopathy and complex cyanotic congenital heart disease. The first case looks at a 10-year-old child with a history of cardiomyopathy and a recent heart transplantation receiving physical therapy as an outpatient. The case includes a video that demonstrates exercising after heart transplantation. The second case looks at a child with complex cyanotic congenital heart disease. The child is presented from birth through age 26. Changes in physical capacity and physical therapy interventions at different ages are described.

The Neonatal Intensive Care Unit

Beth McManus, Yvette Blanchard, Stacey Dusing

Providing services to high-risk infants and their families in the neonatal intensive care unit is a complex subspecialty of pediatric physical therapy requiring knowledge and skills beyond the competencies for entry into practice. Newborns in the neonatal intensive care unit (NICU) are among the most fragile patients that physical therapists treat, and therefore practice in the NICU requires a keen understanding of the influence of prematurity and medical fragility on the infant and family. To this end, pediatric physical therapists (PTs) need advanced education in areas such as early fetal and infant development; infant neurobehavior; family responses to having a sick newborn; the environment of the NICU, physiologic assessment, and monitoring; newborn pathologies, interventions, and outcomes; optimal discharge planning; and collaboration with the members of the health care team.[161]

This chapter describes the neonatal intensive care unit and the role of the physical therapist within this setting. In the Background section we describe conceptual models governing PT practice in the NICU. Next, we review the most common medical complications of the respiratory, neurologic, and gastrointestinal system for infants admitted to the NICU and implications for physical therapy interventions. The Foreground section describes examination and evaluation of infants in the NICU, including tests and measures most commonly administered by PTs. The current evidence base for PT interventions in the NICU is presented, including direct interventions (e.g., handling) as well as best practice for posthospital follow-up of NICU infants and their families. Two case scenarios on the Expert Consult apply knowledge to practice.

BACKGROUND INFORMATION

ADVANCES IN NEONATAL CARE

The NICU is designed to meet the needs of a wide range of infants, from the monitoring of apparently well infants at risk of serious illness to the intensive treatment of infants with acute illness. Since the 1970s the type and range of developmental interventions provided in the NICU for medically fragile infants have changed dramatically. As such, the role of the neonatal physical therapist has evolved tremendously over the last several decades. Two main, yet overlapping, factors have contributed to the evolution of the role of the physical therapist: 1) the evolution of special care nurseries and advances in medical technology in NICU care and 2) a paradigm shift in conceptual frameworks for therapeutic and developmental interventions in the NICU.

Dr. Julian Hess is credited with establishing the first special care nursery in the 1940s. At the time the main principles of neonatal care were support of body temperature, control of nosocomial infection, minimal handling, and provision of special nursing care. Interestingly, nurseries were quiet and lights were dimmed at night. Dr. Hess achieved a neonatal mortality rate for preterm infants of 20%, which was respectable for the time.[225] In response to the increased survival rate of premature infants reported by Hess, the previously mentioned principles of care were implemented in several areas across the United States.[170]

The increase in the availability of special care nurseries led to the development of centers for the care of preterm infants during the 1950s. At this time, management of the medically fragile infant involved transport to one of these regional special care nurseries, if available, while the mother of the baby remained at the birthing hospital under the care of her obstetrician.[87] By the late 1960s, medical advances in microlaboratory techniques for biochemical determinations from minute quantities of blood and the development of miniaturized monitoring equipment, ventilatory support systems, and means to conserve body heat improved the care of the neonate with serious illness. Expansion of neonatal pharmacology, widespread use of phototherapy for management of hyperbilirubinemia, and methods of delivery of high-caloric solutions parenterally when oral feeding was not possible also improved the chances for survival of the very sick neonate.[87]

Paralleling advances in special care medical technology, in 1975, the emergence of the subspecialties of neonatology and perinatology affirmed the need for practitioners skilled in the care of infants in the high-technology nursery.[87] As the field of neonatology and the number of special care nurseries grew, it was evident that separate nurseries with costly medical care were not a sustainable, cost-effective model of care. Rather, there was a need for a system for referrals to regional centers for medically fragile infants.[170] In an attempt to improve access to special care and expand regionalization, the National Health Planning Act of 1974 supported assessment of health service needs locally and at the state level, which fostered planning of activities to improve access to care. In particular, three states—Arizona, Massachusetts, and Wisconsin—were at the forefront of promulgating standards for maternity units and developed regional perinatal care centers.

These entailed early identification of high-risk pregnancies and allowed for the transfer of the mother to a regional perinatal center prior to delivery. In the 1970s, reports from these three states and several professional organizations, including the American Medical Association, the American College of Obstetricians and Gynecologists, the American Academy of Pediatrics, and the Academy of Family Physicians, stimulated the development of the regional organization of perinatal services.[87,170]

The March of Dimes report Toward Improving the Outcome of Pregnancy, published in 1976, articulated the concept of regionalized perinatal care with three levels of maternal and neonatal care.[69,170] A subsequent report restated the importance of regionalization and recommended changes in designations from levels I, II, and III to basic, specialty, and subspecialty with expanded criteria.[184] These designations were updated in 2004[18] and again in 2012 through an AAP policy statement titled Levels of Neonatal Care.[18] The three levels of neonatal care and capabilities within levels recommended by the American Academy of Pediatrics are presented in Box 29.1. Although difficult to accurately assess, recent estimates suggest there are approximately 3 NICU beds per 1000 live births across the United States.[170]

The newborn in the intensive care nursery transitions from the buoyant, warm, enclosed, and relatively quiet and dark environment of the womb to a bright, often noisy, technology filled, gravity-influenced environment and is subjected to procedures that often cause pain and discomfort. The newborn is extremely vulnerable to the environmental effects of the intensive care nursery. Over the last several decades, there has been an increase and an evolution in the research and recommendations to decrease NICU environmental effects and to facilitate the development of the infant in the NICU.

As mentioned previously, the first special care nurseries were dark and quiet environments.[1] The prevailing thought was that medically fragile neonates were overly sensitive to external environmental stimulation and that care should be taken to mimic the in-utero environment and limit the infant's exposure to environmental hazards such as light and sound. However, as the advancement of medical care occurred and opportunities to improve special care for preterm infants emerged, there was a shift toward providing sensory stimulation. Outcomes of preterm infants were still poor compared to their full-term counterparts, and the prevailing thought was that preterm infants experienced sensory deprivation as a result of preterm birth, and the developmental gaps between preterm and full-term infants could be addressed with sensory stimulation programs.[169]

In the 1980s, concern emerged that the typical nursery stay of several weeks may have detrimental effects on later behavior of the infant born at very low birth weight (less than 1500 g).[113] At that time, the neonatal intensive care nursery was characterized by bright lights both night and day, high noise levels, and the intrusive medical procedures characteristic of high-technology treatment.[54,98] Research ensued on the effects of different sensory inputs based on the premise that the neonatal care environment may impact development. Optimal care included modulation of the environment to facilitate development, recognition of infant distress and discomfort, and family-centered care.[256] As the field of neonatal therapy became more prevalent, psychologists, physical therapists, and occupational therapists took the lead in developing sensory stimulation programs. However, the success of such programs was limited and they did not appear to mitigate the disparities in developmental outcomes between preterm and full-term infants. Thus another paradigm shift occurred. The current conceptual framework supports individualized, developmentally supportive care, where sensory stimulation is matched to the unique needs, strengths, and vulnerabilities of the infant.[169,256]

During the past three decades, the availability of neonatal intensive care has improved outcomes for high-risk infants, including premature infants and those with serious medical or surgical conditions.[18] Improved survival for very low birth weight and extremely low birth weight infants has been continuously reported since 1988.[87,138,143,237] This improvement in survival is related to antenatal steroids, more aggressive resuscitation in the delivery room, and advanced treatments given in the special care nursery including surfactant therapy.[139] A recent March of Dimes report[163] suggests that, among the over 180,000 newborns studied, 14% had a neonatal care admission. Of the babies admitted for neonatal care, about half were born preterm (i.e., less than 37 weeks of gestation) and half were full term. Moreover, the study reports an average length of neonatal hospitalization as approximately 13 days.

Prematurity and Low Birth Weight

More than 500,000 infants are born prematurely (gestation of less than 37 weeks) in the United States every year.[102] Approximately 1% of live births are very preterm with

BOX 29.1 Hospital Perinatal Care Levels

Level I: Well-Baby Nursery
Provide neonatal resuscitation at every delivery.
Evaluate and provide postnatal care to stable term newborn infants.
Stabilize and provide care for infants born 35–37 wk gestation who remain physiologically stable
Stabilize newborn infants who are ill and those born at < 35 wk gestation until transfer to a higher level of care.
Level II: Special Care Nursery
Level I capabilities plus:
- Provide care for infants born ≥ 32 wk gestation and weighing ≥ 1500 g who have physiologic immaturity or who are moderately ill with problems that are expected to resolve rapidly and are not anticipated to need subspecialty services on an urgent basis.
- Provide care for infants convalescing after intensive care.
- Provide mechanical ventilation for brief duration (< 24 h) or continuous positive airway pressure or both.
- Stabilize infants born before 32 wk gestation and weighing less than 1500 g until transfer to a neonatal intensive care.

Level III: NICU
Level II capabilities plus:
- Provide sustained life support.
- Provide comprehensive care for infants born < 32 wk gestation and weighing < 1500 g and infants born at all gestational ages and birth weights with critical illness.
- Provide prompt and readily available access to a full range of pediatric medical subspecialists, pediatric surgical specialists, pediatric anesthesiologists, and pediatric ophthalmologists.
- Provide a full range of respiratory support that may include conventional and/or high-frequency ventilation and inhaled nitric oxide.
- Perform advanced imaging, with interpretation on an urgent basis, including computed tomography, MRI, and echocardiography.

Level IV: Regional NICU
Level III capabilities plus:
- Be located within an institution with the capability to provide surgical repair of complex congenital or acquired conditions.
- Maintain a full range of pediatric medical subspecialists, pediatric surgical subspecialists, and pediatric anesthesiologists at the site.
- Facilitate transport and provide outreach education.

From American Academy of Pediatrics Committee on Fetus and Newborn: Levels of neonatal care. Policy statement. Pediatrics 130:587-597, 2012.

gestational age younger than 32 weeks,[269] and 8% of live births (and 74% of all preterm births) are late preterm with gestational age between 34 weeks and 36 ⁶⁄₇ weeks.[154] Preterm birth is a leading cause of infant mortality and morbidity, accounting for over 70% of neonatal deaths and half of long-term neurologic disabilities such as cerebral palsy, cognitive impairment, and behavioral problems.[164,166] The current rate of preterm births in the United States is 12%.[102] Infants born prematurely or who are small for gestational age (SGA) are divided into three major categories: low birth weight (LBW), from 1501 to 2500 g; very low birth weight (VLBW), 1000 to 1500 g; and extremely low birth weight (ELBW), less than 1000 g.

The causes of preterm birth are not clear but seem to involve an interaction of multiple factors including genetic, social, and environmental factors. Spontaneous preterm delivery and birth have recently been described as a common complex disorder like heart disease, diabetes, and cancer.[269] Criteria for complex diseases include family history, recurrence, and racial disparities.[102] American black women have 1.5 times the rate of preterm birth and 4 times the rate of infant mortality because of preterm births compared with white women.[71] Approximately 40% of premature births are believed to be caused by intrauterine or systemic infections or both, which are not diagnosed until the onset of labor.[36] Pregnancy-specific stress is associated with smoking, caffeine consumption, and unhealthy eating, and it is inversely correlated with healthy eating, vitamin use, exercise, and gestational age at delivery.[153] Finally, infants born after assisted reproduction have a lower birth weight and gestational age when compared to matched controls.[158]

There has been a significant increase in survival of infants with VLBW and ELBW[139] as a result of more aggressive delivery room resuscitation, surfactant therapy, and a decreased rate of sepsis.[88,139,271] Approximately half of children surviving extremely low birth weight deliveries have subsequent moderate to severe neurodevelopmental disabilities.[139] Brain injury, retinopathy of prematurity, bronchopulmonary dysplasia, and neonatal infection increase the risk of mortality or neurosensory impairment (described later in this chapter).[32,164]

There is a national focus on preventing preterm birth spearheaded by the March of Dimes National Prematurity Campaign of 2003, recently extended to 2020.[163] The Prematurity Research Expansion and Education for Mothers who Deliver Infants Early (PREEMIE) Act (P.L. 109–450) was passed in 2006 with a subsequent Surgeon General's Conference on the Prevention of Preterm Birth in 2008.[177] The conference objectives were to (1) increase awareness of preterm birth in the United States; (2) review key findings on causes, consequences, and prevention of prematurity; and (3) establish an agenda for public and private sectors to address this public health problem. Conference recommendations included (1) increased research in medicine, epidemiology, psychosocial, and behavioral factors relating to prematurity; (2) professional education and training; (3) communication and outreach to the public; (4) addressing racial disparities; and (5) improvement of quality of care and health services.

ROLE OF THE PHYSICAL THERAPIST IN THE NICU

Newborn medicine changed rapidly with the advent of new drugs and technology. The NICU environment is cutting edge, fast paced, and high stress, but it affords the physical therapist incomparable learning opportunities because of the exceptional range of medical conditions and level of acuity of the infants, numerous exchanges with health care professionals, and the opportunity to have a positive impact on this new family unit. This highly technical subspecialty area offers the opportunity for physical therapists to provide developmental services within a framework that is family centered and that views the infant as fully participating in the development process, principles that are central to pediatric physical therapy practice.

Neonates and infants in the NICU require specialized care due to the complexity of their medical conditions, their physiologic, neurologic, and developmental vulnerabilities, and the need to support the family during this stressful experience. Because of this complexity, physical therapists working in the NICU require specialized training through direct guidance from a highly skilled and experienced neonatal physical therapist or fellowship in neonatology. Clinical practice guidelines for physical therapists working in the NICU have been published in a two-part article series.[245,246] Part 1 articulates the path to professional competence and describes the clinical competencies for physical therapists, NICU clinical training models, and a clinical decision-making algorithm[245]; Part 2 presents the evidence-based practice guidelines, recommendations, and theoretical frameworks that support neonatal physical therapy practice.[246] The Practice Committee of the Section on Pediatrics of the American Physical Therapy Association has also published a Fact Sheet outlining recommendations for developing expertise in neonatal physical therapy practice (http://www.apta.org/NICU/). These sources clearly articulate that physical therapy practice in the NICU is not for the novice therapist.

Teamwork in the NICU

Similar to other areas of pediatric PT, teamwork and collaboration are a critical aspect of in the NICU practice. Teamwork and collaboration encompass "working together in a cooperative and coordinated way in the interest of a common cause."[185] Indeed, there are a number of medical, therapeutic and developmental, and support professionals working in the NICU. The medical team is principally concerned with infants' medical care and typically includes neonatologists, neonatal nurse practitioners, registered nurses, respiratory therapists, and registered dietitians. The organization of the medical team varies across institutions. For example, the presence and number of attending neonatologists, fellows, and neonatal nurse practitioners usually vary depending on whether the institution is an academic teaching, children's, or birthing hospital.[28,255]

The therapeutic and developmental care teams are principally concerned with providing individualized, developmentally supportive care in the NICU. The developmental team can include physical therapists, occupational therapists, speech and language pathologists, and developmental specialists. Typically, members of the therapeutic and developmental care team will receive physician or neonatal nurse practitioner orders to evaluate and treat infants being cared for in the NICU. These orders may be standing orders (e.g., all babies less than 32 weeks receive therapy services) or infant-specific (e.g., infant with tone abnormalities).[28,256] The roles of each developmental professional in the NICU may vary depending on their specialized training and expertise.

The role of the physical therapist in the NICU is multifaceted and includes: (1) the screening and examination of infants to determine the need for direct services in the NICU, referral for consultation by other health care professionals, and referral for developmental services postdischarge through early

intervention or outpatient therapy services; (2) the design and implementation of individualized and developmentally appropriate interventions adapted to the infant's physiologic, motor, neurologic and developmental needs; (3) working in collaboration with other health care professionals to meet the needs of the infant and family members; (4) incorporating family members in the provision of care to best support the infant's developmental outcome. More detail about PT examination, evaluation, and intervention is presented later in the chapter.

The role of the occupational therapist in the NICU is to foster developmentally appropriate occupations, sensorimotor skills, and neurobehavioral organization. The provision of neonatal occupational therapy services includes: (1) caregiver communication, (2) appropriate use of NICU equipment, (3) administering formal assessment tools, (4) developing individualized developmentally supportive interventions, (5) monitoring the infant's response to intervention, (6) family collaboration, (7) providing thorough yet concise documentation, and (8) appropriate discharge planning.[28,255,256]

The role of the speech and language pathologist in the NICU is to assess and provide intervention with infants at risk or who are identified with communication, cognition, feeding, and/or swallowing disorders.[20,28,256] The provision of neonatal speech and language therapy services includes: (1) conducting communication, cognition, feeding/swallowing, and neurodevelopmental assessments; (2) conducting instrumental feeding/swallowing evaluation; (3) providing developmentally supportive, family-centered, evidence-based speech therapy interventions; (4) providing education, consultation, and support to NICU families and staff; (5) team and family collaboration and shared decision-making; (6) quality improvement and risk management; (7) discharge planning; and (8) participating in research, education and advocacy activities for NICU infants and their families.[20]

The role of the developmental specialist is to identify the infant's strengths and vulnerabilities and to: (1) partner with parents to identify and respond contingently to these infant behaviors (e.g., during caregiving episodes); (2) modify the caregiving environment to promote infants' strengths; and (3) promote optimal parent–infant interaction. The professional discipline and role of the developmental specialist will also vary across institutions and could be a physical, occupational, or speech therapist, registered nurse, or psychologist. Special care nurseries that are affiliated with the Newborn Individualized Developmental Care and Assessment Program (NIDCAP) Federation typically have a developmental specialist.[28,50,256]

In addition to the medical and developmental team members described above, there are a number of additional professionals who play a critical role in supporting families in the NICU. Certified lactation consultants provide breastfeeding support to NICU families, which can include assisting with accessing breast pumps, determining a pumping and breastfeeding schedule, and providing support, guidance, and direct interventions related to increasing maternal milk supply and infant feeding development. Social workers provide emotional support to families in the NICU and assist with accessing resources such as the Supplemental Nutrition Program for Women, Infants, and Children (WIC), Supplemental Nutrition Assistance Program (SNAP), or Medicaid. Finally, discharge planners may be social workers or nurses and their primary role is to assist families as they transition from the NICU. Although roles may vary across institutions, discharge planners help families to access home equipment (e.g., oxygen and feeding pumps), address concerns or problems related to health insurance, and coordinate follow-up services for families (e.g., follow-up specialist or pediatrician appointments).[28,256]

Given the wide range of professional disciplines and roles represented within the NICU, teamwork and collaboration are essential. A national expert panel was convened to determine the organizational culture and attributes of NICUs that were required for successful collaboration and quality improvement. The following characteristics of NICU were identified: (1) clear, shared purpose, (2) effective communication among team members, (3) management that leads by example, (4) trusting and respectful environment, (5) established standards of excellence, (6) competence and commitment among team members, and (7) commitment to conflict management.[185]

Models of Service Delivery

There is limited published literature to describe the type, frequency, and variability of NICU therapeutic models of service delivery.[28] However, models of service delivery commonly seen in pediatric rehabilitation are also applicable to the NICU. For example, in some NICUs, the therapeutic and developmental program is represented by only one professional discipline (e.g., physical therapy). In contrast, some NICUs have adopted a multidisciplinary model in which the therapeutic and developmental care team consists of more than one professional discipline (e.g., physical and occupational therapy) (Fig. 29.1). In this model, team members function in distinct but complementary roles.[28] For example, occupational therapists might be responsible for splinting, speech therapists address oral feeding development, and physical therapists focus on positioning and therapeutic handling or massage. Thus the determination of which professional discipline will perform the examination and intervention is guided by the infant's greatest area of need. In our experience the multidisciplinary model of care can foster a targeted use of resources and expertise when a primary infant need (e.g., splinting) is identified. However, as described later in the chapter, infants experience a variety of medical, neurobehavioral, and interactional vulnerabilities that require a multifaceted approach to examination and intervention. As such, a possible limitation to a multidisciplinary approach is that multiple therapists are working with the family, which has the

FIG. 29.1 Multidisciplinary patient care rounds in the NICU. (From Walden M, Elliott E, Gregurich MS: Delphi Survey of Barriers and Organizational Factors Influencing Nurses' Participation in Patient Care Rounds. Newborn Infant Nurs Rev 9(3):169-174, 2009.)

potential to create fragmentation, caregiver burden, and unnecessary handling of fragile infants.

To address potential limitations of a multidisciplinary model, a transdisciplinary model of care adopts a comprehensive and holistic view of the infant. As such, the transdisciplinary model requires that team members share professional roles such that the boundaries across disciplines become less distinct.[28,51] For example, all therapeutic and developmental care team members are competent in issues related to oral feeding, positioning, and neonatal massage. This model has a number of strengths such as reducing the number of providers handling the infant, allowing for a unified and integrated approach to care where "the role differentiation between disciplines is defined by the needs of the situation rather than by discipline-specific characteristics."[51] However, this amorphous role delineation can be problematic at times if therapists feel like a particular area of NICU intervention (e.g., oral feeding) is the purview of their professional discipline.[28] As such, the balance between a transdisciplinary model of care and professional role delineation is critical.

In addition to the model of service delivery, there are other important considerations for addressing the needs of infants and families in the NICU. Although therapists in other subspecialties within the hospital typically see 8 to 10 patients per 8-hour day (from 9 am to 5 pm), physical therapists in the NICU are constrained by frequent medical procedures, strict feeding schedules, evening parental visiting schedules, and infection considerations for patients seen outside of the NICU. As such, the model of service delivery needs to be flexible with regard to productivity demands, work hours, and managing schedules of patients other than those in the NICU. The needs and realities of the rehabilitation department and ensuring equity of responsibility among all therapists are additional considerations.

Professional Role Delineation

Depending on NICU staff resources, organizational culture, and type of hospital, physical therapists may work closely with occupational therapists, speech language pathologists, and developmental specialists. As such, professional role delineations related to oral feeding, positioning, infant massage, and facilitation and handling may become blurred. According to the APTA, physical therapists are experts in examination and intervention of impairments in body functions and structures and motor activity limitations of the musculoskeletal and neuromuscular system.[245] To this end, this expertise may cross traditional professional boundaries, and physical therapists should work collaboratively with colleagues from other disciplines while advocating for the growth of their profession. Indeed, as described in the previous sections, the professional roles of each of the therapeutic and developmental care team members overlap. Yet, a unifying theme is developmentally supportive care.[28,256] In our experience, all therapeutic and developmental care team members should be competent in neurobehavioral evaluation and treatment in order to provide family-centered, individualized, developmentally supportive care across different contexts of NICU care (e.g., positioning, routine care, oral feeding, environmental modifications, and parent–infant interaction). Particular team members may choose to pursue advanced clinical practice training in NICU interventions (i.e., infant massage, oral feeding techniques) and can serve as valuable assets to the NICU therapeutic and developmental care team to provide expert consultation when necessary.

THEORETICAL FRAMEWORKS GUIDING PRACTICE IN THE NICU

Three theoretical frameworks for serving infants in the NICU are family systems, the International Classification of Functioning, Disability and Health (ICF) model, and the synactive theory. Those theoretical frameworks address the three main components of physical therapy intervention: communication and coordination, information sharing with parents, and procedural interventions (for more details, refer to Chapters 1 and 30).

Family Systems

Premature birth, followed by the intensity of the experience of the NICU, is highly stressful and sometimes traumatic not only for the baby but also for the parents and the whole family. The NICU experience for parents may vary depending on the severity of the infant's illness and the level of preparedness parents have prior to the infant's admission to the NICU.[180,256] Although prior knowledge of a possible premature or complicated birth may soften the intensity of the experience at first, all parents of premature infants are particularly vulnerable throughout their infant's neonatal period. The foremost concern is for survival. Once survival is certain, concern shifts to the quality of the infant's developmental outcome. The parents themselves can be considered to be "premature parents" and may be mourning the loss of the "imagined" or "wished-for baby" as they struggle to develop a bond with their "real baby."[52,133] Parents report that the NICU experience often leaves them with a temporary loss of their parental role and identity and that at time of discharge they may feel overwhelmed, worried, and even panicked, especially if their infant had required ventilation while in the NICU.[209] The phase immediately after discharge from the hospital is often one of anxious adjustment during which mothers express their lack of confidence and insecurity in caring for their preterm infant.[199] We encourage physical therapists to reflect on the impact of an early birth or birth of a sick infant on parents, on the sense of temporary loss of parental roles and identity, and feeling overwhelmed at time of discharge.

The length of stay for infants admitted to the NICU varies widely according to the severity of the condition leading to the admission. Some infants may spend as little as 1 day in the NICU (e.g., due to respiratory distress); others may spend months (e.g., due to extreme prematurity, short gut). Research on parental response to having their newborn admitted to the NICU has been fairly consistent in reporting a high level of parental stress and anxiety, which may lead to a posttraumatic stress reaction (PTSR). PTSR is a predictor of infant sleep and eating problems at 18 months.[200] The prevalence of postpartum depression (PPD) in mothers of newborns admitted to the NICU (45%) is higher compared to PPD in first-time mothers of healthy infants (8% to 15%).[33] On a more positive note a recent study reported that the implementation of the "parent friendly" changes as seen in most hospitals across the United States contributed to helping parents make a more successful adaptation to having an infant in the NICU.[62]

Admission of the newborn to the NICU happens at a critical time in the development of the family unit. For the infant, biobehavioral transition from intrauterine to extrauterine life occurs in the first months of life.[180] For the parents, the first months are a time when they search for "the goodness of fit" between themselves and their new baby.[249] The core challenge

for parents is to engage with their baby in a way that is unique to them and fosters the baby's development.[234] Many factors may render the relationship between parents and their premature infant vulnerable. Premature infants have poor abilities to self-regulate physiologic rhythms, and attention is limited, which can disrupt the parent–infant synchrony so critical during interactive episodes.[89] Preterm infants are more irritable, smile less, and have facial signals that are less clear than full-term infants,[229] all of which affect the parents' ability to read and respond to their infant's cues.[89] Steinberg contended that posttraumatic stress reaction and depression interfere with the parents' ability to read their baby's cues and respond sensitively to the baby's needs.[233] Nevertheless, a number of studies have demonstrated that during this difficult hospital time, helping parents understand their baby's behavior appears to be critical in helping them maintain their role as parents and mitigate levels of stress.[141,156,210]

Physical therapists, with their unique skills in infant behavioral observation and developmental intervention, play an important role in the support offered parents during this difficult time. The physical therapist can help the parents read their baby's cues and provide feedback on their baby's responses. Several studies have reported long-term effects ranging from 9 months to 2 years of behaviorally based interventions on infant development, parent–infant interaction, maternal confidence and self-esteem, and paternal attitudes toward and involvement in caregiving.[73,97,192,208] Primarily derived from the Neonatal Behavioral Assessment Scale (NBAS) (described later in the chapter), behaviorally based intervention tools that have been developed to promote parent and child outcomes are summarized in Table 29.1 and may be useful resources of therapists working in the NICU.

Family-Centered Care

Family-centered care (FCC) was first defined in 1987 as part of former surgeon general Everett Koop's initiative for family-centered, community-based, coordinated care for children with special health care needs and their families. The American Academy of Pediatrics (AAP) recognizes the importance of FCC as an approach to health care[178] and stresses the importance of the role that families play in patient outcomes.[160] At the heart of family-centered care is the recognition that the family is the constant in a child's life. For this reason, family-centered care is built on partnerships between families and professionals. The Institute for Family-Centered Care has identified eight core concepts of FCC that guide the delivery of services to families with children with health care needs: (1) respect, (2) choice, (3) information, (4) collaboration, (5) strengths, (6) support, (7) empowerment, and (8) flexibility (www.familycenteredcare.org).

Many medical institutions and NICUs across the country have instituted their own FCC guidelines and practices, but for the most part they all share the pursuit of being responsive to the priorities and choices of families. Cleveland published a systematic review of the literature to identify the needs of parents in the NICU and the type of nursing support most helpful during their stay in the NICU (see Table 29.1).[66] Parents need accurate information, to have contact with their infant, and to be fully included in their infant's care. Individualized care and knowing that the NICU staff is watching over and protecting their infant is also important to parents. The types of behaviors that best support parents in the NICU are those where they feel welcome at all times, are encouraged to participate in their child's care, and are engaged in a therapeutic relationship with the nursing staff. Parent-to-parent groups provide families with additional emotional support.[66,83] Parents report a preference for multiple presentations of different formats including hands on, written, and group sessions to learn how to support their infant's development as they prepare for NICU discharge.[83] The physical therapist can consider these recommendations in the implementation of family-centered interventions in the NICU. Readers are encouraged to reflect on the multiple ways physical therapists can support families of infants in the NICU.

TABLE 29.1 Needs of Parents Who Have Infants in the NICU and the Types of Support That Are Most Helpful

Needs of Parents	Behaviors That Support Parents
Accurate information	Emotional support
Contact with the infant	Parent empowerment
Inclusion in the infant's care	A welcoming environment with supportive unit policies
Vigilant watching-over and protecting the infant	Parent education with an opportunity to practice new skills through guided participation
Being positively perceived by the nursery staff	
Individualized care	
A therapeutic relationship with the nursing staff

International Classification of Functioning, Disability and Health

The International Classification of Functioning, Disability and Health, commonly referred to as the ICF, is a framework for understanding relationships between health and disability at both individual and population levels that is described in Chapter 1.[274] The ICF was developed to create a common language to improve communication among health care providers, researchers, policy makers, and people with disabilities and to provide a scientific basis for understanding and studying health and health-related states, outcomes, and determinants.[189] The health-related domains are classified from body, individual, and societal perspectives by means of two lists: a list of body functions and structures and a list of domains of activity and participation. Because an individual's functioning and disability occur in a context, the ICF also includes a list of environmental and personal factors (for more information, see www.who.int/classifications/icf/en).

The ICF provides a framework to guide the choice of examination procedures and intervention strategies for infants receiving services in the NICU. High-risk neonates frequently demonstrate impairments in muscle tone, range of motion, sensory organization, and postural reactions. These impairments in body functions and structures may contribute to limitations in activity such as difficulty in breathing, feeding, visual and auditory responsiveness, and motor activities such as head control and movement of hands to mouth. The interaction between impairments and activity limitations may contribute to restrictions in parent–infant interaction (participation). The ICF model also considers personal and environmental factors as relevant influences on body functions and structures, activity,

and participation. Personal factors include an infant's health complications and temperament. Environmental factors range from levels of lighting and noise in the special care nursery to family and community support such as appropriate shelter and access to necessary food and supplies that will directly influence the infant's outcome and well-being (Table 29.2 shows an example of the ICF model adapted for the infant in the NICU).

Synactive Theory

Since the late 1980s, advances in perinatal and newborn intensive care have dramatically decreased the mortality rates of preterm and sick newborns at high risk for developmental problems. As premature infants have become younger in gestational age at birth (as young as 23 weeks of gestation) and smaller in birth weight (as little as 450 g), there has been a growing concern among health care professionals to not only ensure their survival but to optimize their developmental course and outcome. Better known as developmental care, the intervention model designed to address these issues focuses on the detailed observation of infant neurobehavioral functioning to design highly individualized plans of care and provide developmentally appropriate experiential opportunities for the newborn in the hospital setting and the provision of supportive care for the infant's family.[12] Recent research suggests that individualized developmental care may improve some medical complications and short-term outcomes such as length of stay, level of alertness, and feeding progression.[167,196]

Als's synactive theory provides a framework for the neurobehavioral functioning of the young infant.[5] Infant neurobehavioral functioning is understood as the unfolding of sequential achievements in four interdependent behavioral dimensions organized as subsystems.[5] The infant (1) stabilizes her autonomic or physiologic behavior, (2) regulates or controls her motor behavior, (3) organizes her behavioral states and her responsiveness through interaction with her social and physical environment, and (4) orients to animate and inanimate objects. Through maturation and experience, the infant is able to organize her behavior subsystems and actively participate in her social world including interactions with caregivers to meet her needs.[5,48] Competency in behavioral organization can be determined through the careful observation of the behaviors displayed by the infant within each of the behavioral dimensions. Als has categorized behaviors within each of the behavioral dimensions as either "approach/regulatory" or "avoidance/stress."[5] Regulatory behaviors indicate a state of well-being and are observed when an infant's self-regulatory abilities are able to support the social and environmental demands placed on her; she is then described as organized.[72] Stress behaviors indicate a state of exhaustion and are observed when the infant's threshold for self-regulation is exceeded by the demands placed on her; she is then described as disorganized.[72]

The application of neurobehavioral observations to clinical practice has been formalized with the Newborn Individualized Developmental Care and Assessment Program (NIDCAP).[8,9] The NIDCAP proposes a structured method of weekly observation and assessment of infant behavior by a NIDCAP-certified developmental specialist or physical therapist. Based on these observations and following consultations with the infant's family and medical team, an individualized care plan is developed and implemented. Intervention is aimed at facilitating prolonged periods of organization by reinforcing the infant's individual self-regulatory style while supporting families to nurture and care for their infant.[11,12,42] Research indicates that the NIDCAP is associated with reduced length of hospital stay and incidence of brain hemorrhage and improved long-term medical and developmental outcomes.[8,12,167]

MEDICAL COMPLICATIONS OF INFANTS ADMITTED TO THE NICU

Knowledge of medical complications common in infants admitted to the NICU is important for understanding how health conditions may affect the infant's capacity for handling and physical activity, growth and development, and the parents' experience in the NICU.

Respiratory System

Several pulmonary, neurologic, cardiac, and other health conditions in neonates are associated with increased risk for impairments in body functions and structures that affect cognitive,

TABLE 29.2 Application of the International Classification of Functioning, Disability, and Health for Infants in the Neonatal Intensive Care Unit

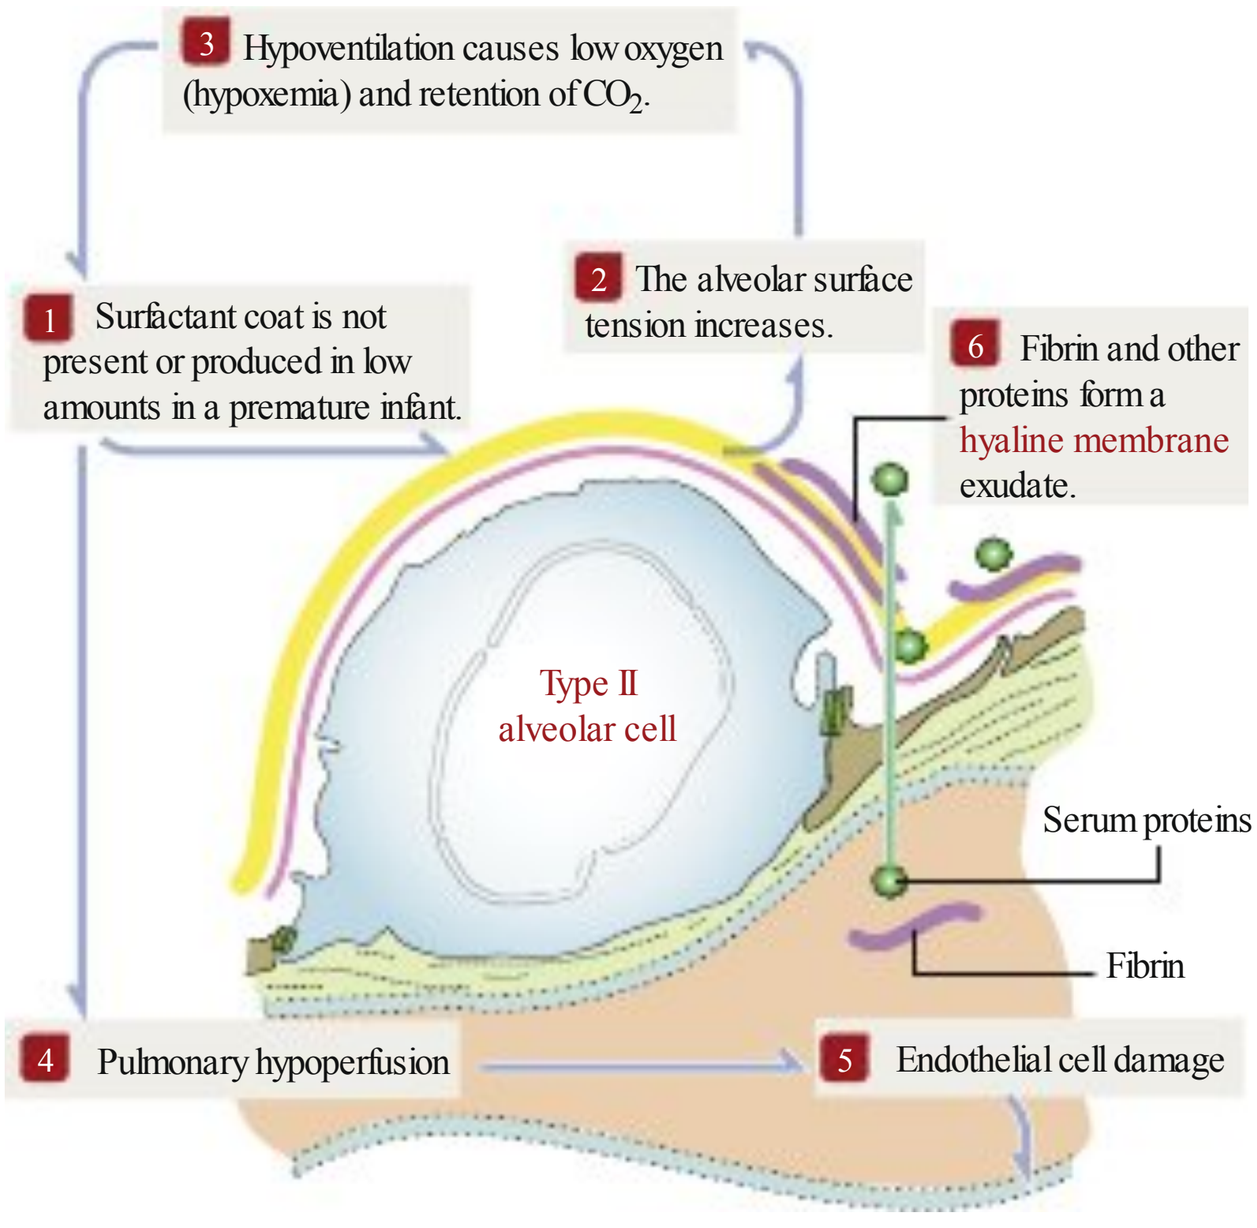
Health Condition (Includes disease or injury)

Examples: prematurity, respiratory distress, intraventricular hemorrhage, periventricular leukomalacia, arthrogryposis, spina bifida, failure to thrive, short gut, Down syndrome

Body Functions and Structures	Activities	Participation
Physiologic and Psychological Functions of Body Systems Examples: muscle tone, postural reactions, range of motion, sensory organization, behavioral state control, neurobehavioral functioning, physiologic stability↓	**Execution of a Task or Action by an Individual** Examples: breathing, sucking, crying, head control, hand to mouth, kicking, grasping, visual and auditory responsiveness↓	**Individual's Involvement in NICU Life Situations** Examples: parent-infant interaction, communication, being held by parents, feeding, sleeping, growing↓
Impairments Examples: skeletal deformity, fluctuating tone, startles, deafness, decreased range of motion, behavioral disorganization	**Activity Limitations** Examples: cannot breathe on own, tube fed, cannot locate sound, self-calm, brings hand to mouth	**Participation Restrictions** Examples: cannot be held or fed by parents because of the inability to maintain physiologic stability and neurobehavioral organization

Environmental Factors	Personal Factors
Physical, Social, and Attitudinal Features of the Family and NICU Setting Examples: lighting and noise levels, maternity leave, family support, family's distance to travel to hospital, siblings	**Personal Characteristics of the Individual** Examples: medical complications, temperament, sensitivity, preferences

motor, sensory, behavioral, and psychosocial development and may result in long-term activity limitations and participation restrictions.[139] The physical therapist providing services in the NICU should have a working knowledge of physiology of neonates, pathophysiology and associated impairments in body functions and structures, and how impairments affect the infant's behavior. Practice in the NICU is a complex subspecialty of pediatrics, and knowledge and skills should be obtained through advanced didactic and practical education. Clinical guidelines and clinical training models for neonatal physical therapy are outlined by Sweeney, Heriza, and Blanchard[245] and are described later in the chapter.



Respiratory Distress Syndrome

Respiratory distress syndrome (RDS), or hyaline membrane disease, is the single most important cause of illness and death in preterm infants and is the most common single cause of respiratory distress in neonates (Fig. 29.2).[236] RDS occurs in 10% of all premature infants in the United States. The percentage increases to 50% to 60% for infants born less than 29 weeks of gestational age.[19,65] The principal factors in the pathophysiology of RDS are pulmonary immaturity and low production of surfactant. Low surfactant production results in increased surface tension, alveolar collapse, diffuse atelectasis, and decreased lung compliance. These factors cause an increase in pulmonary artery pressure that leads to extrapulmonary right-to-left shunting of blood and ventilation-perfusion mismatching. Clinical manifestations of RDS include grunting respirations, retractions, nasal flaring, cyanosis, and increased oxygen requirement after birth. Prophylactic use of antenatal steroids to accelerate lung maturation in women with preterm labor of up to 34 weeks significantly reduced the incidence of RDS and decreased mortality.[65]

Treatment goals for RDS include improvement in oxygenation and maintaining optimal lung volume.[65] The type of intervention depends on the severity of the respiratory disorder and includes oxygen supplementation, assisted ventilation, surfactant administration, and extracorporeal membrane oxygenation (ECMO). Continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP) is applied to prevent volume loss during expiration. Nasal and nasopharyngeal prongs are used with positive end-expiratory pressure ventilators. Mechanical ventilation via tracheal tube is used in severe cases of RDS. (See Chapter 25 for a more detailed description of ventilators.) Mechanical ventilation may injure the lungs of premature infants through high airway pressure (barotrauma), large gas volumes (volutrauma), alveolar collapse and refill (atelectotrauma), and increased inflammation (biotrauma).[24]

The new generation of ventilators is equipped with microprocessors enabling effective synchronized (patient-triggered) ventilation.[130] High-frequency oscillatory ventilation (HFOV) was developed with the goal of decreasing complications associated with mechanical ventilation. Conventional intermittent positive-pressure ventilation is provided 30 to 80 breaths per minute, whereas HFOV provides "breaths" at 10 to 15 cycles per second or 600 to 900 per minute. At this time, evidence is insufficient to support the routine use of HFOV.[110]

Prophylactic use of surfactant for infants judged to be at risk of developing RDS (infants less than 30 to 32 weeks of gestation) has been demonstrated to decrease the risk of pneumothorax, pulmonary interstitial emphysema, and mortality.[236] Early administration of multiple doses of natural or synthetic surfactant extract results in improved clinical outcome and appears to be the most effective method of administration. When a choice of natural or synthetic surfactant is available, natural surfactant

Surfactant deficiency

Surfactant is synthesized by type II alveolar cells after the 35th week of gestation. Corticosteroids induce the synthesis of surfactant in the fetus. High levels of insulin (diabetic mothers) can antagonize the effect of corticosteroids. Infants of diabetic mothers have a higher risk of developing hyaline membrane disease.

Surfactant reduces surface tension within the alveoli. Less pressure is required to keep alveoli open.

Surfactant also maintains alveolar expansion by modulating surface tension with alveolar size. In the newborn, surfactant deficiency causes the lungs to collapse (atelectatic lung) with each successive breath. A lack of O_2 impairs surfactant synthesis.

RDS in premature infants is complicated by a protein-rich, fibrin-rich exudation into the alveolar space, forming a hyaline membrane that leads to CO_2 retention.

FIG. 29.2 Neonatal respiratory distress syndrome (RDS) (From Kierszenbaum TL: Histology and cell biology: an introduction to pathology. 4th ed. Philadelphia: Saunders, 2016.)

shows greater early decrease in requirement for ventilatory support.[228,277] Newer synthetic surfactants include whole surfactant proteins or parts of the proteins (peptides). A clinical trial showed that these preparations decreased mortality and rates of necrotizing enterocolitis with other clinical outcomes being similar to those of natural surfactant preparations.[204] A pilot study showed that an inhaled steroid, budesonide, delivered intratracheally with surfactant administration to very low birth weight infants with severe RDS reduced mortality and chronic lung disease with no immediate adverse effects.[276]

ECMO is a technique of cardiopulmonary bypass modified from techniques developed for open-heart surgery that are used to support heart and lung function (for review of ECMO and implications for pediatric physical therapy, see[193]). In newborns with acute respiratory failure, the immature lungs are allowed to rest and recover to avoid the damaging effects of mechanical ventilation. Because of the need for systemic administration of heparin and the resultant risk of systemic and intracranial hemorrhage, ECMO is reserved for use with infants who are at least 34 weeks of gestational age, weigh more than 2000 g, have no evidence of intracranial bleeding, require less than 10 days of assisted ventilation, and have reversible lung disease.[240] ECMO is contraindicated for infants younger than 34 weeks of age because of high rates of intracranial hemorrhage, perhaps because of systemic anticoagulation necessary with ECMO or abnormal cerebrovascular pressures and flows accompanying ECMO. ECMO is used to manage intractable hypoxemia in near-term infants and newborns with meconium aspiration, RDS, pneumonia sepsis, and congenital diaphragmatic hernia.[65]

Although prognosis of infants with RDS is related to the severity of the original disease, the cause of infant mortality is most often complications of extreme prematurity such as infections, necrotizing enterocolitis, and intracranial hemorrhage rather than acute respiratory failure.[130] Infants who do not require assisted ventilation recover without developmental or medical sequelae, but the clinical course of the very immature infant may be complicated by air leaks in the lungs and BPD. Infants who survive severe RDS often require frequent hospitalization for upper respiratory tract infections and have an increased incidence of neurologic sequelae.[116]

Technologies for management of RDS include inhalation of nitrous oxide, liquid ventilation, or a hybrid of liquid and gas ventilation. The rationale for using liquid ventilation is to decrease alveolar surface tension by eliminating the air-liquid interface by filling the alveolus with liquid.[65] Inhalation of nitrous oxide helps decrease pulmonary artery resistance and cytokine-induced lung inflammation and increase gas exchange. Findings regarding the use of nitrous oxide (NO) and prevention of chronic lung disease and neurologic injury are inconclusive.[22] Inhaled nitric oxide for severe RDS is an experimental treatment that may decrease chronic lung disease and mortality. However, increase in intracranial hemorrhage caused a termination of a study in 2006.[114]

Bronchopulmonary Dysplasia and Chronic Lung Disease of Infancy

Very premature birth occurs during a stage of parenchymal development when oxygenation without support is not always feasible,[25] leading to the need for supplemental oxygenation and/or mechanical ventilation support. As a consequence, many preterm infants develop bronchopulmonary dysplasia (BPD) and are later diagnosed with chronic lung disease (CLD) of infancy. The major predictors of BPD are lower gestational age and mechanical ventilation on day 7; however, the ability to identify infants at risk for BPD is imperfect at best.[123,243] The National Institute of Child Health and Human Development defines infants with mild BPD as requiring oxygen supplementation for 28 days but in room air at 36 weeks postmenstrual age (PMA), those with moderate BPD as requiring oxygen for first 28 days and oxygen < 30% at 36 weeks PMA, and those with severe BPD as requiring oxygen the first 28 days and oxygen > 30% and ventilatory support at 36 PMA.[124,239] Stoll and colleagues report rates of mild BPD as 27%, moderate as 23%, and severe as 18% in a cohort of 9575 infants born between 2003 and 2007.[239] The incidence of BPD increases as birth weight decreases, and infants with birth weights < 1250g constitute 97% of the population of infants with this condition.[262] CLD is diagnosed at 36 weeks of postmenstrual age if there is a continued need for supplemental oxygen, abnormal physical examination, and abnormal chest radiograph.

The cause of BPD is multifactorial but is primarily related to very premature birth and lung injury secondary to the ventilation and oxygen support provided to sustain these very premature infants.[25] The relationship between chorioamnionitis (antenatal infection) and BPD is unclear but may influence the infant's response to surfactant treatment.[123] Findings by Balinotti and his colleagues suggest that abnormal growth and development of the lung parenchyma occur even in clinically stable infants and toddlers with mild lung disease, and the degree of lung parenchyma development and gestational age at birth may be relevant factors in later alveolar development.[25] The lung tissue at 24 to 26 weeks is in the late canalicular stage of development and in the saccular stage between 30 to 32 weeks. During these phases, lung growth is marked with extensive vasculogenesis within the developing terminal saccules that then form secondary crests along with interstitial extracellular matrix loss and remodeling. Although alveoli are present in some infants at 32 weeks of gestation, they are not uniformly present until 36 weeks, during the alveolar stage of development. Thus premature birth and initiation of pulmonary gas exchange interrupts normal alveolar and distal vascular development.[68] The consistent lesion seen in BPD is alveolar simplification (decrease in alveolization) and enlargement, which results from an impairment, not an arrest, in postnatal alveolization in an extremely immature lung following preterm birth, an abnormal capillary morphology, and an interstitium with variable cellularity/fibrloproliferation.[67,68]

Because BPD is an evolving process of lung injury and recovery, the pathophysiology is likely to differ at different times.[262] Walsh and his colleagues propose three stages in the progression of BPD to guide the implementation of specific therapeutic modalities. Stage 1 is for the prevention of BPD and occurs during the perinatal (before birth and up to 4 days of age) and early postnatal (up to 7 days of age); stage 2 constitutes the phase of treatment of evolving BPD beginning at 7 to 14 days of age; stage 3 is for the treatment of established BPD beginning at 28 days of life. In stage 1 inflammation is the predominant issue needed to be addressed with anti-inflammatory treatments (e.g., antenatal corticosteroids, antioxidant therapies). In stage 2 the goal is to stop or minimize the development of the disease with therapies directed at controlling inflammation and lung water with systemic or inhaled corticosteroids, anti-inflammatory agents, and diuretics. In stage 3, where BPD is established, issues are related to overly reactive airways, lung fluid retention,

and an oxygenation defect. Jobe advocates efforts to decrease the invasive nature of NICU care in general while empowering the premature infant to breathe spontaneously and grow.[123]

Meconium Aspiration Syndrome

Meconium aspiration syndrome (MAS) is defined as respiratory distress in an infant born through meconium-stained amniotic fluid whose symptoms cannot be otherwise explained.[87] It can be characterized by early-onset respiratory distress in term and near-term infants with symptoms of respiratory distress, poor lung compliance, and hypoxemia and radiographic findings of hyperinflation and patchy opacifications with rales and rhonchi on auscultation.[268] Because of the frequent occurrence of air leaks in these infants, positive-pressure ventilation is contraindicated. It is unclear whether the meconium itself causes pneumonitis severe enough to lead to the above symptoms or if the presence of meconium in the amniotic fluid is a result of other events such as stressed labor, postmaturity, and depressed cord pH that may have predisposed the fetus to severe pulmonary disease.[65] It is recommended that the infant with depressed physiologic function and meconium-stained fluid be suctioned endotracheally because pharyngeal suctioning does not reduce MAS.[251] Antibiotics are often given until bacterial infection is ruled out. The infant is hypersensitive to environmental stimuli and should be treated in the quietest environment possible. According to a Cochrane review in 2014, surfactant administration may reduce the severity of MAS and decrease the number of infants requiring ECMO.[85,224] Obstetric approaches to the prevention of MAS such as intrapartum surveillance, amnioinfusion, and delivery room management have not demonstrated a decrease in MAS.[275] Approximately 20% of infants with MAS demonstrated neurodevelopmental delays up to 3 years of age even though they responded well to conventional treatment.[34]

Cardiac System

Cardiac conditions common to neonates in the NICU include congenital heart defects such as patent ductus arteriosis (PDA), pulmonary atresia, tetralogy of Fallot (TOF), coarctation of the aorta (COA), and pulmonary atresia. Cardiac conditions are presented in Chapter 28.

Neurologic System

Intraventricular Hemorrhage and Periventricular Hemorrhage

Intraventricular hemorrhage (IVH) occurs in about 45% of infants with birth weights between 500–750 g and in about 20% of infants with birth weights < 1500 g.[121,270] Despite medical advances, IVH remains a major problem for the premature infant. Most hemorrhages occur within the first 48 hours after birth and are related to the fragility of the germinal matrix located on the head of the caudate nucleus and underneath the ventricular ependymal.[26] When the hemorrhage is substantial, the ependymal breaks and the blood spills into the ventricles.[26] Diagnosis is based on routine or symptom-driven screening through cranial ultrasound. Papile developed a four-level grading scale based on ultrasound scan to classify hemorrhages.[190] Grade I is a hemorrhage isolated to the germinal matrix; grade II is an IVH with normal-sized ventricles that occurs when hemorrhage in the subependymal germinal matrix ruptures through the ependyma into the lateral ventricles; grade III is an IVH with acute ventricular dilation; and, grade IV is a hemorrhage that spreads into the periventricular white matter. IVH is primarily associated with the fragility of the germinal matrix vasculature, disturbances in the cerebral blood flow (CBF), and platelet and coagulation disorders.[26] Risk factors that can disturb CBF include vaginal delivery, low Apgar score, severe respiratory distress syndrome, pneumothorax, hypoxia, hypercapnia, seizures, patent ductus arteriosus, thrombocytopenia, infection,[26] and mechanical ventilation.[16]

The signs and symptoms of IVH may range from subtle and nonspecific to catastrophic. Clinical signs include abnormalities in the level of consciousness, movement, muscle tone, respiration, and eye movement. Catastrophic deterioration involves major acute hemorrhages with clinical signs of stupor progressing to coma, respiratory distress progressing to apnea, generalized tonic seizures, decerebrate posturing, generalized tonic seizure, and flaccid quadriparesis.[26]

Premature infants with grade I–II IVH are at risk for neurosensory impairment, developmental delay, cerebral palsy, and deafness at 2–3 years of age[44]; for those with more severe IVH, especially grade IV, the risk for cerebral palsy can be present in up to 39% of infants, hydrocephalus in up to 37% of infants with declines in cognitive functioning from a mental developmental index of 97 for grade I to 77.5 for grade IV.[206] Clearly, the occurrence of IVH in the premature infant has lifelong implications, even for those with lower-grade hemorrhages.

Efforts to prevent IVH directed at strengthening the germinal matrix vasculature with angiogenic inhibitors and stabilizing the CBF through the reduction of stimulation to the infants have met with varying degrees of success.[27] Prenatal care aiming at reducing premature birth includes preventive obstetric care for high-risk pregnancy, treatment of bacterial vaginosis, and prevention of preterm labor.[165] The use of antenatal steroids (betamethasone, dexamethasone) has been shown to reduce both the severity and incidence of severe IVH.[63] Indomethacin, commonly used to close patent ductus arteriosus, has been shown to prevent IVH as well.[27]

Interventions following IVH include close monitoring and management of ventricular dilation. Acute treatment includes physiologic support to maintain oxygenation, perfusion, body temperature, and blood glucose level. Physical handling is minimized. Management of ventricular dilation includes ventriculoperitoneal shunting or temporary ventricular draining.

Periventricular Leukomalacia

Periventricular leukomalacia (PVL) is a form of cerebral white matter injury consisting of periventricular focal necrosis, with subsequent cystic formation and diffuse cerebral gliosis in the surrounding white matter.[21,260] It is the leading known cause of cerebral palsy (CP) and commonly associated with cognitive impairment and visual disturbances.[260] It is more common in premature than term infants and occurs more frequently with decreasing gestational age and birth weight.[76] The pathogenesis of PVL is mainly linked to ischemia and inflammation in the preterm infant[131] and may occur with intraventricular and periventricular hemorrhage.[2] A case-control study conducted to examine the impact of potential risk factors other than prematurity on the incidence of PVL identified maternal obesity and chorioamnionitis as the only factors associated with PVL regardless of gestational age. Maternal age (> 35), preexisting and gestational diabetes, in vitro fertilization, severe preeclampsia, no prenatal steroids, vaginal delivery, and small for gestational age were not associated with PVL.[111]

PVL is caused by a cascade of events leading to a reduction in cerebral blood flow in the highly vulnerable periventricular

region of the brain where the arterial "end zones" of the middle, posterior, and anterior cerebral arteries meet and is often associated with IVH.[260] Decreased cerebral blood flow leads to ischemia and a decrease in antioxidants. The resulting release of free oxygen radicals and glutamate toxicity primarily target premyelinated oligodendrocytes that predominate in the periventricular regions between 24–34 weeks of gestation.[126] The incidence of white matter damage increased in premature infants with decreased gestational age due to the added presence of an immature vascular supply and impairments in cerebral autoregulation.[132,260] PVL also affects subplate neurons that lie just below the developing cerebral cortex until programmed apoptosis (cell death). Subplate neurons play an essential role in axonal targeting of thalamocortical synapses, and their loss may contribute to motor, visual, and cognitive impairments.[76]

The area primarily affected by intraventricular or periventricular hemorrhaging includes the white matter through which long descending motor tracts travel from the motor cortex to the spinal cord. Because the motor tracts involved in the control of leg movements are closest to the ventricles and therefore more likely to be damaged, bilateral cerebral palsy with primary lower extremity involvement is the most common motor impairment. If the lesion extends laterally, the arms may be involved, resulting in bilateral cerebral palsy with both upper extremity and lower extremity involvement. Visual impairments may also result from damage to the optic radiations.[272]

Cranial ultrasonography (CUS) after birth is commonly used for routine screening of hemorrhaging lesions; later, CUS allows diagnosis of white matter abnormalities such as seen in PVL,[215] which can later be confirmed with magnetic resonance imaging. Later detection at or around term age of white matter abnormalities has the highest correlation with neuropathologic findings and subsequent neurodevelopmental outcome (cerebral palsy and cognitive impairments). Cerebral palsy occurs in more than 90% of infants who develop bilateral cysts larger than 3 mm in diameter in the parietal or occipital areas.[75]

Medical management focuses on prevention of events leading to decreased cerebral blood flow and IVH and includes prevention of intrauterine hypoxic or ischemic events, postnatal maintenance of adequate ventilation and perfusion, avoidance of systemic hypotension, and control of seizures.[260] Prevention of intrauterine hypoxic and ischemic events includes identification of high-risk pregnancies, fetal monitoring, fetal blood sampling, and cesarean section as indicated. Maintenance of adequate ventilation includes avoiding common causes of hypoxemia such as inappropriate feeding, inserting or removing ventilator connections, painful procedures and examinations, handling, and excessive noise. Adequate perfusion can be maintained with appropriate treatment if the infant exhibits apnea and severe bradycardia.

Hypoxic Ischemic Encephalopathy

Hypoxic ischemic encephalopathy (HIE) is the result of either hypoxemia or ischemia leading to the deprivation of oxygen and glucose to the neural tissue. Hypoxemia is a decrease in the amount of oxygen circulating in the blood while ischemia is a decrease in the blood flow able to perfuse the brain. Of the two, ischemia is the more problematic because delivery of glucose to the brain is decreased.[257] HIE is a type of neonatal encephalopathy diagnosed in infants who present with fetal abnormalities (fetal heart rate abnormalities, fetal distress), an acute event followed by a characteristic clinical presentation (respiratory depression, abnormalities of tone, disturbance in cranial nerve function, and often, seizures), an arterial blood gas indicative of metabolic acidosis (pH < 7.0), depressed Apgar scores (≤ 5 at 5 and/or 10 minutes, need for respiratory support), and imaging findings consistent with hypoxic-ischemic disease.[259] Symptoms typically evolve over of period of 72 hours after birth. Ischemia appears to be the main cause of the brain lesions seen in HIE, typically located in the distribution of vascular end zones and border zones and involving neurons and premyelinating oligodendrocytes that are intrinsically vulnerable (e.g., to excitoxicity).[260] The presence of hypoxia and ischemia leads to cellular energy failure, acidosis, glutamate release, intracellular accumulation of calcium, lipid peroxidation, and nitric oxide neurotoxicity, which in turn leads to the destruction of essential components of the cell, culminating in cell death.[257] The extent of the damage will be consistent with the timing, severity, and duration of the hypoxic-ischemic event leading to necrosis and neuronal cell death in the affected zones.

The incidence of HIE ranges between 1 and 8 per 1000 live births.[137] Causes of HIE are multiple and can occur from maternal (e.g., hypotension, insulin-dependent diabetes mellitus, cardiac arrest), uteroplacental (e.g., placental vasculopathy), intrapartum (e.g., prolapsed cord, abruption placentae, traumatic delivery with asphyxia), or fetal complications.[147] The Sarnat and Sarnat[216] staging of encephalopathy using clinical and electroencephalogram criteria, with classification into mild, moderate, and severe stages has been a useful tool in documenting the clinical progression of the severity of the injury and correlates well with neurodevelopmental impairment in infancy.[222] Predictors of neurologic and developmental outcome include abnormal neurologic examination, neonatal seizures, abnormal EEG and MRI with seizures highly correlated with poor developmental outcome at 1 year of age.[95] Neurodevelopmental outcome depends on the severity and extent of the cerebral lesions and is often profound and multisensorial.

Treatment of neonatal HIE includes the provision of adequate perfusion, ventilation, and oxygenation with control of seizures if present.[257] Whole body hypothermia to a target temperature of 33–34°C for 72 hours has been shown to reduce death or morbidity[222] but has not shown to completely resolve the adverse effects of HIE. Hypothermia is instituted within the first 6 hours of age to be most effective. The infant is placed on a precooled blanket and an esophageal temperature probe is inserted through the nose to a level of T6-9 to monitor body temperature for 72 hours.[257] Other neuroprotective interventions being studied include oxygen free radical scavengers and excitatory amino acid antagonists such as allopurinol and glutamate receptor antagonists.[257]

There is a 10% risk of death with moderate HIE, and up to 30% of infants manifest bilateral cerebral palsy with upper and lower extremity involvement and cognitive impairment resulting from cortical and subcortical injury in a parasagittal distribution.[260] In moderate HIE, the infant's initial clinical presentation includes lethargy, moderate feeding problems, high tone, and seizures. In severe HIE, mortality is 60% and the majority of all survivors will have long-term morbidity associated with damage to the thalami, basal ganglia, hippocampi, and mesencephalic structures. Long-term sequelae include cognitive impairment, spastic quadriparesis, seizure disorder, ataxia, bulbar and pseudobulbar palsy, atonic quadriparesis, hyperactivity, and impaired attention. The initial clinical presentation

of the infant with severe HIE includes coma, ventilation support, severe feeding problems, flaccid tone, and seizures.[216]

Pain

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage and is best described by self-report.[105] Obviously the neonate cannot report on pain but may express pain through specific pain behaviors, physiologic changes, changes in cerebral blood flow, and cellular and molecular changes in pain-processing pathways. Adverse sequelae may "include death, poor neurologic outcomes, abnormal somatization and response to pain later in life."[105] The peripheral nervous system is capable of responding to stimuli by 20 weeks postconception. Both the number and types of peripheral receptors are similar to those of adults by 20 to 24 weeks of gestation with a resulting increased density of receptors in the newborn as compared with adult. Spinal cord and brain stem tracts are not fully myelinated; therefore central nerve conduction is slow. There is evidence that pain pathways, cortical and subcortical centers of pain perception, and neurochemical systems associated with pain transmission are functional in premature neonates of 20 to 24 weeks of gestational age.[92]

Most nociceptive impulses are transmitted by nonmyelinated C fibers but also by A delta and A beta fibers, which transmit light touch and proprioception in adults.[105] However, the pain modulatory tracts, which can inhibit pain through release of inhibitory neurotransmitters such as serotonin, dopamine, and norepinephrine, are not developed until 36 to 40 weeks of gestation. As a consequence, the preterm infant is more sensitive to pain than term or older infants.[105,235] Painful stimuli resulting from medical conditions and medical procedures (such as heel sticks, intubation, ventilation, ocular exam, and IV placement) can lead to prolonged structural and functional alterations in pain pathways that may persist into adult life.[39,92] The infant also may associate touch with painful input, which can interfere with bonding and attachment.

Although it is difficult to assess pain in the neonate, the physical therapist working in the NICU should be aware of methods of examination and nonpharmacologic intervention to alleviate pain. Both physiologic and behavioral responses of the neonate to nociceptive or painful stimuli have been identified. Physiologic manifestations of pain include increased heart rate, heart rate variability, blood pressure, and respirations, with evidence of decreased oxygenation. Skin color and character include pallor or flushing, diaphoresis, and palmar sweating. Other indicators of pain are increased muscle tone, dilated pupils, and laboratory evidence of metabolic or endocrine changes.[207] Neonatal behavioral responses to nociceptive input include sustained and intense crying; facial expression of grimaces, furrowed brow, quivering chin, or eyes tightly closed; motor behavior such as limb withdrawal, thrashing, rigidity, flaccidity, fist clenching, finger splaying, and limb extension; and changes in behavioral state.[104] Pain may lead to poor nutritional intake, delayed wound healing, impaired mobility, sleep disturbances, withdrawal, irritability, and other developmental regression.[261]

Nonpharmacologic methods to alleviate pain include decreasing the number of noxious stimuli, decreasing stimulation, swaddling, nonnutritive sucking, tactile comfort measures, rocking, containment, and music.[261] Preterm neonates demonstrated a lower mean heart rate, shorter crying time, and shorter mean sleep disruption after heel stick with facilitated tucking (containing the infant with hands softly holding the infant's extremities in soft flexion) than without (Fig. 29.3).[70,265] Administration of breast milk, sucrose solution, and nonnutritive sucking may help decrease the pain response in newborn infants.[142,220] Sensorial stimulation, which includes subtle tactile, vestibular, gustative, olfactory, auditory, and visual modalities, was found to be effective in decreasing pain responses of premature infants receiving heel sticks.[35]

Other Complications

Gastroesophageal Reflux

Two thirds of otherwise healthy infants will have gastroesophageal reflux (GER) and seek advice from their pediatricians or other health care providers.[148] GER is defined as the passage of gastric contents into the esophagus and is distinguished from gastroesophageal reflux disease (GERD), which includes troublesome symptoms or complications associated with GER. GERD is far less common that GER.[254] GER, considered a normal physiologic process that occurs several times a day in infants, children, and adults, is generally associated with transient relaxations of the lower esophageal sphincter independent of swallowing, which permits gastric content to enter the esophagus.[148] GER typically occurs after meals and causes few or no symptoms. In infants, GER may be associated with regurgitation, spitting up, and even vomiting.[212] The content of the reflux is generally nonacidic and improves with maturation.[148]

GERD can be classified as either esophageal or extraesophageal and be further characterized by findings of mucosal injury on upper endoscopy.[148] Esophageal GERD conditions include vomiting, irritability, poor weight gain, dysphagia, abdominal or substernal pain, and esophagitis.[148] Extraesophageal conditions can include respiratory symptoms, including cough and laryngitis, as well as wheezing in infancy.[223] Dental erosions, pharyngitis, sinusitis, and recurrent otitis media can also be present as the child gets older. Children with neurologic impairment, certain genetic disorders, esophageal atresia, chronic lung disease, cystic fibrosis, and prematurity are at higher risk for GERD than other populations. The incidence of GERD is also lower in breastfed infants compared to formula-fed infants.[188]

FIG. 29.3 Handling is slow and based on infant's cues. (From VandenBerg KA: Individualized developmental care for high risk newborns in the NICU: a practice guideline. Early Hum Dev 83(7):433-442, 2007.)

Diagnosis of GER is typically based on the infant's symptoms and physical examination. If the infant is growing and generally healthy, further testing is not indicated. Diagnostic tests for GERD include esophageal pH monitoring to measure the acidity of the infant's esophagus. A tube is inserted through the infant's nostril or mouth and left in place for 24 hours to monitor the frequency and duration of esophageal acid exposure.[148] X-rays may be needed if an obstruction is suspected, and an upper endoscopy may be done to rule out problems in the esophagus (stricture or inflammation). Upper GI tract contrast radiography is an option when infants are able to tolerate testing. A GERD behavioral scale questionnaire called the Infant Gastroesophageal Reflux Questionnaire (I-GERQ) has been shown to be valid and specific[134] and has been modified by Birch and Newell for premature infants.[40]

Management of GER is done through lifestyle modifications to minimize symptoms and does not require medication. Lifestyle modifications for both GER and GERD include a combination of feeding changes and positioning therapy. Modifying maternal diet in breastfed infants, changing formulas, reducing feeding volume while increasing frequency of feedings, and using thickened feedings are strategies shown to be effective in managing the symptoms of GER and milder symptoms of GERD.[254] Pharmacotherapeutic agents include acid suppressants, antacids, histamine 2 receptor antagonists (H2RAs), proton pump inhibitors (PPIs), and prokinetic agents. Surgical intervention is reserved for children with intractable symptoms or who are at risk for life-threatening complications of GERD. Surgical options include fundoplication, where the gastric fundus is wrapped around the distal esophagus, and total esophagogastric dissociation if fundoplication has failed.

Neonatal Abstinence Syndrome

Neonatal abstinence syndrome (NAS) or neonatal withdrawal is a term used to describe an array of signs and neurobehaviors seen in the newborn after abrupt termination of gestational exposure to substances taken by the mother during pregnancy, principally opioids.[122] Common substances and drugs include opioids such as heroin and methadone, prescription medications containing opioids such as hydrocodone or oxycodone, benzodiazepines, alcohol, antidepressants, and antipsychotics. These drugs are metabolized by the placenta and their metabolites cross the placental barrier through varied diffusion and transportation processes.[37] Further complicating the situation for the exposed infant is the possibility of polysubstance use, psychiatric co-morbidities, and other life factors such as violence, lack of prenatal care, and poor nutrition.[122]

Common clinical presentations in the neonate include high-pitched cry, irritability, sleep-wake disturbances, hyperactive primitive reflexes, transient tone alterations (tremors, hypertonicity), feeding difficulties, gastrointestinal disturbances (vomiting and loose stools), autonomic dysfunction (mottling, tachypnea, sweating, sneezing, nasal stuffiness, fever, yawning), failure to thrive, and seizures.[91] Symptoms of withdrawal usually occur within 72 hours after birth.[219]

The diagnosis of NAS is made based on maternal history, maternal and infant toxicology lab tests, and clinical examination of the infant. The severity of withdrawal or abstinence is commonly scored using the Finnegan Scoring System[91] on a list of 21 symptoms that are most frequently observed in opiate-exposed infants. Each symptom and its associated degree of severity are assigned a score, and the total abstinence score is determined by totaling the score assigned to each symptom over the scoring period. Neurobehavioral functioning and recovery can be assessed with the Neonatal Intensive Care Unit Network Neurobehavioral Scale (NNNs), which was designed to provide a comprehensive assessment of both neurologic integrity and behavioral functions.[144]

Infants with withdrawal symptoms may require admission to the NICU for close monitoring and pharmacologic treatment with closely monitored administration of opioid-containing medications (morphine, tincture of opium, or methadone) or buprenorphine, which is gradually weaned as withdrawal symptoms decline. Contingently to medication, supportive measures are offered to support the infant's ability to eat, sleep, and interact. Supportive therapeutic modalities include nonnutritive sucking, positioning/swaddling, gentle handling, demand feeding, minimal stimulation, and environmental modifications to promote a quiet and subdued environment for the infant.[135]

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is an acute inflammatory disease of the bowel that occurs most frequently in premature infants weighing less than 2000 g during the first 6 weeks of life.[99,157] Although the cause is not known, several factors appear to play a role in the pathogenesis of NEC. Many of these factors involve impaired blood flow to the intestine that results in death of mucosal cells lining the bowel wall making it permeable to gas-forming bacteria that invade the damaged area to produce pneumatosis intestinalis, air in the submucosal or subserosal surfaces of the bowel.[149]

Signs of obstruction of the bowels include vomiting, distention of the abdomen, increased gastric aspirates, passing of bloody stools, retention of stools, lethargy, decreased urine output, and alterations in respiratory status. Diagnosis of NEC is made by physical examination, laboratory tests, and radiography. Radiographic or abdominal ultrasonography is used to follow the course of the disease, with lucent bubbles appearing as the gas-forming bacteria enter the intestinal wall.[117] Medical treatment of NEC includes discontinuation of all oral feedings, abdominal decompression via nasogastric suction, administration of intravenous antibiotics, and correction of fluid and electrolyte imbalances.[45] Surgical intervention is indicated when there is radiographic evidence of fixed, dilated intestinal loops accompanied by intestinal distention, perforation, intestinal gangrene, and abdominal wall edema.

Retinopathy of Prematurity

Retinopathy of prematurity (ROP) is caused by proliferation of abnormal blood vessels in the newborn retina, which occurs in two phases. Phase I is delayed growth of retinal blood vessels after premature birth. Phase II occurs when the hypoxia created during phase I stimulates growth of new blood vessels.[162] The outcome of ROP varies from normal vision to total loss of vision if there is advanced scarring from the retina to the lens resulting in retinal detachment.[242] The incidence of ROP increases with lower gestational age, lower birth weight, and BPD.[162]

The classification system for ROP uses a standard description of the location of the retinopathy using zones and clock hours, the severity of the disease or stage, and presence of special risk factors.[119] The classification system was revised in 2005 to include a rapid progressive form of ROP.[120] Classification of ROP includes five stages.[241] Stage 1 is characterized by a visible

line of demarcation between the posterior vascularized retina and the anterior avascular retina. Stage 2 is characterized by pathologic neovascularization that is confined to the retina and appears as a ridge at the vascular/avascular junction. Stage 3 includes new vascularization and migration into the vitreous gel. Stage 4 is characterized by a subtotal retinal detachment. Stage 5 is complete retinal detachment.

Hyperbilirubinemia

Hyperbilirubinemia, or physiologic jaundice, is the accumulation of excessive amounts of bilirubin in the blood. Bilirubin is one of the breakdown products of hemoglobin from red blood cells. This condition is seen commonly in premature infants who have immature hepatic function, an increased hemolysis of red blood cells as a result of high concentrations of circulating red blood cells, a shorter life span of red blood cells, and possible polycythemia from birth injuries. The pathogenesis of hyperbilirubinemia may be multifactorial and associated with late preterm gestational age, exclusive breastfeeding, and ABO hemolytic disease (blood incompatibility between mother and fetus).[266] The primary goal in treatment of hyperbilirubinemia is the prevention of kernicterus, which is the deposition of unconjugated bilirubin in the brain, especially in the basal ganglia, cranial nerve nuclei, anterior horn cells, and hippocampus. Phototherapy is administered via a bank of lights or fiberoptic blankets.

FOREGROUND INFORMATION

EXAMINATION AND EVALUATION

The purposes of the physical therapy examination and evaluation of infants in the NICU are to identify (1) impairments in body function and structure that contribute to activity limitations and participation restrictions, (2) the developmental status of the infant, (3) the infant's individualized responses to stress and self-regulation, (4) needs for skilled positioning and handling, and (5) environmental adaptations to optimize growth and development. The examination and evaluation must support goals aimed at the infant's participation in age-appropriate developmental activities (e.g., feeding, tucking, self-soothing, social interaction with caregivers) and interactions with the family (e.g., relationship-building, attachment).

Neurobehavioral Observation

The examination and evaluation of high-risk infants are best conducted using a combination of observation and handling techniques that occur over several sessions. Infants hospitalized in the NICU will often not tolerate a full standardized developmental examination. Rather, the physical therapist often formulates a neurobehavioral profile based on observation of the infant's behaviors. That is, the physical therapist describes the infant's successes and difficulties in achieving and maintaining self-regulation and identifies the strategies that best support the infant's own self-regulatory efforts and developmental level of the infant (Box 29.2).[42]

Physical therapy interventions must be appropriately timed and modulated to match the neurobehavioral profile of the infant because handling of medically fragile infants can impose physiologic stress. In accord with family-centered practice, examination and intervention should be in partnership with the family to assist with bonding, facilitate developmentally supportive positioning and handling, and allow for carryover of therapeutic strategies. Lastly, the physical therapist is part of an interdisciplinary team of health care providers. Consistent with the Guide to Physical Therapist Practice (http://guidetoptpractice.apta.org), effective communication and collaboration with professionals from all disciplines and accurate documentation are critical. In the next section, a neurobehavioral framework is presented for examination of the high-risk infant with examples of considerations for specific diagnoses.

BOX 29.2 Recommendations for Physical Therapist Examination and Evaluation of Infants in the NICU

- Protect the infant's fragile neurobehavioral system, particularly for infants who may not tolerate handling or a standardized evaluation.
- Repeat observations over time.
- Partner with parents and members of the NICU team.
- Observe, interpret, and communicate infant behaviors to parents and members of the NICU team.

Behavioral State

States of consciousness were originally proposed by Wolff and have been expanded to include six behavioral states: (1) deep sleep, (2) light sleep, (3) drowsy, (4) quiet awake, (5) active awake, and (6) crying.[273] Thus the terms *states of consciousness* and *behavioral states* are often used interchangeably by clinicians conducting neurobehavioral observations. That is, each state of consciousness is characterized by a set of associated behaviors. Als has expanded this paradigm to include 12 states to distinguish between the adaptive and maladaptive self-regulatory strategies of fragile infants.[8] As infants mature, they are able to transition smoothly and predictably between states. Important observations include: the range, clarity and robustness of behavioral states, the lability and transition patterns from state to state, and the ability to self-sooth. For example, an infant who is 25 weeks of corrected gestational age (CGA) will likely spend most of the day in a light sleep state and will have brief periods of quiet awake. Comparatively, an infant who is 40 weeks of CGA should have longer periods of quiet awake time, particularly before and following feedings. An infant's ability to achieve and maintain sleep and awake states will be compromised by her medical and neurodevelopmental status. The physical therapist plays a key role in educating parents and staff to identify state transitions and optimize the environment (e.g., modifications to light, sound, and interaction) to facilitate smooth transitions to and from sleep.

Infants with neonatal abstinence syndrome (NAS, described later in Common Diagnoses of Infants Hospitalized in the NICU) demonstrate difficulty with state organization.[217] During the examination of the infant with NAS, the PT should carefully observe the infant's state transition patterns, duration of each state, and self-soothing strategies. Before the examination, the infant's care team should be consulted to determine how NAS symptoms are being assessed (e.g., a standardized scoring method) and managed medically.

Autonomic System

During the examination of the autonomic system, the physical therapist obtains the infant's heart and respiratory rate from the cardiorespiratory monitor and observes the infant's

breathing pattern, skin color, visceral signs, twitches, startles, and tremors. In the neonate, heart rates range from 120 to 180 beats per minute and respiratory rate ranges from 40 to 60 breaths per minute.[155] In addition, respiratory effort and digestive function during rest, routine care, handling, and social interaction should be noted. Irregular respirations or paling around the mouth, eyes, and nose; spitting up; straining; bowel movements; and hiccoughs indicate instability or difficulty in achieving self-regulation. Smooth respirations; even color; and minimal startles, tremors, and digestive instability indicate that the demands of the situation have not exceeded the infant's capacity for self-regulation.

Infants with chronic lung disease (CLD, described later in Common Diagnoses of Infants Hospitalized in the NICU) have limited endurance for functional activities. Changes in respiratory effort during the examination should be carefully observed. Costal retractions, head bobbing, and nasal flaring are evidence of increased work of breathing, and their presence, timing, and resolution should be carefully noted.[191] Collaboration with nursing and respiratory therapy staff to facilitate the developmental examination is necessary in order to coincide with optimal timing of diuretic therapy, how modification to oxygen therapy will be managed including the upper and lower parameters of oxygen, and whether the mode of oxygen therapy can be modified for the examination to allow for greater bedside mobility. The examination of the infant with CLD requires frequent breaks, appropriate pacing of activity, and modification of the environment (e.g., lighting, sound, and social interaction) to allow the infant to utilize strategies for self-regulation.

Motor System

Physical therapists are among the most highly qualified members of the health care team to examine the motor system of a fragile infant and interpret findings. Examination should include observation of the infant's muscle tone and posture at rest and active movements during quiet awake periods, routine care, social interaction, and feeding. Movements should be interpreted according to the progression of active flexion patterns that emerge with increasing gestational age. Typically these occur at 32 weeks for lower extremities, 35 weeks for upper extremities, and 37 to 39 weeks for head and trunk.[256] Thus the immature neuromotor system of the preterm infant often precludes independent antigravity flexion movements and predisposes the infant to "compensations," including retracted scapulae, externally rotated and abducted lower extremities, and extension and rotation postures of the cervical spine and trunk.[247] Applying the frameworks previously described, less emphasis is placed on testing reflexes. Rather, the physical therapist examination evaluates reflexes deemed more "functional" (e.g., suck, swallow, palmar and plantar grasp, and early righting responses).[176]

Infants with IVH are at risk for neuromotor impairments that range from mild to severe.[112,164] When examining an infant with IVH, the therapist should note asymmetries in postural muscles and active movements of the extremities, including absence of isolated distal or rotational movements. Clonus should be tested in both ankles. Muscle tone at rest and during active movement should be observed and changes documented. Flexor tone and antigravity movements should be evaluated and movement patterns observed when the infant is awake and alert because behavioral state influences motor system activity and hence infant motor control.

Social Interaction

Infants enter the world predisposed to socialize. While healthy, full-term infants can visually track faces or brightly colored objects and alert to familiar voices and orient to familiar voices,[39] preterm or medically fragile infants may be able to complete these tasks with support and facilitation from the caregiver or therapist.[8,41] A developmental examination may include presenting visual and auditory stimulation to an infant. Physical therapists should judiciously offer opportunities for the infant to socially interact because these complex tasks can be distressful and overwhelm the infant's capacity for self-regulation. The physical therapist plays a critical role in facilitating social interaction between infants and caregivers by modeling developmentally supportive interactions, modifying the environment as needed, and providing parents with anticipatory guidance about the progression of their infant's social interaction skills.[43]

TESTS AND MEASURES

Results of tests and measures are used to: (1) objectively document infant functioning over time, (2) justify the need for developmental interventions in the NICU, (3) evaluate intervention outcomes, and (4) identify the need for developmental follow-up and intervention after discharge from the NICU. Administration of tests to infants who are fragile and have medically complex conditions requires clinical judgment and constant monitoring of physiologic stability to determine whether the administration of the test is well tolerated by the infant and the results are representative of the infant's current abilities. Many infants will not have the physiologic stability required to withstand the stress of being handled during the administration of the test. For infants who are not physiologically stable, testing will have to be either postponed or done in multiple brief periods.

Most useful to the physical therapist are tests and measures of neurologic function, neurobehavioral functioning, motor behavior, and oral-motor function. The tests and measures used by physical therapists vary widely but the Test of Infant Motor Performance (TIMP), designed by and for physical therapists working with infants as young as 32 weeks of gestation, has become the most widely used assessment of infant functional motor behavior in the NICU.[179] Derived from traditional neurobehavioral assessments, the Newborn Behavioral Observation system NBO is a neurobehavioral relationship-building tool that supports the efforts of the physical therapist to establish a rapport with families and share with them developmental information about their infant in a positive context.[179] The Dubowitz, used to establish the gestational age of the infant at birth, provides physical therapists with an excellent opportunity to learn about neurologic maturity of infants in the weeks before term age.[81] Some tests such as the Newborn Individualized Developmental Care and Assessment Program (NIDCAP), Neonatal Behavioral Assessment Scale (NBAS), and the Assessment of Preterm Infant Behavior (APIB) require certification and take as long as 90 minutes to administer, score, and interpret. A team approach and sharing of information between professionals may help in addressing time and cost issues and improve coordination of care. Certification on the TIMP, NIDCAP, NBAS, or APIB will greatly enhance the clinical skills of physical therapists working with young infants. Table 29.3 provides a list of tests and measures commonly used by physical therapists in the NICU and described in this section.

TABLE 29.3 Tests and Measures Used to Assess Infants in the Neonatal Intensive Care Unit

Name	Domain(s) of the ICF Model Covered by the Test or Measure
Neurological Assessment of the Preterm and Full-Term Newborn Infant[a]	Body Structures and Functions Activities
Neonatal Behavioral Assessment Scale (NBAS)[b]	Body Structures and Functions Activities
Newborn Behavioral Observation System (NBO)[c]	Body Structures and Functions Activities Participation
Newborn Individualized Developmental Care and Assessment Program (NIDCAP)[d]	Body Structures and Functions Activities Participation
Assessment of Preterm Infant Behavior (APIB)[e]	Body Structures and Functions Activities
NICU Network Neurobehavioral Scale (NNNS)[f]	Body Structures and Functions Activities
Test of Infant Motor Performance (TIMP)[g]	Body Structures and Functions Activities
General Movement (GM) Assessment	Body Structures and Functions Activities
Neurobehavioral Assessment of the Preterm Infant (NAPI)	Body Structures and Functions Activities
Neonatal Oral-Motor Assessment Scale (NOMAS)[h]	Body Structures and Functions Activities
Nursing Child Assessment Feeding Scale (NCAFS)[i]	Body Structures and Functions Activities Participation
Early Feeding Skills Assessment (EFS)[j]	Body Structures and Functions Activities

Neurological Assessment of the Preterm and Full-Term Newborn Infant

The Neurological Assessment of the Preterm and Full-Term Newborn Infant, commonly known as the Dubowitz, is a systematic, quickly administered, neurologic and neurobehavioral assessment developed to document changes in neonatal behavior in the preterm infant after birth, to compare preterm infants with newborn infants of corresponding postmenstrual age, and to detect deviations in neurologic signs and their subsequent evolution.[80,81] The assessment takes 15 minutes or less to administer and is divided into six sections: (1) posture and tone, (2) tone patterns, (3) reflexes, (4) movements, (5) abnormal signs/patterns, and (6) orientation and behavior. Scoring is based on patterns of response rather than a summary or total score. Although the Dubowitz has a long tradition in the NICU, it is mostly used by physicians and medical residents to establish gestational age at birth by observation. For physical therapists working in the NICU, learning to administer the Dubowitz will contribute to the knowledge and expertise in evaluating the tone and posture of very young infants.

Neonatal Behavioral Assessment Scale

The Neonatal Behavioral Assessment Scale (NBAS) is the most commonly used assessment of infant neurobehavioral functioning in the world today.[47] Used extensively in research, the NBAS includes 28 behavioral items scored on a 9-point scale and 18 reflex items scored on a 4-point scale. The reflex items can be used to identify gross neurologic abnormalities but are not intended to provide a neurologic diagnosis. The NBAS also includes a set of seven supplementary items designed to summarize the quality of the infant's responsiveness and the amount of examination facilitation needed to support the infant during the assessment. These supplementary items were originally included to better capture the quality of behaviors seen in high-risk infants. Therefore the NBAS is well suited for use with the high-risk population. The NBAS is appropriate for use with term infants and stable high-risk infants near term age until the end of the second month of life postterm.

The NBAS has been used extensively in research to study and document the effects of prematurity; intrauterine growth retardation; and prenatal exposure to cocaine, alcohol, caffeine, and tobacco on newborn behavior.[182] The NBAS has also inspired others to develop scales for use with diverse populations. Examples include the Assessment of Preterm Infant Behavior for use with premature infants[10] and the NICU Network Neurobehavioral Scale for use with infants exposed to drugs in utero,[145] both described in this section. The NBAS's central focus on the facilitation of infant competence by a trained and sensitive examiner has also brought to light its powerful qualities as an intervention tool for use with a wide range of families. This subsequently led to the development of a number of NBAS-based relationship-building tools such as the Mother's Assessment of the Behavior of the Infant (MABI),[267] the Combined Physical Exam and Behavioral Exam (PEBE),[127] the Family Administered Neonatal Activities (FANA),[61] and most recently the Newborn Behavioral Observation (NBO) system described in this section.[180] More information on the NBAS is available at www.brazelton-institute.com.

Newborn Behavioral Observation System

As previously mentioned, the NBO is not an assessment tool but a relationship-building tool designed to help practitioners sensitize parents to their child's competencies and uniqueness, support the development of a positive and nurturing parent–infant relationship, and foster the development of the practitioner–parent relationship.[180] The NBO consists of 18 neurobehavioral items used to elicit infant competencies and make observations of newborn behavior, such as sleep behavior, the baby's interactive capacities and threshold for stimulation, motor capacities, crying, consolability, and state regulation.[180] Because it is conceptualized as an interactive behavioral observation, the NBO is administered in the presence of the family

to provide a forum for parents and the practitioner to observe and discuss the newborn's behavior. The NBO takes 45 minutes or longer to administer and can be completed from term age (and in some cases in infants as young as 36 weeks corrected gestational age who are medically stable) to the end of the second month of life postterm. The NBO has been used in diverse settings such as routine pediatric postpartum exams in hospital, clinic, and home settings and is feasible to administer amidst the multiple demands placed on pediatric PTs because it can be easily incorporated into clinical practice settings. Research suggests that the NBO is effective in helping professionals support parents' confidence and competence in caring for their infant and promotes a collaborative relationship between parents and clinicians.[171,181,214] More information on the NBO is available at www.brazelton-institute.com.

Newborn Individualized Developmental Care and Assessment Program

The NIDCAP is a comprehensive approach to care for infants in the NICU that is developmentally supportive and individualized to the infant's goals and level of stability.[8,9] The NIDCAP is inclusive of families and professionals. Completion initially involves direct and systematic observation, without the observer manipulating or interacting, of the preterm or full-term infant in the nursery before, during, and after a caregiving event. Observation is guided by a behavioral checklist to record the caregiving event; positioning; environmental characteristics such as light, sound, and activity; and the infant's behaviors. The observation begins 10 minutes before care, to observe the infant's stability and behavioral reactions when undisturbed; observation continues until care is completed and for another 10 minutes thereafter or until the infant reaches preobservation stability levels. The behavior observation checklist is marked every 2 minutes for heart and respiratory rates, oxygen saturation levels, position of the infant, and the caregiving event taking place. The observation time can be minutes or hours depending on the caregiving event and the stability of the infant. Following this observation, a narrative is written that describes the caregiving event from the infant's perspective, highlighting in great detail the infant's behaviors in relationship with the caregiving and environmental events taking place simultaneously.

Suggestions for caregiving modifications to support the infant's physiologic maturation and strategies at self-regulation are developed from the narrative. A physical therapist trained and certified in the NIDCAP can share this information with the NICU team and provide suggestions for modifying the environment and caregiving activities. These suggestions may pertain to lighting, noise level, activity level, bedding, aids to self-regulation, interaction, timing of manipulations, and facilitation of transitions from one activity to another. The NIDCAP has been found to be most effective in influencing medical outcome,[11,12] and it is suggested to be a causative agent in altering brain function and structure.[6,7] More information and a list of NIDCAP training centers may be obtained at www.nidcap.org.

Assessment of Preterm Infant Behavior

The APIB is a comprehensive and systematic neurobehavioral assessment of preterm and high-risk infants[10,13,14] that is based on the Neonatal Behavioral Assessment Scale.[249] Also viewed as a neuropsychologic assessment, the APIB provides a detailed assessment of infants' self-regulatory efforts and thresholds to disorganization as viewed through the infant's behaviors. The exam proceeds through a series of maneuvers that increase in vigor as well as tactile and vestibular demands to determine the infant's self-regulatory abilities. The APIB may take up to an hour, depending on the level of stability of the infant, whereas scoring may take between 30 and 45 minutes. Writing the clinical assessment report from the APIB may take up to 3 hours, depending on the complexity of the medical history, developmental issues, and recommendations.[184] To be safely handled for the duration of the assessment, the infant must be physiologically stable and 32 weeks of postconceptional age or older. The APIB is appropriate for use with high-risk infants until approximately 44 to 48 weeks of postconceptional age. Training is extensive and available for clinicians and developmental professionals in the NICU and follow-up clinical settings. More information is available at www.nidcap.org.

NICU Network Neurobehavioral Scale

The NICU Network Neurobehavioral Scale (NNNs) is designed for the neurobehavioral assessment of medically stable drug-exposed and other high-risk infants, especially preterm infants between the ages of 30 and 46 to 48 weeks of postconceptional age.[145] The NNNs is used to document and describe developmental and behavioral maturation, central nervous system integrity, and infant stress responses. Although similar to the NBAS in content, the NNNs differs in the order of item administration. For example, items are skipped if the infant is not in the appropriate behavioral state, and deviations in administration are recorded. Additionally, the time required to administer the NNNs is shorter than the NBAS because the NNNs is less focused on infant best performance and the infant-examiner interaction. The NNNs comprises 115 items, 45 of which require specific manipulation of the infant, whereas the other 70 items are observed over the course of the examination. It is divided in three parts: (1) an Examination Scale that includes neurologic items that assess passive and active tone and primitive reflexes and items that reflect central nervous system integrity; (2) an Examiner Ratings Scale that includes behavioral items including state, sensory, and interactive responses; and (3) a Stress/Abstinence Scale that includes seven categories of items designed to capture behavioral signs of stress typical of high-risk infants and signs of neonatal abstinence or withdrawal commonly seen in drug-exposed infants.[145] The NNNs has been used to describe the neurobehavioral profile of infants exposed to methamphetamine,[194,227] cocaine,[213] and marijuana.[74]

Test of Infant Motor Performance

The TIMP is a test of functional motor behavior in infants for use by physical and occupational therapists and other professionals in the NICU and early intervention or diagnostic follow-up settings.[55] The TIMP can be used to assess the infants between the ages of 34 weeks of postconceptional age and 4 months postterm. The test examines postural and selective control of movement needed for functional motor performance in early infancy. The TIMP requires approximately 25 to 45 minutes for administration and scoring.[55] Spontaneous and elicited movements constitute separate subscales. The Observed Scale consists of 13 dichotomously scored items that assess the infant's spontaneous attempts to orient the body, to selectively move individual body segments, and to perform qualitative movements such as ballistic or oscillating movements.[57] Examples of observed behaviors include individual finger and ankle movements, reaching, and aligning the head in midline while supine.

The Elicited Scale consists of 29 items scored on a 5-, 6-, or 7-point hierarchic scale.[73] Elicited behaviors reflect the infant's response to positioning and handling in a variety of spatial orientations and to visual and auditory stimuli. Examples include rolling prone with head righting when the leg is rotated across the body and turning the head to follow a visual stimulus or to search for a sound in prone.

The TIMP has been shown to have excellent test-retest and rater reliability, good construct validity,[57,176] concurrent validity,[56] and predictive validity.[55,58,93,230] The TIMP can be used for the early identification of very young infants at risk for poor motor performance[58,93] and cerebral palsy as early as 2 months of adjusted age.[29,30] A shorter version used for screening purposes, the Test of Infant Motor Performance Screening Items (TIMPSI), is now available.[59] The TIMPSI takes half the time to administer when compared to the TIMP and is considered useful for fragile babies or for rapid screening that reduces the need for full TIMP testing in infants who do well on the TIMPSI. Users of the TIMPSI must have previous knowledge and training of the full TIMP in order to use it effectively. More information about the TIMP and TIMPSI can be found at www.timp.com. A video demonstrating administration of the TIMP is on Expert Consult.

General Movements Assessment

The General Movements (GM) Assessment is an assessment to identify movements and movement patterns that are predictive of cerebral palsy.[205] The underlying motor theory is that the emergence of typical movement patterns follows a predictable course whereby infants' movements can be characterized as writhing (from term to 8 weeks' postterm), fidgety, and voluntary (after 8 to 20 weeks' postterm). The purpose of the GM Assessment is to observe infant movement patterns for deviations from this theorized, typical trajectory. Examples of atypical movements include, in the prenatal period (i.e., until term): a limited movement repertoire or poor differentiation of movements; from term to 8 weeks' postterm: rigid and chaotic movements that lack smoothness and fluency (e.g., cramped synchronous movements); and from 6 weeks to 20 weeks' postterm: absent or abnormal fidgety movements. The GM Assessment is based upon observation or a video recorded while the infant is in an alert behavioral state, which makes it appropriate for even the most fragile NICU infants. It is particularly designed for infants at high-risk for cerebral palsy because the main purpose of the GM Assessment is to predict risk for cerebral palsy.[205]

The GM Assessment has been shown to have excellent (i.e., 90%) interrater reliability when assessed by trained examiners from videos. In addition, the persistence of cramped synchronous movements and the absence of fidgety movements are a valid predictor of cerebral palsy with 95% sensitivity and 96% specificity.[179,205] Both basic and advanced courses are available to learn the GM Assessment (http://general-movements-trust.info/46/invitation).

Neurobehavioral Assessment of Preterm Infant

The Neurobehavioral Assessment of the Preterm Infant (NAPI) is designed to monitor early infant development and evaluate the effects of interventions in the neonatal period. The NAPI is appropriate for infants 32 weeks to term age. The NAPI consists of seven domains: motor development, scarf sign, popliteal angle, attention and orientation, percent sleep, irritability, and vigor of the infant's cry.[136] The NPAI has been shown to have good interrater reliability and stability of the domains over time. In addition, the NPAI has strong construct validity and detects changes over time in neonatal neurobehavioral development in response to intervention. However, the NAPI appears to be weakly correlated with neonatal physiologic measures.[179] More information about the NAPI can be found at: http://med.stanford.edu/NAPI/.

Oral-Motor Examination

Oral-motor examination is an advanced competency. Two useful measures are the Neonatal Oral-Motor Assessment Scale (NOMAS)[46,94] and the Nursing Child Assessment Feeding Scale (NCAFS).[31,244] The NOMAS measures components of nutritive and nonnutritive sucking. Variables assessed during sucking include rate, rhythmicity, jaw excursion, tongue configuration, and tongue movement. A pilot study determined cutoff scores for oral-motor disorganization and dysfunction. The NCAFS assesses parent–infant feeding interaction and evaluates the responsiveness of parents to their infant's cues, signs of distress, and social interaction during feeding. Both of those assessment tools require highly specialized training but provide an excellent diagnostic framework for fragile feeders. Neonatal physical therapists may also find useful the Early Feeding Skills Assessment (EFS) as a tool to assess infant readiness and tolerance for feeding and to identify a profile of an infant's specific skills relative to a developmental progression of oral feeding competencies.[250]

A systematic review of neuromotor and neurobehavioral assessment for preterm infants up to four months corrected gestational age identified GM Assessment, the TIMP, and the NAPI as having strong reliability and validity.[179] Specifically, the NNNs and APIB have strong reliability and validity and are very well suited for research. Similarly, the GM Assessment, TIMP, and NAPI are valid and reliable instruments and appear to be well suited and feasible for use in clinical settings. Finally, the results of the systematic review suggest that the GM Assessment is most accurate in prediction of cerebral palsy.[179]

With the variety of tests and measures available to pediatric PTs practicing in the NICU, the question often arises, What is the best assessment tool? In our experience the answer to this question depends on the purpose of administering the measure and the resources available to support use of the measure in clinical practice. For example, as noted above, tests and measures vary in their purpose from predicting CP (i.e., GM Assessment) to promoting the parent–infant relationship (i.e., NBO). If the primary purposes are to promote parent–infant bonding and to document the infant's self-regulatory behaviors, we often use the NBO in our clinical practice. If the primary purpose is to assess neuromotor skills, especially using a measure that can be repeated in a follow-up program, the TIMP is the choice we would make in our clinical practice. It is common for a combination of these tools to be used to describe the child's developmental abilities. However, as research scientist PTs in the NICU we typically use the TIMP because it has strong psychometric properties and is suited to the research questions we investigate on prediction of outcomes and efficacy of interventions.

Another important consideration in choice of measures is the monetary and time resources available to the PT or development and therapeutic team to choose a particular measure. For example, some measures require extensive resources not only to purchase the measure but also to train with an experienced

clinician to become reliable in administering it (for example, NIDCAP and APIB require training by credentialed instructors). These measures also tend to be lengthy to administer, score, and document. Thus PTs must consider their productivity requirements and workload as well as the capacity of the therapeutic team to integrate lengthy evaluation tools into busy NICU practice. In our experience the PT who is the NICU's developmental specialist is typically trained in the NIDCAP and APIB and typically has the scheduling flexibility to administer these instruments. Moreover, the PT with expertise and mentoring in the NICU can learn to do the TIMP through continuing education courses and training DVDs followed by reliability checks. The TIMP can be included and billed as part of the clinical examination; administration may occur over two sessions, which typically aligns well with scheduling and productivity requirements. Thus the purpose of the assessment, training and resources of the PT, and time should also be considered in selecting clinical assessment tools.

PHYSICAL THERAPIST INTERVENTION

Developmental interventions in the NICU are designed to provide the infant: (1) sensory experiences that are individualized in type and intensity to the infant's developmental and physiologic capacity, (2) movement opportunities that promote positive movement experiences that may lead to adaptive neuroplasticity,[203,226] and (3) developmental support during the transition from the NICU to home provided by caregivers who have confidence and competency in caring for their infant.[83,84]

To the extent possible, developmental interventions should be integrated into the care and day/night routines of the infant. Cost-benefit is an important consideration. We recommend that physical therapist interventions be individualized, framed within a 24-hour care perspective, and part of an interdisciplinary team approach. Physical therapists should carefully assess and reflect on the relevance of all interventions provided in the NICU. Interventions of any kind, especially those based on theory, may in fact be harmful unless consideration is given to an infant's physiologic, sensory, and neurologic capacity and the environment. An infant whose sleep is interrupted numerous times during the day and night may benefit more from sleep protection than from sensory experiences and movement opportunities. Table 29.4 summarizes systematic reviews relevant to developmental interventions in the NICU. A summary of general recommendations for developmental care, direct interventions provided by physical therapists, and discharge planning presented in the following sections is provided in Table 29.5. It is important to note that research evidence is not sufficient to support specific interventions.

Developmental Care

Developmental care is a broadly defined term used in many NICUs and in research to describe the use of environmental interventions, such as sound and light reduction, along with sleep preservation or clustered care in order to support the infant's development.[248] Developmental care also encompasses an individualized developmental care plan followed by all members of the team including the physical therapist. As part of an interdisciplinary team providing developmental care in the NICU, physical therapists have an important role in coordination of care. This includes recommendations related to the NICU environment as a whole or for a specific infant.

The NIDCAP is a highly structured system of assessing the infant's behavioral responses to a caregiving event and subsequent design of an individualized developmental care plan. NIDCAP is typically implemented by an entire NICU with a developmental specialist or physical therapists providing the individualized assessments and recommendations. Although there have been no reports of adverse events or negative consequences from the use of the developmental care or NIDCAP, there is conflicting evidence on the short- and long-term outcomes. There is debate regarding the finding reported in a systematic review indicating that there was no significant difference in developmental outcomes for infants who had care provided with or without a NIDCAP approach.[15,107,186,187] Although some studies reported short-term improvements in developmental outcome, faster weight gain, and shorter length of stay in the NICU, other studies found no lasting gains. Other small studies found improved long-term developmental outcomes.[168] NIDCAP is a specific intervention approach, but many characteristics of NIDCAP are integrated in NICUs that do not specifically follow a NIDCAP approach with standardized assessment intervals. Thus the findings specific to NIDCAP should be considered as one component of developmental care, rather than being mutually exclusive.[107] Physical therapists who provide care in the NICU benefit from the NIDCAP training because it provides an outstanding opportunity to learn about the theoretical background of interaction with medically fragile infants.

Because physical therapists support the goals of developmental care or NIDCAP within a NICU, they must consider environmental factors including light, sound, and pain that are potential stressors for an infant in the NICU.[100,101,140,152,198] These factors need to be considered when the infant is at rest in an isolette or crib as well as during parent or therapist interactions with the infant. The recommendations for light and sound in the NICU are that (1) ambient light should be in the range of 10–600 Lux and (2) acoustic sound should not exceed 45 decibels.[152] Infants in the NICU are bombarded with sounds from the lifesaving equipment, staff, family, and other infants. Preterm birth results in the infant being exposed to sounds of greater than 250 Hz that are typically muted by the uterine walls throughout gestation. Thus the infant born preterm needs to cope with high-frequency sounds that may cause physiologic stress.[198] A Cochrane review on the use of sound-reduction interventions on growth and development of infants born very preterm identified only one study.[4] The single study reported that use of infant ear plugs in the NICU was associated with higher mental developmental index scores on the Bayley at 18 to 22 months. However, the Cochrane review reports the evidence is too limited to consider use in clinical practice.[1,4]

Environmental modification including the use of single infant or family rooms, rather than an open unit with multiple bed spaces, has been found to reduce environmental noise (Fig. 29.4).[151] However, other studies have raised concerns that the limited infant stimulation provided in single family rooms goes too far toward reducing stimulation and results in altered brain development and language delays at developmental follow-up.[202]

As part of general developmental care or environmental changes in the NICU, modification of lighting is common. However, there is debate on the best practices between the use of reduced lighting all day or the use of cycled lighting. Isolette covers or dimming room lights are common practices to reduce

TABLE 29.4 Systematic Reviews on Topics Relevant to Developmental Interventions of the High-Risk Infant in the NICU

Topic of Review	Conclusive Statement
Sound reduction in the NICU[a]	A Cochrane review on the use of sound reduction interventions on growth and development of infants born very preterm identified only one study that completed a RCT or quasi-RCT to determine if reduced sound impacted infant outcomes. The single study reports that use of infant ear plugs in the NICU were associated with higher mental developmental index scores on the Bayley at 18 to 22 months; however, the Cochrane review reports the evidence is too limited to consider use in clinical practice.
Developmental care[b]	The evidence suggests that these interventions may have some benefit to the outcomes of preterm infants; however, there continues to be conflicting evidence among the multiple studies. Therefore there is so far no clear evidence demonstrating consistent effects of developmental care interventions on important short- and long-term outcomes.
Developmental care[c]	No significant difference in developmental outcomes for infants who had care provided with or without a NIDCAP approach. Although some studies report short-term improvements in developmental outcome, faster weight gain, and shorter length of stay in the NICU, other studies find no lasting gains. The high cost of providing NIDCAP needs to be considered against these findings of limited to no developmental gains.
Cycled lighting[d]	A cycled light systematic review found that cycled light may be beneficial compared to continuous bright light. Infants in the cycled light groups may sleep more, have increased activity levels during the day, and demonstrate earlier feeding readiness or fewer days of ventilator support. However, this interpretation is based on few studies for each outcome measures and with limited comparison between reduced light and cycled light.
Light reduction in the prevention of retinopathy of prematurity[e]	Considerable research has been done on this, and the evidence suggests that bright light is not the cause of retinopathy of prematurity and it does not add to the problem.
Infant position during mechanical ventilation[f]	There is no clear evidence that body position during mechanical ventilation in newborn babies is effective in producing relevant and sustained improvement. However, putting infants on assisted ventilation in the face-down position for a short time slightly improves their oxygenation and infants in the prone position undergo fewer episodes of poor oxygenation.
Nonnutritive sucking[g]	The review of literature suggests that weight gain was similar with and without use of a pacifier. In two studies, preterm infants with pacifiers had shorter hospital stays (lower hospital costs), showed less defensive behaviors during tube feedings, spent less time in fussy and active states during and after tube feedings, and settled more quickly into sleep than those without pacifiers. Their transition to full enteral (by tube or mouth) or bottle feeds (three studies) and bottle-feeding performance, in general (one study), was easier. No negative outcomes were reported.
Physical activity programs for promoting bone mineralization and growth[h]	This review found that physical activity might have a small benefit on bone development and growth over a short term. There were inadequate data to assess long-term benefits and harms. Based on current knowledge, physical activity programs cannot be recommended as a standard procedure for premature babies.
Massage[i]	The review only included randomized controlled trials, studies in which a group of babies received massage or "still, gentle touch," in which nurses put their hands on babies but did not rub or stroke them. In most of these studies, babies were rubbed or stroked for about 15 minutes, three or four times a day, usually for 5 or 10 days. On average, the studies found that babies receiving massage, but not "still, gentle touch," gained more weight each day (about 5 g). They spent less time in the hospital, had slightly better scores on developmental tests, and had slightly fewer postnatal complications, although there were problems with how reliable these findings are. The studies did not show any negative effects of massage.
Early developmental intervention programs after hospital discharge[j]	The early developmental intervention programs in this review had to commence within the first 12 months of life, focus on the parent–infant relationship or infant development, and, although they could commence while the baby was still in hospital, they had to have a component that was delivered postdischarge from the hospital. A review of trials suggests those programs for preterm infants are effective at improving cognitive development in the short to medium term (up to preschool age). There is limited evidence that early developmental interventions improve motor outcome or long-term cognitive outcome (up to school age). The variability in the intervention programs limits the conclusions that can be made about the effectiveness of early developmental interventions.
Early developmental intervention programs after hospital discharge[k]	This update to the above study suggests that a little more evidence is present for the ability to interventions programs post NICU discharge to improve motor outcomes in the short term and cognitive outcomes through the preschool years.
Positioning for acute respiratory distress[l]	A total of 21 studies were assessed altogether. Three quarters of the 436 children were preterm babies and were mostly (71%) ventilated by machine. The prone position was better than supine for oxygenating the blood, but the difference was small. The increase in oxygen saturation on average increased by 2%. This finding was based on eight studies (183 children, 153 preterm and 95 ventilated) measuring this outcome. The rapid rate of breathing with respiratory distress was slightly lower in the prone position (on average four breaths/min lower) based on five studies (100 infants aged up to 1 month, 59 ventilated). There were no obvious differences with other positions. Note: It is important to remember that these children were hospitalized. Therefore given the association of the prone position with sudden infant death syndrome (SIDS), the prone position should not be used for children unless they are in hospital and where their breathing is constantly monitored.

TABLE 29.4 Systematic Reviews on Topics Relevant to Developmental Interventions of the High-Risk Infant in the NICU—cont'd

Topic of Review	Conclusive Statement
Kangaroo mother care to reduce morbidity and mortality in low birth weight infants[m,n]	Kangaroo mother care (KMC) involves skin-to-skin contact between mother and her newborn, frequent and exclusive or nearly exclusive breastfeeding, and early discharge from hospital. Compared with conventional care, KMC was found to reduce severe illness, infection, breastfeeding problems, and maternal dissatisfaction with method of care and improve some outcomes of mother-baby bonding. There was no difference in infant mortality. However, serious concerns about the methodologic quality of the included trials weaken credibility in these findings. More research is needed.

TABLE 29.5 General Recommendations for NICU Practice Based on the Authors' Interpretation of the Limited Evidence for Developmental Care and Physical Therapy in the NICU

Developmental Care	Reduce light and noise Clustered care with limited interruptions during sleep Culture of parent participation in caregiving including use of kangaroo mother care/skin-to-skin holding, frequent visitation, and infant interaction Pain management
Direct Interventions	Positioning with extremities and head in midline, arms and legs flexed close to the body Massage ideally provided by parents in the form of firm touch Graded movement experience timed with infant's readiness for social engagement
Discharge Planning	Family support Education and readings on developmental cues and developmental supports available at home Referral to NICU follow-up programs and early intervention

FIG. 29.4 Single-room NICU. (From Lester BM, Miller RJ, Hawes K, et al.: Infant neurobehavioral development. Semin Perinatol 35(1):8-19, 2011.)

light exposure. Cycled lights typically included low light levels for 12 hours at night and unrestricted light for 12 hours during the day. A systematic review found that cycled light may be beneficial compared to continuous bright light.[175] Infants in the cycled light groups may sleep more, have increased activity levels during the day, and demonstrate earlier feeding readiness or fewer days of ventilator support. However, this interpretation is based on few studies for each outcome measure and with limited comparison between reduced light and cycled light.[100]

Kangaroo Mother Care, or skin-to-skin holding, is an intervention provided by parents in which the infant is held by a parent, usually the mother, on the parent's bare chest (Fig. 29.5). The experience of kangaroo care has been shown to foster maternal attachment, improve maternal confidence in caring for her premature infant,[125] and improve the odds of breastfeeding at discharge from the NICU and into the first year of life.[108,183] A systematic review of kangaroo care suggested that mothers have reduced stress and depression following the use of kangaroo care.[23] In addition, mother–child interactions are improved in the NICU and some studies suggest through 6 months of age.[23] Feldman showed that preterm infants receiving kangaroo care in the NICU had more mature neurobehavioral profiles on the NBAS when compared to control infants.[89] Being held in the kangaroo position (on the mother's chest facing the mother with a cloth strip holding the infant in place for 8–12 hours per day) may also contribute to the development of increased trunk and leg flexion. One study showed increase surface electromyography activity following

FIG. 29.5 Kangaroo mother care. (From Coughlin M: The Sobreviver (Survive) Project. Newborn Infant Nurs Rev 15(4):169-173, 2015.)

FIG. 29.6 Preterm infant placed in the left sidelying position. The arms and legs are in a flexed, midline position close to the body. (From Gouna G, Rakza T, Kuissi E, et al.: Positioning effects on lung function and breathing pattern in premature newborns. J Pediatr 162(6):1133-1137, 2013.)

96 hours of being positioned in the kangaroo care position.[77] The overwhelming data supporting the benefits and limited risks of kangaroo care lead to a 2013 consensus statement encouraging the international adoption of the standard use of kangaroo care in the care of all infants born preterm.[86] Although this practice has been adopted widely in NICUs, physical therapists can play an important role in encouraging kangaroo care as part of routine developmental care. In addition, physical therapists can work with families to engage them in caring for their infant and providing developmental support in the first weeks after birth.

Some NICUs have changed their environment from a large room with multiple beds to single-family or infant rooms based on recommendations for reduced sound, reduced or cycled light, and use of kangaroo care. Some studies suggest that single-family rooms increased family engagement and parents' sense of control and decreased maternal stressors and led to increased use of kangaroo care resulting in slight improvement in medical and developmental outcomes.[109,146] A systematic review of medical and development outcomes in single rooms suggested lower infection rates and possibly shorter length of stay.[221] While the majority of studies still suggest benefit, as noted earlier, other studies suggest that single-family rooms may be associated with delayed language.[101]

Direct Interventions by Physical Therapists

Infants in the NICU present with a wide range of conditions that have an impact on their later developmental outcome, including prematurity, neonatal seizures, intraventricular hemorrhage, stroke, hydrocephalus, respiratory distress syndrome, bronchopulmonary dysplasia, cystic fibrosis, spina bifida, arthrogryposis, and osteogenesis imperfecta. These conditions lead to impairments that affect the infant's activity levels and interactions with parents and caregivers. Physical therapists provide direct intervention and help parents learn how to provide movement experiences for their infant born preterm to address impairments in body functions or structures and/or activity limitations. See the section on discharge planning for additional parent-therapist intervention approaches.

A review of the literature on interventions in the NICU indicates that interventions vary in focus and scope. It is difficult to reach consensus on effectiveness of any particular intervention because of the limited number of studies of well-defined interventions, the variety of outcome measures used, and heterogeneity of samples. We will provide a brief review of interventions focusing on positioning, massage, facilitated handling, physical activity to promote bone mineral density, and parent education because these interventions have more evidence than any others. Some consensus is available on these intervention modalities through systematic reviews, well-designed research trials, or reviews published by the Cochrane Collaboration, an international not-for-profit organization that provides up-to-date systematic reviews about the effects of health care (see Table 29.5).

Positioning

The musculoskeletal system of a preterm infant is very susceptible to positional deformities resulting from NICU positioning. In addition, infants born preterm may demonstrate instability of the autonomic nervous system in response to changes in position or a lack of postural support. Physical therapists have an important role in collaborating with the nursing team and parents on recommendations for positioning, especially for very preterm infants. Although some evidence exists for specific positioning devices or strategies,[128,159,252] there is not enough evidence to support a specific approach. As a result, physical therapists typically apply general positioning principles and work with nursing staff to implement positioning recommendations.[195]

Generally, the goals of positioning are to encourage midline head position, arms and legs flexed and close to the body. This simulates the intrauterine environment that contributes to typical skeletal alignment (Fig. 29.6). This position is often achieved with the use of blanket rolls or positioning aids to encourage alignment and aid in autonomic nervous system regulation.[103,159] Infants cared for with support of midline head position, flexed and supported extremities, had improved leg

and shoulder alignment during functional tasks and improved quality of movement.[90,174]

When positioning a young infant who is medically fragile, skeletal alignment and the impact of the position on cerebral blood flow are important considerations. Infants who are medically fragile can have decreased jugular blood flow, decreased tissue oxygenation, and increased cerebral blood flow velocities when they are positioned in 90 degrees of cervical rotation. Use of midline head positioning and head elevation 30 degrees for 72 hours after delivery is considered as best practice to reduce the incidence of IVH.[161] After 3 days of age a variety of positions including prone, supine, and sidelying are recommended to promote skeletal alignment and reduce the likelihood of skeletal deformations including plagiocephaly and scaphocephaly.[253]

Although prone position has been thought to improve oxygenation, a 2012 Cochrane review found there is no evidence of improved apnea, oxygenation, or bradycardia in any position in infants who are breathing spontaneously.[49] However, there is some evidence that infants have better gastric emptying and reduced stress when positioned in prone.[60,64] Infants requiring phototherapy can receive adequate light exposure to reduce bilirubin positioned in either prone or supine.[38]

The AAP recommends that all infants sleep in supine to reduce the rate of sudden infant death syndrome. However, many infants are cared for in the NICU using a prone position. Although there is no evidence base to guide the time to transition preterm infants to supine, it must be done in the hospital before discharge to help the infant adjust to supine and facilitate the transition to home.[172] Hospitals with policies regarding transition to supine are more consistent in making the transition 1 week prior to discharge. Those without hospital policies are more likely to transition infants only 24 hours prior to discharge, which may add to the stress experienced by families during this difficult time.[173]

Massage

Massage for infants in the NICU ranges from light pressure with the hand staying still in the youngest infants to a kinesthetic program of providing full body infant massage, visual and vestibular input in infants nearing discharge. Massage is typically provided about 60 minutes before a feeding and, like all interactions, needs to be progressed in response to the infant's cues.

A Cochrane review and recent meta-analysis summarized the evidence on massage that included both tactile and kinesthetic stimulation in most of the studies. Massage with kinesthetic stimulation increased weight gain and decreased length of stay by 4.4 days but does not appear to impact NBAS scores.[258,264] No studies found negative effects of the massage interventions. Only a few studies have compared massage to other interventions. One found that massage and kangaroo care were equally effective in reducing length of stay and increasing weight in infants after 5 days of intervention 3 times per day. While additional research is needed on the effect of massage provided by staff versus parents, the similar results between massage and kangaroo care suggest that parents can support their infant's development through either intervention.

Physical Activity

Infants born preterm are at high risk for osteopenia, which may increase with limited physical activity in the NICU. Several studies have been conducted to determine the efficacy of physical activity programs to increase bone mineral density and weight gain. The physical activity programs typically consist of extension and flexion, range-of-motion exercises with end range holding in flexion to elicit pushing against resistance of the infant's upper and lower limb movement. Physical activity programs are administered for several minutes at a time several times a week for at least 2 weeks. A Cochrane review concluded that physical activity for hospitalized preterm infants may have small short-term but no long-term effects on bone mineralization and growth.[64] Physical activity programs are not recommended based on the evidence and high staff time commitment required.[218]

Facilitated Movement

Physical therapists and parents can play a role in supporting the development of infants born preterm during medical procedures. Facilitated tucking during suctioning has been found to reduce stress and pain in some studies while not in others.[3,106,197] Supporting an infant during painful or stressful caregiving procedures provides the physical therapist the opportunity to observe the infant's behavioral responses and identify individualized therapeutic strategies to enhance the infant's efforts at self-regulation. In addition, facilitation may promote movement patterns similar to those used by the infant while in utero and reduce maladaptive motor behaviors during caregiving.

Although the primary role of the physical therapist in the NICU is to support the development of the infant through a team-based intervention, there are times when direct intervention is warranted. However, direct therapy in the NICU needs to be based on the infant's readiness to interact and in support of the team and family goals to enhance development. Only a few studies have evaluated the outcomes from direct therapy intervention in the NICU, providing mixed results that are preliminary in nature.[53,84,96] Interventions that combine direct intervention and parent education in order to prepare the parent to provide the interventions are ideal.[231] Spittle et al. published a Cochrane review summarizing the findings of interventions that started in the NICU in most cases and continued into the home. Although additional research is needed, the review concluded that early intervention including parent and therapist interaction with the infant could improve cognitive outcomes at least in the short term.[231,232] Collaboration with parents will allow for the goal of daily positive motor and developmental experiences prior to NICU discharge and into the community.

Discharge Planning

Parents are a consistent presence in the lives of most infants born preterm and are best suited to support the infant's development. This process must start at the time of NICU admission and continue during the transition to home after NICU discharge. In the NICU, parents can play a role in many aspects of caregiving. As discussed previously, parents can provide support through kangaroo care, facilitated tucking, and incorporating sensory monitoring practices into their interaction. However, all NICU staff must be involved in this goal of engaging parents in the developmental care of their preterm infant.[82]

In preparation for the infant's discharge to home, parents may benefit from more focused education on ways to support development. Many parents report they are not sure how to support their infant's development in the first weeks and months at home.[83] Parent education programs on caregiving have been developed and implemented by nursing staff or developmental care teams in the NICU with a goal of reducing maternal stress

or increasing mother–child interactions.[115,181,214] However, few interventions have focused on helping parents learn to support development through social interaction and age-appropriate play in the first months of life.[53,84] Physical therapists working in the NICU have an important role in helping parents prepare to support their infant's development during and after the transition to home. Physical therapists can help parents build a developmentally supportive relationship with their infant prior to discharge that will extend into the home environment. Working with parents to identify the infant's readiness cues for social interaction in the NICU will increase their ability to identify opportunities for tummy time, reaching, and other developmental play that support motor and cognitive development in the first year of life.

In addition to helping parents support their infants' development, physical therapists have a key role in helping to engage parents in NICU follow-up programs and community-based interventions. Although providers in the NICU may assume that all parents will seek developmental services after discharge, evidence suggests this is not always the case. In one study, the degree of parental developmental concerns and intent to access early intervention services were more related to maternal factors than infant factors, including the presence of IVH or white matter brain injury.[201] This suggests that prior to discharge NICU providers should open a dialogue about risk factors and parental beliefs and share any available evidence on time-sensitive interventions while recognizing the parents' right to opt in and out of developmental services during the transition to home.

Developmental Follow-up

For many high-risk infants and their families, life after discharge from the NICU may involve referrals to a number of medical specialists (e.g., pulmonary, neurology, neurosurgery, ear nose and throat, gastroenterology, craniofacial, orthopedics), a local early intervention program, and developmental follow-up to a hospital-based multidisciplinary clinic. Public law 108–446, known as the Individuals with Disabilities Education Improvement Act of 2004, or IDEA, ensures access to a free and appropriate public education to all children with disabilities. Part C of that law guarantees access to early intervention that may include physical therapy services in the home or other natural settings through local early intervention programs for children from birth up to age 3. Chapter 30 discusses early intervention services under IDEA.

In some states, infants born very preterm with neonatal brain injury or other conditions warranting care in an NICU are automatically eligible for early intervention services. In other states, infants are required to show developmental delays. For infants who are eligible, referral before NICU discharge can ease the process for parents. The physical therapist plays an important role in the transition of infants and families to early intervention services. It is vital that therapists know the local laws and policies, have access to educational materials, and understand the referral process. The physical therapist should communicate with the therapist or agency providing early intervention services to the infant and family. Ideally, providers from the local early intervention agency would meet the family before the infant's discharge from the NICU and thus ensure a smooth and less stressful transition into the family's community. When this situation is not possible, the physical therapist can make contact with the community therapist and provide as much information as possible on the infant's current development and interventions while in the NICU. Medical and developmental documentation may be helpful or necessary during the process of determining eligibility for early intervention. For infants who are not eligible at NICU discharge but may be in the future, providing parents with an understanding of what early intervention is and when to contact their local program is recommended. Referral to early intervention can be a complicated process for NICU providers, parents, and families. As in many settings, a navigator to help families complete the enrollment process for early intervention prior to or following discharge from the NICU is recommended.[150]

Infants born preterm or with NICU stays are at risk for developmental delays and medical complications that require ongoing follow-up. The onus is on NICU staff to ensure that the parents of each infant have a clear understanding of the recommendations for both medical and developmental follow-up care.[78] The AAP and other organizations have outlined recommendations for follow-up of preterm infants.[17,78,118,263] Many level III and IV nurseries as well as hospitals with neonatology fellowship programs in medicine and physical therapy have a developmental or NICU follow-up clinic for high-risk infants. Clinics vary in staffing and criteria for follow-up care. Factors such as birth weight, gestational age, Apgar scores, time on a ventilator, IVH, seizures, and environmental factors such as maternal drug or alcohol use are commonly used criteria. These follow-up programs monitor the health outcomes of graduates of the NICU.[238]

Results of developmental assessments administered at the follow-up clinic are useful in determining whether specialized therapy services are necessary beyond the provision of general recommendations for development and parent education. Referrals for nutrition, audiology, and ophthalmology also are made when necessary. As a team member in the follow-up clinic or early intervention, the physical therapist plays an important role in the examination and monitoring of infant neuromotor development, provides parent education and anticipatory guidance, and assists the family with coordination of care and referrals to other professionals and community agencies when appropriate.

RESOURCES AND PROFESSIONAL DEVELOPMENT

According to the practice guidelines endorsed by the American Physical Therapy Association (APTA),[245] physical therapists in the NICU should meet a series of competencies across multiple domains of neonatal clinical practice ranging from theoretical frameworks to social policy governing practice involving high-risk infants. In addition, physical therapists should participate in a minimum of 6 months of precepting in the NICU. Many NICUs lack an established training program where experienced clinical specialists provide precepting and ongoing mentoring to physical therapists new to neonatal care. Physical therapists may need to advocate for education and training resources.

Fellowship and Residency Programs

Advanced training in neonatal physical therapy is available through pediatric residency and neonatal fellowship programs that are accredited by the American Physical Therapy Association (APTA). Currently, there are 17 APTA pediatric residencies offered across the United States. Although the focus of pediatric residencies is general pediatric physical therapy,

many residencies offer opportunities for clinical practice in the NICU. More information about the APTA-accredited pediatric residency program can be found at: http://www.abptrfe.org/apta/abptrfe/Directory.aspx?navID=10737432672.

In addition, there are currently two APTA-accredited neonatology fellowship programs. The goal of the fellowships is to prepare physical therapists for evidence-based, ethical, and appropriate neonatal physical therapist practice. More information about the fellowships is available at http://www.abptrfe.org/apta/abptrfe/Directory.aspx?ProgramType=Fellowship&navID=10737432673.

NICU Special Interest Groups

An additional resource for physical therapists working in the NICU is the Neonatology Special Interest Group within the Section on Pediatrics of the APTA. Members can access resources such as clinical guidelines, APTA conference activities (e.g., Section on Pediatrics Annual Conference) related to neonatal physical therapist practice, and resources lists. There are also a number of opportunities to connect with other neonatal physical therapists either through social media and member groups. More information about the Neonatology Special Interest Group is available at: www.pediatricapta.org/special-interest-groups/neonatology/index.cfm.

Therapists Who Are New to the NICU

Many therapists who practice in the NICU have previous experience with infants in outpatient or early interventions settings and in working with critically ill children in the pediatric intensive care unit. Therapists who are considering providing care in the NICU are encouraged to start their training with a mentored experience in the NICU follow-up program. This provides the therapist with an understanding of the likely range of outcomes for infants in the NICU. Onsight mentorship from an experienced NICU therapist is vital. Beginning with observation and gradually transitioning to supervised and then independent interaction with infant is considered best practice. Therapists new to the NICU should begin working with the least medically fragile infants approaching discharge and gradually increase acuity. Therapists will also benefit from shadowing other health care disciplines in the NICU to gain an appreciation for the role of nursing, physicians, and respiratory therapists in the NICU.

Cases Scenarios on Expert Consult

The website includes three case scenarios. The first is a video demonstrating a physical therapy intervention in a Level II NICU. One written case is about an infant born extremely preterm who has significant respiratory difficulties, which affect his oral feeding development. The second is about an infant, born full-term, with Down syndrome. There is concern from the medical team that the infant's mother has not bonded with her daughter. The website also includes a video demonstrating administration of the Test of Infant Motor Performance (TIMP).

Infants, Toddlers, and Their Families: Early Intervention Services Under IDEA

Lisa Chiarello, Tricia Catalino

This chapter focuses on early intervention services in home and community settings under the US Individuals with Disabilities Education Improvement Act (IDEA) of 2004.[107] Part C of the IDEA authorizes federal assistance to states to implement a system of early intervention services for eligible infants and toddlers, from birth to 3 years of age, and their families. The law mandates family-centered services in natural environments to promote the child's development and participation in daily activities and routines. A relationship-based approach to early intervention in which the relationships among family members, providers, and administrators are valued as the foundation to effective care is recognized as best practice.[57] The organizational system climate for Part C can be challenging as the federal and state governments strive to fiscally support this program. Providing services in early intervention is complex but very rewarding as therapists advocate for quality care for young children and their families. Therapists practicing in early intervention truly have the opportunity to integrate the science and art of physical therapy. This chapter critiques theory, policy, and methods of service delivery and analyzes research. The role of the physical therapist in this service system is discussed, with an emphasis on both unique contributions and the team processes needed for collaborative decision making and service provision. This chapter describes the components of our conceptual framework for physical therapy practice in early intervention presented in Fig. 30.1. These components include the factors (policy, philosophy, and people) and processes (evidence-informed service delivery, family engagement, team collaboration, and service integration) that influence child and family outcomes in early intervention.

BACKGROUND INFORMATION

Early intervention is a multifaceted process to support infants and toddlers with developmental delay and disability and their families. Early intervention is predicated on the notion that early childhood is a sensitive period in development and families have the primary role of nurturing and providing early learning experiences for their children. The concept of sensitive period in early childhood refers to the significant influence the environment and experiences have on brain maturation during this time.[100] Shonkoff and Meisels[130] defined early intervention as follows:

> Multidisciplinary services … to promote child health and well-being, enhance emerging competencies, minimize developmental delays, remediate existing or emerging disabilities, prevent functional deterioration, and promote adaptive parenting and overall family functioning. These goals are accomplished by providing individualized developmental, educational, and therapeutic services for children in conjunction with mutually planned support for their families. (pp xvii–xviii)

This definition embraces the concepts of prevention, remediation, experiential learning, individuality, and family centeredness and is consistent with the definition of early intervention in IDEA. IDEA defines early intervention as follows:

> Developmental services that are provided under public supervision, are provided at no cost except where federal or state law provides for a system of payments by families, including a schedule of sliding fees, and are designed to meet the developmental needs of an infant or toddler with disability in any one or more of the following areas: physical development; cognitive development; communication development; social or emotional development; or adaptive development.

In addition, IDEA stipulates that services are selected in collaboration with the parent. This definition emphasizes the service delivery aspect of early intervention; the primary premises are that services must be developmental and involve parent collaboration. Hebbeler and colleagues[70] have discussed that the Part C early intervention program is diverse in that it serves as both an intervention program to ameliorate the effects of disability for children with moderate to severe involvement and as a prevention and intervention program for children at risk for delay or with mild involvement who will attain skills comparable with their peers.

To be effective in early intervention, physical therapists must embrace responsibilities that go beyond technical knowledge and skill. Early intervention providers are required to partner with families and other providers, deliver services in multiple environments, comply with federal and state policy, and provide interventions informed by current evidence and principles of best practice. In addition to expertise in motor development, adaptive function, and self-care, it is essential that physical therapists have practical knowledge of family ecology and children's social, emotional, cognitive, communication, and language development.[89,131]

IDEA PART C: INFANTS AND TODDLERS

The Education of the Handicapped Act Amendments of 1986[108] provided for family-centered services for infants and toddlers from birth to 3 years of age. This law was subsequently reauthorized and amended as Part C of the Individuals with Disabilities

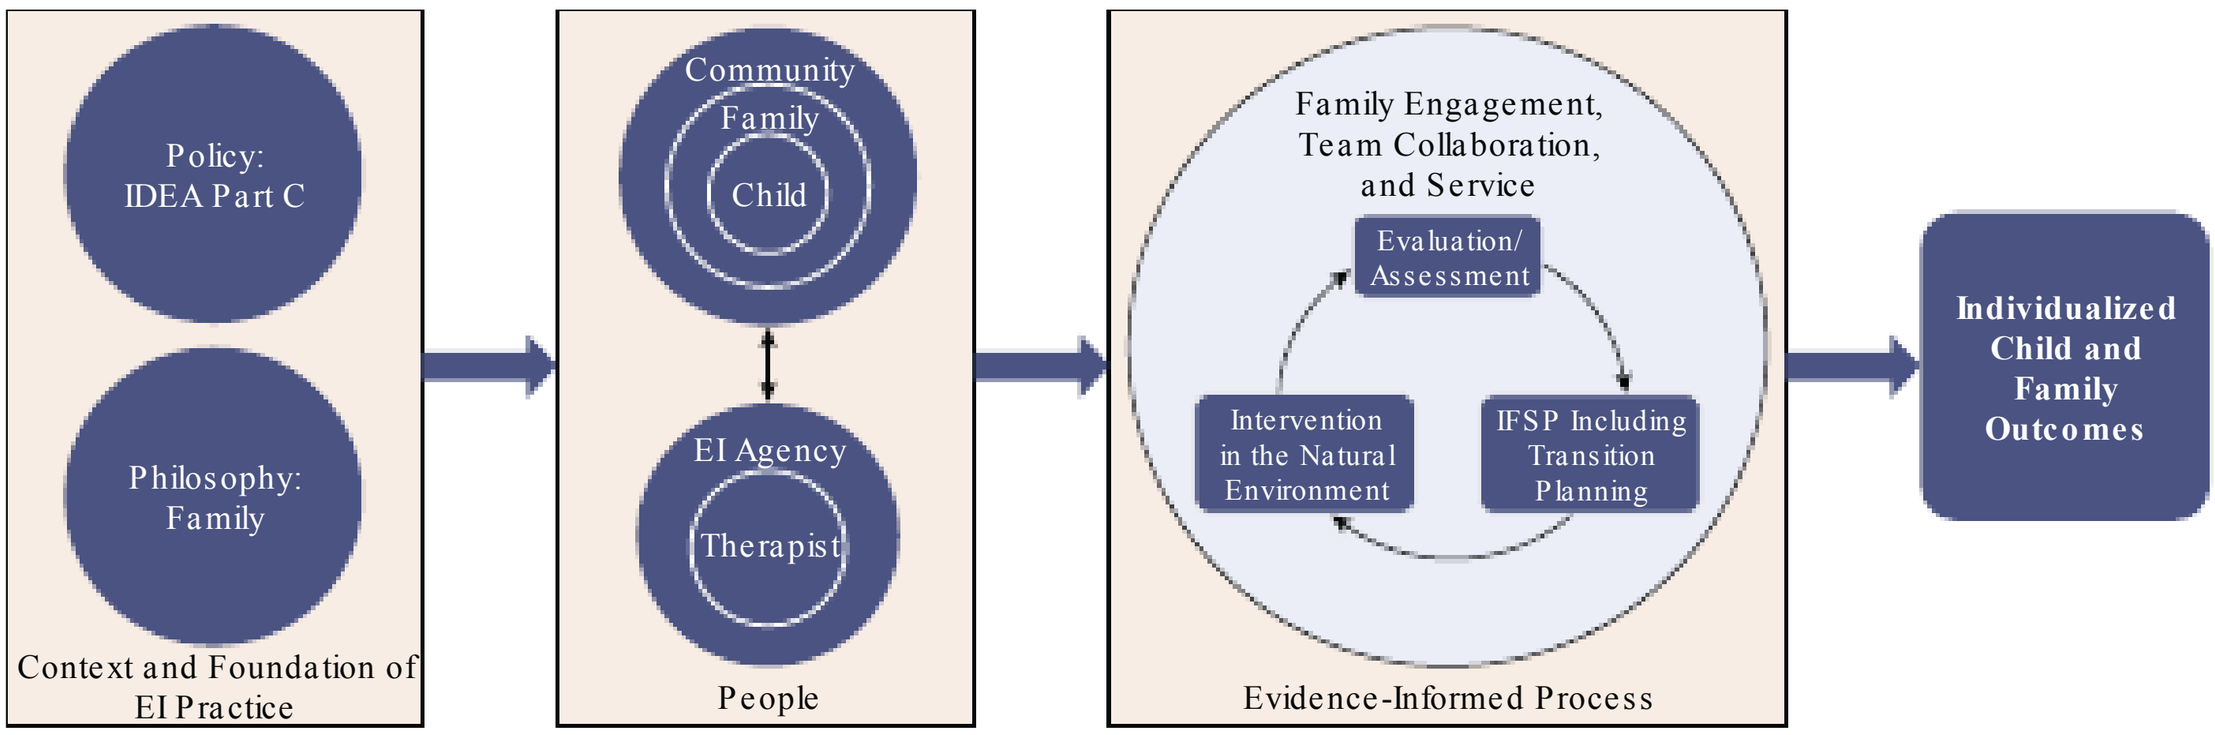

FIG. 30.1 Conceptual framework for physical therapy practice in early intervention.

Education Act Amendment (IDEA) of 1997[106] and Individuals with Disabilities Education Improvement Act (IDEIA) of 2004,[107] commonly referred to as IDEA. Part C mandates early intervention services based on the following declaration:

> [That] Congress finds that there is an urgent and substantial need (1) to enhance the development of infants and toddlers with disabilities and to minimize their potential for developmental delay, and to recognize the significant brain development that occurs during a child's first 3 years of life; (2) to reduce the educational costs to our society, including our Nation's schools, by minimizing the need for special education and related services after infants and toddlers with disabilities reach school age; (3) to maximize the potential for their independently living in society; (4) to enhance the capacity of families to meet the special needs of their infants and toddlers with disabilities; and (5) to enhance the capacity of state and local agencies and service providers to identify, evaluate, and meet the needs of all children, particularly minority, low-income, inner-city, and rural children and infants and toddlers in foster care. (IDEIA, Part C, Sec. 631)

BOX 30.1 Early Intervention Services Included in the Individuals With Disabilities Education Improvement Act

- Family training, counseling, home visits
- Special instruction
- Speech-language pathology and audiology services and sign language and cued language services
- Occupational therapy
- Physical therapy
- Psychological services
- Service coordination
- Medical services only for diagnostic or evaluation purposes
- Early identification, screening, and assessment services
- Health services necessary to enable the infant or toddler to benefit from the other early intervention services
- Social work services
- Vision services
- Assistive technology devices and services
- Transportation and related costs necessary to receive early intervention services

The legislation details the conditions that a state must meet in order to receive federal funding. In addition, Part C clearly articulates particular philosophies of care related to individualized family care, coordination of services, and services in natural environments.

Part C stipulates that early intervention services are designed to meet the developmental needs of an infant or toddler with a developmental delay or disability (or diagnosed physical or mental condition with high probability of resulting in developmental delay) in any one or more of the following areas: physical development, cognitive development, communication development, social or emotional development, and adaptive development. Each state has its own definition of developmental delay, and thus eligibility for early intervention varies from state to state.[70] In Alabama, children have to demonstrate a developmental delay of 25% in one of five areas; in the District of Columbia, children have to demonstrate a delay of 25% in two areas; and in Arizona, children have to demonstrate a delay of 50% in one area. The list of early intervention services identified in the legislation is provided in Box 30.1. Services are to be provided by qualified personnel based on state licensing or certification requirements. Physical therapists are included under qualified personnel.

The components of service delivery identified in Part C are included in Box 30.2. The five major components are as follows:

- A public awareness program
- A central directory of information
- A comprehensive child find system
- Comprehensive evaluations and assessments
- An individualized family service plan (IFSP)

To receive funding under Part C, the states must comply with all provisions as detailed in IDEA. The law also states general guidelines on when, how, and where evaluations/assessments, IFSPs, and interventions must be planned, conducted, and implemented. For detailed information, therapists are advised to read the legislation and regulations, which can be accessed through several websites. The document *Providing Physical Therapy Services Under Parts B & C of the Individuals with Disabilities Education Act* (2nd edition) published by the American Physical Therapy Association[95] elaborates on the federal law and the role of the physical therapist.

BOX 30.2 Components of the Part C Infant and Toddler Program of the Individuals With Disabilities Education Improvement Act

- Early intervention services for all infants and toddlers with disabilities (from birth to age 3) and their families
- Child Find: a system to identify, locate, and evaluate children with disabilities
- Comprehensive, multidisciplinary evaluation (MDE)
- Individualized family service plan (IFSP)
- Procedural safeguards
- Public awareness program
- Central directory
- Comprehensive system of personnel development
- Administration by a lead agency
- State interagency coordinating council

FAMILY-CENTERED CARE

Although family-centered care is considered best practice in providing health care to all children, in early intervention this philosophy of care is essential because families are considered a direct recipient of services. Family-centered care is based on the premise that the family plays the central role in the life of a child. Parent self-efficacy beliefs have a direct influence on child development, adaptive behavior, and psychological well-being.[49,138] The underlying tenet is that optimal family functioning promotes optimal child development.[131] Family-centered care is a process that respects the rights and roles of family members while providing intervention to achieve child and family outcomes that promote well-being and quality of life. Family-centered care is a comprehensive approach to service that when individualized may include aspects of both child- and parent-centered approaches as therapists support the child's development and function and endeavor to address the concerns of the family.

Several definitions of family-centered intervention have been presented.[3,50,82,87,94] The common threads are that it is a philosophy and approach to service delivery based on core beliefs of (1) respect for children and families, (2) appreciation of the family's impact on the child's well-being, and (3) family-professional collaboration. The definition by Law et al.[87] is widely used:

> Family-centered service is made up of a set of values, attitudes, and approaches to services for children with special needs and their families. Family-centered service recognizes that each family is unique; that the family is the constant in the child's life; and that they are the experts on the child's abilities and needs. The family works with service providers to make informed decisions about the services and supports the child and family receive. In family-centered service, the strengths and needs of all family members are considered.

Perhaps the most important differences between family-centered and professional-driven approaches are that the professional's role is partly defined by the resources and priorities of each child and family and that service decisions are not based solely on the professional's knowledge and expertise. Initially, the less-defined role may be unsettling to professionals, whose education and expertise are biased toward addressing a child's impairments and activity limitations. In a review of early intervention approaches internationally, Dirks and Hadders-Algra[38] stated, "a major change in attitude and behavior is needed to implement family-centered services."

The key elements of family-centered care, proposed by the American Academy of Pediatrics and the Institute for Patient and Family-Centered Care,[3] influence provision of services to families and children. The elements are as follows:

- Listening to and respecting each child and family, honoring diversity, and including family preferences in service delivery.
- Having flexible organization systems to offer family choices and providing services that are responsive to family needs, beliefs, and cultural values.
- Sharing complete and honest information in useful ways so family can participate in decision making and care.
- Ensuring formal and informal support to the child and family.
- Promoting family-professional collaboration at all levels of health care.
- Appreciating and fostering strengths and building family capacity.

These elements appear to be common sense and often conceal the complexity of application to practice. Service providers may be inclined to regard family-centered care as not being different from what they have always practiced. Implicit in the family-centered approach is that the role of the family extends beyond involvement in the care of the child, to being beneficiaries of interventions.[48] The informational, educational, and health needs of the family are addressed in concert with those of the child based on the premise that supporting the family promotes the child's development.

Family-centered care is founded on a parent–professional partnership. Dunst, Trivette, and Snyder defined parent–professional partnership as follows[51]:

> Parents and other family members working together with professionals in pursuit of a common goal where the relationship between the family and the professional is based on shared decision-making and responsibility and mutual trust and respect.

Practitioners provide information and support to enable the family to make decisions and to enhance family competency in caring for and nurturing the child.[48] Information sharing is reciprocal and acknowledges that families know their children the best.[21] Families share valuable information about the child and family, priorities and concerns, and expectations of early intervention. Practitioners inquire about the child's health, development, daily activities and routines, and family resources and supports. Practitioners are responsive to the family's need for information about their child, community resources, and preparation for the future to enable families to effectively advocate for their children. As an example, therapists provide families information regarding their child's diagnosis and prognosis with honesty and collaborate to identify opportunities and supports so children can participate in life to their fullest potential. Dunst and Dempsey have found that a positive parent–professional partnership is related to parent's self-efficacy and sense of control.[46]

Parents value providers who are caring individuals with positive interpersonal and communication skills with families and children.[93] To provide family-centered care, physical therapists are encouraged to expand their knowledge to include

understanding of the multidimensional aspects of the family including cultural values, interests, child-rearing practices, resources, and supports. It is important for the early intervention team to address the basic needs of the family.[127] Knowledge of the family is critical to avoid the concerns that with family-centered care professionals may be expecting too much from families, thus becoming a source of stress, as opposed to support.[88,93]

Effectiveness of Family-Centered Care

Several reviews support the effectiveness of family-centered care.[37,47,49,50,60,62,85] Similar to other areas of research in early intervention, a thorough synthesis of findings is challenging because studies vary in how family-centered care is defined, characteristics of families and children, service settings, and outcomes measured. For children with developmental disabilities, as noted in these reviews, family outcomes associated with family-centered care include knowledge of child development, perception of children's behavior, participation in intervention programs, satisfaction with services, developmental appropriateness of the home environment, parenting behaviors and competence, the parent–child relationship, enjoyment of parenting, family functioning, self-efficacy, sense of control, and empowerment. Family-centered care has also been associated with children's health, development, social-emotional competence, and functioning. Elements of family-centered care associated with these positive outcomes include communication, information sharing, collaboration, fostering family involvement and choice, building on strengths, and providing support. Despite the evidence, the complex and multidimensional nature of family-centered care and early intervention services under Part C of IDEA make it difficult to translate research into practice.

A meaningful understanding of the effectiveness of family-centered behaviors requires consideration of the characteristics of the child, family, therapists, intervention strategies, and service delivery systems.[43] Research on processes of family-centered care indicates that outcomes for children and families are mediated by parent self-efficacy.[37,47,49,138] Provider behaviors fostering parent involvement and choice are more strongly associated with positive outcomes than behaviors related to fostering the parent–professional relationship.[50]

Parent Self-Efficacy, Family Engagement, and Participation

As parental self-efficacy is a key mediator of family-centered care, it is important for services to focus on optimizing parents' beliefs that they (1) can access resources and supports and (2) have control and ability to take actions to ensure the outcomes they want for their family. We recommend that therapists have conversations with families to discuss whether family priorities and concerns are being addressed. It is also important to understand if families feel competent in nurturing their children's development. These conversations will enable therapists to learn how best to support the family, build on family strengths, enhance family competence,[48] and foster collaborative processes.

The family-centered approach, in addition to expanding the role of service providers, expands the role of the family, particularly parents. This might include learning and using skills related to advocacy, negotiation, collaboration, and intervention strategies. Because of the fragmented child health system, parents have to coordinate not only developmental services but also services for primary health care, public health programs, specialized medical care, and behavioral health services. Some families may not be receiving the services they need and require assistance in accessing and utilizing services and community resources. Families experiencing difficulty in adapting to caring for a child with special needs may need more formal support from the early intervention team.[16]

We believe that it is important for families to be engaged in the early intervention process. King and Chiarello[82] have proposed that family engagement may also be a mediator between family-centered practices and outcomes. Family engagement refers to their active investment and involvement as a partner in the intervention.[83] Engagement reflects a family receptiveness and commitment to the process and their confidence with participating in the intervention. Engagement is a complex and dynamic process that involves a relationship between the family and the service providers. Engagement can vary over time and may be influenced by characteristics of the family, providers, intervention approach, and system of care. Three dimensions of engagement are affective, cognitive, and behavioral investment.[83] *Affective engagement* refers to emotional involvement including having a hopeful attitude and trusting in the process and provider. *Cognitive engagement* entails a commitment to the goals, a belief in the relevance of the intervention, and a willingness to invest time and effort. *Behavioral engagement* signifies confidence in being able and supported to participate in intervention tasks. "Client engagement requires a sharing of power and therapist skill in creating a therapeutic environment that is safe, open, and truly collaborative."[82]

As supported by research,[48,50,60,62] we encourage practitioners to provide opportunities for and support family involvement and choice in the early intervention process. The extent and type of participation will vary depending on factors unique to each family. The premise is that families have a right and responsibility to select the way in which they will be involved in early intervention services. Family involvement is viewed as a continuum rather than a hierarchy and may change over time. At times some parents may be minimally involved, either because of unfamiliarity with the service delivery system or because of the difficulty balancing work and family commitments. A family with a demanding work schedule may give permission for professionals to provide early intervention at a child's child care center but not at home. Parents may view the child care provider as an important person in the child's life who is helping support the family's goals for the child. It is important for practitioners to be flexible and responsive to family choices. Families may actively seek information from the professional team regarding the child's diagnosis, prognosis, and ideas on how to enhance their children's development. Collaboration and partnership are achieved when a family not only seeks information from professionals but also offers information and actively participates in the development and implementation of service plans. Service coordination and advocacy represent levels of family participation that involve management of services provided and educating others about children with special needs. Ongoing communication between the family and practitioners and revisiting family needs and participation are integral to family-centered services. Box 30.3 highlights reflections and considerations for engaging families in the intervention process. It is important for physical therapists to invite parents to participate, identify and discuss barriers, and provide supports to enable their participation.

BOX 30.3 Engaging Families: Reflections and Considerations

Therapists providing services in early intervention may experience a situation in which a parent watches TV, talks on the phone, or does a chore during the session. Instead of making a judgment about the parent, we encourage therapists to reflect on the situation and consider how they can respond.

Reflections

The parent may not understand or have a different perspective regarding family involvement.

The parent may need respite: time alone or to accomplish a task.

Considerations

- Share with the family the philosophy of early intervention and how much their role is valued.
- Discuss the various ways they can be involved during a session.
- Ask what they would like the focus of the session to be.
- Share how we can provide support to enable them to be involved.
- Be patient, share highlights of the session, find moments during the session to connect with the family, and continue to invite families to be involved.
- Incorporate watching TV and chores into the session activities and together develop strategies on opportunities to interact with the child or possibilities to have the child involved in self-play.
- Agree on a balance so the family has some time to rest or accomplish a task and some time to be involved in the session activities.
- Discuss family's interest in or need for respite resources.

EFFECTIVENESS OF EARLY INTERVENTION

Research on the benefits of early intervention are equivocal and vary across children and families.[25,61,65] This reflects the complex and multifaceted nature of early intervention services. Methodologic challenges have contributed to limited research and ability to generalize findings across children and settings. Research has focused on interventions for infants and toddlers experiencing delays who are at environmental or biologic risk. Interventions tend to be broad in scope with little detail on specific strategies and procedures, and the potential range of child and family outcomes has not been explored. Research is recommended to help therapists understand the complex influences, both direct and indirect, of child, family, environment, and service factors on meaningful outcomes for children and families.[17] Consequently, the knowledge of what interventions are most effective based on child and family characteristics remains unclear.

Physical therapists will find it particularly challenging to integrate and apply research findings on early intervention for three reasons: (1) a large proportion of the literature and research comes from the fields of medicine, psychology, sociology, and early childhood education and concentrates on health, cognition, and behavior; (2) the role of physical therapy as part of an early intervention team has seldom been addressed; and (3) well-designed studies with large samples, such as the Infant Health and Development Program,[18,110] have targeted "at-risk populations" of infants at risk for global developmental delay, speech and language disorders, or social-emotional maladjustment.[25,61]

Outcomes for children and families participating in Part C early intervention are generally positive. The National Early Intervention Longitudinal Study[69] found that infants and toddlers participating in Part C increased motor, social, and cognitive functioning and families felt competent in caring for their children's basic needs and felt they knew how to help their children learn and develop.[13] Data collected by states on child outcomes showed that 66% to 71% of the children receiving Part C early intervention had greater than expected growth in social relationships, use of knowledge and skills, and taking action to meet needs, and 59% to 61% exited early intervention functioning within age expectations in these areas.[56] The states also reported that 87% to 90% of families receiving Part C services know their rights, effectively communicate their children's needs, and help their children develop and learn.[55] A positive relationship among parents' perceptions of Part C services, state-collected data on family outcomes, and enhanced family quality of life has been reported.[58] Although results are encouraging, there are concerns about the quality of the data, as states continue to improve the reliability and validity of their data collection and reporting.

Empirical support for early intervention for children with physical disabilities and their families is inconclusive. Children with motor impairment have shown fewer functional gains compared to children with delays in other areas.[68] Findings for children with disabilities indicate that severity, not the type of physical disability, is a strong predictor of change; children with mild disabilities showed greater gains than children with severe disabilities, regardless of the intensity of services.[68] Norm-referenced developmental assessments are not responsive to changes that children with severe physical disabilities are capable of achieving.[99] Reviews and meta-analyses on the effectiveness of early intervention practices on motor outcomes include studies that are not specific to Part C,[20,65,98,102] define early intervention broadly to include interventions that take place in the neonatal intensive care unit or other program specific settings,[102] only include infants at risk for cerebral palsy,[65,98] or the interventions were heterogeneous making it difficult to generalize results.[20,65,98,102]

As an example, a systematic review of the effects of early intervention on motor development included studies with children both at high risk for or with developmental motor disorder.[20] This review did consider separate effects of interventions provided in the neonatal intensive care unit from interventions conducted later in infancy and early childhood. Among studies conducted following discharge from the neonatal intensive care unit, positive effects on motor development were found for what was categorized as specific or general developmental programs, whereas no support was found for interventions categorized as neurodevelopmental treatment or Vojta. It is challenging to translate this evidence to practice because of the variety of interventions considered as specific or general developmental programs, ranging from treadmill training to enhancing parent–infant interaction, and differences in method of service delivery including who provided the intervention. There is limited evidence on the effects of early intervention on adaptive function, participation in family and community life, ease of caregiving, and family functioning.

Keeping abreast of current research related to amounts and types of interventions for young children is important as therapists and families make decisions about early intervention services. However, evidence on the effects of specific procedural interventions and the amount of physical therapy services is hard to interpret and apply to early intervention. In early intervention, the team makes decisions regarding types and amount of services based on child and family needs. Studies on amount

of services do not account for the confounding effects of practice and learning supported by family and other caregivers throughout a child's daily life. Research is needed to examine the effects of various schedules of service delivery in early intervention such as scheduling more frequent visits during team-identified periods when children are on the verge of learning a new activity or less frequent visits when families feel comfortable and confident implementing successful strategies with their children during daily routines.

FOREGROUND INFORMATION

PROVIDING EARLY INTERVENTION SERVICES

Role of the Physical Therapist

Part C of IDEA and the American Physical Therapy Association[122] support the role of physical therapists in early intervention. Acquisition of motor skills is a major part of early development, and young children are sensorimotor learners.[89] Physical therapists, as members of the early intervention team, provide interventions to promote children's activity and participation, including motor learning, environmental adaptations, assistive technology, family support, and education. As health care professionals recognized as movement specialists,[5] physical therapists have expertise in developing body functions and structures of the neuromuscular, musculoskeletal, cardiopulmonary, and integumentary systems and how impairments in these systems impact early development. This enables therapists to provide individualized recommendations for activities, activity adaptations, and environmental modifications that not only promote motor development but also enable exploration, social interactions, and play. Physical therapists also have a role in health promotion and prevention,[124] including discerning risk factors for secondary health complications (e.g., limitation in physical activity and obesity), fostering safety in the environment (e.g., use of outlet protectors, baby gates), and identifying signs and symptoms that indicate the need for referral to another health care professional[5] (e.g., lethargy, weight loss, persistent fever).

Even though physical therapists have a unique role in early intervention,[33] there is an overlap of expertise among service providers. Therefore communication and coordination among the team are crucial. Providers are encouraged to openly discuss the overlap in their areas of expertise and respect the contributions of all service providers. Physical therapists may experience overlap in roles and responsibilities with occupational therapy colleagues in the areas of motor and adaptive development as well as assistive technology. It is also important for physical therapists to collaborate with early childhood education specialists who have broad knowledge of early development and expertise in cognitive and social development.[39] Decisions on how each member of the team will contribute to the plan of care for a child and family are made based on who can best support the identified outcomes.

It is particularly valuable to consider the role of the physical therapist from the consumer perspective. Thirty-six parents of children with disabilities participated in focus groups to explore their perceptions of competent physical, occupational, and speech therapists in early intervention.[30,97] Parents discussed the skills and attributes of therapists that were important to them. The discussions were audiotaped, transcribed, and analyzed for themes. The nine themes that emerged are described in Box 30.4. The themes reflect interactions among administration issues, expectations for "best practice," and the importance of the family–therapist relationship.

Elements of Early Intervention

This section presents the major elements of intervention included in Part C of IDEA. The elements are team collaboration, evaluation and assessment, the IFSP, providing services in natural environments, and transition. These elements are consistent with the recommendations for children from birth to 5 years of age with or at risk of developmental delays or disabilities developed by the Division for Early Childhood (DEC) of the Council for Exceptional Children.[40] It is through these elements of service provision that therapists implement family-centered care.

Team Collaboration

Team collaboration is the process of forming partnerships among family members, service providers, supervisors, administrators, systems of care, and the community with the common goal of enhancing the child's development and supporting the family.[104] "It is the sum of these interrelated relationships that create a web of support for children, their families, and those who support them."[57] At the systems level, federal legislation mandates interagency coordination to provide families with efficient and effective mechanisms to access and utilize services from multiple agencies.[107] The need for coordination of services among health care professionals, early intervention providers, and families has long been recognized.[22] The American Academy of Pediatrics advocates for collaboration between children's primary care and Part C early intervention services.[2] Care coordination is based on the assumption that integrated and coordinated services will result in improved outcomes, reduced costs, and more positive service experiences for children and families.[4] Part C of the IDEA

BOX 30.4 Families' Perspective of Desired Competencies of Early Intervention Therapists

Early intervention knowledge. Therapists have previously acquired or have access to general and disability-specific information relevant to family needs or requests related to their child.

Team coordination. Therapists actively support the coordination and planning among team members, including the family.

Family as part of therapy visits. Therapists are able to actively engage and include family members in therapy sessions.

Information sharing between the therapist and the family. Therapists share and support the use of therapy techniques throughout child and family daily routines and activities.

Commitment of the therapist. Therapists view their role as potentially impacting families and children, not simply as a job.

Flexibility of scheduling. Therapists are willing to juggle their schedules in order to work with families and children.

Respect for individual families. Therapists have respect for families in that they are sensitive to the family context and changes over time, use parent-friendly language, use active listening, and provide families with positive feedback.

Appreciation for the child. Therapists demonstrate appreciation for the child by using a strength-based intervention approach and have the ability to be "in tune" with the child.

Therapist as a person. Therapists possess a personality reflective of them as honest, patient, personable, creative, and humorous.

delineates that service coordinators are responsible for the implementation of the IFSP, coordination with other agencies, and assisting families with access to services.[107] Research supports the need for team collaboration and service coordination; interpersonal characteristics and organizational factors are interrelated and serve as either facilitators or barriers to team collaboration and service integration.[21,28,67,73,103]

Characteristics of team collaboration described by Briggs[23] and supported by the recommendations for early intervention by the Division for Early Childhood,[40] synthesis of literature on service integration,[103] and qualitative research[21] are summarized in Box 30.5. Team members demonstrate respect for each other by valuing cultural differences and acknowledging the expertise and competence each person brings to the team. Positive interpersonal relationships and clear behavioral expectations are important for effective collaboration. Opportunities for team members to share information and willingness to adapt to individual situations are viewed as important for collaboration.

Communication is an essential skill for effective collaboration.[111] Effective communication is the process of sharing knowledge and information among team members to facilitate coordination of services. Each member must be committed to keeping the team informed of important issues. Communication begins with listening, an essential process to understand and appreciate everyone's perspective, foster relationships,[81] and support parents' engagement and self-efficacy. It is important for practitioners to "listen mindfully, sensitively and with intent—to be authentic and present in the moment with the client."[81] King and colleagues[81] distinguished four types of listening skills: (1) receptive listening to attend to clients and be open to what they are saying, (2) exploratory listening to have a dialogue and facilitate deeper communication, (3) consensus-oriented listening to arrive at a shared understanding, and (4) action-oriented listening to establish decisions for a plan of care. To avoid miscommunication, it is helpful to restate what was heard to demonstrate understanding[81] and to ask for clarification or an example when information is not clear. Prompt follow-through communicates investment in the team. At the same time, being patient reflects an understanding of the group process. When discussing issues, it is essential to provide suggestions and options, a solution-focused versus problem-focused approach. A sense of humor helps to bring humanism to day-to-day team struggles.

BOX 30.5 Characteristics of Effective Teams and Collaborative Relationships

- In the developmental phase, team members take time to learn about each other.
- Members demonstrate honesty, trust, responsiveness, and mutual respect for each other.
- Membership is stable and all members demonstrate commitment and leadership.
- All share a common philosophy and goal.
- The group has a structure for interaction and organization.
- Open communication, exchange of information, meaningful discussion, and negotiation are practiced.
- Equal participation is encouraged, and partners contribute specific skills and strengths.
- Plans, priorities, and decisions are made together.
- Action plans with appropriate authority are used for implementing team recommendations.

A family-centered organizational culture enables the development and implementation of organizational structures and processes that support team collaboration.[21,67,73,103] The following strategies and practices are recommended to enhance collaboration[2,4,21,28,67,73,103]:

- Communication, teamwork, and advocacy training for families and providers
- Education on systems of care including the services and resources available
- Referral forms that establish ongoing collaboration including sharing of medical and development records
- Mechanisms and time for regular communication among team members including interagency systems
- Comprehensive policies, funding, and resources for care coordination services
- Documentation on the IFSP of all programs and services across the community and systems of care
- Determination of the service coordinator based on an appropriate match to support family's priorities and concerns
- Development of collaboration goals and action plans
- Maintenance of a list of services and resources for families
- Service options shared with families
- Flexibility in scheduling and staffing
- Options for service format including co-visits by team members, group and individual therapy, and center-based programs

At the system level, states lack policy and funding to support service coordination.[4,67,103,127] In regard to collaboration between medical and early intervention providers, family members and practitioners noted limited communication, lack of trust and understanding, and challenges in resolving differences in practice philosophies.[73] Families of young children with complex medical and developmental conditions expend considerable time and resources to coordinate care and meet their children's health, education, and development needs.[73] At the agency level, large caseloads, lack of consistency of staff, and problems with contracted employees have been cited as interfering with collaboration.[103] Although struggles may exist for "turf," power, or authority, more commonly problems appear to arise from a workplace structure that isolates service providers or one that does not have dedicated time or procedures in place for collaboration.[71,73,103] Providing services in natural environments requires time for travel and reduces direct contact among team members. It is important for administrators to support procedures and mechanisms for communication such as team meetings at a community-based center, electronic sharing of information, and time in the workload for phone calls and consultation.

Progressive leadership and administration at all levels are essential to discover solutions to barriers and to support practices that enable team collaboration.[40,41,57,86] Leaders establish interagency partnerships to foster service coordination.[40] Administrators need to set a tone that values and supports a deep level of teamwork, communication, and problem solving. Organizations need to secure funding to support the otherwise nonreimbursed time required for essential functions such as teamwork, planning, training, and supervision.[57] Despite a federal mandate for service coordination in early intervention and advances in the medical home, "a collective paradigm shift at the provider, agency, interagency, government and societal levels is necessary to provide coordinated care to families."[82] Partnership among policy makers, administrators, practitioners, and families is critical to influence system reform (e.g., funding, policies, and interdisciplinary education). Therapists

BOX 30.6 Addressing the Challenges in the Primary Service Provider Approach: Advocating for Meaningful Decision Making

The following is an example of how the team can advocate for individualized care when practicing the primary service provider approach.

Megan is a physical therapist working for a county early intervention system that uses the primary service provider approach. She values the approach and has found it beneficial for many children and families. Currently she serves as the primary service provider for Declan, a two-year-old boy with cerebral palsy, Gross Motor Functional Classification System level IV, and is collaborating with the family on adapting a powered-mobility ride toy. Megan is feeling overwhelmed in being able to support the child's communication and to prepare him for preschool. Her supervisor has approved a 1-hour consultation visit with the speech therapist but has indicated that only 1 hour is permitted for this 6-month period. During the visit, Megan, the family, and the speech therapist assess Declan's current receptive and expressive communication function and discuss strategies for a communication system. Megan is appreciative of the co-visit but does not feel that she has the competency to set up the system and teach Declan and his family without additional support. Megan, the speech therapist, and the parents hold an additional online audio-conference at night, on the therapists' personal time, to share and discuss options:

- The speech therapist has documented the consultation visit, which includes a recommendation for additional services by the speech therapist.
- Megan as the primary service provider will write a formal request for additional service visits by the speech therapist and a full team meeting. She notes that the full team meeting is needed to collaborate on this new strategy for communication as well as to receive further guidance from the early childhood education specialist and the occupational therapist regarding supporting the IFSP outcome related to preparation for preschool.
- The family will investigate their medical insurance coverage for durable medical equipment and outpatient services.
- The speech therapist will contact the regional children's hospital to gather information on the augmentative communication clinic and outpatient services.
- The team will discuss the possibility of switching the primary service provider to the speech therapist in 3 months at the next IFSP review meeting. This 3-month period will provide Megan the opportunity to make sure that Declan and the family are confident with using the powered mobility ride toy.

Re*fl*ection on the primary service provider approach in action: Implementation of the primary service provider approach varies by state and may not encompass all of the teaming strategies explained by Rush and Shelden.[116] For example, in this vignette Megan used her personal time to communicate and coordinate with the team and family. In some states this teaming time is reimbursed, as it is essential to the approach and to carry out the strategies outlined in the IFSP. Another example that varies by state is the option to switch the primary service provider depending on the needs of the child and family. Therapists who work in states using the primary service provider approach are encouraged to advocate for the time and resources needed to implement the approach effectively. The American Physical Therapy Association Section on Pediatrics created a Fact Sheet that addresses common questions on the primary service provider approach and can be accessed on the section's website.[128]

are encouraged to embrace the interpersonal facilitators of team collaboration, advocate for implementation of system strategies, and participate in the leadership process[40,86] to enable coordinated care to become a reality.

Various approaches to team interaction exist in early intervention. In an *interdisciplinary approach*, team collaboration is necessary because multiple team members with various areas of expertise work together with the family to support one set of outcomes. However, a framework for team collaboration, specifically intensive team interactions, is an essential feature of the *transdisciplinary* approach to service delivery.[84,125] The transdisciplinary approach involves one primary service provider who implements the IFSP with the family with consultation from other team members. An advantage of the transdisciplinary approach is that the family and child interact primarily with one service provider but do have access to other team members as needed. The transdisciplinary approach is dependent on sharing of roles and crossing of disciplinary boundaries. Great variability exists in how this approach is actually implemented, and therapists may need to advocate for appropriate supports. If services are implemented without opportunities for consultation and supervision and do not include the option for additional team members to provide direct service when needed, then a child may not be receiving the services and strategies necessary to support the IFSP. Box 30.6 presents a vignette that highlights how a team can address challenges when implementing a primary service provider approach.

A specific approach to team interaction associated with the transdisciplinary care termed *coaching* has also been promoted in early intervention.[63,115,116] This approach advocates for family involvement in the intervention process, respects the family's strengths and expertise, and supports the family in expanding current abilities and learning new skills within their natural environments. Coaching is characterized as being "consistent with adult learning, capacity building, non-directive, goal-oriented, solution focused, performance based, reflective, collaborative, context driven, and as hands on as it needs to be."[116] Rush and Shelden[116] synthesized the five critical processes: joint planning, observation, action, reflection, and feedback. After collaborative discussions and observations, the family and practitioner jointly select intervention strategies. The practitioner and family jointly interact with the child and practice the strategies together. Suggestions for asking families to practice strategies in ways that are family-centered and supportive are presented in Box 30.7. The family then implements

BOX 30.7 Supporting Families to Practice and Use Intervention Strategies

Therapists may find it helpful to share with families that trying a new intervention strategy was and at times still is not easy for them. Therapists can provide families with options on how they would best like to learn and practice the strategy:

- Would you like to try this together?
- What can I do to make it comfortable for you to try this strategy?
- Would you like me to try the strategy and you can first watch and ask me questions?
- Would you like to try the strategy and I can talk you through the steps?
- Would having a video of doing the strategy be helpful?
- Would you prefer to practice the strategy on your own this week?

Once a family has tried a strategy it is important to ask for feedback to ensure family members are confident using the strategy:

- What did you like best about trying the strategy?
- Do you feel comfortable using the strategy?
- Are there any parts of the strategy that are hard or difficult to do?
- What would make the strategy easier?
- Are there situations or circumstances when the strategy is easier or harder to use?

the strategies throughout the child's daily routines. The practitioner follows up with the family to reflect on the strategies and whether they are having the intended effect. Collaboratively the practitioner and family determine whether modifications or changes are needed and, if the goal has been achieved, how to progress to the next step. During this process the practitioner may provide modeling, demonstration, and direct teaching as well as guidance and feedback when the family is practicing and mastering the intervention strategies.[63] This collaborative interactive process can be applied during all aspects of service delivery and can also be utilized during interactions with other team members.

Evaluation and Assessment

The IDEA addresses assessment of the child, family, and service needs. The IDEA specifies that assessment of the child is performed by qualified and trained personnel and includes review of the child's relevant medical records, observation of the child, informed opinion, and determination of the child's unique strengths and needs and functioning in five areas of development (physical, cognitive, communication, social or emotional, and adaptive). Comprehensive developmental tests and measures may be used for determining eligibility and documenting developmental progress; however, routines-based ecologic assessment of the child's functioning is also indicated to identify outcomes and guide interventions in natural environments.[8,10] The physical therapist synthesizes findings for motor development and adaptive function within the context of findings for all areas of development, social interactions, activities, and daily routines of the child and family. The assessment of the family includes a voluntary interview with the family to identify (1) their resources, priorities, and concerns and (2) the supports and services they need to strengthen their ability to meet their child's developmental needs.

Several key points on the evaluation and assessment process merit emphasis. Evaluation and assessment must be comprehensive and nondiscriminatory. A team approach supports a holistic view of the child. Information from multiple sources across various situations, including reports from families, is valued. Professional judgment of therapists and consensus decision making among parents and practitioners are important aspects of the evaluation and assessment process.[9] The team uses findings from child and family assessments to determine the child's initial and continued eligibility for early intervention. This determination cannot be made based on a single assessment procedure; however, medical records can be used to determine eligibility without additional assessment if they report information on the child's level of functioning in the five developmental areas. If a child is eligible for early intervention, the team evaluates the assessment information to determine the child's service needs.

Evaluation and assessment are to be provided in an individualized, strengths-based, and collaborative manner.[10,40] The purpose and process of the evaluation and assessment should be discussed in advance. Family input is requested in deciding *who* should attend, *what* activities and routines will be observed, *where* the evaluation or assessment should take place, and w*hen* the session will occur (date and time). Family members can take on many different roles during the evaluation and assessment. Some family members may elect to guide the process, interacting with their child in a variety of activities. Others may prefer to assist the therapist with activities. Another option for a family member is to be a narrator, reflecting on the child's behaviors and providing commentary and elaboration to the other team members. Some families are comfortable with spontaneous exchange of ideas, and other families prefer to answer specific questions. At times, a family member may just want to observe and listen. Families can share photos, videos, and journals highlighting the child's performance in their daily life. At the end of the evaluation and assessment, it is important to ask the family to share their perspective on the process and whether the child's performance was representative of her or his current abilities.

To maximize the value of evaluation and assessment, consideration should be given to the information needed to make decisions on outcomes, the intervention plan, and how progress will be monitored and documented.[10] This process begins with the identification of child and family competencies that serve as a foundation for determining the child's readiness for learning new skills. In addition, an understanding of the family's culture and interests provides the framework for deciding on meaningful intervention strategies. This information is best gathered through the initial interview, ongoing conversation with the family, and systematic observation of the child and family during daily activities and routines.[10,77,78]

Family interview. An initial step in the process of evaluation and assessment is a family interview. The initial interview begins the process of developing a trusting relationship and partnership with the family and child.[15] The purpose of the interview is to learn from the family about the child's health, development, and personality; the child and family's daily routines and interests; the family's priorities and concerns; what resources and strategies are available to enhance the child's development; their perceptions about therapy; and their expectations of early intervention.[15,96,133] For some families, the interview process may be a new experience; therefore therapists encourage, support, and respect the various levels of involvement and value the information that families provide.[15] It is important for therapists to recognize and respect that families are being asked to share personal information.

An effective interview requires sufficient time and is characterized by the ability to have a conversation with the family, listen, acknowledge the child and family's strengths, expand the conversation with appropriate guiding questions, use friendly nonverbal communication, and demonstrate empathy.[15,96] A personable approach facilitates a comfortable environment, welcoming the family to share their thoughts. Inviting parents to share their story and use of open-ended questions fosters an informal, flexible approach that is acceptable to families.[15] This approach conveys to families that therapists are interested in learning and understanding the family's culture. For some families who have difficulty expressing themselves, it is important for therapists to provide guidance while being careful not to misrepresent the family's perspective.

Active listening is another key to effective interviewing and to establishing partnerships with families and collaboration on the IFSP. Active listening and acknowledging the family's concerns demonstrate respect and value for the family's priorities and help the therapist develop a deeper appreciation for the family's daily routines, opportunities for collaboration, how the family frames its resources, and the extent of the family's support network. Another effective interview strategy is the use of silence. There are times when silence is more helpful than questioning. Silence, with some nonverbal gesture of acceptance, may enable a family time to reflect and consider their response.

To support therapy in natural environments, a major component of the interview is gathering information on child and family daily routines in order to identify the context for intervention to promote children's participation in family and community life. Through conversations and open-ended questions, such as "tell me about your child" and "describe for me a typical day in your family," therapists gather information on family members' roles, interests, strengths, interactions, and daily experiences. Rosenbaum has advocated for a strengths-based approach that begins with asking families to share what they enjoy and are proud of regarding their child.[112] Therapists are encouraged to thoughtfully discuss with families their current routines related to play, self-care, and community outings. McWilliam and colleagues[96] emphasized the importance of identifying the needs of all family members and considering what the family would like to be able to do. Woods and Lindeman[144] discussed the importance of the interview being a reciprocal process where providers share information on the value of natural learning opportunities and families share information on daily activities and routines including child and family interests. The interview around daily routines is also an opportunity to begin collaborative problem solving with the family to discover the strategies and resources the family has to address challenges in caring for and promoting their child's development.[144] We believe the interview is a critical process, deserving of time and attention, in which the therapist and family are beginning a relationship, learning from each other, and setting the foundation for the family's engagement in early intervention.

Observation. The second step entails observations of the child within his or her natural environment. *Natural environment* is a broad construct referring to the everyday experiences that are part of the child's home and community settings. Observations in the natural environment may focus on family household routines, parent–child interaction, play, and other daily activities such as feeding, bathing, and dressing. Within the construct of the International Classification of Functioning, Disability and Health (ICF),[146] ecologic assessment encompasses the relationships among participation, activity, body function and structures, and environmental and personal factors.

The physical therapist's unique role as part of the team is to focus on postural control and mobility during play, exploration of the physical environment, self-care, and interactions with objects and people.[33] The family and therapist select the settings and activities that are most important for the therapist to observe. While observing, the therapist notes the following:

- What the child enjoys doing
- How the child interacts with others
- Opportunities for safe movement and sensorimotor exploration
- How often and under what circumstances the child moves
- Toys and materials that are available
- Areas of the home accessible to the child
- How much adult assistance or guidance is provided
- Abilities and resources the child needs to become more successful
- Musculoskeletal, neuromuscular, cardiopulmonary, integumentary and personal characteristics of the child that may facilitate or be a barrier to the child's participation

During the observation, the physical therapist engages in a conversation with the family members to learn about their perspective of the child's typical performance, abilities, strengths, and needs. Based on her or his observations, the therapist also shares information on the child's and family's strengths and may begin to discuss or try simple strategies to optimize the child's abilities. Information about the child's activity and participation in settings that are not observed can be gathered during the interview, or the therapist may elect to engage the child in an activity that is not the exact context of the daily routine.

The most meaningful observation occurs when watching a child do something enjoyable with a familiar adult or child. Parent–child interactions are sensorimotor experiences. Motor control, sensory integration, and muscle performance are part of parent–child interactions. In addition to looking at the motor components of the interaction, consideration is also given to social patterns of interaction between the child and caregiver. Kelly and Barnard[79] provided a comprehensive overview of assessment of parent–child interactions.

Play is the primary occupational behavior of childhood and is a naturally occurring situation during which children learn and develop new skills. In reference to observing play activities, it is important to look at both independent play as well as play with caregivers, siblings, and peers. Therapists gather information on what toys and play activities the child engages in (sensory/exploratory play, manipulative play, imaginative/dramatic play, or motor/physical play) and the child's likes and dislikes. Therapists consider the interplay between motor abilities and play skills. Is the child able to initiate play experiences? What positions can the child play in? Can the child freely move around to reach toys or play activities of interest? Further analysis considers if the child's movements are goal directed, the variability of movement to meet environmental demands, and the child's reaction to movement (i.e., level of enjoyment, safety, and body awareness). Lastly, a focus on the process of play provides valuable insights into the child's playfulness. Playfulness is concerned with a child's approach to an activity and includes observations related to the child's enjoyment, engagement, responsiveness, motivation, and locus of control.[101]

In addition to the family interview and ecologic observations, therapists use various tests and measures to evaluate motor development, function, and body functions and structures. These assessment tools are described in Chapter 2 and elsewhere.[90,123,137] An important consideration is that developmental measures normed on children without delay are valid for determining present level of development and eligibility but often are not valid for planning intervention and measuring change over time. Based on the top-down approach to service delivery,[141] considerations of body functions and structures are conducted after the team has a clear understanding of the family and child's goals and current abilities and relate to the team's hypothesis for impairments that may be a cause of limitations in activities and restrictions in participation. During observation and completion of standardized measures, the therapist notes impairments that appear to limit a child's activity and participation and, subsequently, screens for impairments in body functions and structures and determines when in-depth assessment is required. Therapists in early intervention may keep supplemental documentation of examination findings that are not included in the team report.[6]

Finally, therapists collaborate with the team to document the child's functioning related to three outcome areas of the national accountability system for Part C of IDEA.[69] These areas are "positive socio-emotional skills (including social relationships), acquisition and use of knowledge and skills (including

early language/communication), and use of appropriate behaviors to meet their needs." These outcomes represent an integration of abilities across developmental domains and reflect a value for children's adaptive behavior, participation in meaningful activities, relationships with others, and self-determination. When children exit early intervention, data in aggregate form are collected to report the percentage of children who made improvements in these areas in relation to their same-age peers. This information is for progress monitoring of the early intervention system as a whole and is not meant to capture the individualized experience of a child.

Individualized Family Service Plan

The culmination of the evaluation and assessment process is the development of the individualized family service plan (IFSP). The principle underlying an IFSP is that families have diverse priorities and concerns based on their individual values and life situations. For intervention to be meaningful for the child, the individuality of each family must be recognized. The team members involved in the development of the IFSP include parents, caregivers, other family members, the family advocate, the service coordinator, practitioners involved with the assessment and evaluation, and, as appropriate, practitioners who will be providing the service.

The family should be provided with information that will enable them to make informed decisions and choices *before* the IFSP meeting in order to negotiate for the types of support they need and to ensure equal partnership and ownership in this process. This information may be shared face-to-face with the family during the information-gathering stages, in a meeting after the evaluation, or in writing in the form of an evaluation report. When feasible, questions the family may have pertaining to the evaluation results should also be addressed before the IFSP meeting so that questions related to the logistics of service provision can be fully discussed during the meeting. This will also help reduce the prolonged process that sometimes characterizes IFSP meetings. Another benefit to sharing the information before the IFSP meeting is that the family members can decide on whom they want to invite to the meeting, something that families consider to be a valuable form of support.

An initial IFSP must be developed in a timely manner at a meeting time and place convenient for the family. Logistics often make it difficult to arrange the meetings at nights or weekends, thus it is important to recognize that not all key family members may be able to attend and participate. If a service provider cannot attend, a representative or written information can be sent. Scheduling challenges are an area of concern and can be a barrier to the collaborative process when not all team members are present. In some regions, administrative efforts to comply with policies on nonbiased evaluations and timely initiation of services have resulted in long meetings where the evaluation and the development of the IFSP occur during the same visit by an independent team who will not then provide the services in the IFSP.[1] Although this practice meets legal requirements, it does not represent the spirit of the IFSP process. Parents often need to tend to their children during the meeting and have not had an opportunity to assimilate the evaluation findings. Another challenge is that when professionals are more occupied with completing paperwork for the IFSP, engagement and meaningful discussion with the family may be limited.[1,144]

Therapists working in states where evaluations are conducted by independent teams need to be sensitive to the issues that may arise. Therapists on the evaluation team recognize that although their relationship with the family is of short duration, it is still important to engage with the family in meaningful ways to support their active participation in the evaluation process. Therapists who are providers of service recognize that families now have to begin a relationship with another professional and that it may be challenging to have to tell their story again.

Although the federal law specifies the content of the IFSP (Box 30.8), it does not specify the format of the document or the process for its development. Typically the service coordinator leads the discussion and records the information. Family members can elect, however, to take the role of team leader. During the meeting, the team discusses the evaluation and assessment findings, shares information on the philosophy of early intervention to ascertain if this matches the family's expectations and priorities, and collaborates to develop the IFSP. The team promotes family participation, and decisions are made collaboratively. Applying federal law has been challenging, but reports indicate that families are participating in the development of the IFSP.[1,70] Aaron and colleagues however, reported that family involvement regarding decisions on the types and amounts of services was limited.[1] The findings from a study on quality indicators of IFSP documents were also mixed.[76] A high rating was noted for a focus on child strengths, and 86% of the outcomes were related to family concerns and priorities. However, IFSP documents contained technical jargon, and the family often had a limited role in the IFSP process.

Identification of IFSP outcomes that are family centered and participation based is essential for evidence-based early intervention supports and services. There are two types of outcomes: child focused and family focused. Child-focused outcomes are grounded in important routines or activities in the child's life that are meaningful to the family. Family-focused outcomes are based on the family's priorities and interests and support their access to community resources and supports.[92,128] Family-focused outcomes also increase capacity of the family to care for and support the child's development. Well-written IFSP outcome statements reflect real-life situations, cross developmental domains, are discipline- and jargon-free, emphasize

BOX 30.8 Content of the Individualized Family Service Plan

- Statement of present levels of development based on objective criteria: cognitive, communication, physical (motor, vision, hearing, health), social or emotional, adaptive
- Statement of the family's resources, priorities, and concerns related to enhancing the development of the child
- Statement of measurable outcomes expected with criteria, procedures, and timelines to determine progress
- Specific early intervention services based on peer-reviewed research needed to meet the needs of the child and family, including frequency, intensity, and method of delivery
- Statement of the natural environments in which services are to be provided (if services are not going to be provided in natural environments, a justification must be included)
- Determination of other services to enhance the child's development and a plan to secure such services through other public or private resources, such as medical resources
- Projected dates for the initiation of services and duration of services
- Identification of the service coordinator
- Transition plan: steps to be taken to assure smooth transition to preschool services or other suitable services if appropriate (at age 3)

the positive, and use active words.[92,128] IFSP teams often do not identify family-focused outcomes; however, there is some evidence that the routines-based interview (RBI) leads to more family-focused outcomes than traditional IFSP practices.[96]

The Early Childhood Outcomes Center, funded in 2003 by the US Department of Education, Office of Special Education Programs, has developed a family outcome measure for early intervention.[53] The global outcomes on this measure may assist providers in discussions with families to identify specific individualized family-focused outcomes to guide appropriate decisions about the supports and services they want or need. The global family outcomes[12] state that the family does the following:

- Understands their child's strengths, ability, and special needs
- Knows their rights and advocates effectively for their child
- Helps their child develop and learn
- Has support systems
- Can access desired services and activities in their community

Recognizing the importance of providing services that build family capacity[136] and self-determination, we encourage physical therapists to expand their knowledge to engage families in conversation of outcomes that are meaningful to them and support their autonomy (control and choice), relatedness (connected and supported), and competence (capable and confident).[105] However, identifying family-centered, participation-based outcomes can be challenging. Several issues often arise during this process. Table 30.1 outlines several situations that may be challenging and presents considerations and recommendations for the team. We recommend the collaborative process described by Baldwin and colleagues[14] where the team honors the family's hopes for their child's future and engages them in a thoughtful conversation to develop outcomes and strategies together.

Teams might feel overwhelmed when numerous child and family needs are identified and then struggle to address all of the priorities in the IFSP outcome statements. Prioritizing a routine or activity that is important to the family might help the team create more cohesive and meaningful outcomes statements for the IFSP. For example, if the family identifies a current activity that is challenging and a high priority (e.g., visiting grandparents), the team might explore the reasons why the activity is challenging to address in one or more outcome statements. In this case, it might be reasonable to address challenges in communication, mobility, and self-help in an outcome statement about visiting grandparents. A case scenario highlighting the development and prioritization of IFSP outcomes is available on Expert Consult.

Identification of the types and amounts of services (frequency and length of early intervention sessions) to support the child's and family's outcomes requires an open discussion, team collaboration, an understanding of the expertise of various service providers, an appreciation of family preferences, and circumstances. This discussion also includes options for methods of service delivery, interagency collaboration, financial responsibilities, and transition planning for when the child turns 3 years old. Little is known about the types of supports and services that may be appropriate to address family-focused IFSP outcomes.[139] Family-directed service involves providing families with a range of supports including information, access to resources, care coordination, counseling, social work services, and respite care. Although the early intervention team is not expected to be able to provide all of the supports that a family may need, plans are made to assist families in accessing and coordinating appropriate community social services.

The discussion of supports and intervention strategies is essential to promote coordinated and complementary care. Mutually identified recommendations for strategies to address the child's and family's outcomes and to facilitate mobility, communication, adaptive behavior, self-care, and play enable all team members to contribute their knowledge and provide supports in a comprehensive manner. When selecting strategies, the team considers evidence-based practice and the provision of services in natural environments. For example, before suggesting a strategy of daily sessions of supported walking on a treadmill for an infant with Down syndrome,[140] we recommend that the team must consider the family's priorities, preferences, routines, and resources; the health of the infant; and other developmental needs.

The IFSP is not just a legal document; it is a process of collaboration between the family and practitioners to design a service plan that is acceptable to the family and addresses the child's needs. The IFSP serves as a means for coordinating services, a guide for intervention, and a standard for evaluating outcomes. The IFSP is reviewed every 6 months or more often at the request of a team member, and a formal meeting is held annually. Periodic IFSP reviews allow for renegotiations or revisions of the service plan, as well as monitoring of goal attainment. During an IFSP review, family satisfaction, effectiveness of the IFSP process, and status of the outcomes are discussed. If outcomes were not achieved, reflection of the appropriateness

TABLE 30.1 Considerations to Foster Development of Family-Centered Individualized Family Service Plan Outcomes

Situation	Considerations
Families look to the professionals for guidance in identifying outcomes	Avoid writing outcome statements that are based on therapist's priorities or are discipline specific Individualized family service plans that reflect what the practitioners determine to be the needs instead of what the family believes its needs are often do not include important family-focused outcomes, especially for families from diverse cultural backgrounds.[147] Review and discuss information gathered during the family interview to inform the identification of outcomes.[128] Knowledge of family beliefs, customs, and rituals not only helps teams to identify meaningful family-focused outcomes but also builds trust and communication.
Families prioritize skill-based outcomes that the child may not have the readiness or potential to achieve	Acknowledge family priorities. Explore why the outcome is important to the family. Discuss family insights about what their child may be ready to learn related to the outcome area they have identified. Share information about the child's condition to enable informed decision making.
Families express outcomes in ways that are not measurable	Ask family members to describe what the child will be doing in 6 months if everything goes well.[7]
Families focus on a child behavior they want to stop and state an outcome in negative terms	Probe for more information to determine routines and activities the child's behavior interferes with, and collaborate to create a positive outcome statement.

of the outcomes, service, and strategies is needed to effectively revise the IFSP.

Therapists practicing in early intervention require effective interpersonal and communication skills to be able to invite and support the family to contribute their insights, recommendations, and priorities. Anecdotal stories indicate that the IFSP process can be overwhelming and intimidating for families, especially when families do not believe that their opinions are valued. To make sure family's priorities and concerns are valued, any recommendation made by a therapist should align with information gathered during the family interview. Framing recommendations as questions allows the family the opportunity to agree or disagree. Additional strategies to make these experiences more positive include a focus on child and family strengths, use of lay language, and flexibility to allow informal conversation and sharing of ideas instead of rigidly following a predetermined format. Lastly, it is important to acknowledge that variability exists in how states have implemented the IFSP process. Therapists are encouraged to serve as an advocate to ensure that the spirit of family-centered care and individualization are honored.

Providing Services in Natural Environments

IDEA defines natural environments as "settings that are natural or normal for the child's age peers who have no disabilities." More meaningful is that natural environments are "a variety of settings where children live, learn, and play."[121] The *Mission and Key Principles for Providing Services in Natural Environments* of the National Early Childhood Technical Assistance Center (NECTAC) states that "early intervention builds upon and provides supports and resources to assist family members and caregivers to enhance children's learning and development through everyday learning opportunities."[145] The natural environment is not limited to the home but rather is defined as any place where children participate in activities and routines that provide learning opportunities that promote a child's behavior, function, and development. This includes child care settings, parks, grocery stores, YMCAs, and libraries.

Although natural environment implies a physical location, such as a playground, it goes beyond the physical place. It includes the people and relationships, the activities and routines the child and family typically engage in at that location, and the learning opportunities afforded by those activities. Dunst and colleagues[45] have identified common routines in a variety of family and community settings and present an approach for discussing with families activities and learning opportunities. These activities and learning opportunities include family routines (household chores and errands), caregiving routines (bathing, dressing, eating, grooming, bedtime), family rituals and celebrations (holidays, birthdays, religious events), outdoor activities (gardening, visits to the park/zoo), social activities (visiting friends, play groups), play activities (physical play and play with toys), and learning activities (listening to stories, looking at books/pictures). Physical therapists are encouraged to become familiar with the communities they serve including formal and informal leisure and recreational opportunities for families and young children.

Developmental frameworks and theories, such as the developmental systems theory,[64] the ecologic theory of human development,[24] and the transactional theory,[117] along with the ICF[146] are based on the assumption that the physical, social, and attitudinal environment is a mediator of child health, development, and participation. Evidence suggests that the environment, especially related to socioeconomic status, is a determinant of early childhood development and therefore significantly related to health and well-being across the life span.[132] Shelter and food insecurity, lack of transportation, and community violence are factors that increase family stress and the ability to provide developmentally supportive caregiving. For example, a family's ability to establish consistent routines around eating, sleeping, and fitness is affected by the social and physical factors of their home and community environments. Families may struggle to engage in positive parent–child interactions when experiencing stress, therefore affecting infant mental health.[148] Understanding that the natural environment might not be optimal (home or community) for all children is essential when considering the factors that influence their development as well as the choices families make regarding their concerns and priorities. With this in mind, we recommend sensitivity to the family's personal situation when discussing, prioritizing, and implementing strategies—especially when optimizing outcomes for children requires optimizing their environment.

Natural environments match the purpose of early intervention: "support families in promoting their children's development, learning, and participation in family and community life."[121] This approach embraces family-centered care by recognizing that the family has a primary role in nurturing the child and fostering growth, development, and learning. Campbell and Sawyer found that when service is focused on natural learning environments, caregivers are actively participating in the session and interactions revolve around the caregiver–child dyad.[29] When providing interventions in natural environments, therapists can easily focus on the children's function, promote socialization with their family and friends, and "strengthen and develop lifelong natural supports for children and families"[121] (Fig. 30.2).

For infants and young children, self-determined behavior, the parent–child relationship,[80] and play form the foundation to support the child's role in the family and to prepare the child for interactions with peers and school (Fig. 30.3). Brotherson and colleagues[26] observed the families and home environments of 30 young children with disabilities and found that families provide a variety of opportunities in the home to

FIG. 30.2 When providing therapy in the home, the family and therapist may consider inviting the grandmother to participate in the visit to support her role as a resource for the family in nurturing her grandchild. (Copyright iStock.com.)

FIG. 30.3 Involvement of siblings in caregiving activities during therapy visits promotes family bonds and supports family routines. (From Hockenberry M, Wilson D: Wong's nursing care of infants and children, ed 10, St. Louis, MO, 2015, Mosby.)

promote the development of their children's self-determination. The themes to describe these strategies included *choice and decision making*, *support of self-esteem*, *engagement with home environment and others*, and *control and regulation of the home environment*. Therapists can build on these strategies and reflect with parents on ways to support what the child does, what the family does, and what the environment affords to foster development of self-determination.[59] Chai and colleagues[34] identified socially and culturally based interactions as the common theme across various conceptual frameworks on natural environments. Therapists build a relationship with the family and provide support, feedback, and guidance to promote parent–child interactions that foster trust and competence.[80] Supporting play captures the essence of children in their daily lives. Therapists are encouraged to not simply address the physical components of play but rather to collaborate with the team to identify enjoyable play activities that incorporate all areas of development and involve parents, siblings, and friends to promote socialization.

Interventions for caregiving and self-care activities such as sleeping, feeding, bathing, dressing, and moving throughout the environment are essential (Fig. 30.4). Families of young children with cerebral palsy have identified self-care as their highest priority.[36] However, even in the natural environment, practitioners are more likely to employ teaching strategies in the context of toy play rather than naturally occurring routines and activities.[27] It is important for physical therapists to support feeding and nutrition needs, as this is a primary concern of families and critical for children's energy to move and grow.[143] As health care professionals, physical therapists have knowledge and skills in differential diagnosis, feeding disorders, pharmacology, oral-motor functioning, assistive technology, and community resources. Physical therapists also promote fitness, wellness, and injury/disease prevention of young children and families through parent education about daily age-appropriate physical activity and safety measures

FIG. 30.4 It is important for therapists to partner with fathers and support their role in caregiving activities. (Copyright iStock.com.)

such as use of car seats, baby-proofing the home, and healthy lifting for caregivers.

Providing services in natural environments is supported by principles of motor learning[141] and grounded cognition through perceptual-motor experiences.[89] Practice and repetition of activities in natural contexts and settings are more effective for learning and generalization. These places and activities are interesting and engaging and thus naturally motivating to children. This includes opportunities to learn by interacting with the people and objects in their environment[89] and through imitating peers and family members. Based on the family's daily life, therapists guide families on how to structure practice to promote learning of contextualized motor skills. Therapists help families to provide prompts and cues and, when necessary, physical assistance to enable the child to learn skills in self-care and mobility. Scales, McEwen, and Murray[118] found that although parents perceived benefits of instruction from providers, they noted that for some families, instruction may be a source of stress. Therapists are encouraged to collaborate with families to prioritize the activities and strategies and to support families in this process.

Therapists also collaborate with the family to adapt the physical environment, activities, and materials to enhance the child's participation in and access to learning opportunities. Examples include minor changes to the layout of a room or use of adapted toys or positioning and mobility devices. Assistive technology is an important component of intervention for children with severe physical disabilities.[135] Assistive technology, such as switches to activate toys, is underutilized for children under age 3.[42,91] Young children with physical disabilities can successfully learn to operate switches to produce meaningful outcomes.[32] Similarly, power wheelchair mobility or power adapted ride-on toys may afford infants and toddlers with limitations in mobility the opportunity for independence.[72,75,109] Planning forms and charts are available to guide the team in the decision-making process for designing and implementing adaptations.[31]

On one hand, consumers and professionals value services in natural environments. Research suggests that family routines provide the mechanism through which parents influence child outcomes.[133] Bernheimer and Weisner[19] gathered information on the daily lives of 102 families of children with disabilities and

concluded, "If there is one message for practitioners from our parents and from our longitudinal studies, it is that no intervention, no matter how well designed or implemented, will have an impact if it cannot find a slot in the daily routines of an organization, family, or individual." In a national survey, families and providers identified critical outcomes of services in natural environments: child mastery, parent–child interactions, inclusion, and child learning opportunities.[43] Furthermore, learning opportunities characterized as being interesting, engaging, competence-producing, and mastery-oriented predicted positive child outcomes.[44]

On the other hand, challenges exist in providing services in natural environments, and therapists are encouraged to seek creative solutions.[66] Challenges include logistic concerns, such as the costs, safety, and time to travel to the child's natural environments as well as philosophic concerns that by mandating a particular approach to service delivery, the system may not be providing options to meet families' individualized needs and circumstances. It is important for agencies to develop and implement policies to ensure staff safety such as the use of cell phones, co-visits, and soliciting advocacy efforts from neighborhood child watch organizations. Visits can occur in a variety of community locations such as the library, town centers, and recreational facilities. When service is provided in a community child care setting, it is important to schedule periodic visits with the family as well as to collaborate with the child care providers. Information on child care regulations, philosophy, and early childhood curriculum will assist the therapist in partnering with child care providers (Fig. 30.5).

Implementation of intervention in natural environments requires insights and planning. The first step is to consider the family-identified priorities and IFSP outcomes. It is essential for there to be a match between the information from families regarding their concerns, priorities, and resources and the services provided. The next step is to discuss with the family the activities, routines, and people that are part of their daily life. Box 30.9 provides questions to consider when collaborating with families to identify activities. Therapists are encouraged to identify the functional learning opportunities that occur during each activity. If a child-focused IFSP outcome is for the child to be able to play at the park, riding a swing may be an activity to consider. The therapist may identify a variety of learning opportunities for the child, such as grasping with two hands, pumping with his or her legs, holding the head and trunk up, understanding high and low, and making sounds. Therapists integrate intervention strategies within the context of family activities and learning opportunities. Therapists are encouraged to balance adult-directed learning opportunities with child-directed activities to promote self-determination.[52] Therapeutic techniques are used to improve the body functions and structures necessary to achieve a functional ability and to prevent secondary complications related to the cardiopulmonary, musculoskeletal, and neuromuscular systems. When possible, therapists are encouraged to integrate impairment-focused interventions into practice of activities.[141] Therapists use their expertise to guide families and teach children through meaningful natural learning opportunities; however, they may struggle with providing interventions in natural environments. It is important for therapists to advocate for the support and training they need to be able to provide services in natural environments. A work group through the Office of Special Education Programs provides concrete guidelines on intervention practices that support natural environments.[145] Box 30.10 summarizes intervention strategies for physical therapists in early intervention.

FIG. 30.5 Therapy at a child care setting can focus on promoting social interactions with peers and functional mobility to participate in activities on the playground. (From Hockenberry M, Wilson D: Wong's nursing care of infants and children, ed 10, St. Louis, MO, 2015, Mosby.)

BOX 30.9 Questions to Discuss With Families When Establishing Activities for Services in Natural Environments

- What activities make up your weekdays and weekends?
- What activities are going well, and which are not going well?
- What activities would you like support for?
- What activities does the child prefer to participate in?
- What activities provide natural learning opportunities?
- What activities provide opportunities for child initiation?
- What activities provide opportunities for peer interaction?
- Are there new activities that you would like to try?

The Transition Plan

The transition plan is part of the IFSP process that deserves special attention because of its essential role in assuring the child's progression in the educational system and participation in the community. The transition process is complex and can be a challenging experience for families. Child, family, program, and community characteristics influence the transition process,[113] and effective practices are comprehensive in order to address all dimensions.[114] Therapists, as early intervention team members, can take an active role in the transition process.

The first step is to become knowledgeable about how Part B Preschool Services (IDEA, 2004)[107] are implemented and about resources and service options in the community. IDEA provides for increased coordination between Part C and Part B programs. Parents may invite or permit one or more representatives from the Part C program to attend the initial Individualized Education Program (IEP) meeting when the child is transitioning to preschool services. In addition, IDEA provides states the flexibility to make Part C services

BOX 30.10 Intervention Strategies for Physical Therapists in Early Intervention

Team Collaboration

- Schedule periodic early intervention team meetings as needed.
- Conduct co-visits of early intervention team providers.
- Identify and access of community resources through community mapping.
- Establish interagency coordination plans as part of the IFSP.
- Visit or phone-conference with other health care professionals.
- Share documentation among early intervention team members and other agencies/practitioners serving the family.

Natural Environments

- Provide information and resources on family-identified concerns.
- Embed intervention strategies into the child's and family's daily life.
- Conduct visits when family members who are important in the child's life can participate.
- Conduct visits at community locations identified by the family.
- Provide intervention in different rooms in the home and outside to support a variety of daily activities and routines.
- Use the coaching process to engage families and children in the intervention process to foster self-determination and self-efficacy.
- Use family materials and toys, create simple objects with the family, and assist the family in accessing other toys and equipment to support IFSP outcomes.
- Implement adaptations, functional training, and restorative/preventive techniques to support self-regulation, adaptive behavior, parent-child interactions, self-care, mobility, play, and sibling/peer interactions.

available to children until they enter kindergarten or elementary school.

Second, it is important to make the commitment to collaborate with the early intervention and preschool teams. Focus groups have identified interagency relationships and communication as essential factors in the transition process.[114] This step includes an open discussion regarding the environmental characteristics that will support the child's learning and development including attention to the safety of the child in the new environment and during transportation. Therapists can offer, with the family's permission, to share information that will help the staff of the preschool program to meet the child's needs. The American Physical Therapy Association (APTA) Section on Pediatrics developed a transition worksheet to help share information between early intervention and school-based physical therapists.[126]

Third, therapists collaborate with families and provide them with resources, information, and support as they prepare for their child's transition. This support enables families to take an active role in the transition process. Most important, therapists serve as advocates, keeping in mind the family's dreams and vision for the child. Box 30.11 outlines strategies for collaborating with families.

Finally, therapists can focus on preparing children for the preschool environment and promote the development of school readiness skills. Awareness of early learning guidelines (ELGs)[119] and strategies to foster self-determination of young children[59,129] helps therapists collaborate with families to prepare young children for the preschool environment. Early learning guidelines are documents published by each state describing what children should know and be able to do before they start kindergarten. The five most common domains used in ELGs are health and physical development, social and emotional development, approaches to learning, language and communication development, and cognitive development.[120] Dimensions of self-determination such as self-awareness, self-regulation, engagement, self-initiation, making choices, problem solving, persistence, and self-efficacy can be nurtured in early childhood. Early intervention provides an opportunity to begin at a young age to influence children's self-esteem, ability to express themselves, make choices, and the belief that their actions have an impact on their world—competencies that are important for well-being and quality of life. Box 30.12 presents examples of strategies that physical therapists can incorporate during early intervention.

BOX 30.11 Strategies for Collaborating With Families to Support Transition From Early Intervention

- Listen to the family.
- Provide positive, but realistic, support for the preschool program:
  - Guide the family in gathering information without introducing your bias.
  - Provide the family with survey and interview guidelines for preschool programs.
  - Visit a program with the family and help orient the family and child to the new agency.
- Discuss separation from the child as a natural process.
- Celebrate graduation from early intervention with the family and child.
- Consider a follow-up communication with the family after transition.

BOX 30.12 Strategies to Prepare a Child for Preschool

- Provide the child with opportunities to play with other children (i.e., siblings, neighbors, play groups).
- Promote independent playtime.
- Encourage the child to participate in a variety of play experiences.
- Encourage self-care skills.
- Give the child an opportunity to practice following simple directions.
- Make the child responsible for small tasks, like putting away toys.
- Have the child make choices, and encourage the child to express wants and needs.
- Read stories about school.

PROGRAM EVALUATION

Program evaluation in early intervention determines the extent to which services are provided in an efficient and effective manner, including stakeholders' level of satisfaction and the degree to which child and family outcomes are achieved. Information from a program evaluation helps early intervention personnel at all levels (e.g., state and county lead agency administrators and practitioners) and families understand areas of strengths and, importantly, areas that need improvement. A four-tiered approach to program evaluation has been described.[74,142] Through the first tier, a needs assessment, the needs of the population being served are determined, policy or programs to meet the needs are proposed, and a monitoring system is developed to document progress. Through the second tier, monitoring and accountability, services are systematically documented to

assist in program planning and decision making. Through the third tier, quality process, the quality of the services is judged to provide information for program improvement. Through the fourth tier, achieving outcomes, the extent to which IFSP outcomes are met and attributed to early intervention services is determined to provide information for program improvement and contribute to the knowledge base.

Program evaluation is recommended to determine how early intervention is actually implemented and to assess the outcomes for families and children. As previously discussed, a national accountability system is now in place to monitor the impact of early intervention on global child and family outcomes. However, individual programs are encouraged to engage in the program evaluation process to guide decisions on service delivery. Stuberg and DeJong[134] provided a useful example of how to implement a program evaluation for physical therapy service within early intervention and school settings. They reported that 91% of the children's individualized objectives were either achieved or progress was made. Children in early intervention and preschool had higher achievements than older children, and children with more severe disability had fewer achievements than children with less severe disability. These findings may guide program developers in how best to establish appropriate and meaningful individualized outcomes.

Bailey[11] proposed a framework for program evaluation in early intervention to assess family involvement and support. He discussed three levels of accountability: (1) providing what the legislation requires, (2) providing services that reflect current best practices, and (3) achieving family outcomes. Program evaluation is challenging secondary to the multiple dimensions of early intervention, the variability in the characteristics of children and families served, and the individualized needs of families and children. However, through program evaluation, facilitators, barriers to quality and effective services are identified and recommendations are provided for program improvements.

PROFESSIONAL DEVELOPMENT

Personnel preparation in early intervention (entry level and practice level) is an area of concern across disciplines and national efforts are under way to create integrated and comprehensive professional development models for practitioners who serve young children with disabilities and their families.[54] Physical therapists in early intervention are challenged to participate in ongoing professional development not only for licensure but to build their capacity to provide evidence-informed and family-centered services in natural environments.[33] Therapists are encouraged to participate in continuing education and implement new knowledge and skills during their interactions with children, families, and other practitioners. Reflecting on practice, creating a professional development plan, and seeking a mentor to discuss opportunities for professional growth are also recommended. Experienced and novice therapists, especially those new to early intervention, should strive to achieve the competencies for physical therapy early intervention practice.[35] The competencies are a valuable tool both to measure personal professional development and to identify the common and unique roles of the physical therapist on the early intervention team. Therapists are encouraged to use resources from the Early Childhood Personnel Center,[54] the Division for Early Childhood,[40,41] and the APTA Section on Pediatrics website (www.pediatricapta.org) and to advocate for state- and agency-sponsored interdisciplinary professional development activities.

SUMMARY

Physical therapists in early intervention support the implementation of IDEA by establishing collaborative partnerships with children, families, and practitioners from multiple disciplines to provide individualized, coordinated, and comprehensive care in natural environments. Physical therapists integrate their expertise of the movement system with knowledge of early childhood development, family ecology, and the environment to promote the child's development and participation in family and community life, as well as to support the family. This unique practice setting enables therapists to embrace the art of caring, prepare children for their roles in school, and foster health and well-being.

Case Scenarios on Expert Consult

Two case scenarios illustrate how the physical therapist, as a member of the early intervention team, provides family-centered services under the IDEA. The first case highlights Mateo, a 22-month-old with global developmental delay and failure to thrive, and his mother, Jenni. The process of discussing, writing, and prioritizing IFSP outcomes and strategies when multiple needs are identified is described. The second, a video-based case scenario, illustrates how intervention strategies for Andrew and his family are implemented through a collaborative, family-centered team approach in natural environments. The case scenario also includes a sample activity matrix to illustrate how intervention strategies can be integrated into family daily routines to support desired outcomes for the child.

The Educational Environment

Susan Effgen, Marcia K. Kaminker

Almost from the start of physical therapy in the United States, physical therapists have worked in educational environments. The civil rights movement of the 1960s and federal legislation of the1970s, however, marked the beginning of major changes in services for all children with special needs in school settings. As a consequence of continued federal and state mandates for the education of students with disabilities, the school system has become the practice setting that employs the greatest number of pediatric physical therapists. Since 1975, a generation of physical therapists has been instrumental in advocating for school-based practice and the development of standards for practice.[46] The educational setting is unique in emphasizing individualized outcomes for student participation in the education program and continues to present opportunities and challenges for pediatric therapists. This chapter reviews the history of the delivery of physical therapy in educational environments, in addition to discussing federal legislation and court cases that have changed how children with disabilities are educated and receive physical therapy. Key topics related to physical therapy in educational environments are presented, including inclusive education, models of team interaction, service-delivery models, the individualized educational program (IEP), and intervention strategies. Critical issues facing physical therapists working in educational settings are also highlighted.

BACKGROUND INFORMATION

Although the history of physical therapy in the United States is traced to "reconstruction aides" serving the injured of World War I, it can also be traced to the service of "crippled children," especially those with poliomyelitis. In major cities early in the 20th century, children with physical disabilities were served in hospitals and special schools. The children had a variety of diagnoses, including poliomyelitis and spastic paralysis,[23,56] cardiac disorders, "obstetric arms" (brachial plexus injuries), bone and joint tuberculosis, clubfeet, and osteomyelitis.[16,23,95] By the 1930s, numerous articles had been published describing the delivery of physical therapy in these special schools.[16,95,128,140] Epidemics of poliomyelitis increased the need for special schools and physical therapists. After the vaccine for poliomyelitis was developed in the 1950s, the need for special schools was temporarily reduced, until public awareness increased regarding the needs of children with other disabilities.

Historically, most children in special schools had normal or near-normal intelligence. Many schools required children to be toilet trained, and some required children to walk independently. This trend to serve only those with physical disabilities and normal intelligence continued in many areas of the United States until schools were federally mandated in 1975 to serve all children with disabilities by the enactment of Public Law (PL) 94-142, the Education for All Handicapped Children Act.[116]

FEDERAL LEGISLATION AND LITIGATION

A number of social and political events paved the way for the enactment of the Education for All Handicapped Children Act. In 1954, the historic US Supreme Court decision regarding segregated schools was handed down: Brown *v.* Board of Education of Topeka.[21] Separate-but-equal schools were found inherently unequal. This Supreme Court decision was to end the segregated education of African-American children, but the principles and foundation of this case could also apply to segregated schools for those with disabilities. The call for social equality had begun and would eventually include those with disabilities. President Kennedy's personal experience with his sister who had a disability expedited his establishment in 1961 of the President's Panel on Mental Retardation. Television documentaries exposed institutions in New York, and Blatt and Kaplan's book, *Christmas in Purgatory: A Photographic Essay on Mental Retardation*,[18] raised national concern for the care and treatment of individuals with disabilities. Leaders such as Wolfensberger[144] were influential proponents of deinstitutionalization and normalization. Cruickshank noted that "as is usually the case with major changes in social policy, the normalization trend is not based on empirical data showing greater effectiveness or efficiency of the changes proposed by its advocates".[31] Instead, it focused on the civil rights of individuals, a prevailing anti-institutional attitude—especially governmental institutions—and a commitment "to the democratic, the individualistic, and the humanitarian".[31] The federal Developmental Disabilities Assistance and Bill of Rights Act of 1975 (PL 94-103)[115] included a provision that states had to develop and incorporate a "deinstitutionalization and institutional reform plan".[20] Advocacy groups had gained power, and they used the judicial system to win their rights.

The Pennsylvania Association for Retarded Citizens (PARC) *v.* Commonwealth of Pennsylvania (1971)[103] was the historic, decisive court case establishing the uncompromising right to an education for all children with disabilities. This was a class-action suit on behalf of 14 specific children and all other children who were in a similar class to those with trainable mental retardation. In Pennsylvania, a child was excluded from public school if a psychologist or other mental health professional certified that attendance at school was no longer beneficial for that

child. The local school board could refuse to accept or retain a child who had not reached the mental age of 5 years. Children classified as trainable mentally retarded, therefore, were unable to receive a public education in Pennsylvania. The court sided with the children.

In PARC *v.* Commonwealth of Pennsylvania, the court found that all children between 6 and 21 years of age, regardless of degree of disability, were to be given a "free and appropriate public education (FAPE)."[103] Children with disabilities were to be educated with children without disabilities in the least restrictive environment (LRE). The educational system was ordered to stop applying exclusionary laws, parents were to become involved in the child's program, and reevaluations were to be conducted. This landmark court case established many important principles that were later incorporated into the Education for All Handicapped Children Act. Simultaneous with the PARC case, other important court cases were being decided. Mills *v.* Board of Education of the District of Columbia (1972)[92] was filed on behalf of all children excluded by public schools for a disability of any kind, including behavioral problems. The major result of this case was that all children, no matter how severe their mental retardation, behavioral problem, or disability, were educable and must be provided for suitably by the public school system. Related services, including physical therapy, were to be part of their educational program.

In Maryland Association for Retarded Citizens *v.* Maryland (1972),[92] it was ruled that children have the right to tuition subsidies, the right to transportation, and the right to be educated with children who are not disabled. These cases and others across the nation began to establish the right of all children to a "free and appropriate public education." It was in this climate that PL 94-142 was enacted.

PL 94-142: EDUCATION FOR ALL HANDICAPPED CHILDREN ACT

Provisions

On November 29, 1975, the US Congress passed PL 94-142, the Education for All Handicapped Children Act.[116] The law included the elements won in individual court cases across the nation and provided for a "free and appropriate public education" for all children with disabilities from ages 6 to 21 years (age 5 years if a state provided public education to children without disabilities at age 5 years). The major provisions of PL 94-142, still in place today, concern the concepts of zero reject, education in the least restrictive environment, right to due process, nondiscriminatory evaluation, individualized educational program, parent participation, and the right to related services, which include physical therapy.

Zero Reject

All children, including children with severe or profound disabilities, are to receive an education. Initially these children were to receive priority for service because they probably were not receiving appropriate service at that time.

Least Restrictive Environment

Public agencies are to ensure the following:

> To the maximum extent appropriate, children with disabilities, including children in public or private institutions or other care facilities, are educated with children who are not disabled, and special classes, separate schooling, or other removal of children with disabilities from the regular educational environment occurs only when the nature or severity of the disability of a child is such that education in regular classes with the use of supplementary aids and services cannot be achieved satisfactorily. [PL 108-446, 118 Stat. 2677, § 612 (a)(5)(A)][112]

Right to Due Process

The law provides parents with numerous rights. Parents have the right to an impartial hearing, the right to be represented by counsel, and the right to a verbatim transcript of a hearing and written findings. They can appeal and obtain an independent evaluation. Later, under PL 99-372, the Handicapped Children's Protection Act [1986, 20 USC § 1415(e)(4), (f)], parents would be able to be reimbursed for legal fees if they prevailed in a court case.[117]

Nondiscriminatory Evaluation

Several court cases had noted the discriminatory nature of the testing and placement procedures used in many school systems. Nondiscriminatory tests were to be administered, and no one test could be the sole criterion on which placement was based. Nondiscriminatory testing is critical in the cognitive and language domain; however, physical therapists, too, should be careful to determine that their tests are not biased. When possible, standardized tests that have norms for different racial and cultural groups should be used.

Individualized Educational Program

Every child receiving special education must have an individualized educational program (IEP). This is the comprehensive program outlining the specific special education, related services, and supports the child is to receive. It includes measurable annual goals. The IEP is developed annually at an IEP meeting.

Parent Participation

Active participation of parents is encouraged under PL 94-142. Parents are the individuals responsible for continuity of services for their child and should be the child's best advocates. Parents are major decision makers in the development of the IEP. They must give permission for an evaluation, they can restrict the release of information, they have access to their child's records, and they can request due process hearings.

Related Services

Related services, such as transportation, speech-language pathology, audiology, psychological services, physical therapy, occupational therapy, recreation, and medical and counseling services, are to be provided "as may be required to assist a child with a disability to benefit from special education" [PL 94-142, 89 Stat. 775, PL 108-446, 118 Stat. 2657, § 602 (26);].[111,116] This quotation from the law has been interpreted in many different ways. Physical therapy "to assist a child with a disability to benefit from special education" in some school systems is limited to only those activities that help the child write or sit properly in class. Other school systems more appropriately interpret the law to mean physical therapy that can help the child explore the environment, perform activities of daily living, improve function in school, prepare for vocational training, and improve physical fitness to be better prepared to learn and participate in a full life after school. This

fulfills the purpose of IDEA, to prepare children "for further education, employment, and independent living [PL 108-446, Section 601 (d)(1)(A)].[112] Related service personnel are also now referred to as specialized instructional support personnel (SISP).

PL 99-457: EDUCATION OF THE HANDICAPPED ACT AMENDMENTS OF 1986; PL 102-119: INDIVIDUALS WITH DISABILITIES EDUCATION ACT AMENDMENTS OF 1991; PL 105-17: INDIVIDUALS WITH DISABILITIES EDUCATION ACT AMENDMENTS OF 1997; PL 108-446: INDIVIDUALS WITH DISABILITIES EDUCATION IMPROVEMENT ACT OF 2004

Congress must reauthorize the law at set intervals. At each reauthorization, the number of the public law changes to indicate which Congress is reauthorizing the law (the first number after PL) and which bill it is for that Congress (second number). In 1986, the reauthorization, PL 99-457, the Education of the Handicapped Act Amendments of 1986,[118] was particularly critical because this act extended services to infants, toddlers, and preschoolers with disabilities and their families. Services to infants and toddlers, now covered under Part C of the law, are discussed in Chapter 30. On October 7, 1991, PL 94-142 and PL 99-457 were reauthorized and amended as PL 102-119, the Individuals with Disabilities Education Act Amendments of 1991 (IDEA).[108] PL 105-17 was signed into law in June 1997,[109] and PL 108-446, the Individuals with Disabilities Education Improvement Act of 2004,[112] was signed on December 3, 2004. PL 108-446 was to be reauthorized in 2010, but this has been delayed. The reader is urged to check for information on the reauthorization and any new rules and regulations. The key elements of these reauthorizations, which comprise refinement and reorganization of the previous amendments, are described in this section.

Part A: General Provisions

Congress found the following:

> Disability is a natural part of the human experience and in no way diminishes the right of individuals to participate in or contribute to society. Improving educational outcomes for children with disabilities is an essential element of our national policy of ensuring equality of opportunity, full participation, independent living, and economic self-sufficiency for individuals with disabilities. [PL 108-446, 118 Stat. 2649, § 601(c)][112]

Critical to this policy is the recognition that education encompasses more than traditional academics and is also intended to prepare children for independent living and self-sufficiency. This expands the goals that can be considered "educationally relevant." Additionally, principles of universal design, which are part of the Assistive Technology Act of 1998,[110] have been added to IDEA 2004. These include the design of products that can be usable by all people, to the greatest extent possible, with minimal need for adaptations and accommodations. These elements strengthen the physical therapist's role in providing access to the educational environment and learning materials.

Part B: Assistance for Education of All Children With Disabilities

Part B outlines the right for all children 3 to 21 years of age to "a free appropriate public education [FAPE], that emphasizes special education and related services designed to meet their unique needs and prepare them for further education, employment, and independent living" [20 USC 1400. Sec. 601. (d)(1)(A)].[112] Children 3 to 5 and 18 to 21 years of age might not be served if inconsistent with state law. States are mandated to identify, locate, and evaluate all children with disabilities. Children considered eligible for special education and related services are those having one or more of the following disabilities:

> mental retardation [now referred to as intellectual impairment], hearing impairments (including deafness), speech or language impairments, visual impairments (including blindness), … emotional disturbance, orthopedic impairments, autism, traumatic brain injury, other health impairments, or specific learning disabilities and who, by reason thereof, need special education and related services. (20 USC 1401. Sec. 602. (3)(A)(i)

At the discretion of the state, a child with a disability might also include those experiencing developmental delays at age 3 to 9 years.

Children 3 to 5 years of age are to have IEPs, as are school-age children; however, the 1991 reauthorization, PL 102-119,[108] allowed states the option of using individualized family service plans (IFSPs), required for infants and toddlers, for preschool-age children. The 2004 reauthorization also allows states the option to continue to provide early intervention services to children with disabilities until the child enters kindergarten or elementary school [PL 108-446, 118 Stat. 2746, § 632(5)(B)(ii)].[112] Some professionals believe that preschoolers and their families are better served by the family-centered approach embodied in early intervention.

Least Restrictive Environment

An ongoing area of national effort is the education of children with disabilities in the least restrictive environment (LRE). Children should be educated in their local schools to the maximum extent appropriate. The degree of inclusion in the local school and the general education classroom will vary based on what is appropriate for each child. Children are not merely to be *placed* in general education, but they are to participate fully and have goals related to their academic and social advancement. Since 1990, a significant reduction has occurred in the placement of children with disabilities in separate facilities and segregated classrooms, along with substantial increases in the amount of time they spend in regular classrooms.[138]

Transition

Transition planning was specifically addressed in IDEA 1997,[109] because this important service had often been neglected. Transition planning and required services must be included in the IFSP and IEP. Consideration must be given to transition from early intervention to preschool, from preschool to school, at critical points during school years, and especially from age 16 years to exit from school. Physical therapists and other related service personnel are to be involved in transition planning for post-school activities, as appropriate. Transition to adulthood is presented in Chapter 32.

Assistive Technology

Assistive technology devices and assistive technology services allow the child to benefit fully from the educational program:

> The term "*assistive technology device*" means any item, piece of equipment, or product system, whether acquired commercially off the shelf, modified, or customized, that is used to increase, maintain, or improve the functional capabilities of a child with a disability … "*assistive technology service*" means any service that directly assists a child with a disability in the selection, acquisition, or use of an assistive technology device. [PL 108-446, 118 Stat. 2652, § 602(1)][112]

Assistive technology services include evaluation, selection, purchasing, and coordination with education and rehabilitation plans and programs. This is an important area, as physical therapists frequently provide assistive devices to improve a child's function and participation in school. Therapists adapt seating so children can function better and safely in the classroom. They assist other team members in devising communication systems, along with providing access to switching devices and computers. Physical therapists are generally the key related service providers involved in the choice and maintenance of mobility devices, including walkers, crutches, canes, and manual and power wheelchairs. These mobility devices allow children with disabilities to access the school building and grounds and thereby participate in all aspects of their education program. The extent of assistive technology services and the purchasing of devices vary among school systems. For additional information, see Chapter 33.

Early Intervening Services and Response to Intervention

Early intervening services (EISs) and response to intervention (RTI) are both new to IDEA 2004. An EIS focuses on children from kindergarten to grade 3 who would benefit from additional academic services and behavioral support to succeed in the general education environment.[112] RTI involves high-quality instruction/intervention, using the student's learning rate and level of performance for decision making. Important educational decisions are based on the student's response to instruction/intervention across multiple tiers.[10] RTI is an evaluation and intervention process used to monitor student progress and make data-based decisions about the need for and provision of instructional modification, evidence-based intervention, and increasingly intensified services for students having problems in school. The goal of RTI is to prevent over-identification of children for special education, especially those with potential learning disabilities. RTI is a departure from deficit-based assessments and focuses on possible successful interventions rather than "what is wrong" with the student. It is a multitiered service-delivery model with differentiated instruction to meet the individual needs of all students, not just those with specific disabilities.[4]

RTI holds many promises, in that collaboration and teaming are required to support implementation. RTI is defined by high-quality instruction and provides a curriculum structure that can be implemented in an inclusive setting.[70] RTI allows therapists to participate with the team to meet a student's needs *prior* to establishing eligibility for special education. Therapists may offer expertise in many areas, such as in modifying classrooms, suggesting learning strategies, providing adaptive equipment, or any necessary intervention. The goals incorporate what is required for the student to succeed in the curriculum with the fewest restrictions.

Questions often arise regarding RTI and the need for written parental approval to perform an evaluation, parental approval to provide services, and the extent of documentation necessary for evaluation and intervention. Answers to those questions will depend on individual state physical therapy practice acts and regulations[5]; however, it is usually appropriate to obtain written permission from parents for any form of evaluation and intervention. Documentation of interaction with a child is always an important element of ethical practice.

SECTION 504 OF THE REHABILITATION ACT

Section 504 of the Rehabilitation Act of 1973 (PL 93-112)[114] is a comprehensive antidiscrimination statute designed to ensure that federal funding recipients—including schools—provide equal opportunity to people with disabilities. It has been used to expand a student's eligibility for related services in school. Educational agencies that receive federal funds are not allowed to exclude qualified individuals with disabilities from participation in any program offered by the agency. The definition of qualified "handicapped person" under Section 504 is broader than it is in IDEA. Under Section 504, "*qualified handicapped person* means any person who (i) has a physical or mental impairment which substantially limits one or more major life activities, (ii) has a record of such an impairment, or (iii) is regarded as having such an impairment" [34CFR104.3(j)(1)].[114] "*Major life activities* means functions such as caring for one's self, performing manual tasks, walking, seeing, hearing, speaking, breathing, learning, and working" [34CFR104.3(j)(2)(ii)]. The Americans with Disabilities Amendments Act of 2008 (ADAAA)[113] includes a "conforming amendment" to Section 504, which means that the expanded coverage of ADAAA also applies to Section 504. The ADAAA retains the definition of disability under Section 504 but emphasizes that it should be interpreted broadly[139]:

> [The ADAAA] directs that the ameliorating effects of mitigating measures (other than ordinary eyeglasses or contact lenses) not be considered in determining whether an individual has a disability; expands the scope of "major life activities" by providing a non-exhaustive list of general activities and a non-exhaustive list of major bodily functions; clarifies that an impairment that is episodic or in remission is a disability if it would substantially limit a major life activity when active.[139]

Thus it is possible that a child who does not require special education according to the accepted definitions of disabilities under IDEA, but who is a *qualified handicapped person,* might be able to receive all the aids, services, and accommodations necessary to receive a free and appropriate public education through Section 504. Nationally, only 1.2% of public school students are Section 504 students, with the greatest numbers in middle and high school having attention deficit hyperactivity disorder.[64] The ADAAA means that more students will qualify for support under Section 504.[74] Interpretation of Section 504 varies among states and even among individual school districts; in some districts, students with 504 plans may receive direct physical therapy services or consultation, but in other districts they may not.

PL 101-336: AMERICANS WITH DISABILITIES ACT

The Americans with Disabilities Act (ADA) (PL 101-336)[107] was signed into law on July 26, 1990. It "extends to individuals with disabilities comprehensive civil rights protection similar to those provided to persons on the basis of race, sex, national origin, and religion under the Civil Rights Act of 1964." The regulations cover employment; public service, including public transportation, public accommodations, and telecommunications; and miscellaneous provisions. Although the law does not specifically address issues related to children in school, the provisions of ADA assist students with disabilities. The law is especially applicable to day care centers and transition to employment. Public buildings, including schools, must be accessible, and children should be able to use public transportation to get to school, work, and social activities. Children with disabilities should expect to use the skills learned at school in an accessible workplace. The ADA is also discussed in Chapter 32, Transition to Adulthood for Youth With Disabilities.

ELEMENTARY AND SECONDARY EDUCATION ACT

The Elementary and Secondary Education Act of 1965 (ESEA) was passed as part of the "War on Poverty." ESEA emphasizes equal access to education of all children and encourages high standards and accountability. The law provides federal funding for education programs that are administered by the states.

Congress amended and reauthorized ESEA as the No Child Left Behind Act of 2001 (NCLB) (PL 107-110).[112] This federal legislation was to ensure that all children, including those with disabilities, receive a high-quality education. To achieve this goal, all children were to demonstrate "adequate yearly progress" on standardized tests. There has been considerable criticism of this legislation. "Among these concerns are: over-emphasizing standardized testing, narrowing curriculum and instruction to focus on test preparation rather than richer academic learning, over-identifying schools in need of improvement, using sanctions that do not help improve schools, inappropriately excluding children with low-scores in order to boost test results, and inadequate funding."[97] In 2003, new federal provisions were announced, in recognition of the failure of NCLB to properly address the testing of children with disabilities and to meet annual yearly progress for closing the achievement gap. Under these provisions, local educational agencies (LEAs) have greater flexibility in meeting the requirements of NCLB.[50] Each state is now responsible for determining the definition of *significant cognitive disabilities*. To assist with the demands of NCLB, physical therapists working in school systems should ensure that children are properly positioned and have appropriate writing implements or computer access for testing situations. ESEA is being reviewed for reauthorization and the reader should seek information on how the reauthorized law might impact physical therapy service delivery.

CASE LAW

A law as comprehensive and complex as IDEA was bound to lead to some controversy. All possible situations could not be anticipated, and some issues were expected to be resolved by the courts. Disagreements that have led to due process hearings involving physical therapy have generally focused on (1) adequacy of physical therapy services, (2) qualifications and training of personnel, (3) need for services over the summer or during school breaks, (4) compensatory physical therapy, and (5) types of intervention provided.[73] As a result of due process disagreements, a number of state and federal court cases have helped define the scope of the law. Those of interest to physical therapists include cases involving related services, best possible education, extended school year (ESY), and LRE.

Related Services

Tatro *v.* Texas[84] was one of the early major cases involving PL 94-142. Amber Tatro had spina bifida and required clean intermittent catheterization several times during the school day. Her parents wanted assistance with catheterization at school. School officials refused, claiming that catheterization is a medical procedure, and Amber could not attend school unless her parents handled the procedure. The parents then initiated what turned out to be a 10-year legal battle. During the legal process, they were told that although catheterization was necessary to sustain Amber's life, it was not necessary to benefit from education; the school system, therefore, was not obligated to provide the service. After a complicated course through the court system, the US Supreme Court heard the case. Amber attempted to attend the proceedings, only to discover that the building was not wheelchair accessible. The Supreme Court ruled that clean intermittent catheterization was a related service that enabled the child to benefit from special education:

> A service that enables a handicapped child to remain at school during the day is an important means of providing students with the meaningful access to education that Congress envisioned. The Act makes specific provision for services, like transportation, for example, that do no more than enable a child to be physically present in class.[69]

This case led to the "bright-line" physician-nonphysician rule that a school district is not required to provide services of a physician (other than for diagnostic and evaluation purposes) but must offer those of a nurse or qualified layperson. This case is important to physical therapists because the realm of related services was expanded, as was the meaning of "required to benefit from special education."

Court cases have also involved related services and children who are medically fragile and require extensive services of a nurse and others. Some states advocate the use of an extent/nature test, in which decision making focuses on the individual case and considers the complexity of and need for services. The US Supreme Court in Cedar Rapids Community School District *v.* Garret F (1999)[27] reaffirmed that related services (in this case, nursing services) were not excluded medical services under IDEA and must be provided in schools, irrespective of the intensity or complexity of the services. This decision supported the right to an education for children with complex health care needs.

Best Possible Education

Board of Education of Hendrick Hudson Central School District *v.* Rowley[19] involved Amy Rowley, who was deaf. She had a special tutor, her teachers were trained in basic sign language, and she was provided with a sound amplifier. After experimenting with a sign language interpreter in a general education class, the school system decided she did not need the service. Her parents believed she needed the interpreter and went through due

process to continue interpreter services. A district court held that Amy was not receiving a free and appropriate public education because she did not have "an opportunity to achieve her full potential commensurate with the opportunity provided to other children." The school district appealed, and the case eventually went to the US Supreme Court. The 1982 Supreme Court decision held that Congress did not intend to give children with disabilities the right to the best possible education (i.e., education that would "maximize their potential").[19] It rejected the standard used by the lower courts that children with disabilities are entitled to an educational opportunity "commensurate with the education available to nonhandicapped children." The decision set two standards: (1) a state is required to provide meaningful access to education for each child with a disability, and (2) sufficient supportive and related services must be provided to permit the child to benefit educationally from special education instruction.

When the Supreme Court applied these standards in Rowley, it found that Amy did not need interpreter services because she was making "exemplary progress in the regular education system" with the help of the extensive special services. The Supreme Court was careful to point out that merely passing from grade to grade does not mean a child's education is appropriate.

The Rowley decision has had a major impact on the provision of related services, including physical therapy. Unfortunately, in some school systems it has been used to limit the amount of physical therapy provided on the premise that schools are not obligated to provide the "best services." Therapists should recognize that "exemplary progress" may be a reason to terminate services unless an educational need for physical therapy can be substantiated.

Extended School Year

As children with special needs began to benefit from their educational programs, some parents realized that their children's skills were regressing during the summer and that it took several months to regain those skills when the children returned to school in the fall. Because the US Congress had realized that more than the traditional 12 years of schooling might be necessary for children with disabilities to reach their potential, perhaps it could be inferred that if a child regressed during the summer, extended school year services might be necessary.[84]

Several court cases addressed this issue. In both Battle *v.* Commonwealth of Pennsylvania (1981)[17] and Georgia Association of Retarded Citizens *v.* McDaniel (1981),[54] parents sought to extend the school year. In Pennsylvania, it was found that the state's policy of defining a school year as 180 days could not be used to prevent the provision of an extended school year. In Georgia, the court ruled that an extended school year must be based on individual cases. The child must show significant regression following school breaks, the extended year must be part of the IEP, and an extended year does not mean 5 days a week for 52 weeks but must be based on a program to attain goals.

Eligibility for extended school year (ESY) services is based on several criteria. These include "individual need, nature and severity of the disability, educational benefit, regression and recoupment, self-sufficiency and independence, and failing to meet short-term goals and objectives" (p 16).[124] The possibility of receiving services for the entire year has many implications for physical therapy. The children most likely to require ESY services are usually those with the most severe disabilities, often requiring physical therapy. Some children may be deemed eligible for ESY academic services but not need ESY physical therapy services. One criterion used to qualify for ESY services is documentation of regression during vacations and the length of time it takes to recoup or relearn skills. It is therefore vital for physical therapists to do an examination and evaluation before and after school breaks. Documentation of regression, especially during short breaks, might enable a child to receive physical therapy during the summer. Using the child's status at the end of the summer as the basis for ESY physical therapy services might be confounded, however, if the child receives private physical therapy during the summer and regression is prevented.

An ethical dilemma can arise for some physical therapists over the ESY issue. Some school therapists provide private physical therapy during the summer and might prefer that the school system not provide the service. Others might not want the obligation of having to provide services during the summer, either through the school or privately. Therapists must be careful to recognize these potential conflicts of interest.

Least Restrictive Environment

The issue of LRE, also referred to as *inclusion,* has generated much discussion over the years; it has also generated many due process hearings and lawsuits. Outcomes have been mixed. During the early 1990s, the party seeking inclusion, usually the parent, prevailed in a series of court cases, the most noted being Oberti (3d Cir. 1993) and Daniel R.R. (5th Cir. 1989).[146] Later cases ruled against inclusive, general education placements as the LRE for students who were past elementary-school age and had severe disabilities. A rational approach must prevail in issues regarding inclusion. As discussed later in the chapter, options must exist for locations and types of services available to the child that can and should change over time.

EDUCATIONAL MILIEU

Although for many years, physical therapists have served children with disabilities in the general education setting, educational administrators and teachers vary in their perceptions of the role of physical therapy. Similarly, physical therapists have different perspectives of their role in the educational milieu. Hence, open communication and collaboration are essential. To create an effective working environment, physical therapists must take the time to develop relationships with administrators, teachers, and staff, and they need to understand the written and unwritten rules of the educational environment.

Least Restrictive Environment

Education of all children in the LRE, no matter how severe their disabilities, is the intent of the federal laws and is considered "best practice" (PL 105-17; PL 108-446).[91,136] The conceptual framework for education in the LRE started in the 1960s. Reynolds[125] advocated a continuum of placement options from most restrictive to least restrictive. Deno[36] named this the *cascade of educational placements.* The cascade of environments, from most to least restrictive, includes the residential setting, homebound services, special schools, special classes in neighborhood schools, general classes with resource assistance in neighborhood schools, and general classes in the neighborhood school without resource assistance. Taylor,[136] a longtime advocate for total integration of people with severe disabilities, proposed that the focus must change from expecting individuals

to fit into existing programs to providing services and supports necessary for full participation in community life. Terminology used to describe LRE has evolved from *mainstreaming,* to *integrated,* to *inclusive*. The differences in terms are more than merely a change in language.

Inclusive education at its best involves the whole school where children with disabilities are served in the general education environment with the required "supplementary aids and services."[83] Models for meeting a student's needs in an inclusive setting include (1) general education and special education teachers co-teaching during all or part of the curriculum; (2) indirect, consultative support from the special education teacher; (3) material adaptation by the special education teacher; (4) including the special education teacher as a member of the team serving the child; and (5) a schoolwide approach whereby the entire staff takes responsibility for all students.[83] As part of inclusive education, therapists are encouraged to provide services in the context of the student's education program with other students present.

Compliance with LRE requirements occurs to varying degrees across the nation. Physical therapists need to develop collaborative working relationships with all appropriate personnel for maximum communication and team effectiveness and for optimal student outcomes. Therapists must be prepared to work with administrators, teachers, and staff who may know little about children with disabilities and the role of the physical therapist in educational settings. This presents a challenging and potentially rewarding opportunity for therapists to share their knowledge about the health conditions of students with disabilities including activity accommodations, assistive technology, and environmental modifications to enable full participation in the education program. Interaction with other physical therapists is often limited when only a few children receive physical therapy services at each school. Therapists might also need to travel long distances to see a single child, and scheduling services and times to meet with teachers can be difficult. The reader is encouraged to examine other references for a more in-depth discussion of positive outcomes and aspects of inclusion.[25,28,57,86,121,127]

BOX 31.1 Models of Team Interaction

Unidisciplinary: Professional works independently of all others.

Intradisciplinary: Members of the same profession work together without significant communication with members of other professions.

Multidisciplinary: Discipline-specific roles are well defined and professionals work independently but recognize and value the contributions of other disciplines. There may be little interaction among professionals. However, the Rules and Regulations (Federal Register, June 22, 1989, p 26313) for PL 99-457 redefine multidisciplinary to mean "the involvement of two or more disciplines or professions in the provision of integrated and coordinated services, including evaluation and assessment."

Interdisciplinary: Discipline-specific roles are well defined; however, individuals from different disciplines work together cooperatively on planning, implementation, and evaluation of services. Emphasis is on teamwork. Role definitions are relaxed.

Transdisciplinary: Professionals are committed to working across disciplines and sharing information. Role release occurs when a team member assumes the responsibilities of other disciplines for service delivery.

Collaborative: The team interaction of the transdisciplinary model is combined with the integrated service-delivery model. Professionals provide services across disciplinary boundaries as part of the natural routine of the school and community.

Models of Team Interaction

An evolution in the models of team interaction has occurred. The hierarchy of team interaction is presented in Box 31.1. A unidisciplinary model is not collaborative and should rarely, if ever, be used in school settings. The multidisciplinary model involves several professionals conducting independent evaluations and then meeting to discuss their evaluations and determine goals, objectives, and a plan of action. The meaning of *multidisciplinary* has changed since 1986 because of its usage in PL 99-457.[118] In the law, the term *multidisciplinary* is used to describe an interdisciplinary model, causing frequent confusion.

The definition and application of the transdisciplinary model are also ambiguous. For some, the continuous sharing of information across disciplines is sufficient for a transdisciplinary model. For others, there must be complete role release, which involves not just the sharing of information but also the sharing of performance competencies. Team members teach each other interventions so that all can provide greater consistency and frequency in meeting the child's needs. Occasionally in a transdisciplinary model, only one individual provides the intervention, thereby increasing consistency and allowing rapport to be established with the child and family.

As the team process has developed, several authors have advocated use of terms that describe the dynamics of team interaction and may include a combination of models based on the specific needs of educators, therapists, children, and families.[61,66,122,131] The defining characteristics of collaborative teamwork, as conceptualized by Rainforth and York-Barr,[122] are summarized in Box 31.2. Advantages of the collaborative model are derived from the diverse perspectives, skills, and knowledge available among individuals on the educational team. This combined talent is an enormous resource for problem solving and support. Collaborative teams are of vital importance when working with children with multiple disabilities or with those who are severely or profoundly disabled.

When joining a team, physical therapists should ask for clarification regarding models or expectations of team interaction. All individuals should have the same understanding to avoid miscommunication and conflict.

BOX 31.2 Characteristics of Collaborative Teamwork

- Equal participation in the team process by family members and service providers
- Consensus decision making in determining priorities for goals and objectives
- Consensus decision making about the type and amount of intervention
- All skills, including motor and communication skills, embedded throughout the intervention program
- Infusion of knowledge and skills from different disciplines into the design and application of intervention
- Role release to enable team members to develop the confidence and competence necessary to facilitate the child's learning

Adapted from Rainforth B, York-Barr J: Collaborative teams for students with severe disabilities, ed 2, Baltimore, 1997, Paul H. Brookes.

TABLE 31.1 Physical Therapy Service-Delivery Models in Educational Settings

	Direct	Integrated	Consultative	Monitoring	Collaborative	Relational Goal-Oriented[72]
Therapist's primary contact	Student	Student, teacher, parent, aide	Teacher, parent, aide, student	Student	Entire team, student	Entire team, student
Environment for service delivery	Distraction-free environment (may need to be separate from learning environment) Specialized equipment needed	Learning environment and other natural settings Therapy area if necessary for a specific child	Learning environment and other natural settings	Learning environment Therapy area if necessary for a specific child	Learning environment and other natural settings	Learning environment and other natural settings
Methods of intervention	Educationally related functional activities Specific therapeutic techniques that cannot safely be delegated Emphasis on acquisition of new motor skills	Educationally related functional activities Positioning Emphasis on practice of newly acquired motor skills in the daily routine	Educationally related activities Positioning Adaptive materials Emphasis on adapting to learning environment and generalization of acquired skills	Emphasis on ensuring that child maintains status to benefit from special education	Educationally related activities	Emphasis on overarching goals and desired outcomes that require relationship skills
Amount of actual service times	Regularly scheduled sessions, generally at least weekly	Routinely scheduled Flexible amount of time depending on needs of staff or pupil	Intermittent or as needed, depending on needs of staff or pupil	Intermittent, depending on needs of pupil, may be as infrequent as once in 6 months	Ongoing intervention Discipline-referenced knowledge shared among team members, so relevant activities occur throughout the day	Customized
Implementer of activities	PT, PTA	PT, PTA, teacher, parent, aide, OT, OTA	Teacher, parent, aide	PT	Team	Team
Individualized education program (IEP) objectives	Specific to therapy programs as related to educational needs	Specific to educational program	Specific to educational program	Specific to being able to maintain educational program	Organized around life domains in an ecologic curriculum	Short term to have positive child experience; mid-term to reduce impairment, optimize function, and enhance participation; long term to optimize adaptation and adjustment

IEP, individualized educational program; OTA, occupational therapist assistant; OT, occupational therapist; PT, physical therapist; and PTA, physical therapist assistant.
Adapted from Iowa Department of Education: Iowa guidelines for educationally related physical services, Des Moines, IA, 1996, State of Iowa, Department of Education.

Models of Service Delivery

Service-delivery models are frameworks that describe the format in which intervention is provided.[78] Common models include direct, integrated, consultative, monitoring, collaborative, and relational goal-oriented models. In their nationwide survey of school-based physical therapists, Kaminker and colleagues[76] found that therapists reported providing services most often through a combination of these models (Table 31.1). Effgen and colleagues found that most of the service was provided directly to the student without other students present[42] and separate from a school activity.[47]

Direct Model

In the direct model, the therapist is the primary service provider for the child. This is the most common model of physical therapy service delivery across practice settings. Direct intervention is provided when there is emphasis on acquisition of motor skills and when therapeutic techniques cannot be safely delegated. It may take place in the context of the student's natural environment or, if necessary, in an isolated *pullout* setting; in either case, ongoing consultation with parents, teachers, and other team members is essential.[61] A child may receive direct intervention for one goal, whereas other models of service delivery are used to achieve other goals. A combination of several models of service delivery is consistent with the integrated and collaborative service-delivery models.

Integrated Model

The Iowa State Department of Education[63] defines the integrated model as one in which (1) the therapist interacts not only with the child but also with the teacher, aide, and family; (2) services are provided in the learning environment; and (3) several people are involved in implementation of the therapy program. Team collaboration is a key feature of the model. The integrated model frequently includes direct and consultative physical therapy services. Goals and objectives should be

developed collaboratively, and all individuals serving the child should be instructed on how to incorporate objectives into the child's education program. Direct services, if appropriate, are provided in the least restrictive environment. Only when it is in the best interests of the child should the intervention be provided in a restrictive environment, such as a special room, because skills learned in one setting do not necessarily generalize to other settings.[22] Common examples of when therapy might be acceptable in a more restrictive environment are when the child is participating in academic courses, when extensive equipment is required, when the child is highly distractible, or when it is necessary for the child's safety.

Consultative Model

In the consultative model, the therapist interacts in the learning environment with appropriate members of the educational team, including the parents, who then implement the recommended activities. The physical therapist provides instruction and demonstration without direct intervention. Responsibility for the outcome lies with the individuals receiving the consultation.

Consultation may be provided for a specific child, as outlined in Table 31.1, but it might also include programmatic consultation with the education staff involving issues related to safety, transportation, architectural barriers, equipment, documentation, continuing education, and improvement of program quality.[82] Programmatic consultation should be the major activity of the therapist at the beginning of each academic year and may often be more important than child-specific goals and objectives. Once the environment is safe, the child is properly positioned throughout the day, and a safe means of mobility is determined, goals pertaining to skill development can be addressed.

Monitoring Model

In the monitoring model, the physical therapist shares information and provides instruction to team members, maintains regular contact with the child to check on status, and assumes responsibility for the outcome of the intervention. Similar to the consultative model, the therapist does not intervene directly. Monitoring is important for follow-up of children who have participation restrictions, activity limitations, or impairments that might become more pronounced over time. It also allows the therapist to check adaptive equipment and assistive devices. Monitoring may be an important way to determine whether a child is progressing as necessary for transition to the next level of educational or vocational services. It is useful for transition from direct or integrated services to discontinuation of services, and it provides the family, child, and therapist a sense of security that the child is being observed. If the need for direct services is identified, services are initiated because physical therapy is already listed on the IEP.

Collaborative Model

"School-based collaboration is an interactive team process that focuses student, family, education and related service partners on enhancing the academic achievement and functional performance of *all* students in school" (p 3).[61] Emphasis is on team operations and management and ways to seamlessly interact with team members to select and blend services. Collaboration should be part of all service-delivery models, although not everyone would consider it a model of service delivery.[61] However, because collaboration is frequently defined as a combination of transdisciplinary team interaction and an integrated service-delivery model, it is discussed here as part of service delivery.[122] As noted in Box 31.2 and Table 31.1, services in a collaborative model are provided by all team members, as in an integrated model, but the degree of role release and crossing of disciplinary boundaries is greater. The team assumes responsibility for developing a consensus on the goals and objectives, as well as on implementation of program activities, which are educationally relevant and are conducted in the natural routine of the school and community. Theoretically, in the collaborative model, the amount of time the child practices an activity should be greater than in other models, because the entire team participates in the program. In reality, this might not be the case, because of the varied ability levels of team members, insufficient natural opportunities to practice skills, competing priorities in the student's schedule, and the student's difficulty in performing some activities. Research by Hunt and associates[66] suggests that for students with severe disabilities, collaborative teaming increases academic skills, engagement in classroom activities, interactions with peers, and student-initiated interactions. The researchers indicated that parents played a critical role in the development and implementation of the programs, and flexibility was essential to the practicality and applicability of suggestions.

In the past, many believed that state physical therapy practice acts prohibited other school personnel from performing procedures that are within the scope of physical therapy practice. Generally, this is not the case as long as the individual does not represent himself or herself as a physical therapist, does not bill for physical therapy, and does not perform a physical therapy evaluation.[120] In fact, a study by Rainforth[120] indicates few limitations on the delegation of procedures by others, especially of the nature likely to occur in an educational environment. Team members do not actually perform physical therapy but rather carry out activities that are recommended to assist the child to learn and practice motor skills in multiple environments.[89]

Relational Goal-Oriented Model

The relational goal-oriented model (RGM) of service delivery to children was developed by King[78] and builds on the framework of the life needs model of pediatric service delivery.[80] The life needs model addresses the "why" and "what" of service delivery, whereas the RGM focuses on the "how" of service delivery and incorporates relationship-based practice with goal orientation. The model consists of six elements: (1) overarching goals; (2) desired outcomes; (3) fundamental needs; (4) relational processes; (5) approaches, worldviews, and priorities; and (6) strategies. These elements are applied to client-practitioner and practitioner-organization relationships.

PROGRAM DEVELOPMENT

Eligibility for Physical Therapy

As noted previously, for school-age children, a motor delay or disability does not necessarily qualify a student for special education and related services. The child must have an educational need for special education. Once a child meets the criteria for special education, the related service needs are determined as "required to assist a child with a disability to benefit from special education" [PL 108-446, 118 Stat. 2657, § 602 (26)].[112] The requirements of federal law, state, and local regulations may include additional elements related to eligibility.

Many states have developed guidelines for school practice that can assist therapists in their decisions regarding both a student's need for physical therapy and service delivery. Generally, these guidelines can be found on the website of the state's Department of Education, the state's Physical Therapy Association, or both. For example, the document developed in Maryland (*Occupational and Physical Therapy Early Intervention and School-Based Services in Maryland: A Guide to Practice*),[85] published in December 2008, describes the process for determining the need for school-based occupational and physical therapy services as follows:

> Once the IEP team agrees on the present levels of the student's performance and IEP goals/objectives, the team then determines whether the unique expertise of an OT or PT is required for the student to be able to access, participate, and progress in the learning environment in preparation for success in his/her postsecondary life. Based on the individual needs of the student, the PLs [present levels], goals and objectives, the IEP team with recommendations from the OT or PT team member(s) determines necessary related services.[85]

The *Guidance of the Related Services of Occupational Therapy, Physical Therapy, and Speech/Language Therapy in Kentucky Public Schools* reminds therapists to ask a fundamental question: "Is an occupational therapist's, speech therapist's, or physical therapist's knowledge and expertise a necessary component of the student's educational program in order for him/her to achieve identified outcomes?"[77] Additional key questions regarding service determination listed in the Kentucky guidelines include the following:

- Does the challenge significantly interfere with the student's ability to participate in the general education curriculum and in preparation for employment and independent living?
- Does the challenge in an identified area appear to be caused by limitations in a motor, sensory, or communication area?
- Have the research-based instruction and intervention services successfully alleviated the concerns?
- Can the educational team manage the student's deficit areas without the expertise of an occupational, physical, or speech-language therapist?
- Does the student show potential to steadily progress without services?
- Can the student's deficit areas be managed through classroom accommodations or modifications?[77]

If a child is not eligible for special education, he or she may be eligible for related services under Section 504 of the Rehabilitation Act.[114] The need for related services must be based on the individual needs of the child. Some school districts have attempted to develop generalized exclusionary criteria such as *performance discrepancy criteria,* also called *cognitive referencing*. Performance discrepancy criteria limit services to children whose cognitive development is below their motor development.[24] Aside from the legal[119] and ethical questions, research does not support cognitive referencing.[14,29]

Evaluation

Results of the evaluation are used to make decisions about the need for school-based physical therapy services, IEP goals, frequency and duration of services, and ESY services. The elements of patient/client management in the *Guide to Physical Therapist Practice*[3] differ somewhat from those of federal education laws. In the school setting, evaluations are conducted to "assist in determining whether the child is a child with a disability" [PL 108-446, 118 Stat. 27045, § 614(b)(2)][112]; they are also used to determine the educational needs of the child. The process of evaluation, therefore, is comparable with examination and evaluation in the *Guide*.

A comprehensive team evaluation should be conducted "at least every 3 years, unless the parent and the local educational agency agree that a re-evaluation is unnecessary" [PL 108-446, 118 Stat. 2704, § 614 (a)(2)].[112] It may be performed no more often than once a year, unless both parent and educational agency agree to more frequent evaluations. Physical therapy evaluation may need to be done more frequently according to the requirements of individual state practice acts and best practice guidelines. All therapists should be familiar with their state's requirements.

Physical therapy evaluation in the educational environment should be consistent with the framework of the World Health Organization's International Classification of Functioning, Disability and Health (ICF),[145] as discussed throughout this text, and is consistent with the 2014 revision to the *Guide*.[2] Evaluation should describe the student's participation (engagement in life situations), activities (tasks), and body functions (physiology) and structures (anatomy), with consideration of personal and environmental factors. These elements are reported from the perspective of access, participation, and progress in the educational program. Although the emphasis is on enablement, rather than disablement, the evaluation should incorporate participation restrictions (with required adaptations and assistance), activity limitations, and impairments in body functions and structures.[89] Evaluation should also make the distinction between capacity (what the student *can* do in controlled conditions) and performance (what the student actually *does* in the natural settings of daily life). Intervention strategies to reduce impairments of body functions and structures may be necessary to meet the student's educational needs. Examination should also include a review of body systems from the perspective of school function: musculoskeletal, neuromuscular, cardiovascular/pulmonary, and integumentary.[3]

IDEA 2004 mandates that goals and interventions be based on academic demands and functional performance within the educational setting.[112] However, many of the assessments currently used by occupational and physical therapists in school-based settings to create these goals and objectives focus on developmental skills as compared with those of same-age or same-grade peers.[35] These developmental assessments provide little information about the student's ability to participate in school-related tasks and reflect a conflict with the principles of IDEA 2004.[35] In addition, these measures do not provide information about performance in context and therefore are not appropriate outcome measures. Based on a model of inclusion for students with disabilities, assessments used in the educational setting should instead focus on participation and functional performance. They should identify to what extent the student requires assistance from an individual, accommodations, or modification of the environment to participate in the educational process.

Tests and measures should be technically sound and should be administered by trained and knowledgeable personnel, in accordance with instructions and in the child's native language without racial or cultural bias [PL 108-446, 118 Stat. 2705, § 614(b)(3)].[111] Selection of standardized tests should be based

on professional judgment and dictated by the characteristics of the individual child. Therapists should collaborate with school personnel to identify appropriate tests and measures that gather relevant functional and developmental information. The child's abilities should be assessed in the natural environment when possible: in the classroom, hallway, playground, stairs, and other school settings.

The *School Function Assessment* (SFA), developed by Coster and coworkers,[30] is a standardized measure of participation in all aspects of the educational program for students in kindergarten through sixth grade. Findings may be used to identify IEP goals and develop the intervention plan, including the frequency and duration of services. The SFA measures skills that promote participation in the natural environmental settings of regular or special education, addressing both individual and contextual factors. It is a judgment-based, criterion-referenced measure that is both discriminative (identifies functional limitations) and evaluative (measures change over time). It assesses the student's levels of activity, required support, and performance in daily school routines; by contrast, other standardized assessments measure the student's capacity (optimal abilities under controlled conditions). Function is defined by the outcome of performance, not by the methods used; for example, travel over a designated distance is assessed by consistency of performance and level of assistance required, not by whether the student walks or uses a wheelchair, though those parameters are listed as well. The SFA comprises three major categories of student performance—participation, task supports, and activity performance—and includes 21 domains (12 physical tasks and 9 cognitive/behavioral tasks), with the required level of assistance and adaptations. Criterion cutoff scores are provided for children in grades K through 3 and grades 4 through 6, as are item maps that provide a visual (graphic) representation of scores. All members of the school team who are familiar with the student's levels of activity and performance in school-related tasks and environments can complete the SFA. It has high internal consistency (ranging from .92 to .98) and high test-retest reliability (Pearson *r* ranging from .80 to .99, and intraclass coefficients [ICC] ranging from .80 to .99); it is a valid instrument for use in school settings.[67]

For the student presented in the case scenario for this chapter, the five mobility domains of the SFA were completed collaboratively by the school physical therapist and the classroom teacher, both of whom are well acquainted with the student and her levels of performance. That process took about 20 minutes. Although the test is intended to be conducted in its entirety by staff members representing several disciplines, other staff members chose not to do so; it is not uncommon for some to be reluctant to participate in the full assessment, claiming that it is too time consuming. Perhaps, in time, the school physical therapist may be successful in persuading other members of the team to appreciate the value of information derived through the SFA. The Pediatric Evaluation of Disability Inventory Computer Adaptive Test (PEDI-CAT) is described in the discussion of measurement in Chapter 2.

The *School Outcomes Measure* (SOM) is another assessment developed specifically for the education setting.[11] The SOM is a minimal data set designed to measure outcomes of students who receive school-based occupational therapy and physical therapy. The SOM includes 30 functional status items that cover five general student ability areas traditionally addressed in school-based practice: self-care, mobility, assuming a student's role, expressing learning, and behavior. Data are recorded on student and therapist demographics, as are details on information from the student's IEP, therapy services provided, and therapeutic procedures used.[11] The SOM focuses on the measure of student functional status to enhance participation in the natural environments of school, home, and community. It allows teachers, parents, and others with knowledge of the student to provide information for any areas for which the therapist is not certain of the student's abilities.

Research supports the content validity, interrater reliability,[90] and test-retest reliability of the SOM for students who receive occupational and physical therapy.[11] The minimal data set was more responsive to children with mild/moderate functional limitations but less responsive to changes in children with severe disabilities.[12] Arnold and McEwen[11] reported that use of the SOM is suitable on an annual basis to evaluate outcomes for students, in conjunction with IEP goals, and that it is appropriate for use in outcomes research.

The SOM provides several advantages to the school-based therapist. The measure takes about 10 to 15 minutes to administer once a therapist is familiar with the student; this is clearly an asset for therapists attempting to balance caseload and essential evaluation/outcome data. Another asset is that the SOM requires no manipulatives or supplies.

The *Pediatric Evaluation of Disability Inventory* (PEDI)[59] is a judgment-based, criterion-referenced measure that preceded the SFA. It has been expanded to include children up to 20 years of age and is now a computer adaptive test (PEDI-CAT).[58] With the expanded age range, ease, and brevity of administration, the PEDI-CAT should be considered for use in the school setting. It provides a global assessment of daily activities, mobility, social/cognitive function, and responsibility. Wilson and colleagues[143] found fairly consistent concurrent validity between the SOM and the PEDI, indicating that motor performance was consistent across home and school environments. Other standardized tests and measures, as discussed throughout this text, may assist in determining the level of a child's physical functioning and assist in documenting student outcomes. The PEDI-CAT is described in Chapter 2.

Single-item measures such as the 6-minute walk test and timed up and go are described in Chapter 2 and may be useful for selected students.

Individualized Educational Program

The IEP is the document that guides the program of special education and related services for the school-age child, 5 to 21 years of age. It is also the document used in most states for the educational program of children ages 3 to 5 years attending preschool. The IEP is developed at a meeting involving the child's parents; at least one regular educator (if the child is or will be participating in the regular education environment); not less than one special education teacher; a representative of the local educational agency who is qualified to provide or supervise specially designed instruction and is knowledgeable about the general education curriculum and resources; an individual who can interpret the instructional implications of the evaluation; and "at the discretion of the parent or the agency, other individuals who have knowledge or special expertise regarding the child, including related services personnel as appropriate; and whenever appropriate, the child" [PL 108-446, 118 Stat. 2709, § 614(d)(1)(B)].[112] The physical therapist has a professional obligation to participate when decisions regarding physical therapy are being made. The physical therapist's contribution to the IEP must relate to the educational needs of the child. Individualized measurable annual

academic and functional goals are developed at the IEP meeting. Short-term objectives are no longer required under IDEA 2004, except for those children who take alternate assessments; however, they are essential under "best practice" guidelines, and many school districts continue to expect them.[112] Even if the educational system does not require them, therapists should still develop short-term objectives to monitor and report intervention outcomes as required for the plan of care. Physical therapists must adhere to their state physical therapy practice acts, which may demand more documentation than the educational system requires, including a detailed plan of care. Table 31.2 describes the different elements of outcomes measures.

Attendance at IEP meetings may not be mandatory for all members of the team:

> If the parent of a child with a disability and the local educational agency agree that the attendance of such a member is not necessary because the member's area of curriculum or related services is not being modified or discussed …. [a] member of the IEP team may be excused … if the parent and the local educational agency consent to the excusal; and the member submits, in writing to the parent and the IEP team, input into the development of the IEP prior to the meeting. [PL 108-446, 118 Stat. 2710, § 614(d)(1)(C)][112]

Therapists who are providing services for a child are now required to either attend the IEP meeting or receive approval not to attend and then submit their recommendations in writing. This new requirement of written input might encourage greater participation by therapists at IEP meetings.

Under IDEA 2004, the IEP document must include the following:

(I) a statement of the child's present levels of academic achievement and functional performance, including—
(aa) how the child's disability affects the child's involvement and progress in the general curriculum;
(bb) for preschool children, as appropriate, how the disability affects the child's participation in appropriate activities; and
(cc) for children with disabilities who take alternate assessments aligned to alternate achievement standards, a description of benchmarks or short-term objectives;
(II) a statement of measurable annual goals, including academic and functional goals, designed to—
(aa) meet the child's needs that result from the child's disability to enable the child to be involved in and make progress in the general curriculum; and
(bb) meet each of the child's other educational needs that result from the child's disability;
(III) description of how the child's progress toward meeting the annual goals… … will be measured and when periodic reports on the progress the child is making toward meeting the annual goals (such as through the use of quarterly or other periodic reports, concurrent with the issuance of report cards) will be provided;
(IV) a statement of the special education and related services and supplementary aids and services, based on peer-reviewed research to the extent practicable, to be provided to the child, or on behalf of the child, and a statement of the program modifications or supports for school personnel that will be provided for the child—
(aa) to advance appropriately toward attaining the annual goals;
(bb) to be involved and progress in the general curriculum…… and to participate in extracurricular and other nonacademic activities; and
(cc) to be educated and participate with other children with disabilities and nondisabled children;
(V) an explanation of the extent, if any, to which the child will not participate with nondisabled children in the regular class;……
(VI) (aa) a statement of any individual accommodations that are necessary to measure the academic achievement and functional performance of the child on State and district wide assessments;……
(bb) if the IEP Team determines that the child shall take an alternate assessment… …a statement of why the child cannot participate in the regular assessment……
(VII) the projected date for the beginning of services and modifications……and the anticipated frequency, location, and duration of those services and modifications; and
(VIII) beginning not later than the first IEP to be in effect when the child is 16, and updated annually thereafter—
(aa) appropriate measurable postsecondary goals based upon age appropriate transition assessments related to training, education, employment, and, where appropriate, independent living skills;
(bb) transition services (including courses of study) needed to assist the child in reaching these goals; and
(cc) beginning not later than 1 year before the age of majority under State law, a statement that the child has been informed of the child's rights under this title [PL 108-446, 118 Stat. 2707-2709, § 614(d)(1)(A)].[112]

TABLE 31.2 Elements of Outcome Measures

Measures	Part of Individualized Educational Program	Measurable	Time Frame	Dimension	Discipline Specific
Annual goals	Yes	Yes	School year	Participation Activities	No
Long-term objectives	Yes	Yes	School year	Participation Activities	No
Short-term objectives	Not required by federal law except for students who take alternate assessments*	Yes	Months, a grading period	Participation Activities Body functions and structures	Varies, some objectives might be within the domain of one discipline
Benchmarks	Yes, but not always	Yes	School year or months	Participation Activities	No, although objectives might be within the domain of one discipline

*Might be required by local educational agency or state physical therapist practice act as part of plan of care.

The IEP is a written commitment by the educational agency of the resources that will be provided to enable a child with a disability to receive necessary special education and related services. It also serves as a management, compliance, and monitoring tool and is used to evaluate a child's progress toward achievement of goals and objectives. IDEA does not require that teachers or other school personnel be held accountable if a child with a disability does not achieve the goals set forth in the IEP; however, calls for greater accountability are increasing.

In the past, the IEP could not be changed without initiating another IEP meeting; however, in IDEA 2004 there are provisions for making changes. The parent "and the local educational agency may agree not to convene an IEP meeting for the purposes of making such changes, and instead may develop a written document to amend or modify the child's current IEP" [PL 108-446, 118 Stat. 2712, § 614(d)(3)(D)].[112] This change could result in problems for both the child and service providers. For example, therapy services might be added or deleted without input from the therapist. Ongoing team communication and collaboration are essential to ensure that flexibility in modifying the IEP results in positive outcomes.

Developing Goals and Objectives

The physical therapist, as part of the collaborative team, assists in developing appropriate measurable annual goals, including academic and functional goals. For children requiring alternate assessment, short-term objectives must also be developed. Short-term objectives break down more global, comprehensive goals into manageable elements. They assist in determining whether the child is progressing in reasonable periods of time and help define criteria for the required progress reports. Short-term objectives also assist in clearly identifying when related services might be indicated. For example, instruction by a general or special education teacher might be considered sufficient for an annual goal regarding independently using the cafeteria or the library. A child who is just learning to use a walker around the school, however, may need the services of a physical therapist. General and special education teachers may not have the expertise to teach the child to use a walker and perform the task of opening the library and cafeteria doors, then entering and picking up a book or tray. Achievement of the annual goal might require a physical therapist to teach mobility activities and transfers, an occupational therapist to instruct in feeding activities, and a speech-language pathologist to work on communication in the food line or library.

For establishment of goals and objectives, the desired outcomes must first be identified. Determining desired outcomes might be as simple as merely asking the child, or it might require several team meetings. Outcome statements do not need to be measurable, but they should be functional. *Functional* in the federal regulations "refer to activities and skills that are not considered academic or related to a child's academic achievement."[49] Once the desired outcomes are selected, the IEP team must define the goals that are necessary for the student to achieve them. Goals should be context specific, defined by relevant life skills or academic tasks in a school setting.[88] Educational goals should also be discipline-free—that is, they are goals for the student, rather than goals for physical therapy or occupational therapy.[89] They must be measurable, reflecting best practice[3,81,88,123] and the requirements of IDEA 2004 (Public Law 108-446).[112] In an educational setting, goals are written to be achieved within the school year.

For students requiring alternate assessment and others, depending on state law, measurable short-term objectives are developed after desired outcomes and annual goals are identified. "Objectives are developed based on a logical breakdown of the major components of the annual goals, and can serve as milestones for measuring progress towards meeting the goals."[51] Objectives must relate to the educational program of the child, are based on a task analysis of the annual goal, and are not discipline specific (see Table 31.2). They should be functional and educationally relevant, and they might be written into the IEP. In some situations, a short-term objective for reduction of impairment is relevant, because that step is limiting the child's achievement of the annual goal. Short-term objectives for reducing impairments may be important to document progress toward achievement of the annual goal, but because they are not directly relevant to the educational program, they should not be part of the IEP.

To explain the relationships among impairments, activity limitations, and participation restrictions, a therapist might use reading as an analogy. Reading is a very important goal of education, and few teachers would dispute the importance of the child's first learning the prerequisite alphabet. The alphabet in itself has little value, just as complete knee range of motion has little value as an objective by itself. However, knowing the alphabet is critical for reading and writing, and knee range of motion is critical for walking and stair climbing. The ability to walk or climb stairs expands the child's ability to explore his environment, learn, and, most important, achieve the goal of IDEA of "independent living, and economic self-sufficiency for individuals with disabilities" [PL 108-446, 118 Stat. 2649, Part A, § 601(c)(1)].[112] Eliminating short-term objectives in the IEP is unfortunate, because they offer an excellent way of monitoring outcomes for progress reports, and they are often better indicators of the services required than are annual goals. Regardless of whether school districts continue to require short-term objectives, therapists might need to include them in their plans of care based on their state physical therapy practice act.

The physical therapist should participate in the IEP meeting to assist in determining the child's measurable annual goals for the next year. Consensus among experts in pediatric occupational and physical therapy indicates that outcomes should (1) relate to functional skills and activities, (2) enhance the child's performance in school, (3) be easily understood, (4) be free of professional jargon, and (5) be realistic and achievable within the time frame of the IEP.[37] These experts suggested that if a skill or activity cannot be observed or measured during the student's typical school day, then it might not be relevant to the student's educational needs and, therefore, may not be appropriate to include as an IEP goal. The therapists surveyed did not reach consensus on whether generalization of skills across settings is important. An example of a desired outcome and the objectives involving independent stair climbing is illustrated in Box 31.3. To climb stairs at school independently, a child should have 90 degrees of knee flexion and good strength in the quadriceps muscles. Educationally relevant objectives are included in the child's IEP, and the other short-term objectives, which may or may not be considered educationally relevant, are included in the therapist's plan of care. Documentation of progress toward achievement of each objective is important to share with the child and family. Attainment of short-term objectives should be recognized and rewarded in lieu of waiting, perhaps a long time, for achievement of the long-term goal.

BOX 31.3 Example of Desired Outcome, Annual Goal, and Short-Term Objectives

Desired Outcome

Jonathan says: "I want to be able to climb the steps to get into school."

Annual Goal (Long-Term Objective) That Is Measurable and Educationally Relevant

Jonathan will walk up and down the school stairs independently without using the railing.

Short-Term Objectives That Are Measurable and Educationally Relevant

1. Jonathan will climb up eight stairs to enter the school with standby supervision using a railing.
2. Jonathan will climb up eight stairs to enter the school with standby supervision without using a railing.
3. Jonathan will climb down eight stairs to enter the school with standby supervision using a railing.
4. Jonathan will climb down eight stairs to enter the school with standby supervision without using a railing.
5. Jonathan will climb up eight stairs to enter the school without supervision or using a railing.
6. Jonathan will climb down eight stairs to enter the school without supervision or using a railing.

Short-Term Objectives That Are Measurable but Not Directly Educationally Relevant

These objectives, which relate to impairments in body functions and structures, are necessary to achieve the educationally relevant short-term and annual goals and would be part of the therapist's plan of care but not in the individualized educational program.

1. Jonathan will progress from 30° to 50° of active flexion of his right knee.
2. Jonathan will progress from a poor (1/5) to a fair (3/5) muscle-strength grade in his left quadriceps.
3. Jonathan will achieve 90° of active flexion of his right knee.
4. Jonathan will achieve a good (4/5) muscle-strength grade in his left quadriceps.

Measurable annual goals and objectives should contain a statement of the behavior to be achieved, under what conditions, and the criteria to be used to determine achievement.[39,81] "SMART" is a commonly used acronym that can guide the development of goals and objectives: specific, measurable, achievable, realistic, and time based.[133] When performing a task analysis and developing the short-term objectives, several variables should be considered: (1) changes in the behavior itself, (2) changes in the conditions under which the behavior is performed, and (3) changes in the criteria expected for ultimate performance.[1] Changes in behavior may reflect a progression from basic skills to more complex skills or to increasing levels of functional ability. Changes in conditions may range from simple to complex, such as walking in an empty hallway to walking in a hallway with other students.

Criteria for progression may be qualitative or quantitative. They might include the qualitative measure of perceived exertion during stair climbing or the quantitative measure of walking speed. Use of quantitative criteria, such as judgment by three of four trials, or 80% of the time, should be considered carefully for their practicability. Successfully crossing the street only 80% of the time can be fatal! Selection of the behavior, conditions, and criteria for judging attainment of each objective for each individual child must be based on sound professional judgment. Books, computer programs, and other materials that provide lists of potential objectives should not replace professional judgment. In addition to the task variables, consideration should be given to the hierarchy of response competence.[1] A behavior is acquired and then refined as fluency or proficiency develops. The skill must then be maintained and then generalized or transferred to multiple environments, individuals, and equipment. *Acquisition, fluency, maintenance,* and *generalization of behaviors* are the terms used by educators that can be applied to motor learning. The concepts of efficiency, flexibility, and consistency have also been used to define skill components of goals. Use of this terminology is important when there is a need to convey the rationale for providing services past the acquisition phase.

TABLE 31.3 Example of Annual Goal Using Goal Attainment Scaling

−2 Baseline	When leaving 5 minutes ahead of class, Alicia walks using her walker from class to the playground (400 feet), 3 of the 5 days.
−1	When leaving 2 minutes ahead of class, Alicia walks independently using her walker from class to the playground (400 feet), 3 of the 5 days.
0 Desired level	When walking from class to the playground (400 feet), Alicia walks independently at end of line with her class using her walker, 3 of the 5 days.
+1	When walking from class to playground (400 feet), Alicia walks independently in middle of line with her class using her walker, 3 of the 5 days.
+2	When walking from class to playground (400 feet), Alicia walks independently as line leader using her walker, 3 of the 5 days.

Another option or format for writing short-term goals is the use of goal attainment scaling (GAS). GAS is an individualized criterion-referenced outcome measure that has demonstrated good content validity, reliability, and responsiveness in studies of children, as discussed in Chapter 2. It has been used to study school-based therapy practice[48,79] and is recommended as a useful tool to assess student outcomes for therapist performance appraisal. Table 31.3 provides an example of a student's GAS goal with a focus on participation.

Therapists are encouraged to consider using a prompting system as a strategy to achieve an objective and as a variable in writing the criteria for judging attainment of the objective (Fig. 31.1). Systematic delivery of levels of prompting assistance may be implemented in two ways. One is the "system of maximum prompts," and the other is the "system of least prompts."[1,39] The prompts are usually verbal or visual cues, demonstration or modeling, partial assistance or physical guidance, and maximum assistance. In the system of maximum prompts, the therapist initially provides maximum assistance and then gradually, over successive sessions, reduces the amount of assistance as the child achieves more independence. This is also referred to as *fading*. It is a common technique used by therapists and allows for maximal success during learning. This system is best suited for acquisition of skills, when it is important to avoid unsafe movement, and for a complex series of tasks such as some activities of daily living.

In the system of least prompts, the child is initially provided the least amount of assistance, usually a verbal or visual cue, and then progresses as necessary to model, guide, or maximal assistance. This approach allows the child to display

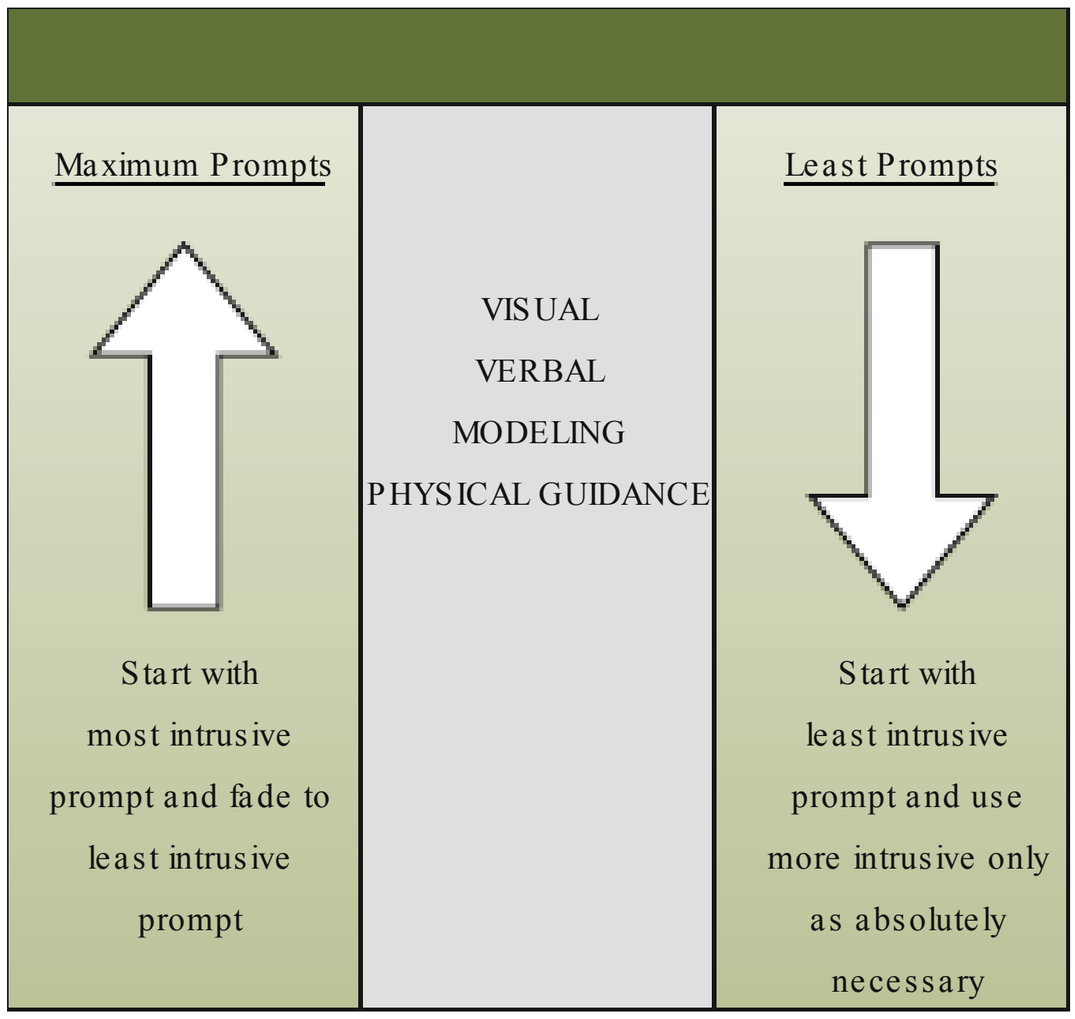

FIG. 31.1 Hierarchy of prompting assistance.

his or her best effort before the therapist prematurely provides unnecessary assistance. The system of least prompts is best for tasks in which the child has some ability or is developing fluency or generalization to new settings, individuals, or equipment.

Therapists should incorporate other principles of motor learning into the development of short-term objectives and intervention sessions. Increasing muscle strength can contribute to improved motor control and function, particularly improved walking.[94] Practice of motor skills should be structured in ways to promote learning through consideration of part versus whole practice, use of contextual interference, blocked versus random practice, massed versus distributed practice, schedules of feedback, knowledge of performance, and knowledge of results.[129] Breaking down any of these elements into a progression of simpler to more complex skills can lead to achievement of objectives. In the education literature, this is referred to as *scaffolding* (see Chapter 3).

Frequency and Intensity of Intervention

At the IEP meeting, the frequency and intensity of all services should be determined by the entire team. The American Physical Therapy Association (APTA) Section on Pediatrics uses the terminology of *dosage* to refer to a combination of the frequency of intervention sessions, duration of each session, and length of an episode of care.[7] The physical therapist collaborates with other team members to determine the appropriate amount of physical therapy intervention, combined with the child's other interventions, the educational program, and recreational activities. Competing priorities need to be considered so that other areas of importance are not neglected for the child to receive therapy. An appropriate balance among education, therapy, and leisure (play) is an important issue for discussion with parents, particularly with those who believe that more is better. The availability of physical therapists should not be a factor in determining services. However, Kaminker and colleagues[75] found regional differences in frequencies of intervention provided by school-based physical therapists, corresponding to ratios of available therapists to students.

The amount of the physical therapy services required to achieve a specific goal is neither well understood nor well documented.[13,68] Until sufficient peer-reviewed evidence is obtained, decisions on how much intervention is required to achieve a goal depend largely on professional judgment and consideration of the needs of the individual child. Numerous factors enter into decision making and include (1) potential for improvement, (2) critical period for skill development, (3) amount of training required to carry out an intervention (if anyone can assist with the intervention, then less therapist time is required), (4) significance of the problem for the child's education, (5) history of physical therapy intervention, and (6) medical status of the student.[68] Table 31.4 depicts a matrix of factors to consider when deciding on the extent of physical therapy services required. Guidance is provided on using four dosing intensities: intensive, frequent, periodic, and intermittent, based on a number of considerations.[7] On this scale, a student with several considerations indicating the need for intensive intervention would require more intervention than a student with predominant indications of periodic intervention.

Without the use of an accepted clinical reasoning tool or objective measure for establishing educational need, school-based physical therapists have difficulty making decisions that support the intent of IDEA while withstanding outside pressures. The *Considerations for Educationally Relevant Therapy for Occupational Therapy and Physical Therapy* (CERT)[53] and the *Determination of Relevant Therapy Tool* (DRTT)[26] are two examples of clinical reasoning models that provide objective data for school-based therapy decision making.

Therapists in Florida have been developing the CERT since the 1990s.[53] The CERT is not an assessment but rather "a summary of educational considerations based on a review of student records, evaluations, observations, progress notes, parent/teacher information and other data."[53] It includes a summary sheet, a student profile, and a therapy profile completed by the therapist. The student profile rates the student's abilities in personal care, mobility, gross motor skills, fine motor/visual motor skills, and sensory processing. The therapy profile indicates the number of years the student has received educationally relevant therapy, potential response to educationally relevant therapy, the student's learning environment, therapy services provided to the student, and support services provided to school staff or parents. Detailed information on the CERT is available at http://www.fldoe.org/ESE/cert.asp.

The DRTT was developed in Maryland to assist in occupational therapy and physical therapy service recommendations to the IEP team.[26] For therapists new to the educational setting, this method encompasses the range of roles and responsibilities of therapists and requires the user to consider all aspects of therapeutic and educational programming prior to decision making. For therapists who have experience in school practice, use of the DRTT provides a means to validate decisions related to models and delivery of services, beyond the use of clinical judgment alone. Consistent service delivery among therapists in any jurisdiction helps to alleviate the disputes between families and teams that may arise regarding service recommendations, as well as to support administration with appropriate staffing ratios to meet IEP needs, while managing therapist costs.

TABLE 31.4 Factors to Consider When Determining the Intensity and Frequency (Dosage) of Physical Therapy (PT)

Considerations	Intensive	Frequent	Periodic	Intermittent
	A highly concentrated amount of PT intervention provided over an episode of care. Example: Weekly sessions lasting 45 minutes or more or a frequency of 2× or more/week.	A moderate amount of PT intervention provided at consistent intervals over an episode of care. Example: Weekly or bimonthly sessions lasting less than 45 minutes.	A lower amount of PT intervention provided at regularly scheduled intervals for a specified number of minutes over an episode of care. Example: 1–2×/quarter for 20 minutes each session.	A low amount of PT intervention provided irregularly or when needed over an episode of care. Length of therapy session may vary. Example: 2–5×/year for a total of 60 minutes.
Participation Restrictions Student demonstrates restrictions of functional or foundational skills that limit participation.	Intensive PT intervention is needed to facilitate participation. Student is highly motivated and desires to participate.	Regular PT intervention is needed to facilitate ongoing participation.	Participation restrictions addressed by a physical therapist through periodic review.	Participation restrictions addressed through established accommodations, assistive technology devices, classroom programs, or adult assistance.
Chronologic Age/Readiness for Skill Acquisition The number of services must reflect the potential for skill acquisition during a critical period of development and the student's intrinsic desire to participate.	Extremely critical period when student is demonstrating emerging skills that require PT intervention for further development.	Critical period when student is demonstrating emerging skills, is experiencing a growth spurt, or is approaching a transitional period.	Outside a critical period but may have periodic challenges identified.	Not in critical period, based on age, and limited gains are expected through PT intervention.
Impact of PT Intervention The physical therapist makes decisions regarding the student's potential to benefit from PT intervention.	Student has potential for rapid progress toward established goals or has potential for rapid decline or loss of functional skills.	Student demonstrates motivation and continual progress toward established goals. Potential for regression or loss of skills could occur with service reduction.	Student demonstrates a reduced rate of goal attainment or shows decline solely due to the disease process.	Student demonstrates limited progress toward goal attainment or is near maximum benefit.
Support Available at School Considers the expertise and competency of other school-based providers who may support the student.	Student or staff requires extensive support of the physical therapist to assist the student's participation in the educational setting and progress toward goals.	Student requires regular PT support in the educational setting, where support staff is being trained to promote participation and progress toward goals. Other school staff is available and can contribute to meeting the specific areas of need.	Level of support in educational setting is adequate to maintain student's skills, meet new challenges, and allow participation in curriculum. Periodic review of required accommodations or modifications continues to be necessary.	Student is able to participate in educational program with assistance of support staff or specialized programs. Occasional monitoring may be needed to address modifications.
Transitions Student's transition to and present level of performance in a new program, placement, or environment are considered, as well as available supports.	Student requires the physical therapist to assist with acquisition of significant additional skills for access and participation related to the transition.	Student requires PT intervention for refinement or expansion of skills related to the transition.	Student's level of support in new program or environment is adequate to maintain skills, meet new challenges, and allow participation.	Student's level of support in new program or environment is adequate to allow participation, with intermittent PT services to review equipment, accommodations, or modifications.
Expertise, Clinical Decision Making, and Problem Solving Needed From a Physical Therapist Physical therapists are movement specialists who assist in optimizing movement for participation.	Student requires the clinical skills and problem solving of a physical therapist for a significant part of the educational program.	Student requires the clinical skills and problem solving of a physical therapist for part of the educational program, and other aspects can be safely performed by student or staff.	Student requires the clinical skills and problem solving of a physical therapist to periodically reassess student status and update educational program.	Classroom program can be safely performed by student or staff.
Previous Physical Therapy Intervention Considers the extent of and response to previous PT intervention.	Student continues to make significant progress with PT intervention.	Student has made steady progress with PT intervention.	Student has reached a plateau in skill acquisition. May need periodic examination for signs of readiness for new skill acquisition, generalization, or regression of skills.	Student has made limited progress despite PT intervention. May need intermittent examination for signs of regression or equipment/device management.

TABLE 31.4 Factors to Consider When Determining the Intensity and Frequency (Dosage) of Physical Therapy (PT)—cont'd

Considerations	Intensive	Frequent	Periodic	Intermittent
Health Condition A student who experiences a change in medical status may require modifications to school-based PT services.	Student with a significant change in health condition may initially require intensive PT intervention to address altered needs, training of school staff, and acquisition/fitting of assistive technology.	Student with moderate or ongoing changes in health condition that impact functional abilities may require frequent PT intervention.	Student with stable or gradual changes in health condition may require periodic PT intervention to monitor functional abilities, assistive technology, or training of staff.	Student with stable health condition or whose needs are appropriately managed by the student or school staff may require intermittent PT for monitoring.
Assistive Technology (AT) Intensity of PT services decreases as student/staff proficiency with AT increases.	Student requires intensive PT intervention for determination of complex AT needs. Staff requires extensive training with devices to ensure safe participation.	Student requires frequent PT intervention for determination of AT needs. Staff requires training with unfamiliar devices to ensure safe participation.	Student or staff use AT appropriately. Periodic PT intervention needed to monitor changes, safety, and maintenance.	Student or staff use all AT appropriately. Intermittent PT intervention needed to monitor devices/equipment.

Adapted from American Physical Therapy Association Section on Pediatrics. Dosage Considerations: recommending school-based physical therapy intervention under IDEA resource manual. Retrieved from: https://pediatricapta.org/includes/fact-sheets/pdfs/15%20Dosage%20Consideration%20Resource%20Manual.pdf; Bailes A, Reder R, Burch C: Development of guidelines for determining frequency of therapy services in a pediatric medical setting, Pediatr Phys Ther 20:194-198, 2008; Iowa Department of Education: Iowa guidelines for educationally related physical therapy services, Des Moines, IA, 2001, State of Iowa, Department of Education.

INTERVENTION

Intervention must be based on the needs of the child, not of the system or professionals. The content, goals, frequency, location, and intensity of intervention are decided collaboratively by the IEP team at the IEP meeting. Effective communication among team members is crucial for the planning, provision, and coordination of services and to avoid an overlap of services, missed services, and conflict.[89] The *Guide to Physical Therapist Practice*[3] describes three components of intervention, all of which are essential in the educational environment: coordination, communication, and documentation; patient/client-related instruction; and procedural interventions. The amount of time and effort devoted to each will depend on the needs of the child and may vary at different times during the school year.

Coordination, Communication, and Documentation

Coordination, communication, and documentation are particularly important in schools where the therapist is in the building only occasionally, and direct interaction with other team members is limited. Frequent communication with parents, teachers, and other related service personnel must be established and maintained. This may be accomplished through regularly scheduled meetings, informal conversation, and written progress reports, as well as by telephone and electronic communication.

Documentation must follow local, state, and national requirements for both education and physical therapy. This means that, although the education agencies might dictate that progress reports are provided to the family only at the same frequency as for children who do not have a disability, the state physical therapy practice act might require documentation after each intervention session. The APTA Defensible Documentation Resource[9] suggests the following: (1) documentation is required for every visit/encounter, (2) documentation should indicate cancellations, (3) documentation must comply with regulatory requirements, (4) entries must be made in ink and properly authenticated, (5) electronic entries should be secure, and (6) documentation in pediatrics should be aligned with family-centered care and should emphasize the functional abilities of the child. Specific to school settings, the physical therapist should "document all strategies, interventions, staff/student training and education, and communication with the student's parents/guardians or community based services."[9] In addition, although the IEP team might decide that physical therapy services are no longer required, discontinuation of physical therapy must be documented by the physical therapist in a final summary to close that episode of care. Services billed through Medicaid and other insurance providers usually require additional documentation. There is great variation across the country with regard to documentation of school-based physical therapy services; therapists must consult their state practice acts to ensure that they are in full compliance.

Child- and Family-Related Instruction

Child- and family-related instruction, along with instruction to other team members, is a critical area of practice in school settings. Practice is essential for the acquisition, fluency, and generalization of skills[32,141]; consequently, the family and the IEP team may be largely responsible for assisting the child in carrying out or practicing motor skills. Instruction of parents and appropriate staff members should be a major component of all intervention plans. Instruction should begin and continue as needed: at the start of every school year, at the initiation of physical therapy services, when a child enters a new school, and when a new staff member becomes involved in the care of the child.

In the integrated and collaborative service-delivery models, teachers, staff members, and parents participate in the delivery of some aspects of the intervention. Their involvement may be as simple as using proper positioning techniques or as complicated as handling procedures for transfers and mobility. These individuals must be instructed in proper positioning of the student, safe body mechanics of the caregiver, use of adaptive equipment, and ways to encourage selected motor activities. It is generally prudent for the physical therapist to provide the primary instruction at the initial acquisition stage of motor learning, relinquishing care to the classroom staff at the fluency and generalization stages.

The selection of activities to teach other caregivers is a professional decision that must be based on characteristics of the individual child, the specific activity, and the capabilities and interest of the other individuals. In a series of single-subject design studies, Prieto[106] found that teachers are more likely to encourage children to perform gross motor activities when they have been properly instructed. Soccio[132] compared the frequency of opportunities to practice specific gross motor skills during individual physical therapy sessions and group early intervention classes. There was no difference in the number of opportunities to practice head control when direct physical therapy was compared with integrated group sessions for a child with severe disabilities. Two children with cerebral palsy, however, had more opportunities to practice standing and ambulation activities during direct, individual physical therapy sessions than during integrated group sessions in the classroom. In studies of preschool classes, students sit for approximately 40 minutes of every hour and are in stability positions for about 50 minutes of every hour, which leaves very little time to practice their recommended mobility activities.[114,101] These results suggest that the opportunity to practice motor activities in the classroom varies, based on the type of movement and the class routines. Therapists must select carefully the activities they delegate to others because opportunities for active gross motor movement in classrooms may be very limited.[101]

Procedural Interventions

Procedural interventions in school settings are frequently not as important as the other two components of intervention. However, as noted in Table 31.4, some situations would suggest a need for direct intervention, such as (1) when a child is at a critical period of skill acquisition or regression, (2) when the interventions require the expertise of a physical therapist, and (3) when integrating therapy interferes with the educational program. Best practice, research, and federal law indicate that most, if not all, intervention should occur in the natural environment, with an emphasis on providing multiple opportunities to practice specific skills.[42,43,57,60,121,135] When gross motor skills are learned in isolated settings, such as a physical therapy department, there is little generalization to the more natural environments of the home, school, or recreational settings.[22]

Assessment of the school environment and safety considerations take precedence initially over direct interventions. The physical therapist should participate in the development of written plans for emergency evacuation from the school building and the school bus, in addition to instructing appropriate personnel on the implementation of these plans. The physical therapist should be present during evacuation drills and might assist in the practice of safe techniques using weighted dummies and different models of wheelchairs.

The physical therapist's assessment of the student's environment should begin with proper positioning on the bus and in classrooms. Safety of the aisles for walking or wheelchair mobility should be considered. Architectural barriers must be evaluated and appropriate actions taken to eliminate or lessen them. Teachers and family should be consulted regarding their concerns, and they should be instructed in proper handling, positioning, and use of body mechanics.

Direct intervention, if indicated, should start in the natural environment of the classroom. This is accomplished easily with preschoolers.[57] It is more difficult for children whose educational programs consist primarily of academic subjects that occur in the general education classroom. Physical therapy in the algebra class or school library, after the initial consultation, is generally inappropriate. Common sense must prevail. Perhaps therapy can be delivered during gross motor time in a preschool or during physical education. This is not always appropriate, however, because this might be the only time the child has to engage in free play and physical activity with peers. Taking this opportunity away from the child might affect motivation, cooperation, and the development of important social skills that occurs during these activities.

Merely moving traditional intervention from a special room to a more natural environment is also not in the spirit of best practice. The therapist must adjust intervention to the unique opportunities afforded by the natural environment. Available furniture or classroom items should be used, as opposed to bringing in special equipment. Use of these common objects increases the likelihood that the child might use them to practice and develop motor skills when the therapist is not present and allows the therapist to model their use for the parent or teacher. The specific type of intervention provided depends on the needs of the individual child and the education, training, and experience of the therapist. IDEA 2004 requires that interventions be provided "based on peer-reviewed research to the extent practicable" [PL 108-446, 118 Stat. 2707-2709, § 614(d)(1)(A)(IV)].[112] Although physical therapy intervention has been advancing toward evidence-based practice, many interventions are not supported by sufficient peer-reviewed research. Throughout this text, peer-reviewed research and evidence-based practice are presented when available. Effgen and McEwen[44,45] published systematic reviews of common interventions used in educational settings. Therapists must learn to search the literature for recent developments in research to support the interventions they use. If the appropriate intervention cannot be provided for a school-age child because it is not educationally relevant and is not related to the objectives in the IEP, the therapist has a professional obligation to inform the parents. Once the parents are aware of the focus of school-based physical therapy, they might obtain additional therapy elsewhere.

Careful monitoring of progress is critical in determining the effectiveness of and the need for continued intervention. David[34] outlined a measurement process that has been developed for use by collaborative educational teams. The system involves (1) defining the performance problem, (2) identifying the performance expected and outcome criteria, (3) developing a systematic, simple, and time-efficient measurement strategy, (4) creating a data-graphing system, (5) providing intervention, (6) monitoring progress, and (7) participating in systematic decision making and intervention changes. David stated that "monitoring without decision making is a waste of valuable time and effort."[34] A recommended tool is a simple but comprehensive system of data collection using self-graphing data-collection sheets.[39] The availability of laptop computers has also made data collection and its graphic presentation much easier for many therapists. Extensive documentation is necessary to support the need to increase, decrease, or discontinue intervention. Documentation of the child's status before and after short and long school breaks is important in determining the need for ESY services.

Physical therapy intervention is not a lifelong activity such as learning and fitness. Both therapists and parents must recognize that, after a period of service delivery with no measurable

progress, intervention should be discontinued or the model should be changed to monitoring. A persistent desire for walking, for example, is not justification for continued therapy after due diligence in trying to achieve a goal. Therapists report that the most important factor in successful discontinuation of services is the child's achievement of functional goals.[40] Choosing to discontinue direct intervention when goals have not been met continues to be a challenging area of decision making, although tools like the CERT and DRTT should help in the process.

TRANSITION PLANNING

Change can be difficult for anyone, and the transition from one environment to another can be stressful for both children and their parents, especially for those students with a limited repertoire of response competence. Because all transitions are important, two critical times were identified in IDEA when attention must be paid to transition and the provision of transition services. These times include (1) when the child is preparing to move from family-centered early intervention services under Part C to preschool services under Part B[62] and (2) when the student is preparing to transition out of secondary school into the community.[52]

Although the transition from family-centered early intervention services to preschool services is intended to be seamless, the transition process is often difficult for both the child and the family. It is usually accompanied by a change in the state agency providing the services, which typically includes a change in the method of service delivery and in personnel. Family-centered services of early intervention are replaced by school-system services with reduced family involvement and with service providers focused on educational goals. Communication between parents and providers may also become more challenging. Physical therapists have not been as engaged as they should be in the transition process for children from early intervention to preschool. They rarely attend transition team meetings and have not received specialized training in transition, but they do report that they work with families during the transition process.[137] Greater involvement in the transition planning process includes practices supporting communication, collaboration, and strong, positive relationships with early intervention and preschool programs.[96] The School-Based Physical Therapy and the Early-Intervention Special Interest Groups of APTA's Section on Pediatrics collaborated in developing a worksheet to facilitate the communication of pertinent information from the early-intervention therapist to the school-based therapist.[6]

Under IDEA 2004, transition services for postsecondary education constitute

> a coordinated set of activities for a child with a disability that is designed within a results-oriented process that is focused on improving academic and functional achievement of the child with a disability to facilitate the child's movement from school to post-school activities, including postsecondary education, vocational education, integrated employment (including supported employment), continuing and adult education, adult services, independent living, or community participation; is based on the individual child's needs, taking into account the child's strengths, preferences, and interests; and includes instruction, related services, community experiences, the development of employment and other post-school adult living objectives, and, when appropriate, acquisition of daily living skills and functional vocational evaluation. [PL 108-446, 118 Stat. 2658, § 602(34)][112]

Transition assessments and services must begin no later than the first IEP to be in effect when the child is 16 years of age[112] or younger if determined appropriate by the IEP team.[49] Physical therapists should serve on transition teams for children with physical disabilities who are currently receiving services, as well as for those for whom services have been discontinued. A young adult may no longer have a school-related need for physical therapy, but the therapist can assist in evaluating and intervening to facilitate post-school planning and services.

All transition planning should be determined collaboratively by the school team along with both the student and the family. Emphasis should be placed on self-determination, person centeredness, and career orientation.[52] The role of the physical therapist in transition planning and in services for students with physical disabilities might include the following:

- Communication with the family and other transition team members regarding daily routines, physical expectations, and demands of the anticipated new environment
- Communication with the student's vocational rehabilitation counselor, occupational therapist, and teachers regarding preparation for mobility and functional activities in the new setting
- Onsite evaluation of the new physical environment and intervention to ensure the student's ability to physically maneuver throughout the setting
- Evaluation of the accessibility of required transportation systems and intervention as required
- Onsite consultation and education of the student, family, and staff related to the student's physical functioning in that environment
- Onsite assessment and identification of assistive technology needs of the student for the new environment
- Assistance in securing assistive technology and instruction in its use
- Attendance at IEP and other meetings, as appropriate
- Consultation throughout the transition process to ensure that recommendations are appropriate and that the student is successful[130]

Effective transition services can be impeded by issues related to collaboration and communication among team members. These include the following:

- Lack of shared information across agencies
- Follow-up data that could improve services
- Attention to health insurance and transportation
- Systematic transition planning with the agencies that will have responsibility for post-school services
- Anticipating the future needs of the student
- Effective management practices[72]

Although the physical therapist is usually not in a leadership role to make major changes in the transition service system, the therapist can provide assistance in several of the problem areas noted. The therapist has the ability to provide information on health insurance; evaluation of transportation needs; equipment for mobility, positioning, and self-care; and anticipation of the post-school physical demands required of the student. A therapist's knowledge of the physical demands of postschool settings, such as college or work environments, would help the team to assist the student in effective transitioning to those environments. Chapter 32, Transition to Adulthood for Youth with Disabilities, addresses the preparation of youth with disabilities for adult roles, including the use of transition services provided within the education and health care systems.

MANAGEMENT OF PHYSICAL THERAPY SERVICES

Successful management and service delivery in educational environments depend on an understanding of the importance of the team process. The physical therapist, as a member of the educational team, must collaborate effectively with the child, the family, and professionals of other disciplines to promote the child's total well-being through each phase of the educational process. Just as team leaders or case managers are important to intervention teams, a manager or director of physical therapy is also needed in school settings. A majority of directors of physical therapy services in school systems across the nation are not physical therapists or, indeed, any type of related-service personnel.[43] This has serious implications. To understand professional roles and responsibilities and how to nurture a professional, one must understand the profession. Many of the problems encountered in school systems could probably be prevented if an experienced therapist provided supervision. Therapist managers understand the profession and are able to address appropriately management issues. States such as Iowa and North Carolina, where therapists are employed by the state department of education, have become national leaders in setting policy for related-service providers. These therapists help to coordinate services throughout the state and educate both therapists and educators regarding the role of physical therapists in educational environments.

Therapists, unlike teachers, are educated to work in a wide variety of settings, but few have the opportunity to learn about school-based practice. Those who are new to practice in educational environments in general and those who are new to a particular school system should receive orientation, mentoring, and in-service education. The roles and responsibilities of the therapist and all support staff should be clearly identified in a detailed job description that complies with federal and state laws, as well as the state's physical therapy practice act. As part of a planned orientation program, therapists should be introduced to the entire team of professionals with whom they will be working at all sites. They need to know whom to ask for equipment, space, and other items necessary for successful intervention. Therapists need to know how referrals are received and handled; how workloads and caseloads are determined; how team meetings are planned and when they are scheduled; the written policies and procedures; how peer review or quality improvement is done; emergency procedures; and the policy for continuing education, to name but a few issues. These are not unusual requests, and they can be addressed easily and cost-effectively in any system.

After the therapist is properly introduced and oriented to the school district, administrators and therapists must continue to communicate regularly before problems arise, especially with therapists who are not school employees. Contracted therapists report rarely being included in school activities.[65] Frequent areas of discontent include too much travel among school buildings, as well as insufficient continuing-education opportunities, peer contact, a place to work, and time allotted for administrative tasks and meetings.[43,65] More time and effort should be spent on retention of physical therapists to reduce the need for recruitment and for continuity of care for the students.

All state physical therapy state practice acts in the United States now allow a therapist to examine and evaluate without a physician's referral, and most also permit therapists to provide intervention without a referral, though specific requirements vary by state.[10] In states where physician authorization is required for intervention, a system should be developed for obtaining referrals. The referral allows the therapist to determine and provide appropriate intervention. Depending on the complexity of the student's medical problems and the need for pertinent information, it might be prudent for the therapist to obtain a referral even when it is not legally required. Collaboration with physicians and all other members of the child's medical and educational team promotes optimal service delivery.

School districts need to develop guidelines to determine therapy workloads, as well as for decision making with regard to who should receive intervention and how much intervention should be provided. This can be a difficult task. The CERT, DRTT, and the APTA Section on Pediatrics fact sheet on dosage considerations (see Table 31.4) should assist in the decision-making process.[7,26,53] Children with critical needs for therapy require more intense intervention than do those with lesser needs. A therapist whose workload primarily includes children who require extensive therapy can serve fewer children than a therapist whose caseload mostly comprises children with minimal needs. A clear system of documentation is needed to support the complex, sensitive decisions regarding allocation of physical therapy services. The American Occupational Therapy Association, APTA, and the American Speech-Language-Hearing Association have produced a joint document on the workload approach for more effective service delivery and student outcomes.[2]

Through the American Recovery and Reinvestment Act of 2009 (ARRA), the Race to the Top Fund provided $4.35 billion in competitive-grant funding aimed at improving student achievement. A major component of that legislation focused on evaluating teacher effectiveness, based on both professional performance and student outcomes. In many states, related service providers, like physical therapists, are included in this initiative. Each state has established its own guidelines, and school districts within each state have chosen their own evaluation tools. Some states use modified versions of the Danielson[33] or Stronge[134] model. The School-Based Physical Therapy Special Interest Group of APTA's Section on Pediatrics developed a document that outlines an appropriate evaluation tool for physical therapists, based on the competencies described by Effgen, Chiarello, and Milbourne.[46]

ISSUES IN SCHOOL-BASED PRACTICE

Shortage of Pediatric Physical Therapists

Insufficient numbers of pediatric physical therapists with the skill set for serving children in the educational setting has been an ongoing problem. It may become worse as many of the therapists initially hired with the enactment of PL 94-142 begin to retire. Shortages of therapists may be attributed to relatively low pay, professional isolation, benefits of other areas of practice, and challenges of working with children. Solutions are numerous and sometimes complex, but one of the easiest is often neglected. An effective way to train and then recruit new physical therapists is to offer student clinical affiliations in educational settings.

Physical therapy is not the only school-based profession where shortages exist. The National Coalition on Personnel Shortages in Special Education and Related Services (NCPSSERS) notes that 49 states report shortages of special education teachers and

specialized instructional support personnel.[98] The coalition represents 30 national, state, and local professional organizations from eight different disciplines. Its stated mission is "to sustain a discussion among all stakeholders on the need for and value of special education, related services, and early intervention; and to identify, disseminate, and support implementation of national, state, and local strategies to remedy personnel shortages and persistent vacancies for the benefit of all children and youth."[98]

Service-Delivery System

A dearth of qualified school-based physical therapists has affected the type of service-delivery system used and the roles assumed by school personnel. The literature supports integrated or collaborative service-delivery models.[61,122] There are obvious advantages to more frequent practice in natural settings with the support of all those who interact with the student. An appropriately administered therapy program in the natural environment might require more, not fewer, personnel. Training all staff members in an integrated or collaborative model requires a great deal of time for instruction and meetings.[55] There are those, however, who incorrectly think that these models can be used to decrease the time required for physical therapy. It should be noted that "Teams Take Time" (the three T's). Instead of direct intervention by a therapist, unqualified staff might perform activities without adequate supervised instruction, or a teacher might be forced to provide an intervention for which he or she is not properly trained. Instead of providing the intervention in a room with necessary equipment, a classroom or hallway is used in the name of natural environment. Rarely are empirical data sufficient to support any specific service-delivery system.

A national study, *Physical Therapy Related Child Outcomes in the Schools* (PT COUNTS),[41] found that students were seen for physical therapy an average of 26.8 minutes/week. The majority of physical therapy services were provided individually (average 23.3 minutes per week) and separate from school activities (average 19.6 minutes per week). Very little time was spent on activities within the context of school (average 9.5 minutes per week). Therapists spent approximately 13.2 minutes per week providing services on behalf of the student, which primarily included consultation, collaboration, and documentation. As measured on the School Function Assessment (SFA), students who were younger than 8 years of age with higher gross motor function improved more than students who were older and had lower gross motor function. There were statistically significant differences based on Gross Motor Function Classification[102] (GMFCS) levels; students at levels IV/V (lowest functional ability) made less improvement in all SFA subscales except *Travel*. On the individualized goal outcomes measured using GAS, on average, students achieved and slightly exceeded their expected goal attainment for their primary goal, as well as the goals categorized as *posture/mobility, recreation/fitness,* and *self-care*. The majority of students improved on their primary goal (75%), with 35% achieving goal expectations and 40% exceeding goal expectations. Goal attainment did not differ significantly for students by GMFCS level, diagnostic group, or between those receiving or not receiving outpatient physical therapy. Students 5 to 7 years of age had higher goal attainment for their primary goal compared to students 8 to 12 years of age. More minutes spent on services on behalf of the student (consultation/collaboration and documentation) were predictive of higher levels of goal attainment for *posture/mobility*. More minutes in self-care activities and services on behalf of the students were associated with exceeding goal expectations. An increase in 100 minutes of services on behalf of the student (5 minutes per week) increased the odds of exceeding goal expectations by 24%.[47] Consulting and collaborating with teachers, parents, and others were likely to have positively influenced student outcomes, probably by providing an understanding of the student's goals involving physical therapy and educating others on the importance of providing practice opportunities for fluency and generalization of skills. Documentation requires a thoughtful review of what was and what will be done with the student. This reflection might lead to more appropriate interventions with positive outcomes.

Professional Roles

In school systems with a full staff, professionals can collaborate to decide on the role of each team member. Overlap of professional roles is acknowledged, and divisions of responsibility are made that are best suited to the needs of the child, school system, and professional staff.[142] In general, the overlap in physical therapy, occupational therapy, and education is greatest when professionals from these disciplines are serving young children. For older children, less overlap in professional roles exists. Areas of frequent overlap between occupational therapy and physical therapy include programs for strength and endurance, body awareness, classroom positioning and adaptations, enhancement of motor experience, and sensory integration. Areas of overlap between physical therapists and educators might include advanced gross motor skills, endurance training, and transfers. In systems with a critical shortage of physical therapists, the breadth of roles assumed by other staff members increases, based on need and not necessarily on professional skill.

Educationally Relevant Physical Therapy

For decades, parents of children with disabilities, school administrators, teachers, and school-based physical therapists have debated the role of school-based physical therapy as compared with clinic-based services. In school districts with an adequate number of therapists, where there is a commitment to providing appropriate services for students with disabilities, the definition of educationally relevant physical therapy is comprehensive; it depends on the individual needs of the child, as addressed at the IEP meeting. IDEA clearly indicates that education is intended to prepare students for independent living and economic self-sufficiency, which have broad implications for the provision of physical therapy.[112]

Physical therapy is perceived as more educationally relevant when the entire IEP team mutually agrees upon goals and objectives. The educational system was never meant to provide for all of the child's therapy needs. Physical therapy may be provided outside of the educational system as needed; all therapists serving the child should collaborate and coordinate services. Therapists and parents must remember that therapy takes time away from other educational and social opportunities that are vital to the total well-being of the child. These competing priorities must be considered when making decisions regarding service delivery.[8] Educators and therapists alike must continually ask themselves if they are truly meeting the needs of each individual child.

Reimbursement for Services

The cost of providing related services in educational environments is a serious concern of program administrators. IDEA provides some federal funding to states, but it has never been sufficient to encompass the full spectrum of services needed by students in special education. To cover the costs of physical therapy, some school districts are charging third-party payers. This can be problematic because of the lifetime cap on many insurance policies, limited therapy coverage, and the possibility of losing insurance if bills are too high. Parents are not required to have their insurance company pay for these services, and they should not be intimidated into thinking that their child will not receive services without insurance payment. School districts may also bill Medicaid directly for physical therapy; however, reimbursement is usually based on direct services, and consultation, team intervention, and group services are discouraged. Medicaid rules and regulations are determined by each individual state, and therapists should be active at the state level to make certain that these rules and regulations facilitate and do not hinder appropriate school-based intervention.

Transportation

Transportation of children receiving special education is a required related service. Ensuring that they are transported safely and efficiently is the responsibility of the school district. Many individuals assist in the transportation process, and the National Highway Traffic Safety Administration[99] offers numerous resources that address the safe transportation of children. A physical therapist might be asked to assess the safety of seating of a student with a disability in a school bus seat or wheelchair, embarking and disembarking from the bus, emergency evacuation procedures, and the lifting techniques used by transportation personnel. Central to the therapist's role is an understanding of what makes a wheelchair appropriate for transportation, as well as how to tie down the wheelchair and use occupant-restraint systems. Team discussions regarding plans for emergency evacuation should include issues related to the student's size, weight, and height; implications of different medical diagnoses (e.g., osteogenesis imperfecta); orthopedic concerns; physical limitations; ability of the student to assist; whether a student stays in the wheelchair; and who gets off the bus first and last. Competence in transportation issues, which may be overlooked by some school-based therapists, is a critical component of service delivery.

Therapists New to the Educational Environment

Many school-based physical therapists begin their careers by working in adult or other pediatric settings. Upon entering the educational environment, those who are parents enjoy the benefit of having the same school hours and vacation schedules as their children. Therefore it is not uncommon for experienced therapists to seek employment in school settings with little or no background in pediatrics and lacking an understanding of the unique requirements of working under IDEA. Therapists who are new to school practice must immediately learn the rules and regulations of IDEA, as outlined in this chapter and as available from the suggested websites and references. In addition, they must be aware of individual state education laws, special education laws, and their state physical therapy practice act. It is the therapists' responsibility to be knowledgeable of the laws that govern practice in schools, just as they should know the rules for reimbursement and practice in hospital settings. In this era of limited resources, administrators have been known to say that services are not appropriate for a child with a disability because they want to avoid paying for such a service. They might also say that because a therapist is not available, therapy cannot be recommended in the IEP. Of course, this is incorrect, but most parents and many therapists will not know that unless they are well versed in the laws.

School-based therapists need to become effective members of a team, using the various models described in this chapter. Those who have worked in other pediatric settings, such as early intervention and pediatric hospitals, may be accustomed to working with a team, as may therapists who have worked in rehabilitation settings. Therapists who have practiced in outpatient physical therapy settings, however, may not be adequately familiar with team functioning and the degree of role release and collaboration required in the school setting.

Intervention is also somewhat different from in educational environments than in other settings. As discussed in this chapter, goals and objectives must be educationally relevant. Intervention is based on the *Guide,*[3] including coordination, communication, and documentation, as well as patient/client-related instruction. For children who demonstrate a need for physical therapy as outlined in Table 31.4, procedural interventions might be provided. However, many students do not require direct intervention, and this change in focus can be difficult for some therapists who are accustomed to providing direct services.

Therapists new to school practice would be wise to seek an experienced mentor, either within or outside the school system. Many school therapists work in isolation, and they do not have access to the guidance and support provided in other clinical settings. They work frequently with teachers but not necessarily with other therapists who can evaluate their knowledge and skills and with whom they can discuss cases. School administrators need to recognize the effect of this professional isolation for both experienced therapists and those new to the school environment, and they should support the therapist in finding a mentor.

Therapists, especially new graduates and those new to educational environments, should strive to achieve the competencies for school-based physical therapists as outlined in Box 31.4.[46] For therapist performance appraisal, the APTA Section on Pediatrics has added competencies in advocacy and administration. These competencies may also be shared with administrators to help define the role of school-based physical therapy and to identify the resources necessary for effective service delivery. Therapists should continually read professional literature, participate in continuing education, take postprofessional courses, join journal clubs, and engage in dialogue with colleagues. The APTA Section on Pediatrics offers a wide variety of excellent resources for school-based therapists. Employers need to support therapists' efforts at ongoing professional development.

Physical Fitness for All Students

Although school-based physical therapists are usually employed to serve students with disabilities who have IEPs or Section 504 plans, some school districts are more inclusive and involve therapists in a broader range of services. This might include determination of architectural barriers, safe transportation, prevention of athletic injuries, and promoting developmentally appropriate motor programs. The national crisis regarding obesity and physical fitness of all students suggests that

BOX 31.4 Competencies for School-Based Physical Therapists

Content Area 1: The Context of Therapy Practice in Schools

1. Describe competencies for school-based physical therapists.
   a. Diagram the functional and supervisory organization of the education system served by the therapist.
   b. Identify the goals and outcomes of the educational curriculum from preschool through high school.
   c. Demonstrate an understanding of the eventual goals of independent living and working.
   d. Apply knowledge of the outcomes-based education curriculum.
2. Demonstrate knowledge of federal (for example, IDEA, Rehabilitation Act of 1973, ADA), state, and local laws and regulations that affect the delivery of services to students with disabilities.
   a. Discuss the implications of the laws (national, state, and local).
   b. Apply the guidelines of federal, state, and local regulations.
   c. Identify and use information sources for federal, state, and local legislation and regulation changes.
   d. Discuss and demonstrate professional behavior regarding ethical and legal responsibilities.
   e. Discuss professional competencies as defined by professional organizations and state regulations.
   f. Advocate to support services related to educational entitlements.
3. Apply knowledge of the theoretical and functional orientation of a variety of professionals serving students within the educational system.
   a. Initiate dialogue with colleagues to exchange professional perspectives.
   b. Disseminate information about the availability of therapy services, criteria for eligibility, and methods of referral.
   c. Describe evaluations and interventions commonly used by psychologists, diagnostic educators, classroom teachers, speech and language pathologists, adaptive physical educators, nurses, physical therapists, occupational therapists, and professionals in other education and health-related disciplines.
4. Assist students in accessing community organizations, resources, and activities.
   a. Demonstrate awareness of cultural and social differences that relate to family and student participation in the education program.
   b. In collaboration with the educational team, develop a plan for transition into community activities or adult services.
   c. Identify the need to make appropriate student referrals to community therapy and recreational services when school services are not able to meet all of the child's needs.
   d. Include the family in the educational process.
   e. Serve as a resource to family and other team members for information and appropriate community resources (medical, educational, financial, social, recreational, and legal).

Content Area 2: Wellness and Prevention in Schools

1. Implement school-wide screening program with school nurse, physical education teacher, and teachers.
   a. Apply knowledge of risk factors affecting growth, development, and learning.
   b. Identify the etiology, signs, symptoms, and classifications of common pediatric disabilities.
   c. Identify established biologic and environmental factors that affect children's development and learning.
   d. Select, administer, and interpret a variety of screening instruments and standardized measurement tools.
2. Promote child safety and wellness using knowledge of environmental safety measures.
   a. Maintain cardiopulmonary resuscitation (CPR) certification.
   b. Institute an environmental hazards and accident prevention plan.
   c. Recognize child neglect and abuse.

Content Area 3: Team Collaboration

1. Form partnerships and work collaboratively with other team members, especially the teacher to promote an effective plan of care.
   a. Demonstrate effective communication and interpersonal skills.
   b. Refer and coordinate services among family, school professionals, medical service providers, and community agencies.
   c. Implement strategies for team development and management.
   d. Develop mechanism for ongoing team coordination.
2. Function as a consultant.
   a. Identify the administrative and interpersonal factors that influence the effectiveness of a consultant.
   b. Implement effective consultative strategies.
   c. Provide technical assistance to other school team members, community agencies, and medical providers.
3. Educate school personnel and family to promote inclusion of the student within the educational experience.
   a. Assist school administrators with development of policy and procedures.
   b. Provide orientation to teachers and classroom aides.
   c. Conduct in-service sessions.
   d. Develop informational resources.
4. Supervise personnel and professional students.
   a. Apply effective strategies of supervision.
   b. Monitor the implementation of therapy recommendations by other team members.
   c. Establish a student clinical affiliation.
   d. Formally and informally teach or train therapy staff.
5. Serve as an advocate for students, families, and school.
   a. Attend public hearings.
   b. Serve on task force or decision-making committees.
   c. Provide necessary information to support student rights.
   d. Actively participate in the individualized educational program (IEP) process.

Content Area 4: Examination and Evaluation in Schools

1. Identify strengths and needs of student.
   a. Interview student, family, teachers, and other relevant school personnel.
   b. Gather information from medical personnel and records.
   c. Observe student in a variety of educational settings.
2. Collaboratively determine examination and evaluation process.
   a. Designate appropriate professional disciplines.
   b. Identify environments and student activities and routines.
   c. Select instruments.
   d. Establish format for conducting examination.
   e. Inform and prepare the student.
3. Determine student's ability to participate in meaningful school activities by examining and evaluating the following:
   a. Conduct of formal naturalistic observations to determine level of participation and necessary assistance and adaptations.
   b. Functional abilities, including gross motor, fine motor, perceptual motor, cognitive, social and emotional, and activities of daily living (ADLs).
   c. Impairments related to functional ability, including musculoskeletal status, neuromotor organization, sensory function, and cardiopulmonary status.
4. Utilize valid, reliable, cost-effective, and nondiscriminatory instruments for the following:
   a. Identification and eligibility.
   b. Diagnostic purposes.
   c. Individual program planning.
   d. Documentation of progress.

Content Area 5: Planning

1. Actively participate in the development of the IEP.
   a. Determine eligibility related to a student's educational program.
   b. Accurately interpret and communicate examination findings collaboratively with family, student, and other team members.
   c. Discuss prognosis of student performance related to curricular expectations.
   d. Discuss and prioritize outcomes related to student's educational needs based on current and future environmental demands and student and family preferences and goals.
   e. Offer appropriate recommendations for student placement and personnel needs in the least restrictive educational setting with intent to serve children in inclusive environments.

Continued

BOX 31.4 Competencies for School-Based Physical Therapists—cont'd

f. In collaboration with the team, determine how therapy can contribute to the development of an IEP, including the following:
   i. Meaningful student outcomes.
   ii. Functional and measurable goals and objectives.
   iii. Therapy service recommendations.
   iv. Specific intervention methods and strategies.
   v. Determination of frequency, intensity, and duration.
g. Develop mechanism for ongoing coordination and collaboration regarding the following:
   i. Implementation of the IEP.
   ii. Updates or modifications of IEP.
   iii. Transition planning and implementation of the transition plan.
   iv. Interagency activities.

Content Area 6: Intervention

1. Adapt environments to facilitate student access to and participation in student activities.
   a. Recommend adaptive equipment, assistive technology, and environmental adaptations.
   b. Monitor adaptive equipment, assistive technology, and environmental adaptations.
   c. Be able to instruct student and other team members in the appropriate use of adaptive equipment and assistive technology.
   d. Identify sources for obtaining, maintaining, repairing, and financing adaptive equipment, assistive technology, and environmental adaptations.
2. Use various types and methods of service provision for individualized student interventions.
   a. Employ direct, individual, group, integrated, consultative, monitoring, and collaborative approaches.
   b. Develop generic instruction plans and intervention plans that select and sequence strategies to meet the objectives listed on the student's IEP.
3. Promote skill acquisition, fluency, and generalization to enhance overall development, learning, and student participation.
   a. Use creative problem-solving strategies to meet the student's needs.
   b. Explain the basic motor learning theories, and relate them to therapy education programs.
   c. Address neuromuscular, musculoskeletal, sensory processing, and cardiopulmonary functions that support motor, social, emotional, cognitive, and language skills.
4. Embed therapy interventions into the context of student activities and routines.
   a. Implement appropriate positioning, mobility, environmental, and ADL strategies into curriculum, classroom schedule, and routines.
   b. Develop a matrix integrating objectives, routines and activities, and strategies.

Content Area 7: Documentation

1. Produce useful written documentation by doing the following:
   a. Writing reports in commonly understood and meaningful terms.
   b. Maintaining timely and consistent records.
   c. Concisely summarizing relevant information.
   d. Sharing records with family and other team members.
2. Collaboratively monitor and modify student's IEP.
   a. Establish a mechanism for and record ongoing communication with family and other team members.
   b. Establish a plan of action for reevaluation.
   c. Schedule preestablished team meetings to review student progress over the course of the school year.
3. Evaluate and document the effectiveness of therapy education programs.
   a. Establish baseline of student's level of participation and functional status.
   b. Collect ongoing data on the student's progress toward stated IEP outcomes.
   c. Summarize data to determine student's progress.

Content Area 8: Administrative Issues in Schools

1. Demonstrate flexibility, priority setting, and effective time management strategies.
2. Obtain resources and data necessary to justify establishing a new therapy program or altering an existing program.
3. Serve as a leader.
   a. Integrate knowledge of education, health, and social trends that affect therapy services.
   b. Identify and educate others on the overall roles, responsibilities, and functions of therapy services.
   c. Identify and differentiate characteristics of alternative approaches for resolving needs of therapy services.
   d. Identify the administrative needs of the therapy service within the school setting.
   e. Serve as a role model for other therapists regarding professional responsibilities.
4. Serve as a manager.
   a. Develop and analyze job descriptions for therapists.
   b. Implement a recruitment, orientation, mentorship, and professional development program for therapists and staff.
   c. Develop and implement policies and procedures to guide therapy services.
   d. Establish therapy caseloads [workloads], and staffing needs.
   e. Evaluate the performance of therapy personnel.
   f. Plan and implement a therapy quality assurance plan and program evaluation.
   g. Participate in the assessment of school facilities and educational activities.
   h. Make recommendations, especially related to ensuring accessibility and reasonable accommodations to school environments.
   i. Identify and use appropriate school, home, community, state, and national resources, especially funding sources.
   j. Demonstrate the ability to plan and manage a budget for the therapy component of services.

Content Area 9: Research

1. Demonstrate knowledge of current research related to child development, medical care, educational practices, and implications for therapy.
   a. Conduct a literature review.
   b. Seek assistance of experienced researchers in interpreting published research.
   c. Critically evaluate published research.
2. Apply knowledge of research to the selection of therapy intervention strategies, service delivery systems, and therapeutic procedures.
   a. Use objective criteria for evaluation.
   b. Justify rationale for clinical decision making.
   c. Expand clinical treatment case reports into single-subject studies.
3. Partake in program evaluation and clinical research activities with appropriate supervision.
   a. Identify research topics.
   b. Secure resources to support clinical research.
   c. Implement clinical research projects.
   d. Disseminate research findings.

From Effgen SK, Chiarello L, Milbourne S: Updated competencies for physical therapists working in schools, Pediatr Phy Ther 19:266-274, 2007.

school-based physical therapists should address these issues, in collaboration with physical educators.[87,93,104,126] Physical inactivity threatens not only physical but also cognitive health.[63] The evidence strongly supports physical activity programs for students with developmental disabilities to improve aerobic capacity, gross motor performance, and child/parent satisfaction.[71] A systematic review of studies of children and adults with intellectual disabilities also found that exercise interventions assist in decreasing challenging behaviors.[100] Additionally, physical activity has been shown to improve mental health and classroom performance in children with autism and attention deficit hyperactivity disorder.[105] The reader is encouraged to review the national website on Walk/Bike to School (www.walkbiketoschool.org) to learn about fun ways to encourage healthy habits and regular physical activity for all students. Evaluation and intervention for physical fitness are covered in Chapter 6, Physical Fitness During Childhood and Adolescence.

SUMMARY

In the United States, physical therapy is included as part of federally sponsored programs to serve infants, toddlers, children, and youth with disabilities. For preschool- and school-age children, physical therapy is a related service of the educational program under IDEA for children who require special education or under Section 504 of the Rehabilitation Act. The school setting is not the high-tech, health-focused environment of the modern hospital setting or the therapy-focused environment of the rehabilitation setting. Rather, the educational needs of students are the highest priority. To provide effective services and attain personal satisfaction, therapists must become knowledgeable of the educational milieu, including federal, state, and local laws, and regulations that govern physical therapy in the educational environment.

Physical therapists working in school settings witness firsthand the successes and struggles that students with special needs experience in their everyday lives as they participate in the school environment. As members of a team of professionals, physical therapists are asked to solve complex problems to enhance the ability of children to participate in educational programs. The educational environment is rewarding for physical therapists willing and able to meet the unique demands of this practice setting.

Case Scenario on Expert Consult

The case scenario related to this chapter includes a longitudinal case scenario and video on school-based physical therapy. Adrianna is presented. Her case highlights issues and challenges that are frequently encountered by physical therapists in school-based practice, including (1) promotion of the student's participation in the educational program in the least restrictive environment, (2) collaboration with other team members and physicians, (3) flexibility in selecting models of service delivery based on the student's goals, and (4) guidance for transition planning.

Transition to Adulthood for Youth With Disabilities

Nancy Cicirello, Antonette Doty, Robert J. Palisano

Transition to adulthood is a future-oriented process in which youth express their desires and goals and begin planning for adult roles and responsibilities.[19] The transition process is multifaceted and encompasses the health, psychosocial, and educational-vocational needs of adolescents as they move from child-oriented to adult-oriented lifestyles and systems.[146] Parent and youth priorities include functioning as independently as possible with appropriate supports, finding meaningful activities after high school, and establishing supportive social relationships.[113] Rutkowski and Riehie[118] shared the organizational vision of United Cerebral Palsy that people with cerebral palsy and other developmental disabilities will live and participate in their communities, have satisfying lives and valued social roles, have sufficient access to needed support and control over that support so that the assistance they receive contributes to lifestyles they desire, and be safe and healthy in the environments in which they live. The US Individuals with Disabilities Education Improvement Act (IDEA) of 2004 (PL 108-446) mandates transition planning to prepare youth with the knowledge and skills for adult roles. A consensus statement by the American Academy of Pediatrics (AAP), American Academy of Family Physicians, American College of Physicians, and American Society of Internal Medicine advocates a written health care transition plan for all youth with disabilities by age 14.[2] Implementation of comprehensive and coordinated health transition services and supports, however, has not been widely achieved.[2] Furthermore, young adults with intellectual or developmental disability are less likely to be employed, enroll in postsecondary education, and live independently after high school than peers with typical development.[104]

Transition to adulthood presents particular challenges for youth with disabilities, their families, health care professionals, and the broader health care system.[2,18,37,130] Blomquist et al. identified low expectations by parents and professionals, lack of knowledge of existing career and vocational education services, and lack of self-advocacy skills as particular challenges for youth with disabilities.[19] Similarly, Stewart identified lack of preparation, limited information, limited supports, lack of skills for adult roles, and disjointed adult services as potential barriers to successful transition.[126] In a national survey conducted by the PACER center, youth with disabilities identified job training, independent living skills, and college or vocational guidance as their most wanted transition services.[150] Only 45% reported that someone had discussed with them how to make medical decisions, and fewer than 50% had been asked about their work plans.[150] In another national survey, only 6% of families reported that their young adult child with special health care needs had achieved core outcomes for successful transition to adulthood.[109] These findings underscore the need for innovative programs to prepare youth with disabilities for adult roles.

Preparing youth with disabilities for adult roles and meeting the needs of adults with childhood-onset conditions are emerging areas of physical therapy practice. Youth with disabilities often have needs for (1) personal assistance, (2) assistive technology, (3) instruction in self-advocacy, and (4) development of skills needed for postsecondary education and employment.[52,69,127,135] The International Classification of Functioning, Disability and Health (ICF),[149] described in Chapter 1, is a *biopsychosocial model* in which the interaction between the person and environment is critical for understanding health, health-related states, and participation outcomes. The transition experiences of youth across Canada support this perspective; the overall theme that emerged from interviews and focus groups was "complexities related to person-environment interactions."[129]

The objectives of this chapter are to (1) describe the transition process and challenges for youth with physical disabilities and families; (2) appraise transition approaches, services, supports, and outcomes; and (3) provide recommendations for the expanding role of the physical therapist in the transition process in and across educational, community, and hospital settings.

BACKGROUND INFORMATION

PREPARATION OF YOUTH WITH DISABILITIES FOR ADULT ROLES

Transition to adulthood encompasses new roles, responsibilities, and expectations and is influenced by a myriad of personal, familial, community, and societal factors. Havighurst identified tasks of adolescence including (1) forming new and more mature relations with age-mates of both sexes, (2) accepting one's physique and using one's body effectively, (3) achieving emotional independence from parents and other adults, (4) preparing for marriage and family life, (5) gaining economic independence, and (6) desiring and achieving socially responsible behavior.[57] Halfon et al.[53] proposed a lifecourse health development model in which health is conceptualized as an emergent set of developmental capacities that enables individuals to adapt to events and experiences and achieve life goals. Health development is sensitive to the timing and social structuring of environmental experience. These perspectives underscore person-environment transactions as critical to the transition process.

Youth with childhood-onset disabilities are consumers in the life tasks of finding meaningful work, accessing multiple

physical environments, living independently or with self-chosen supports, and successful transition that is enabled by the community.[35] Rosenbaum and Rosenbloom[115] describe the intersection of social and medical systems for improving services to individuals with childhood-onset conditions. They encourage providers to partner with youth and families in advocating strengths-based approaches and participation roles for these youth.

Family Readiness

Collaboration among youth with disabilities, their families, and professionals is essential for successful transition.[8] A general expectation is that as adolescents mature, they will become more autonomous and assume adult roles and responsibilities. Families of youth with disabilities have expressed needs for future planning[107] and concerns about what will happen when they no longer are able to care for their adult child.[21,48,98] Parents of students with disabilities are not always involved in transition planning, even though they are often the primary support for their children after high school. McNair and Rush found that parents wanted more information regarding their child's skill level, work options, adult services, community living, and types of family support, and they desired more involvement in transition planning.[99] Parents of youth with intellectual or developmental disability associated successful transition with: "having an occupation or functional role in society," "moving out of home apart from parent or caregiver," "relationships with peers," and "skills required for success in daily functioning."[62] These findings reinforce the importance of addressing the family's priorities and concerns when transition planning.

Self-Determination

Self-determination is a desirable attribute of youth transitioning to adult roles.[43,92,127] Self-determination is defined as the "combination of skills, knowledge, and beliefs that enable a person to engage in goal directed, self-regulated, autonomous behavior."[44] Self-determination is both person centered and person directed and acknowledges the rights of people with disabilities to take charge of and responsibility for their lives.[73] Youth possessing self-determination are thought to have greater ability to take control of their lives and successfully assume adult roles. Youth with cerebral palsy identified being believed in, believing in yourself, and being accepted by others as important for success in life.[77] Social self-efficacy was associated with independence and persistence in a study of adolescents with physical disabilities.[78] Gall et al. have recommended that the transition process involves a gradual shift in responsibilities from the service provider to the parent/family and finally to the young person.[49]

In a systematic review on self-determination of students with disabilities, it was concluded that self-determination is teachable and outcomes are optimized by instructional or curricular interventions that contained multiple components.[30] Goal setting and self-management were the most frequent intervention strategies. Other components included decision making, planning, problem solving, learning and practicing skills, and self-advocacy. Evans et al. evaluated a multifaceted transition program provided through children's rehabilitation services that combined self-discovery, skill development, and community experiences.[43] Following participation in a 12-month program, youth and young adults with multiple disabilities demonstrated statistically and clinically important improvement in self-determination and their sense of personal control, spending significantly more time engaged in volunteer/work activities and community leisure activities. Adults with cerebral palsy shared that modeling, goal setting, self-awareness, supports from family, friends, and the community, and opportunities to experience and practice self-determination optimized the transition process while attitudinal barriers were often a greater challenge than physical barriers.[6]

Self-Management of Health Condition

To the fullest extent possible, youth with disabilities are encouraged to actively participate in the transition from a pediatric to an adult medical home. The ability to communicate with health care providers, including primary care physicians, specialty physicians, nurses, therapists, and dentists, is an important skill. For youth who require physical assistance for self-care, this includes the ability to instruct care providers. Equally important are skills for health promotion, injury prevention, and prevention of secondary impairments. Youth with disabilities may benefit from experience in coordination of services among their multiple health care providers. Learning to identify one's medical home provider and develop strategies for communicating and coordinating her/his specialty care such as maintaining a health status record and care are examples of outcomes for self-management. This may include a transition plan that is shared with each provider. The electronic medical record has potential to improve communication and coordination of care.

Wellness and Secondary Prevention

Healthy People 2020[140] is an initiative by the U.S. Department of Health and Human Services to promote health and disease prevention. Goals for people with disabilities include greater access to health, wellness, assistive technology, and treatment programs and a reduction in the proportion of people with disabilities who report encountering environmental barriers to participating in home, school, work, or community activities. Comprehensive and coordinated heath care, self-management of one's health condition, and physical activity are important for wellness and secondary prevention. In the Disability and Secondary Conditions section of *Healthy People 2020,* two new objectives are (1) reduce the proportion of people with disabilities reporting delays in receiving primary and periodic preventive care because of specific barriers and (2) increase the proportion of parents or other caregivers of youth with disabilities aged 12 to 17 years who report engaging in transition planning from pediatric to adult health care. The objectives reinforce the importance of introducing aging with disabilities and youth in transition into physical therapy education programs and service delivery.

Finding an Adult Medical Home

With medical advances over the past decades, many children with disabilities are now living into adulthood and facing new challenges in the areas of health and wellness.[14] Newacheck et al. reported that in the United States, 18% (12.6 million) of children and adolescents under 18 years of age have a chronic medical condition requiring health and related services beyond that required by children in general.[103] Ninety percent of youth with special health care needs reach their 21st birthday. An estimated 200,000 to 500,000 individuals with lifelong disabilities are over the age of 60, and this number is expected to double by 2030.[11]

An important outcome for youth with disabilities is continuous, comprehensive, and coordinated services in the adult health care system.[2,34,147] Presently, the health care system in the United States is not designed to facilitate the transition between pediatric and adult services, which results in a patchwork approach that is not likely to change in the near future.[14] Typically, people with a lifelong disability have less access to medical providers in the community than the general population. In addition, they have less preventive care, more emergency medical visits, less insurance coverage, and little to no experience managing their own health care. Forty-five percent of youth with special health care needs do not have a physician who is familiar with their health condition. Further, 30% of 18- to 24-year-olds in the United States lack a payment source for health care, and youth lack access to primary and specialty providers.[14]

Hepburn et al.[63] performed a scoping review of publicly available government documents on transition to adulthood and reported that, internationally, few jurisdictions address transition of care issues in either health or broader social policy documents. Most jurisdictions do not address the policy infrastructure required to support successful transitions or evaluate transition strategies. In the United States, the medical home model is an effort to improve coordination of services and reduce costs by identifying a primary care provider and coordination of health care and community services. The adult health care system, however, is lacking in primary care providers and the specialized health care and rehabilitation services needed by adults with childhood-onset chronic conditions such as cerebral palsy.[15,34,91,125] Lack of transition preparation of young people with disabilities and their families is thought to contribute to problems in transition to adult care.[114]

The American Academy of Pediatrics, American Academy of Family Physicians, American College of Physicians, and American Society of Internal Medicine published a consensus statement recommending that all youth with special health care needs have a written health care transition plan by age 14 years to identify appropriate health care professionals, provide guidelines for primary as well as preventive care, and ensure developmentally appropriate transition services.[2] A clinical report by these organizations advocates a well-timed, coordinated, and individualized plan for transition of youth between the ages of 18 and 21 years from child- to adult-oriented health care.[2] Transition plans should include: the expected age for transition to adult health care, the responsibilities of the youth, family, and/or caregiver, and the responsibilities of medical providers in preparing for transition. This process includes: (1) *Assessing* for transition readiness, (2) *Planning* a dynamic and longitudinal process for accomplishing realistic goals, (3) *Implementing* through education of all involved parties and empowerment of the youth in areas of self-care, and (4) *Documenting* to enable ongoing evaluation and sharing of information with adult care providers. The website for the American Academy of Pediatrics National Center for Medical Home Implementation includes resources for families, youth, and providers on finding a medical home and health care transition (https://medicalhomeinfo.aap.org/Pages/default.aspx). Resources for youth include transition notebooks, a portable medical record form, and videos on topics such as talking with your doctor and other health care professionals and planning for the future.

Tonniges and Roberts investigated health care and transition and found that youth with special health care needs spend more time on crisis management and less on typical life, fun, and activities.[138] Youth with special health care needs are said to live more as a patient and less as a young person, leading to missed school, interruptions in learning, functional declines, social isolation, and low expectations by adults about their abilities and future prospects. Youth express that they would like to live and work independently but often feel they are "treated like a child" and have a loss of control. Many youths feel they are not seen as unique individuals, separate from their condition, and health care providers often defer to their parents. Families of youth with special health care needs would like more information about resources, referrals to services, a written health transition plan, an advocate to assist and explain, and assistance from their medical home.[14]

Physical Activity

The importance of physical activity is a topic of education for youth with disabilities.[47] Promoting lifetime physical fitness is critical for prevention of secondary complications resulting from childhood-onset health conditions. A systematic review concluded that, across all ages and levels of motor function, children and youth with cerebral palsy participated in 13% to 53% less habitual physical activity than their peers. Levels of activity were approximately 30% lower than guidelines for physical activity, and sedentary times were twice the maximum recommended amount.[25] Maltais et al.[95] stress that low levels of physical activity might increase risk for related chronic diseases associated with poor health-related physical fitness. Based on research evidence, Maltais et al.[95] recommend that all children and youth with cerebral palsy engage in regular aerobic, anaerobic, and muscle-strengthening activities to the extent they are capable.

The health benefits of regular exercise include decreased risk of heart disease, cancer, age-related physiologic changes, obesity, and increased social well-being. The Surgeon General report stated that for people with chronic disabling conditions, regular physical activity can improve stamina, muscular strength, and quality of life and prevent disease.[141] The report identified a lack of available and accessible wellness and fitness programs and recommends implementing community-based programs with safe, accessible environments and including people with disabilities and their families in program planning.

Creating a habit of regular exercise is challenging for individuals with lifelong disabilities. Erson stated that fitness activities should be fun, goal oriented, and contribute to health and well-being in order for fitness to become a habit.[42] Exercise can improve academics, reduce maladaptive behaviors, and improve self-esteem and psychosocial functioning of adolescents with disabilities,[40,132] yet as youth advance through the education system, the amount of physical education often decreases.

Exposure to diverse recreation and leisure activities enables youth with disabilities to make informed choices. Making choices enhances self-determination and can decrease problem behavior.[131] Furthermore, preferred recreation and leisure activities are more likely to be enjoyable and sustained over time. Exposure to diverse activities enables youth to select alternative activities if initial choices do not work out. The Americans with Disabilities Act (ADA) legislates equitable access of community recreation programs for persons with disabilities. Participation

of persons with disabilities in age-appropriate, community-based programs should increase public awareness that disability does not equate to ill health.

Physical fitness is addressed in detail in Chapter 6.

Community Living

The reauthorization of Individuals with Disabilities Education Act in 1997 included mandates to improve transition of youth from high school to other opportunities such as postsecondary education, employment, and community living. Johnson et al. suggested that transition challenges to community living and employment include (1) access to full spectrum of general education offerings and learning experiences; (2) education placement, curricular decisions, and diploma options that are based on meaningful indicators of learning and skills; (3) options for postsecondary education, community living, and employment; (4) participation of the student and family; and (5) interagency communication and collaboration.[71]

Young adults with disabilities desire options for community living other than the family home. These options may range in descending order of support from residential group homes (agency owned or operated), residential supported living (private housing with flexible supports such as attendant care), and independent living. Howe, Horner, and Newton evaluated supported community living versus residential group homes among 40 adults with cognitive impairments.[66] Howe et al. define supported living as developing supports needed to best match the individual's preferences and needs over time. The number of housemates for adults in supported independent living varied from 0 to 2, whereas the number of housemates for adults in residential living varied from 1 to 19. Housing provision costs were similar for both living arrangements. Young adults in supported living were either the owner of the residence or listed on the rental agreement, and housemates were identified as the preferred choice of each young adult with developmental disabilities. Young adults in supported living experienced significantly more variety in community activities and did preferred activities more frequently compared with young adults living in group homes.

The National Center for the Study of Postsecondary Educational Supports (NCSPES) has identified competencies for successful transition from secondary education.[102] Competencies include knowledge of self, including one's health condition, and the ability to access services and supports for community living. Life skill curricular content in secondary education such as identifying specific supports needed for living, postsecondary education, or work is recommended for students with special health care needs, regardless of cognitive ability. Curricular content could include accessibility, transportation, and skills for community living and work. Community living skills may include meal preparation, acquisition of food staples, paying bills, laundry, and/or the hiring, managing, or firing personal attendants. Skill sets for work might include the ability to interact with people providing attendant care and to describe and request necessary job accommodations including augmentative communication when needed. Physical therapists working in educational settings are encouraged to anticipate opportunities to be included in life skill programs for students with physical disabilities. Likewise, physical therapists in clinic and hospital practice settings are encouraged to communicate and coordinate with educators and professionals providing related services (transition coordinator, school-based therapists) and to interact with community organizations and agencies to address transition needs.

Postsecondary Education

Today more than ever students with disabilities are participating in postsecondary education. Postsecondary options include vocational/technical schools, community colleges, liberal arts colleges, and state or private universities. The number of students with disabilities applying and being admitted to institutions of higher education is increasing. The June 1999 National Center for Education Statistics: Statistical Analysis Report by Horn, Berktold, and Bobbitt concluded that students with disabilities, overall, fell behind their peers without disabilities in their high school academic preparation. This finding leads to these youth being less qualified for 4-year college admissions and less prepared for college-level courses.

Planning for postsecondary education begins early in high school with selection of coursework and academic requirements.[45] Hitchings, Retisch, and Horvath reported that students with disabilities are often not prepared for postsecondary education.[64] Transition plans of 110 students in grades 10 through 12 who attended two Illinois high schools were reviewed. Student interest in postsecondary education declined over a 3-year period from 77% to 47%. Only four students had 4-year transition plans preparing them for postsecondary education. Based on their findings, the authors stated the following recommendations for successful transition to postsecondary education: (1) students must be successful in general education classes to determine if they can learn academic content and meet teacher and workload requirements with or without accommodations, (2) transition planning should begin in the late elementary years and be sustained throughout high school, (3) students must be their own advocates, (4) students must actively engage in the career development process, and (5) educators and professionals providing related services must have knowledge of current policy for transition planning.

Getzel[51] and Madaus[93] both articulated that students with disabilities experience a significant shift of responsibility according to the legal rights afforded in secondary education under the IDEA as compared to legal rights in postsecondary education mandated by the Americans with Disabilities Act. Darrah et al.[36] examined community services for young adults with motor disabilities and described their thematic findings as a "paradox of services." These authors interviewed 76 individuals (mean age of 25 years, representative of all levels of gross motor function) for the purpose of determining their perceptions of programs and services in the spheres of education, employment, transportation, and assured income. Postsecondary education opportunities were limited in part due to "the fact that the educational programs designed to enrich their social experiences often restricted their future educational choices."

Two significant pieces of legislation support students with disabilities admitted to colleges or universities. Section 504 of the Rehabilitation Act of 1973 and the Americans with Disabilities Act (ADA, P.L. 101-336) ensure nondiscriminatory protection for students with disabilities on campuses of higher education. Section 504 stipulates that any institution that receives federal funding must ensure access for all persons with disabilities and specifically stipulates equal opportunity for "otherwise qualified handicapped individuals." The law also requires an "affirmative action obligation" on the part of institutions of higher education. Two purposes of the ADA are to provide "a national mandate for the elimination of discrimination against individuals with disabilities" and to provide strong "enforceable standards addressing discrimination against this population" (p 201).

The ADA mandates that all public and private businesses and institutions provide reasonable accommodations for persons with disabilities.[61] Federal legislation pertaining to youth with disabilities including the Individuals with Disabilities Education Improvement Act and the Americans with Disabilities Act is presented in Chapter 31.

College Admissions and Enrollment

Whereas education is a given opportunity for all children in the United States through high school, college is a self-chosen endeavor. The guarantees of a free and appropriate public education (FAPE), established under the auspices of IDEA for students with disabilities, do not extend to postsecondary institutions of learning. Instead, colleges and universities use the definition of disability in the ADA. The ADA defines a person with a disability as anyone who has a physical or mental impairment that substantially limits one or more major life activities, has a record of such impairment, or is regarded as having such impairment. Therefore a qualified student with a disability applying to postsecondary education is one who is able to meet a program's admission, academic, and technical standards either with or without accommodation.[136] Section 504 utilizes the term "otherwise qualified" in extending the same recognition to potential students. Rothstein raised the issues of what can be asked at preadmission and when students should disclose a disability.[116] For example, a student may not want to disclose a physical disability before a campus visit; however, by not disclosing this information, the campus personnel may be put at a disadvantage by not having lead time to make adjustments that could facilitate the visit.

Reasonable accommodations in higher education can include barrier-free design, academic modifications (waiver of certain courses, lighter course loads, and alternative methods of testing), and specific disability services such as translators, tutors, and readers. Important considerations are whether accommodations can be provided without altering the nature of the academic program, without jeopardizing the safety of the student of record or others, and without creating an undue burden of a financial or administrative nature.[116]

The ADA underscores the importance of preparing students with disabilities to articulate their specific needs. For high school students with disabilities, an annual goal could be to plan their individualized education plan (IEP) meeting, which would generalize to skills in articulating requests once enrolled in college. More specifically, students with disabilities could be encouraged to generate the accommodations needed to complete the IEP document as well as list the criteria that would indicate goal attainment. An IEP goal in a high school speech and communication class may be that a student develop a plan of action for requesting accommodations and participate in a mock student service meeting to articulate requests. Zadra suggested preregistration interviews between students with disabilities and college counselors as an excellent strategy for students to communicate their needs and counselors to gather accurate and meaningful information.

Campus Accessibility

Misquez, McCarthy, Powell, and Chu reported that the greatest impetus for making accessibility changes was having students with disabilities on college campuses.[101] Encouraging and supporting high school students with physical disabilities to take advantage of college campus visits serves a dual purpose. First, upon requesting to sit in on a college class, students can tour the campus grounds and visit university resource centers, libraries, and dormitories. Such visits provide perspective students with a better understanding of the spatial and temporal perimeters of college campus navigation as compared to a typically enclosed high school campus. Second, as more students with physical disabilities visit and attend institutions of higher education, college/university staff, faculty, and administrators will become more cognizant of accessibility barriers to their respective campus.

A specific IEP goal for the high school junior or senior may be to evaluate the accessibility of two college campuses using multiple resources (web page searches, telephone interviews, and onsite visitations). A student activity accessibility checklist developed by Roger Smith, Jill Warnke, and Dave Edyburn of the University of Wisconsin, Milwaukee, and Daryl Mellard, Noelle Kurth, and Gwen Berry of the University of Kansas is on the Expert Consult. The form provides a comprehensive list of questions for students with disabilities visiting, applying to, and attending a college or university.

Attending college means living away from home for many students. Typically, freshman and sophomore students experience their first extended period away from home living arrangements in college dormitories. Beds, desks, and dressers are standard features, with students bringing the various amenities such as computers, mini-refrigerators, and stereo systems. Students often share living quarters with another student or a group depending on the configurations of the dorm rooms. For the student with a physical disability, room accessibility can be a major challenge.

Physical therapists need to think long term when making recommendations about interventions with students in primary and secondary education that could generalize to college dormitory room independence. The terms *anticipatory guidance* and *future planning* refer to this process. Physical therapists should consider evaluation of dorm room and bathroom accessibility and the accompanying transfer skills to access beds, shower/tub, and toilets. If physical independence is not a feasible goal, the student's ability to direct an attendant in physical management would be a more appropriate goal. In a high school health or physical education class, a student's IEP goals may include competency in directing others for identified tasks where or when physical assistance is needed. Skills for advertising, interviewing, and hiring and firing of attendants are desirable. These skills could be practiced through role-play scenarios in a sociology or communication class.

Issues of Confidentiality

Unlike students with "hidden" disabilities such as a learning disability, students with physical disabilities are readily visible. Despite this, issues of confidentiality need to be respected and adhered to. High school students with disabilities need to know that institutions of higher education have policies regarding confidentiality. These policies should include (1) who can be informed, (2) who should be informed, (3) who must be informed, (4) who should not be informed, and (5) when and how any related waivers should be obtained.[116] High school educators and related services staff can assist students to be proactive in determining how they will disclose information. By being proactive, students with disabilities are demonstrating confidence, maturity, and self-esteem to college personnel.

Interaction With Instructors

Instructors in postsecondary education programs, with different expectations than high school teachers, understandably may exceed a student's comfort zone and create anxiety on the part of both the student and faculty. Amsel and Fichten compared interactions between college students with and without disabilities and their professors.[4] Students with disabilities were less likely to request or accept assistance. Paradoxically, students without disabilities and professors believed it is quite appropriate for students with disabilities to ask for accommodations. The authors concluded that it is imperative that students with disabilities not misperceive the appropriateness of requests for assistance.

Patrick and Wessel,[108] by means of a small qualitative study, concluded that first-year college students with disabilities experienced transitional issues and procured support through faculty mentorship. Postsecondary transitions included both academic and social transitions. The transition of physical separation from the students' families created a demand on becoming independent and making one's own decisions. Additionally, students interviewed shared experiencing inadequacies in taking on the responsibility for the accommodation process. Accommodations in the arenas of campus navigation, informing faculty and requesting academic accommodations, as well as utilizing attendants were new, given that many were accustomed to family members providing bathing, toileting, and dressing assistance. Positives of having established faculty mentorship included (1) advice, (2) awareness of campus resources, (3) getting to know faculty, and (4) individual support. Interviewed students reported faculty mentorship as being positive and that mentorship weaning over the course of their college experience was appropriate.

Employment

One of the major life roles of youth transitioning to adulthood is gaining economic independence.[57] Ninety percent of youth with special health care needs reach their 21st birthday, an age when most young adults are either employed are seeking employment.[20] In the National Longitudinal Transition study, 40% of individuals with childhood onset health conditions were employed 2 years after high school as compared to a 63% employment rate for same-age peers at large.[144] Nationally, 23,000 individuals with severe disabilities participated in supported employment in 1988; by 2002, 118,000 individuals participated.[70] Baker et al.[9] reported that according to the US Census Bureau's population employment survey, 22% of working-age Americans with disability were employed compared to 76% of same age Americans without a disability. It is unknown as to how inclusive the "disability" descriptor was. Though progress is slow, many youths with special health care needs continue wanting to work.

Darrah et al.[36] described an employment paradox for transitioning youth with disabilities. The paradox, as reported by participants in their study, was between solid employment preparation (skill development, job application, interview preparation) and minimal assistance in actual job finding and support once "training preparation" is completed. Employment opportunities, especially if linked to governmental programs, were time limited. Less attention to job accommodation was reported by several interview participants. Michelson et al.,[100] in a Danish study, reported that only 29% of 819 participants diagnosed with CP were competitively employed compared to 82% of controls. Rutkowski and Riehie[118] identified three functional areas vital to job identification and job performance: self-care, physical functioning/mobility, and communication. They also encouraged a paradigm shift of thinking of each individual as a "worker" rather than as a "patient" to emphasize employment potential.

Employment options for people with disabilities can be viewed on a continuum from least restrictive without supports (community based) to most restrictive (segregated programs with supports) (Fig. 32.1). In the 1960s through the 1980s, the primary employment options for people with severe disabilities were adult day programs and sheltered work programs. Supported employment is competitive work in integrated settings for individuals with disabilities for whom competitive employment has not traditionally occurred or for whom employment has been interrupted or intermittent because of a severe disability. These employees need ongoing support services to perform such work.[75] Supported employment includes the following: (1) provision of personalized job development, (2) on-the-job training, (3) ongoing support services, (4) individualized assessment (which is the opposite of norm-referenced assessment and placement), (5) person-centered job selection, which relies on the person's personal network, and (6) use assessment and activities that are meaningful and relevant.

Supported employment uses the services of job coaches and on-the-job training and long-term follow-along by an employment specialist following along if needed. Informal supports provided by friends, family, and coworkers are encouraged. Rusch and Braddock reported a stalled pattern of supported employment since 2000, with work settings limited to people with disabilities outnumbering work settings in the community at large.[117] Competitive employment with supports is a form of customized employment, although not a traditional category of employment. This type of service assists the students who have the ability to work independently but lack the job-seeking skills, interview skills, and organizational skills to obtain employment. With this type of career guidance, students can move on to more challenging careers and postsecondary training.[45]

Recommendations to improve employment of youth with disabilities include development of a national web-based system to coordinate entry into competitive employment, financial support availability through interagency partnerships, expanded guidance counseling services, and access to long-term support services.[117] Commentaries by Johnson[70] and Test[134] concur with Rusch and Braddock. Johnson concluded that improving

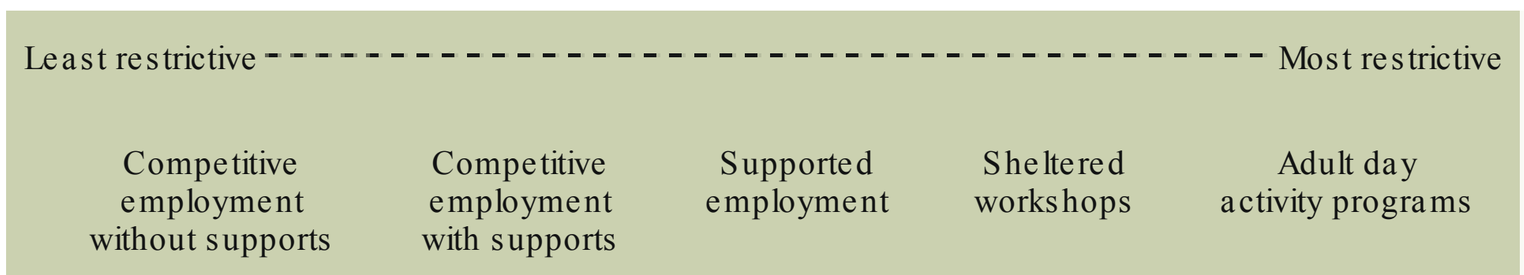

FIG. 32.1 Continuum of employment settings for people with disabilities.

graduation from postsecondary education or employment for students with disabilities outside sheltered workshops will depend on collaborative commitment from a wide base of constituents. Test suggested five strategies for achieving successful and meaningful economic independence: "(a) teach all students self-determination skills, (b) expand the mission of programs for 18- to 21-year-olds, (c) focus on interagency collaboration, (d) improve preparation of personnel, and (e) focus on the positive outcomes of supported employment" (p 248).[134]

Successful work transition is dependent on competencies in essential job functions and provision of appropriate supports or job modifications. Transition services that enable youth to learn essential job functions that are compatible with their abilities should advance individuals toward successful employment. Opportunities for development of work life skills should be incorporated in activities and routines. Examples of work life skills include getting ready for work, accessing transportation, keeping a schedule, learning appropriate work behavior and dress, developing communication with supervisors and work mates, eating and toileting, and directing attendants if and when necessary (Fig. 32.2).

Physical therapists can incorporate learning skills for work transition into therapeutic interventions. For example, a young person receiving physical therapy at an outpatient clinic could be encouraged to schedule or cancel his or her own therapy appointments. Learning how to direct others in physical management is fostered through having youth role play with the therapist in activities such as transfers in and out of a wheelchair, dressing, and donning and doffing orthotics. Youth can be supported to initiate communication with local employment agencies such as Vocational Rehabilitation. Consultation to employers is an unfamiliar area for pediatric physical therapists; however, many colleagues in adult practice have been involved with workplace reentry. Pediatric physical therapists are encouraged to expand their scope of practice to include consultation with community organizations and agencies, such as a job site where specific job-related activities can be observed, analyzed, and solutions with or without accommodations developed. Pediatric therapists may also consider initiating transition to adult practitioner colleagues who are more versed in employment consultation. Darrah et al.[36] suggest that therapists encourage children with disabilities to actively participate in educational and employment opportunities. Additionally, these authors note that "coaching roles" go beyond health care concerns and thus demand therapists adopt the wider participation perspective of the ICF model.

FIG. 32.2 Using a Dynavox communication device, Andy enters books into inventory and prices them for sale at Powell's Books. He hits his right head switch, sending a book onto the conveyor belt to be scanned. His right head switch controls the Dynavox, which acts as a keyboard, sending infrared signals to the store's computer, which causes a price label to be printed.

One of the biggest employment challenges is the potential loss of an individual's Supplemental Security Income (SSI) and Social Security Disability Income (SSDI) if "too much" income is made. Requirements of limited income will keep individuals at or below the poverty line as well as sustaining a dependency rather than building on self-determination, which has been emphasized throughout the chapter as an important element of transition to adulthood. Transition to work must include a review of potential income sources to include supplemental security and work-related income. Youth must understand the delicate balance between benefits such as Medicaid or Medicare and work and optimize the benefits of both at appropriate times during the transition process. For some youth and families, exploring trusts for long-term security and support is a component of future planning. Therapists could consider developing their role and skills in advocacy for local, state, and federal policy development that facilitates continued SSI benefits for physical management support regardless of income earnings.

Transportation

Transportation is critical for all adult roles: education, work, adult living, and community participation. Youth with disabilities often lack reliable, cost-effective transportation options, which can limit social participation, friendships, and opportunities for work.[145] Gaining mobility transportation skills should be addressed as part of a student's IEP and transition plan or a patient's participation goal when therapy services are provided in a clinical setting. Skills such as using mobility devices independently and safely, accessing public transportation, identifying landmarks, and asking for directions can be developed as part of a community-based training program with assistance from the physical therapist, program staff, and family.[45] Lindsey[89] identified transportation as a significant predictor of employment for youth with disabilities transitioning to adulthood. Transportation barriers were identified by Schmidt and Smith[121] and Magill-Evans et al.[94] as well, which should direct therapists to pay greater attention to goals regarding independent mobility and community and workplace transportation negotiations.

Although the Americans with Disabilities Act mandates include public transportation accessibility, barriers still exist because of limited routes and may necessitate relocation to urban areas to increase transportation options. Students who use assistive walking devices or wheeled mobility may not be able to drive; therefore, they need to access alternative modes of transportation such as rides from coworkers or relatives, accessible public transportation, taxis, or program vans.[124] In 2004, President Bush released an executive order on Human Service Transportation Coordination to improve services for individuals with disabilities, older adults, and people with lower incomes. This was an effort to coordinate the 62 programs funding transportation, thereby reducing service duplication, consumer confusion, and service gaps. Partnership between the Coordinating

Council on Access and Mobility (CCAM) and United We Ride was established to provide coordination and common-sense solutions for everyone who needs transportation.[60] In some areas, transportation funding may be offered as part of state Medicaid waiver programs and as part of Impairment Related Work Expenses under the Social Security Administration.

TRANSITION MODELS AND APPROACHES

Transition planning involves communication and coordination among several systems and service providers. Within the health care system, the focus is on transition from the pediatric to the adult health care system. Within the education system, the focus is on preparing graduates for community living, postsecondary education, employment, and social and community participation. Children's rehabilitation services in a small number of communities have programs that address both aspects of transition. Cooperative collaboration amongst multiple systems and service providers is therefore imperative for successful transitions.

Contemporary approaches to preparing youth for life as an adult have an ecologic orientation that emphasizes the importance of real-world experiences, supports, and community accommodations.[76,80] King and colleagues appraised the literature to determine the main types of transition approaches and strategies for youth with disabilities, including those with chronic health conditions, and identified four approaches: skills training, prevocational and vocational guidance, youth- and family-centered approaches, and ecologic and experiential options. Transition programs were often guided by more than one approach and utilized multiple strategies.

The focus of s*kills training* is to prepare youth for independence and success in chosen adult roles. Kingsnorth, Healy, and Macarthur performed a systematic review and identified six studies that included a comparison group.[82] Five reported short-term improvements in targeted skills such as social skills, assertiveness, and self-efficacy. The programs used a variety of strategies including goal setting, coaching, and experiential learning.

Prevocational and vocational guidance aim to enhance self-awareness strategies including planning and goal setting.[50] Emphasis is on support and guidance, job-seeking skills, and on-the-job skills training.[119] Research findings support the importance of involving youth in decisions about their transition-related goals[120] and teaching skills in real-world contexts.[28,29]

The focus of a *youth- and family-centered* approach is empowerment of youth and families through emotional support and knowledge of community resources and supports. There is evidence of the effectiveness of social support in facilitating positive outcomes and increasing self-esteem.[58] Research is needed on the effectiveness of youth- and family-centered transition approaches.

An *ecologic and experiential* approach is based on the principle that real-world opportunities and experiences optimize skill development.[10,23] The focus is on development of life skills, interpersonal relationships, environmental modifications, and task accommodations. Strategies include linking youth and family to community supports, enhancing knowledge of community opportunities, coaching and mentoring, creating individualized opportunities and experiences, and community education and advocacy. The results of the National Longitudinal Transition study indicate that community-based work experience is more useful than school-based programs.[142] Students with and without disabilities who participated in work experiences in high school were twice as likely to have competitive employment 1 year after graduation compared with students without work experience.[13]

Service coordination and interagency collaboration are keys to all transition approaches. Within the education system, the interagency transition team should consist of the student, parents, educators, adult service professionals, employers, and community service agencies. Sharing information, expertise, and problem solving are encouraged among team members in order to meet a student's postsecondary goals. Collaborative practices are facilitated through interagency agreements that clearly define roles, responsibilities, and strategies of each community member. Potential barriers to collaboration include ineffective transition planning meetings, intimidating language, and the complexity of agency procedures.[84,85]

Access and accommodation technologies also referred to as assistive technology and assistive technology services are integral to transition services for youth with severe disabilities.[88,112] Assistive technology is defined as technology applied to people with disabilities to enable productivity, communication, self-care, and mobility; to reduce the need for personal assistance; and to promote self-advocacy.[83] The application of assistive technology requires a team approach that begins with a thorough examination that includes assessment of the individual's needs, abilities, preferences, and features of the environment.[26,65]

TRANSITION PLANNING IN THE EDUCATION SYSTEM

In 1983, Madeline Will, assistant secretary of the US Office of Special Education and Rehabilitation Services, proposed a *bridges model* for transition of youth from school to work that emphasizes linkages between school and post-school environments.[148] Three possible bridges were identified: (1) transition without special services, (2) transition with time-limited services, and (3) transition with ongoing services.[46] Subsequently, Halpern proposed *community adjustment* and *work preparation* models.[46] The *community adjustment* model is based on three pillars of community inclusion: employment, residential environments, and social networks. The *work preparation model* includes the four elements of transition services described in the Individuals with Disabilities Education Improvement Act (IDEA): (1) based on student needs, preferences, and interests, (2) a coordinated set of activities, (3) an outcome-oriented process, and (4) a progression from school to post-school activities.[46,72] Several promising practices for successful transition have been proposed by advocates, researchers, and policy makers.[83,110] These practices include (1) development of student self-efficacy and social skills, (2) community and paid work experiences, (3) technology to improve accessibility and accommodation, (4) secondary curricular reform, (5) vocational career education, (6) supports for postsecondary education, (7) service coordination and interagency collaboration, and (8) individualized backward planning in which the outcome is first identified and then a transition plan is developed.

The Individuals with Disability Act (IDA) of 1990 mandated an outcome-oriented process that included transition services, beginning at age 16. The statement of transition services, also

known as the individualized transition plan (ITP), ensures that IEP activities help prepare the student for roles following secondary education. In most states the ITP is included as a page or section of a student's IEP. The plan is reviewed annually and includes coordinated activities that are based on a student's needs and preferences.[46] Activities might include instruction, community experiences, career development, daily living skills training, functional vocational evaluation, and linkages with adult services.[46] Reauthorization of IDA in 1997 lowered the age to begin transition services to 14 years. District and state testing were mandated in order to hold schools accountable for the student's progress in the general curriculum. Related services, including physical therapy, were added in the definition of transition services. The Perkins Technical and Vocational Act of 1998 (Public Law 105-332) emphasized the quality of vocational education and the need for supplemental services for individuals with special needs.

The Individuals with Disabilities Education Improvement Act of 2004 redefined the age of transition to 16 years and moved to a "results-oriented" process focusing on improving students' academic and functional achievement to promote post-school outcomes. Accountability was emphasized by requiring the transition plan to include appropriate measurable postsecondary goals. Transition services are defined as follows:

> *A coordinated set of activities for a student, with a disability, that: (A) is designed within a results oriented process, that is focused on improving the academic and functional achievement of the child with a disability to facilitate the child's movement from school to post-school activities, including postsecondary education, vocational education, integrated employment (including supported employment), continuing and adult education, adult services, independent living, or community participation; (B) is based on the student's needs, taking into account the student's strengths, preferences and interests; (C) includes instruction, related services, community experiences, the development of employment and other post-school objectives, and, when appropriate, acquisition of daily living skills and functional vocational evaluation. (Section 602, IDEA, 2004)*

Preparation of students with disabilities for postsecondary education, employment (including supported employment), independent living, and community participation must begin no later than 16 years of age under IDEA but can begin earlier. Goals must be measurable and progress tracked and reported. Local education agencies are required to provide students with a summary of their academic and functional performance along with recommendations for postsecondary environments upon exiting from school. Mandates for databased, coordinated transition planning and reporting of outcomes are ambitious and require considerable personnel development for implementation.[111]

Transition planning begins with determining the student's interests, abilities, strengths, and needs. The family and professionals should discuss future options with the student. The transition plan is completed at the IEP/ITP meeting. Post-school outcomes are identified and activities are coordinated within the school team and with external agencies and organizations. Students should be invited to the IEP/ITP meeting, actively participate, and lead the meeting when able. Representatives from adult service agencies often are present to assist the school team in planning services for students who are eligible for their services. The team, which includes the student, determines the types of transition services (instruction, related services, community experiences, daily living skills, and functional vocational evaluation) necessary to promote movement to post-school environments. Finally, the transition plan includes measurable goals developed by the team. A transition plan for a student with severe disabilities who uses powered mobility and a communication device in vocational environments is included on Expert Consult.

Although in the past physical therapists have not always fully participated in the transition process, they have important roles. Physical therapists are encouraged to (1) prepare youth to be active participants and ideally leaders in developing their IEP; (2) participate in the transition planning process when invited by the student; (3) provide consultation and direct services, as needed, for seating, transfers, mobility, self-care, wellness and fitness, instruction for personal care attendants, assistive technology, and environmental modifications; and (4) work collaboratively with school personnel to ensure that health and physical function are adequately addressed in the school-based ITP. The transition plan on the Expert Consult illustrates services and activities that may be supported by a physical therapist.

Transition Outcomes in the Education System

Data from two National Longitudinal Transition Studies authorized by the US Congress identified areas for improvement of transition outcomes. Although the findings may not generalize to current transition outcomes due to the time frame of data collection, the issues identified are pertinent.

In 1983, Congress mandated and funded the first National Longitudinal Transition Study (NLTS). The NLTS was designed to gather data on experiences of students with disabilities during the first 3 to 5 years after high school. Interviews encompassing many facets of transition were completed with 1990 students and families. Although youth with disabilities made substantial progress, their employment rates, wages, postsecondary education, and residential independence were lower than peers without disabilities. Based on the findings, individualized transition planning that reflects the student's goals, strengths, needs, characteristics, and disability was recommended.[17]

Congress authorized a second National Longitudinal Transition Study (NLTS2) conducted from 2000 to 2005. The sample included 11,272 students from 501 local education agencies (LEA). Students 13 to 16 years old when the study began were receiving special education across 12 special education categories. Methods were similar to those of the NLTS. In the NLTS2, fewer students were classified with mental retardation (the current term is *intellectual disability*), whereas the number of students categorized as having other health impairments increased.[143] More youth with disabilities were living with at least one biologic parent, and the heads of households were less likely to be unemployed or high school dropouts. The number of students with intellectual disability or emotional disturbances living in poverty with an unemployed head of household increased between 1987 and 2001.

Parents in both National Longitudinal Transition Studies expected their children with disabilities to graduate from high school with a regular diploma. In the NLTS2, parents of youth with speech or hearing impairments had greater expectations for postsecondary education. Overall, 2-year colleges were considered more of an option in 2001 than in 1987, and

employment expectations were higher. Parental expectations for employment of youth with intellectual disability, hearing impairment, other health impairments, and multiple disabilities increased.[143]

In the NLTS2, participation of students with disabilities in extracurricular activity remained lower than it did for their peers without disability. In 2001, significantly more youth with disabilities had paid jobs 1 year after graduation. The 1-year employment rate was 60%, which is similar to youth in the general population (63%). Youth had an increase in work-study jobs and pay but a decline in the average number of hours worked per week. In social adjustment, more youth with disabilities were suspended or expelled, fired from a job, or arrested in 2001 than in 1987.[143]

The 2010 Harris Poll by the Kessler Foundation and National Organization on Disability revealed that discrepancies in employment still exist. Of all working people, those with disabilities have a 21% employment rate when compared to 59% for the general population. The majority of companies interviewed stated that they had hired someone with a disability in the past 3 years, and most of these employees were recruited through the referral of friends or word of mouth. Finally, people with disabilities made up only 2% of the workforce in these companies, again demonstrating an employment gap.

Using a sample of 1510 students with orthopedic impairments (including cerebral palsy and spina bifida) from the NLTS 2, Bjornson et al.[16] investigated the relationship between occupational therapy and physical therapy services and postsecondary education and employment. At post–high school follow-up, 48% of the sample participated in postsecondary education and 24% had paid employment. Receiving therapy services at ages 13–16 years was significantly associated with enrollment in postsecondary education at 19–21 years. Social interactions and expressive language skills were significantly associated with employment, but high school therapy services were not.[16]

Several factors have been identified as predictors of postsecondary education and employment among students who receive transition services. Vocational education, attending a rural school, work-study participation, and having a learning disability (versus another condition) were predictors of full-time employment after graduation in a random sample of 140 graduates from special education programs interviewed 1 and 3 years following graduation.[7] Attending a suburban school and participating in general education curriculum were predictors of postsecondary education. Benz, Lindstrom, and Yovanoff reported that career-related work experience and completion of student-identified transition goals were associated with improved graduation and employment outcomes.[12] Students valued individualization of services and personalized attention. Halpern et al. identified the following predictors of success in postsecondary education: (1) high scores on a functional achievement inventory, (2) completing instruction successfully in relevant curricular areas, (3) participating in transition planning, (4) parent satisfaction with secondary education, (5) student satisfaction with secondary education, and (6) parent perception that the student no longer needed help in certain critical skill areas.[54] Critical skills that might pertain to physical therapy include community mobility, use of public transportation, use of restroom, positioning and mobility instruction for personal care attendants, positioning for work or postsecondary education activities, and proficiency with assistive technology.

COMMUNITY- AND HOSPITAL-BASED TRANSITION PROGRAMS

Community- and hospital-based transition programs are emerging and vary considerably in focus and scope. Research has identified needs and processes for service delivery. Outcomes have been described, but research is needed to generalize findings. A formidable challenge for community- and hospital-based transition programs is coordination of services with the education system and community organizations and agencies. Skill development, environmental supports, and an individualized approach were identified as important components of transition services in a systematic review by Stewart et al.[130] Binks et al. performed a systematic review of outcomes specific to the transition from child-centered to adult-centered health care for youth with cerebral palsy or spina bifida.[15] Elements associated with successful transition to adult-centered health care were (1) preparation, (2) flexible timing of transition programs with a suggested age of 14 to 16 years, (3) care coordination that includes an up-to-date transition plan, (4) transition clinic visits including a consult with both the child and adult health care providers, and (5) interested adult-centered health care providers.

The Life Needs Model[79] (Fig. 32.3) is a collaborative approach to service delivery designed to meet the long-term goals of community participation and quality of life for children and youth with disabilities. The Life Needs Model incorporates processes supported by research. Core values of community- and hospital-based transition programs for youth with physical disabilities are listed in Box 32.1. The following paragraphs describe characteristics of four innovative transition programs; each illustrates the importance of interagency collaboration.

The Center of Innovation in Transition & Employment (CITE) at Kent State University in Ohio provides leadership in graduate education and transition practices for youth 18 to 21 years old with disabilities (http://www.kent.edu/ehhs/centers/cite). Local high school students with disabilities participate in a continuum of job training, career exploration, and college experiences on the Kent State campus. Graduate students from several disciplines obtain practical experience in providing transition services. The objective of the collaborative is to prepare students with disabilities for competitive employment and postsecondary education by providing them opportunities for future planning, skill development, and self-advocacy and to prepare transition coordinators of the future. Since 1985, 20 to 40 high school students with severe disabilities have been provided career exploration and job training each year. In most cases, these students transition to supported employment and community living. More than 100 graduates have become transition leaders throughout the state and country.

Gillette Children's Specialty Healthcare in Minnesota (http://www.gillettechildrens.org) has a long-standing reputation for comprehensive services for children with physical disabilities. In response to the lack of services available to adults with childhood-onset physical disabilities and young adults who received services from Gillette as children continuing to return for care, the Lifetime Specialty Healthcare for Older Teens and Adults was created.[90] Transition services are available to prepare youth ages 16 and older who are eligible for care through Gillette Lifetime. Transition services include preparing youth to move from pediatric to adult health care, teaching them to manage their medical conditions to the best

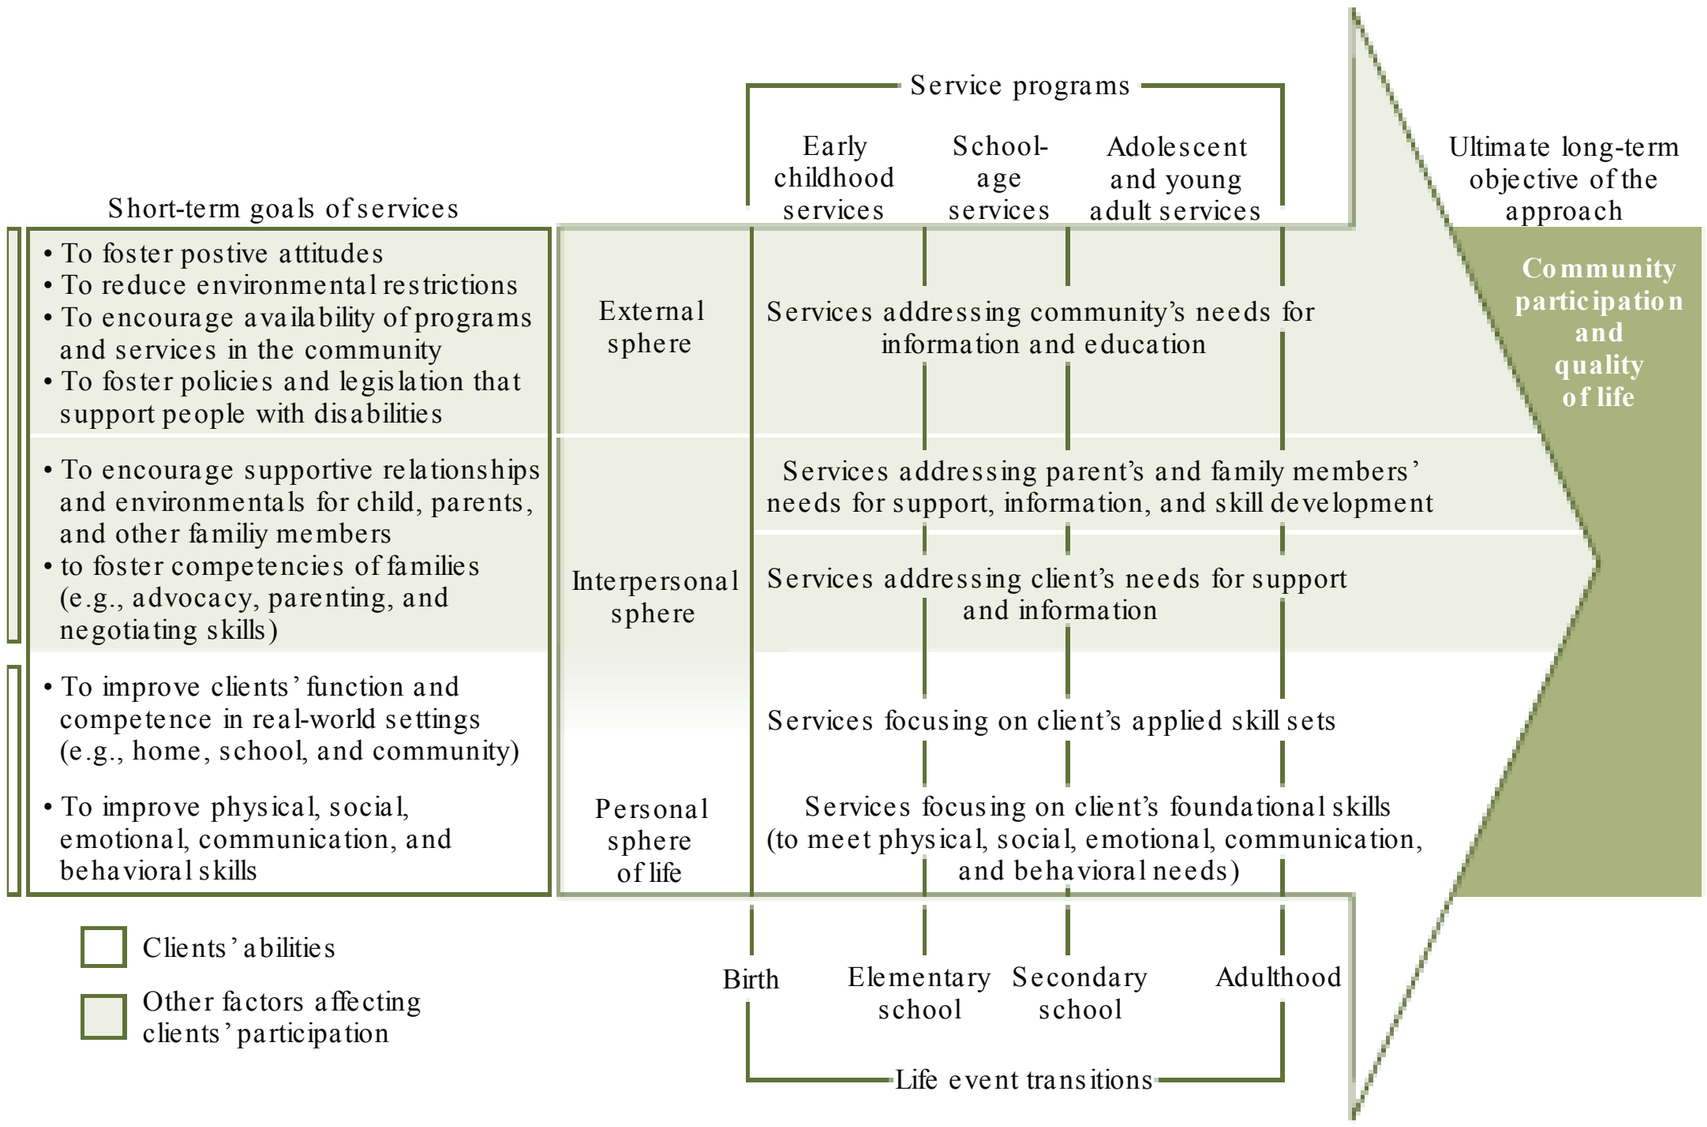

FIG. 32.3 Life needs model of service delivery.

BOX 32.1 Core Values of Community- and Hospital-Based Transition Programs for Youth With Physical Disabilities

Youth and family centered
Partnerships
Strengths based
Self-determination
Experiential learning

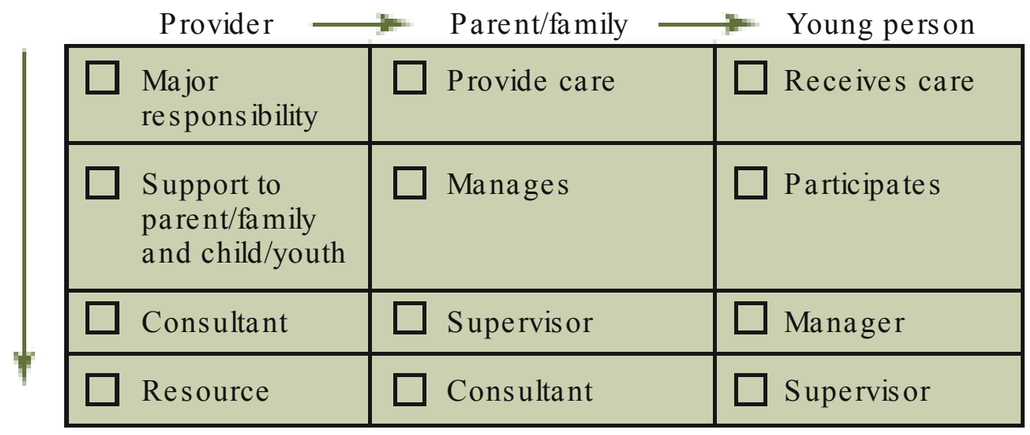

FIG. 32.4 Shared management model. (Data from Kieckhefer GM: Foundations for successful transitions: shared management as one critical component. Keynote presentation at the Hospital for Sick Children, Toronto, Canada, 2002.)

of their ability, and providing education and resources on legal, medical, and independent living. Gillette Lifetime extends services associated with the pediatric health care system to adults including specialty medical and surgical care, physical, occupational and speech therapy, orthotic and prosthetic services, and seating and adaptive equipment. Inpatient care and surgery are available until age 40. Linroth[90] describes the facilities and equipment for serving adults with childhood-onset disabilities and considerations for in-patient care.

Growing Up Ready is a multifaceted program at Holland Bloorview Kids Rehabilitation Hospital in Toronto, Ontario, Canada to help families understand the everyday experiences and skills their children need to become mature, confident adults and how to access them. The program is an outgrowth of a shared management approach to transition services for youth with disabilities by Gall, Kingsnorth, and Healy.[49] The shared management approach is based on the philosophy that development of a therapeutic alliance between youth, families, and health care providers is essential to allow young people with disabilities to develop into independent and healthy adults. As illustrated in Fig. 32.4, the therapeutic alliance is conceptualized as a dynamic relationship in which the roles change over time as the child grows and develops. A gradual shift in responsibilities occurs over time, and leadership is transitioned from the health care provider and parents to the young person to the maximum extent possible. Youth are encouraged to use experiential learning to gain exposure to opportunities and develop life skills. Timetables and checklists of activities to achieve competencies at different ages are available on the program website: http://hollandbloorview.ca/programsandservices/ProgramsServicesAZ/Growingupready.

Holland Bloorview Kids Rehabilitation Hospital and the University Health Network-Toronto Rehabilitation partnered in 2008 to implement the LIFEspan (Living Independently and Fully Engaged) service designed to coordinate transfer of health care between pediatric and adult rehabilitation services. The program serves youth with cerebral palsy and acquired brain injury. Topics of discussion include: health care providers, school, funding, and community participation and knowledge of health care. Eleven clinical and three managerial staff in the LIFEspan program were interviewed regarding their perspective on service delivery.[55] Five service delivery themes were identified: (1) transition readiness and capacity; (2) shifting responsibility for health care management from parents to youth;

(3) determining services based on organizational resources; (4) linking pediatric and adult rehabilitation services; and (5) linking with multisector services. Participants expressed that a challenge to providing coordinated care was service integration with primary care, education, social, and community services. Recommendations included early introduction of transition information and opportunities to practice skills and establishment of formal partnership between agencies and systems.

The Youth En Route Program in London, Ontario, Canada was one of the first transition programs for youth and young adults with multiple disabilities to systematically evaluate processes and outcomes.[43] Jan Evans, a physical therapist, and Patricia Baldwin, an occupational therapist, were instrumental in development of the program. Youth and young adults 16 to 29 years with multiple disabilities who had completed secondary education were eligible for the program. The program was originally implemented through a partnership between Thames Valley Children's Centre and Hutton House, a community agency for adults with disabilities. The service model is based on self-determination and community participation (Fig. 32.5). A multifaceted approach is utilized that includes (1) self-discovery, (2) skill development, and (3) community experience. Self-determination is promoted through coaching and supporting youth to define, lead, and guide the services and supports they want as they learn more about themselves and their communities. Efforts are made to support youth goals for employment, education, voluntarism, and leisure with experiential opportunities within the community. The program evaluation consisted of a 1-year pre/posttest of 34 participants in the program. Statistical and clinically significant improvements were found in self-determination and sense of personal control. At posttest, youth reported spending more time on volunteer/work and community leisure activities. The authors emphasize the importance of a flexible, client-centered approach that offers youth opportunities for self-discovery, skill development, and community experiences. Thames Valley Children's Centre (http://www.tvcc.on.ca/) is one of 21 public funded children's rehabilitation centres in Ontario. Current programs based on model for Youth En Route include Youth Discovery Services and Youth for Youth.

FOREGROUND INFORMATION

ROLE OF THE PHYSICAL THERAPIST IN THE TRANSITION PROCESS

Preparing youth with physical disabilities for transition to the adult care system and postsecondary education, work, and community living is an emerging role of the physical therapist. In 1997, Campbell proposed that preparing individuals with physical disabilities to take personal responsibility for their health and physical fitness should begin at a young age.[24] Although physical therapists have worked in public schools for more than 30 years, the IDEA of 1997 was the first educational law to include related services as mandated services in transition. Several authors have suggested roles for physical therapists in the transition process including the following[3,24,39,68,122,135]:

- Assessing present or future environments utilizing an ecologic approach
- Assessing assistive technology needs and instruction of others in use of assistive technology
- Intervening for positioning, seating, transfers, mobility, and transportation
- Assisting with job development, coaching, and placement options
- Anticipating student needs for community living and work
- Promoting community leisure and health-related fitness activities
- Facilitating transition to adult health care services
- Collaborating with other professionals, staff, and community-based agencies to coordinate services

Physical therapists working in educational settings may provide consultative services during individualized education program (IEP/ITP) meetings. Therapists may provide direct services during times of the day when the student is on the job, at a postsecondary school, or participating in community recreation. Therapists also provide information and instruction of others including care providers, educators, and family members.[3,122] Though likely more challenging because of the nature of third-party payer systems, therapists working in noneducational practice settings are encouraged to consider these universally shared roles to facilitate youth-to-adult transitions.

The *Guide to Physical Therapist Practice* states that physical therapists should provide interventions across the life span in the following areas: (1) environmental barriers, (2) self-care and home management (including activities of daily living), (3) work (job/school/play), (4) community and leisure integration, and (5) orthotic, protective, and supportive devices.

A perspective on the role of the physical therapist in the continuum of care for individuals with childhood-onset disabilities endorsed by the American Physical Therapy Association summarizes issues and provides suggestions for practitioners.[106] The authors emphasize the need to improve transitions from pediatric to adult-oriented health care and adult health care systems that enable healthy living. Challenges experienced in health care transition are summarized, and recommendations are provided for physical therapy practice. An important challenge/barrier is that many physical therapists who serve adults feel ill prepared to provide services to adults with childhood-onset conditions. A recommendation for physical therapy education programs is to embed case studies of adults with childhood-onset developmental disabilities across body systems and clinical courses other than pediatrics so that students embrace the reality that

children with developmental disabilities will be future adult clients who experience similar musculoskeletal and neuromuscular impairments as adults without developmental disabilities. Another recommendation is for physical therapists to consider providing consultation to fitness centers as a means to encourage participation of adults with childhood-onset disabilities at their neighborhood gyms. The authors highlight that adults with childhood-onset disabilities are not seeking services for their specific condition but rather to prevent or remediate secondary impairments that limit their ability to participate in meaningful community and life activities and to live a healthy lifestyle.

Physical therapist examination, evaluation, and intervention are driven by youth concerns, needs, and preferences and should occur in specific and relevant environments, present and future. Three environments that physical therapists are encouraged to consider during the transition years are (1) work or postsecondary education settings, (2) adult living environments, and (3) community settings for leisure or social participation. In addition, examination and intervention must be approached from a perspective of future inclusive community living and work rather than segregated living and work. Box 32.2 lists the types of interventions provided by physical therapists during the transition process. The phrase *student- or youth-related instruction* is preferred in the context of transition services.

Examination and Evaluation

The examination begins with identification of the youth's participation goals, reinforcing a person-centered approach. In the *Guide to Physical Therapist Practice,* this is part of the interview phase of the examination. We believe it is important for youth to express interest in self-discovery, experiential learning, and skill development and that families express a willingness to support and engage in activities to prepare their children for adult roles.

Next, task analysis is performed to identify what is necessary to accomplish the goals. The task analysis will guide the examination and evaluation of what the youth can do (strengths/capacity) and what problems, challenges, and barriers must be addressed for achievement of goals. The examination should be interactive with full participation of the youth and her or his family. Areas of examination by physical therapists are often directed toward optimization of health status, functional ability, and self-management. Evaluation involves interpretation of examination findings to identify participation restrictions, activity limitations, and contributing impairments in body functions and structures. The physical therapist's examination and evaluation contribute to the assessments performed by other members of the interprofessional team, including future planning, knowledge, skills, supports, and current participation in school and community activities related to transition to new environments. Box 32.3 includes considerations for examination and evaluation. Box 32.4 lists selected measures for transition planning focusing on student activity and participation roles. Some of these measures are team oriented and are best completed by the full educational team, including the physical therapist.

Goals and Plan of Care

The collaboration of youth, parent(s), and professionals leads to development of an ITP in the education environment in addition to the physical therapist's plan of care. This plan will include person-centered measurable long-term goals and short-term objectives. Therapists are encouraged to consider long-term, person-centered goals for activity and participation and short-term, person-centered objectives that address body functions and structures, personal, and environmental factors hypothesized to contribute to activity limitations and participation restrictions. The plan of care should include collaboration with community providers, organizations, and agencies. Combining the evaluations of all members of the transition team is essential for identifying youth-centered goals for activity and participation. It is unlikely that a participation goal would focus exclusively on a single domain (motor, cognitive, behavioral, self-help). Key activities, services, time frames, and individuals responsible for implementation should be documented. Therapists are encouraged to identify community collaborators who will provide the necessary support for transition plan goals. Whenever possible, therapists should involve the transitioning youth in this process to further support self-determination skills.

BOX 32.2 Considerations for Physical Therapist Interventions

Coordination, Communication, and Documentation

Participation in the IEP process
Collaboration with agencies: equipment suppliers, transportation agencies
Data collection to document change
Interdisciplinary teamwork (between schools, developmental disabilities agencies, vocational rehabilitation agencies)
Referrals to other professional sources (e.g., assistive technology vendors, orthotists)
Support youth to identify goals and engage in decision making

Student/Youth-Related Instruction

Instruction, education, and skill development of youth and caregiver regarding:
Knowledge of health condition
Enhancement of performance
Health wellness, fitness programs
Transitions across settings
Transitions to new roles (employment, adult living, community participation)
Opportunities for real-word experiences

Procedural Interventions

Positioning for prevention of secondary impairments in body functions and structures
Physical activity
Functional training in self-care, home management, and work (job/school)
Task adaptation for eating, dressing, grooming, toileting
Device use (such as power wheelchairs, communication devices, electronic calendars)
Travel training (public transportation and community mobility)
Shopping, meal preparation, scheduling activities and appointments
Job coaching
Safety across home, work, and postsecondary education environments
Leisure and recreational activities
Prescription, application, fabrication of devices and equipment
Environmental controls through use of assistive technology or rehabilitation engineering
Mobility devices, both ambulatory and powered mobility

BOX 32.3 Considerations for Physical Therapist Examination and Evaluation

What should physical therapists examine for transition planning?

Seating
Transfers
Mobility
Self-care
Leisure interests and activities
Device and equipment use

How should therapists examine students for transition planning?

Measures that describe and quantify
Checklists/scales
Logs, interviews (student interest/preferences survey)
Observations (ecologic assessment/task analysis)
Transportation assessments
Questionnaires
Video/pictures

Where should therapists evaluate students for transition planning?

Home
Community sites including recreation facilities
Postsecondary education environments including university and community
Job site

What data are generated from a physical therapy examination for transition planning?

Descriptions of environment and barriers
Student functioning in the environment
Ability to participate in environments
Need for equipment

BOX 32.4 Selected Measures for Transition Planning

Life Centered Career Education[22]
Canadian Occupational Performance Measure[86]
Children's Assessment of Participation and Enjoyment/Preferences for Activities of Children[81]
Enderle-Severson Transition Rating Scale[41]
Transition Planning Inventory[27]
Student Activity Accessibility Checklist[123]
Choose and Take Action[96]
Transition Assessment and Goal Generator (TAGG)[97]
Supports Intensity Scale (SIS) [137]
Keeping It Together for Youth[128]

Members of the educational interprofessional team will vary based on each youth's strengths, needs, program staff, and community resources. A transition coordinator ensures communication and coordination among team and external agencies and organizations. Although any team member may serve as the transition coordinator, knowledge of community resources and services is important. This knowledge enriches the services and support phase of the transition process. Youth and family learning styles and preferred methods of communication are important in determining formats for providing information, self-determination strategies, educational materials, and instruction. Therapists are encouraged to view their professional role as one that leads to greater independence of the youth with disability and/or his/her family. Guiding youth in this process, rather than becoming the "expert," should be fostered and thus become the emphasis of a therapist's role in transition.

Early communication with adult service providers such as vocational rehabilitation, developmental disability agencies, university disability services centers, and adult health care providers is a key to successful transition. Physical therapists can then direct and guide youth with disabilities and their families to each of these resources. Physical therapists can educate youth about maintaining optimal physical function by adopting a lifestyle that promotes health and wellness through activities and sports. Physical therapists in community and hospital settings can develop and utilize linkages with the school-based team and other local resources to ensure effective communication and coordination of services.

The physical therapist may consult and provide interventions for positioning, transfers, mobility, self-care, transportation, recreation, and leisure activities. Environmental modifications, assistive technology, and task accommodations are important for household management, postsecondary education, and vocational training. Services are designed to optimize safety, efficiency, and independence in performance of functional tasks in real-life settings. Before youth leave the pediatric health care system, physical therapists can help them to identify therapy needs and services and to communicate with the adult health care providers they chose. Box 32.2 is a summary list of intervention areas to be considered by the physical therapist.

Four studies and case reports with transition-age students with cerebral palsy provide examples of involving/supporting youth as active participants in their individualized interventions. Hedgecock, Rapport, and Sutphin[59] described the improvements across the ICF continuum in both strength and functional activity, leading to mastery of participation in personal goals at school and in the community. The examination, intervention, and outcomes of a 3-month episode of physical therapy using functional training and progressive resistive exercise with an 18-year-old with cerebral palsy (GMFCS II) were described. The results included clinically significant improvements in functional strength, agility, and anaerobic power generation. Patient-defined participation increased as he mastered personal goals related to mobility at school and in the community, thereby preparing him for community activities in the postsecondary environment.

Although not part of a transition plan, a case report by Kenyon et al.[74] illustrates the importance of self-exploration and skill acquisition for an 18-year-old female with spastic quadriplegic cerebral palsy (GMFCS level V) and cortical blindness. Intervention included a 12-week power mobility training in an engaging environment focusing on specific skills. The student, who was previously unsuccessful in a onetime powered mobility trial with a standard joystick, now used a head switch to activate the power wheelchair trainer. The student's scores on a standardized measure of power mobility and the health index of life with disabilities improved after training. Improvements with purposeful driving included stop/go and direction-specific

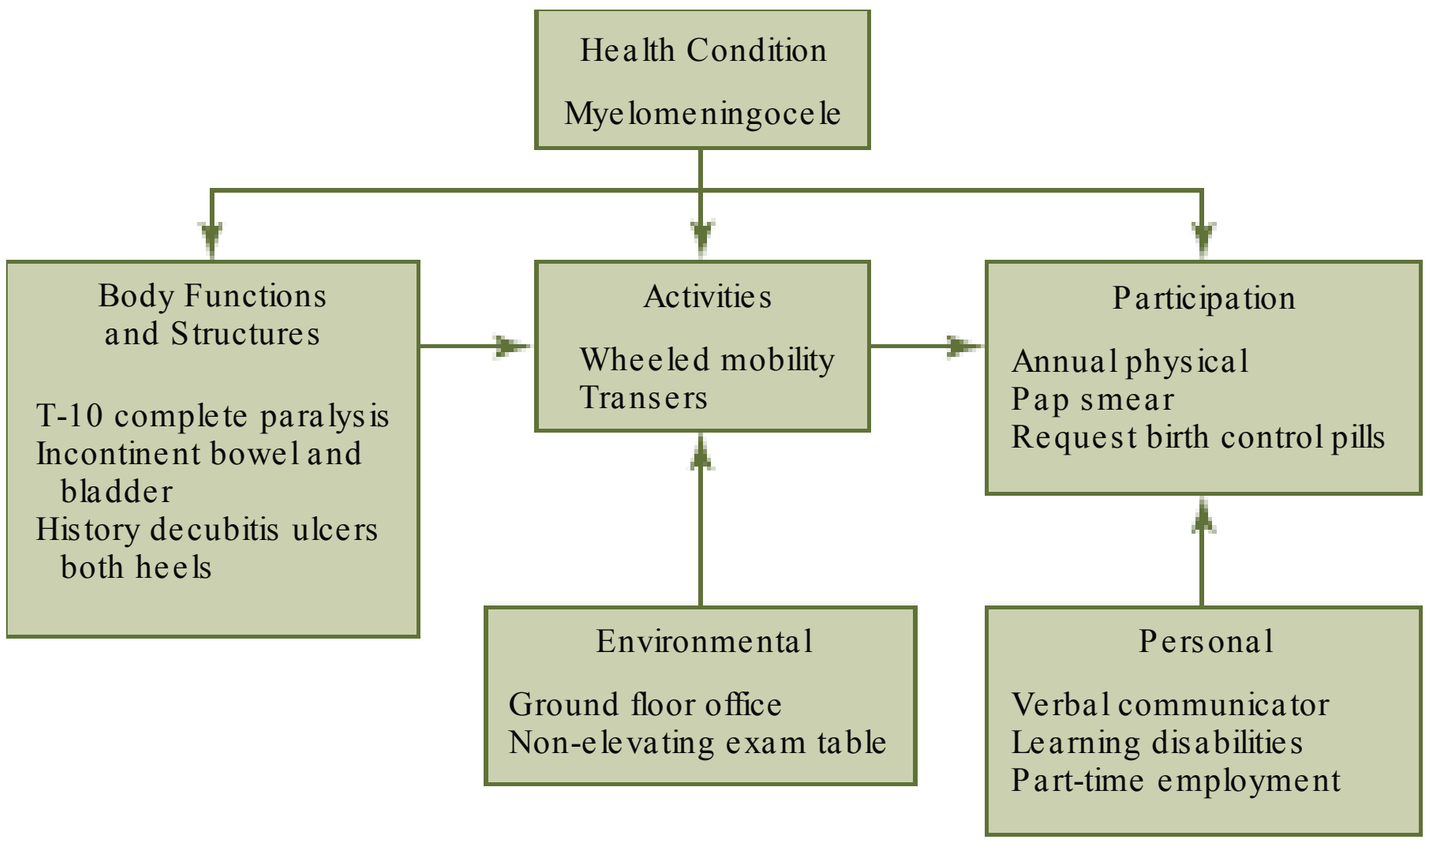

FIG. 32.6 ICF framework applied to an 18-year-old female accessing the adult health care system.

switch activations. Additionally, her mother noted that the participant was more aware of her surroundings. The participant did not achieve the level of driving ability to support funding for a power wheelchair, illustrating the importance of purposeful driving in real-world contexts as the desired long-term outcome.

Lephart and Kaplan[87] reported that that IEP goals for student-initiated communication and powered mobility were achieved through assistive technology for positioning and mobility in a 19-year-old with cerebral palsy (GMFCS level V) and scoliosis. A single-subject design was used to compare a standard planar wheelchair insert to a custom-molded back. The effects on oxygen saturation (SaO_2), heart rate (HR), respiratory rate (RR), body temperature, and processing time to activate switches, and response accuracy at school were assessed. When the student was positioned with the custom-molded back, SaO_2 changed from distressed to normal and fluctuations in HR, RR, and body temperature decreased. Processing time to activate switches decreased and accuracy increased. Student-initiated communication also increased because the student was more interactive when positioned in the custom-molded back. The finding that the custom-molded back not only improved activity and participation but also improved physiologic functions has important implications for seating comfort and endurance.

Sylvester et al.[133] investigated the effects of integrating self-determination strategies into physical therapy interventions and found this to benefit the mobility outcomes of young adults with intensive needs. Clinician-directed and client-directed approaches were compared when providing interventions for mobility skills. Although both interventions improved mobility skills, the client-centered approach using client-chosen goals proved more effective, especially during generalization and maintenance of skills. Findings indicated that clients preferred the self-determined sessions because they chose and were in control of intervention sessions.

The ICF framework is an additional lens from which physical therapists in collaboration with youth and their families can proceed through a transition planning meeting and goal setting. Using the ICF framework, three scenarios are presented for transition services in Figs. 32.6, 32.7, and 32.8. The first case involves a young woman accessing the adult health care system, the second involves a young man attending a university, and the third involves a young man who has applied for a job. As suggested in Chapter 1, the arrows between the three components of health and environmental and personal factors are specific to each case.

Consider the following suggested instructions to apply the ICF framework to your thought processes on the role of the physical therapist in transition planning. Cover up all but the components of activity and participation. What are the environmental contexts for each example? Are the activity and participation entities adult or youth transition oriented? How often have you been future oriented and considered such examples? Now think about and list all the steps (task analysis) necessary to fully accomplish each activity. To avoid preconceived notions, do not look at the health condition of each youth. What physical therapy decisions would you make for each case? What additional information is needed to formulate a plan of care? What tests and measures would you consider administering for each case? What information is specific to physical therapy and what can be acquired through interprofessional collaboration?

Write a long-term goal and short-term objective for each case. Is the goal person/patient/client centered? Is the person/patient/student's goal measurable? Is it an activity or participation goal? Are the objectives toward meeting the long-term goal measurable? Are the measurement criteria appropriate? Based on the goal and objective written for each example, what are indicators that outcomes have been achieved?

What are the current barriers to you embracing this process? Were you able to proceed through this process using the examples in Figs. 32.6, 32.7, and 32.8 without focused attention to the individual health conditions? As an exercise, interchange the health conditions for each example. How does the process change, if at all?

Role of the Physical Therapist in Transition Processes

The extent to which and how physical therapists employed in educational settings participate in the transition planning and services are not well understood and even less so in other practice settings. Findings of earlier studies indicated that occupational therapists and physical therapists did not participate fully in

the transition process for students with severe physical disabilities.[52,135] In reviewing the attendance at IEP meetings, Getzel and DeFur reported that occupational and physical therapists rarely participated in the meetings, although students received services such as material adaptations and assistive technology from these disciplines.[52] In related studies of occupational therapists' involvement in transition, Inge[67] and Anderson[5] found that therapists were minimally involved in transition planning and transition services.

Findings in a national survey investigating the scope of practice for physical therapists working with students in secondary education found more involvement than previously described.[38] More than 50% of the 1041 respondents had high school students on their caseload. Respondents reported more collaboration with school-related personnel in transition planning than adult service agencies or universities and that they *sometimes* attend transition planning meetings. Respondents indicated that *most of the time* they used observation/narrative summaries and considered a student's preferences and interests. They *infrequently or never* used ecologic task analysis, observed students in the community, or used published checklist/tools. The most common practices in IEP/ITP development were providing input for goals/objectives, making decisions as a member of the educational team, and collaborating with teams about intervention ideas. Physical therapists were less involved with attending IEP meetings and completing the summary of performance. The authors concluded that physical therapists working in secondary transition programs need to: (a) complete more comprehensive evaluations across a variety of future environments with students who have intensive support needs; and (b) expand collaborative service delivery to include a student's local community and provide interventions in the community to promote generalizability of skills. Administrative support and in-service education were the strongest predictors of therapist involvement with transition-age students. Education in physical therapy, years of experience in school-based practice, and school-based practice with secondary age students were weak predictors of therapist involvement with transition-age students.

Physical therapists are encouraged to increase their involvement in transition planning and services because they have the expertise to intervene in areas that are often barriers to employment, independent living, and recreation for young adults with disabilities.[24,122] In James' qualitative study of five students with multiple disabilities transitioning to adulthood, students, families, and teachers stated that needs for assistive technology, use of transportation, and difficulties with toileting were insurmountable obstacles.[69] In a survey of pediatric physical therapists and occupational therapists, therapists identified themselves as practicing below an optimal level in promoting community recreation and leisure for children and adolescents

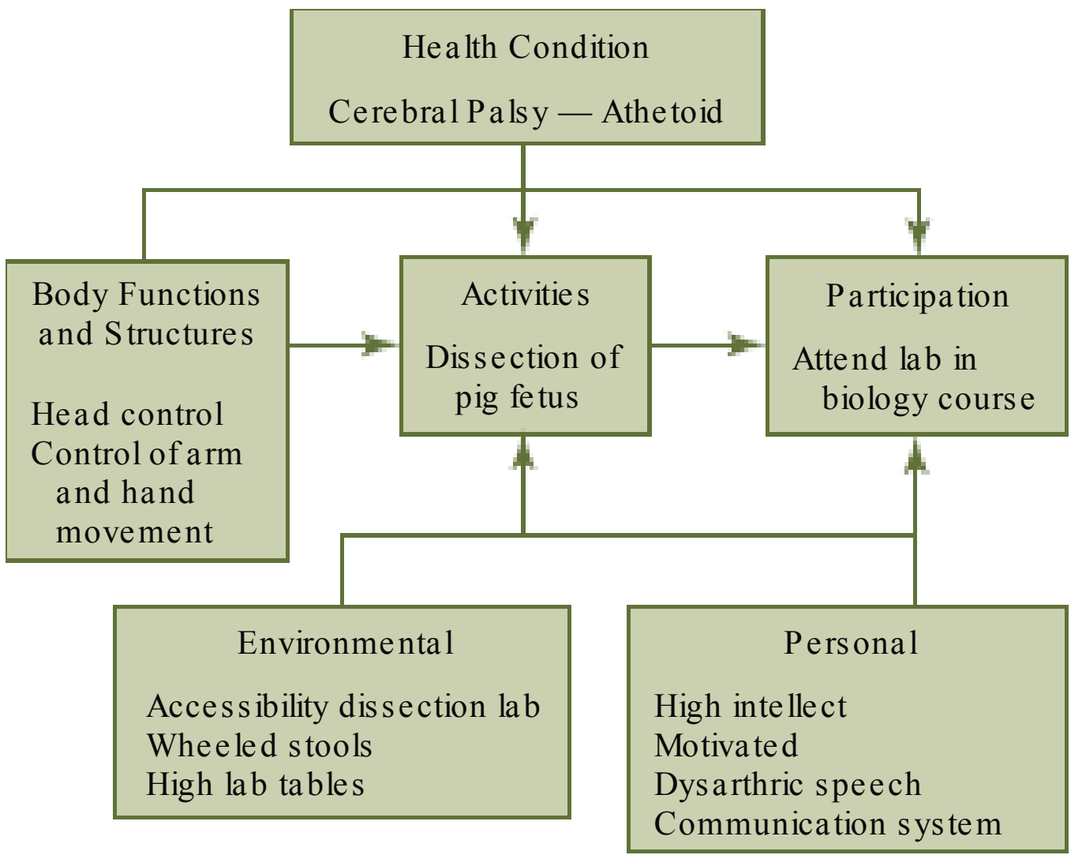

FIG. 32.7 ICF framework applied to a 21-year-old male enrolled in a university biology course.

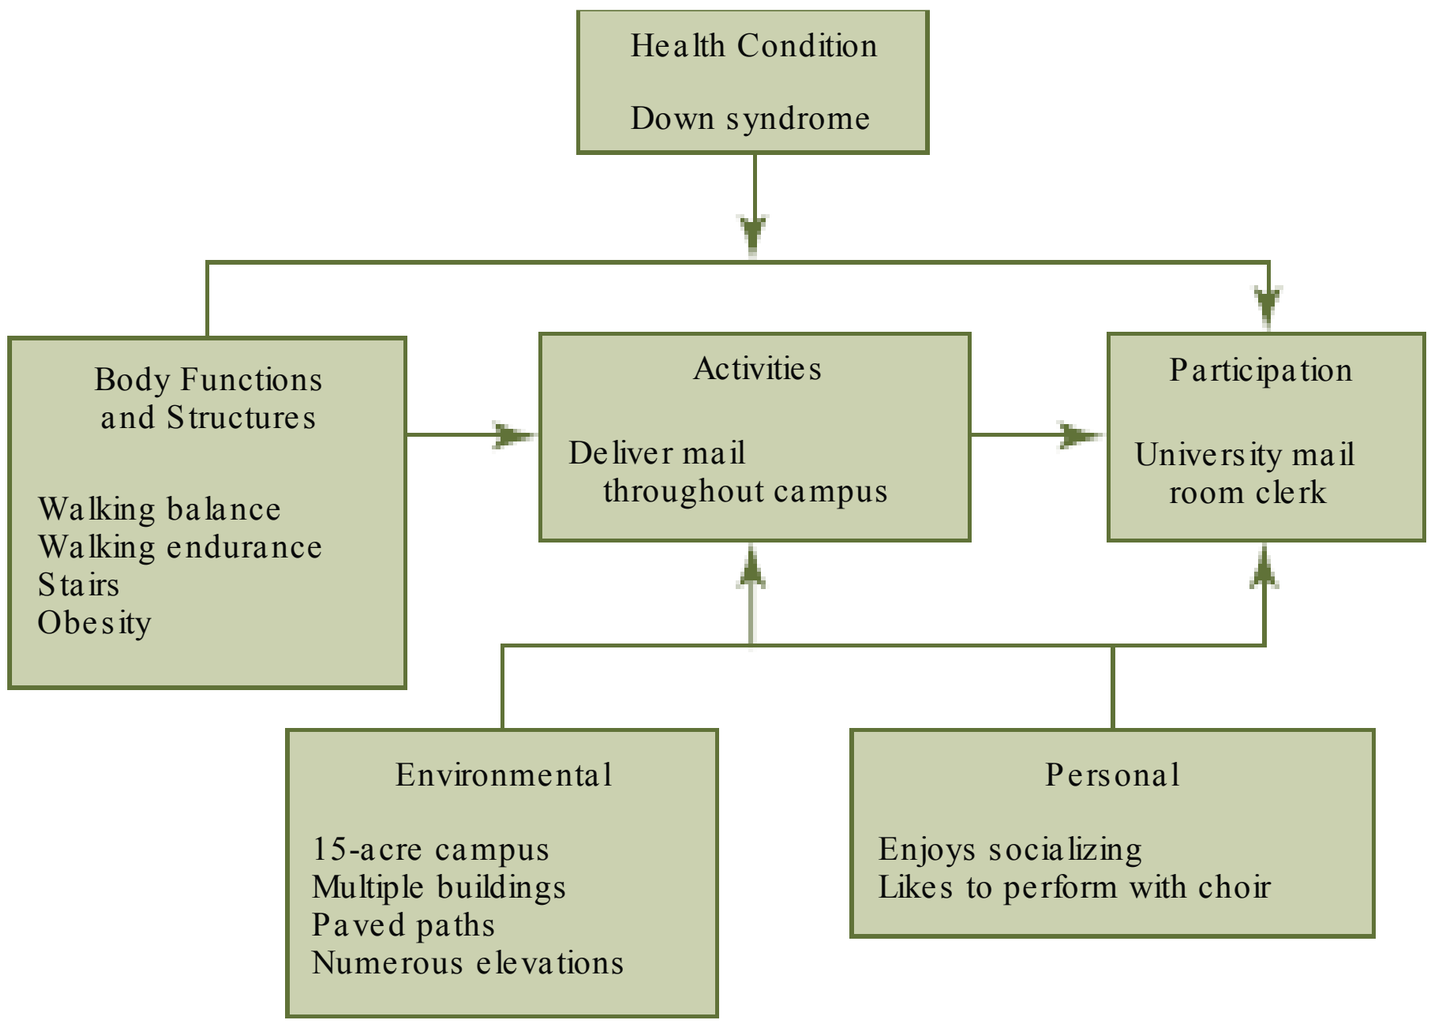

FIG. 32.8 ICF framework applied to work considerations for a young adult applying for a job.

with disabilities and their families.[135] For example, many therapists stated they were not discussing transportation options, barriers to accessing community facilities, or gathering information on social barriers.

Reasons why physical therapists are not routinely involved with transition services for students with physical disabilities in secondary education and the effects of physical therapist intervention on transition outcomes have not been investigated. Factors associated with professional preparation and cost of services may well impact on physical therapist involvement in transition planning and services in all practice settings (school, hospital, community). Professional education in pediatrics usually focuses on young children, with limited content on young and aging adults with developmental disabilities; physical therapists working with adults in hospitals or outpatient clinics are often not aware of issues common to adults with developmental disabilities.[31,32]

Practice settings often dictate the parameters for intervention. In contrast to hospitals and clinics, school-based practice is guided by federal and state legislation. Emphasis is on enhancing student participation in the education program. Transition is a natural part of the education process as the student advances through primary, middle, and secondary grades and schools. Interventions by physical therapists working in the hospital setting may focus on impairments in body functions and structures because of the acute nature of hospital admissions. Outpatient clinics, be they based in a hospital or private practice, generally do not have the typical real-world environment that is the context for activity and participation. Though professional organizations have embraced the ICF framework, the extent the ICF is applied in any of the practice environments is unknown. Communication between practitioners in any or all of these practice environments is especially critical at times of transitions.

ADULTS WITH CHILDHOOD-ONSET DISABILITIES

Demographics on adults with childhood-onset conditions underscore the importance of quality services to prepare youth with disabilities to transition to adulthood. Advances in health care since the late 1980s have increased the life span of individuals with childhood-onset conditions; 50% to 90% of adolescents with cerebral palsy, spina bifida, and acquired brain injury live into adulthood.[151] Approximately 200,000 individuals with developmental disabilities are over the age of 60, a number that is expected to double by 2030.[32] Further, more students with disabilities are pursuing postsecondary, higher education than ever before.[64]

As pediatric physical therapists strive to assist youth and young adults with physical disabilities in their transition to the adult health care system, a number of issues warrant consideration. Depending on the physical therapy education program attended and years since graduation, physical therapists whose practice is limited to adults may have limited knowledge of childhood-onset conditions. As a consequence, they may be uncomfortable providing interventions for secondary impairments such as pain, fatigue, and musculoskeletal contractures in adults with childhood-onset conditions. When referring youth who have aged out of the pediatric health care system, pediatric physical therapists are encouraged to enthusiastically offer consultation or shared intervention with their colleagues in adult practice settings. Proactively preparing youth to interact with adult providers is encouraged. For some youth, this might entail creating a therapeutic/medical vocabulary for their augmentative communication systems in order to independently express concerns and respond to questions during the examination. We must continually ask ourselves how best to prepare young people with disabilities for transition to adulthood.

PROFESSIONAL RESOURCES FOR PHYSICAL THERAPISTS

Expert Consult includes a list of recommended websites with resources on transition for youth, family, and professionals. The websites include transition manuals, forms for screening and assessment, checklists, and transition activities. For the most part, the psychometric properties of measures and the utility of planning and activity resources have not been evaluated.

Adolescents and Adults with Developmental Disabilities Special Interest Group

The Adolescents and Adults with Developmental Disabilities Special Interest Group (AADD SIG) was established by the Section on Pediatrics of the American Physical Therapy Association (APTA) in 2001 to meet the professional development needs of therapists providing services to adolescents and adults with developmental disabilities. The goals are to provide a forum for therapists to meet, network, and promote quality care through education, research, and practice. The focus of the SIG includes (1) examination and prevention of impairments in adults with developmental disabilities to ensure maximum participation in society, (2) development of intervention guidelines for the adult with developmental disabilities, and (3) promotion of advocacy for adults with developmental disabilities through research and education.[33] The membership of the SIG and educational opportunities continue to grow and can be accessed through www.pediatricapta.org.

SUMMARY

Transition to adulthood is a future-oriented process in which youth begin planning for adult roles and responsibilities including finding an adult medical home, living outside the family home, obtaining postsecondary education and employment, and participating in social and community activities. The transition process encompasses the health, psychosocial, and educational-vocational needs of adolescents as they move to adult-oriented lifestyles and systems.

Contemporary approaches to transition services are youth and family centered, involve youth as active participants, and emphasize real-world experiences, development of life skills, environmental supports, and community accommodations. Although transition planning and services are mandated for students with disabilities, physical therapists working in an educational setting have not fully participated in the transition process. Increasingly, community agencies and children's hospitals are providing transition services, although offering coordinated and comprehensive services for adults with childhood-onset disabilities is challenging.

Pediatric physical therapists are encouraged to embrace a lifecourse perspective and future-oriented process to help prepare youth with physical disabilities for adult roles. Complex person-environment issues challenge therapists to critically

think beyond impairment-level interventions. This includes instruction of youth in self-management of their health conditions and instruction of others who provide care. Consultation and direct services are recommended, as needed, for seating, transfers, mobility, self-care, wellness and fitness, assistive technology, and environmental modifications. The very language practitioners are encouraged to use when writing goals and action plans, such as student, employee, resident, and athlete, rather than patient, should direct attention toward participatory outcome measures. Potential niche areas of practice include consultation to institutions of higher education, work environments employing persons with disabilities, health clubs interested in being more inclusive in membership recruitment, and adult-oriented physical therapists interested in serving adults with childhood-onset disabilities.

Case Scenarios on Expert Consult

The case scenarios for this chapter illustrate the application of knowledge to practice. One scenario focuses on the varied roles of the physical therapist as a member of the transition team during a student's last 2 years in secondary education. The second scenario describes the experiences and reflections of a pediatric physical therapist as she expands her practice knowledge to include transition of youth with physical disabilities. Additionally, Matt Freeman shares his thoughts on the transition process. Matt is a doctoral candidate in Rehabilitation Science at McMaster University and author of research on information needs of individuals with cerebral palsy and their families during the transition to adulthood and effective ways of delivering information. Matt has the lived experience as an individual with cerebral palsy.

Assistive Technology

Roberta Kuchler O'Shea, Brenda Sposato Bonfiglio

Pediatric physical therapists have an important role in providing children and youth with impairments in body functions and structures with assistive technology to improve activity and participation. An assistive technology (AT) device is defined in federal legislation as any item, piece of equipment, or product system that increases, maintains, or improves an individual's functional status.[45] In contrast, an AT service is legally defined as any service, such as physical therapy, occupational therapy, or speech therapy, that directly assists someone with a disability in the selection, acquisition, or training of an AT device.[45] AT encompasses a vast range of materials, designs, and applications to enable adapted motor function when skill attainment is unrealistic or impossible.[39] Also referred to as enabling technology, AT can generate opportunities for social participation. Since the 1990s, there has been a virtual explosion in the number and type of assistive devices.

The creation of federally funded rehabilitation engineering centers in 1972 focused efforts on the research and development of new products, as well as on the delivery of services to the consumer.[13] This process brought together professionals from many disciplines including biomedical and rehabilitation engineering, physical therapy, occupational therapy, speech and language pathology, and special education. The Rehabilitation Engineering and Assistive Technology Society of North America (RESNA), an outgrowth of this shared interest, is an interdisciplinary association of professionals interested in applied technology for persons with activity limitations and participation restrictions.

Since 1975, many laws have been enacted to ensure the rights of people with disabilities to be included in natural education and work environments. These laws include Public Law 101-476, the Education of All Handicapped Children Act; the 1990 Amendment to the Individuals with Disabilities Education Act (IDEA); Public Law 101-47, the Technology-Related Assistance for Individuals with Disabilities Act of 1988 (TRAIDA/Tech Act); Public Law 93-112, the Rehabilitation Act; and Public Law 101-336, the Americans with Disabilities Act (ADA). These laws have helped to focus attention on and create a growing market for new technologies and products. Consumer demands for increased durability and performance have induced manufacturers to apply technologies created by the aerospace, medical, and information industries.

TRAIDA was the first federal legislation to define AT devices and services and to recognize the importance of technology in the lives of individuals with disabilities.[10] Grants awarded to states and territories provided funds for projects to improve access to technology and, subsequently, integration and inclusion of individuals with disabilities within the community and workforce. Services currently offered vary from state to state and include information and referral services (databases, 800 numbers, and websites), centers for trying out devices and equipment, equipment exchange and recycling programs, funding resource guides, financial loan programs, mobile van outreach services, protection and advocacy services, and education programs on funding and self-advocacy. The Assistive Technology Act of 1998 provides for development of comprehensive technology-related programs. All states and territories are eligible for 10 years of federal funding, and states that have received 10 years of funding are eligible for an additional 3 years of funding. The 1997 Amendment to the IDEA advocates for consideration of AT devices and services for all individual education plans.

This chapter discusses the major elements of AT and the role of the physical therapist in selecting and obtaining appropriate equipment for children and their families. The five elements include adaptive seating and positioning, wheeled mobility, augmentative and alternative communication (AAC), computers, and electronic aids to daily living (EADLs). Research is appraised to provide evidence to inform the decision-making process.

ASSISTIVE TECHNOLOGY TEAM

Most technological devices require modification or customization in design, implementation, or attachment.[31,46] The complexity and expense of the AT required by individuals with severe physical impairments and activity limitations necessitate a thorough and careful process of selection and construction. All individuals who interact with the child and the equipment on a regular basis need to be considered part of the team. Professionals, the child, the family, and caregivers each contribute a particular area of knowledge and expertise. Lahm and Sizemore[30] contend that despite laws mandating AT assessment teams, the members of the team may have individual agendas. Many factors influence the assessment process, including the needs and preferences of the child and family, individual education and experience levels of team members, specialties represented on the team, and the approach advocated by each assessor. Teams need to be cognizant of their strengths and limitations. Are there members from several disciplines, or from just one or two? Are the child and family integral team members? An outcomes survey found that the professionals with the most experience (therapists) spent the least amount of time with the client and that the professionals with the least amount of training in disability studies (AT suppliers) spent the most time with the family.[30] Lahm

and Sizemore advocate that professional education programs include more information on AT based on their findings that new graduates do not possess sufficient knowledge of AT and AT services.

The configuration of the AT team (Fig. 33.1) will vary depending on child and family needs and the setting in which services are provided. Central to the team are the child and family. Family-centered services emphasize the importance of engaging the child and primary caregivers in the goal-setting and decision-making process to ensure realistic and meaningful solutions.[45] The core team should include professionals with training and experience in the areas being examined (mobility, seating, augmentative and alternative communication, computers, and activities of daily living [ADLs]). The team usually includes some or all of the following professionals: physical therapist, occupational therapist, speech and language pathologist, rehabilitation engineer, and rehabilitation technology supplier.

In addition to the core team, other professionals, organizations, and agencies are involved in decision making and procurement of AT. Professionals involved in the child's education and health care often share roles with the core team and provide information that is essential for decision making. In the educational setting, this may include the physical therapist, occupational therapist, speech and language therapist, classroom teachers and aides, administrative personnel, psychologists, vocational counselors, and work supervisors. Goals and strategies must be coordinated with other service providers. Within the medical setting, the child's family physician, as well as other medical specialists and nurses, may need to be involved. Issues requiring collaboration with medical personnel include management of deformity and contractures, pressure sores, incontinence, self-injury, safety, and visual and other sensory impairments.

The issue of funding involves a third group of contributors that includes third-party payers, state-sponsored medical equipment programs, civic organizations, and other funding agencies. Many clinics employ a funding specialist to assist families in identifying and obtaining funding for prescribed technology. The team may also include other community and family members who engage in day-to-day interactions with the child or who provide special support services such as transportation or revision of architectural barriers.

Team makeup and setting are variable. For example, in many hospitals and rehabilitation centers with comprehensive technology service delivery programs, physicians

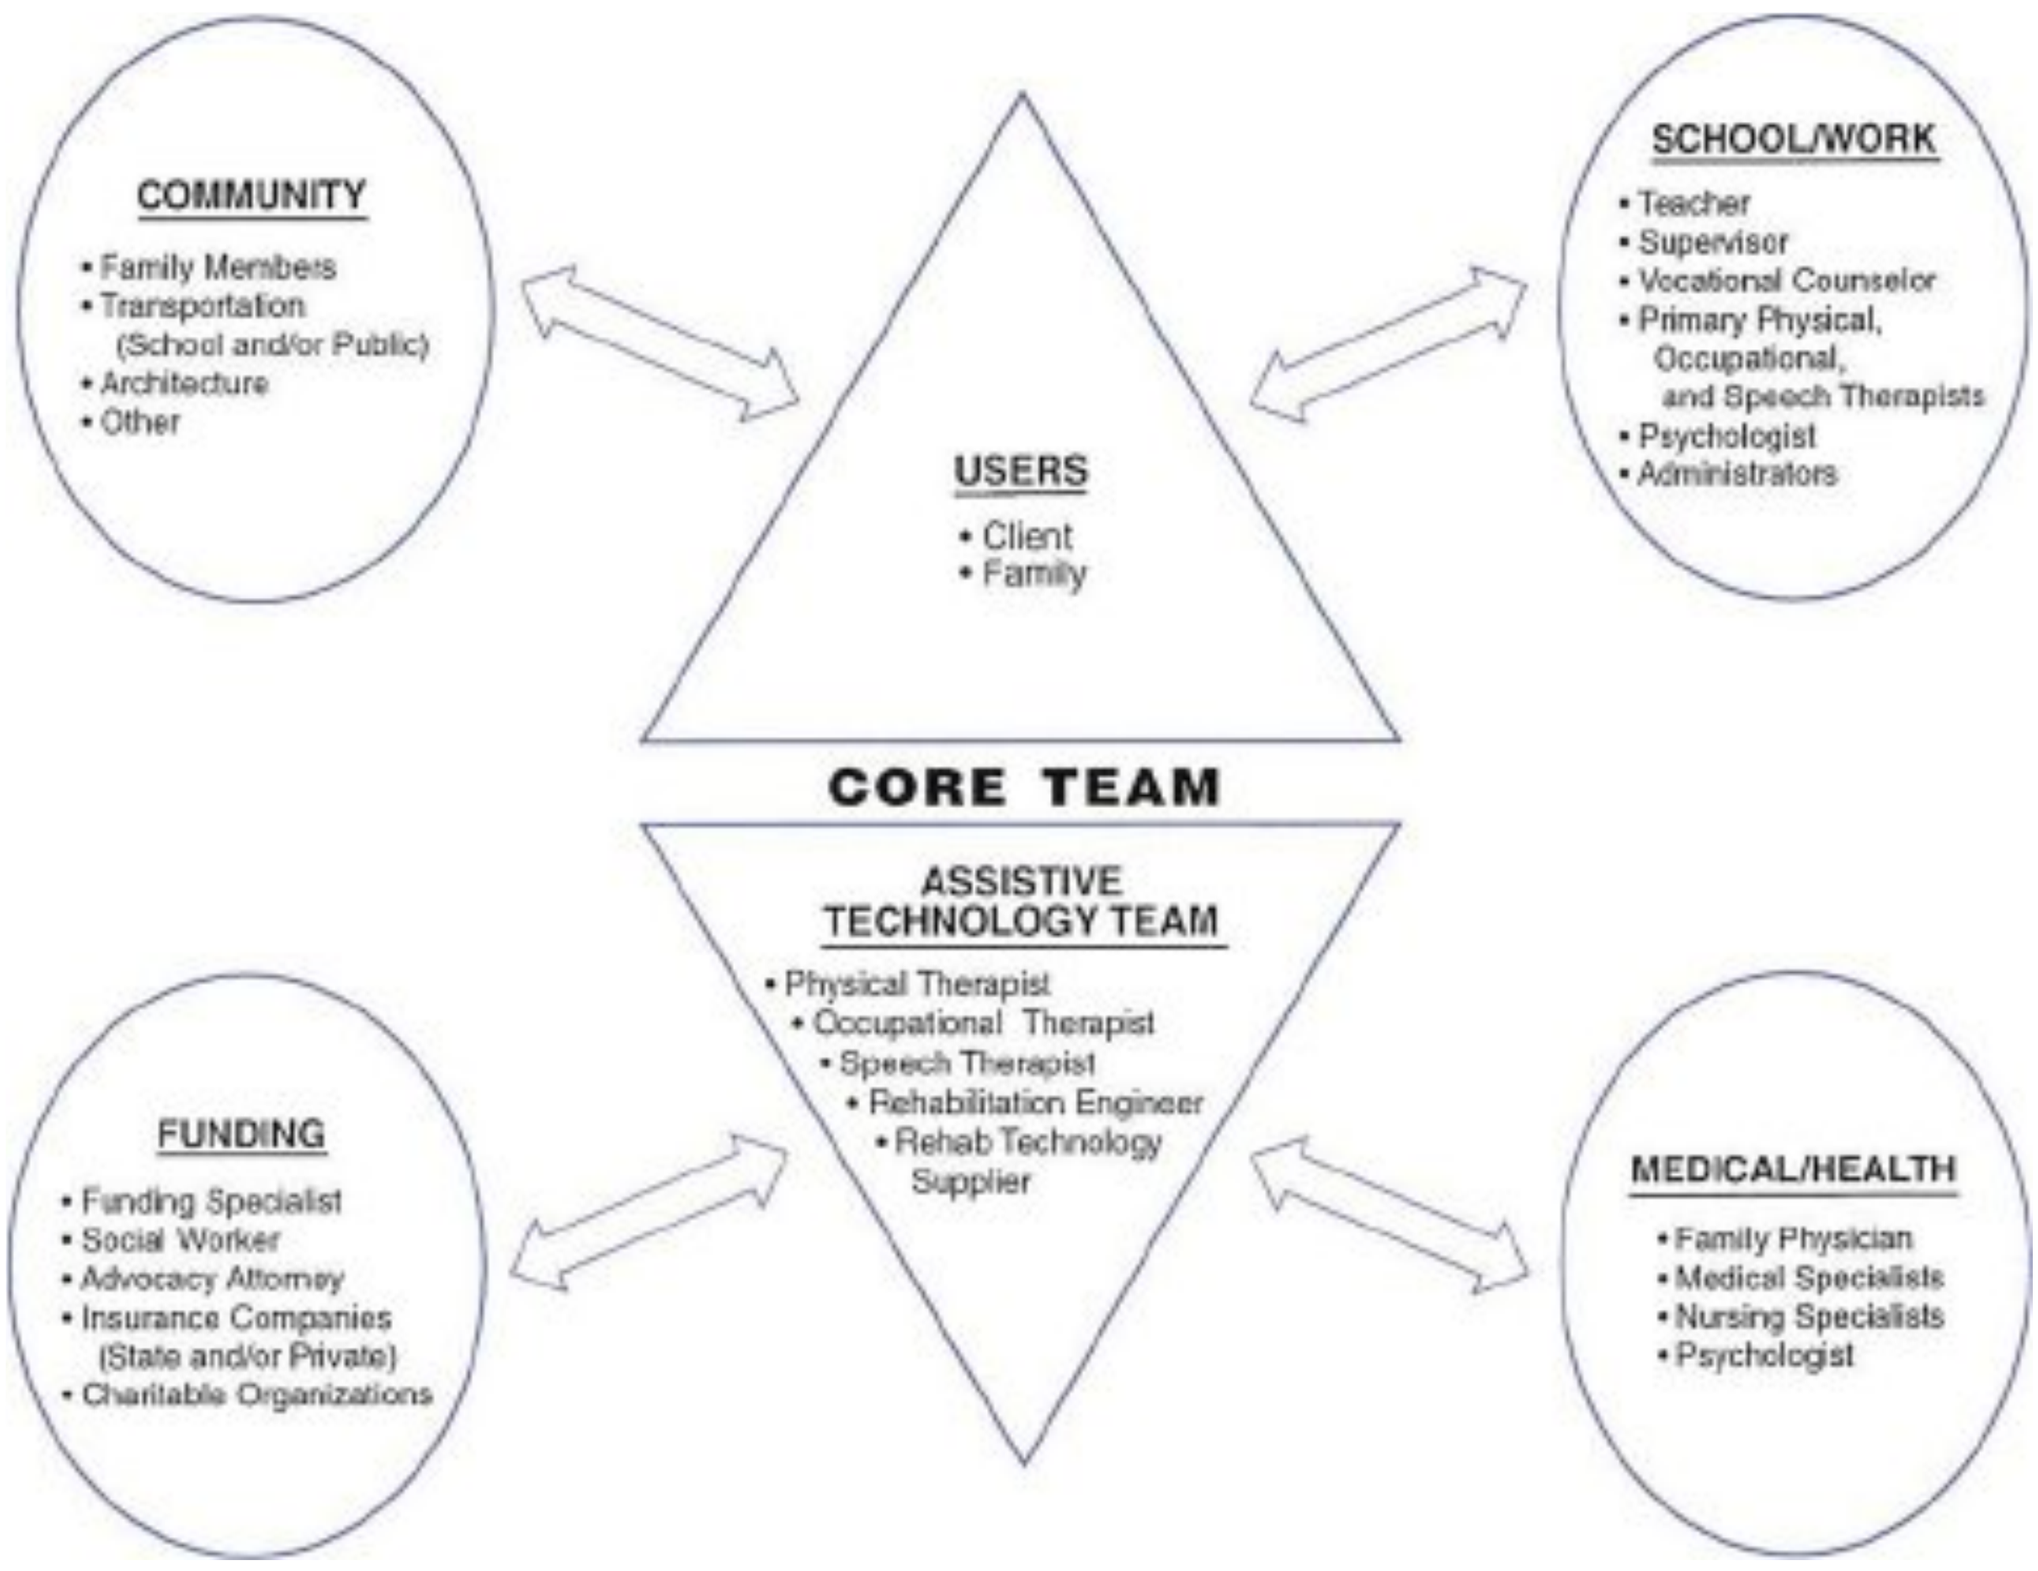

FIG. 33.1 Core team interactions are important for selecting and procuring assistive technology. Members and roles of each component may fluctuate, depending on specific client problems and settings.

(especially physiatrists and orthopedic surgeons) are an integral part of the core team. In schools and residential centers, one or more of the client's primary therapists, along with an equipment supplier, may function as the core team. The core team is responsible for imparting information regarding proper use, training, maintenance, responsibility, and safety relative to the prescribed devices to appropriate individuals.

Effective communication and coordination of care are essential components of intervention to ensure that once obtained, the technology is used. Abandonment of AT is costly for the family and child. There are financial costs of the equipment but also emotional and time costs that cannot be recuped.[26] Four factors were related to abandonment of AT: lack of consideration, ease of procurement, performance, and priorities.[26] Lack of consideration refers to the child's and family's opinion during the selection process. Ease of procurement was a second factor. Items purchased directly from a supplier (without team consultation) were the most likely to be abandoned. A third factor was poor device performance, which reflected the user's perception of the ability of the technology to enhance his or her performance in an easy, reliable, and comfortable manner. The fourth factor was change in users' needs and priorities over time, including functional changes, as well as changes in lifestyle and activities.

In 1995 RESNA began credentialing professionals in AT for the purposes of ensuring consumer safeguards and increasing consumer satisfaction. The credential indicates that the professional has specialized training and experience in AT and promotes a standard for recognizing qualifications and validating the broad-based knowledge required for safe and effective service in the field of AT. The activity technology professional (ATP) credential signifies a service provider who analyzes the needs of individuals with disabilities, assists in the selection of the appropriate equipment, and trains the consumer on how to properly use the specific equipment (see the RESNA website at www.resna.org/certification/index.php).

Professionals who provide AT services to individuals with disabilities should consider obtaining the activity technology professional credential. Professionals include but are not limited to physical therapists, occupational therapists, speech-language pathologists, rehabilitation engineers, special educators, and rehabilitation technology suppliers. The credential is extremely important for physical therapists working with children and adults with seating, positioning, and mobility needs. There is an increasing need for physical therapists who serve children with disabilities and their families to have specialized training and expertise in AT.

A rehabilitation technology supplier (RTS) is an individual who provides enabling technology in areas of wheeled mobility, seating and alternative positioning, ambulation assistance, environmental controls, and ADLs (note that communication systems and computers are not included). A National Registry of Rehabilitation Technology Suppliers (NRRTS) includes the names of suppliers whose qualifications have been verified through an evaluation process that includes work experience, references from professional associates, adherence to the Code of Ethics and Standards of Practice and Protocol, and commitment to continuing education. A certified RTS (CRTS) is a member in good standing of the NRRTS who has successfully completed the RESNA Assistive Technology Supplier examination.

INTERNATIONAL CLASSIFICATION OF FUNCTIONING, DISABILITY AND HEALTH FRAMEWORK FOR DECISION MAKING

Throughout the book, examples are provided of how AT is used to achieve child and family goals for activity and participation. AT devices are designed to improve users' participation in activities that may otherwise be limited by impairments in body structure and function. The International Classification of Functioning, Disability and Health (ICF)[60] is a useful framework to apply when making decisions about AT. Correctly prescribed and used, AT, especially positioning (adaptive seating), may help prevent secondary impairments such as skin breakdown, cardiopulmonary compromise due to scoliosis or slouched posture, and joint contracture or skeletal deformity due to inadequately supported body segments. Benefits of AT also may include reduction of muscle tone or excessive muscle activity and a decrease in nonvolitional movement. By providing a means for the child to compensate for impairments in postural stability and weight shifting, AT can reduce activity limitations in sitting, mobility, use of hands, and speech. AT also may increase the ability of the child to participate in daily activities and routines. A power wheelchair may allow independent access to school or work. Augmentative or alternative communication may facilitate interactions with peers and promote social skills. An EADL may make the difference between less restricted living in a supervised apartment and living in a nursing home or intermediate care facility.

Social policies and attitudes are important determinants of the availability and accessibility of AT. High product and service provider costs require evidence that technology improves the user's quality of life in ways that justify the costs. Reduction in costs of hospitalizations, surgical procedures, out of home residence, and attendant care are outcomes that would support the effectiveness of AT. Technology also has the potential to improve user appearance and visibility. This in turn could have a positive effect on social attitudes regarding the capabilities of people with severe disabilities.

Evaluation of AT is often based empirically on observation and clinical impressions. The literature is replete with descriptions of creative solutions for individual client problems. Less common are controlled studies of the effectiveness of AT intervention.

LIFE SPAN TECHNOLOGY

The needs of children with impairments in body functions and structures change with growth and development and, therefore, AT needs must be continually reevaluated. Careful selection, planning, and implementation of AT optimize child and family outcomes and efficient use of health care resources. During infancy, proper positioning helps to promote social interaction and development of early concepts such as cause and effect and object permanence. Prior to and during the preschool years, switch-activated toys and power-driven mobility toys can help children learn to self-initiate movement and interact with the environment. Children need a reliable way to indicate needs and make choices. The school-age child needs the postural support and comfort to enable learning and adaptive function. The adolescent needs to keep up with peers and be accepted socially. Adolescents should be included in the decision-making process

regarding choice of mobility, seating, or communication options whenever possible. The young adult needs to be able to get to and from a job or day setting and rely as little as possible on others to achieve basic functions, such as position changes, communicating, eating, and toileting. Because individuals with severe limitations in mobility spend many more hours at a time in one position, hygiene and skin care become a priority.

Technology is quickly changing all facets of life. Things only dreamed about just a few years ago become a readily available reality very quickly. The personal digital assistant (PDA) was a handheld device that stored digital information. It is not unusual for academic institutions to utilize electronic versions of textbooks on laptops and tablets as well as Internet-based curriculum platforms. The use of technology is ubiquitous in classrooms today, benefiting all children regardless of abilities. Technology allows children to actively participate in their educational programs without the adult assistance that may have interfered with peer-to-peer and student-to-teacher interactions.[39]

SELECTION PROCESS

A person's environment refers to the surroundings or a setting in which he or she spends a great deal of time. Cooke and Polgar[13] described the human/activity/AT model (HAAT model). This model dovetails well with the International Classification of Functioning, Disability and Health. In the HAAT model, *human* represents someone doing something in some place. *Activity* is the process of doing something, the functional result of human performance. *AT* is the basis for how the human performance will be enhanced during an activity.[26] Thus translating the HAAT model into components of health, AT is designed to minimize impairments in body functions and structures and maximize activity and social participation. The selection process must consider all environments in which AT will be used. In addition, the wheelchair itself, with its adaptive seating and communication systems, is a microenvironment for many children with severe impairments.[14]

The elements of patient/client management in the *Guide to Physical Therapist Practice*[3] correspond with the process for selection and implementation of AT:

Step 1: Examination. Examination is the process of obtaining a history, performing systems reviews, and selecting and administering tests and measures to obtain relevant client information. The process begins with an interview to identify child/family goals and implication for AT. The team records relevant history and social information. The examination includes measurement of myotomes, dermatomes, skin, range of motion (ROM), muscle strength, and motor function, including sitting, transfers, and mobility.

Step 2: Evaluation. The team makes clinical judgments based on data gathered during the examination. Keeping in mind the information gathered in Step 1, the team considers options for AT.

Step 3: Diagnosis. The team makes a decision on the child's needs for AT.

Step 4: Prognosis. The team estimates the level of improvement that might be attained through AT and the amount of instruction and training required.

Step 5: Intervention. The child and family try out options for AT. The team selects the AT system and services to implement a system that will provide maximal independence based on the child's diagnosis and prognosis. Funding is secured. The team may be responsible for gathering prescriptions and writing letters of medical need. The system is ordered, delivered, and fit to the user.

Step 6: Outcomes. Changes associated with the AT are documented, including activity and participation.

Step 7: Follow-up and reevaluation. The process described is usually only one of many repetitions of a cycle. Mechanical and electronic equipment wear out and break down, making repairs and replacement necessary. The child's problems and needs change with age, development of new skills, and change of environments. As technologies continue to improve, new solutions become available.

SEATING SYSTEMS

The purpose of the seating system is to provide external postural support for the child with activity limitations in sitting caused by impairments in body functions and structures. Seating is the interface between the child and the mobility device.[14] The goal is to enable the child to compensate for activity limitations, thereby maximizing participation in life activities. Seating systems can be classified into three categories: linear/planar, generically contoured/modular, and custom molded/custom contoured.

There are several desired outcomes when prescribing seating systems: comfort, neuromuscular management, improved postural control, and maintaining the integumentary system. Comfort is a desired outcome for all individuals using seating and mobility systems.[35] Outcomes for individuals with cerebral palsy (CP) or traumatic brain injury may include muscle tone management and improvement of upper body postural control to enhance head control and hand function. To achieve stable sitting, biomechanical forces and moments in all planes must be balanced.[14] Good positioning usually consists of an upright midline orientation of the entire body with a near-vertical alignment of the trunk and head. In children, the *90-90-90* rule often is used to maintain the hips, knees, and ankles at 90 degrees. As the child grows, it may not be reasonable, due to leg length, to maintain the knees at 90 degrees of flexion. In this case, the decision to go with a different angled front rigging must be made. Additionally, if the child has contractures of the legs or trunk, positioning in 90 degrees of hip, knee, and ankle flexion may not be possible.

Some professionals have questioned the rationale for static positioning, stating that it is unnatural and impedes function.[14] Individuals with abnormal tone may require dynamic components integrated with their wheelchair frames to accommodate for excessive movement. For example, a suspension assembly can be integrated at the seat-to-back angle junction to allow the back canes to move independently of the seat frame. This allows the wheelchair frame components to withstand the forces applied by the individual's extraneous movement. The components absorb the energy that would otherwise be transmitted into the wheelchair. Additionally, the stiffness of the elastomer part of the component can be matched to the force generated by the individual and can be adjusted as needed, minimizing or eliminating damage to the frame.

Research on therapeutic seating for children with neuromuscular disorders has focused on the effects of hip flexion angle (or seat-to-back angle) and orientation of the trunk and head

(or angle-in-space). The former is achieved by independently changing the seat-back angle; the latter is achieved by tilting/rotating the entire system. There has been considerable interest in the anterior tipped (or forward-inclined) seat, in which the front edge of the seat is tilted downward, thus increasing the seat-to-back angle while maintaining a near-vertical back. Most clients with myelodysplasia or spinal cord injuries tolerate and function well in a typical upright position; however, sitting pressures are a concern and prevention of ulcerations a priority. Various types of sitting surfaces and adjustments to improve postural alignment have been studied in the attempt to reduce pressure and decrease the incidence of decubiti. In children with muscular dystrophy, prevention of spinal collapse, preservation of arm and hand function, and comfort are desirable outcomes of positioning. Washington and associates[59] reported that infants with neuromuscular impairments demonstrated better postural alignment and engagement with toys when seated on a contoured foam seat as compared to a regular highchair seat or highchair with a thin foam layer. Mothers of the infants reported that the contoured foam seat was feasible for use within their typical daily routines.

Effects of Adaptive Seating on Body Functions and Structures

Neuromuscular System

A long-standing assumption is that increased muscle tone, here defined as muscle activity at rest, can be reduced by altering seating angle. Seats are oriented either horizontally, wedged (front edge raised), or anterior tipped (front edge lowered). Backs are placed vertically, reclined, or forward inclined (closing the hip angle to more flexion). Several studies have examined the effect of seating angle on electromyographic (EMG) activity in children with CP. In a study that varied the hip angle by reclining the back or wedging the seat, lumbar muscle activity was lowest in vertical sitting, with a horizontal seat and a 90-degree hip angle.[14] Lumbar muscle activity was higher the more reclined the position regardless of the hip angle. Hip adductor activity was decreased when the back was vertical and the seat was wedged 15 degrees.[36]

In children with CP, as well as children without neuromuscular impairments, tilting the seating system 30 degrees posterior while maintaining the hip angle at 90 degrees increased electrical activity of paraspinal and hip adductor muscle groups.[36] The reclined position also resulted in increased electrical activity in the rectus femoris, adductor longus, biceps femoris, and gastrocnemius.[36] The addition of an abduction orthosis decreased leg muscle activity in all positions. For subjects with severe neuromuscular impairments, changes in EMG activity of back extensor and medial hamstring muscles to response to position changes were individualized.[36]

Children with CP who sat on anterior tilted seats without back support showed a decrease in midthoracic muscle activity and an increase in lumbar muscle activity,[36] indicating increased EMG activity of low back musculature relative to midback musculature. Myhr and von Wendt[40] advocate the use of anterior tilted seats, but they added an abduction orthosis and a cutout table for upper extremity support of forward leaning. When wearing the abduction orthosis, EMG activity of leg muscles was lower in the forward-leaning position compared with vertical or reclined sitting. The frequency of spastic or tonic reflex patterns (defined for each subject) was reduced in the anterior tilted sitting position compared with the subjects' own seating systems.[36]

Musculoskeletal System

The assumption that postural support systems prevent contractures and skeletal deformity in children with increased muscle tone has been examined.[33] In theory, maintenance of balanced forces to the trunk and lower extremities should prevent structural changes such as scoliosis and hip dislocation.[14] This theory may apply to young children with asymmetric postures that can be reduced through positioning. Maintenance of balanced forces through a postural control system may not be feasible for children with severely increased muscle tone, strong deforming muscle forces, and asymmetry.

Cardiovascular/Pulmonary System

Most studies have measured how pulmonary function is affected by seating position. Pulmonary function of children with spastic CP improved when the child was sitting in a modular seating system with adjustable support components compared to a wheelchair with standard sling seat and back.[14] The differences were attributed to (1) changes in the shape, structure, and capacity of the thorax and abdomen and (2) improved control of the respiratory muscles in the supported, upright position. Anterior tilted seating systems have potential to improve respiratory function in children with moderate CP.[14]

Integumentary System

Prevention of pressure sores is a goal for children who sit for long periods throughout the day. Insensate tissue compounds the problem of prolonged sitting. Pressure relief is also an important consideration for children with neuromuscular impairments who use wheeled mobility. Skeletal asymmetries, such as pelvic obliquity, hip dislocation, and scoliosis, predispose children who sit in wheelchairs to pressure problems.

Several factors contribute to the development of pressure sores including skin temperature, moisture, and shear and compressive forces.[18] Pressure (compressive force) has been the most-studied variable, because it has a clear relationship to the development of decubiti and is relatively easy to measure and manipulate during wheelchair seating. The risk of a pressure sore is directly related to the length of time soft tissue is compressed and inversely related to the area being compressed.

Pressure mapping devices (Fig. 33.2) are commonly used to study pressure distribution in individuals with and without motor impairment, reduction of seat interface pressure using various seat surfaces, and prevention of decubiti. Adults without physical impairments display even pressure distribution from side to side and a biphasic pattern of pressure concentration with a posterior concentration on the ischial tuberosities and a second but lesser concentration on the distal thighs.[21,29] Patients with "unbalanced sitting" due to pelvic obliquity or scoliosis showed a pronounced shift of pressure laterally and often posteriorly, thereby increasing pressure on the ischial tuberosity.[21,29]

For subjects without impairment, return to upright after a short period of recline in a wheelchair resulted in higher pressures and shear forces compared with the upright position.[27,36] When subjects leaned forward moving away from the backrest, forces returned to initial values. When the footrests were elevated, pressure under the ischial tuberosities increased. There was no difference in pressure under the ischial tuberosities between upright sitting and 10 degrees of recline in adults without impairment, but there was reduction of pressure in both positions when a lumbar support was added.[32] The reclined

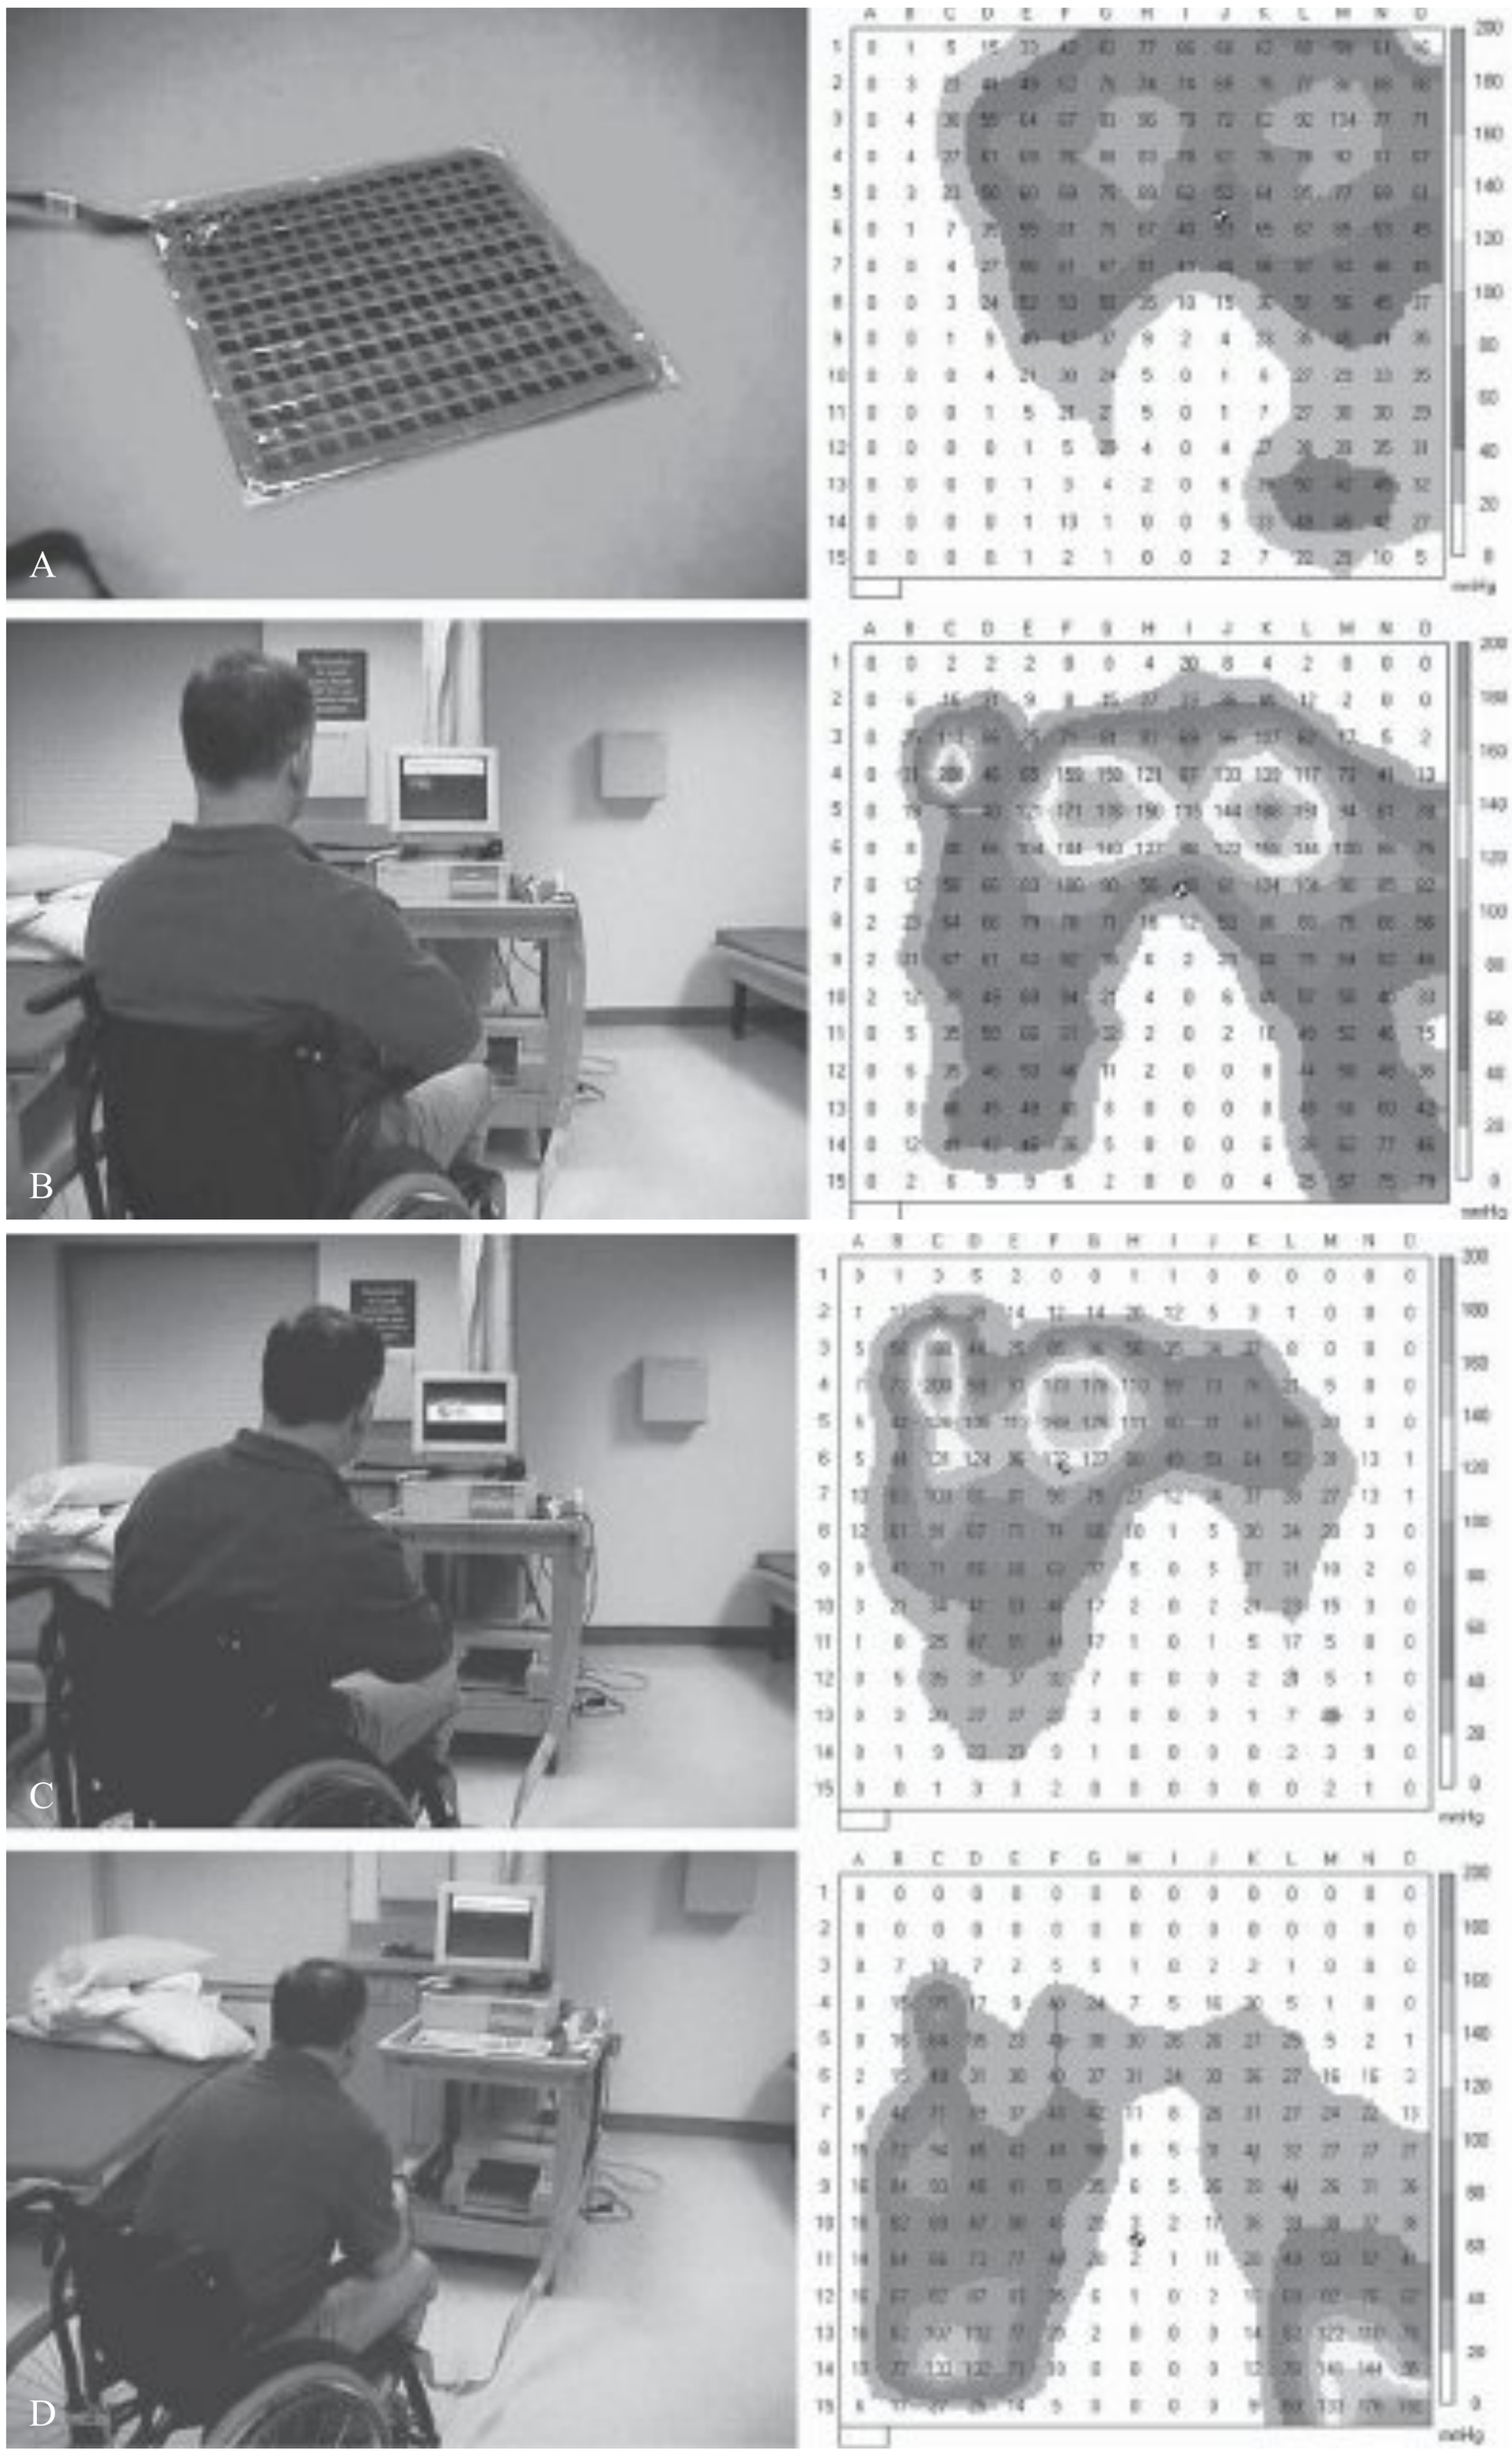

FIG. 33.2 Pressure mapping system and outputs. A, Pressure map (left) with computer screen output (right). B, Individual seated in a wheelchair on a pressure map (left). Output with symmetric sitting posture (right). C, Output with individual leaning to the right while seated. D, Output with individual leaning forward, resting his elbows on his knees while seated.

position with lumbar support was recommended for individuals with spinal cord injury because they slide or rotate off the lumbar support in upright position due to tight hamstrings or weak trunk musculature.

Magnetic resonance imaging (MRI) has been used to evaluate soft tissue contours of the buttocks during loading. In a subject with paraplegia, less sitting pressure was required before soft tissue became compressed by a bony prominence and there was increased stiffness and lateral shifting of the gluteal muscle mass.[33] Foam cushions contoured to match the shape of the buttocks, as opposed to flat foam, improved the load transfer from buttocks to cushion because the total contact surface area was greater.[33] Foam stiffness is also a consideration in determining the seat contours, with dense foam having less deflection under the load. When clients with spinal cord injury were seated on flat versus contoured foam cushions of varying stiffness, pressures were lower on the contoured cushions than on the flat cushions, and they were lower on the more compliant foam than on the stiffer foam.[33] The buttocks were encompassed more on the contoured and softer cushion with less tissue distortion. The authors cautioned that foam that is too soft deforms too much and will "bottom out" quickly. In contrast, when subjects with paraplegia sat with the trunk bent laterally, the mean difference in pressure between the left and right ischial tuberosity was greater on a foam cushion than on a commercial air-bladder cushion.[27]

Several studies have compared sitting pressures, skin temperature, and relative humidity in subjects seated on commercially available cushions.[22,33,53] Findings indicate that no one cushion is effective for all clients and that a variety of cushion options are needed to meet individual needs.

Effect of Adaptive Seating on Activity and Participation

Postural Stability and Control in Sitting

Research has examined the effect of anterior tilted seats on the posture and stability of children with motor impairments using instrumented systems and rating scales. Two typical designs of anterior seats are (1) a flat bench with no trunk support, with feet flat on the floor, and (2) a forward-leaning system with an anterior trunk or upper extremity surface for support.

Children with CP and children with traumatic brain injury sat in a more upright position in an anterior tilted seat compared with a flat seat.[14] Postural sway also decreased in children with CP.[14] The position of the C7 spinous process was tracked to yield a radius of stability, with a smaller radius indicating reduced postural sway and thus increased stability. During quiet sitting on a flat bench, the postural sway of the children with neuromuscular impairments did not differ significantly from that of age-matched controls, although children with neuromuscular impairments demonstrated more variability. When positioned on a seat with a 10-degree anterior tilt, half of the children with CP (described as having spasticity with tight hamstrings) had a decrease in sway and a more upright posture (vertical measurement of C7 height). The other half of the children with CP (described as having low trunk tone and tight hamstrings) had an increase in sway on the anterior seat but also a more upright posture.

Interestingly, varying seat angle by 10 degrees did not affect the postural stability of children with motor impairments.[14] Trunk extension was greatest when children sat on an anterior tilted seat with a leg support to provide weight bearing through the knees and shins.[14] Additionally, postural of the head, trunk, and feet improved when children sat on an anterior tilted seat.[14] Improvement in independent sitting ability, trunk posture in sitting, and powered mobility were observed in children after at least 3 years of using seating and power mobility system.[31,35] The critical features of the seating and mobility system (SAM) were a saddle-type seat, a solid anterior chest support, and a tray to support forward leaning.

Posture and arm movements of young children with CP improved when they were positioned on a seat with some anterior tilt, foot support, and no trunk support compared with sitting on a flat bench.[14,32] A more upright head and trunk and better alignment between body segments improved spinal extension.[14,35]

For most children, a seat-to-back angle of 90 degrees without any pitch (thus the seat is parallel to the floor) is most practical. If the child assumes a posterior pelvic tilt when sitting, anterior tilt of the seat may facilitate trunk extension. Hence the seat-to-back angle is increased or *opened*. For children with increased muscle tone, a seat with a posterior tilt, in which the front edge is relatively higher to the back edge, may reduce extensor spasms and enable a proper seated position. In this case, the seat-to-back angle is reduced or *closed*.

Arm and Hand Function

Wedging the seat did not improve functional hand function in children with marked extensor spasticity,[14] nor did it increase shoulder horizontal adduction movement time to trigger a switch in children with CP.[15] Movement time was fastest when children were positioned with their hips in a 90-degree position compared with in a wedged position and slowest with a hip angle of 50 degrees. When the hips were maintained at 90 degrees of flexion but the entire system tilted posterior 15 degrees or 30 degrees or anterior 5 degrees, performance on the shoulder adduction task was best in the upright position and worst in the anterior position.[14] Infants with neuromuscular impairments demonstrated improved posture and some improved arm use with contoured foam seating systems.[59]

Oral-Motor, Speech, and Communication

Very young children with impairments in multiple systems demonstrated improvements in oral-motor control during eating and drinking when positioned in individualized therapeutic seating devices; however, self-feeding and independent drinking did not improve.[14,34]

Mobility

Researchers have examined the effect of seating position on manual wheelchair propulsion.[14,31,58] Altering seat height, seat inclination, or anterior-posterior orientation for individual subjects improved upper extremity movement and wheeling efficiency. An individual's propulsion was optimized by adjusting the seating configuration in relation to the rear wheel position.[58] Additionally, an appropriate seating system and mobility base can decrease secondary complications and increase participation in the community and workplace.

Social Participation

Families reported increased social participation after their children or adults received adaptive seating equipment that included wheelchairs, travel chairs, and strollers, with custom adaptations as needed.[35] Changes reported following implementation of adapted seating and mobility included increased

ability to sit upright without leaning, more time spent in sitting and less time lying down, increased ability to grasp an object, and improved ability to eat with a spoon. Changes in social behavior reported included an increase in the number of community places visited and more time during the day spent with someone else.

Summary of Research Evidence

The variability in subject characteristics and responses support individualized decision making and the importance of postural support system simulation.[14,58] Research suggests that seating systems that provide external postural support improve pulmonary function in children with CP, reduce scoliosis when combined with a soft orthosis in children with muscular dystrophy, improve arm function in children with CP, and improve oral-motor skills, vocalizations, and social interaction in children with multiple disabilities.[14,58] More specifically, upright orientation is associated with decreased activity of extensor muscles in children with CP, improved pulmonary function in children with muscle weakness, improved upper extremity performance on a shoulder adduction task in children with CP, and an increase in adult-initiated interactions with students who have profound physical and cognitive impairments.[14,58]

Evidence of the effectiveness of an anterior tilted seat is inconclusive.[14] Previously it was thought that anterior tilted seats increase back extension and improve spinal alignment and upper extremity function; however, research has not supported this assumption. Current clinical thinking is that a neutral pelvic position is desirable.

There is evidence that contoured cushions improve pressure distribution as well as spinal support and posture.[59] The effectiveness of commercially available pressure relief cushions is variable; however, most manufacturers include blocks, foam pieces, or other additives to provide custom-contouring of their products.

Summary

Research is needed to identify the features and components of postural support systems that reduce impairment, improve activity, and increase the social participation of individuals with severe physical impairments.[58] More consistent reporting of the specific disorders and severity of impairments is necessary.[58] The impact of AT clinics and programs on the cost of health care has not been determined. Potentially, AT can reduce costs of hospitalizations due to secondary complications. In some cases, the cost of AT and vocational training may increase a client's employability but reduce his or her eligibility for Medicaid or other supplemental assistance. Regional centers that provide comprehensive and coordinated services may be the most effective way to deliver advanced technology to the greatest number of people; however, rural mobile vans may promote a broader range of access.

Principal Concepts in the Prescription of Seating Systems

Assistive seating technology is evolving rapidly, creating a confusion of terminology. RESNA has published a list of standardized terminology that is helpful in improving communication among research and service centers, professionals, clients, and funding sources.[31] It is imperative that the AT team possess knowledge of what components will accomplish child and family goals. If an inappropriate system is recommended, the child/user may lose function and experience secondary musculoskeletal impairment, and financial resources may not be available for a new system.[14,58]

Examination and Evaluation

As part of the process of selecting a seating system, the physical therapist examines the child and evaluates the findings. The physical therapist applies knowledge of anatomy, kinesiology, biomechanics, and principles of neuromuscular control of posture and function when examining the child. Knowledge of biomechanics and movement are essential for assessing and recommending a therapeutic seating system.[14] The child is examined in both supine and sitting positions. ROM measurements at the hips, knees, ankles, trunk, shoulders, elbows, and wrists/hands are part of the examination process. Muscle tone and muscle strength also are examined. Anatomic linear measurements are taken. Precise measurement and documentation will help to determine the most appropriate size and type of the seating system, as well as assist in writing letters of medical necessity to third-party payers. Accurate documentation over time provides valuable information regarding a child's growth and development.

Pelvic alignment and an erect trunk are essential for optimal head control and arm and hand function. For many children, an erect trunk posture is achieved through neutral pelvic alignment. The assessment of posture in a seating system begins with the pelvis and its relationship to the trunk and lower extremities.[14,58] The orientation and range of mobility of the pelvis in all three planes will determine the alignment and support needed at the trunk, head, and extremities. The effect of hip flexion and knee extension ROM on the vertical orientation of the pelvis is among the most critical factors in selecting seating angles and components. If there are minimal contractures of the hamstrings, hip extensors, and hip flexors, passive mobility of the pelvis should be sufficient for vertical alignment of the trunk. If muscles are shortened, the pelvis may be immobile in either an anterior or a posterior tilt, or obliquity, and the child will require a more individualized solution.

Figs. 33.3 to 33.6 illustrate the linear measurements used to design and prescribe a well-fitting seating system. Measurements

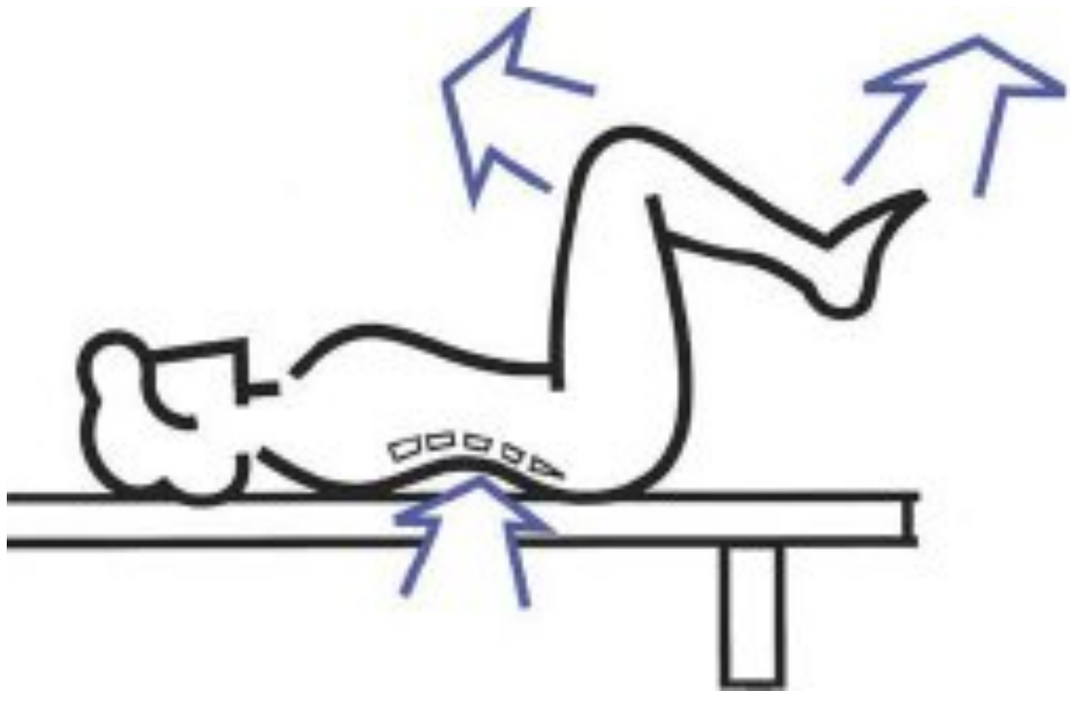

FIG. 33.3 The examiner must monitor the lumbar curve as the hips are flexed and the knees extended. (Redrawn with permission from Bergen AF, Presperin J, Tallman T: Positioning for function: wheelchairs and other assistive technologies, Valhalla, NY, 1990, Valhalla Rehabilitation Publications.)

taken with the child positioned in supine include hip and knee angles, thigh/hip length (Fig. 33.3), and calf length (Fig. 33.4). Measurements taken with the child sitting on a surface with a thin top and with feet supported, not dangling, are illustrated in Fig. 33.5. Measurements taken with the child in sitting include behind hips to popliteal fossa, popliteal fossa to heel, knee flexion angle, sitting surface to pelvic crest, sitting surface to axilla, sitting surface to shoulder, sitting surface to occiput, sitting surface to crown of head, sitting surface to hanging elbow, width across trunk, depth of trunk, width across hips, and heel to toe (Fig. 33.6).

Type and severity of deformity will influence selection of the seating system and components. Vertical and symmetrical head and trunk alignment can often be obtained for a *flexible deformity* (one that can be manually corrected and maintained with a reasonable amount of force) with the appropriate support components. In contrast, *fixed deformity* (one that is not correctable without an undue amount of force) and severe joint contractures must be accommodated in the seating system. Seating systems are not intended to lengthen tight musculature or correct bony deformity. Efforts to do this invariably will compromise achieving the desired posture because the child will attempt to move and avoid the uncomfortable forces.

In the case of a fixed deformity, the seating system will accommodate and support the deformity. The back cushion can support the trunk in neutral alignment or in an alternative posture if there are fixed trunk asymmetries. For children with severe scoliosis and pelvic obliquity, neutral alignment of the pelvis is not always possible and does not result in acceptable trunk and head alignment. In such cases, it is better to start with a relatively vertical head and level shoulders and allow the pelvis to be tilted and rotated.

If a child is unable to be positioned with the hip flexed to 90 degrees, the seat-to-back angle will be determined based on hip ROM. In another scenario, if the child sits with the hips adducted but can achieve neutral hip alignment, the seating

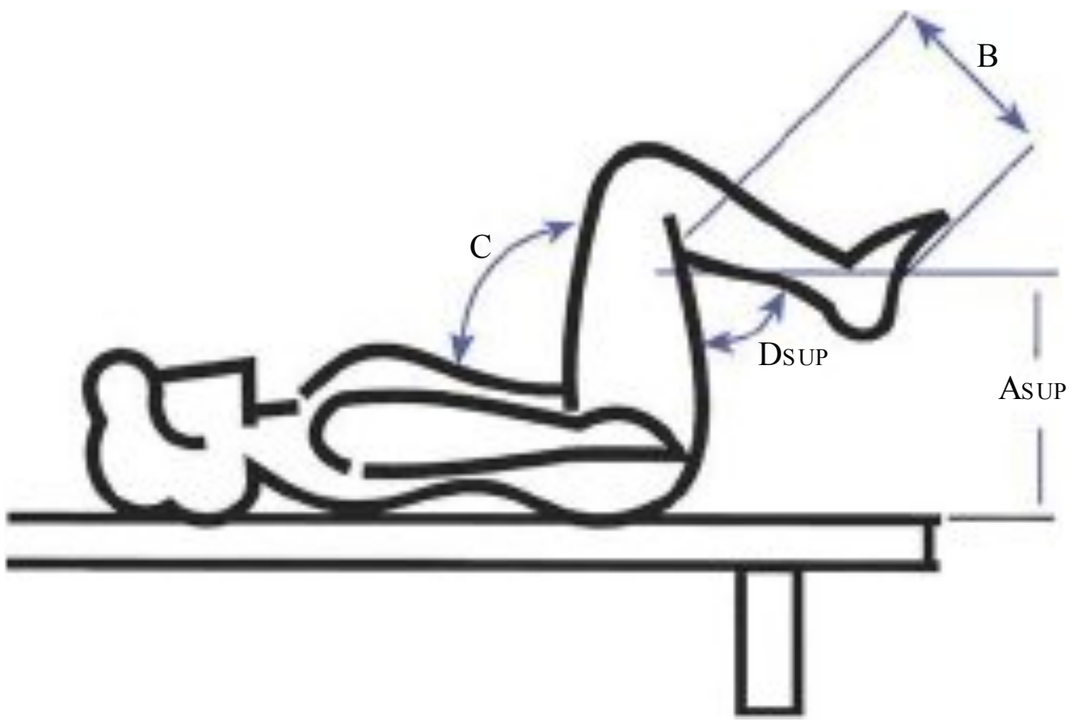

FIG. 33.4 Hip (C) angle, knee (D_{sup}) angle, thigh/hip (A_{sup}) length, and calf length (B) are measured first in supine. (Redrawn with permission from Bergen AF, Presperin J, Tallman T: Positioning for function: wheelchairs and other assistive technologies, Valhalla, NY, 1990, Valhalla Rehabilitation Publications.)

FIG. 33.5 Measurements in sitting must be taken with the client sitting on a surface with a thin top. This will allow the knees to flex as needed. (Redrawn with permission from Bergen AF, Presperin J, Tallman T: Positioning for function: wheelchairs and other assistive technologies, Valhalla, NY, 1990, Valhalla Rehabilitation Publications.)

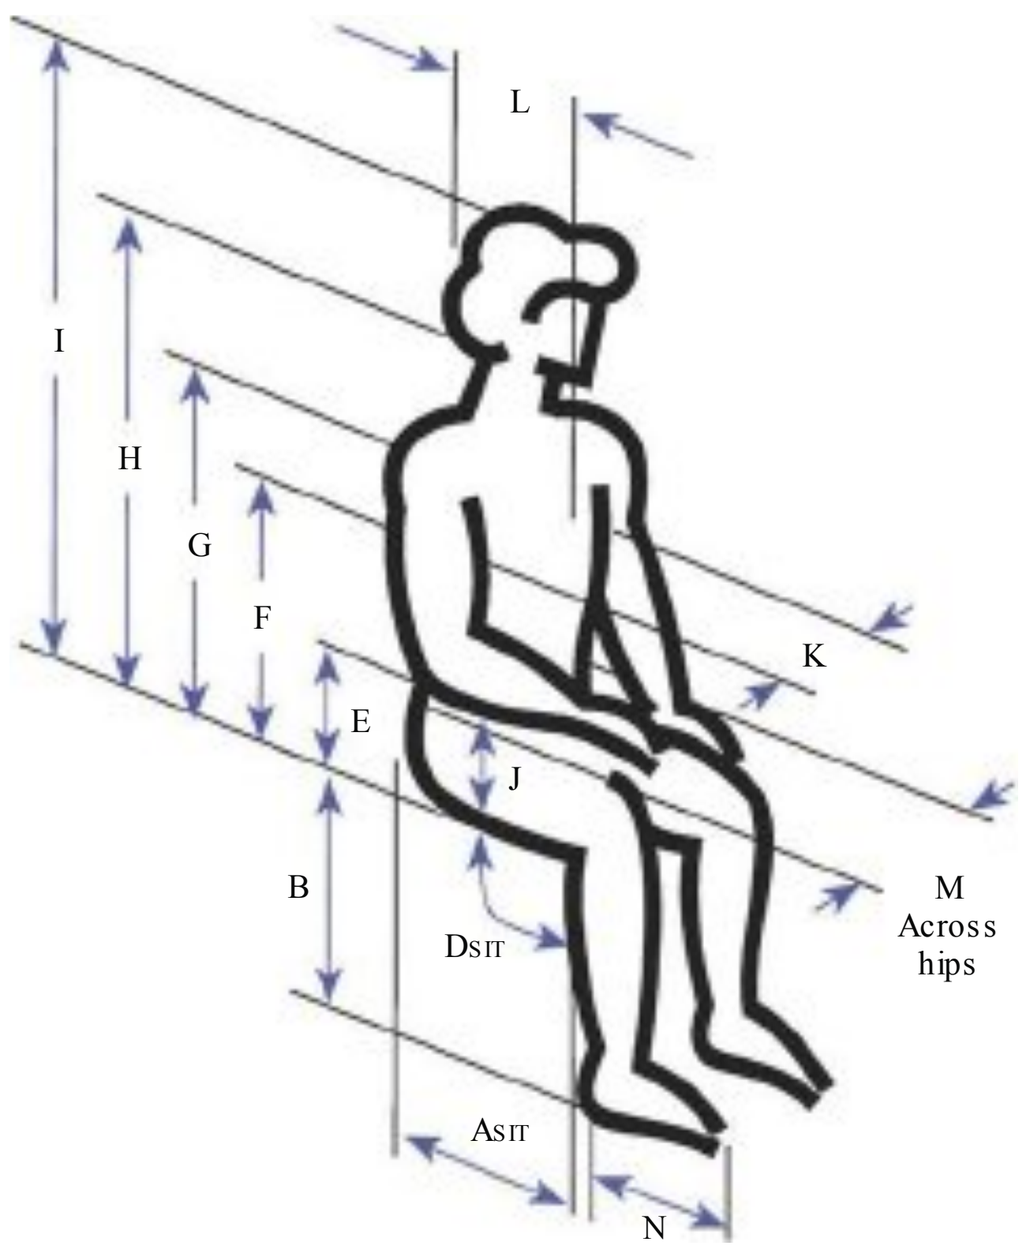

FIG. 33.6 The following figure measurements are added to those taken with the client in supine: A_{sit}, behind hips to popliteal fossa (right and left); B, popliteal fossa to heel (right and left); D_{sit}, knee flexion angle; E, sitting surface to pelvic crest; F, sitting surface to axilla; G, sitting surface to shoulder; H, sitting surface to occiput; I, sitting surface to crown of head; J, sitting surface to flexed elbow; K, width across trunk; L, depth of trunk; M, width across hips; N, heel to toe. (Redrawn with permission from Bergen AF, Presperin J, Tallman T: Positioning for function: wheelchairs and other assistive technologies, Valhalla, NY, 1990, Valhalla Rehabilitation Publications.)

system can hold the hips in an abducted position, or positioning components can be added to the seat to prevent adduction. Conversely, if the child has a tendency to maintain hips in extreme abduction, lateral supports can be used to position the lower extremities in a more neutral alignment. If knee ROM is limited, 60-degree hangars, instead of 90-degree hangars, may be used to accommodate for the loss of range. Modifications or supports are also used to accommodate for lack of ROM in the upper extremities.

In children at risk for skin breakdown, measurement of seat and back interface pressures should be included in the examination process. Pressure mapping systems are increasingly common in the clinic for comparing pressures while seated on various cushions. Variable-tilt and variable-recline features of manual and power wheelchairs can provide another source of pressure relief throughout a long day of sitting for some children.

Matching the Seating System With the Child's Needs

Seating systems and extrinsic positional components typically are classified into three levels: planar or linear, generically contoured, and custom molded/custom contoured. The first and least intensive level is the planar or linear system, which consists of a flat seat and back (Fig. 33.7). Children with good postural stability and sitting balance, a minimum of deformity, are most appropriate for this seating system. The seat and back consist of a solid base (plywood or high density plastic), covered by foam, and upholstered with vinyl or a fabric that stretches in all directions (e.g., Lycra or Dartex.) Trunk and pelvic supports may be added laterally. Many commercial linear systems are available, or a linear system can be constructed in the clinic. This system is easily changed and adapted and it is typically the least expensive.

The second level is the generically contoured or modular system, which provides external postural control by increasing the points of contact, especially laterally (Fig. 33.8). The seat and back surfaces are rounded by shaping layers of foam, air, or a viscous fluid to correspond to the curves of the body. Contours also help distribute pressures more evenly over the entire seat or back surface. A small amount of contouring often improves comfort and stability. A greater amount of contouring is often necessary for children with severe impairments. Today, nearly all generically contoured components are commercially available. Some generically contoured or modular systems include built-in growth capabilities for children.

The third level is the custom-contoured/custom-molded system. It provides an intimate fit by closely conforming to the shape of the child's body, thereby giving the most postural support (Fig. 33.9). Theoretically, when properly fabricated, the custom-molded system provides the greatest amount of pressure relief because it offers the greatest amount of contact surface area. The time and expense involved in the fabrication of custom-molded systems are considerable, and the molding process requires a great deal of skill. Production of the mold can involve a chemical reaction of liquid foams injected into a special bag, a vacuum consolidation method, or a computer digitization method. Several custom-molded systems are available, including those that can be completed on site and those that are sent to a central fabrication center.

Computer-aided design technology by mapping and digitizing body shape data directly using an instrumented simulator eliminates the need to make a mold. Information is transferred to a computer-driven carving machine that

produces the cushion. Typically, custom-molded systems do not allow for growth and cannot be modified. Additionally, if a child is not positioned properly within the molded cushion, pressure spots can develop and cause breakdown of underlying soft tissue.

In summary, the general rule of thumb in selecting a system is that less is better. If a child can control his or her head and trunk without supports or the use of minimal supports, has no history of skin breakdown, and can achieve independent pressure relief, a linear/planar seating system is generally acceptable. However, if the child cannot maintain proper positioning with supports and has a history of skin breakdown or is at risk for skin breakdown, a generic contour/modular seating system warrants consideration. Linear and generic contour systems can be changed and modified without great difficulty. The child with extensive positioning needs or who is at high risk for skin breakdown may benefit from a custom-molded seating system. The custom-molded systems are not adjustable or modifiable, so clinicians must take into account growth and musculoskeletal changes that may occur. Often, a hybrid system is recommended. The hybrid seating system includes components from different categories; for instance, a system might consist of a planar seat with a generically contoured back or a back that is custom molded exclusively along the paraspinal area and left flat on the periphery, which allows for the addition of adjustable lateral trunk supports.

Selection of a Seating System

The scope of this chapter and the rapidly evolving nature of technology preclude a thorough discussion of all options and features of postural support systems. Many excellent resources provide detailed descriptions, problem-solving lists, and charts.[14,44] Regardless of the level of postural support required, there are several important considerations to keep in mind. This section presents some of the most salient points in the decision-making process.

Seat cushions.

The seat cushion is often the most critical element of the seating system. The seat cushion can be classified into the three previously mentioned categories: linear/planar, generically contoured, or custom contoured. The use of true planar seats is becoming less common because most therapists have found that a small amount of lateral contouring adds comfort and stability.[14] A number of commercially available cushions that include air or viscous fluid for pressure management have foam blocks and wedges that can be integrated to allow customization of cushion shape. Strategically placing commercial viscous fluid pads in a custom-made, contoured foam cushion can provide the extra, critical amount of pressure relief needed by some children. In antithrust seats, a block of high-density foam placed just anterior to the ischial tuberosities prevents the pelvis from sliding forward and equalizes pressure distribution along the thighs (Fig. 33.10). Antithrust seats can be added to planar as well as contoured systems, but they are thought to work best with deep lateral contours of the pelvis and lateral thigh supports (adductor pads).

Seat placement within the wheelchair frame is an important consideration. A thick cushion or inappropriate mounting hardware can place the seat too high and alter the child's center of gravity. This might reduce head and trunk stability and loss of independent transfers or wheeling. Forward or backward placement, especially in small children, can affect the knee angle required for foot placement on the footrests, access to the wheel rims for wheeling, and loading or unloading the front casters. For individuals who propel with their lower extremities, it is important to maintain a lower seat-to-floor height and a flat front edge of the seat cushion. These modifications relieve the pressure from the front edge of the seat and allow full knee flexion without irritating the hamstrings.

Back supports.

Back supports also fall into three categories: linear/planar, generically contoured, and custom contoured. A back support with a gently curved surface can improve lateral trunk stability, posture, and comfort. Simple contouring and

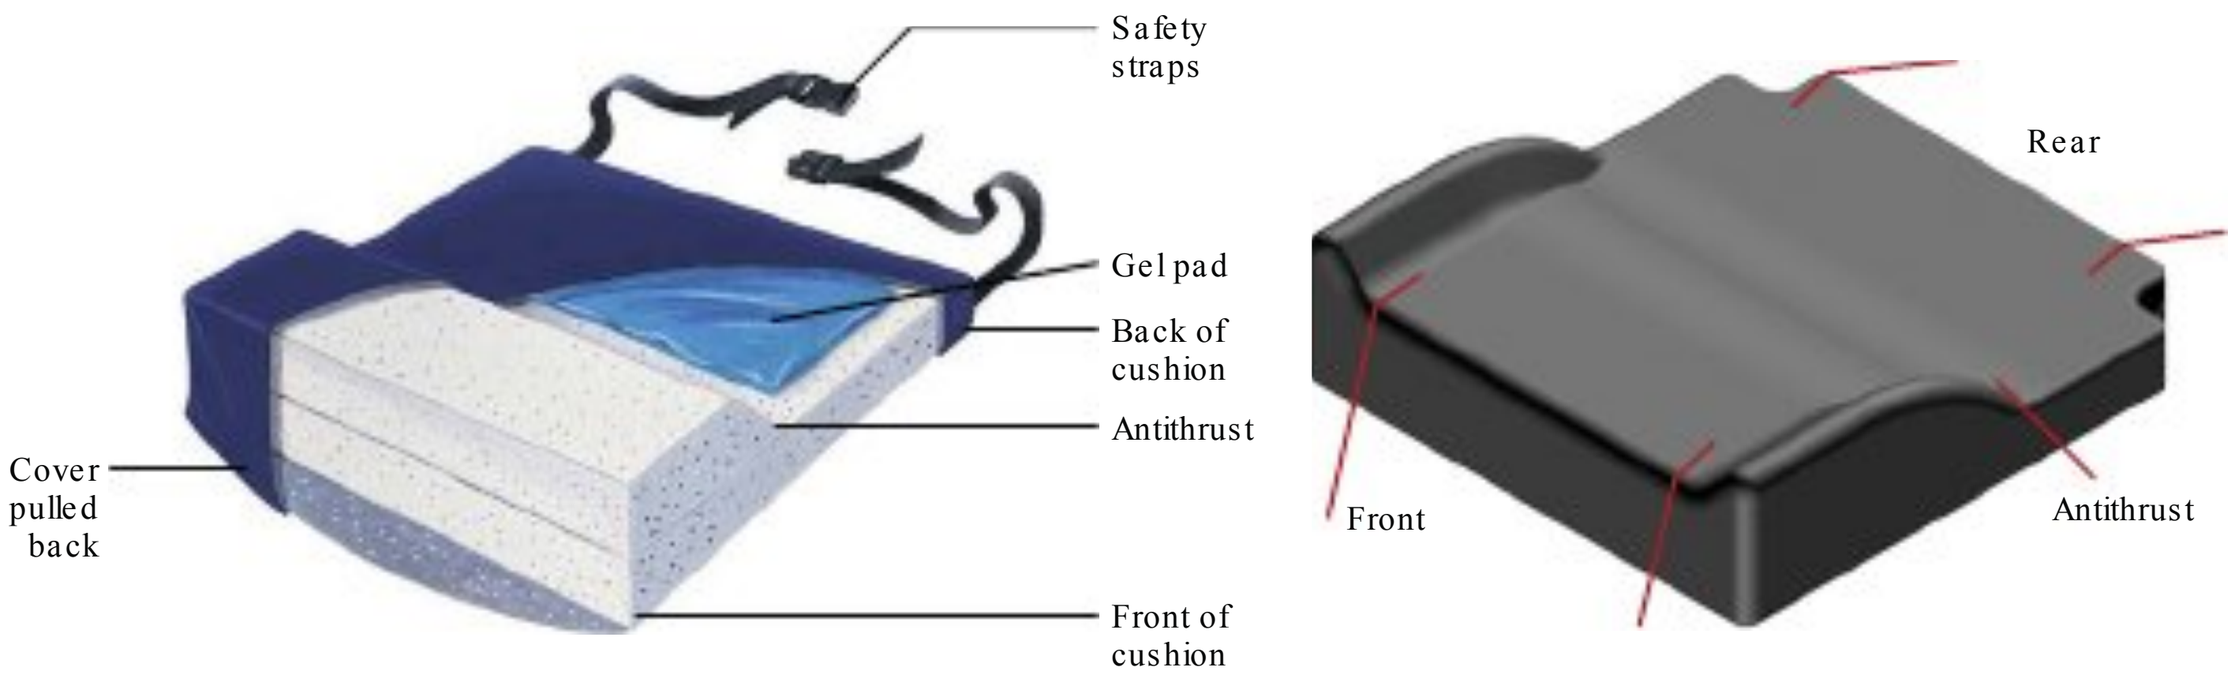

FIG. 33.10 An antithrust seat can help hold the pelvis back on the seat by blocking forward sliding of the ischial tuberosities (IT). (Left, Courtesy Skil-Care Corporation, Yonkers, NY; right, Courtesy Freedom Designs, Inc, Simi Valley, CA.)

lateral support can often be achieved within the integrity of the overall support. Many back supports are available with customized support options. More substantial contouring can be achieved using blocks/wedges of high-density foam. A custom-molded back should be considered for children with severe fixed spinal deformity. Some children who need contact and support along the paraspinal muscles, but who are still growing, benefit from a hybrid back support. A custom-molded back support can be contoured along the paraspinal region and then flatten laterally. Linear lateral trunk supports are then added to the contoured back. This allows for growth and maintains support along the spine.

Alignment of the spine in the sagittal plane has traditionally been adjusted using lumbar rolls; however, control of sagittal curves begins with the pelvis and sacrum rather than the lumbar spine.[14,58]

Pelvic stabilization. Techniques to improve pelvic control are largely a matter of clinical opinion and user preference. A pelvic support placed at a 45-degree angle at the seat-back junction is the most typical form of pelvic stabilization. Placement of the belt across the anterior thighs, just in front of the hips, allows more natural active trunk and pelvic mobility.[14,58] The pelvic positioning belt can use a two-point attachment system or a four-point attachment system. The four-point system allows for more control of pelvic alignment and greater distribution of pressure (Fig. 33.11). The subanterior superior iliac spine (sub-ASIS) bar is a form of rigid pelvic stabilization consisting of a padded bar attached to mounting plates lateral to the pelvis.[13] The pelvis must be maintained in a vertical orientation or the child will slide under the bar. Dynamic pelvic stabilization is achieved through the use of contoured pads that are placed around the pelvis, with a pivot mechanism allowing anterior-posterior tilting of the pelvis without loss of stability.[14,58] Adjustments are made to accommodate the deformity, control of direction and amount of tilting, and exert a dynamic force to return the pelvis to a neutral position.

Angles. There is no consensus as to the effects of seat and spatial angles on alignment and function. Factors to consider in determining seat angle include severity and type of impairment in muscle tone, joint contractures, skeletal deformities; postural control in sitting; and design and purpose of the mobility base. Although the concept of upright 90-90-90 sitting is theoretically sound, it may not always be the best option. Slight anterior wedging of the seat may improve head alignment or keep very young children from sliding. Opening the hip angle (tipping the front seat edge) may be necessary when hip extension contractures are present. Allowing the knees to flex reduces the rotation force on the pelvis, minimizing the effect of tight hamstrings.

A seat with an anterior tilt has potential benefits for children with lower extremity muscle hypoextensibility but fair-to-good upper body control who "sacral sit" on a flat surface. A seat with an anterior tilt in a forward-lean position with a solid anterior chest support is also used for children with severe impairments. Good pelvic stabilization must be achieved to prevent sliding.

Variable seat-to-back angles allow adjustments of tilt and recline throughout the day. Tilt is useful for relieving pressure or trunk or neck fatigue, and it provides a combination of active sitting and rest positions. When in a tilt system, the seat-to-back angle does not change. Recline is useful for relief of fatigue, for hip or back pain, and if catheterization or other hygiene procedures must be performed in the chair. In a reclining seating system, the seat-to-back angle changes as the reclining position changes.

Dynamic or compliant seating systems are used for clients with severe and abrupt extensor spasms. Often the severity of tone or spasms is exacerbated by the rigidity of a conventional system. Dynamic or compliant devices use hinges, pivot points, and springs to allow movement of the seat or back with the child and provide a gentle returning force. Clients who used these systems exhibited a decrease in the severity of spasms or fluctuating tone over a period of weeks; comfort and ease of transfers also improved.

Upholstery. Upholstery for the seat cushion and back support can be made out of a variety of materials and is an important feature of the seating system. When choosing a covering, consideration must be given to whether the child is incontinent, if the child is typically hot, whether the child has allergies to specific fabrics, and who will care for the coverings. A fabric with a two-way stretch is ideal to allow for full benefit of the seat cushion and back support materials. Vinyl is a durable cushion covering; however, it can be hot and slippery and typically cannot be removed from the seating system. In addition, it is a very stiff fabric. As such, it typically does not allow for the full

FIG. 33.11 A, Two-point pelvic belt. B, Two-point pelvic belt attached to seating system. C, Four-point pelvic belt. D, Four-point pelvic belt attached to seating system. (A and C, Courtesy Adaptive Engineering Labs, Milwaukee, WI. B, From Cook AM, Polgar JM: Assistive technologies: principles and practice, ed 4, St. Louis, 2015, Mosby.)

benefit of using different density foams or viscous fluid layers. Synthetic knit fabrics with waterproof backing are also a popular choice of covering. They are less slippery, thus decreasing shear, and can be removable for easy cleaning. Ideally, a child should have at least two sets of cushion covers, thus allowing one to be laundered while the other is being used.

Front riggings. Although a component of the mobility base, front riggings, or leg supports, are discussed in this section because of their direct influence on the entire seating system. Elevated leg rests are offset forward of the seat more than nonelevating leg rests and can contribute to forward sliding on the seat or poor positioning of the feet for weight bearing. Elevating leg rests should be ordered only when required, for instance, to control dependent edema or when the lower extremity is immobilized. Selection of footrests on small, pediatric chairs is often challenging because they may interfere with caster movement. Footplates that extend backward under the seat are helpful when clients have tight hamstrings. Footplates can be positioned parallel to the floor or angled to match foot/ankle position. Shoe holders and foot straps hold the feet in the desired location to assist with lower body stability and weight bearing. For clients with deformity or limited joint movement, forcing the foot into neutral alignment on the footrest may impose undesirable stresses at the knees or hips. Children who are able to make postural adjustments during weight shifting and actively place their feet should not have their feet constrained. If the child is able or learning to transfer independently or actively assists in a sit-to-stand transfer, the front riggings and footplates should swing out to the sides. The child whose seating system has tapered front riggings and a fixed footplate will transfer by either stepping over the footplates or stepping onto the footplates and then stepping down. Alternatively, children carefully lower themselves onto the footplate and transfer from there.

Lateral and medial supports. Lateral trunk supports vary from simple, flat, padded blocks to contoured, wraparound supports. Swivel or swing-away mounting hardware allows the wraparound supports to fit properly, especially with varying seasonal clothing. In addition, the child is able to transfer into and out of the seating system without interference.

Contoured seats typically provide the most effective lateral thigh and pelvic support, as well as good pressure relief. Square or rectangular pads used as lateral thigh supports can maintain position of the legs and allow for growth. Medial thigh supports

(abductor wedges or pommels) maintain hip alignment in neutral or slight abduction but do not stretch tight adductors or prevent forward sliding of the pelvis. Removable or swing-away pommels facilitate transfers and urinal or catheter use.

Anterior supports. Anterior trunk supports are designed to maintain the spine erect and upright over the pelvis. Anterior support can be gained via an H-harness or horizontal anterior chest strap. Butterfly-shaped supports should be used with caution as they present with extreme safety hazards. Typically, the lower straps are secured to the wheelchair seat frame or the back support itself. Then, the upper straps are used to adjust the tension of the fit, preventing the pad from sliding upward to the neck. Padded axillary straps, sometimes known as *Bobath straps* or *backpack straps,* also help maintain the trunk in an upright posture. They attach to the underside of the lateral thoracic support, are directed superiorly and medially over the front of the axilla, and attach at the top of the backrest, controlling shoulder protraction without crossing the chest. Trefler and Angelo[116] reported that the type of anterior chest supports used by children with CP did not influence performance on a switch activation task. They concluded that style of anterior chest support should be based on the child's needs and preference.

Headrest. Facilitating good head position in children who have poor voluntary control is challenging. In children with limited postural control, poor head positioning can make an otherwise effective postural support system fail. On the other hand, barium swallow studies suggest that some clients with the most severe physical and cognitive impairments may need to adopt a forward-hanging head position to cope with increased oral secretions or reflux.[12] For such clients, supporting the head in a position that "looks good" may increase the risk of aspiration or choking.[12]

Support under the occiput provides better head support than a flat contact on the back of the head. A pad with an occipital ledge and contoured head supports is available in several options. Some head supports can include a static or dynamic forehead strap to assist in maintaining an upright head position. Care must be taken that the head support does not unduly block the child's peripheral vision. Head supports can be the ideal mounting location for switches that control other AT such as augmentative communication systems.

Upper extremity supports. Trays are a common type of upper extremity support and can be designed for a multitude of special purposes. Posterior elbow blocks help to reduce the tendency to retract the arms and maintain the upper extremities in a forward position. Clients with severe dystonia often prefer wrist or arm cuffs to reduce unwanted movement of one or both arms.

WHEELED MOBILITY

The purpose of the mobility base depends on the child's level of function. For some, the primary purpose will be independent mobility, and the team must determine how best to achieve this. For others, the purpose of the base is to provide a means of being transported by a caregiver, and this must be accomplished in a safe, comfortable, and efficient manner. In either case, the base serves the additional role of supporting the seating system. Selection of a mobility base requires consideration of the seating system, the child's lifestyle, and the physical features of the environments in which the system will be used. Examination and evaluation for a new mobility base should be done concurrently with simulation for the postural support system, because the success of the entire system depends on all of the parts working together.

Excessive energy expenditure during locomotion is a common impairment of people with movement dysfunction. Persons with physical disability who walk with decreased speed and require an assistive device or who manually propel a wheelchair may prefer power mobility to reduce energy expenditure. Children with CP were reported to walk at nearly half the velocity of children without disability and consume more oxygen per kilogram of body weight per minute when walking.[7] Wheeled mobility is a more efficient mobility method than walking with braces and an assistive mobility device for children with myelomeningocele. Fifty percent of children with myelomeningocele who were ambulatory with braces stopped walking between ages 10 and 20 years.[49] Ambulation was 218% less energy efficient for children with myelomeningocele compared with children without disability. Children with muscle control at the L2 level or above expended energy equal to their maximal aerobic capacity when walking at slow speed, whereas children with muscle control at L3-L4 used 85% of their maximal aerobic capacity.[14] In contrast, wheelchair propulsion required 42% less energy than crutch walking at the same speed. Oxygen consumption during wheelchair propulsion was only 9% greater than the oxygen consumption of children without disability during walking.[49] Energy expenditure and speed of mobility during wheelchair propulsion of children with myelomeningocele were efficient and as fast as walking in children without disabilities.[44a] Fatigue associated with excessive energy expenditure during locomotion may adversely affect academic performance.[7] Academic performance (reading fluency, visual motor accuracy, and manual dexterity) was measured in three students with myelomeningocele attending middle school who alternated propelling their wheelchair or walking with assistive devices throughout the school day. Visual motor accuracy decreased for all three subjects when they walked. Manual dexterity decreased on days walked for one subject, and reading fluency did not change for any of the subjects.

Many factors affect the ability to manually propel a wheelchair, including physiologic capacities, such as strength and endurance, which are dependent on the user's diagnosis, age, sex, lifestyle, and build.[14,42,58] The position of the individual within the wheelchair, particularly in relation to the position of the rear wheels and access to the hand rims, determines the mechanical advantage of the user to propel the chair. Wheelchair factors that affect mobility are rolling resistance, control, maneuverability, stability, and movement dynamics. These factors are dependent on the quality and construction of the wheelchair, such as weight, rigidity of the frame, wheel alignment, mass distribution, and suspension. Wheelchair propulsion in children with spinal cord injury was similar to that in a neurologically matched group of adults.[54] The adults wheeled faster, but the children spent a similar proportion of the wheeling cycle in propulsion, and the angular changes in the kinematics of the elbow and shoulder were the same for both groups. Therefore, methods used to improve wheeling efficiency in adults may be applicable to children.

Self-mobility has important implications for development. The infant's experience with independent mobility impacts on perceptual, cognitive, emotional, and social processes.[42] For children who lack mobility, early provision of mobility aids has the potential to enhance development of spatial, cognitive, affective, and social functions. Prone scooters, caster carts, and

walkers are alternatives for some young children with sufficient arm strength. For the child with more severe involvement, early power mobility offers the best choice and allows the child to increase his or her self-initiated movements during play.[16]

Historically, power mobility was considered a last mobility option put off until children reached their teens, when all attempts at effective ambulation were exhausted. Power wheelchairs were considered too expensive and too difficult for young children to learn to drive, and walking was too important a goal to give up. Research does not support this perspective. Studies indicate that children as young as 24 months can successfully learn independent power mobility within a few weeks.[9,24] A comprehensive evaluation is necessary to determine if a child is appropriate for powered mobility. The performance characteristics of the power base must be matched with the child's intended use, lifestyle, and comfort as part of the selection process.[46] The assessment should include an informative intake and a preliminary examination including an assessment of the child's performance in natural environments. Factors that influence a child's success or failure with power mobility include cognition, behavior, motor control, funding, family support, and transportation.[24] Benefits associated with power mobility include an increase in self-initiated behavior, including change in location, rate of interaction with objects, and frequency of communication.[46] Benefits to social participation that have been reported are increased peer interaction; increased interest in other forms of locomotion, including walking; increased family integration such as inclusion in outings; and decreased perception of helplessness by family members.[19] Major factors affecting performance of powered mobility were cognition, motor ability, driving as an activity, technology features of the mobility device, features of the environment, and a combination of these factors.[42] Instruction and training are important considerations in making decisions about power mobility devices for children. Inexperienced drivers improved their overall driving performance after simulator training.[46]

An interdisciplinary US Wheelchair Standards Committee, administered through RESNA and approved by the American National Standards Institute (ANSI), has produced a document on wheelchair standards. The standards represent a comprehensive approach to testing and disclosing information about wheelchairs. Manufacturers, suppliers, and consumers can use this information to improve their products, select chairs with the best performance for the cost, and identify chairs that meet performance needs.

Selection of a Mobility Base

The goal in selecting a mobility base is to provide an appropriate and efficient means of getting from one location to another. It is inappropriate to require someone to rely on his or her everyday mobility for exercise. Prohibiting children with limited ability to walk from using a manual wheelchair and children with limited ability to self-propel a wheelchair from using power mobility may compromise functional and academic performance due to excessive energy expenditure. A creative and structured fitness program is a more appropriate way of addressing strength and cardiovascular endurance goals.

It is generally agreed that the child's positioning needs are the most important factor when selecting a mobility system. At the same time, the design of the seating system should maximize potential for independent function in the wheelchair. This, in turn, influences chair modifications and the interface hardware needed. For example, if a 3-inch thick modular foam seat cushion is necessary for positioning and pressure relief, yet the child has short extremities, as in myelodysplasia, both independent transfers and wheeling may be more difficult. A possible solution is to order a chair frame with a lower seat-to-floor height and without sling seat upholstery so that a solid seat board with drop brackets can be used to lower the cushion between the seat rails.

To assess driving skills and controller placement, a supportive trial seating system must be attached to a power base for evaluation. An attendant-held control can override the user's control, ensuring safety and appropriate feedback during assessment and training. The child should be provided the opportunity to test a variety of bases with appropriately simulated postural support.

The first step is to determine the type of mobility base desired. Mobility bases for children include strollers, manual wheelchairs and power wheelchairs. Manual wheelchairs can be configured for independent mobility (self-propulsion) or dependent mobility (another person pushes the chair) depending on the child's needs and abilities. Ideally, the selection is based on the potential level of independent mobility. However, other considerations that are often equally as important include the type of housing, method of transportation, availability of training or supervision, and availability of funding.

Once the mobility base is chosen, the next consideration is the style of the base. Within each type, there are several styles with different features and performance characteristics. Factors that influence this choice are the level and type of seating system required, the level of independence in transfers and ADLs, the environments in which the chair will be used, the method of transportation, and the needs of caregivers.

The size of the mobility device is based on the child's physical size, expected growth, the capability of the chair to accommodate growth, and the size and style of the seating system. Mobility bases designed for children are available in a variety of sizes and designs. The ability of mobility bases to expand and accommodate physical growth has improved as funding sources have demanded longer life from purchased items.

A final consideration is the model and manufacturer of the chair. Often the details of construction are important at this stage, such as the dimensions (seat width and depth) of the chair, angles, orientations, adjustability of parts such as footrests and armrests, and swing-away, detachment, or folding mechanisms. Other important factors are performance characteristics, styling, comfort, durability, availability of parts, service record, and cost. Regional preferences for various models and manufacturers are evident across North America.

Strollers

Stroller style mobility bases are appropriate for infants (0–3 years of age) and often preschool-age children (3–5 years of age) primarily because their designs are very similar to regular baby strollers. Basic models include sling seat and back upholstery with a 5-point safety harness (Fig. 33.12A). Models designed for the children with greater physical limitations include a supportive seat and back system along with a variety of positioning components that can be integrated to provide additional positioning support (Fig. 33.12B). These models also include an adjustable push handle that allows the child to face toward or away from the caregiver. For infants and young children, a stroller style mobility base is socially acceptable, is easy to fold

FIG. 33.12 A, Ottobock Kimba stroller base with modular positioning components. B, Ormesa Bug seating system on stroller base (jogger base and high-low base also available). (A, Courtesy Ottobock Rehab, Austin, TX. B, Courtesy ORMESA S.r.l., Foligno, Italy.)

for transport in an automobile, and is not perceived as medical equipment. By virtue of the design, stroller mobility bases include storage areas that can be used for items such as ventilators or suction equipment. In addition, some designs include the option of removing the seating system and attaching it to a high-low base for use in the home as a highchair and a floor sitter (Fig. 33.12C). Disadvantages of this style base are that it is not designed for independent propulsion and the child is not always at peer level. Also, for the 4- or 5-year-old, this style base can look childish, causing the child to appear younger than peers of the same age.

When selecting a mobility base for a stroller, it is imperative to consider the parents' preferences, as this can be an emotional decision. Consideration must also be given to how this base will transition with the child into a school-based program and be secured on school bus transportation. Strollers are considered a mobility device. Families and providers need to be cautious when using insurance dollars to purchase a stroller base, as this may impact coverage for a manual wheelchair within 5 years.

Manual Wheelchairs

The standard manual wheelchair has two large wheels, usually in back, for independent propulsion, and two small swiveling casters in front. Some models are specifically designed for the very young child (2–4 years of age) with low seat-to-floor heights to facilitate independent transfers along with wider tires that are easier for smaller hands to manipulate. In addition, the frame can be configured with the larger wheels in front instead of the back, often making it easier for young children to propel (Figs. 33.13A and B).

Pediatric styles often include designs and colors that are appealing to the young child (Fig. 33.13C). They can be configured for dependent mobility where a caregiver pushes the wheelchair or independent mobility where specific dimensions and features are critical to successful independent propulsion. For independent propellers, the 1980s and 1990s were the new age of manual wheelchairs when lightweight chairs and chairs designed for recreational use and athletic competition became widely available. Lightweight and durable metals and fabrics, alternative wheel placement, improved frame dimensions and designs, adjustability, and adaptability to custom seating have all helped streamline the manual wheelchair to improve efficiency and control, ease of transfer, portability, and appearance. For the very active person, ultra-lightweight, high-performance chairs incorporate rigid frames and lightweight materials for optimal performance. The serious athlete can find specialized designs dedicated to performance needs that barely resemble the traditional concept of a wheelchair (Fig. 33.13D).

One-arm-drive wheelchairs are designed for individuals with functional limitation in one arm that prevents bimanual propulsion (Fig. 33.14). The classic style is the double hand rim on one side, with a linkage system to the other wheel. Styles that use a pumping action with a lever and ratchet system, although rarely used, are generally easier and more effective for wheeling and steering but create more problems in dependent wheeling by caregivers. It is imperative for a child to have the opportunity to try this style of base during the assessment process. Manipulation of the dual rim requires requisite cognitive capability as well as good unilateral upper extremity control. It is also important to observe the efficiency of propulsion and the occurrence of additional movement patterns. For children with impairments in muscle tone such as CP, operation of a one-arm-drive chair may exacerbate existing asymmetry.

Manual tilt-in-space (also referred to as rotational systems) and recline features are available on manual wheelchairs. For some children, a fixed angle of tilt or recline can be incorporated into the design of the seating system and its attachment to the wheelchair. Although this angle is not easily changed, it can enhance function. For others, the ability to vary the amount of tilt or recline throughout the day is critical for functional and physiologic reasons. In these cases, tilt-in-space or recline is integrated into the wheelchair frame design

itself. Although the features have similar uses and benefits, it is important to note that they differ in design. Tilt-in-space frames maintain all seated angles throughout the rotational phase. This means that all positioning support achieved with the seating system components is preserved at all times. The angles at the hips, knees, and elbows remain constant while the weight is shifted off of the buttocks and thighs. Recliner frames incorporate the ability to change the seated angles by moving the wheelchair back canes backward in relation to the seat. This changes the hip and elbow angles while the overall weight is redistributed over a larger surface area. Seated pressures originally on the buttocks and thighs are now distributed

FIG. 33.13 A, Zippie Kidz in standard rear wheel. B, Zippie Kidz with reverse rear wheel configuration. C, Invacare MyOn Jr. pediatric manual wheelchair. D, Invacare TopEnd XLT Jr. handcycle. (A and B, Courtesy Sunrise Medical, Boulder, CO. C and D, Courtesy Invacare Corporation, Elyria, OH.)

FIG. 33.14 One-arm manual wheelchair. A, Rear view of one-arm drive linkage on manual wheelchair. B, View of double hand rims for one-arm drive manual wheelchair.

over the buttocks, thighs, back, and back of the head. Recliner frames often include elevating leg rests to provide an alternate lower extremity position as well.

Both features provide a change in position relative to gravity that can increase tolerance for upright positioning post surgical or post injury, maintain good skin integrity to prevent pressure sores and decrease fatigue and discomfort. To unweight the buttocks and thighs sufficiently, the frame must be tilted a minimum of 45° from level in a tilt system. Similarly, in a recliner frame, the back canes must be reclined a minimum of 30° from fully upright to achieve adequate pressure relief. In addition, these features can facilitate access into and within a wheelchair-accessible van where clearances can become an issue as the child grows.

Each feature, on its own, can add significant functional benefits. Tilt-in-space can be essential to assist with transfers into and out of the wheelchair as well as aid in repositioning, allowing gravity to assist the process. Recline can also assist with transfers, dressing, and bowel/bladder management. It also provides passive range of motion at the hips, elbows, and knees (with use of elevating leg rests). Understanding the design features and functions is essential to match the benefits with the child's needs. For example, it is important to know that the child's relationship to the seating components will change when using the recliner, making use of custom-molded seats and back supports or modular components with significant contours problematic and not advisable. In addition, the recliner frame can trigger the atypical movement pattern for a child with strong tone, having a negative effect on the child's function.

The current technology design uses a weight-shifting rotational system rather than a gas spring tilt system. The weight-shifting system maintains the user's center of mass within the wheelbase during the tilt phase, resulting in a more stable system when the child is not upright. The wheelbase in this design is shorter than its gas spring tilt predecessor (Fig. 33.15).

Power Mobility

Four categories of function have been described in children using power mobility.[9] The first category includes children who do not walk or have a means of independent mobility other than use of a power device. The second category includes children with inefficient mobility—that is, they walk or use a manual wheelchair but with speed or endurance that is not sufficient to accomplish daily activities and routines. The third category includes children who have lost independent mobility through disease, brain injury, or spinal cord trauma. For this group, the developmental implications of independent mobility may be less important, but the acceptance of assisted mobility is a major issue. The fourth category includes children who require assisted mobility temporarily. This includes young children who are expected to walk as they get older, children who are recovering from surgery, and children who are recovering from an injury or trauma such as a brain injury.

Advances in technology have brought independent power mobility to a greater number of individuals with more severe disabilities than ever before. A wide variety of power bases and options are available, with more reliable and precise controls than ever before possible. The three main types of power wheelchairs are the conventional design with integral seat and chassis (evolved from the traditional, tubular manual wheelchair frame, rarely seen today), the power base or modular design with separate seat and chassis (typical designs found today), and scooters with either three- or four-wheeled platforms. Power chairs may be ordered with seats that tilt, backs that recline, units that recline and tilt, and units with seats and leg rests that elevate, all with the touch of a switch. Manufacturers have responded to an increased demand for child-sized power wheelchairs by producing wheelchairs that are lighter in weight, correctly proportioned for children, and have growth capabilities. Major advances in electronics have produced a greater variety of controls that are easier to access, more durable, and easier to adjust and customize. Power chairs are available in rear-wheel, mid-wheel, or front-wheel drive options. Each provides a different

FIG. 33.15 A, Manual wheelchair with mechanical lock tilt-in-space mechanism. B, Manual wheelchair with weight-shifting, tilt-in-space mechanism. (A, Courtesy Invacare, Elyria, OH. B, Courtesy Sunrise Medical, Boulder, CO.)

sense of maneuverability. It is important that the individual have the opportunity to test-drive the different models before a final recommendation is made (Fig. 33.16A and B).

The style of power mobility base chosen will depend in part on the child's upper body control. Scooters are steered using a tiller that requires good sitting balance and arm active range of motion (Fig. 33.16C). The control functions are usually mounted on the tiller and require a grip-type action of the thumb or fingers. Scooters can be disassembled for transport in the trunk of a car and look least like a wheelchair. Although wheelchair bases are generally easy to adapt to a seating system, seating systems for scooters have limited adjustability and adaptability. Scooters are considered a power mobility device. As with strollers, families and providers need to be cautious of the timeline when using insurance dollars to purchase a scooter, as this may impact the insurance coverage decision in the future to fund a power wheelchair.

Today's power-base designs offer the greatest range of seating and control options. The entire seating unit can be removed from the pedestal mount of the modular base. The traditional belt-driven chair is obsolete. The direct-drive motors improve power, as well as control in turning. Front-, mid-, and rear-wheel drive designs offer different advantages and disadvantages in stability while driving and stopping, stability during recline or tilt, maneuverability in tight spaces, and the ability to climb curbs. The type of power wheelchair for a child must be as carefully selected as any other component of the wheelchair and seating system.

Power recline and power tilt capabilities offer excellent alternatives for children who require position changes throughout a long day of sitting to perform different functions or to prevent pain, fatigue, or pressure sores. The act of reclining, however, causes shearing of tissues due to the disproportionate movement between the child and the seating system. On returning

FIG. 33.16 Power mobility styles. A, Midwheel drive base. B, Front-wheel drive base. C, Three-wheeled scooter. (A, Courtesy Invacare Corporation, Elyria, OH. B, Courtesy Permobil, Timrå, Sweden. C, Courtesy Pride Mobility Products, Exeter, PA.)

to the upright position, most clients will have shifted position in the system, and the more complex the seating system, the more likely the position shift. Power recliners are available in reduced-shear models to help address these problems. Power tilt-in-space models work well for children with severe hypertonia or contractures who cannot tolerate having the seat-to-back angle opened up or who, once having done so, cannot return to an upright position without sliding.

Controls for power wheelchairs are available in two basic types: proportional and digital. The former has a proportional relationship between movement of the joystick and speed of the chair or sharpness of turning, whereas the latter has an on/off relationship to chair movement. An example of a proportional control is a standard joystick found on most power wheelchairs. It is customarily mounted on either the right or left armrest and will move in a 360-degree arc. The movement of the joystick controls the speed and the direction of the wheelchair. An alternative to the standard joystick is a joystick that is smaller and more compact. This feature allows a great deal of flexibility for joystick placement, provided sturdy mounting hardware is used. Proportional joysticks are also available in short-throw models that require less movement and force for activation and in heavy-duty models that can withstand a great deal of force. Head control joysticks are available for some wheelchairs.

An example of a digital multiple switch control system consists of four separate switches, with each switch controlling one direction—forward, reverse, left, and right. There are a variety of mechanical switches commercially available for selection of the most appropriate switch for a given individual. Use of digital switches during assessment allows for evaluation of different configurations. For example, the switches may be separated and set up in arrays to evaluate head control, or each of the four switches may be positioned at different body sites. The wafer board and arm-slot control are examples of alternative (switch) controls for wheelchair driving. Switch-driven chairs tend to be less precise and smooth while turning and changing directions because each direction is controlled by a separate switch.

With the recognition that age is no longer the determining factor in the successful use of power mobility has come the need to define selection criteria. Children under the age of 2 have successfully used power mobility independently as their primary means of mobility.[28] Furumasu, Tefft, and Guerette[20] developed an assessment to determine a child's readiness for powered mobility. This tool is based on Piagetian theories of development and evaluates the child on several learning domains. Furumasu, Tefft, and Guerette have also developed a 6-hour protocol for instruction of young children. The protocol is composed of activities performed in increasingly more complex environments ranging from free play in an open gym to activities performed in community environments such as the mall or clinic.

An alternative perspective is that children may learn spatial relationships implicitly through training in a power device. Jones et al.[28] provided a compelling argument for power mobility for very young children based on the importance of mobility rather than "readiness for driving" skills. She suggested that the child be allowed to explore movement in the device over a period of time, initially being restricted to a single turning direction in a small, safe environment. As the child's control over the power device improves and verbal labels for what she or he is doing are provided, the concept of independent mobility will develop. Joystick or switch-activated toys that are available at local toy stores make an excellent inexpensive alternative for power training of young children when the devices can be suitably adapted for seating and control.

Simulators have proved to be successful training tools.[1] Hasdai and colleagues[47] found that inexperienced drivers following a simulator driving program improved their accuracy and performance. Whizz-Kidz in the United Kingdom provides a training program that includes basic, intermediate, and advanced training for manual and power chair users. The children are paired with a spotter and buddy to learn advanced skills that allow them to be safer and more independent in the community. The program information can be found at www.whizz-kidz.org.uk.

Virtual reality (VR) technology has enabled video gaming experiences to become wheelchair driver training experiences.[43,47] Harrison et al.[25] investigated the effectiveness of wheelchair training using virtual environments. All six participants demonstrated improved skills; however, they agreed that the VR wheelchair was more difficult to control than their own wheelchair. The authors recommended that a VR training environment is useful, although care must be taken not to make the environment overly complicated. Criteria for safe driving include the ability to turn the chair on and off, follow a straight course, turn both left and right, back the chair up, maneuver around objects and persons, and stop quickly.[15,48]

The *marginal driver* is one of any age who may show borderline cognitive or physical skills or whose visual-perceptual problems interfere with driving ability. With supervision, these individuals may do well driving in a familiar setting, such as their school, but are not successful in novel or unpredictable community settings. The value of a power chair in increasing self-esteem and promoting independence in specific skills must be carefully weighed against the expense and amount of training and supervision required.

Several practical considerations are essential for the selection of power mobility. Building accessibility and space will affect where and how the device is used. Often the power chair is kept and maintained at school and a manual base is used at home. Care and maintenance of a power chair are more complex than for manual systems. Transportation is also a more complicated issue. Some school districts refuse to transport certain types of power wheelchairs such as scooters. The family may need a van for transporting the chair, and a ramp or a lift may be required for loading and unloading. Funding options for more expensive power wheelchairs may be more restrictive. Usually a backup manual chair is also required, especially during maintenance or repair of the power system. Responsibility for supervision, training, and routine wheelchair maintenance should be determined prior to ordering the system.

The examination and evaluation process for a power mobility system are often more complicated than for other types of wheelchairs. First, a variety of power bases should be available for trial and preferably with capabilities to adjust speed, acceleration, deceleration, turning speed, sensitivity, and tremor dampening of the joystick. Children generally perform better in a child-sized wheelchair rather than an adult-sized wheelchair. Because proper support is critical to performance in a power wheelchair, the therapist needs access to a variety of seating components, supports, and straps to provide the stability that is necessary to optimize the child's motor function for operating the controls. A variety of controls and mounting options should be available for trial. Evaluation may take place over a period of

several days to weeks and ideally in a variety of settings, especially for young and inexperienced drivers, who may require much practice with different options before making a decision.

A standard proportional control mounted on the armrest is preferred for children with some active control of arm and hand movements. This is the simplest and least expensive control. If a more midline position of the joystick is desired, placement of the control bracket on the inside of the wheelchair armrest is relatively easy.

Site options for the control increase with the use of a remote joystick and the proper hardware. Some possibilities include center mounting of the joystick close to the user to compensate for decreased range of motion or strength, mounting the joystick at arm's length on top of a lap tray to provide support and increased stability for children with dyskinetic movements or fluctuating muscle tone, or mounting the joystick for chin or foot operation. For children with limited functional movements and site options, an integrated control permits operation not only of the wheelchair but also of other equipment such as a communication aid, EADL, or computer equipment.

Transportation Safety

The US society is generally mobile and on the go. This includes children and adults who use wheeled mobility. RESNA and ANSI have set federal standards for using wheelchairs within vehicle transportation. Best practice dictates that, when at all possible, wheelchair users should transfer out of their wheelchair and into an age- or weight-appropriate vehicle seat and occupant restraint system that meets all the federal safety standards. The wheelchair should be stored and secured within the vehicle to prevent it from becoming a harmful projectile. Wheelchair occupants should ride in an upright position with back reclined less than 30 degrees. The headrest should be positioned to support the head and neck, and trays should be removed and secured.

If the occupant cannot transfer, a seating system is required that can be attached to a transit wheelchair frame. Transport wheelchairs meet ANSI/RESNA/WC19 standards, have been frontal crash tested, and have several advantageous features for use in vehicular transport compared with standard wheelchairs. A WC19 transport wheelchair can be secured at four crash-tested sites located on the floor of the vehicle, in less than 10 seconds per site, from areas accessible from one side of the wheelchair in an enclosed space. Transit wheelchairs have crashworthy frames, better accommodation of vehicle anchored belts, and proper instructions for use as a seat in a motor vehicle. It is imperative that the wheelchair and occupant face toward the front of the vehicle.

WC19 also set standards for lateral stability of a wheelchair in a forward-moving vehicle. This is due to the fact that wheelchair users are often injured when the wheelchair tips after the vehicle makes a quick stop or sharp turn. Effective in May 2002, regulations allow that a wheelchair occupant can use a crashworthy pelvic belt secured to the wheelchair frame, in which a separate vehicle-mounted shoulder belt could be inserted. This configuration may allow restraint systems to fit more securely. Information regarding WC19 can be found at the Rehabilitation Engineering Research Center on Wheelchair Transportation Safety website at www.rercwts.org.

If the occupant cannot transfer and cannot use the transport wheelchair, a wheelchair with a metal frame should be used with a wheelchair tie-down and occupant restraint system (WTORS). Restraint systems that meet WTORS standards are labeled SAE J2249. Four tie-down straps are attached to strong places on the wheelchair frame such as the welded frame joints. Attachment points should be as high as possible but below the seat surface. Rear tie-down straps should maintain a 30- to 45-degree angle with the vehicle floor. The four-point tie-down system is considered the universal system. When used properly, the four-point system is effective and affordable. Tie-down straps should meet SAE J2249 standards.

Just as the wheelchair frame needs to be secured to the vehicle, the occupant needs to be secured with crashworthy lap and shoulder safety belts. Standard positioning belts and harnesses are not meant to restrain an occupant in a vehicle crash. Currently, most lap and shoulder belts anchor to the vehicle independent of the wheelchair user. Newer models of WC19 wheelchairs have crash-tested occupant restraints mounted directly to the frame and allow the vehicle-mounted shoulder belts to attach directly to the lap belt.[50]

EXAMINATION AND EVALUATION FOR OTHER ASSISTIVE TECHNOLOGY

Assistive technologies offer children with physical disabilities an opportunity to participate more fully and become more independent in their daily lives. In addition to manual or powered mobility and specialized seating, these technologies include specialized switches, communication devices, computers, and EADLs. Often the term *assistive technology* is used to designate these latter four types of electric or electronic devices, although the Tech Act and RESNA include all forms of mobility, positioning, and related devices in the definition of AT. The assessment and selection process for each type of AT tends to be similar.

The physical therapist, as a member of the AT team, is responsible for completing the physical skills examination needed for technology use. Regardless of impairment or functional limitations, children should be optimally positioned prior to completing an AT device evaluation. Proper positioning is essential for reducing fatigue, as well as for achieving optimal control of head, trunk, and upper extremity movements for selection of appropriate AT devices and services. A comprehensive physical examination includes but is not limited to ROM, muscle strength, muscle tone, endurance, gross and fine motor abilities, and sensory impairments. The therapist also examines postural control, righting and equilibrium reactions, and notes the presence of primitive reflexes. These data provide the team with information concerning a child's functional motor abilities such as head and trunk control, the variety and quality of active movements, and the ability to isolate one movement from another. For successful technology use, functional movements must be voluntary, reliable, repeatable, and in some cases sustainable. The child's movement patterns should not contribute to fatigue or pain nor should they elicit pathologic reflexes or increase postural tone.[14,23,39,44]

Collaboration among health professionals and agencies is important to prevent duplication of services and unnecessary expense to families and third-party payers. Recent examinations by the child's physical therapist should be shared with a consulting AT team. A detailed written report, video or still pictures, a telemedicine videoconference, and participation of the child's physical therapist in the examination process are examples of different ways in which recommendations for positioning can be shared and services coordinated.

The physical therapist, along with the other team members, also contributes information regarding the child's sensory, perceptual-motor, and cognitive abilities. Sensory skills needed for successful AT device use include visual and auditory discrimination and responses to tactile, kinesthetic, and proprioceptive input. Visual acuity allows a young child to focus on an image, such as a switch, joystick, or computer screen, and visual accommodation allows the eyes to adjust to near and far objects. Assessment of the child's visual field is necessary for placement of controls or displays. Tracking is the ability to follow a moving object with the eyes, and scanning is when the eyes move to find an object—these are necessary skills for successful technology use. Hearing impairments compromise a child's ability to receive auditory information, as well as the ability to produce and monitor speech output.[14] After members of the AT team are aware of how a child processes sensory information, they are able to select devices that are motivating and ensure success. Devices that provide a variety of sensory cues, such as auditory clicks or beeps, visual light displays, or tactile and proprioceptive cues such as textured or vibrating switches, can be highly motivating and may facilitate learning.

Knowledge of a child's cognitive function level and learning style is important for selection of appropriate access, feedback, application, and training with the various devices. During the assessment, the team directly observes a child's attention span; short-term memory; understanding of cause and effect; ability to follow directions, sequence, and problem solve; and intention and motivation for technology use.[17,26] Whenever possible, the child should participate in the decision-making process. This may be as simple as picking the color of his or her mobility device, cushion covers, or switches. In other words, the team should heed the "Nothing about me without me" saying.[56]

SWITCHES, CONTROLS, AND ACCESS SITES

Children with motor impairments may require special switches or controls to operate communication aids, computers, power wheelchairs, or EADLs. Switches are also called *control interfaces* and *input devices*. Switch technology can help teach cause and effect, encourage independent play, promote group participation, and give a child control over a part of his or her environment.

Typically, an access site (a body part that can produce a consistent movement) is selected, and then the switch or control to operate a device is chosen. If a child has purposeful, controlled movement of any body part, the team can identify a suitable switch site. A variety of switches and controls are available from manufacturers who specialize in technology aids for people with special needs. They vary in size, shape, cost, performance capabilities, and ways in which they are activated. Switches may be single (perform an on/off function), dual (perform on/off and a select function), or multiple (perform on/off and several functions). Examples of multiple-switch configurations are joysticks, wafer boards, slot controls, head arrays, and keyboards. Methods for activating switches include pressure (direct touch or breath) or signal transmission (infrared, Bluetooth, etc.). Switch activation can be timed (with use of a timer setting), latched (where the action begins with one touch and occurs until the switch is touched again, similar to a light switch), momentary (the action occurs only while the switch is activated and stops when the switch is released, similar to a doorbell), or proportional (the speed generated relates directly to the amount of pressure applied to the switch, similar to a car gas pedal).[54]

Children as young as 6 months are capable of using hand or head switches for computer access.[54] Using the hands to activate switches is the typical mode for most children; however, switches can be operated by other body parts such as the head, chin, tongue, eyebrows, elbows, or lower extremities. At times, children will require additional support or extension devices to use a switch or control such as a head or chin pointer, a mouth stick, finger or hand splints, styluses, mobile arm supports, or overhead slings (Fig. 33.17).

Some switches have been specially designed to use with a certain body part such as an eyebrow switch, an eye blink switch, or a tongue touch keypad. Proximity switches will activate when a user gets near the switch, but actual physical contact is not required. A practical application of this technology is to imbed four proximity switches (one each for forward, reverse, right, and left) in a lap tray to operate a power wheelchair. Heavy-duty contact switches may be the most suitable choice for children with fluctuating muscle tone who have difficulty controlling the force of their movements, and tiny fiberoptic switches may be suitable for the user with limited range and strength. At one spinal cord treatment facility, switch evaluations are performed at bedside as soon as the patient is stable. Functional movements are examined, including use of tongue, lips, eyes, eyelids, eyebrows, and jaw.[4] Persons with high-level spinal cord injuries often use pneumatic breath control switches to operate AT devices, and many find that integrated control systems provide them with access to several types of technology.

An integrated control system is one in which several AT devices are operated/controlled using a single input device (e.g., switch, joystick). For example, a power wheelchair can be configured with an electronic controller that allows joystick use for driving the wheelchair, as well as for operation of a communication device, computer equipment, or environmental controls. Criteria to determine when an integrated control is the optimal choice include (1) the user has a single reliable access site; (2) the access method is the same for all devices used; (3) speed, accuracy, or endurance improve; and (4) the child or family has a preference.[4] There are also disadvantages to using integrated controls, including the higher cost of more sophisticated electronics required to perform several functions. In addition, because the individual uses the same input device for all of his or her technology, if the power wheelchair were to break down or need repair, the individual loses access to all of the technology. For this reason, it is extremely important that backup systems are in place for all of the individual's technologies.

AUGMENTATIVE AND ALTERNATIVE COMMUNICATION

In addition to spoken or verbal output, communication includes body language, gestures, facial expressions, and written output. Speech limitations in children may occur as a result of congenital or acquired dysarthria, developmental apraxia, developmental aphasia, congenital anomalies, cognitive impairments, autism, or hearing impairments.[44] When the ability to verbally communicate and interact is limited or absent, some form of AAC should be explored. Augmentative communication is any procedure or device that facilitates speech or spoken language. Alternative communication refers to the communication method used by a person without vocal ability.[2] Ideally, AAC

FIG. 33.17 Devices for pointing or indicating that may be used with communication aids or electronic aids to daily living (EADLs). Chin pointer (A), head stick (B), and adjustable stylus with velcro straps (C). (A and B, Courtesy Patterson Medical, Warrenville, IL. C, Courtesy Enabling Devices, Hawthorne, NY.)

should enable individuals to efficiently and effectively communicate in a variety of social situations.[37] Users of AAC include individuals with cognitive impairments, those requiring written augmentation, and individuals with a temporary limitation in expression due to illness or injury.

The speech and language pathologist along with the child and family members assume the lead roles in identifying the best choice for an AAC system. The physical therapist plays an important ongoing role in determining positions that optimize use of equipment for communication. Many classrooms contain a variety of chairs, corner chairs, prone or supine standers, and sidelyers, which require adjustment or adaptation for a particular child. The physical therapist instructs other team members in the proper use of positioning devices that enhance a child's communication. Therapists working in early intervention are in a unique position to influence the development of communication in infants and young children. Therapists should establish intervention goals that include allowing the child to indicate choices such as the ability to separate head and neck movements from eye movements. This provides the child a method of indicating needs. Additionally, family members are encouraged to talk to and read to their youngsters during daily activities and routines.

A number of techniques and devices for augmenting communication are available and classified as *high tech* and *low tech*. Low-tech equipment includes devices that are powered by batteries or electricity or nothing at all. High-tech equipment includes devices with adapted computers and switching systems.[44] Unaided techniques, such as eye gaze, signing, or gesturing do not require external devices or equipment but rely on the child's ability to physically respond in some consistent manner. Aided techniques include the use of an external device, which may or may not be electronic. A communication sheet or notebook (with pictures, symbols, or words) is an example of a nonelectronic communication aid.

Electronic communication aids offer a much greater range of capabilities and options for users. Simple devices may run less than $100; high-end devices cost several thousand dollars. Some low-cost durable devices play a single message or series of messages, whereas others offer four, eight, or more messages. Generally, the messages can be quickly changed as desired. New devices are continually evolving that are more compact, durable, lighter in weight, and easier to transport. The operation and programming of newer AAC devices have simplified over time. There are several downloadable applications that can be added to a smart phone or tablet. Given the ever-expanding variety of

AAC devices available, the AT team should be able to identify a device that meets the motor and cognitive abilities of each child.

At the high end of the spectrum are sophisticated, computer-based AAC devices that allow a variety of input methods (direct or scanning), high-quality voice output, storage capability for vocabulary and phrases, and the capability to operate computer-based software or EADLs through the device. Third-party payers may deny funding for these devices if they are viewed as educational equipment that the student's local education agency should provide.

The input, or selection, method for AAC devices and computers typically includes direct select or scanning. Direct selection is faster and often the preferred method to operate a communication system. Children with mild-to-moderate impairments often have sufficient motor control for direct selection. The child simply makes a choice from the options presented. For example, when a child touches a location on a communication device with a picture of a glass, the spoken response might be "May I have a drink please?"

Children with severe motor impairments may need to rely on scanning to operate their AAC or computer. The device runs through a sequence of choices (usually rows, then columns), repeating the sequence until the user makes a selection. The scanning rate is adjustable, which allows beginners ample time to become familiar with the new equipment and build confidence and accuracy before increasing speed. In most cases, the selection is made by using a special switch positioned to allow independent access. Examples include a pressure switch mounted on a lap tray and activated with the touch of the hand, a lever switch positioned near the side of the head and operated with lateral head movements, and a chin switch mounted on a collar and operated by flexion and extension movements of the head. Scanning can be both physically and cognitively demanding for some users because they must be able to wait for the appropriate selection, activate the switch at the right moment, release the switch, and repeat these steps for the next selection.

COMPUTER TECHNOLOGY

Computers are typically used for word processing to compose and edit the written word, data collection and storage, graphics for drawing and publishing, and communication via e-mail, the Internet, and social media as well as various educational and recreational activities. Typically, a computer is operated through a keyboard, the mouse, or both. Computers, as well as many computer-based devices such as communication aids, environmental controls, and power mobility controllers, are readily adaptable, can be customized as needed, and can be accessed using a variety of input methods. Voice activation, for example, allows individuals to use voice commands as an input to their electronic device. Typically voice activation systems require training to ensure consistent output accuracy. Hundreds of products are commercially available to adapt a computer for an individual with special needs. This variety is important for users whose needs may change. Input to computers and communication devices can be direct or indirect (scanning or Morse code), with direct access being faster and generally more intuitive.

Keyboard Adaptations and Alternatives

To successfully access the computer, the child with a disability may require some customized accessing method to interface with the computer. These interfaces are often provided by additional software or additional hardware for the computer. Software is available to decrease the need for additional keystrokes using word prediction capabilities, to minimize repetition of the same key, and to allow activation of more than one key at a time. Some computer systems have accessibility features built into the standard software package.

Many external options are available as well. A keyguard attached over a keyboard is used to prevent unwanted keystrokes when fine motor control or finger isolation is impaired (Fig. 33.18). Ergonomic keyboards or wrist-arm supports are used with children who require distal support or if tremor, pain, fatigue, or lack of endurance interferes with typing. Mobile arm supports and overhead slings may benefit users with muscle weakness.

Alternatives to the standard keyboard include mini-keyboards, expanded keyboards, and one-handed keyboards (Fig. 33.19). Mini-keyboards have advantages for children with muscular dystrophy who have fine motor control but limited ROM, decreased strength, or low endurance. Expanded or enlarged keyboards are helpful for children with poor coordination and the ability to isolate movement of a finger. These keyboards have up to 128 pressure-sensitive areas referred to as keys, and because the number, size, shape, and location of these keys can

be modified, the possibilities for customization are numerous. For example, expanded keyboards could be set up to offer four choices with large contact areas, rather than 128 choices. Standard keyboards, mini-keyboards, and enlarged keyboards may be set up in the QWERTY (typical keyboard) pattern, in an alphabetic layout, or in a frequency-of-use layout. Keyboard patterns can be customized to place frequently used keys near the home row and are available in one-handed or two-handed models.[5]

Computers and tablets are available with integrated touch screens. Because touch screens use direct selection, they tend to be less cognitively demanding, which may be important to children being introduced to computer technology.[14]

Children with visual impairments require technology specific to their needs, such as software or hardware adaptations to provide auditory feedback, tactile keyboards, optical character recognition systems (screen readers that translate text to the spoken word), screen magnification systems, software that will enlarge the text, or Braille technology.

Mouse Alternatives

Mouse functions include moving the cursor on the screen, dragging a selected item on the screen, and clicking or double-clicking to select items and functions. Change in cursor size, color, or speed may make it easier for a child to locate the cursor on the computer screen. Keyboard functions using the arrow keys or the numeric keypad may assist a child who is unable to use a mouse effectively. Alternative mouse options are available, both on the general market and through manufacturers of special equipment, and include joysticks, trackballs, mouse pads, keypad mouse, and head-controlled mouse (Fig. 33.20). Therapists are encouraged to become familiar with commercially available input systems, as well as those developed for users with special needs, because they are often less expensive.

Virtual or onscreen keyboards display an image of a keyboard on the monitor, and the user moves the cursor to the desired key with a mouse, joystick, trackball, head-controlled mouse, or switch array. A selection is then made using a second switch or by dwelling on the key for a predetermined amount of time. Onscreen keyboards with scanning programs are commonly used by children who rely on a single or dual switch to access AT devices. Keyboard and mouse functions can also be achieved using light beams, Bluetooth, infrared, ultrasonic, and speech recognition technology.

Rate Enhancement

Therapists are encouraged not only to become familiar with different access and input methods but also to try them, because each access and input method requires different motor responses and cognitive processes. Consider that a trained typist without a disability is capable of transcribing text at an average of 100 words per minute. The same person typing while composing text averages 50 words per minute. Court reporters, using special keyboards, enter text at 150 words per minute. Contrast that with an average of 10 to 12 words per minute for a person typing with just one finger. The person using scanning usually averages 3 to 5 words per minute.[14] Overall speed of production, although not an issue for all users, can become an issue for students in regular education who are expected to produce a similar amount of written output as their classmates.

FIG. 33.20 Alternatives to a traditional mouse. (Courtesy AbleNet, Inc, Roseville, MN.)

Productivity also becomes an issue during transition planning if computer proficiency is a condition for employment.

When a computer or communication device is effortful and time consuming, use of macros, abbreviation expansion, or word prediction to enhance productivity should be investigated. Macro programs allow users to combine and automate tasks. Abbreviation expansion automatically types out an entire word or phrase when two or three letters have been typed. For example, a user can command the computer to type out "physical therapy" each time the user inputs the letters "PT." With word prediction software, a word is displayed after only two or three characters are entered. A list of likely choices appears on the screen and the correct number is selected.

ELECTRONIC AIDS TO DAILY LIVING

An electronic aid to daily living (EADL), previously known as an environmental control unit (ECU), is a device or system of devices that allows the operation of electrical appliances or equipment in a variety of ways and places. The purpose of an EADL is to apply technology to facilitate the user's control over the environment, to promote independent access to items required for daily living, and to improve the quality of life and participation in society.[32] Each of us encounters this technology on a daily basis in the form of energy- and time-saving devices such as electronic garage door openers, portable telephones, and remote controls for television and audio equipment. Many of these affordable, commercially available products require precise manual control, which often precludes their use by children with motor impairments; however, a range of environmental control devices are available from manufacturers of equipment for children and adults with physical challenges.

Control of the environment for an older child might include operating a blender with a head-activated switch to prepare treats at school or for a younger child or activating a pressure switch with the hand to operate a battery toy during free time (Fig. 33.21). A child may use a head stick to operate the television remote control to select a channel, control the volume, and turn off the set when done. Adapted phone equipment can be programmed to store several numbers, automatically dial a number, and answer calls with the touch of a switch, allowing the user to have access to important, age-appropriate socialization. These independent, functional activities help instill a sense of responsibility and independence from caregivers.

FIG. 33.21 A pressure switch can be used to activate a battery-operated toy. (Courtesy AbleNet, Inc, Roseville, MN.)

In young adults, EADLs may increase personal satisfaction, increased participation in life activities, possible employment, and possible reduction in cost for personal care attendants.[30] The use of EADLs in one residential facility to operate personal entertainment devices such as televisions, radios, and lights reduced the amount of nursing care required by about 2 hours per day per participant.[114] Both residents and nursing staff reported reduced frustration following the introduction of EADLs. Persons with spinal cord injuries who used EADLs used the telephone more often, were more inclined to travel, and spent more time in educational pursuits than nonusers.[33]

An EADL generally includes three parts: the main control unit (central processing unit), the switch (transducer), and any devices (peripherals) to be controlled or activated. Most EADLs emit some type of tactile, visual, or auditory feedback that indicates which function has been selected before the function is activated. Feedback can be an essential feature to the user.

The two basic types of EADLs are direct and remote. In a direct system, the devices to be controlled are plugged directly into the main control unit. In a remote system, the control unit acts as a transmitter, sending signals to remote receivers, which in turn activate the device. The remote system has the advantages of operating a number of devices or appliances from one location, such as a wheelchair or bed, and the absence of wires running from the unit to the device.[14]

Capabilities of systems vary from simply turning one device on and off to operating a whole-house configuration and integrated computer systems. Common functions include operation of a small electrical appliance, television, light fixture, door lock, intercom or call signal, electric bed, and telephone and computer equipment. EADLs can be activated through the wide variety of switches and controls described previously, through voice activation, or through the user's power wheelchair controller, electronic communication aid, or computer. Lange has produced several charts to assist practitioners in comparing the various features of popular EADLs that are commercially available. They include input options, what type of equipment can be controlled, what devices the EADL will interface with such as a computer or communication aid, whether battery backup is included, cost, and comments (http://www.atilange.com/Resources.html, accessed May 6, 2016).

EFFECTS OF MANAGED CARE ON ACQUISITION OF ASSISTIVE TECHNOLOGY

State-funded Medicaid programs, traditionally a major source of funding for children with disabilities, have contracted much of their coverage to private managed care insurance organizations, and in many cases this has affected accessibility to durable medical equipment and specialized devices.[12,24,52] Denials for requested items may increase, either because a narrower interpretation is used in determining medical necessity or because nonstandard or customized items do not fit the billing codes. The time between the initial request and approval may be prolonged if the reviewers are less experienced in the needs of children with physical disabilities and require more explanation, making repeated requests and justification necessary. Choice of products may be restricted because the amount that will be paid

is often based on simpler adult equipment designs and does not cover the full cost of more expensive or more customized pediatric designs.

The capitation rate paid to medical equipment suppliers is often inadequate to cover actual expenses, thereby cutting profit margins and making it difficult to provide and service sophisticated or customized equipment. Medical and equipment needs of individuals with disabilities are much higher than what many private companies anticipate. If a managed care company discontinues its contract for state Medicaid patients, this could leave those individuals with little or no choice of coverage and may require a change of provider. There is often a struggle with reconciling the variety of devices that are available for achieving independent function with the increasing restrictions in funding and availability.

SUMMARY

Assistive technology (AT) is a critical component of intervention for children with impairments in body functions and structures and activity limitations in communication, mobility, and self-care. Five major areas for AT are seating and positioning, wheeled mobility, augmentative and alternative communication, computer accessing, and electronic aids to daily living. Current best practice involves a multidisciplinary team—which includes the child and family, AT specialists, and the child's service providers, including therapists, teachers, and medical staff—and a multilevel assessment. Although there is research evidence for AT, the needs and preferences of each child and family and the environments in which AT will be used are essential considerations for decision making. Additionally, funding is often a primary consideration. As a member of the team, the physical therapist should be knowledgeable of AT and aware that products are being improved and new technology is being developed. The potential impact of AT on a child's quality of life underlies the importance of evidence-based decision making that is individualized to the child, family, and environment and increases the child and young adult's ability to participate at home, school, and in their communities.

Development and Analysis of Gait

Jean Stout

One of the first questions asked by many parents whose child has recently been diagnosed as having a motor impairment or whose child has experienced an injury that affects movement is: "Will my child walk?" or "Will my child walk again?" The reason for emphasis on the task of walking apart from many other abilities (which are sometimes more functional), I believe, is the measure of independence and social acceptance with which the task is associated. The ultimate goal for families, and sometimes pediatric therapists as well, becomes independent walking for the child. Although the variables that contribute to this important ability are numerous and complex, a child is usually able to stand and walk by 8 to 17 months of age (average 12 months). Normative data from Canadian infants on the Alberta Infant Motor Scale (AIMS) indicate that 50% of infants will achieve independent standing by the age of 10.5 months, take first steps by 11 months, and walk independently by the age of 11.5 months.[89] Furthermore, the pattern is mature in typically developing children by the age of 3.5 years.[124] The complexity of walking has been studied extensively since the days of Saunders[102] and Murray,[78] and study continues today. Improved computerized techniques and new theories of motor control and balance contribute to better understanding of the components of walking. Understanding how we walk was once required only for those in the fields of child development and rehabilitation. Today, walking is studied by many disciplines, including engineering.

The purpose of this chapter is to provide an overview of the aspects of gait important to physical therapists providing intervention for children. These include the development of gait and its refinement in childhood, the typical components of walking as identified by gait analysis, and a description of some of the common gait deviations found in children with physical disabilities. Guidelines for when a computerized gait analysis is desirable also will be addressed. Those interested in more extensive information are referred to a number of excellent resources on the topic.[47–49,61,83,86,98,105,106,119,120,123–125,148–151]

DEVELOPMENT OF GAIT

Gage[49] suggests that typical walking has five major attributes: (1) stability in stance, (2) sufficient foot clearance in swing, (3) appropriate prepositioning of the foot for initial contact, (4) adequate step length, and (5) energy conservation. When independent ambulation begins in the toddler, only the prerequisites for these attributes are present. The prerequisites, however, are likely to be more important to the attainment of walking than the attributes themselves. The attributes develop over time with typical growth, maturation, and refinement of the skill. Scales of motor development illustrate that even during the time period between first steps and independent walking important balance abilities are achieved.[16,89] This includes rudimentary anticipatory postural adjustments for gait initiation.[2,6] Inability to achieve the prerequisites or loss of prerequisite attributes is characteristic of atypical. Prerequisite attributes include adequate motor control and central nervous system (CNS) maturation (implying an intact neurologic system), adequate range of motion (ROM), strength, appropriate bone structure and composition, and intact sensation (proprioception).[57] More recent research suggests that muscle activation patterns for pelvis stabilization are also a prerequisite.[6] The development of a motor pattern (in this case walking) depends on a combination of mechanical (including structural), neurologic, cognitive, and perceptual factors. When these factors are controlled, chronologic age is less significant than previously thought. Changes in body dimensions and speed, however, are important.[1,2,56] The following is a brief description of the neurologic and biomechanical factors that contribute to the development and refinement of walking follows.

Neurologic Factors

The neural mechanism for locomotion is hypothesized to include a central pattern generator (CPG) located in either the spinal cord or in the brain stem.[33,52–54] Modulation of the CPG depends on both descending neural input and peripheral input, which modify the output to adapt the execution to stability requirements and the demands of the specific task and environment. Most CPG research involves animals (including mammals and other vertebrates). CPGs are thought to exist for many movements, and the CPG for walking is believed to organize the activation and firing sequence of muscles during gait. The presence of stepping movements in the human fetus, the early onset of infant stepping in premature infants, the parallels between developing animals and humans, and the parallels between the sequencing and timing of infant stepping, kicking, and locomotion in infants with and without disabilities[46,130,134,135,139,155] have led individuals to suggest that the neural foundations for locomotion in humans are established during embryogenesis as in other animals.[17,18,23] Postnatally, the major periods of accelerated brain growth in relation to body growth occur between 3 and 10 months of age,[41,42] and the myelination that develops during this time probably contributes to the neural organization required for independent

locomotion. Sufficient maturation of information-processing capabilities of the CNS for both internal and external stimuli is also believed to play a role.[6,154]

A growing body of research building on the concept of CPGs and the capability of the nervous system to organize and coordinate patterns of activity to produce motor actions and movements has emerged that is impacting rehabilitation.[30,31,62,138] The term *muscle synergy,* defined as "coordinated patterns of muscle activity that flexibly combine to produce functional motor behaviors,"[138] is strikingly similar to the subcortical "motion synergy" concept used by Brunnstrom as the basis for rehabilitation of adults with hemiplegia.[22] Muscle synergies are combinations of muscle activity or modules that represent the building blocks of any movement, including locomotion. Individual muscles have different "weights" or contribution. The building blocks or synergies can be mathematically identified from electromyographic (EMG) data. Research has demonstrated that the number of muscle synergies used stepping increase during the first year and are correlated to changes in the biomechanics of the walking pattern.[39,129] Coordination and interplay between neural development and the biomechanical factors are discussed in the next section. Of note, muscle synergies have been used to describe alterations of gait patterns in children with disabilities.[109,118,128]

Biomechanical Factors

Adequate ROM, strength, appropriate bone structure and composition, and body composition are mechanical factors that affect the development and refinement of walking. ROM, strength, bony structure, and the ability to manage gravitational and inertial forces of the lower extremities affect the early patterns of walking. Constraints in any of these mechanical variables change gait patterns; as the constraints change, so do muscle activity, joint kinematics, and kinetics. Typical growth is periodic and often occurs in spurts. Changes seen in the development of many movements may be the result of critical dimension changes in the body of the growing child and adaptation to those changes.[72,73] In 1984, Thelen and colleagues described how physical growth could be an explanation for the disappearance of the stepping reflex. This study was republished in 2002.[132]

More recent work also corroborates the importance of mechanical factors, suggesting that infants often have to physically grow into the body dimensions needed for optimal functioning, and the velocity of nerve conduction must increase for activation of CPGs.[1,33,63,64,122] An extensive review of musculoskeletal development and adaptation can be found in Chapter 5.

Determinants of Walking

The seminal work of Sutherland and colleagues[124] identified five important determinants of mature walking: duration of single-limb stance, walking velocity, cadence, step length, and the ratio of pelvic span to ankle spread. The determinants distinguish "mature" walking (age 3 years and older) from "immature" walking (age 2.5 years and younger). Among the 13 variables analyzed the variable with the least discriminating power was the presence or absence of a heel strike at initial contact.

The duration of single-limb stance is, as the name implies, the length of time during which only one foot is on the ground during stance phase. As a child's postural stability and motor control mature, the duration of single-limb stance increases. The most rapid change occurs between 1.5 and 3.5 years of age.

Walking velocity, cadence, and step length are temporal distance parameters that are influenced by growth. A linear relationship between step length and leg length is present from age 1 to age 7. A linear relationship between step length and age exists from age 1 to age 4. Walking velocity also increases with age up to age 7, although the rate of change decreases from age 4 to age 7. Cadence gradually decreases with age throughout childhood. The most rapid reduction in cadence occurs between the ages of 1 and 2 years. Because of this strong correlation among age, leg length, and stature, methods of normalization have been used to better understand the influence of these variables on temporal distance parameters.[60,82,106,115] Using a geometric normalization technique on Sutherland's data, it was demonstrated that preferred stride length and cadence increase and decrease, respectively, up to age 3.5 and then remain essentially constant into adulthood.[59] The variability of individual step length from step-to-step in infants has brought into question the practice of averaging step lengths in early walkers.[8]

Age-Related Changes in Gait

Birth to Age 9 Months

The disproportionate contribution of fat content to overall body mass during the first 8 months of postnatal life causes infants to be relatively weak during a time when they are developing the motor control and coordination for independent ambulation.[131,132] Studies suggest that bigger, fatter infants achieve locomotor milestones later than their smaller peers for this reason.[3] From birth to 6 months of age, body fat increases from 12% to 25% of body mass.[112] Adipose tissue is a major component of weight gain during the first 4 months of postnatal life, with increases in lipids accounting for more than 40% of total weight gain.[44] Between 4 and 12 months of age increased lipid content accounts for approximately 20% of increased weight. With increasing age and mobility, fat content drops and muscle mass increases.

Body proportions also change as infants grow. During the first few months of life, the fastest rate of growth occurs in the extremities as opposed to the head and trunk. Leg length increases 130% from birth to 2 years, but crown-to-rump length increases only 69% in the same period.[77] Inertial characteristics of body segments change with growth and the effects of gravity. Resistance to motion in limb segments (segment moments of inertia) more than doubles and triples during the first 6 months of life.[63,122] The rate of change in gravitational moments along the axial skeleton has been shown to decrease in a cephalocaudal progression as infants grow. This suggests that development of head and trunk extension against gravity is at least in part attributable to physical factors.[64]

The body structure of infants affects their posture and movement patterns when they begin to stand upright with support and cruise. Flexion "contractures" are present at the hips, and range of hip external rotation is slightly greater than range of internal rotation. Range of hip abduction slowly decreases following birth but remains slightly increased at 8 to 9 months of age.[34,55,88,123,145] Femoral anteversion (a forward or anterior orientation of the head and neck with respect to the frontal plane) and femoral antetorsion (a twist of the bone in its longitudinal axis) of the hips are both present.[14,15,35,40,43] The magnitude of the femoral torsion is 40° to 50°. (Femoral anteversion and

femoral antetorsion are often used as synonymous terms in orthopedic literature to refer to the torsion or the medial twist between the axis of the head and neck of the femur and the axis of the femoral condyles.)

Structurally, the knees in the frontal plane exhibit genu varum, or bowing in the tibiofemoral angle (Fig. 34.1).[100,126] The tibia and fibula exhibit neutral alignment about the longitudinal axis, which represents slight internal torsion relative to adult values.[113,114] A medial inclination of the talotibial articulation is present in the infant, producing an everted talocrural mortise.[13,94,127,140] The medial inclination of the joint is manifested in an everted heel position in weight bearing. Supported walking at this age is characterized by wide abduction, external rotation and flexion at the hips,[16] bowed legs, and an everted heel position.

The postural control, antigravity muscle strength, and control of gravitational moments that develop during the first 9 months of life are important precursors to independent ambulation. Standing balance also is a necessary precursor to upright motor skill. The frequency and the amount of practice of activities, such as kicking, have been shown to affect the age of onset of ambulation in infants with and without disabilities.[3,139] Antigravity strength of the hip flexors begins to develop early on through kicking movements from the supine position.

Hip extensor strength in both concentric and eccentric muscle contractions, similar to those used in ambulation, begins to develop during activities in the prone position and gradually increases as the infant begins creeping and kneeling activities. Bly describes infants of 8 months of age exhibiting the ability to rise from a kneeling to standing position, which requires closed chain hip and knee extension. Control of gravitational moments at the hip by the hip flexor and extensor muscles typically occurs by 8 to 9 months of age.[64] Cruising along furniture builds strength of the hip abductors.[16]

By 8 months of age, when infants are displaced in a seated position, the visual, proprioceptive, and vestibular systems work together to consistently bring the center of mass back to a stable position.[152] Postural corrections in response to visual flow often predate the development of sitting and standing.[3,24,58,152] For example, Butterworth and Hicks[24] demonstrated that infants who could sit alone but could not stand independently exhibited the same appropriate postural adjustments to visual information that simulated movement as did infants who were able to walk independently.

FIG. 34.1 An 8-month-old infant with physiologic varus in the tibiofemoral angle. (From Shutterstock.com.)

9 to 15 Months

At the onset of walking, lower extremity alignment is characterized by a wide base of support and hip abduction, flexion, and slight external rotation. The tibias display mild internal torsion, and varus is still present in the tibiofemoral angle; the heel position in weight bearing remains everted because of the inclination of the mortise joint. The child's center of mass is proportionately closer to the head and upper trunk (at the lower thoracic level) than in an older child, whose center of mass is located at midlumbar level, or in an adult, whose center of mass is located at the sacral level.[84] Although differential growth rates of the extremities are allowing the head to become relatively smaller than the rest of the body, the head is still proportionately large. The ratio of body fat to muscle mass is still high, contributing to weakness relative to the demands of upright posture. The upright position against the force of gravity puts an increased demand on muscle function. Muscles (particularly the abdominals, hip flexors, knee extensors, and ankle dorsiflexors) must work in antigravity positions, which further increase functional weakness. Despite the structural limitations and the typical inability to walk at constant average forward or lateral speed, infants exhibit the necessary postural responses to compensate for visual and support-surface perturbations that are inherent in the task of upright locomotion.[12,24,103,110,133,152]

The rate-limiting factors associated with walking are (1) sufficient extensor muscle strength to support the body's weight on a single-limb base of support, (2) dynamic balance, and (3) postural control in the form of anticipatory and integrative postural adjustments.[6,33,133] The critical dimension of the body to be controlled is the head within the limits of stability of the base of support. The base of support in an infant at the onset of walking is wide for both structural and stability reasons. Mediolateral (side-to-side) stability is achieved, but anteroposterior stability is limited. Progression takes place in the sagittal plane; if the head moves outside the limits of stability at the base of support, balance is lost. Recent work has demonstrated that even though forward progression takes place, infants do not walk with either constant forward or lateral speeds, step lengths, or other joint parameters.[8,56,103]

Anticipatory postural adjustments used for gait initiation during the postural phase (mainly the lateral shift of body weight toward the stance limb) are present at the onset of walking; however, anticipatory postural adjustments during the locomotor phase (control of the swing side pelvic drop) are not.[6] Because the hip is the interface between the locomotor movements of the legs and head-arms-trunk postural control, strength and control at the hip are very important. Studies have shown that at the onset of ambulation, hip strength is inadequate to control the gravitational forces during gait and maintain balance. Infants actually "walk by falling," but they also learn adaptive strategies from the falling experience.[21,65] If balance is perturbed, control is regained by rudimentary mechanisms requiring torque adjustments at multiple joints.[56,93]

The pattern displayed by a beginning walker is similar to that of an experienced walker on a slippery surface (i.e., small steps, a widened base of support, and maintenance of the body and limbs very upright in an extended, stiff position). Postural adjustments are made using movements of the entire body. The work of Sutherland and colleagues[123] characterizes infant ambulation as consisting of a wide base of support, increased hip and knee flexion, full foot initial contact in plantar flexion, a short stride, increased cadence, and a relative footdrop in swing phase.

Motorically, the initial pattern and execution of the first steps are thought to be related to the patterns used in stepping and kicking during early infancy,[130] and walking may be constrained by this pattern. That is, just as the structural makeup of the body drives the initial posture, so may the primitive generator for kicking and stepping drive muscle activity for early walking. The reduced frequency of kicking in children with Down syndrome has been shown to be correlated with a later age of walking than in typically developing infants.[139] Both kicking and stepping are alternating reciprocal patterns of movement between the limbs. Each has a flexion phase (in gait, analogous to swing) and an extension phase (in gait, analogous to stance). Thelen and colleagues[133] suggest that the ability to generate steplike patterns is continuous from the newborn period through independent locomotion and that the pattern demonstrated when beginning to walk is a modified, more flexible version of the earlier pattern that has been modified by changes in strength, neurologic maturation, and the mechanics of upright posture. This has been substantiated by the muscle synergy work by Dominici and colleagues, who have shown that EMG muscle synergies increase in number from two in the neonate to four in the toddler.[38] The EMG patterns of activity at the onset of walking demonstrate co-contraction across antagonistic muscle groups—the anterior tibialis and gastrocnemius during swing phase and the quadriceps and hamstrings muscles during stance phase. Reciprocal patterns in single stance also emerge in conjunction with the co-contraction of the antagonistic muscle groups as a feature of the redundancy and variability within the motor system.[28,39,79,80,123,124,130] Co-activation patterns result from the need for stability, and decreases are noted with as little as 1 month of walking experience. After 3 months of independent walking, further refinement of excessive co-contraction is noted with an increase in the number of muscle synergies. Stable patterns emerge via exploration, selection, and practice. With practice and time, the high levels of co-contraction decrease and reciprocal patterns increase.

As stated previously, Thelen and colleagues suggest that it is not the pattern-generating capabilities or motor control postural abilities that constrain the onset of walking. Development of sufficient extensor strength is believed to be the critical variable.[133] This belief is consistent with other views for the requirements of walking, including stance phase stability,[49] the need to maintain a net extensor muscle support moment as described by Winter,[149,151] and the inability of the hip to completely control the gravitational forces for balance.[21]

18 to 24 Months

Between 18–24 months, neurologic maturation, growth-related changes in body structure, increases in strength, and walking experience all play a part in altering the walking pattern. By 18 months of age, the varus angulation of the tibiofemoral angle in the frontal plane has resolved and the limb is straight (Fig. 34.2)[126] (see also Chapter 5). No change is noted in excessive femoral antetorsion, although limitation in hip extension ROM is reduced to an average of 4°, indicating that remodeling is occurring.[43,88] Range of hip abduction is no longer excessive. Because of decreased abduction and improved stability, the base of support has decreased. Dynamic balance and strength have also improved. A heel strike has not consistently emerged in the 18-month-old child,[123,124] but it has been reported with kinematics.[56] The decreased base of support allows for more anterior-posterior movement over the planted foot and coincides with an increased ankle plantar flexion moment.[56] Heel position remains everted.[94,140] The viscoelastic and inertial properties of the stretched stance limb facilitate propulsion of the leg in swing.[130] A knee flexion wave begins to emerge during initial stance phase as a heel strike develops and knee extensor contraction absorbs some of the impact of floor contact.[56,123,124] Knee extension in the middle of stance phase also emerges. The duration of stance phase remains prolonged, and cadence is increased relative to mature gait but is significantly faster than that observed in 12-month-old infants.[67]

The efficiency of walking slowly improves from 18–24 months as the center of mass descends from a position high above the lower extremities to one in close proximity to proximal muscles in the legs that generate power for walking. Stability of any body is inversely related to the distance of its center of mass from its base of support. Between the first and second years of life, the legs are growing proportionately longer, becoming the most rapidly increasing dimension of the body. These events bring the center of mass closer to the proximal end of the lower limbs.[84] This, in conjunction with the repetition and practice of walking experience, results in a reduction of early high levels of muscle co-contraction and energy recovery as quickly as 3 to 5 months after walking begins.[28,67]

FIG. 34.2 Standing posture of an 18-month-old toddler. The varus in the tibiofemoral angle has resolved, and the limb is straight. (From iStock.com.)

Controversy exists over whether heel strike develops as a result of neurologic maturation or gradual changes in body structure, base of support, improved strength, and improved stability.[45,46,130,133] It is likely that each variable is important. A consistent heel strike develops by 24 months of age.[123,124] Requirements include refined motor control, strength, and dynamic balance to sustain stability on a small area of contact (the heel). Children with impaired walking ability lack a heel strike at initial contact. This may be caused by either lack of motor control or the inherent choice of maintaining stability by use of a larger area of initial contact.[49]

With 6 to 12 months of walking experience, new strategies are employed for balance and postural control. Decreases in peak head and trunk oscillations are noted during the first weeks and months of independent walking.[75] Backward inclination of the trunk occurs at this age rather than the anticipatory forward inclination of older children and adults.[6] Velocity normalized for height is increasing during this time. The deficit between muscular strength at the hip and vertical acceleration of the center of mass diminishes, which improves the control of the gravitational forces and the postural capacity of the musculoskeletal system as a whole.[21] As a result, single limb stance is more stable.

The role of walking experience cannot be overestimated. Adolph and colleagues have shown that after controlling for body dimensions and testing age, walking experience explained an additional 19% to 26% of variance in improvement in walking skill in a group of 210 infants of differing ages. Previous diary studies have demonstrated that infants may take as many as 9000 steps in a given day and travel the equivalent of 29 football fields.[2,4] Both walking experience and the experience of falling assist in the development of anticipatory postural control to adapt locomotion to threats to balance such as uneven terrain or obstacles.[65]

EMG patterns at 18–24 months show decreasing co-contraction in antagonistic muscle groups, implying increased control and stability. The primary changes occur in the duration of stance phase activity.[28,80,123,124] The durations of stance phase quadriceps, medial hamstring, and anterior tibialis muscle activity are all decreased in the 18- to 24-month-old as compared with those seen in the 12-month-old. The late swing phase–early stance phase EMG activity in the gastrocnemius-soleus observed at 12- to 18-months is no longer present at 24 months.[28,123,124]

3 to 3.5 Years

Between 3 and 3.5 years of age, the joint angles associated with walking mature into the adult pattern, but the joint torques and propulsion patterns remain immature.[28,101,123,124] Structurally, the tibiofemoral angle, which was neutral at 18 months of age, now shows maximum valgus alignment[100] (Fig. 34.3). Femoral antetorsion of the hip is decreasing but remains increased in relation to that measured in an adult. The center of mass is closer to the extremities as the rate of lower extremity growth stabilizes.[84] Heel eversion in weight bearing is decreasing. Motion analysis demonstrates that a heel strike is consistently present in conjunction with a knee flexion wave in early stance.[123,124] EMG activity has a mature pattern by this age.

Balance mechanisms continue to be refined during this period. Children under 4 years of age do not demonstrate integrated postural development and often "collide" with the boundaries of their base of support at gait initiation and during other perturbations.[6,7] Neither the visual system nor the vestibular systems are mature at this age.[25,51] Torque profiles of perturbation responses and calculation of external work demonstrate that children 3–3.5 years of age continue to exhibit an immature pattern, but the pattern is clearly different from children with less walking experience.[93,103] The vertical acceleration of the center of mass at foot contact reflects limited capacity of the stance leg muscles to control balance. However, walking velocity normalized for height is consistent with that of adults.[21]

6 to 7 Years

By age 7 the gait patterns by standards of movement or motion are fully mature. Minimal changes are noted when compared with the adult pattern. Dimensionless time and distance parameters are fairly constant.[50,116,123,124] Joint torque and propulsion patterns are similar to the adult pattern with the exception of the ankle joint, where lesser values were noted.[29,50] Speed-related changes in joint motion and joint torques are noted.[106] Balance and postural control enable renewed stability after a period of disequilibrium. Where previous research suggested that postural control reached maturity by age 7, with the visual, vestibular, and proprioceptive systems becoming more efficiently coordinated,[21,93,110,152] recent research suggests maturity of these systems is not present until 10–12 years of age.[51,87] Study of a cycling task suggests that intermuscular coordination rather than muscular power limits movement speed and that children younger than 10 years of age do not show an adult pattern.[70] Structurally, the tibiofemoral angle is neutral,[126] and femoral antetorsion is largely resolved but still slightly higher than that measured in the adult.[15,43] The inclination of the talotibial joint is no longer present, and heel position is neutral by age 7.[140] A period of disproportionate growth of body dimensions has also passed. The center of mass is still slightly higher than in the adult, at the level of the third lumbar vertebra.[84]

COMPONENTS OF GAIT AND GAIT ANALYSIS

As stated previously, extensive research has been done and continues to be done on gait. Numerous textbooks and basic research articles have been written on gait.[47-49,61,83,86,97,98,105,106,108,120,123–125,148–151,153] This section describes the components of mature walking as identified by three-dimensional computerized analysis of movement and forces, electromyography, and energy expenditure in a functional context.

One complete gait cycle refers to a single stride that begins when one foot strikes the ground and ends when the same foot strikes the ground again. The gait cycle is divided into two major phases: stance and swing. Stance phase is associated with the period of time when the foot is on the ground; swing phase is the period of time when the foot is in the air. The stance phase of the gait cycle occupies approximately 60% of the cycle, and the swing phase occupies approximately 40%.

Perry[86] developed a generic terminology for the functional phases of gait that further divided the gait cycle into eight subphases. Each subphase has a functional objective that assists in the accomplishment of one of three basic tasks of the walking cycle: weight acceptance, single-limb support, and limb advancement.[92] The basic tasks that Perry's group described are similar to the "attributes" discussed by Gage[49]: weight acceptance and single-limb support (stability in stance and prepositioning of the foot for initial contact) and limb advancement (foot clearance in swing, prepositioning of the foot for initial contact, and adequate step length).

Stance phase is divided into five subphases or instantaneous events (Fig. 34.4):

1. Initial contact (0%–2% of the cycle)
2. Loading response (0%–10% of the cycle)
3. Midstance (10%–30% of the cycle)
4. Terminal stance (30%–50% of the cycle)
5. Preswing (50%–60% of the cycle)

Opposite leg toe-off and opposite initial contact occur at 10% and 50% of the gait cycle, respectively. Thus there are two periods of double support during the walking cycle when both feet are on the ground. These occur during loading response (just after initial contact) and preswing (just before toe-off). Each occupies approximately 10% of the gait cycle.

Swing phase begins at toe-off and occurs during the period of single support of the stance limb. Three subphases are identified (see Fig. 34.4):

1. Initial swing (60%–73% of the cycle)
2. Midswing (73%–87% of the cycle)
3. Terminal swing (87%–100% of the cycle)

Temporal Measurement Definitions and Common Terms

The following definitions will be helpful in the description of walking as used in gait analysis:

Cadence: The frequency of steps taken in a given amount of time, usually measured in steps per minute.

Concentric muscle contraction: A shortening contraction that produces acceleration. Positive work results and power generation occurs.

Eccentric muscle contraction: A lengthening contraction that produces deceleration. Negative work results and power absorption occurs. The efficiency of negative work or power absorption by a muscle is three to nine times higher than that of positive work.[61]

External load: Ground reaction forces, inertial forces, and gravitational forces that affect joint motion.

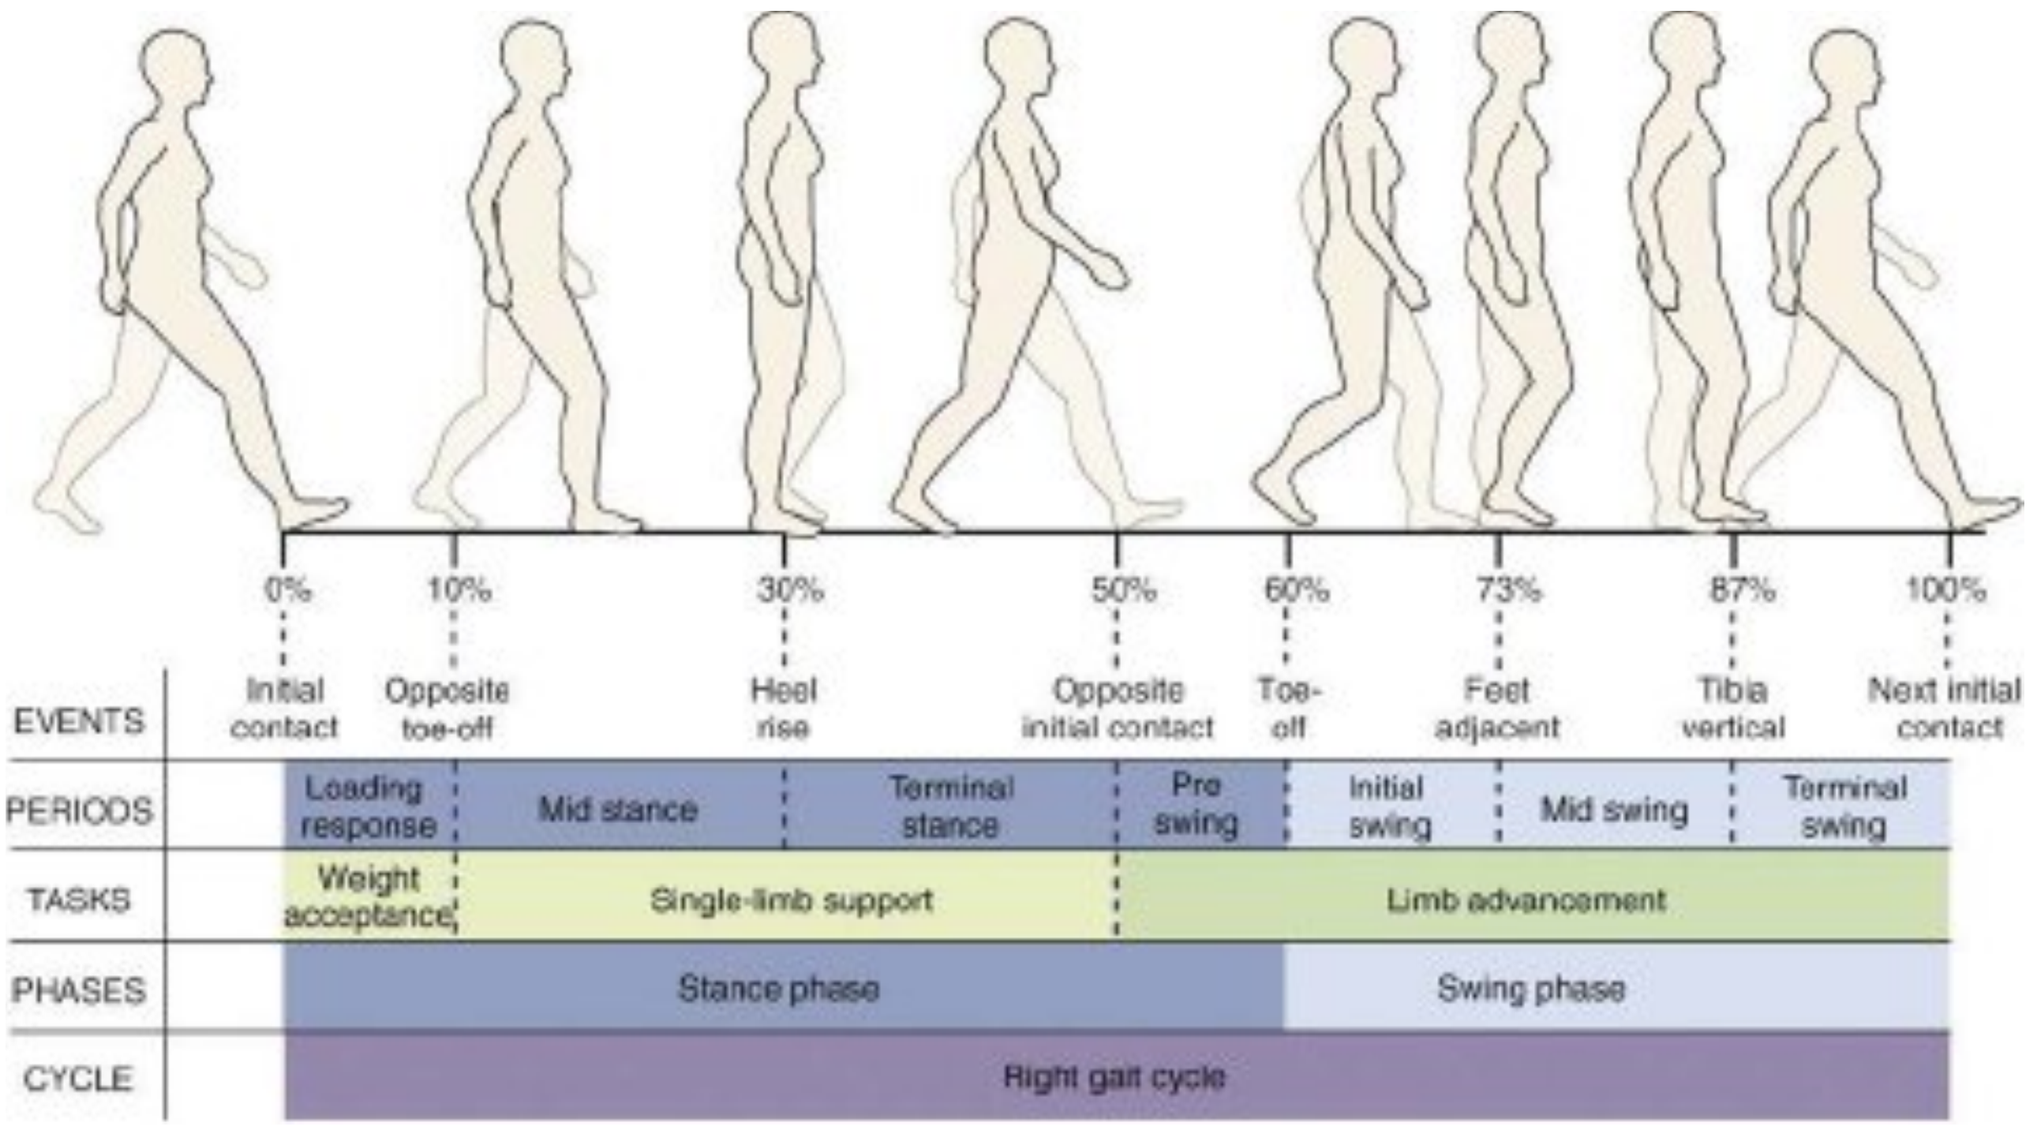

FIG. 34.4 One complete gait cycle depicting stance phase and swing phase. The cycle begins with initial contact of the right foot. Stance phase has four subphases after initial contact; swing phase has three subphases. Initial contact and toe-off are instantaneous events. (From Neumann DA: Kinesiology of the musculoskeletal system: foundations for rehabilitation. 3rd ed. St. Louis: Mosby, 2010.)

Isometric muscle contraction: A stabilizing contraction that produces no net power. Force is produced without length change in the muscle.

Joint moment: A force acting at a distance from an axis causing a rotation about that axis is called a *torque* or *moment* (moment equals force times perpendicular distance). In the body, moments are produced external to the body by ground reaction forces, forces related to gravity, and inertial forces. Moments internal to the body are produced by muscle forces, ligamentous forces, or forces produced by joint capsules. Joint moments in this chapter will represent the physiologic response of the body generated in response to an external load or the net internal moments, in accordance with the definition used by Ounpuu and colleagues.[83]

Joint power: The net rate of energy absorption or generation. Mechanical power is defined as the work performed per unit of time. Joint power is defined as the product of the net joint moment and the joint angular velocity. Muscles are the primary internal power producers in the body. Muscles can also be internal power absorbers. Ligaments usually absorb power.

Kinematics: The parameters used to describe motion without regard to forces. These include linear or angular displacements, velocities, and accelerations.

Kinetics: The parameters that describe the causes of the movement. These include external and internal forces such as gravitational forces, ground reaction forces, inertial forces, muscle or ligament forces, joint moments, and joint powers.

Step length: The longitudinal distance between the two feet. Right step length is measured from the first point of contact of the left foot to the first point of contact of the right foot.

Stride length: The longitudinal distance between the initial contact of one foot and the next initial contact of the same foot. It is the sum of the right and left step lengths and represents the distance traversed in one complete gait cycle.

Walking velocity: The rate of walking or the distance traversed in a specified length of time. Velocity can be expressed as stride length divided by cycle time or the product of step length and cadence. Because of the correlation with leg length and therefore age, methods of normalization are used to evaluate comparisons of different velocities.

Kinematics

Kinematics in gait analysis can be collected in either two or three dimensions. Common to all types of computerized motion analysis is a reference system such as the use of external markers or targets placed on the body and aligned with respect to specific anatomic landmarks. Two-dimensional motion systems provide joint angles that are a direct measure of the motion of the marker set placed on the skin. Three-dimensional systems reference the marker coordinate system to an internal coordinate system based on an estimation of the locations of the anatomic joint centers. The outputs, regardless of two- or three-dimensional technique, are typically displayed as a series of graphs of a single gait cycle for each joint in a given plane of motion. Fig. 34.5 gives an example of three-dimensional motion data. Systems now have the resolution to differentiate smaller targets on the foot allowing multisegment foot kinematics to become more routine in conventional gait analysis (Fig. 34.6).[74,111,117] This technological advance has enhanced the understanding of the complexities of foot motion and its role in pediatric foot disorders and balance.[136]

Kinetics

Kinetics represent the parameters that describe the causes of the movement. These include external and internal forces such as gravitational forces, ground reaction forces, inertial forces, muscle or ligament forces, joint moments, and joint powers. Kinetic data as part of two- or three-dimensional gait analysis are obtained from a combination of force plate and kinematic information. They are displayed as joint moments and joint powers. The force plate provides information regarding the ground reaction force, and the kinematics provide information regarding the joint angular velocities. Anthropometric measurements of the body are required to locate the joint centers. The method commonly used to calculate joint moments and powers is called *inverse dynamics* and is based on a linked segment model approach.[149] A ground reaction force method is another method sometimes used.[149]

A moment or torque is a force acting at a distance that causes an object to rotate. A joint moment represents the physiologic response of the body generated in response to an external load.[83] At Gillette Children's what is displayed on the graphs is the net joint moment, which represents the sum of all internal joint moments in a particular plane at a particular joint. The moments refer primarily to the muscle forces that are acting to control segment rotation, but internal joint moments can be generated by ligaments, joint capsules, and fascia as well. The net joint moment depicts which muscle group is dominant but does not denote the relative contributions of muscle groups on either side of the joint. For example, in the sagittal plane a net extensor moment at the hip during stance phase implies that the hip extensors are dominant. Hip flexors may or may not contribute, but the overall moment is an extensor moment. The hip extensor muscles are active to counteract an external moment created by the ground reaction force that is tending to flex the hip (Fig. 34.7). The ground reaction force tends to flex the hip because it is anterior to the joint center.

Power, in mechanical terms, is defined as the rate of doing work. Joint power is defined as the product of the net joint moment and the joint angular velocity. Muscles are the primary internal power producers in the body. A muscle's ability to produce power is affected by its cross-sectional area. Other factors that affect power include muscle fiber type, the length-tension ratio, and the degree of fatigue (see Chapter 5). Muscles can also be internal power absorbers. Ligaments usually absorb power. The power graphs display whether power is generated (positive work) or absorbed (negative work). Concentric muscle action is associated with power generation, and eccentric muscle action is associated with power absorption. In the previous example the hip is extending in the presence of a net extensor moment; therefore power generation occurs (Fig. 34.8). Typical sagittal plane kinematics and kinetics can be found in Fig. 34.9.

Electromyography

The electrical signal associated with the neuromuscular activation of a muscle is measured by electromyography.[11,149] It represents the pattern of motor unit activation. Electromyographic data can provide information about the timing of muscle activity and, in some cases, about the intensity of muscle contraction. Under some conditions, EMG amplitude has been shown to be related to force,[68,144] but the usefulness of this aspect for assessment of

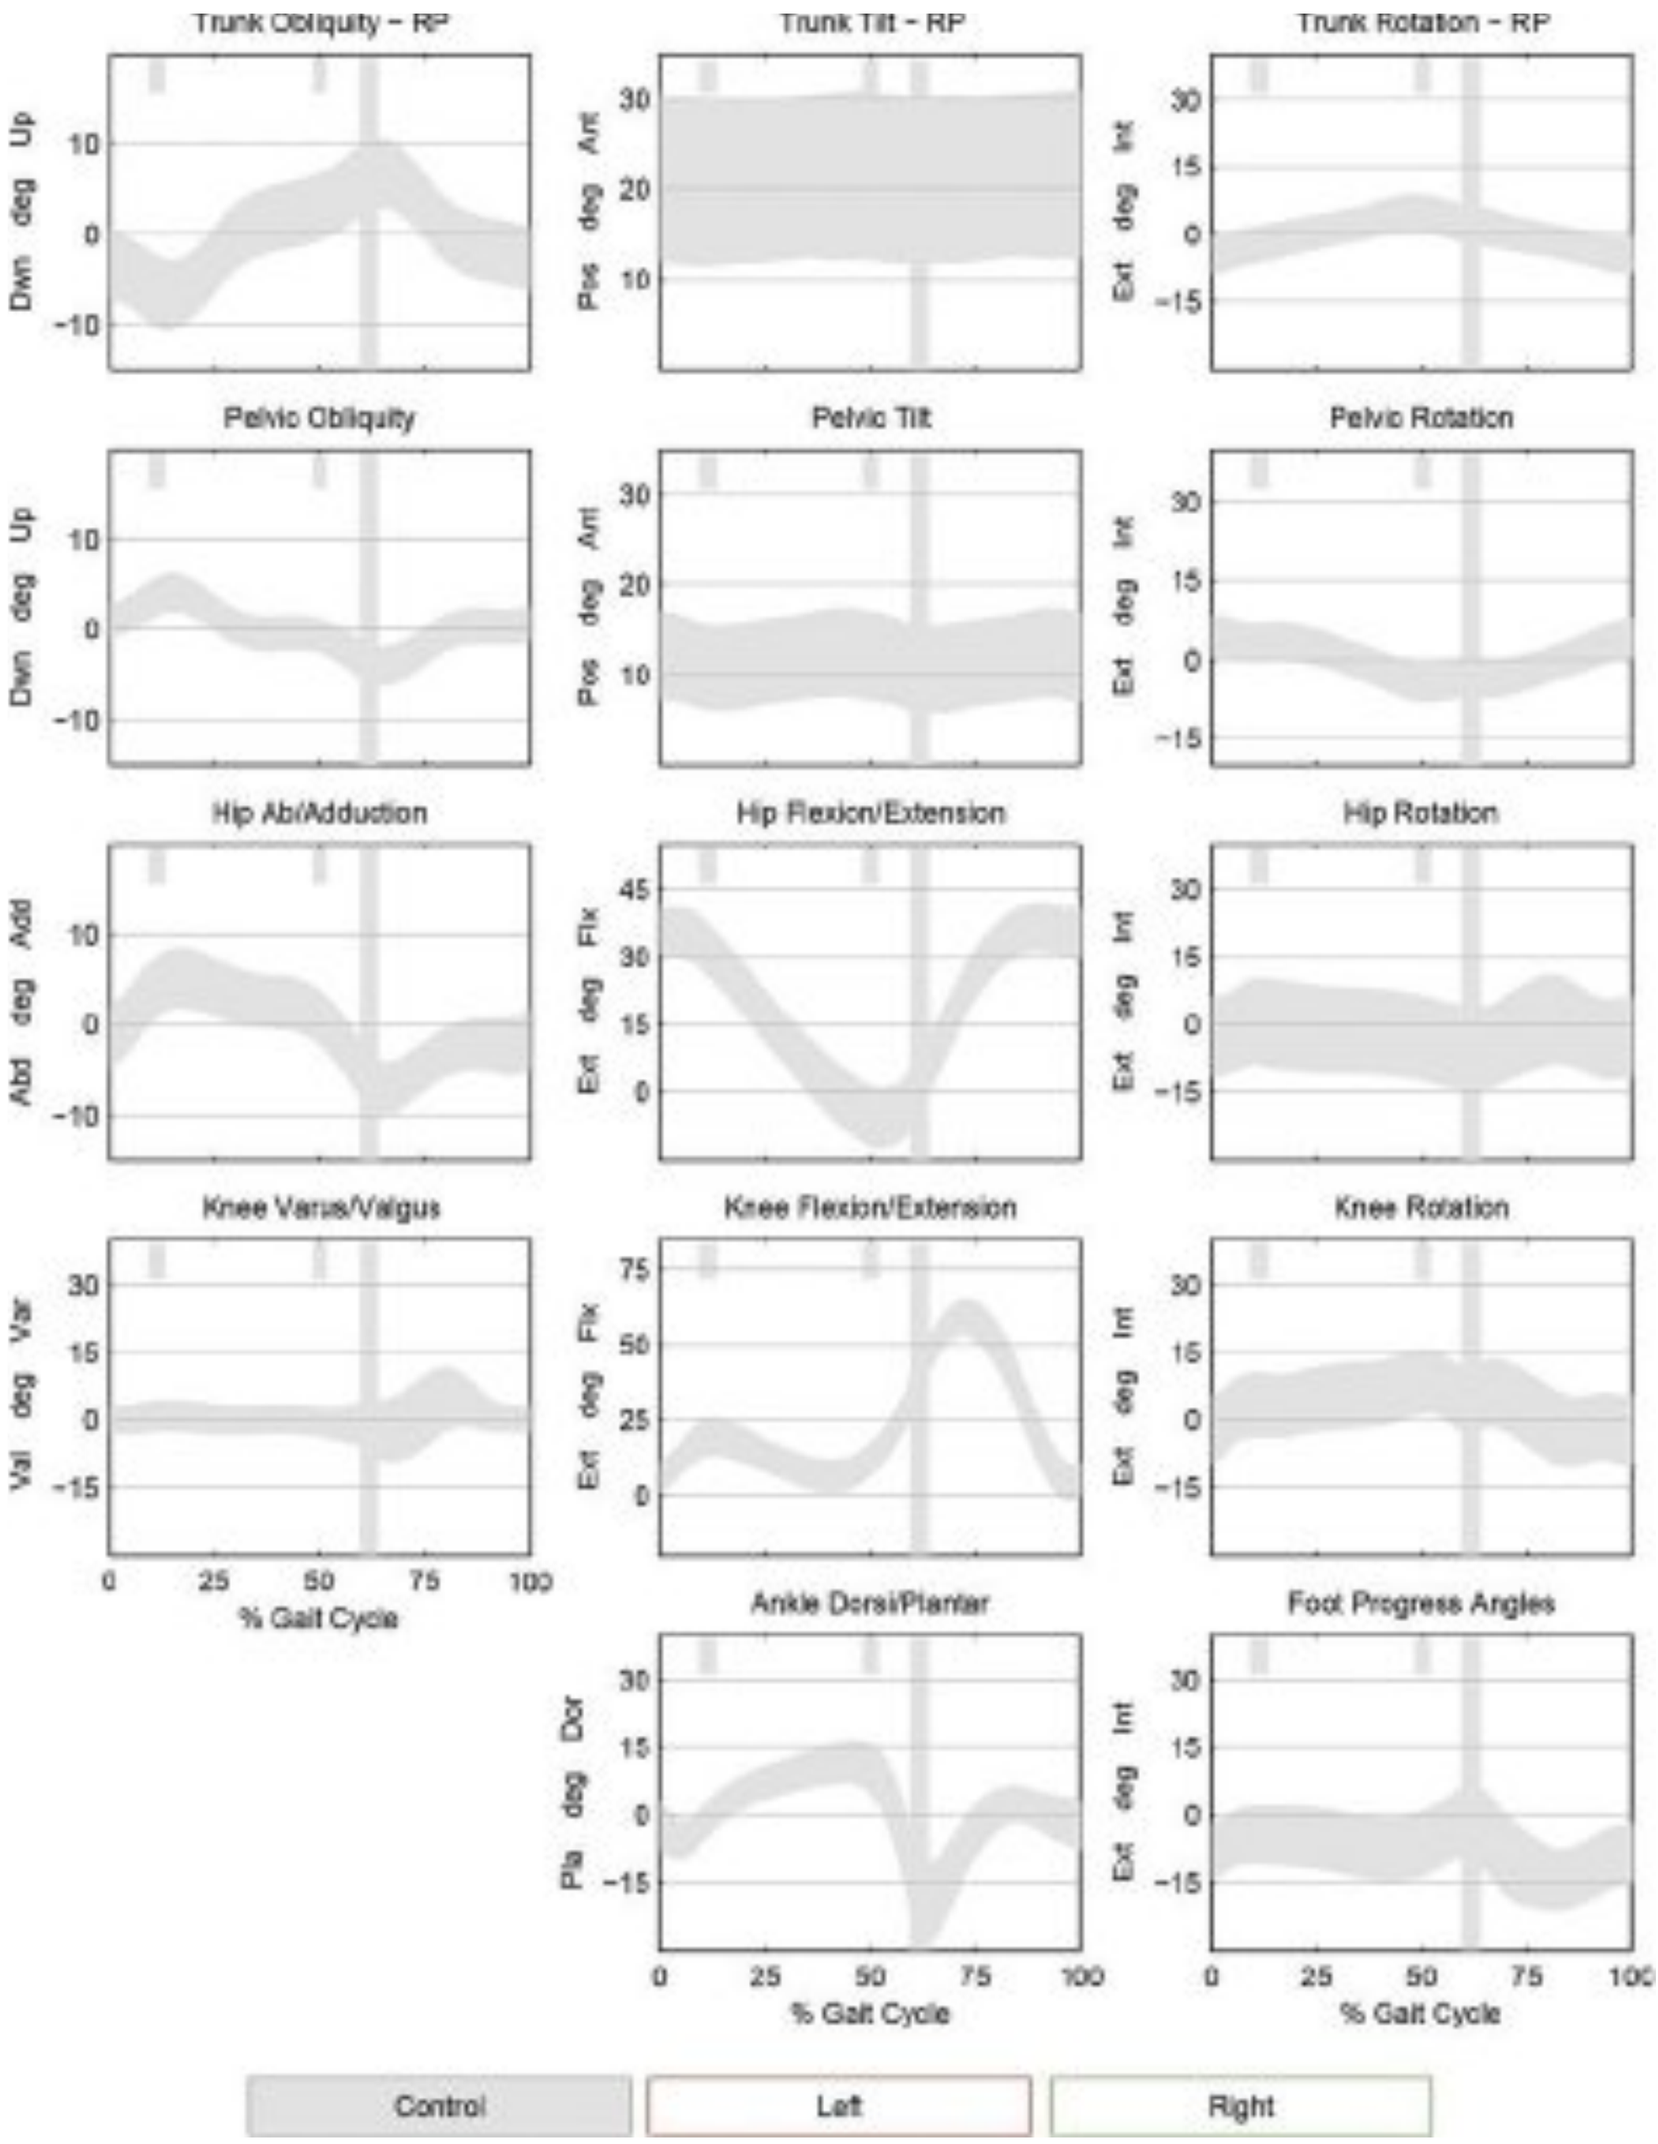

FIG. 34.5 Representative typical three-dimensional kinematic data from the James R. Gage Center for Gait and Motion Analysis of Gillette Children's Specialty Healthcare. In this figure, one complete gait cycle is depicted and is normalized to 100% of the stride. Degrees of motion are on the ordinate. The gray band represents the mean and plus or minus one standard deviation of composite data collected from children ages 4 to 17 years. Stance phase is separated from swing phase in each graph by the vertical bar. Each graph represents the same walking cycle. Each row displays a different joint: from top to bottom are trunk, pelvis, hip, knee, and ankle. Each column displays the movements of a different joint in the same plane of motion; from left to right are the coronal plane (front view), sagittal plane (side view), and transverse plane (rotation view). Note: The pelvis is measured with respect to laboratory coordinates. The trunk and hip are measured with respect to the pelvis, the knee with respect to the thigh, and the sagittal plane ankle with respect to the shank. Foot rotation graph represents foot progression angle with respect to laboratory coordinates, not rotation of the foot with respect to the tibia.

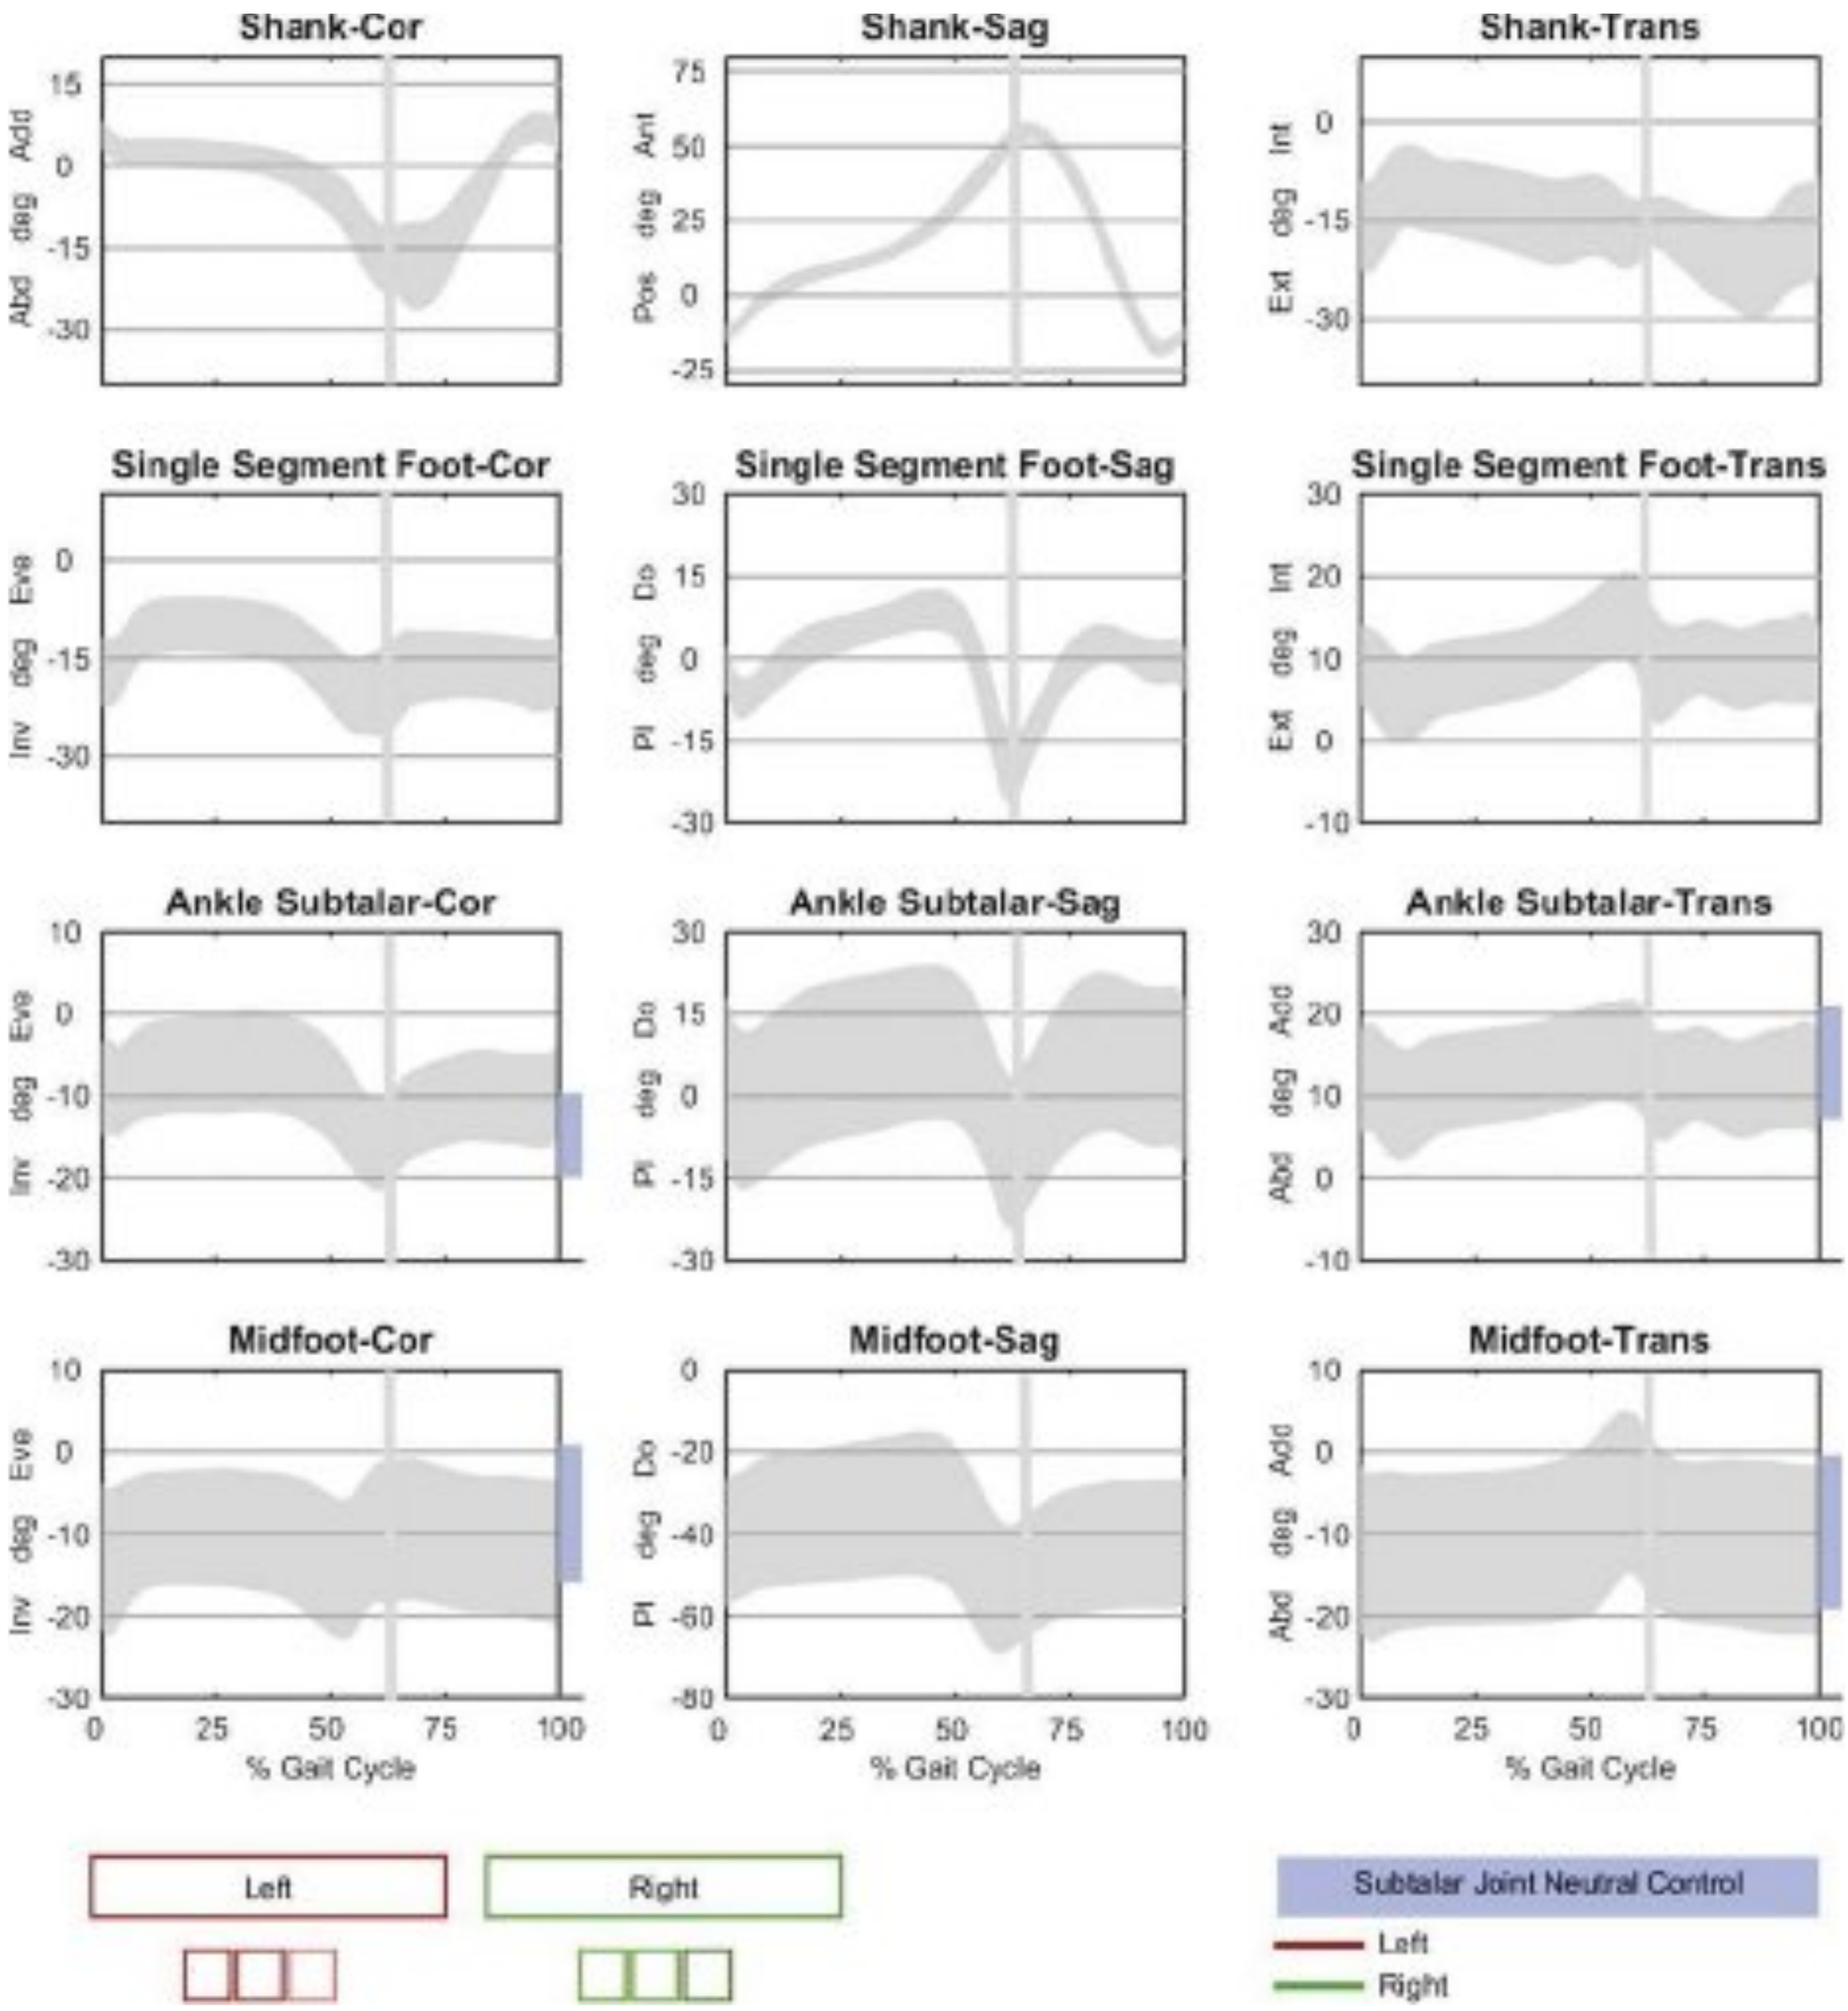

FIG. 34.6 Representative multisegment foot kinematic data from the James R. Gage Center for Gait and Motion Analysis of Gillette Children's Specialty Healthcare. Each graph depicts one complete gait cycle normalized to 100% of the stride on the x axis. Degrees of motion are depicted on the y axis. The gray band represents the mean and plus or minus one standard deviation of a composite of data collected from children ages 4 to 17 years. Stance phase is separated from swing phase in each graph by the vertical bar. Each graph represents the same walking cycle. Each row displays a different segment: from top to bottom are shank, single-segment foot, ankle subtalar, and midfoot/forefoot. Each column displays the movements of a segment in the same plane of motion; from left to right are the coronal plane (front view), sagittal plane (side view), and transverse plane (rotation view). Note: The shank is measured with respect to laboratory coordinates. The ankle subtalar segments represent the hindfoot with respect to the shank across all planes, and the midfoot segments represent the forefoot relative to the hindfoot across all planes. The vertical blue bar represents the non–weight-bearing subtalar joint neutral position of the hindfoot relative to the shank (ankle subtalar) and the forefoot relative to the hindfoot (midfoot) in the coronal and transverse planes as measured by the motion capture system.

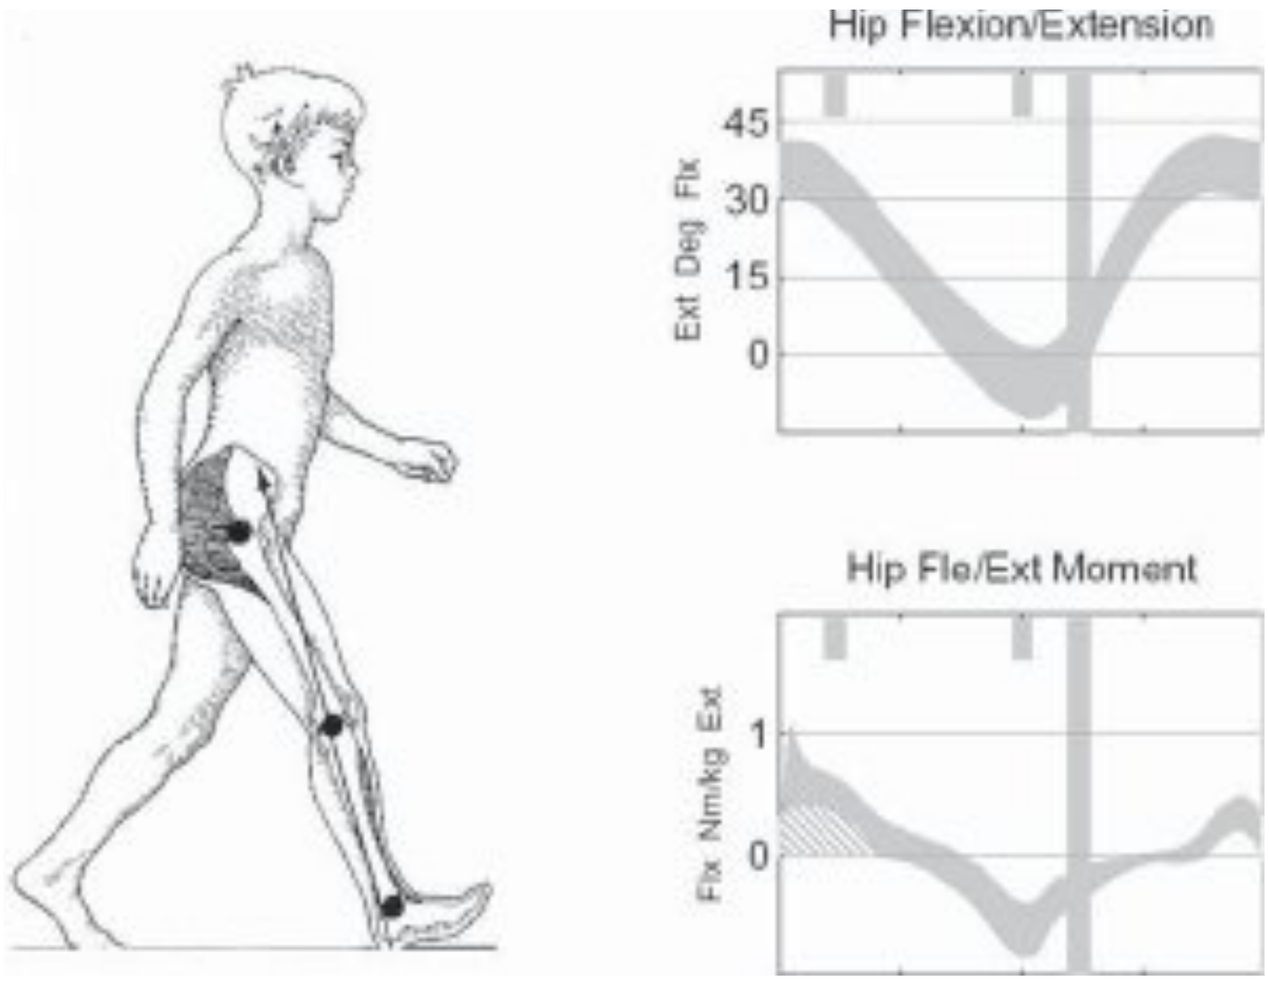

FIG. 34.7 An example of an internal joint moment produced at the right hip. Because the ground reaction force falls anterior to the hip joint, the joint would flex without internally produced resistance. The joint moment graph demonstrates a net extensor moment at the hip (shaded) as the body's internal resistance to the external force. The internal moment is produced by dominant action of the hip extensor muscles. (Adapted in part from Gage JR: Gait analysis in cerebral palsy. London: Mac Keith Press, 1991.)

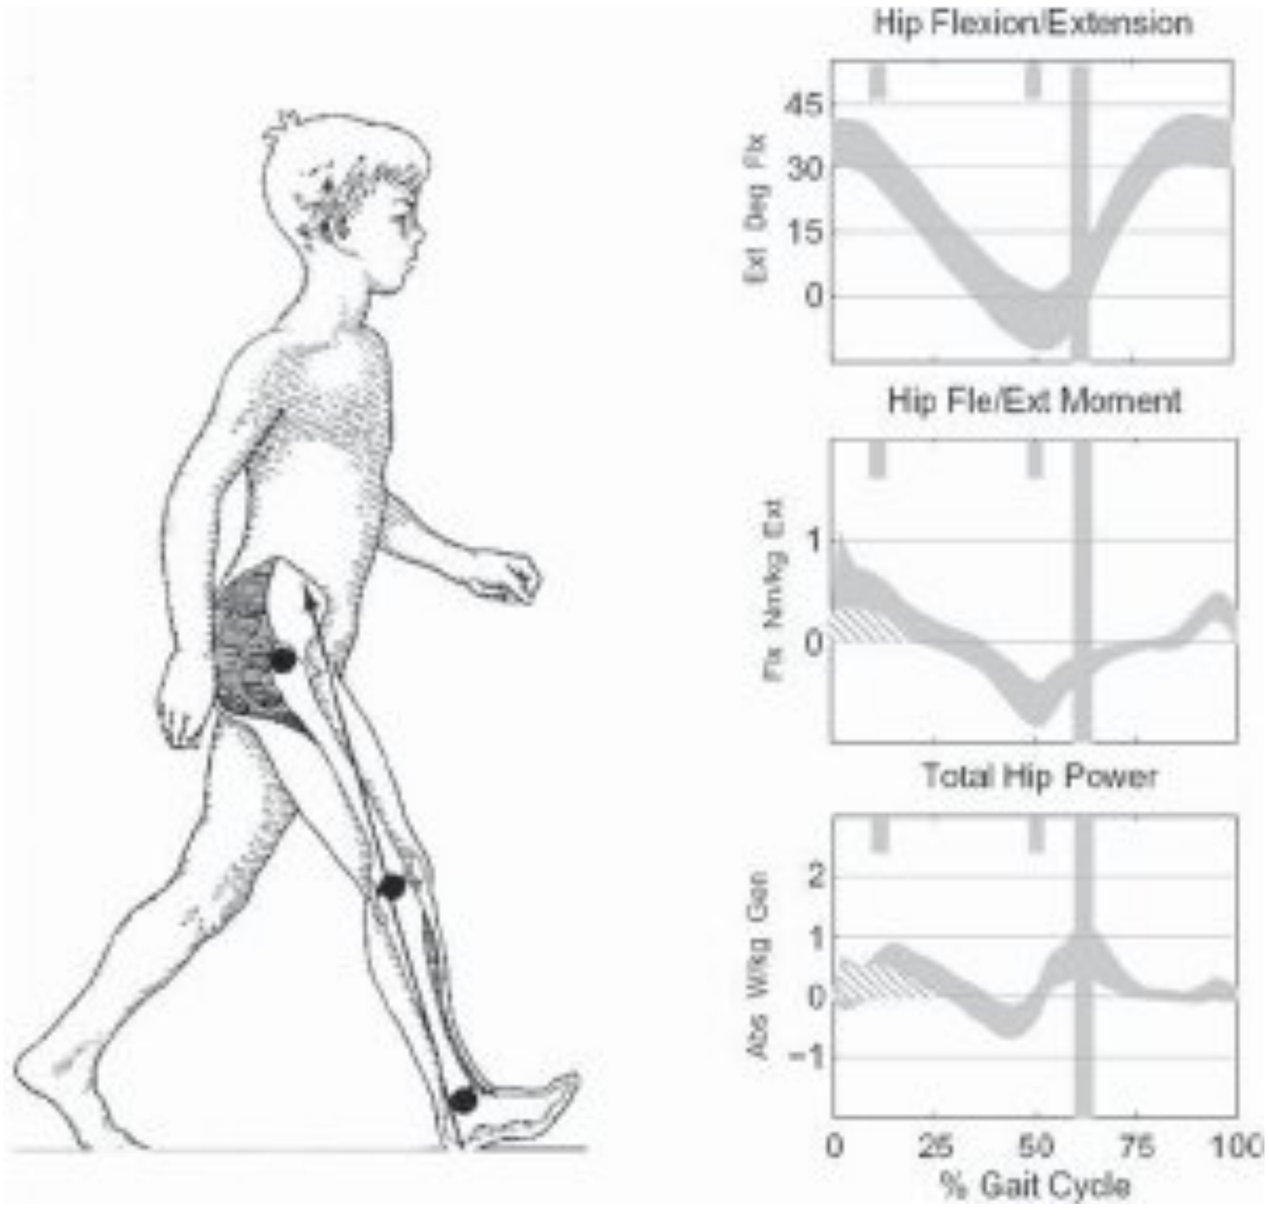

FIG. 34.8 An example of power generation at the right hip. Because the hip is extending and a net extensor moment is present, power generation (shaded) occurs. The units for power are watts per kilogram. By convention, power generation is represented by positive deflection on the graph; power absorption is negative. (Adapted in part from Gage JR: Gait analysis in cerebral palsy. London: Mac Keith Press, 1991.)

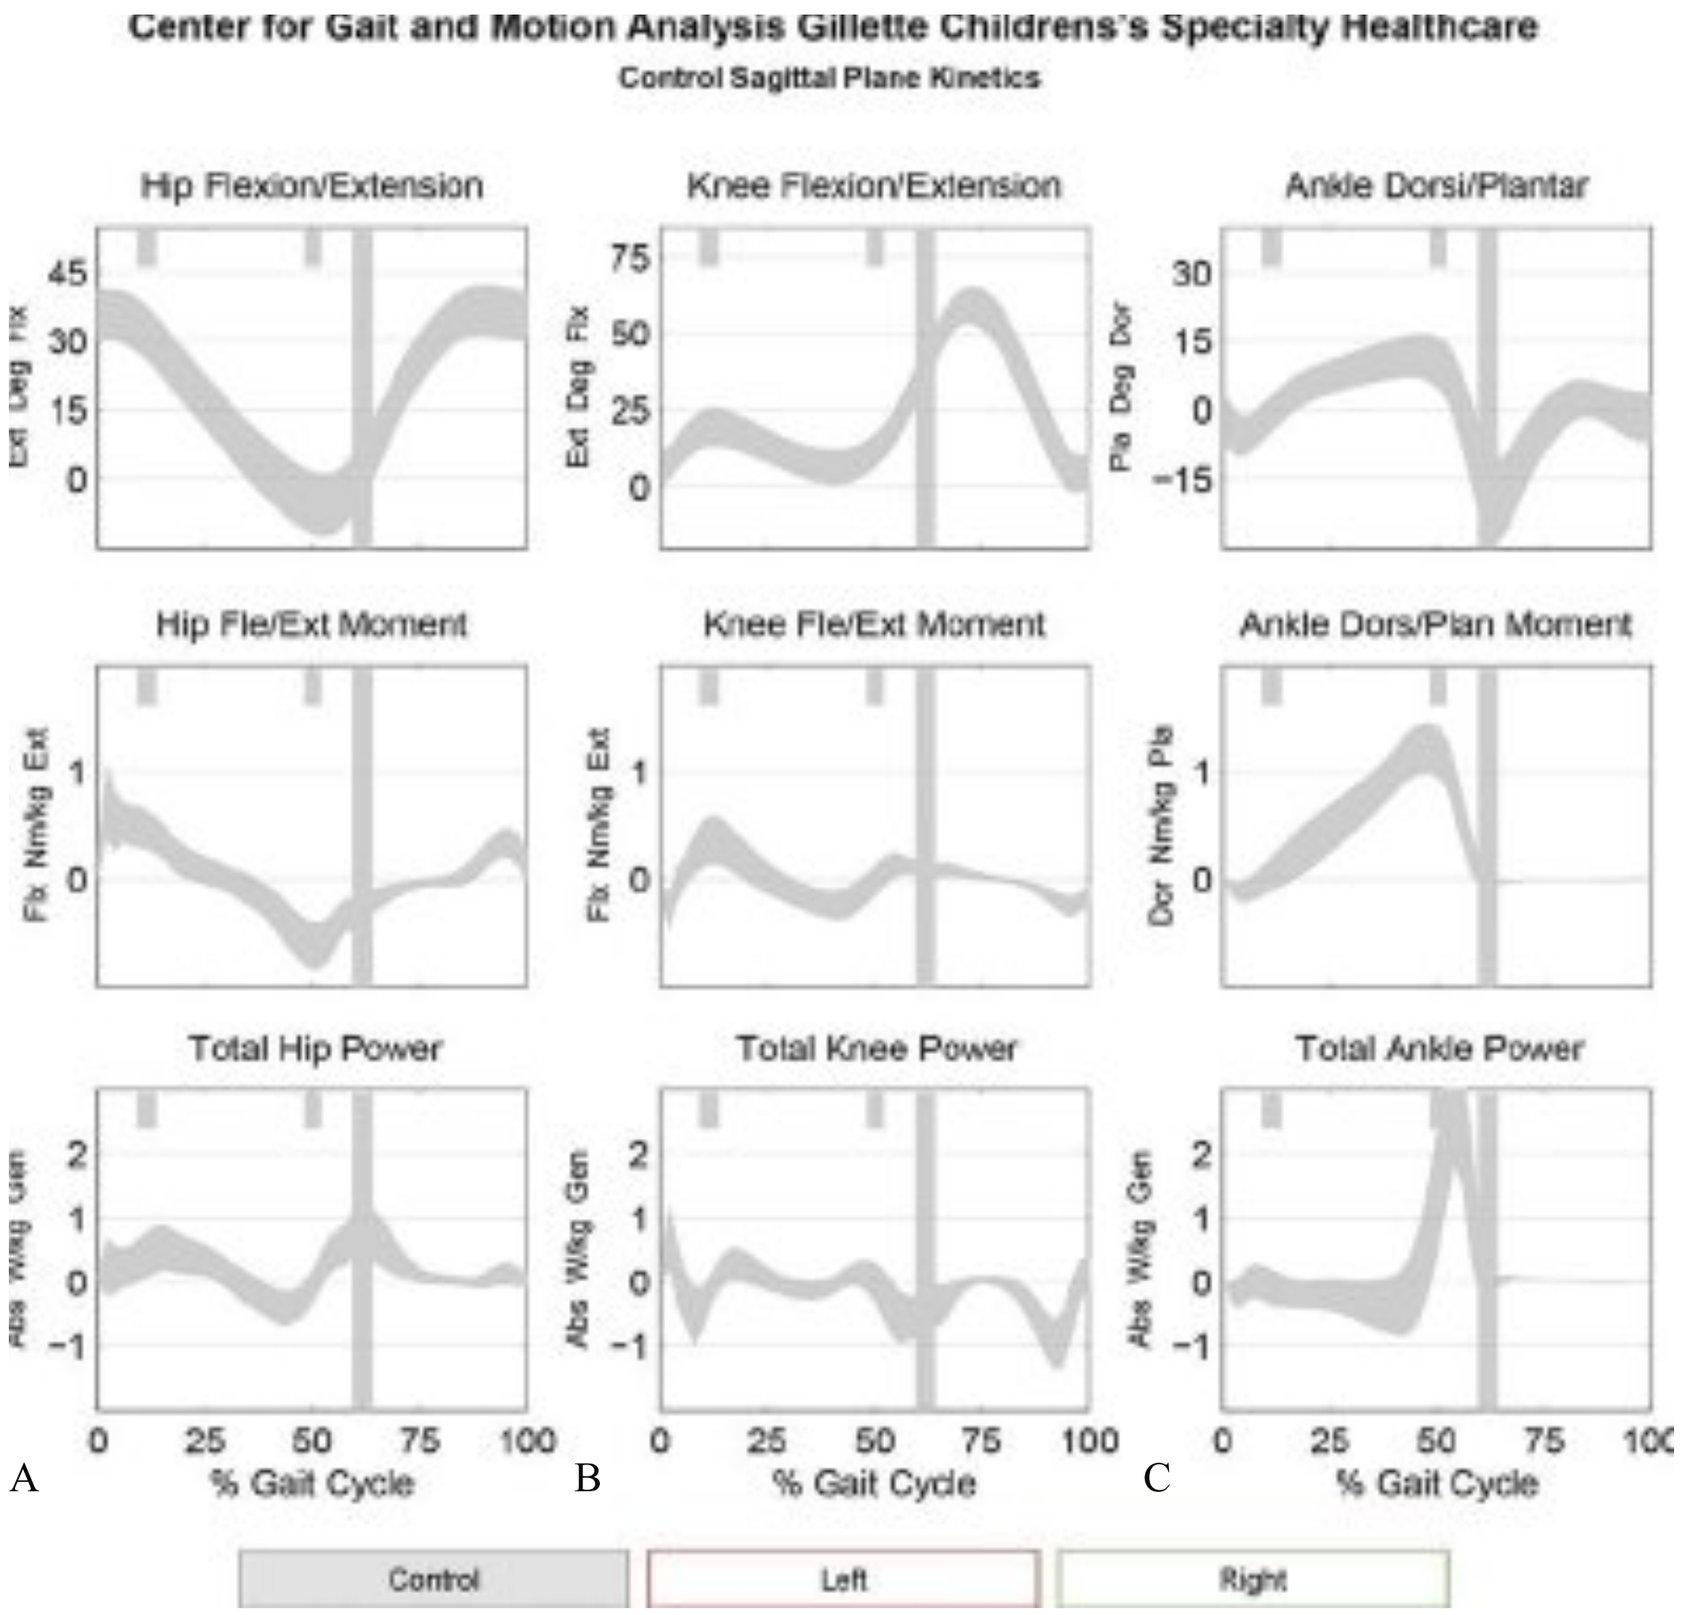

FIG. 34.9 Sagittal plane kinematics and kinetics of the hip (A), knee (B), and ankle (C). Each graph represents the same walking cycle, with the mean (solid line) and one standard deviation (dashed line). The top row shows the kinematic graphs; the middle row, the joint moments; and the bottom row, the joint powers. Units for the kinematics are degrees. The units for joint moments (newton-meters/kilogram) and powers (watts/kilogram) are standardized for body weight.

walking is limited because the relationship is valid only under isometric conditions and when no co-activation is occurring.

The amplitude of an EMG signal is affected by the rate of motor unit firing and the number of motor units active at any given time. The type of motor units firing and the proportion of different motor units firing also affect amplitude. Walking speed has been shown to influence both the timing of the muscle firing and amplitude.[106] In addition, many external factors, including electrode location, type of electrode used, interelectrode distance, skin temperature, and amount of subcutaneous fat, also affect the amplitude of the signal.[11] Comparing EMG amplitudes across muscles, or within or between subjects, should be done with caution and adequate understanding of the complexity involved in interpretation. Understanding the relationship of muscle activity and force with joint kinematics and kinetics using engineering principles and neural network representations continues to be a focus of research.[10,27,108,153]

Each muscle has a particular time during the walking cycle when activity is present or absent and a particular pattern of increasing or decreasing motor unit activity. These timings have been documented for both children and adults.[83,86,106,123,147] An example can be found in Fig. 34.10. EMG data can be collected using surface or fine wire (indwelling) electrodes. Reviews on the advantages and disadvantages of each have been published.[66]

KINEMATICS, KINETICS, AND ELECTROMYOGRAPHY IN NORMAL GAIT

A detailed description of activity in the lower extremities during each phase of the gait cycle is presented in this section, including a summary of hip, knee, and ankle kinematics and kinetics with associated muscle activity. Sagittal plane events are emphasized. The reader should refer to the kinematic and kinetic plots and videos (located on ExpertConsult) associated with each description.

Sagittal Plane

At initial contact (0% of the gait cycle) the ankle is in a position of neutral dorsiflexion, the knee is in minimal flexion, and the hip is in approximately 35 degrees of flexion. The objective of this event is appropriate prepositioning of the foot to begin the gait cycle. The ground reaction force at initial contact is passing through the heel

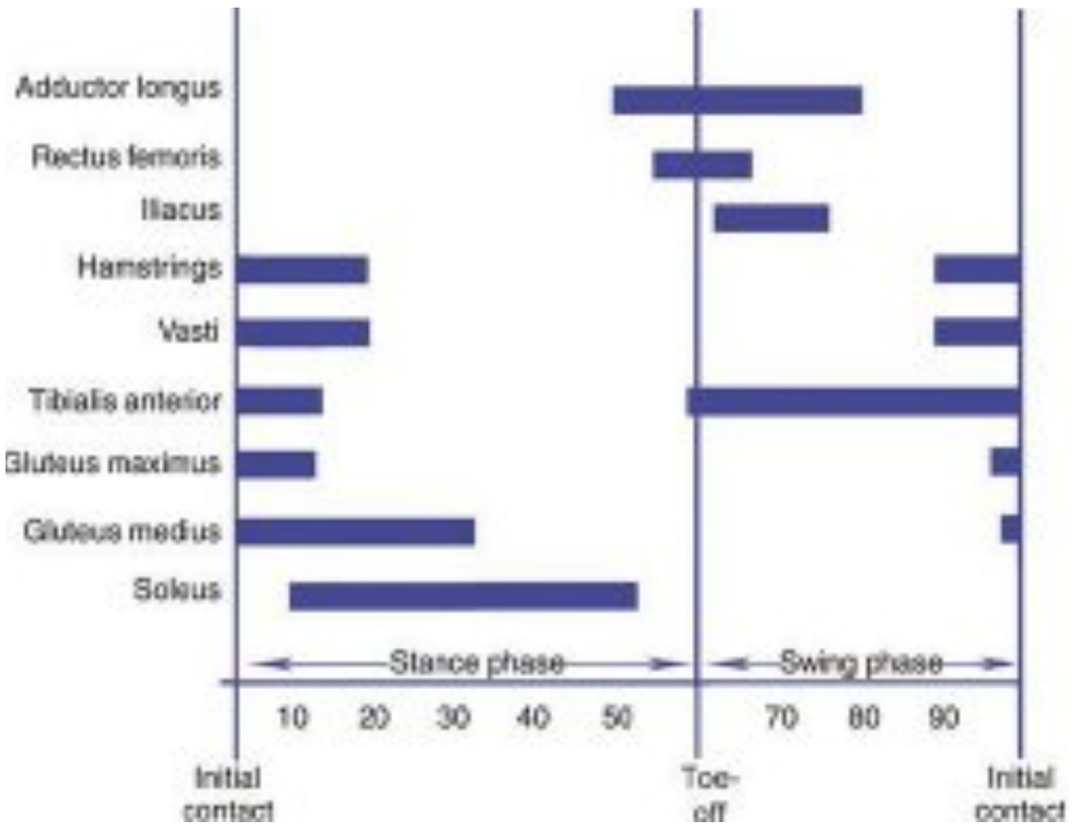

FIG. 34.10 The phasic (on/off) EMG activity of the major muscles used during walking. (Based on data from the Center for Gait and Motion Analysis, Gillette Children's Specialty Healthcare.)

FIG. 34.11 Initial contact of the gait cycle. (From Gage JR: Gait analysis in cerebral palsy. London: Mac Keith Press, 1991.)

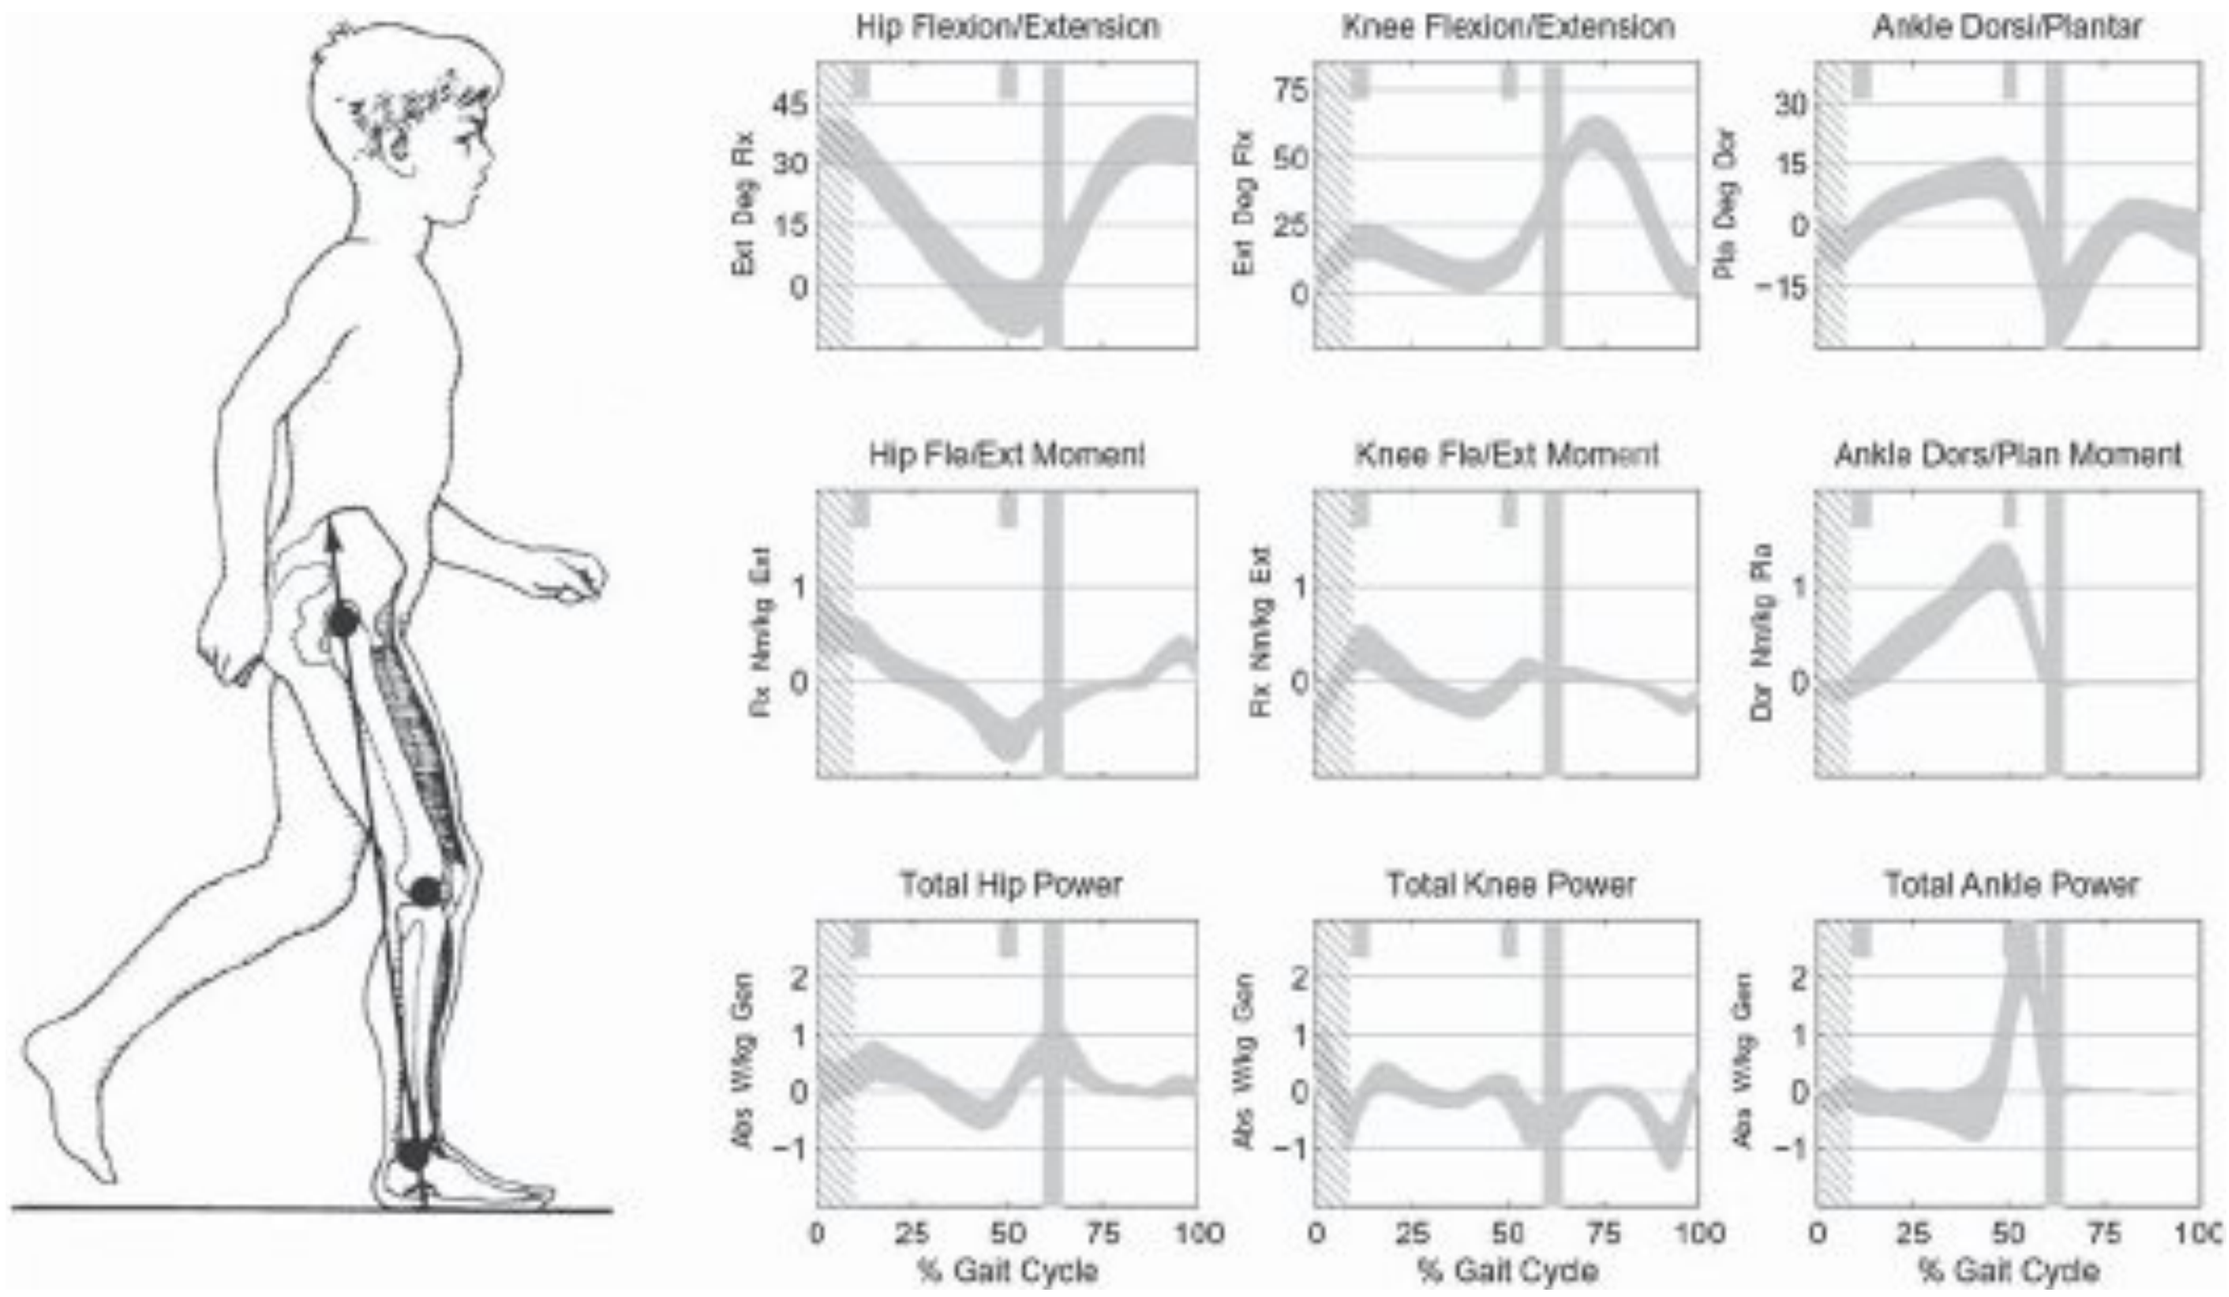

FIG. 34.12 Loading response (0% to 10% of the gait cycle). (Adapted from Gage, JR: Gait analysis in cerebral palsy. London: Mac Keith Press, 1991.)

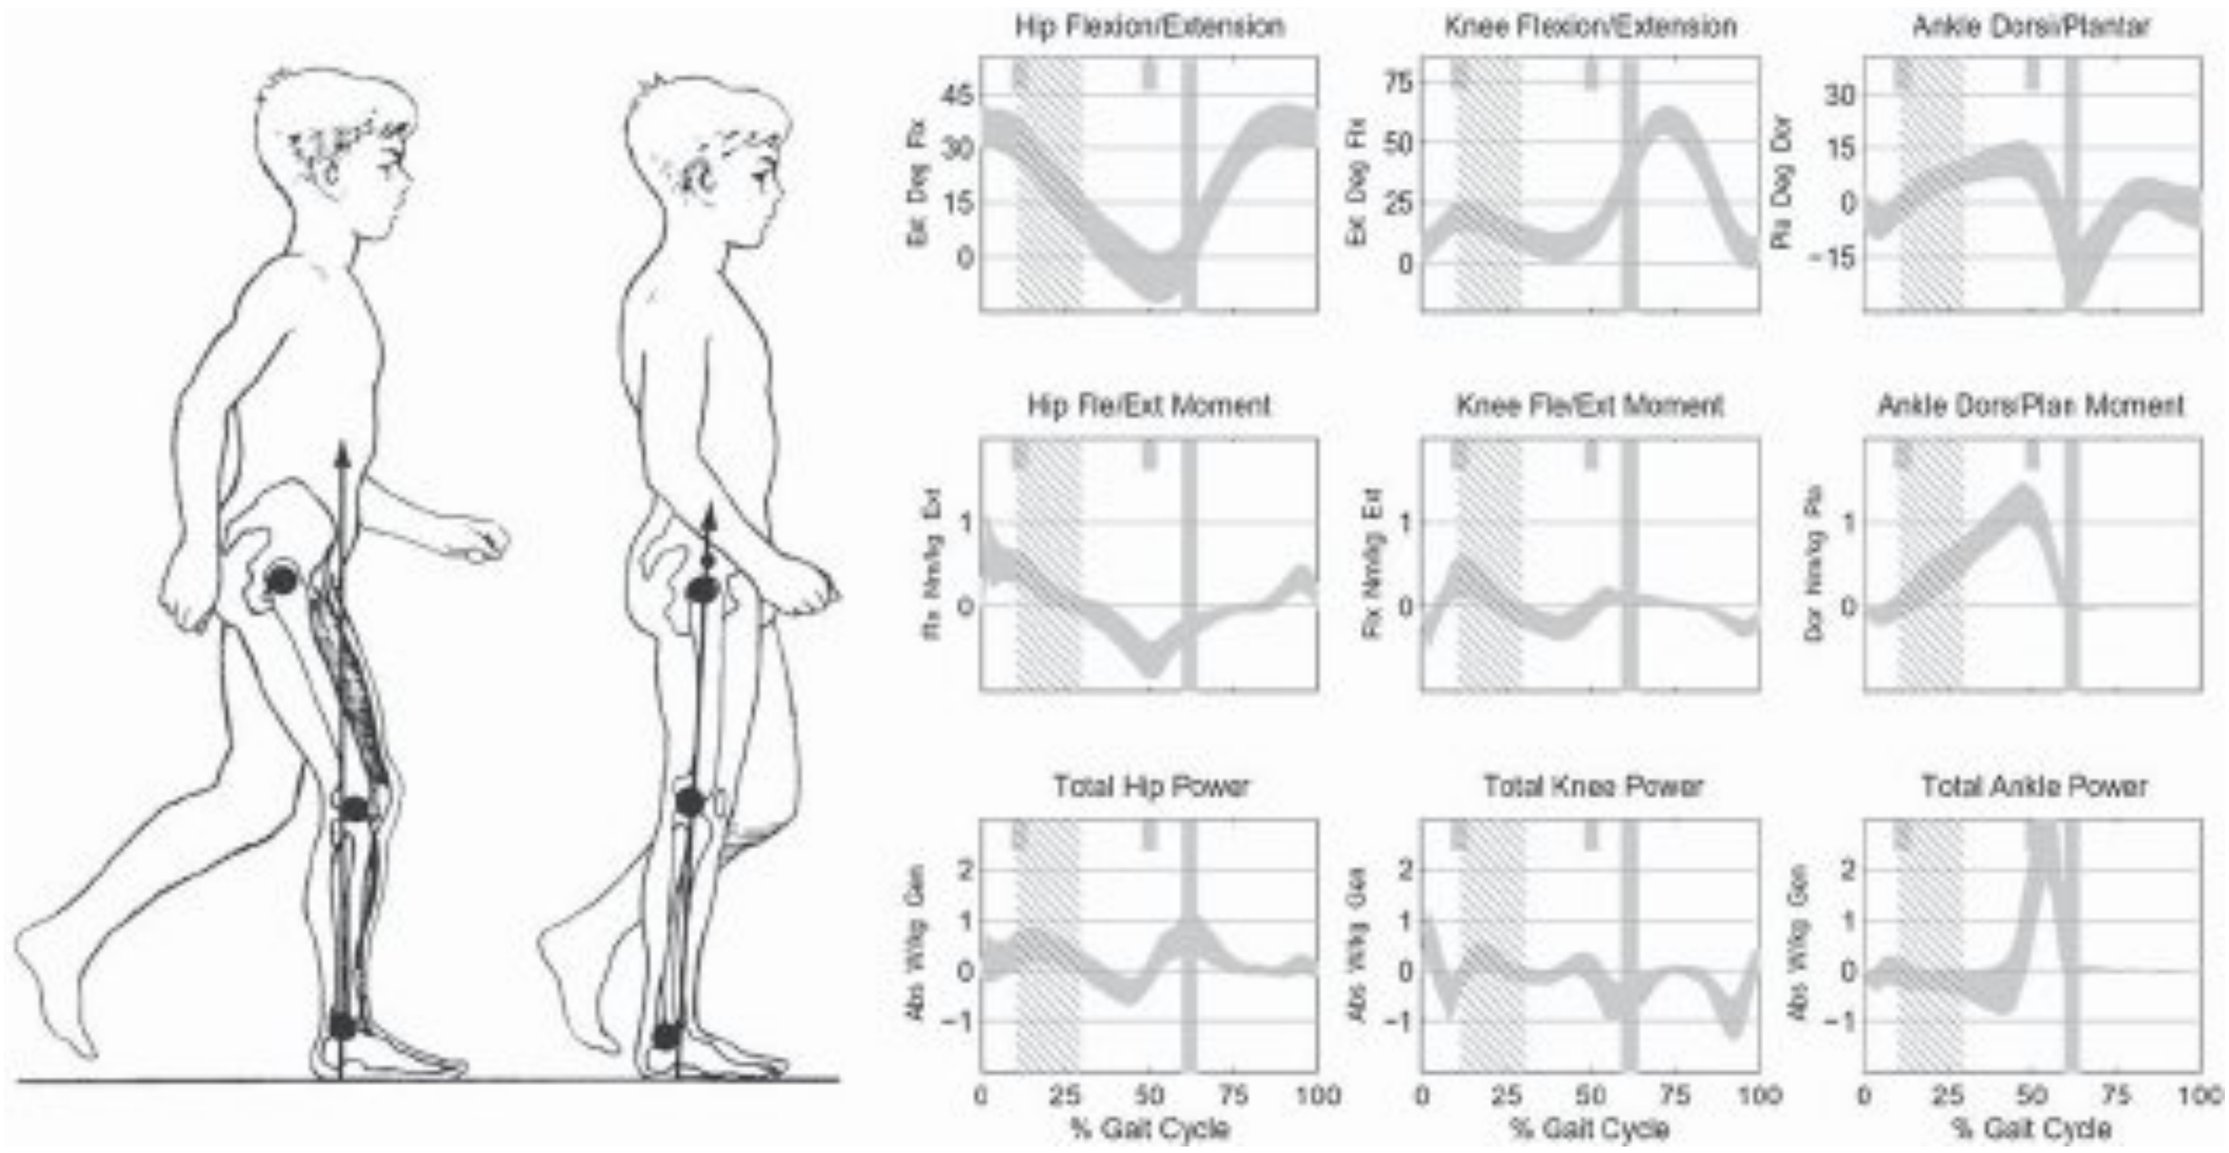

FIG. 34.13 Midstance (at 10% to 30% of the gait cycle). (Adapted from Gage JR: An overview of normal walking. In Greene WB, editor: Instructional course lectures. vol 39. Park Ridge, IL: American Academy of Orthopaedic Surgeons, 1990.)

and is anterior to both the knee and the hip. The gluteus maximus and hamstrings muscles are active to control the external flexor moment at the hip. The hamstrings also assist in preventing knee hyperextension. Anterior tibialis and quadriceps activity initiates the loading response (Fig. 34.11; see video *Initial Contact*).

Loading response (Fig. 34.12; see video *Loading Response*) is a period of acceptance of body weight while maintaining stability and progression. The purpose of loading response is to cushion or absorb the impact of the body's moment of inertia. It is the first period of double support and occurs between 0% and 10% of the gait cycle, beginning after initial contact and ending when the entire foot is in contact with the floor. The ankle is plantar flexing at this time under controlled eccentric contraction of the anterior tibialis muscle. The internal moment at the ankle is a net dorsiflexor moment because the dorsiflexor muscles are dominant. The power curve depicts absorption because the anterior tibialis muscle is contracting eccentrically. Gage,[48,49] Gage and Schwartz,[105] and Perry[86] refer to loading response as the first "rocker" of ankle stance phase.

During loading response the knee undergoes an initial phase of flexion to approximately 15° (average value). Both hamstring activity and quadriceps muscle activity are present. Because the quadriceps muscles are acting eccentrically to decelerate knee flexion, the power graph depicts absorption. Whenever the joint movement and the joint moment are opposite each other, power absorption is occurring.

Concentric action of the gluteus maximus, gluteus minimus, and hamstring muscles extends the hip. The hamstrings are able to work as hip extensors because knee motion is stabilized by the single-joint muscles of the quadriceps. The net internal joint moment is extensor, and the power graph depicts generation. Because the external ground reaction force falls anterior to the hip joint, without the action of the hip extensors the joint would collapse into flexion.

Midstance (Fig. 34.13; see video *Midstance*) is the beginning of the single-support phase of the gait cycle and extends from the period of 10% to 30% of the cycle. The goal during midstance is to maintain trunk and limb stability and allow smooth progression over a stationary foot when the entire plantar surface is in contact with the floor. The ankle is in a period of increasing dorsiflexion that is controlled by eccentric contraction of the soleus muscle. The moment graph demonstrates a dominant plantar flexor moment and the power graph a period of absorption. The second rocker of ankle stance phase occurs during midstance.[47-49]

The knee extends during midstance. The vastus medialis, vastus intermedius, and vastus lateralis muscles work initially to stabilize the knee until the ground reaction force passes anterior to the knee joint. Once the ground reaction force is anterior to the knee, extension is passive. The joint moment at the knee is an extensor moment. The power graph shows initial decreasing absorption followed by generation. This period of power generation is the only one produced at the knee during the entire gait cycle.

The hip continues to extend during midstance. The joint moment is extensor, and power is generated, implicating concentric action of the hip extensor muscles. The internal extension moment, however, is decreasing during this time. When the ground reaction force becomes posterior to the hip joint, a transition occurs from a concentric (power generation) extensor moment to an eccentric (power absorption) flexor moment.

Terminal stance (Fig. 34.14; see video *Terminal Stance*) is the second half of the single-support phase and occurs from 30% to 50% of the gait cycle. This period begins when the ground reaction force passes anterior to the knee and posterior to the hip and often occurs with heel rise. During this phase of the gait

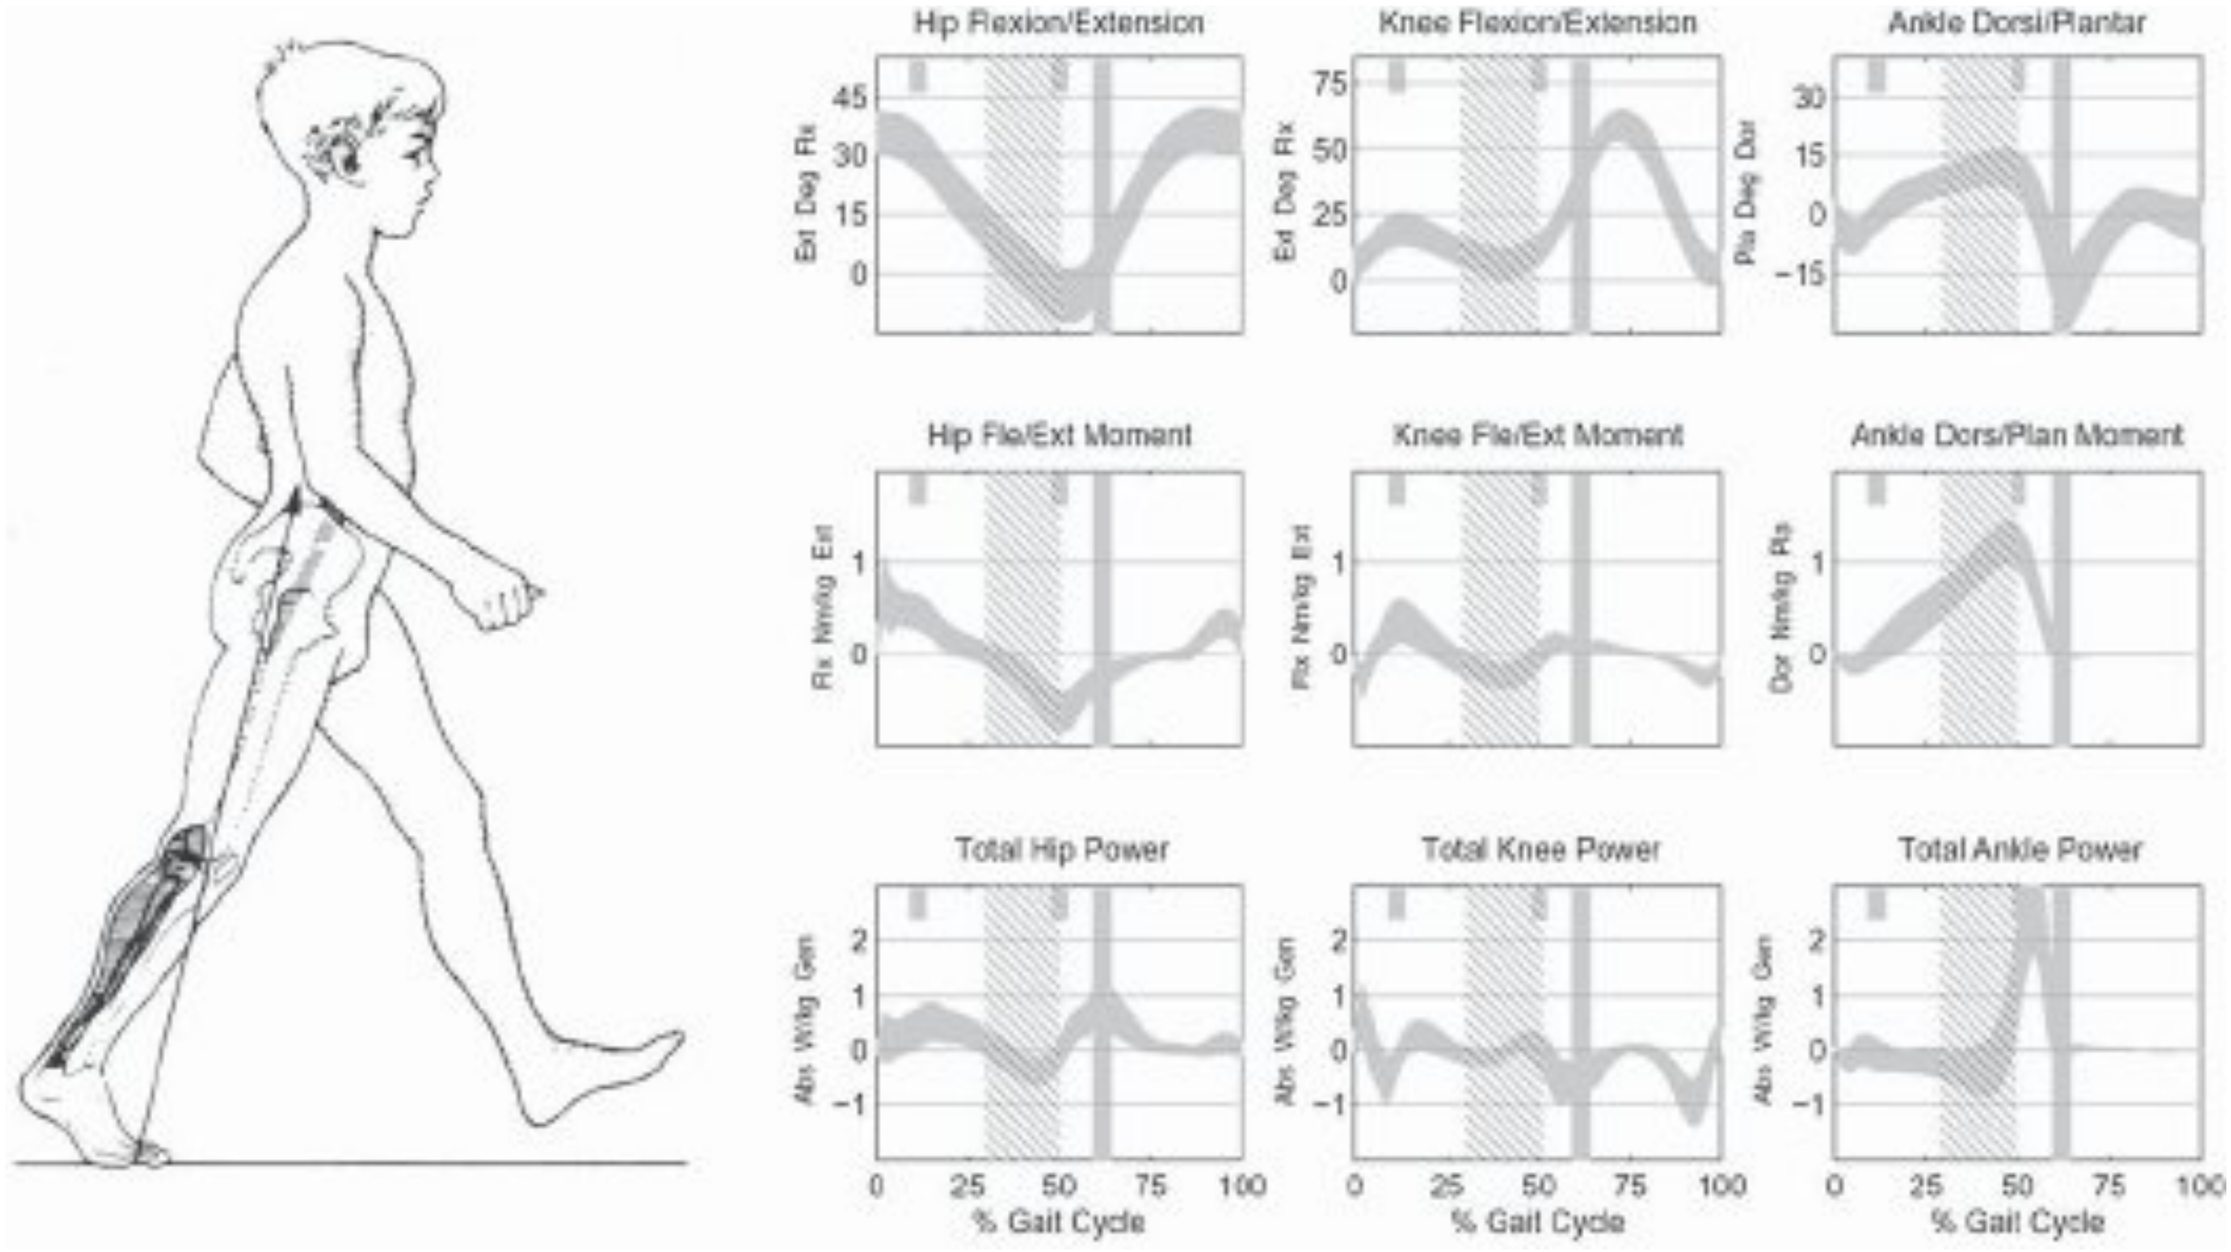

FIG. 34.14 Terminal stance (at 30% to 50% of the gait cycle). (Adapted from Gage JR: Gait analysis in cerebral palsy. London: Mac Keith Press, 1991.)

cycle, forward progression of the tibia is arrested and further increase in dorsiflexion is limited. The ankle begins a period of decreasing dorsiflexion by concentric contraction of the gastrocnemius and soleus muscles, producing power generation. One of the primary power productions that propels an individual through the walking cycle is generated at the ankle during terminal stance (36% of the total power generation produced during the walking cycle).[83,151] Heel rise marks the period of the third rocker of ankle stance phase.[47–49]

The knee moves from relative extension to increasing flexion during terminal stance. An internal net flexor moment is dominant because the ground reaction force falls in front of the knee. Power is absorbed. The internal flexor moment is produced by a combination of ligamentous resistance and flexor activity of the gastrocnemius muscle.

The hip continues to extend during terminal stance. Because the ground reaction force is posterior to the joint center, extension is resisted by an internal flexor moment. Power is absorbed, suggesting that the flexor moment is produced by tension force of the iliofemoral ligament.

Preswing (Fig. 34.15, see video *Preswing*) is the second period of double support during the walking cycle and occurs at 50% to 60% of the cycle. The function of preswing is to advance the limb into swing; preswing ends at toe-off. The stance phase extremity is unweighted because weight is accepted on the opposite limb. The ankle is now in true plantar flexion, and the plantar flexor moment remains dominant. The magnitude of the moment is rapidly decreasing, however, and power generation falls quickly to zero.

The knee joint is flexing during preswing and reaches approximately 45° (average value) at toe-off. The internal muscle moment is extensor, and power is absorbed. Activity of the rectus femoris muscle is probably responsible for this activity and assists the deceleration of the moment of inertia of the shank.

The hip begins to flex in preswing. The dominant moment is a flexor moment, and power is generated. Concentric action of the hip flexor muscles, primarily the iliopsoas, produces the activity. Occasionally, the rectus femoris muscle is active to augment hip flexion. This usually occurs at faster walking speeds. Peak flexor power of the hip is generated at toe-off. Hip musculature (both extensors and flexors) is responsible for the majority of positive work performed during the walking cycle (56%), with most being produced during stance phase.[83]

The objective of initial swing (Fig. 34.16; see video *Swing Phase*) is foot clearance and limb advancement. Initial swing occurs from 60% to 73% of the gait cycle. Maximum plantar flexion occurs at the ankle in initial swing. At the same time, peak knee flexion occurs, uniquely timed for optimal clearance of the foot. The ankle then begins to dorsiflex by activity of the anterior tibialis muscle. The dominant muscle moment is a dorsiflexor moment. Power output is negligible. The hip flexes during initial swing, which also assists foot clearance. A flexor moment remains dominant, and power generation is occurring by concentric activity of the hip flexors.

The goals of midswing (Fig. 34.17; see video *Swing Phase*) remain foot clearance and limb advancement, and it occurs between 73% and 87% of the gait cycle. The ankle is dorsiflexing during this time by concentric action of the anterior tibialis muscle. The knee is extending by inertial forces without muscle activity. The hip is flexing.

The primary purpose of terminal swing (Fig. 34.18; see video *Swing Phase*) is prepositioning of the limb for weight acceptance. This phase occupies the period between 87% and 100% of the gait cycle. The ankle begins to plantar flex by eccentric

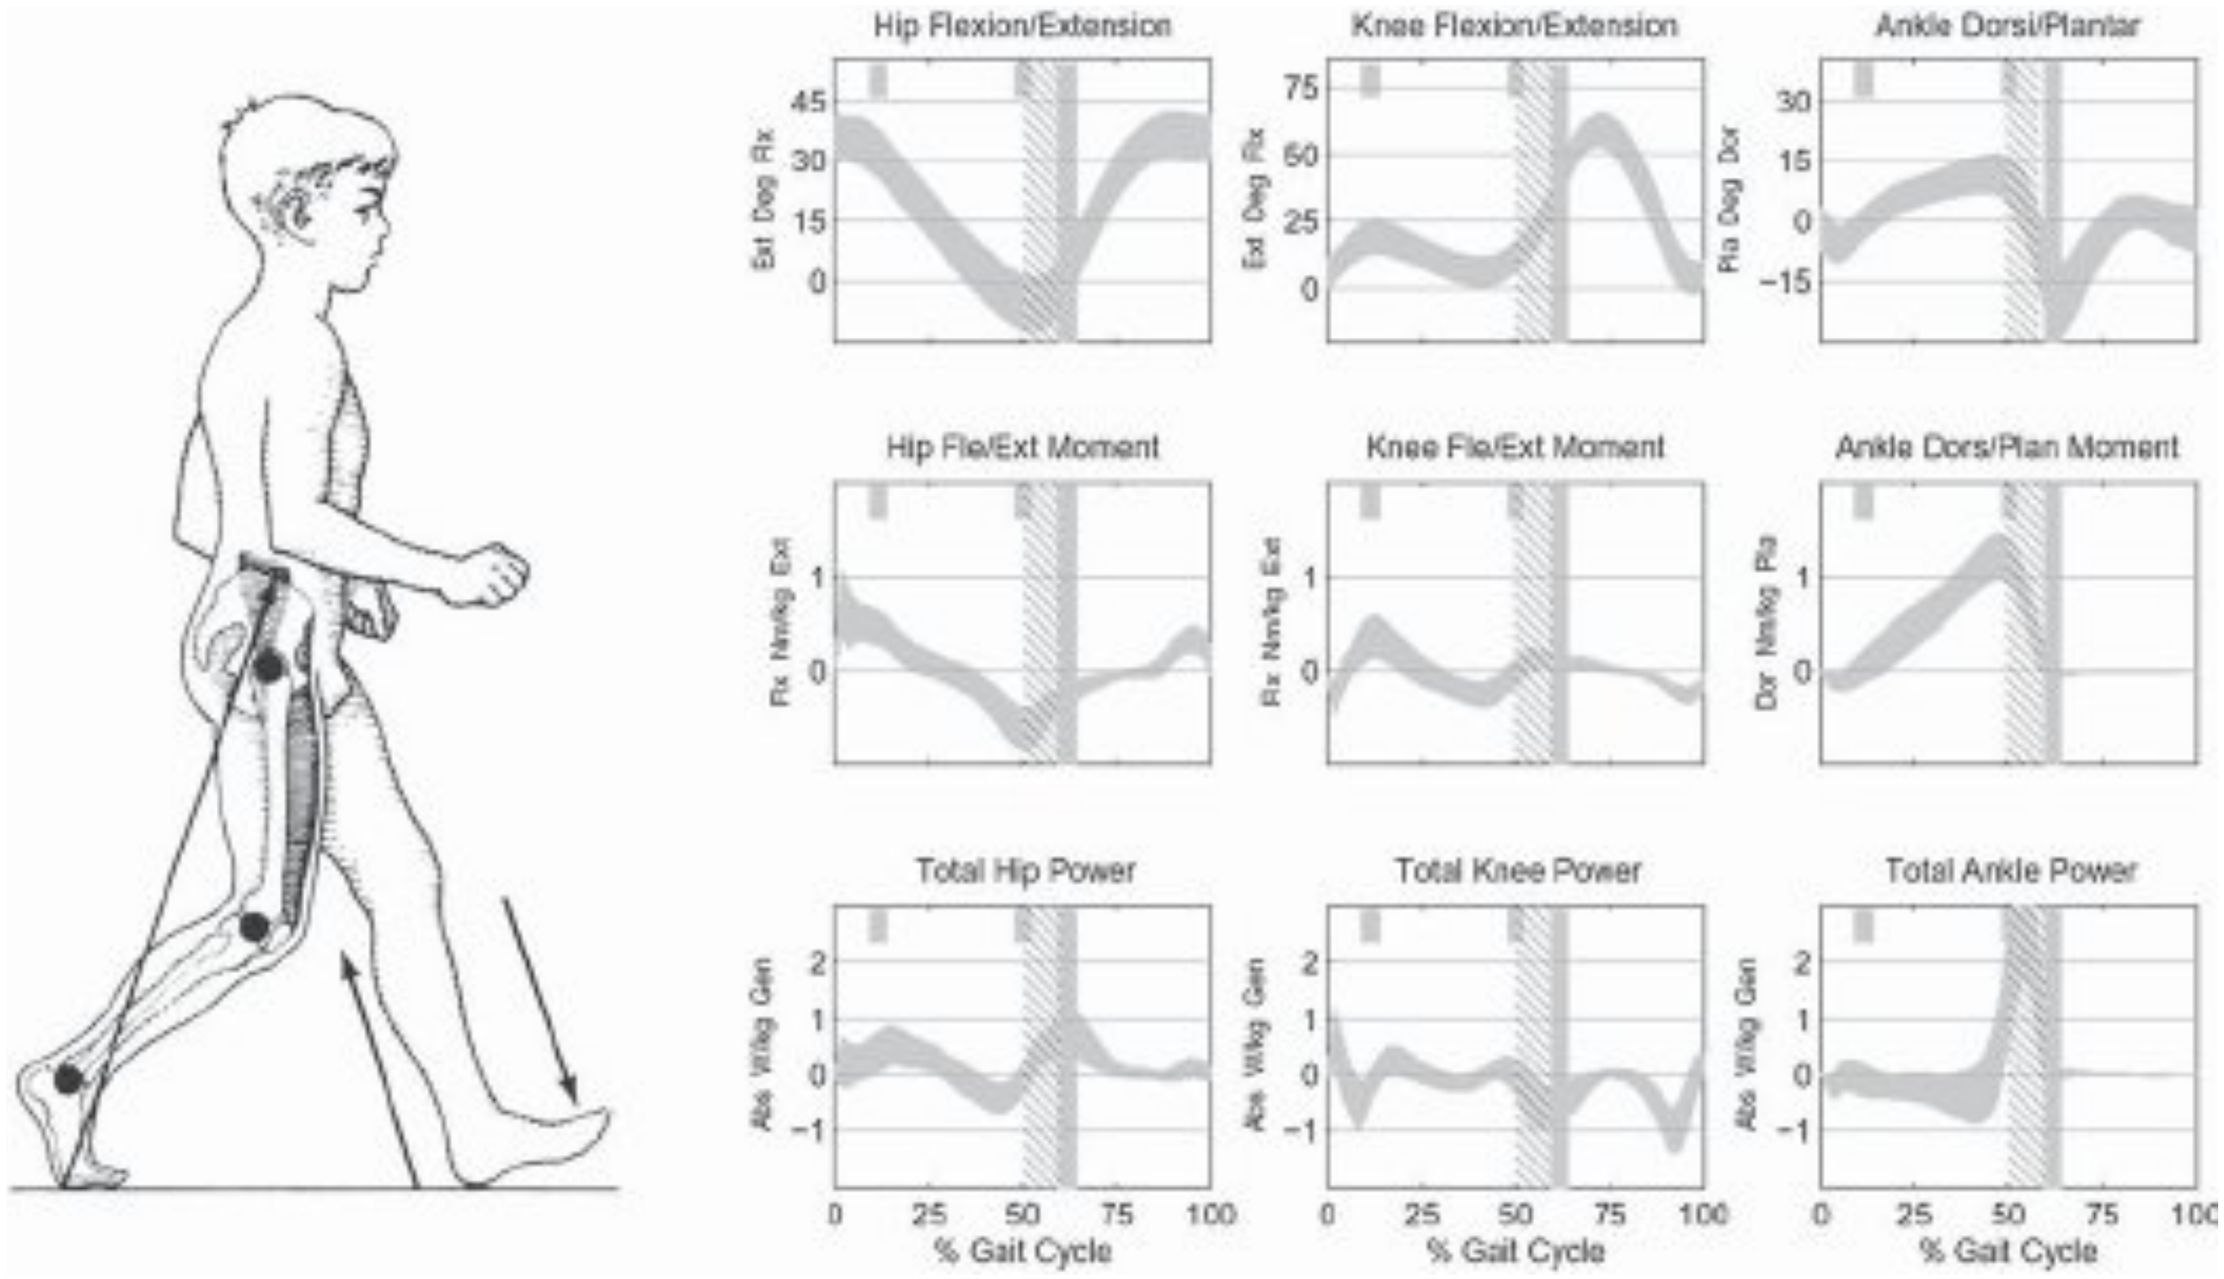

FIG. 34.15 Preswing (at 50% to 60% of the gait cycle). (Adapted from Gage JR: Gait analysis in cerebral palsy. London: Mac Keith Press, 1991.)

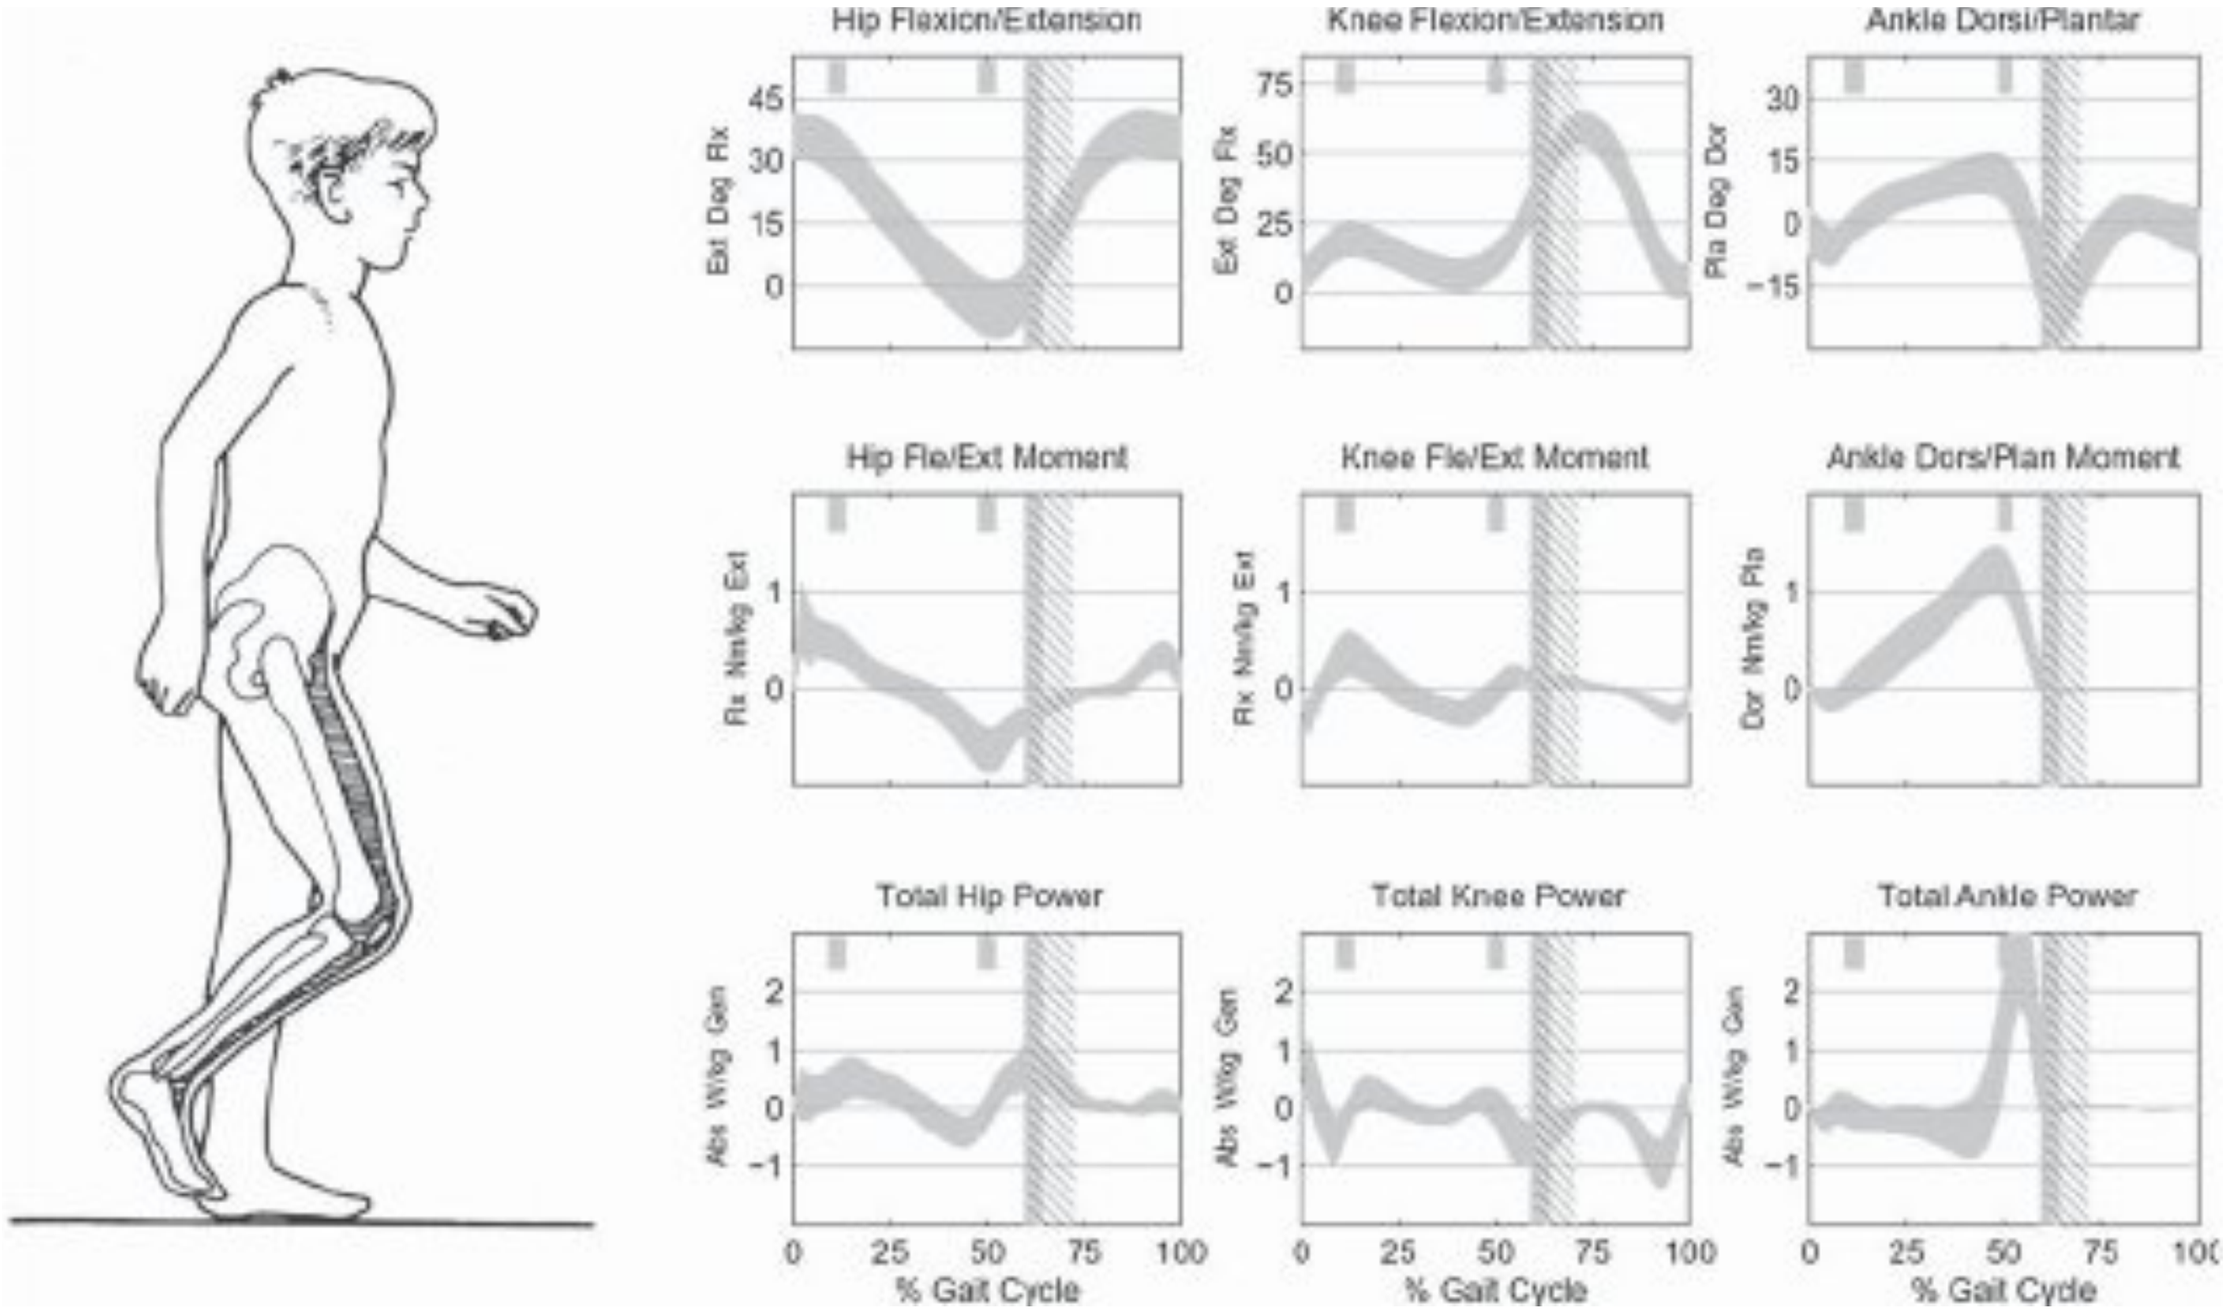

FIG. 34.16 Initial swing (at 60% to 73% of the gait cycle). (Adapted from Gage JR: An overview of normal walking. In Greene WB, editor: Instructional course lectures. vol 39. Park Ridge, IL: American Academy of Orthopaedic Surgeons, 1990.)

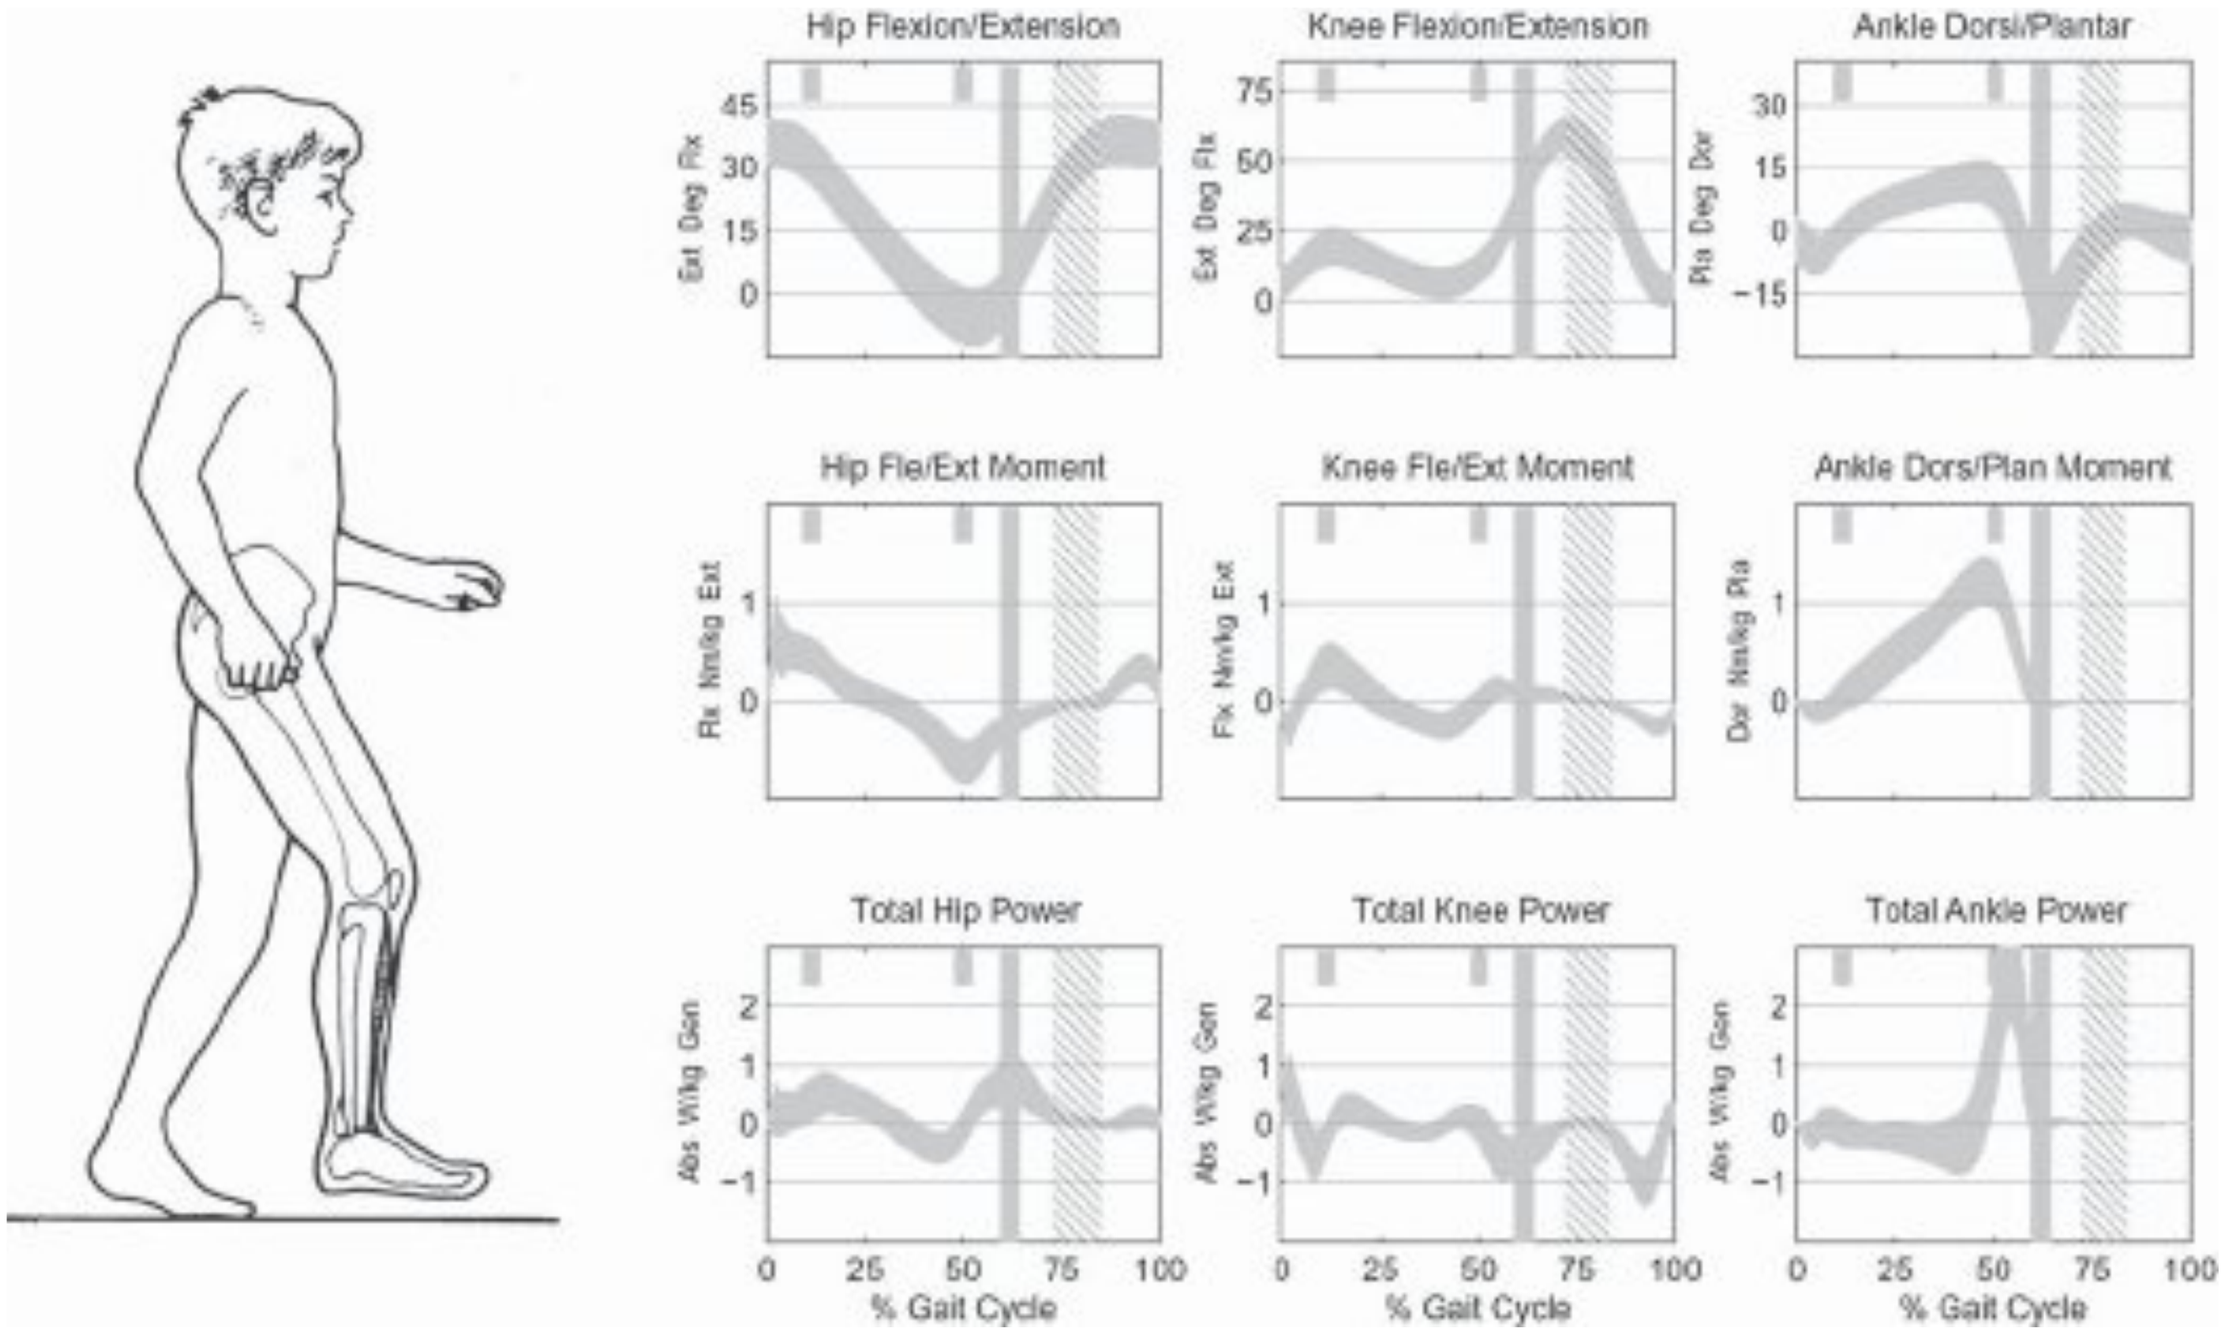

FIG. 34.17 Midswing (at 73% to 87% of the gait cycle). (Adapted from Gage JR. An overview of normal walking. In Greene WB, editor: Instructional course lectures. vol 39. Park Ridge, IL: American Academy of Orthopaedic Surgeons, 1990.)

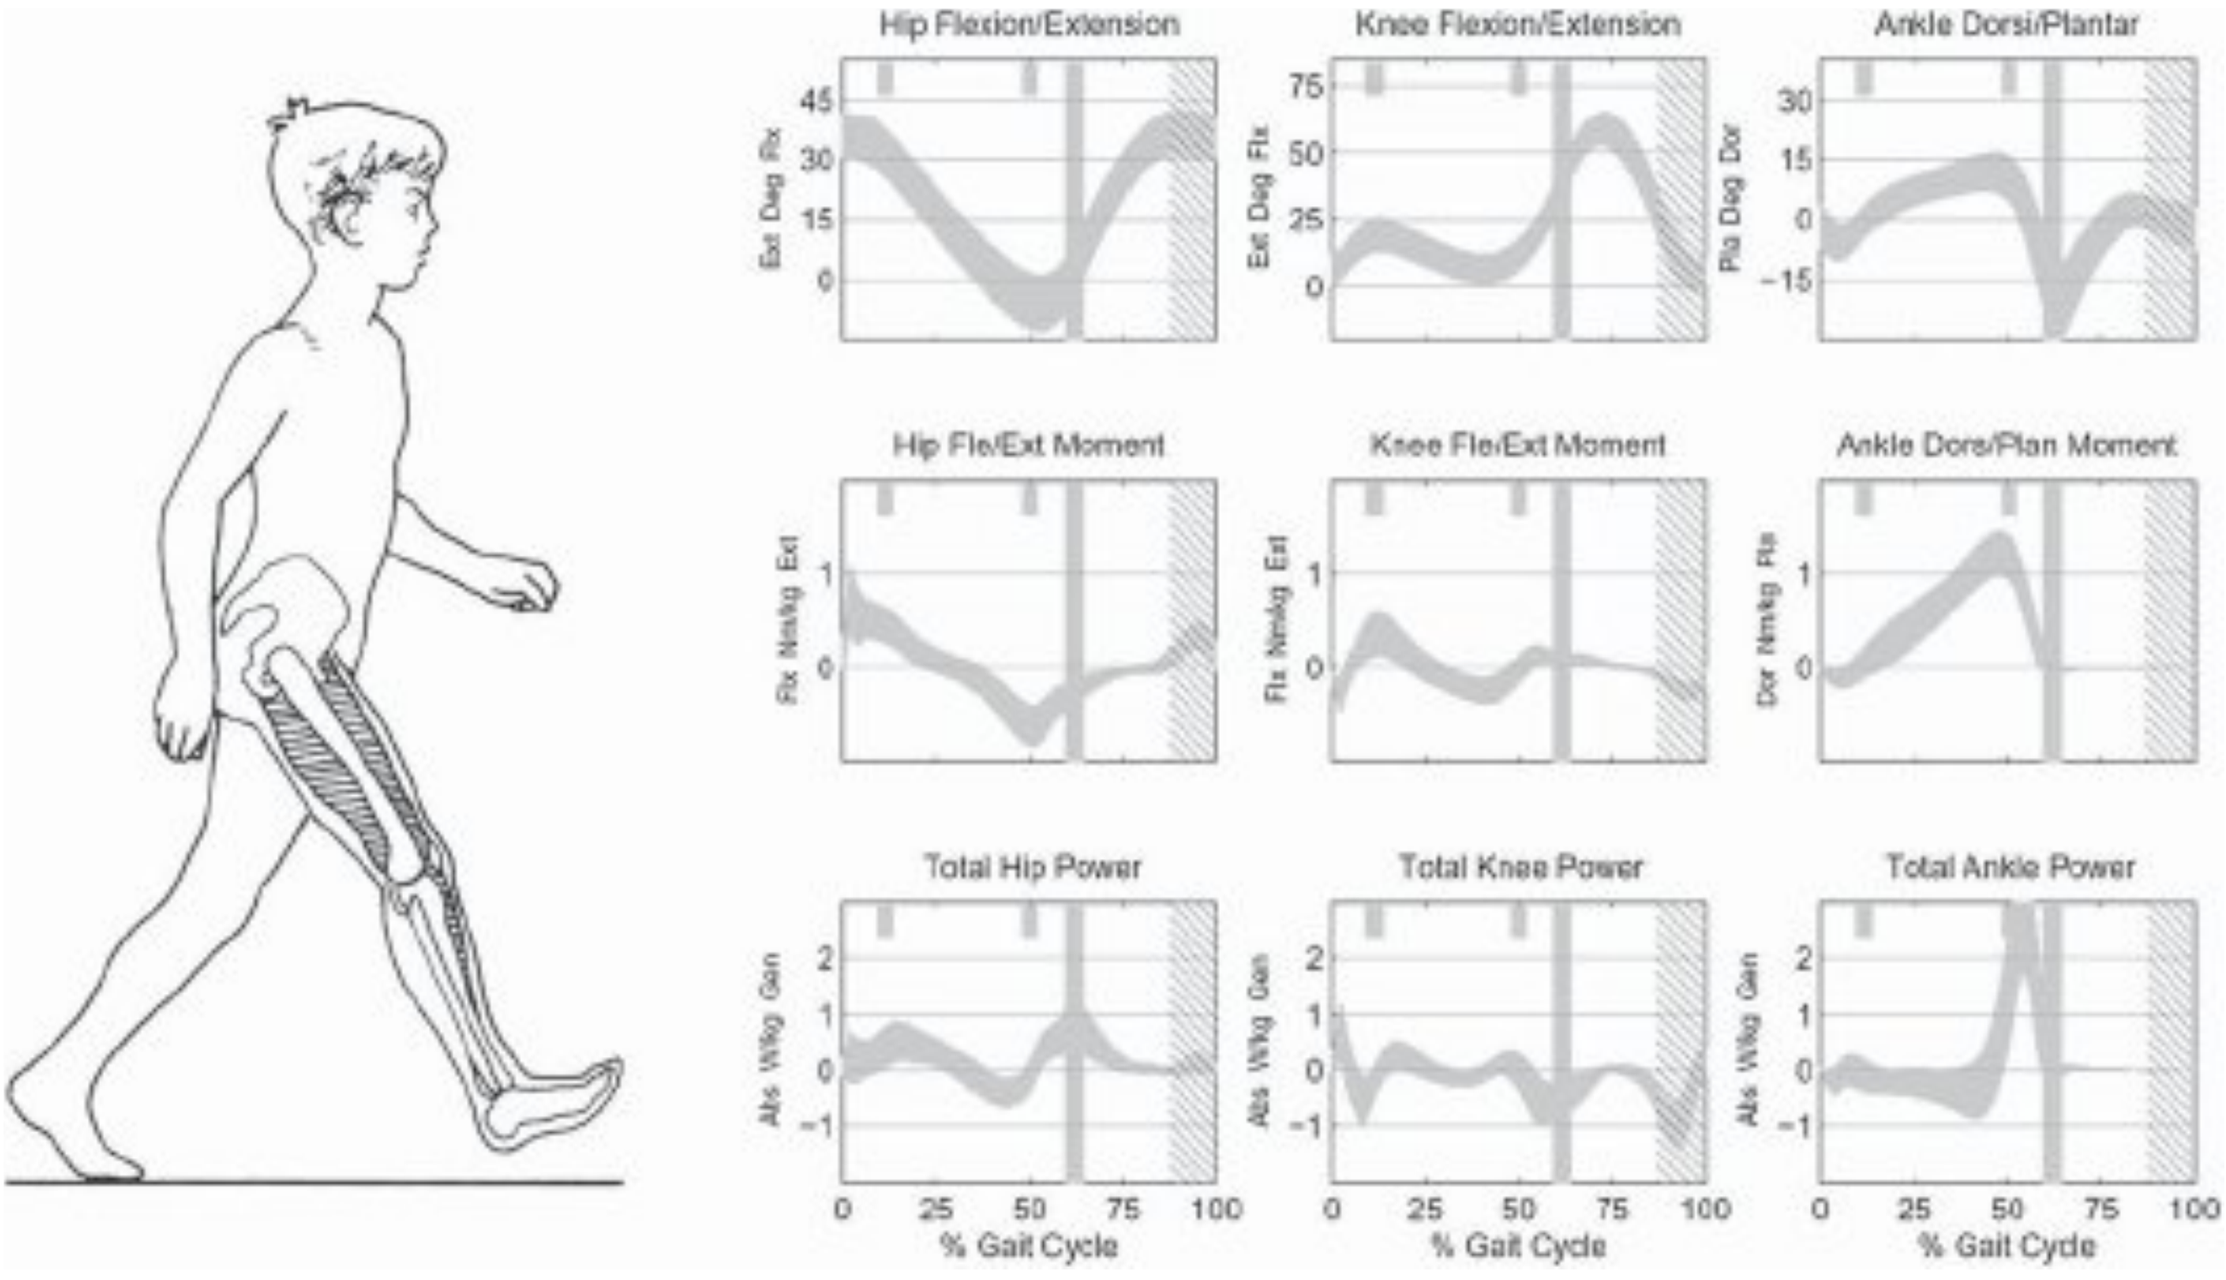

FIG. 34.18 Terminal swing (at 87% to 100% of the gait cycle). (Adapted from Gage JR: An overview of normal walking. In Greene WB, editor: Instructional course lectures. vol 39. Park Ridge, IL: American Academy of Orthopaedic Surgeons, 1990.)

action of the anterior tibialis muscle to position the ankle in neutral. A flexor moment is dominant at the knee with power absorption as knee extension is controlled by eccentric action of the hamstrings to decelerate the forward swing of the thigh. The quadriceps muscles also become active to assist with control of the knee. Minimal movement is noted at the hip at this time.

Coronal Plane

The function of hip and pelvis motion in the coronal plane is to optimize the vertical excursion of the center of mass (Fig. 34.19; see also Fig. 34.5). At initial contact the pelvis in the coronal plane is level and the hip is in neutral abduction and adduction. The stance side of the pelvis rises 5° at the beginning of loading response in conjunction with adduction of the stance limb. The dropping of the pelvis on the unsupported limb is caused by the ground reaction force on the supported limb, which produces an external adduction moment at hip, knee, and ankle. The external adduction moment is resisted by eccentric control of the hip abductors. This allows the stance side of the pelvis to rise and the unsupported side to drop.

The pelvis and hip motion reverse in midstance as concentric control by the hip abductors of the stance limb acts to raise the pelvis. This action assists clearance on the swing side. During preswing the hip on the stance side goes into abduction in preparation for toe-off.

Ankle and foot motion in the coronal plane are complex, but they are also very important to efficient gait. It is not routinely measured during full body gait analysis because of inadequate multisegment foot models appropriate for the pediatric client with neuromuscular issues. The literature is confusing because of variations in the terms used to describe motions occurring in the foot. The following description is consistent with nomenclature used by Perry.[86]

At initial contact, as stated earlier, an external adduction moment is present at the ankle and foot. The position of the anatomic body of the calcaneus, which accepts floor contact, is lateral to the tibia, which transmits body weight onto the talus from above. This causes the calcaneus to evert on the talus and reduces the support the calcaneus provides the talus (Fig. 34.20 A). The eversion of the calcaneus on the talus occurs during the initial part of the gait cycle (loading response and early midstance). It is controlled by ligaments surrounding the subtalar joint, as well as eccentric muscle action of the anterior tibialis and posterior tibialis muscles. Maximum eversion occurs at the onset of single-leg stance (15% of the gait cycle). Motion reverses during the remainder of midstance under muscular action of the posterior tibialis and the soleus and the gradual shift of weight bearing to the forefoot. Subtalar joint neutral is reached by 40% of the gait cycle: the midpoint of terminal stance. Inversion locks the midtarsal joint and provides increased stability of the foot during weight bearing on the forefoot. It also moves the calcaneus back under the talus (Fig. 34.20 B). Peak inversion occurs at the end of terminal stance, when ankle power generation is at its peak. Excessive inversion is avoided by co-contraction of the peroneal muscles (peroneus longus and peroneus brevis) during terminal stance and preswing. The subtalar joint is

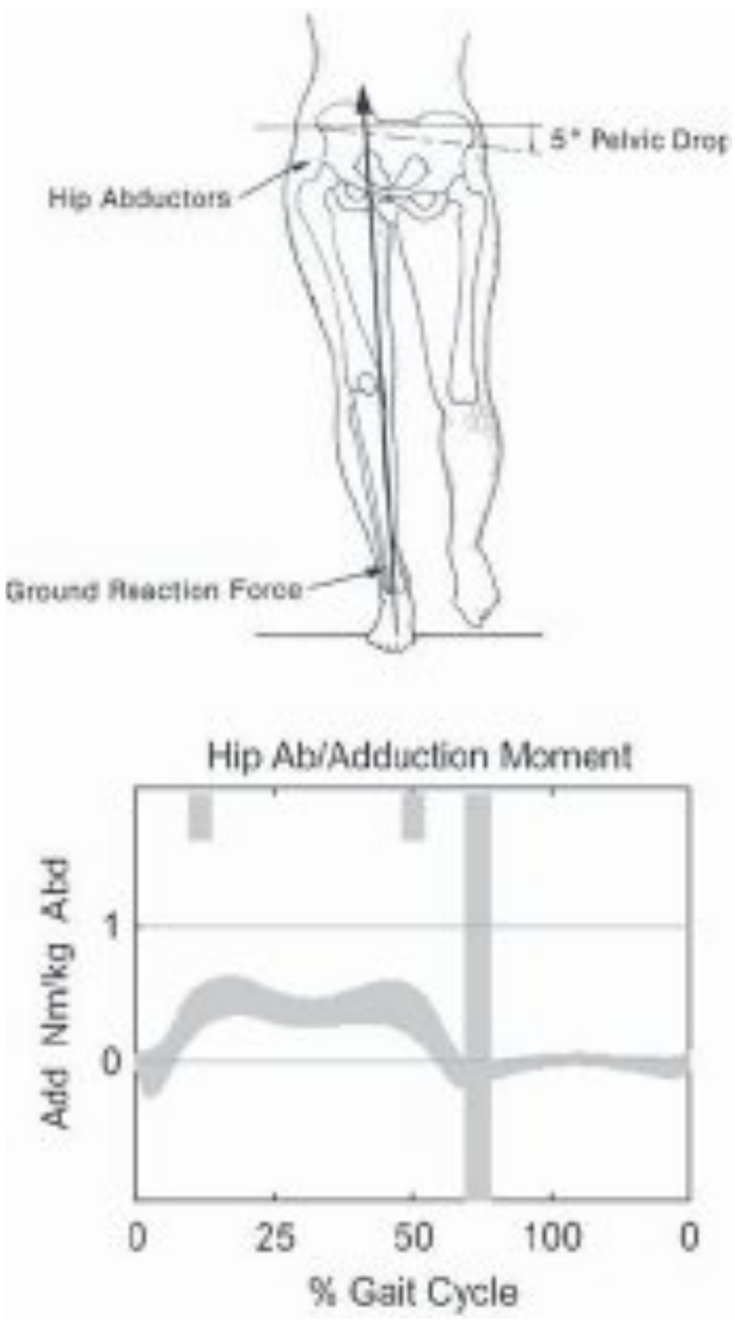

FIG. 34.19 Coronal plane hip joint kinetics. (From Gage JR: Gait analysis in cerebral palsy. London: Mac Keith Press, 1991.)

FIG. 34.20 Subtalar action during stance phase. (A) The offset in alignment between the body of the calcaneus, which accepts floor contact, and the tibia, which transmits body weight, causes the calcaneus to evert on the talus. The long axis of the calcaneus and the long axis of the talus diverge from each other as the talus rotates inward. (B) Subtalar joint inversion during terminal stance repositions the calcaneus under the talus, and the long axis of the bones converge but are not parallel.

typically in a neutral position during swing phase until slight inversion begins again during the last 20% of the gait cycle.

Transverse Plane

The end result of transverse plane motion is stride elongation (see Fig. 34.5). This is accomplished by internal pelvis and hip rotation under the control of the adductor magnus muscle. During the first half of stance phase internal rotation occurs at the pelvis and hip that reverses in the last half of stance. The pelvis is at its maximum posterior position at toe-off. The foot is positioned 5 to 10 degrees (average value) external to the line of progression throughout the entire walking cycle. Subtalar joint action produces rotation of the tibia as part of the closed chain mortise joint. The reader is referred to other texts for explanation of the transverse plane motions at the ankle and knee.[61,86]

Energy Expenditure

The purpose of many of the events in the walking cycle in all three planes of motion is to optimize energy expenditure or reduce the vertical translation of the center of mass. Gage[48,49] includes energy conservation as one of the five attributes of normal gait and states that variation in this attribute encompasses the deviations of the other four attributes.

The mechanisms that the body uses to conserve energy are optimizing the excursion of the center of mass, control of momentum, and active or passive transfer of energy between body segments. The vertical and horizontal displacements of the center of mass are almost sinusoidal and are equal and opposite during typical walking.[151] The body accomplishes this through the three pelvic rotations (rotation, tilt, and obliquity) and coordinated knee and ankle motion. Inman and colleagues[61] demonstrated that without pelvic rotation and with stiff limbs, the center of mass of the body would be lifted approximately 9.5 cm with each step. Normal vertical excursion of the body averages approximately 4.5 cm.

Determination of energy expenditure in gait has been a topic of research since the 1950s.[32,85,91] Various estimates are used to measure energy. Ralston[91] hypothesized that individuals naturally select a speed of walking that allows a minimum of energy expenditure. More recent studies also support this hypothesis.[26,37] This has direct implications for the child with a motor impairment.

Research in energy expenditure specifically in children has revealed that younger children consume more energy than teenagers and adults (mass-specific gross rate of oxygen consumption, ml/min-kg).[37,69,141,146] Despite the fact that children and adults walk in geometrically similar ways, size, changes in morphology, muscular efficiency, and motor skill during growth potentially have an effect on energy expenditure. Smaller children perform a greater amount of work per unit mass and per unit time to maintain a given walking speed than larger children and have a more variable basal metabolic rate. Children under the age of 5 years have more lean body mass and a greater surface area-to-body mass ratio,[37,90] resulting in a higher resting energy expenditure. Because of this a given walking speed is not functionally equivalent at different ages. However, when alternative normalization methods are used to eliminate effects of body size, differences between children of different ages and adults are no longer present.[5,37,104] This suggests that changes in the neuromuscular system play a relatively minor role in energy expenditure differences after 3 years of age. Controversy remains over which normalization scheme is most appropriate for use in clinical populations—gross expenditure (resting expenditure + movement expenditure) or net expenditure (gross expenditure − resting expenditure).[19,20,104,137] A comparison between mass-normalized gross rate of oxygen consumption and net rate of oxygen consumption with a nondimensional normalization scheme is found in Fig. 34.21.

An alternative to the use of measuring oxygen consumption to estimate energy expenditure involves calculation of the mechanical work required for walking. Kinematic measurements, anthropometric measurements, and kinetic analyses of internal and external loads are required for use of this method.[81,149] The advantage of mechanical energy estimation is that the energy requirements of individual joints can be calculated. One of the disadvantages, particularly in the assessment

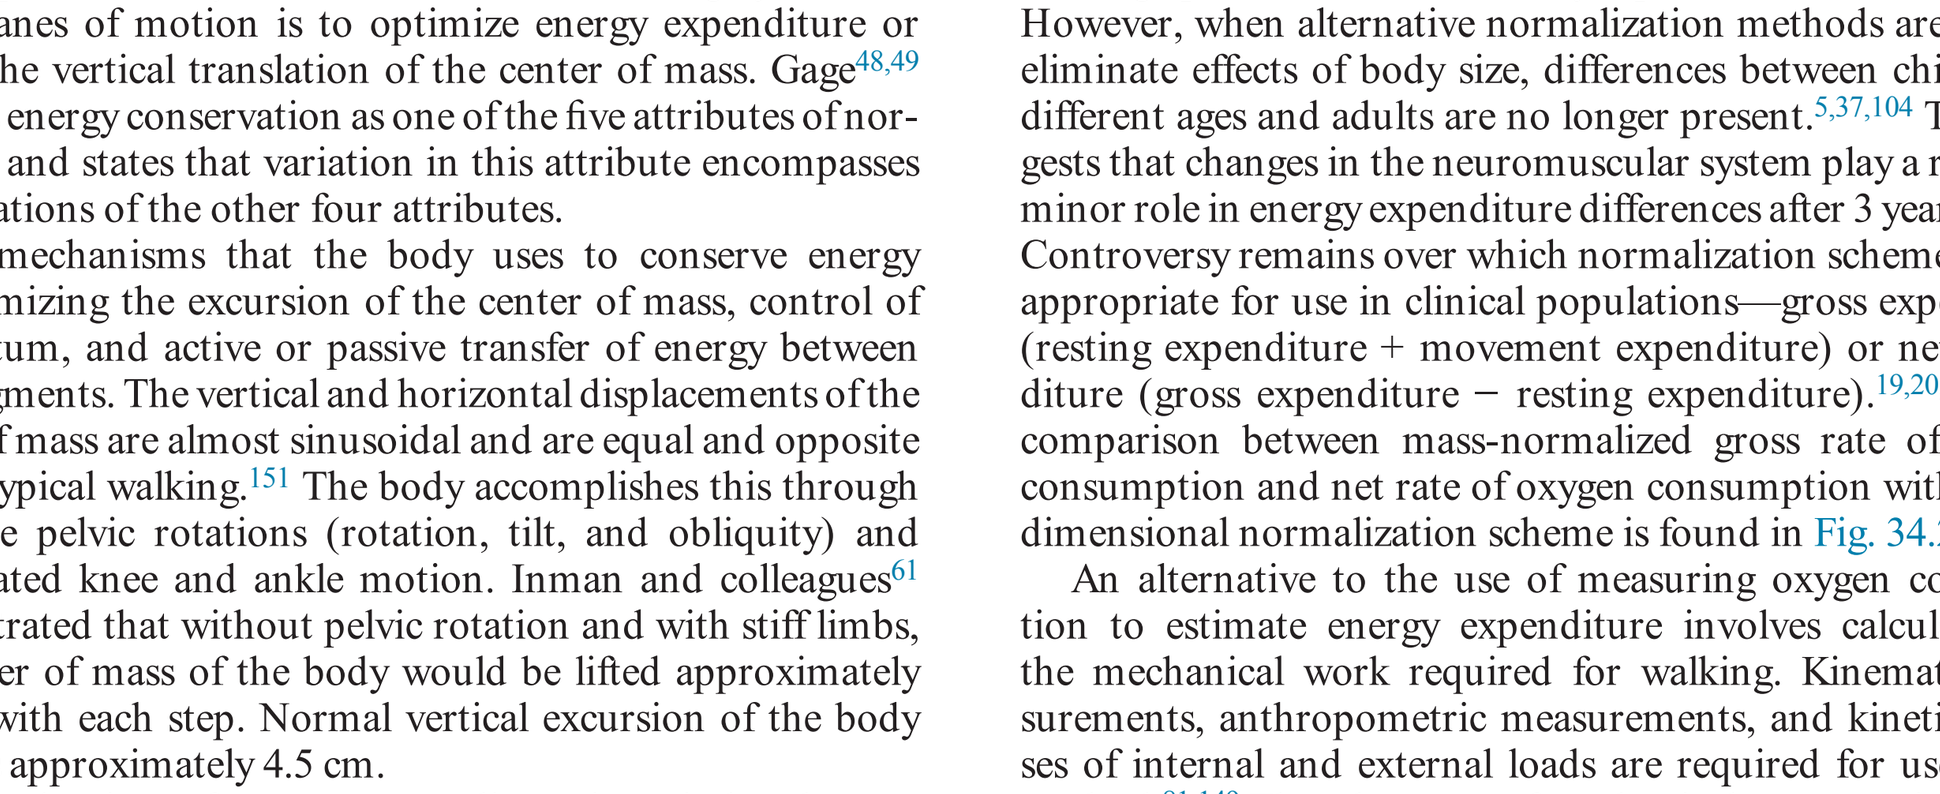

FIG. 34.21 (A) Typical values of the rate of metabolic oxygen consumption versus velocity for 150 children 2 to 19 years of age. The units for oxygen consumption are normalized by body weight. No normalization of velocity is used. The mean and 2 standard deviations are displayed. (B) The same data presented normalized using nondimensional variables for both rate of oxygen consumption and velocity.

of atypical gait, is that the use of external loads to judge the work associated with walking does not measure the body's ability to efficiently respond to the external loads. Co-contraction associated with spasticity is unaccounted.[98] A review of mechanical and metabolic estimations of energy expenditure can be found elsewhere.[121]

Heart rate is often used as a substitute clinical measure for oxygen uptake and therefore metabolic energy expenditure because of the linear relationship of heart rate to oxygen uptake.[95,96] Low mechanical efficiency, however, creates disproportionately high submaximal heart rates in individuals with cerebral palsy (CP), making submaximal heart rate a poor predictor of aerobic capacity in this group.[9] Recent work has demonstrated that day-to-day variability in heart rate in typically developing children is approximately 6%.[137] A lack of correlation between measures using heart rate and direct measures of oxygen cost was also noted. I have observed high and inconsistent heart rate in relation to oxygen uptake in various clinical populations including children with CP. Caution should be taken if consideration is being given to this method of estimation of energy expenditure. See Chapter 6 for more information on aerobic capacity.

USE OF GAIT ANALYSIS IN ASSESSING IMPAIRMENTS

Gait analysis is a useful tool in examining walking impairments in children with physical disabilities because it provides objective measurement of the magnitude of deviations. It also allows the interpreter to analyze data from all planes of motion for a single gait cycle. Just as computed tomography has improved on radiography, gait analysis improves on the evaluator's clinical examination and visual observation. Gait analysis data in the hands of a critical evaluator will never be used in isolation. Clinical examination by a physician, physical therapist, or trained kinesiologist and x-rays are vital aspects of the evaluation. The child's and family's goals for intervention are important as well.

Guidelines for Referral

Guidelines for determining when instrumented gait analysis should be recommended in the plan of care for a child with a walking disability depend on many factors. The child's age, diagnosis, progress in physical therapy, and goals of intervention are all taken into consideration. Analysis is best when the child's gait pattern is mature, but waiting for a mature walking pattern is not always possible. One key to remember is that current gait analysis techniques provide a single "snapshot" in time. Even if a gait pattern is consistent from cycle to cycle on a given day, if it is not consistent from 1 week or 1 month to the next, the value of that single snapshot for decision making is more limited. The utility of a gait analysis for children, adolescents, or adults who are making rapid progress in rehabilitation is more limited in scope for this reason.

Typically, the impetus for referral for gait analysis is a change in a child's gait pattern and/or functional ability when walking. That decision on plan of care may or may not be surgical or pharmacologic in nature. Bracing or a prosthetic, change in medication that may affect balance or walking, and physical therapy are other considerations for decision making. A three-dimensional gait analysis may not be the best measurement tool for assessing results of changes in a physical therapy program unless the intervention specifically affects the child's walking.

Children under age 3 are not candidates for three-dimensional gait analysis because of their small physical size, their reluctance to cooperate for the duration of the required testing, and their immature gait patterns. Children between 3 and 5 years of age can be tested in the laboratory if their size, behavior, and walking are adequate for the testing process. Because their age and maturity of gait pattern are not ideal, analysis is usually reserved for use as a baseline before surgical intervention. In this age range, interventions such as selective dorsal rhizotomy have increased the number of children who have a gait analysis before the age of 5 years.

The optimal age for a formal three-dimensional gait analysis is typically from age 6 onward. Intervention outcomes, whether they are bracing or prosthetic changes, medication changes, or surgical interventions, can be evaluated. Analysis before an intervention provides a baseline to assist in the decision-making process. Sometimes, no specific treatment changes are recommended. Analysis after treatment provides evaluation of the effects of that treatment. Many people do not appreciate the importance of posttreatment assessment. What they fail to realize is objective measurement of change following intervention cannot occur without posttreatment assessment. Knowledge of outcomes of previous interventions is useful for decisions on the plan of care when new problems arise.

Assessing Gait Impairments

A gait analysis laboratory should be considered a measurement tool. The results of gait analysis can assist in differentiation of primary impairments from secondary compensations. Primary impairments are abnormalities that are a direct result of neuromuscular impairments such as spasticity; secondary impairments are musculoskeletal impairments such as soft tissue tightness that develop over time as a result of the primary impairments and compensations (mechanisms used by the individual to circumvent the primary impairments). In addition to use in management of children with conditions such as cerebral palsy and myelomeningocele, gait data can also be used to assess the effects of orthotic devices in various populations or of different prosthetic devices in individuals with amputations. Gait analysis at repetitive intervals can assist in monitoring the progression of a particular deformity or condition or evaluation of the effects of a controlled treatment regimen (including surgery, medication, and physical therapy).

Specific physical therapy recommendations are often difficult to determine with gait laboratory data alone. Assessment during a gait analysis typically includes only a limited documentation of physical findings and is not a complete physical therapy examination. The EMG information from most gait laboratories does not provide information about strength of muscle contraction and cannot be used to determine which muscles are to be strengthened and how. A thorough knowledge of muscle mechanics and typical gait combined with manual muscle testing allows the therapist to make evidence-based decisions. EMG activity, however, can determine whether muscle activity is present or absent and the timing of that muscle activity, which can be useful in determining whether strengthening is an option and in conjecturing about what the consequences of strengthening might be. Kinetic analysis provides joint moment and power information that are sometimes useful for this purpose. Data on coordination of muscle timing

and co-contraction can be incorporated into treatment as well and are useful for decisions on the focus of physical therapy. In summary, the gait laboratory can be an objective measuring tool for the physical therapist.

Gait deviations may occur as a result of impairments in motor control, spasticity, limited ROM, decreased strength, poor sensation, and bony deformity. Each can result in primary or secondary impairments and compensatory mechanisms used to produce or to maintain the ability to walk. Gait analysis can be used to identify areas of bony abnormality and lack of functional ROM and to document areas of relative weakness or spasticity. The information is always used in conjunction with a clinical examination. The use of gait analysis in assessment of impairments in children with CP is discussed here as an example of how information is used and interpreted. Limitations of gait analysis are also discussed.

Common Gait Deviations of Children with Cerebral Palsy

Bony Deformity

Bony deformities are assessed best by clinical examination and radiography. Gait analysis data measure the functional effect of the bony deformity on the individual's walking. Bony deformities are examples of secondary impairments because they are not caused directly by the CNS lesion. They can result from failure of physiologic bone remodeling, the effects of spasticity and muscle imbalance, disuse, attempts to function, or any combination of these factors. These deformities (except for leg length discrepancies) are best assessed in the transverse plane. Once a bony deformity is present, the primary focus is orthopedic treatment because correction will not occur by conservative management such as physical therapy. Three common bony abnormalities seen in children with CP are internal femoral torsion, tibial torsion, and subtalar joint subluxation.

Internal femoral torsion (femoral antetorsion). Visually, internal femoral torsion appears as internal rotation of the femur during walking and is measured by kinematic analysis. Antetorsion (forward torsion) or internal femoral torsion is a true structural twist deformity of the long axis of the femur. The cause is a combination of (1) persistence of alignment in early infancy because of delayed weight bearing and (2) abnormal muscle forces created by spasticity.[15,48,49] Internal femoral torsion is not synonymous with valgus angulation of the femoral neck-shaft angle (coxa valga) or the anterior or forward position of the head and neck of the femur relative to the frontal plane (anteversion). Clinically, however, femoral anteversion is a surrogate measurement for internal torsion. Femoral anteversion is measured as the degree of internal femoral rotation in the prone position required to position the greater trochanter most "lateral" or parallel to the supporting surface.[99] In the presence of internal femoral torsion there is often loss of passive external rotation range and the range of internal rotation is excessive. Often the ratio of internal to external rotation is equal to or greater than 3:1. Internal femoral torsion and the degree of internal rotation measured from kinematic data are correlated, but they are not synonymous. Not all individuals with an internal twist in the femur walk with excessive internal rotation through the hip joint, but it is common (Fig. 34.22; see video *Patient with internal twist in the femur demonstrating a walk with excessive internal rotation through the hip joint*).

Tibial torsion. External tibial torsion is more common than internal tibial torsion in children with CP. External tibial torsion is an external rotation or torsion of the long axis of the tibia. Internal tibial torsion is an internal rotation or torsion of the long axis of the tibia. Both are measured by physical examination of the transmalleolar axis or thigh-foot axis, but variability in these measurements between and within examiners is known to be high. Functional methods of measurement using the motion capture system for determination of the knee axis have improved the precision of this measurement.[107] Both external and internal tibial torsion are true bony deformities. External tibial torsion often develops as a secondary impairment to internal femoral torsion. Limited knee motion that results in repetitive dragging of the foot in an externally rotated posture for clearance can also result in the deformity. In the presence of internal femoral torsion, external tibial torsion is difficult to observe visually because the foot progression angle may not appear abnormal. The knee sometimes has a valgus appearance, but it is not a coronal plane abnormality. The internal torsion of the femur is compensated by external torsion of the tibia so that the foot remains in the direction of progression (Fig. 34.23). Internal tibial torsion may remain from a lack of proper remodeling from infancy but can develop as a secondary deformity as well (see Fig. 34.22).

Pes valgus (subtalar joint subluxation). Pes valgus is most common in children with spastic diplegic or spastic quadriplegic types of CP and less often occurs in children with spastic hemiplegia. Caused by a relative subluxation of the talus on the os calcis, it usually develops because of plantar flexor muscle tightness and a relative muscle imbalance between the posterior tibialis and peroneals (with a dominance of peroneal overactivity). Visually, the calcaneus is everted. Multisegment foot kinematics can differentiate deformities between the hindfoot and the shank and those between the forefoot and the hindfoot. Data from the physical and radiographic examination are essential.

Inadequate Range of Motion and Spasticity

Gage[49] often refers to CP as a condition that preferentially affects two-joint muscles because it is primarily in the two-joint muscles that spasticity contributes to the abnormalities associated with walking. Most two-joint muscles are predominantly fast-twitch muscles used for rapid force production. Loss of ROM creates static contracture; spasticity imposes loss of ROM in dynamic situations because of resistance to stretch.[71,97] The effects of inadequate ROM and spasticity can be measured in all three planes of motion but are most prevalently seen in the sagittal plane. Examples measured by gait analysis are an abnormal plantar flexion–knee extension couple, crouch gait, and limited swing-phase knee motion.

Abnormal plantar flexion–knee extension couple. During normal walking, the plantar flexion–knee extension couple is a force couple whereby the soleus muscle controls forward momentum and the forward progression of the ground reaction force by eccentric contraction. Children with CP often have footflat initial contact, which places the gastrocnemius under tension at both ends of the muscle. Gage[49] postulated that, in response to the stretch, spasticity is elicited that can restrict tibial advancement, produce knee extension (hyperextension), and reduce the extent of dorsiflexion (plantar flexion). The spastic response is revealed during stance phase as a biphasic pattern of increasing and then decreasing dorsiflexion kinematics and by an abnormal plantar flexor power generation coincident in time with

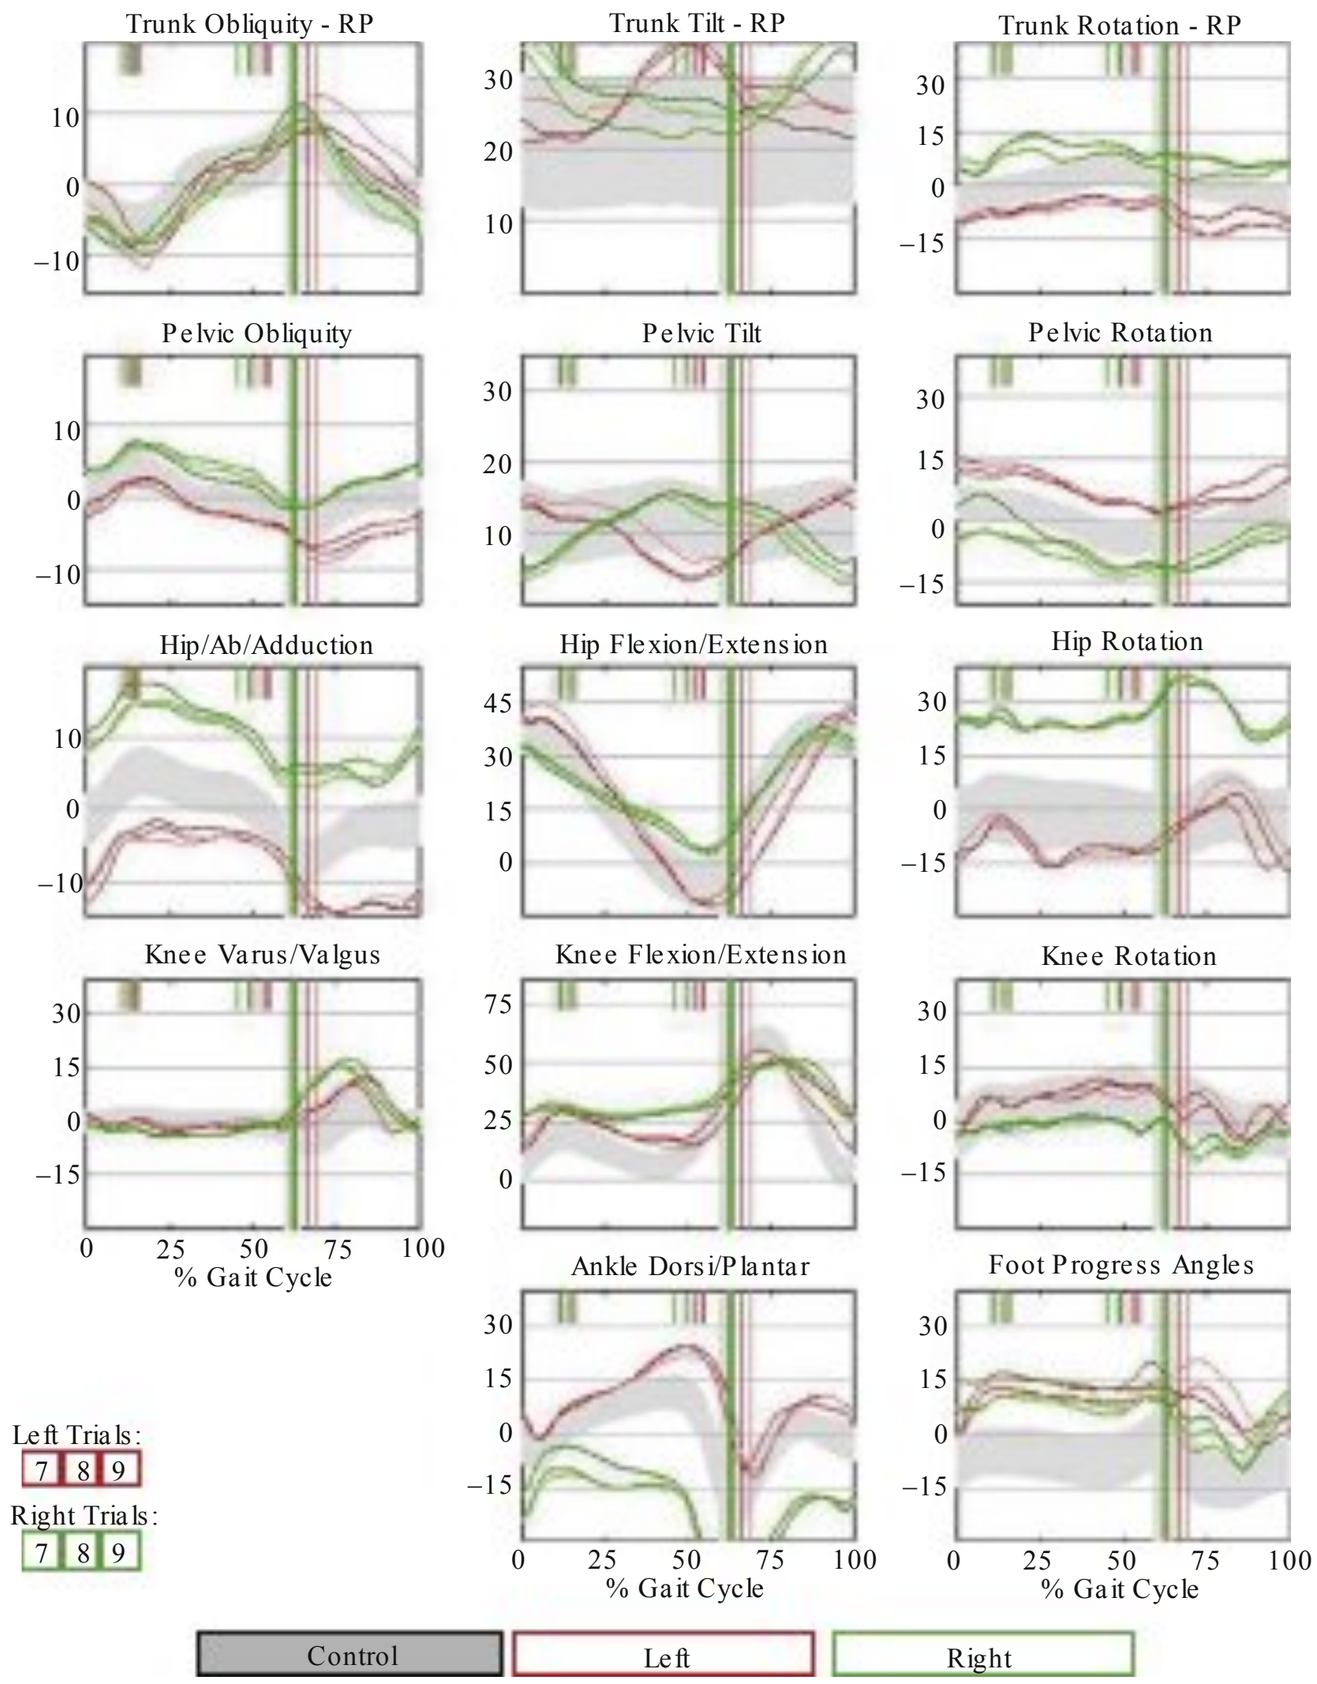

FIG. 34.22 An example of kinematic graphs from a 14-year-old child with spastic hemiplegia cerebral palsy. Gait cycle percentage is on the abscissa and the degrees of motion in the ordinate. The vertical bar at about 60% of the gait cycle delineates stance from swing. The gray band indicates the typical mean ±1 standard deviation of typical motion. The red line denotes the left side and the green denotes the right. The pathology is coming primarily from the right side. The transverse plane (right column) demonstrates internal hip rotation on the right. This child has evidence of internal femoral torsion on physical examination. Internal foot progression angles are noted on both sides. Because hip rotation is external on the left, the internal foot progression angle on the left is the result of internal tibial torsion or foot deformity. Physical exam identifies an internal tibial torsion. The sagittal plane kinematics (center column) demonstrate the typical findings of a child with hemiplegia (progressive anterior tilt from initial contact until preswing, incomplete hip and knee extension in stance, restricted knee flexion in swing, and ankle plantarflexion).

the first decrease of dorsiflexion in the cycle in the kinetics. Occasionally, the EMG activity is biphasic as well (Fig. 34.24). The abnormal power generation elevates the body's center of mass and functionally increases energy expenditure.

Crouched posture. Caused by hip flexion contractures or tightness, knee flexion contractures or tightness, excessive plantar flexor muscle weakness, impairments in motor control, or any combination of these conditions, increased flexion is seen at all joints in the sagittal plane in crouched gait (Fig. 34.25; see video *Patient demonstrating crouched gait*).

Limited swing-phase knee motion. Limitation of motion at the knee in swing phase usually begins in preswing, when motion is inadequate. Momentum for swing phase in normal gait is generated by the acceleration force of the gastrocnemius muscle that drives the ground reaction force behind the knee. When the gastrocnemius force generation is reduced, as is often the case in CP, the hip flexors supply the momentum to clear the extremity. The rectus femoris muscle is often recruited as a hip flexor. If this muscle is spastic, it maintains its action as a knee extensor. The

FIG. 34.23 A 15-year-old with spastic diplegic cerebral palsy. Note the internal hip position on the right side (knee in) and the foot progression angle that is neutral to the line of progression. His foot progression angle is external on the left with a thigh alignment that appears neutral. This individual has an external tibial torsion on both the right and left sides.

already-diminished knee flexion in preswing is further inhibited by spastic restraint that does not allow further knee flexion (see Fig. 34.25).

Weakness

Weakness cannot be measured directly by gait analysis. The type of electromyography typically used does not provide information regarding strength. Kinematic data measure only the effects; it is up to the clinician to interpret whether the pattern is present as the result of weakness or tightness. Kinetic data do provide a limited measure of weakness if full ROM is available at the joint. Power can be produced only if joint movement is present. The best measure of strength is by physical examination, although this is complicated by the presence of spasticity.

Use of gait analysis methodologies to increase insight into weakness has become a promising area of research. Computer simulations provide evidence to support clinical knowledge that gait is adversely affected by weakness in plantar flexors, hip extensors, and hip abductors.[142] Novel methods of EMG analysis have been proposed to understand the relationship between EMG activity and functional muscle strength.[143] Further insights into analysis of kinetics and its associations to strength have advanced interpretation of particular kinetic patterns.[36] Collectively, the increased body of knowledge of the correlates between gait analysis data and strength will help therapists develop and design interventions better suited to individual gait pathologies.

Hip abductor weakness. Weakness of the hip abductor muscles in children with CP, as in any type of gait disorder, produces an uncontrolled pelvic drop on the swing side and lateral trunk shift over the stance limb. The ground reaction force in the coronal plane produces an external adduction moment at all joints of the stance limb. If abductor strength is insufficient, the lateral trunk shift positions the ground reaction force through the hip joint center so no abductor moment is needed. Hip abductor muscle weakness is frequently (but not necessarily) seen in children with internal femoral torsion because the torsion creates an inadequate lever arm over which the gluteus medius muscle is able to act, imposing functional weakness. On kinematic graphs, hip abductor weakness is displayed as increased adduction. Differentiation between hip abductor muscle weakness and hip adductor tightness cannot be done solely using kinematic data.

Gastrocnemius-soleus weakness. Plantar flexor muscle weakness primarily affects terminal stance and preswing phases of the gait cycle, but midstance is also affected. During midstance the soleus is not able to control the progression of the ground reaction force that is anterior to the ankle, and excessive dorsiflexion results. Heel rise is delayed in terminal stance because gastrocnemius power may also be insufficient. Excessive dorsiflexion can increase knee flexion as well. Quadriceps muscle activity may be required to maintain an upright posture if the trunk is vertical, resulting in increased energy expense. Foot clearance is achieved by the proximal hip flexors because the plantar flexor muscles alone are insufficient. This results in insufficient acceleration force in terminal stance and a slower gait velocity.

SUMMARY

The objective of this chapter was to provide an overview of development and refinement of gait in childhood, the components of gait measured by instrumented gait analysis, and a brief introduction to the use of gait analysis in examination of children with impaired gait. A gait laboratory is only a measuring tool and a supplement, not a substitute, for other tools used to assess gait deviations.

Research in the area of gait continues to be a topic of great interest. As measurement techniques improve, our knowledge of walking and its development will be more refined. With a clear understanding of typical gait, we can better understand the altered patterns of gait that occur in children with neuromuscular and musculoskeletal impairments. The role of the physical therapist in the interpretation of gait for children relies not only on knowledge of development, gait biomechanics, and muscle firing patterns but the integration of strength, motor control, and spasticity assessment as well. Gait analysis represents the breadth and depth of physical therapist knowledge and contributions to a team of professionals devoted to improving walking function in children. The future directions of instrumented movement analysis will continue to depend on physical therapists' expertise in movement.

ACKNOWLEDGMENTS

I would like to thank Dr. Jim Gage and Dr. Steven Koop, whose philosophy and understanding of normal gait and treatment of children with gait pathologies are significant contributions to this chapter. I am privileged to work with both of them.

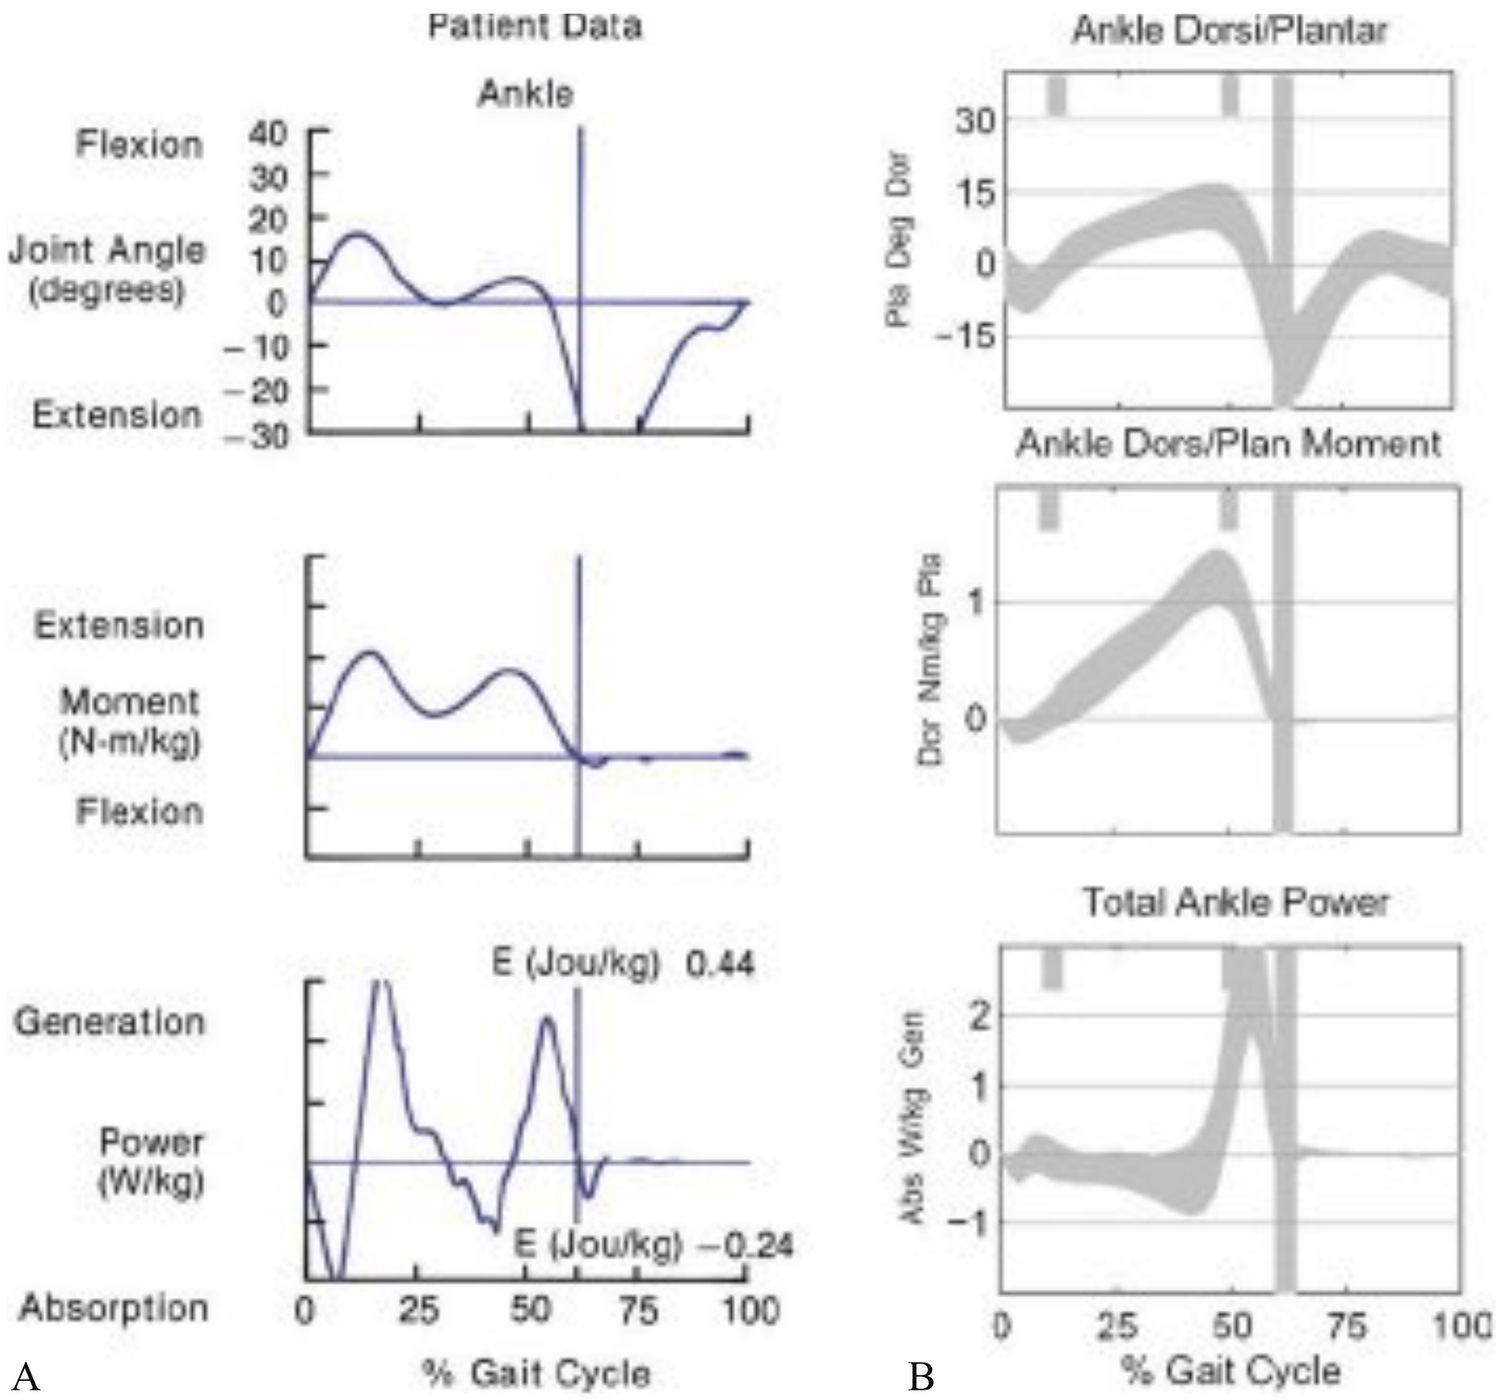

FIG. 34.24 Kinematics and kinetics at the ankle joint demonstrating an abnormal plantar flexion–knee extension couple in a child with cerebral palsy (A) compared with normal (B). The ankle kinematics of the patient display a biphasic pattern in stance phase—increasing dorsiflexion–decreasing dorsiflexion—that repeats itself. This results in a biphasic plantar flexor moment as well and an inappropriate midstance power generation. (C) Surface EMG record from the gastrocnemius-soleus complex also exhibits two bursts of activity coinciding with the power generation.

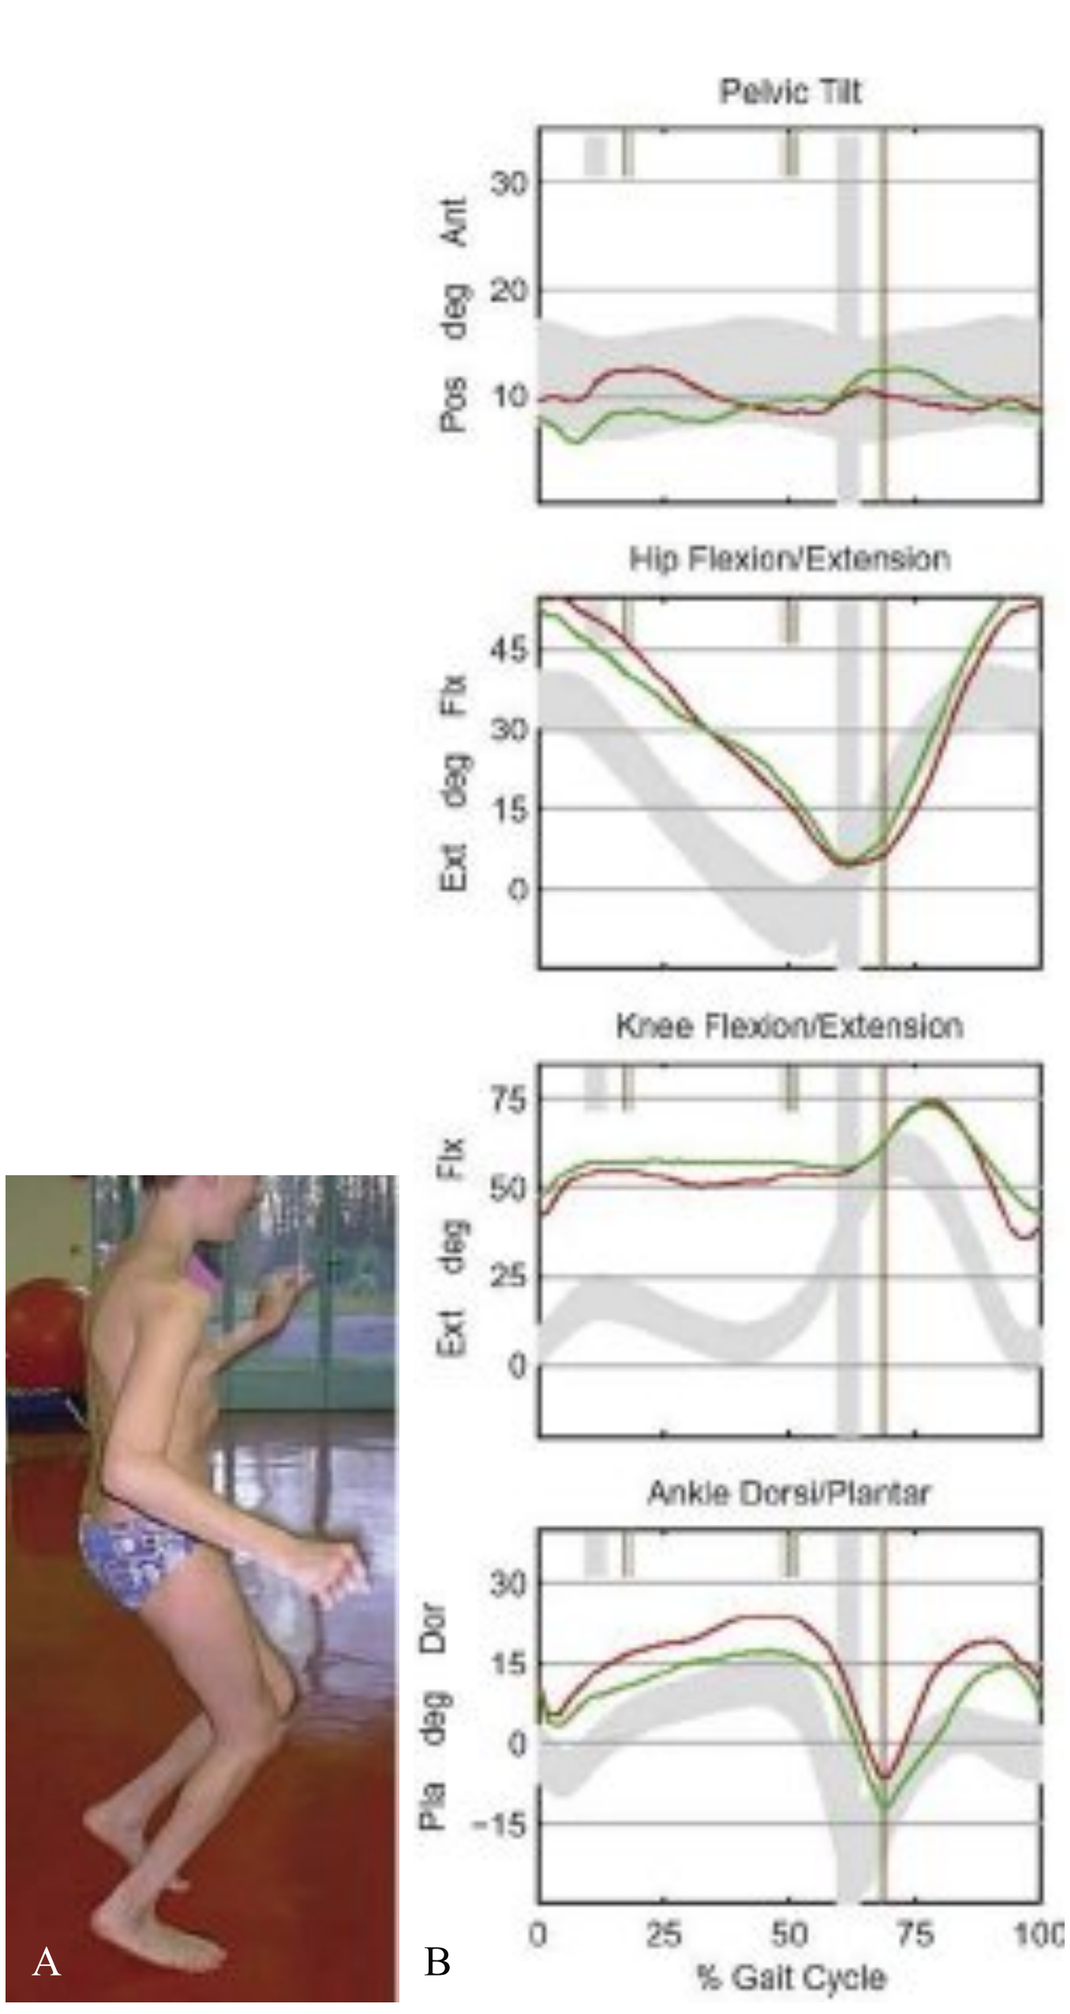

FIG. 34.25 (A) Example of a crouched posture of increased hip and knee flexion in the sagittal plane of a 13-year-old child with cerebral palsy. (B) Patient data compare the child's right side (green) with the left (red). The posture at the ankle is asymmetric, with slightly more dorsiflexion on the left side. Total knee range of motion is limited bilaterally. (The gray shading represents control.) (A, From Hodgkinson I, Bérard C: Assessment of spasticity in pediatric patients. Oper Tech Neurosurg 7(3):109-112, 2004.)
