Treatment: After determining the infecting organism, antimicrobial treatment is instituted. The fluid has to be removed by aspiration and this measure is essential to allay fever and toxemia. When the pus is too thick to be aspirated, or if it reaccumulates rapidly, underwater tube drainage has to be established. Clearance of the pleural space and full re-expansion of the lung may take several weeks to complete. Thick pus which is difficult to be aspirated can be liquefied by the instillation of proteolytic enzymes like streptokinase and streptodornase. In most cases chemotherapy and surgical drainage are adequate to clear the empyema. Rarely an intractable empyema may have to be excised surgically.

Tumours of the Pleura

Primary tumour (mesothelioma) is rare, whereas secondary tumours are common. Mesothelioma may be benign or more commonly malignant. Pleural malignancy is more common in persons chronically exposed to asbestos. Secondary tumours arise from carcinomas of the bronchus, stomach, liver, and other structures. Malignant lesions in the pleura give rise to hemorrhagic pleural effusion.

Pneumothorax

Presence of air in the pleural cavity is known as pneumothorax. Pneumothorax may be spontaneous, traumatic, and iatrogenic (*artificial*). Another classification is to divide

them into *open*, *closed*, and *valvular pneumothorax* (*tension pneumothorax*). In open pneumothorax there is a free rent on the surface of the lung through which air gets in and out of the pleural cavity during inspiration and expiration. In closed pneumothorax the pleura does not communicate with the exterior. In tension pneumothorax there is a valvular slit on the surface of the lung through which air enters the pleural cavity, but does not escape. As a result tension pneumothorax develops leading to respiratory and cardiac embarrassment.

Spontaneous pneumothorax: This results from rupture of pulmonary lesion leading to escape of air into the pleura. Pneumothorax may be primary where there is no obvious underlying lesion or secondary to pulmonary lesions such as cavitation, emphysema, bullae and others.

Subpleural blebs or bullae, pulmonary tuberculosis, congenital cystic disease of the lungs, chronic bronchitis with emphysema, bronchial asthma, pneumoconiosis and staphylococcal pneumonia are the common medical causes. Fracture of a rib, thoracotomy, puncture of the lung at needle biopsy, and rupture of a bronchus are the common surgical causes. Sometimes pneumothorax is produced artificially for diagnostic radiology of the lungs or as a therapy to arrest massive hemoptysis. The lung collapses towards the hilum, when air enters the pleura and abolishes the negative pressure.

CLINICAL FEATURES

Onset is with unilateral pleuritic pain and dyspnea. A feeling of something having given way is complained of by many. Shortness of breath and unproductive cough develop soon. In tension pneumothorax respiratory embarrassment and cyanosis may be evident.

Fig. 144.4: X-ray chest—Pneumothorax-left. Note: (1) The airfilled thoracic cavity. (2) collapsed lung-arrow

The affected side is prominent and it does not move with respiration. Midline structures are shifted to the opposite side. Percussion note is hyper-resonant. Breath sounds are absent in many cases. If air enters the pleural cavity as in tension pneumothorax and open pneumothorax, *amphoric breath sounds* may be heard. A special percussion phenomenon is the '*coin sound*'. A coin kept firmly over the front of the chest wall is struck with another coin. Auscultation at the back of the chest reveals a metallic note. Adventitious sounds like clicking sounds synchronous with the heart beat may be heard in a left sided pneumothorax.

Differential diagnosis of pneumothorax includes other painful conditions associated with dyspnea such as myocardial infarction and pulmonary infarction. Severe emphysema, large bullae and diaphragmatic hernia may cause problems in diagnosis.

Radiological features: The radiological features are diagnostic in a well developed case. The affected side is hypertranslucent due to the collection of free air in the pleural cavity and absence of normal lung markings. The outer margin of the collapsed lung is seen as a sharp margin against the background of air. There is shift of the trachea and mediastinum to the opposite side (Fig. 144.4). Skiagram should be taken in the erect posture so that even small collections of air will not be missed.

Complications: Though in the majority of cases spontaneous pneumothorax is uncomplicated, serious complications may develop in some cases. These are: (1) Severe cardiorespiratory embarrassment due to compression of the normal lung by the displaced mediastinum in cases of tension pneumothorax; (2) air embolism; (3) surgical emphysema; (4) infection of the

Fig. 144.5: X-ray chest pneumothorax left. Note: (1) hyper-translucency left hemithorax (2) collapsed lung adjacent to the left cardiac border (3) shift of mediastinum to the right (4) horizontal level of fluid in the left pleural cavity (the pneumothorax is complicated by the development of effusion)

pleural cavity resulting in the formation of hydro- or pyopneumothorax; (5) pneumothorax on the opposite side from pre-existing disease of the lung; and (6) failure of expansion of the collapsed lung.

Hydropneumothorax

When both air and fluid are present in the pleural cavity, it is known as hydropneumothorax. This is usually the result of rupture of a pulmonary lesion letting in air and exudates into the pleural cavity. In many cases it is caused by tuberculosis. Other causes include lung abscess, bronchiectasis, bronchogenic carcinoma, and trauma to the chest. Some cases of pneumothorax get converted into hydropneumothorax when effusion develops as a result of infection (Fig. 144.5).

In hydropneumothorax a horizontal upper level of dullness caused by the fluid can be demonstrated which shifts when the patient is made to adopt different positions (*shifting dullness*). On shaking the patient gently while auscultating on the air-fluid interphase, a *succussion splash* is heard. Chest radiograph reveals a horizontal upper level of fluid with the findings of pneumothorax above it (Fig. 144.6).

Management of pneumothorax: Small closed pneumothorax which is not severely symptomatic can be left alone with bed rest and analgesics, since the air will be absorbed within a few days. Simple aspiration may hasten recovery.

Tension pneumothorax may present as a life-threatening emergency. Unless the tension is relieved by letting out the air, the patient may die of cardiorespiratory failure.

Fig. 144.6: Hydropneumothorax with collapsed lung. Note: On the right side (1) air above and fluid below with horizontal level of fluid (2) shift of mediastinum to the left and (3) collapsed lung on the right hilum

Emergency management: The air is let out by inserting a wide bore hypodermic needle into the second intercostal

space 2-3 cm outside the lateral border of the sternum. The needle is connected to a rubber tube which is led under water, to prevent re-entry of air (underwater seal). This procedure may have to be instituted even outside the hospital at times. Though this procedure may save life in an emergency, sooner or later the needle gets blocked and air reaccumulates with recurrence of symptoms. So it is ideal to hospitalize the patient for further management.

In the hospital the ideal procedure is to establish drainage of the pleura by a rubber tubing—connected to an underwater seal. The tube may have to be kept in place for a few days or weeks. Antibiotics are given to prevent secondary infection of the pleura. Any obvious underlying condition is treated with specific drugs. Recovery of pulmonary function is facilitated by starting physiotherapy at an early stage.

If the lungs fail to expand spontaneously suction of the pleural cavity may help. Surgical repair of the pleural surface may be required in intractable cases.

145

Diseases of the Chest Wall

K.E. Rajan

Chapter Summary

Kyphoscoliosis 961
Ankylosing Spondylitis 962
Straight Back Syndrome 962
Pectus Excavatum 962
Pectus Carinatum 963
Injuries to the Thoracic Cage 963
Flail Chest 963

The integrity of the chest wall and muscular action of the intercostals muscles and diaphragm are necessary to ensure proper ventilation. Though minor deformities may not be functionally significant, gross bony deformities and

muscular paralysis impair ventilation and give rise to respiratory embarrassment.

Kyphoscoliosis

Kyphosis is the abnormal curvature of the thoracic spine with convexity directed posteriorly. Scoliosis denotes gradual lateral curvature of the thoracic spine, with rotation of the vertebrae in their longitudinal axis. In kyphoscoliosis, there is progressive deformity of spine consisting of lateral and posterior curvatures. Spine is curved in both coronal and sagittal planes.

Kyphoscoliosis may be congenital or acquired. In majority of patients, it is **idiopathic** in origin. Congenital kyphoscoliosis results from developmental anomalies.

Acquired kyphoscoliosis results from poliomyelitis, myopathies, muscular dystrophies, and diseases of the vertebrae such as osteoporosis. Primary respiratory diseases like pulmonary fibrosis or atelectasis may be associated with this deformity. Causes of acquired kyphosis include ankylosing spondylitis, infections like tuberculosis, connective tissue disorders, disc degeneration, Paget's disease and tumours.

Clinical Picture: The deformity may remain asymptomatic for variable periods of time. It may result in shortening of height. A relative may observe the deformity and bring the patient to medical attention. Mobility of chest wall is impaired. The lung on the narrowed side is compressed. The opposite lung shows compensatory emphysema. Position and relationship of mediastinal structures are altered. Physical examination may demonstrate displaced apical impulse, pulsations at unusual locations, altered tactile/vocal fremitus and variations in intensity of breath sounds.

Chest X-ray shows distortion of spine. Spirometry shows reduction of vital capacity and total lung capacity with preservation of FEV₁. Breathing is shallow and rapid with low tidal volumes. The ventilation-perfusion ratio is grossly reduced and this results in hypoxemia. These subjects are prone to develop repeated respiratory infections. In severe cases, respiratory failure may develop. Cardio-respiratory embarrassment develops in severe kyphosis where the angle of curvature exceeds 20° and in severe scoliosis with the angle less than 100°. Advanced kyphoscoliosis may lead to chronic cor pulmonale.

Management: Milwaukee brace controls moderate deformities. Surgical correction is attempted in selected cases to fix the spine and arrest progression of the deformity. Respiratory physiotherapy improves ventilation. Domiciliary oxygen on a long-term basis may be necessary in patients with significant hypoxemia. Special attention must be paid to prevent respiratory infection.

Ankylosing Spondylitis

In this condition there is marked flexion and rigidity of the thoracic spine. Ventilation is carried out mainly by diaphragmatic movement. Though the vital capacity is reduced, signs of frank respiratory embarrassment are few.

Straight Back Syndrome

Straight back syndrome is a benign abnormality of the spine in which the upper dorsal kyphosis is abolished, giving rise to diminution of anteroposterior diameter of the chest. The heart is shifted to the left and forwards giving rise to prominent parasternal impulses on the second to fourth intercostal spaces and Grade 1-3

Fig. 145.1: Pectus excavatum. Note: The abnormal hollow in the midline below the sternal angle

pulmonary ejection systolic murmur. Pulmonary second sound may be split so as to mimic atrial septal defect. Diagnosis can be made from X-ray of the chest. There is greater incidence of straight back syndrome in association with mitral valve prolapse. It is important to recognize this condition so as to avoid unnecessary invasive investigations.

Pectus Deformities

These deformities usually result from a genetic disorder, which causes an abnormal growth of 4 or more pairs of costal cartilages.

In pectus excavatum (Funnel chest), the sternum is pushed inward. The thoracic cage may be flattened antero-posteriorly. A furrow develops in front of the chest, which is deepest just above the xiphoid process. In many cases, it is familial. Though present at birth, the deformity may aggravate during adolescence. Their severity usually remains the same after age 18 years (Fig. 145.1).

Symptoms include cosmetic problems, shortness of breath, discomfort/pain in the lower anterior chest and decreased exercise endurance. The heart is rotated and displaced to the left to varying degrees. This may give rise to systolic murmurs along the left sternal border. Compression of the heart will reduce the stroke volume and cardiac output in moderate to severe deformities leading to early fatigue. There is compensatory tachycardia during exercise. The sternal depression decreases the intrathoracic volume. Respiratory movements are shallow and rapid.

In Pectus Carinatum (Pigeon Chest)

The sternum gets pushed forwards with the ribs sloping steeply on either side. This deformity used to be a sequel

Fig. 145.2: Flail chest. Note: The paradoxical movements of lung

to childhood rickets. There is increased incidence of respiratory infections. Pectus carinatum prevents complete expiration of air from the lungs and significant air trapping. These patients often experience wheezing and occasionally mild to moderate asthma. On exercise, carinatum patients develop tachypnea.

Management: Surgical correction is needed in symptomatic patients. It consists of removal of a small segment of the deformed cartilages medially and laterally on each side of the sternum and bringing the sternum to the desired position with a metal bar support.

Injuries to the Thoracic Cage

The thoracic cage is often injured in accidents. Fractures of individual ribs, contusion of the chest wall/lungs, open wounds (which lead to pneumothorax or hemothorax) and surgical emphysema may be seen. In comatose subjects, injury to the chest wall or viscera may be missed, resulting in fatalities. The need for careful examination to exclude thoracic and abdominal injuries in cases of accidental injuries cannot be overemphasized since at the first examination they may be missed.

Flail Chest

Flail chest results when ribs are fractured in two places. The fractured segment of the thoracic wall floats

independently of the rest of the chest wall and moves paradoxically. The negative intrathoracic pressure during inspiration causes the fractured ribs to be sucked in, thereby preventing expansion of the lung. During expiration this segment moves outwards. When the injury is unilateral air from the lung of the affected side passes into the opposite healthy lung during inspiration and air is sucked into it from the normal lung, during expiration. This type of paradoxical respiration is called “*pendulum breathing*” (Fig. 145.2). This results in serious respiratory insufficiency and respiratory failure.

Management: As first aid, the chest wall should be stabilized to avoid suffocation. Immediate requirement is to prevent the flail segment from moving out paradoxically during expiration. A firm chest wrap is used to support the flail segment. Making the patient lie down with the flail segment against the cot or trolley surface may help. Applying towel clips to the area of paradoxical movement and exerting traction during inspiration is another method. Oxygen supplementation is advisable in all symptomatic patients.

The patient is transported to hospital at the earliest. Stabilization of the flail segment has to be maintained by weight traction. Definitive treatment of flail chest depends upon the degree of respiratory distress. Local anesthetic block is useful to relieve pain. In severe cases where the flail segment is impairing gas exchange or contributing to hypoxemia, internal fixation is done surgically.

Diseases of the Diaphragm

K.E. Rajan

Chapter Summary

- Diaphragmatic Paralysis 964
- Eventration of Diaphragm 964
- Diaphragmatic Hernia 965
- Hiccough 965
- Diaphragmatic Flutter 966

Diaphragmatic Paralysis

The diaphragm is supplied by the phrenic nerve, which has a long intrathoracic course. Involvement of this nerve anywhere in its course is a common cause of paralysis of the diaphragm. The paralyzed dome is pushed up by the intra-abdominal pressure. It moves paradoxically with respiration, i.e., during inspiration it is drawn up and vice versa.

Diaphragmatic paralysis may be unilateral or bilateral. Table 146.1 gives causes of diaphragmatic paralysis.

Rarely rheumatic fever, typhoid, pneumonia, mediastinitis, pericarditis, and encephalitis lethargica may lead to diaphragmatic paralysis.

Clinical features: Unilateral diaphragmatic paralysis may reduce ventilatory capacity by 20%. Otherwise healthy subjects may remain asymptomatic and may be detected during physical examination or by radiology. Sometimes left-sided paralysis may produce gaseous dyspepsia. In bilateral diaphragmatic paralysis, dyspnea may occur because of ventilatory insufficiency. During inspiration the lower part of the chest moves horizontally, the subcostal angle widens, and the epigastrium and hypochondria recede. Absence of the normal peeling movements of the diaphragm visible on the thoracic cage is known as “Litten’s sign”. Abdomen is drawn in, during inspiration.

Radiologically the dome of the diaphragm on the paralyzed side is seen to be elevated. Unilateral diaphragmatic paralysis has to be differentiated from other causes of elevated hemidiaphragm. Pulmonary fibrosis, atelectasis, eventration of the diaphragm, pulmonary infarct,

TABLE 146.1

Causes of diaphragmatic paralysis

Unilateral	Birth injuries Viral infections (e.g. <i>H. zoster</i>) Carcinomatous infiltration Trauma
Bilateral	Guillain-Barré syndrome Cervical cord lesions Motor neuron disease Poliomyelitis Myasthenia gravis Muscular dystrophies

subphrenic abscess and large space occupying lesions of the liver may cause elevation of the dome. Screening or ultrasound study may confirm the diagnosis by asking the patient to perform sniffing during the procedure. In diaphragmatic paralysis the movement is paradoxical, whereas in pulmonary fibrosis and atelectasis the movement of the elevated diaphragm is considerably restricted.

Treatment: Respiratory embarrassment caused by acute diaphragmatic paralysis may have to be treated by intensive respiratory care and ventilatory support.

Eventration of Diaphragm

Eventration is the abnormal elevation of the diaphragm at a site of weakness. It is seen more often on the left side. This may be a congenital or acquired condition. Congenital diaphragmatic eventration results from the defective development of septum transversum. Affected areas include the vertebrocostal triangle and the central tendon. Acquired eventration is more common, resulting from atrophy of muscle fibers secondary to phrenic nerve injury. In eventration, the diaphragmatic movement is paradoxical. The absence of any underlying cause and, persistence over several years should suggest the possibility of eventration (Fig.146.1). Infants with extensive muscular defect of the diaphragm may present with acute respiratory distress. Many patients remain asymptomatic till accidentally found out by skiagram in

Fig. 146.1: Chest X-ray. Eventration of diaphragm

adult life. Eventration has to be differentiated from a Morgagni's hernia.

Diaphragmatic Hernia

The diaphragm acts as a musculotendinous partition between the thoracic and abdominal cavities. The peritoneum and pleura on either side strengthen it further. Inferior vena cava, esophagus, and aorta pass through the diaphragm. The apertures through which they pass are covered and sealed by the serous membranes. When the apertures become lax or other defects develop, abdominal contents herniate into the thoracic cavity.

Herniation may be spontaneous without any known cause or it may be traumatic. Traumatic hernia is more common on the left side. Though any part may be ruptured, the common site is between the central tendon and ninth rib laterally.

Non-traumatic hernias may occur congenitally or may be acquired. Maldevelopment of the diaphragm or laxity of the apertures occurs in congenital hernias. Four common sites through which herniation occurs are: (1) esophageal hiatus, (2) Foramen of Morgagni (between the sternal and costal slips of origin of the diaphragm) (Figs 146.2 and 146.3), (3) Foramen of Bochdalek (pleuroperitoneal hiatus), and (4) through areas of partial absence of the diaphragm. Among these, in more than 75% cases, herniation occurs through the esophageal hiatus.

Herniation of abdominal viscera into the thorax produces clinical features of decreased intensity of breath sounds on the affected side. Bowel sounds may be heard in the thorax. Congenital hernias may be associated with other anomalies such as dextrocardia. The diagnosis is confirmed by a barium meal follow through examination,

which will show the presence of stomach and/or intestines above the diaphragm.

Hiccough

Syn: Hiccup

This is a common reflex phenomenon resulting from sudden spasmodic involuntary contraction of the diaphragm with the glottis remaining closed. The afferent limb of the reflex arc is the vagus and the sensory fibers of the phrenic nerve. The efferent limb is the motor part of the phrenic nerve. The reflex center is in the upper cervical cord. The increased intrathoracic pressure forces air through the glottis. This produces the characteristic sound of hiccough. In most cases the onset and termination of hiccup may be spontaneous and abrupt. Hasty ingestion of food and fluids may trigger off an attack.

In a gravely ill patient the muscular effort and discomfort caused by hiccup may hasten death. In hiccup due to central causes both sides of the diaphragm contract. In conditions caused by local irritation, the contraction may be unilateral.

Causes of Hiccough

1. Local
 - Irritation of diaphragm
 - a. Gaseous distension of stomach and intestines
 - b. Diaphragmatic pleurisy
 - c. Pneumonia
 - d. Subphrenic abscess
 - e. Peritonitis
 - f. Acute myocardial infarction
 - g. Pregnancy
 - Irritation of phrenic nerve
 - a. Pericarditis
 - b. Mediastinitis
 - c. Compression by tumors
 - d. Surgery of thorax or upper abdomen
2. Metabolic
 - a. Renal failure
 - b. Hepatic failure
 - c. Diabetic ketoacidosis
 - d. Respiratory failure
 - e. Electrolyte disturbances
3. Others
 - a. Cerebrovascular accidents
 - b. Encephalitis
 - c. Brain tumours
 - d. Psychogenic

Persistent hiccough is one which lasts for more than 2 days. It has to be distinguished from diaphragmatic flutter.

Figs 146.2A and B: (A) X-ray chest diaphragmatic hernia right side (B) HRCT scan

Fig. 146.3: X-ray lateral view of diaphragmatic hernia (left) and HRCT scan of the same.
Note: The presence of abdominal viscera above the diaphragm

14

Management: Though many cases stop spontaneously, in resistant cases treatment is unsatisfactory. Simple physical measures such as drinking cold water, pressure over the eyeball, Valsalva maneuver, pull on the tongue, stimulation of the phrenic nerve by pressure in the neck or rebreathing into a paper bag may stop the hiccup in many cases. Inhalation of 5 to 10% carbon dioxide is effective. Unilateral hiccup can be arrested by local infiltration of the phrenic nerve with procaine. In cases with abdominal distension, aspiration of gastric contents through a nasogastric tube may provide prompt relief. Some cases are distressing when the attacks cannot be terminated by simple measures. Chlorpromazine given intramuscularly in a dose of 25-50 mg brings about sedation and relief of the hiccough. Other drugs, which may be tried, are metoclopramide in a dose of 10 mg or cisapride in a dose of 10 mg. Some cases recover when sedated for 8-12 hours.

Diaphragmatic Flutter

Sometimes the diaphragm manifests paroxysmal wavelike rhythmic movements at rates going up to 100/min or more. The exact mechanism or cause is not clear. When the condition persists, ventilation may be jeopardized. The term “*diaphragmatic tic*” is given to flutter occurring at a slower rate. Diaphragmatic flutter is seen more frequently in patients recovering from cerebrovascular accidents or encephalitis.

Treatment: The condition responds to anticonvulsant drugs such as dilantin sodium or carbamazepine. In intractable cases temporary phrenic paralysis may have to be induced by crushing the nerve.

147 Diseases of the Mediastinum

C. Sudheendra Ghosh, Dinesa Prabhu V.

Chapter Summary

- Mediastinal Tumours 967
- Cysts 968
- Pneumomediastinum 968

Mediastinal Tumours

An imaginary plane at the lower border of the manubrium sterni divides the mediastinum into superior mediastinum above and anterior, middle, and posterior mediastinum below (Fig. 147.1). Space-occupying lesions in the mediastinum are not uncommon. Due to their location they produce characteristic clinical picture, totally referred to as the mediastinal syndrome. *Diseases of the mediastinum may affect any or all structures with in the chest. It is broadly classified as (a) non-neoplastic disorders, (b) neoplastic disorders, (c) congenital cysts and developmental anomalies.*

Common non-neoplastic diseases of the mediastinum are acute medistinitis, due to mediastinal perforation, post sternotomy mediastinitis, and fibrosing mediastinitis. Pneumomediastinum can be spontaneous or associated with mechanical ventilation.

Tumours: The most common mediastinal tumours are metastases from bronchogenic carcinoma, and lymphomas. Neurofibromas, ganglioneuromas, schwannomas, neuroblastomas, teratomas, dermoids, thymomas and cysts

Fig. 147.1: Subdivisions of mediastinum

are seen less commonly. The majority of cases are asymptomatic. Symptoms are caused by obstruction and infiltration. These are lymphatic and superior venacaval obstruction, hoarseness of voice due to recurrent laryngeal nerve paralysis, Horner’s syndrome caused by pressure on the sympathetic chain, dysphagia due to pressure on the esophagus, and cough and dyspnea due to pressure on the trachea. Neural tumours may elaborate hormones, e.g. pheochromocytoma.

Investigations

Both invasive and non invasive procedures are needed for detailed evaluation. Noninvasive are skiagrams in

Superior and Anterior Mediastinum	Middle Mediastinum	Posterior Mediastinum
Thymic tumours	Congenital cysts	Neurogenic tumours
Aberrant Thyroid	Primary cardiac and vascular tumours	Lymphoma
Germ cell tumours	Lymphoma	Mesenchymal tumours
Malignant Lymphomas	Neural crest tumours	
Giant Lymph node hypoplasia		
Teratoma		
Parathyroid tumours		
Mesen chymal and soft tissue tumors		
Lymphovascular tumors		
Primary and secondary carcinoma		

Fig. 147.2: X-ray chest: Mediastinal tumour – widening of the mediastinum

Fig. 147.3: X-ray chest lateral view. Note: The opacity of the superior mediastinum due to retrosternal tumour

Fig. 147.4: Pneumomediastinum HRCT

Enteric cysts develop in relation to the esophagus. Their lining may resemble the gastric or intestinal mucosa.

Pericardial cysts develop by the side of the pericardium without communicating with its cavity.

Pneumomediastinum

Syn: Mediastinal emphysema

Presence of air within the planes of the mediastinum is called pneumomediastinum. This may occur spontaneously or result from trauma to the chest or perforation of the trachea and esophagus. Surgical emphysema occurring in the fascial planes of the neck or retroperitoneal region may spread to the mediastinum. In emphysema and conditions associated with violent cough, alveolar air may enter the interstitium and reach the mediastinum through the hilum. Other rare causes include Caisson disease and perforation of the esophagus during instrumentation.

Clinical features: The condition may be asymptomatic in many cases. Others complain of retrosternal pain, dyspnea, cough and dysphagia. Crepitus may be felt over the upper part of the chest. Crunching adventitious sounds may be heard on auscultating the heart (Hamman’s sign). In severe cases cardiac failure may develop. Skiagrams reveal the air in tissues (Fig. 147.4).

Treatment

Measures to abolish pain and prevent infection are sufficient in spontaneous cases. In traumatic cases the surgical defects have to be repaired.

different views (Figs 147.2 and 147.3), computed tomography, magnetic resonance imaging, ultrasonography, radionuclide scanning, and biochemical tumor markers. Invasive procedures include bronchoscopy, mediastinoscopy and biopsy of nodes by thoracotomy. Vast majority of the mediastinal lesions can be detected clearly by MRI and CT.

Cysts

The anterior and middle mediastinum may be the seat of benign cysts, the majority of which are asymptomatic.

Bronchogenic cysts are seen by the side of the trachea or the carina most frequently. These cysts do not communicate with the air passages.

Blood Formation

As early as the third week of gestation, blood cells are formed in the yolk sac outside the embryo. Hematopoiesis is taken up by the liver and spleen after a few weeks. The bone marrow progressively takes over this function after the 20th week. After birth, hepatic and splenic hematopoiesis ceases and bone marrow is the only site for blood formation. Normally in adults only the marrow in the axial skeleton, skull, and ends of long bones is active, the rest remains in a dormant stage, but it can become active in times of need. In the adult 30% of hemopoiesis takes place in the pelvic bones.

The bone marrow is a highly organized tissue supported by reticular cells and anchored on a spoke-like vascular structure. Functionally there are two components.

1. **The microenvironment** consists of the stromal cells, accessory cells and extracellular matrix formed by them. The stromal cells include fibroblasts, macrophages, endothelial cells and adipocytes. The macrophages elaborate a wide range of cytokines which influence growth of marrow cells—either stimulatory or inhibitory.

Function of stroma is to provide a structural framework for the blood-forming cells and to produce cytokines.

2. **The hematopoietic stem cells in various stages of proliferation and maturation:** A rich network of blood vessels empties blood into sinuses. The hematopoietic cells lie in cords or islands between the

vascular sinuses in a meshwork of reticular cells. Erythrocytes, myeloid cells, and megakaryocytes develop outside the vascular compartment. The marrow contains a rich supply of nerve cells which are sensitive to changes in intramedullary pressure. They are packed into fronds consisting of a network of reticular fibroblastoid cells surrounded by endothelial cells. As the blood cells mature they extricate themselves from this network, pass through the gaps between the endothelial cells and are liberated into the sinusoidal blood. From the sluggish circulation in the sinusoids, ultimately they reach the mainstream of circulation. Each day an adult produces 200 billion erythrocytes, 100 billion leukocytes and 100 billion platelets. These rates can be increased by 10-folds in times of need.

The pluripotent stem cell differentiates first into the myeloid cell progenitor CFU-S (colony forming unit spleen). From this cell the progenitors of erythroid (BFU-E), myeloid and monocytic cells (CFU-GM) and megakaryocytes (CFU-MK) arise. CFU-GM further differentiates into the precursors of macrophages (CFU-M) and granulocytes (CFU-G) (Figs 148.1 and 148.2).

Several growth factors and differentiating factors are produced by different cells which help proliferation of the hematopoietic cell precursors.

Lymphoid cells arise in the bone marrow from the lymphocyte precursor.

Erythrocyte

The most primitive committed erythropoietic precursor cells are called “*erythroid burst-forming cells*” (BFU-E) since they give rise to multiple sub-colonies when they are grown *in vitro*. The burst promoting activity is brought about by the secretions of specific types of T-cells and monocytes occurring in close proximity to each other. As the primitive progenitor cells replicate and mature they become increasingly sensitive to erythropoietin and form erythroid colonies more rapidly (*erythrocyte colony forming units*: CFU-E). These develop into *erythroblasts* and *erythrocytes*. Erythropoietin is the main hormone

Fig. 148.1: Scheme of hematopoiesis

Fig. 148.2: Normal bone marrow $\times 400$

which controls the proliferation and maturation of erythroid precursors.

Stages in the Development of the Erythrocyte

Different stages are recognisable in the process of maturation of the erythrocyte. These are the proerythroblast,

basophilic, polychromatophilic, and eosinophilic normoblasts, reticulocytes, and mature erythrocytes. The nucleus of the normoblast degenerates and it is extruded to give rise to the reticulocyte. In this cell, ribosomes, mitochondria, and Golgi apparatus persist for a short time. These cytoplasmic organelles reveal a granular or strand-like pattern when stained with vital stains like brilliant cresyl blue or aqueous methylene blue. These are called reticulocytes. The remnants of the degenerating nucleus which are in the process of extrusion are demonstrable as *Howell-Jolly bodies* and *Cabot's rings*.

In the normal adult 2×10^{11} erythrocytes die everyday. In replacing this number the marrow synthesises 4×10^{14} molecules of hemoglobin every second. Hemoglobin consists of heme and globin. Heme is synthesised by inserting an atom of iron into an intensely coloured ring of protoporphyrin IX by the developing erythroblast. Simultaneously the developing red cell produces alpha and beta-globin chains which are joined to the heme molecule. This process proceeds in a precisely programmed manner. Heme is formed in the mitochondria from where it has to

move out into the cytoplasm where globin chains are formed. Disruption of these processes leads to disorders such as thalassemias where globin chain synthesis is defective and sideroblastic anemias where incorporation of iron into heme is defective.

The mature erythrocyte is a non-nucleated biconcave disc most suited to perform the function of gaseous exchange. It is a highly specialised, metabolically active cell which obtains energy by utilising glucose by anaerobic pathways. It is provided with enzymes required for metabolism of glucose. Some of the important enzymes which take part in anaerobic glycolysis are hexokinase, glucose-6-phosphate isomerase, phosphofructokinase, and aldolase. Those taking part in oxidative glycolysis are glucose-6-phosphate dehydrogenase (G-6-PD), 6-phospho-gluconate dehydrogenase, transketolase and transaldolase. This pathway is connected with glutathione metabolism through the enzymes glutathione reductase and glutathione peroxidase.

The red cell membrane is unique in that it maintains the biconcave shape of the red cell, it is capable of accommodating increase and decrease of volume of the contents, and it is deformable so as to pass through blood vessels of smaller caliber. The membrane consists of a bilayer of lipids and integral proteins attached to an underlying protein skeleton. The protein skeleton consists of a two dimensional mesh of spectrin tetramers and oligomers, cross linked by protein 4.1 and actin. The protein skeleton is attached to the membrane by the binding of spectrin to ankyrin, and of ankyrin to another protein called band-3 which is an anion exchanger. Other membrane proteins include pallidin. Abnormalities of these membrane proteins lead to early destruction of the erythrocytes.

The protein skeleton helps to maintain the shape of the red cell. The deformability is grossly affected in defects of membrane of the erythrocyte as occurs in spherocytosis and elliptocytosis and also when abnormal hemoglobins such as HbS induce polymerisation under anoxic environment. Normal erythrocyte does not freely adhere to endothelium while in circulation. Under abnormal conditions the adhesive properties of the membrane also changes, rendering them more adherent to endothelium.

The erythrocyte membrane has a major role in ion transport which is mediated by several membrane channels or pumps that can maintain the osmotic gradient within the cell. These functions which require energy can be modified by hormones, cyclic nucleotides, calcium and calmodulin.

Anaerobic metabolism supplies 90% of the energy requirement and only 10% is supplied by the aerobic or pentose phosphate cycle. The mature red cell is incapable of protein synthesis. The full complement of hemoglobin and enzymes present in erythrocytes is handed down by

the erythroblast. Life of the red cells is 120 days. They are destroyed in the reticuloendothelial system subsequently. The red cell number remains nearly constant in the range of 5-6 millions per cmm ($5-6 \times 10^{12}$ /litre) throughout life.

Hemoglobin is a complex molecule consisting of the heme moiety (the red pigment) comprising iron and porphyrin, and the protein moiety, globin. In adult hemoglobin (HbA) the globin consists of two alpha chains, each containing 141 amino acids and two beta chains each with 146 amino acids. The fetal hemoglobin (HbF) consists of two alpha chains and two gamma chains. After birth, within 5-6 months the synthesis of gamma chains stops and beta chains are formed in the required amounts. By the age of six months 98-99% of hemoglobin is made up of HbA. The rate and amount of production of the alpha, beta and gamma chains and their synthesis to form normal and abnormal hemoglobins are controlled by specific genes. In normal persons the production of gamma chains fall rapidly after birth and give place to rapid increase in the production of beta chains. For the continuous production of red cells and synthesis of hemoglobin several nutrients are required. These are mainly iron, proteins, vitamin B₁₂, folic acid, pyridoxine, vitamin C, nicotinic acid, copper and cobalt.

The blood group antigens are attached to the red cell membrane. The molecular basis for the remarkable diversity of the blood group polymorphism includes single base substitutions, deletions and insertions in the genes that encode their protein products.

Mature RBC has no nucleus or mitochondria. Energy is derived through the glycolytic Embden-Meyerhof pathway in which glucose is metabolised with the production of lactate.

Hemoglobin is responsible for transport of oxygen from lungs to tissues and removal of carbon dioxide from tissues and delivery to the lungs. The oxygen dissociation curve of hemoglobin depicts these events. Rise in H⁺ ion concentration and CO₂ levels in the environment reduce the oxygen binding capacity of hemoglobin. This is known as the Bohr effect. Increase in oxygenation of hemoglobin reduces its affinity to CO₂. This is known as the Haldane effect.

Androgens also stimulate the production of erythropoietin and also directly activate the stem cells. Estrogens suppress erythropoietin production and hence depress erythropoiesis. Thyroxine probably stimulates erythropoiesis by producing tissue anoxia. Hypothyroidism leads to a mild degree of anemia, which can be corrected by thyroxine.

HEMATOPOIETIC GROWTH FACTORS

The expansion of the stem cell pool, maturation and expansion of precursor cells and their liberation into circulation are all under control of well defined humoral

influences. These include erythropoietin (EPO), granulocyte colony stimulating factor (G-CSF), macrophage colony stimulating factor, granulocyte-macrophage colony stimulating factor (GM-CSF) and interleukin-3 (also known as multiclonal stimulating factor).

Erythropoietin (EPO): During fetal life it is produced in the liver. In postnatal life, by far the main source is the kidneys (90%), a small amount is also produced in the liver (10%). In the kidneys the erythropoietin producing cells are found in the renal cortex, lying outside the renal tubular basement membrane. These cells are derived either from a subset of interstitial cells or capillary endothelial cells which can sense oxygen levels by a complicated mechanism. Action of erythropoietin on the erythroid precursor cells is receptor mediated.

Erythropoietin is a glycoprotein with a molecular weight of 30,000 daltons. Its principal actions are on the developing erythroid precursor cells after they have become sensitive to erythropoietin. The erythroid precursors are stimulated to proliferate and differentiate and thus accelerate erythropoiesis. Normal apoptotic mechanisms play a role in regulating erythrocyte maturation and disposal.

The viability of the developing erythroid cells is also maintained by this hormone. It is a survival factor for them. Erythropoietin production is tightly controlled to prevent inappropriate rise in red cell mass. Main stimulus for erythropoietin production is anoxia. Rise in red cell mass and viscosity of blood depress erythropoietin production independent of the tissue oxygenation status. Small rise in erythropoietin levels do occur with slight fall in hemoglobin, up to 10 g/dL, but not beyond the normal ranges. The normal range of plasma erythropoietin is 5-25 units/L. In response to anemia or arterial hypoxemia the serum level of EPO may go above 25 u/L.

There is only one form of circulating erythropoietin. Production is controlled at the gene level. There are no stores and the production and clearance are independent of the plasma levels. Erythropoietin gene transcription is inhibited by inflammatory cytokines such as interleukin-1 and tumour necrosis factor.

Actions of EPO

1. EPO leads to proliferation of erythroid precursors which differentiate into normoblasts, which leave the bone marrow after extrusion of the nucleus. Reticulocyte counts start rising within 1-2 weeks of EPO administration.
2. EPO crosses blood brain barrier and it plays a protective role in ischemic neurons. It has also tissue protecting activity in the myocardium and the kidney.

Various conditions such as renal parenchymal diseases, hyperviscosity, cancer, infection, inflammation,

chronic liver diseases, surgery, pregnancy and prematurity suppress erythropoietin production without regard to tissue oxygenation. Erythropoietin is metabolised by erythroid progenitor cells. In hypoplastic anemia, due to defective utilization of erythropoietin, the serum levels are relatively high. Erythropoietins (EPO), their analogues and mimetics are produced by recombinant technology. These include recombinant erythropoietin, darbepoietin alfa which has longer duration of action compared to EPO, continuous erythropoietin receptor activator (CERA), synthetic erythropoietin protein, erythropoietin fusion protein, and erythropoietin-mimetic peptides. All these are under different stages of drug development at present.

Hematopoietic growth factors other than erythropoietin are produced by fibroblasts, endothelial cells, monocytes and lymphocytes which are widely distributed. In experimental studies, stimulation with bacterial endotoxin, monokines and lectins increase the production of these growth promoting factors. They act on progenitor cells to produce precursor cells and simultaneously expand the progenitor pool.

Granulocyte-macrophage colony stimulating factor (GM-CSF) acts on the precursors of granulocytes, monocytes, macrophages, erythrocytes and also megakaryocytes.

GM-CSF is produced by several cell types. It stimulates the proliferation of several myeloid cell lines and megakaryocytes. The result is increased production of neutrophils and other granulocytes and monocytes and improvement in neutrophil survival. GM-CSF stimulates the production of neutrophils, eosinophils, basophils, monocytes and dendritic cells in culture and activates most of these cells into action.

Granulocyte colony stimulating factor G-CSF G-CSF is produced by endothelial cells, fibroblasts and macrophages in virtually all organs. It stimulates growth of neutrophil colonies in vitro and stimulates neutrophils into activity such as phagocytosis and bacterial killing. It leads to release of young neutrophils into the circulation leading to shift to the left of neutrophil distribution. It also causes the presence of toxic granules in the neutrophils in peripheral blood, which is a morphological correlate of their heightened functional state. In inflammation, cytokines such as tumour necrosis factor (TNF α), interleukin-1 and interleukin-6, derived from activated monocytes stimulate G-CSF production. Recombinant G-CSF is available for therapy as injection containing 30 MU (300 μ g)/mL. After injection, peripheral blood neutrophil count rises within 48 hours. Monocytes and eosinophils may show slight rise. The dose is 0.5 MU (5 μ g)/kg bw given SC or as IV infusion.

G-CSF mobilises stem cells from the bone marrow to peripheral blood and therefore increases the yield of stem cells from peripheral blood. G-CSF therapy helps to

prevent chemotherapy-induced neutropenia. G-CSF therapy may increase incidence of treatment related myeloid leukemia especially when co-administered with cyclophosphamide or doxorubicin.

Haemopoietic growth factors are administered for four groups of conditions

1. Correction of cytopenias
2. For harvesting stem cells and progenitor cells
3. Augmentation of hematopoiesis to compensate for accelerated cell destruction
4. Activation of mature hemopoietic cells.

Clinical Applications

Erythropoietin is very successful in correcting anemia and improving the general well-being in chronic renal failure when given in a dose of 75-150 IU/kg body weight thrice a week (total dose required annually for an adult being 2-12 mg). Erythropoietin is also used to stimulate red cell production preparatory to autologous transfusion at a later date.

Erythropoietin is given by SC injection. Indications for erythropoietin include;

1. *Anemia of chronic renal failure (CRF).*
2. *Anemia of cancer.* Patients with Hb< 10g/dL benefit by EPO which also prolongs life.
3. *In patients recovering from myelosuppressive chemotherapy.* Chemotherapy induces apoptosis both in cancer cells and erythroid precursors. EPO blocks the apoptosis of erythroid precursor cells.

Repeated use over long periods may lead to the development of anti-erythropoietin antibody which neutralizes endogenous and exogenous erythropoietin. The patient becomes unresponsive to the use of erythropoietin and may develop pure red-cell aplasia (PRCA). This condition responds to immunosuppressive therapy. Another adverse side effect is the development of hypertension with rise in erythrocyte counts.

A long-acting analogue of erythropoietin which is also used in therapy is *darbepoietin alfa*.

GM-CSF is employed in doses of 10 µg/kg body weight, in order to stimulate neutrophils, monocytes and circulating stem cells, and thereby reducing the duration of dangerous neutropenia following intensive chemotherapy and bone marrow transplantation. For harvesting circulating stem cells preliminary to stem-cell transplantation which is an alternative to bone marrow transplantation, GM-CSF is employed. It is also used in some cases of cyclical neutropenia and agranulocytosis where other therapeutic measures are not fully effective.

G-CSF is also used extensively in leukopenic states and chemotherapy induced neutropenia, both prophylactically and therapeutically.

Leukocytes

White blood cells originate from pluripotent hemopoietic stem cells. Under the influence of various external stimuli including cytokines, matrix proteins and accessory cells, the stem cells differentiate into hemopoietic progenitor cells.

Cytokines involved in the production of different leukocytes	
Cell type	Cytokine involved
Neutrophil	G-CSF, GM-CSF, IL 3, and macrophage colony stimulating factor (M-CSF)
Monocytes	GM-CSF, and M-CSF
Eosinophils	GM-CSF, IL3 and IL 5
T-lymphocytes	A complex process IL 2 and IL 3
B-lymphocytes	IL 7

Broadly they may be divided into phagocytes and lymphocytes. The former includes the neutrophils, eosinophils, basophils (granulocytes), and monocytes (Table 148.1).

The granulocytes are formed from the stem cell through the stages of myeloblasts, promyelocytes, myelocytes and metamyelocytes. As the neutrophil ages, the number of lobes in the nucleus increases and age of the cell can be assessed this way. The cytoplasmic granules are lysosomal in origin and are of two types—the *primary granules* which appear at the promyelocytic stage and the *secondary granules* which appear at the myelocytic stage. Primary granules contain myeloperoxidases, acid phosphatases and other acid hydrolases. Secondary granules contain alkaline phosphatase and lysozyme. The latter predominates in the mature neutrophil. Myeloblasts are the earliest recognizable precursors seen in the bone marrow. The nucleus contains 2-5 nucleoli and the cytoplasm is clear, nongranular and basophilic. In normal

TABLE 148.1

The normal distribution of leukocytes in peripheral blood		
	Range per litre	Percent of total
Total leukocytes (Adults)	5-10 × 10 ⁹	
Neutrophils	3.5-7 × 10 ⁹	60-70%
Eosinophils	0.1-0.6 × 10 ⁹	2-6%
Basophils	0.01-0.1 × 10 ⁹	0-1%
Monocytes	0.2-0.5 × 10 ⁹	2-5%
Lymphocytes	1.5-3 × 10 ⁹	25-35%

Note: 1 × 10⁹/litre = 1000 cells/cmm. Children have slightly higher leukocyte counts.

marrow the myeloblasts do not exceed 4%. Promyelocytes are formed by division of myeloblasts. The nucleoli disappear and the cytoplasm acquires primary granules. The promyelocytes give rise to myelocytes which show specific secondary granules in the cytoplasm. The nucleus is more condensed and nucleoli are absent. Neutrophils, eosinophils, and basophils arise from corresponding myelocytes. Myelocytes divide to form metamyelocytes which do not divide further. Metamyelocytes have indented or horse shoe-shaped nucleus and cytoplasm filled with primary and secondary granules. These cells develop into 'band forms' or *juvenile neutrophils* in which the nucleus starts to show lobulation, but the distinct filamentous constriction between the lobes is absent.

Myeloblasts, promyelocytes, and myelocytes are together known as the proliferative or *mitotic pool*, and the metamyelocytes, band forms, and segmented neutrophils are known as the *postmitotic maturation pool*. The store of granulocytes present in the marrow is 10-15 times the circulating pool. Majority of the marrow granulocytic cells are myelocytes and neutrophils. After release from the bone marrow granulocytes circulate in the peripheral blood for about 10 hours and then enter tissue for phagocytosis. In the peripheral blood, half of the neutrophils circulate freely (*circulating pool* included in the blood count) and the other half forms the *marginating pool* which adheres to vessel wall (not included in the blood count). In the tissues, the granulocytes remain for 4-5 days before they perish during defensive action or due to aging.

The various compartments in the peripheral blood, tissues and bone marrow are regulated by a feedback mechanism. Leukopoietins, analogous to erythropoietin, have been described.

Functions of neutrophils: These include chemotaxis, phagocytosis, intracytoplasmic killing, and destruction of foreign particles and microbes. Neutrophils are phagocytic and this activity is of prime importance in microbial killing. In many inflammatory diseases further processes mediated by the cytokines liberated by neutrophils tend to perpetuate the inflammatory and tissue destructive processes. Functional defects of neutrophils may occur at times. In this condition there will be defects of any or all the functions.

Neutrophils adhere to cells and surfaces by receptor mediated activity and the cell surface glycoproteins are important for this function. Neutrophils activated by phagocytic stimuli or chemo-attractants produce large amounts of microbicidal oxidants. The neutrophils contain cytoplasmic granules of different sizes. The azurophil granules are lysozyme-like, and contain various enzymes and other proteins possessing antibacterial and antifungal properties. The lysosomal granules contain myeloperoxidase. Neutrophil-specific (secondary) granules are rich in

glycoproteins. Deficiency of the contents of granules make the neutrophils functionally defective.

Functional Defects of Neutrophils

This may be acquired or congenital.

Defect in chemotaxis (lazy leukocyte syndrome) occurs in alcoholism, hyperosmolar states, myelogenous leukemia, abnormalities of complement, and rarely as a congenital condition. Drugs like aspirin and corticosteroids impair chemotaxis further.

Defective phagocytosis occurs in hypogammaglobulinemia, hypocomplementemia, post-splenectomy states, and sickle cell anemia.

The killing function is reduced in granulomatous disease, myeloperoxidase deficiency, Chédiak-Higashi syndrome, acute and chronic granulocytic leukemias, preleukemia, and myelodysplastic states.

Alteration in Neutrophil Counts

Neutrophil leukocytosis (count above $7.5 \times 10^9/\text{litre}$): This condition occurs in many bacterial infections, inflammations, tissue necrosis, metabolic disorders such as renal failure, gout, acidosis, toxemias of pregnancy, malignant neoplasms, acute hemorrhage, acute hemolysis, and corticosteroid therapy. Myeloproliferative disorders are characterized by very high granulocyte counts. A rapid increase in the production of neutrophils is generally associated with the appearance of many young forms (*shift to the left*) and the presence of myelocytes in peripheral blood.

Neutropenia (counts below $1 \times 10^9/\text{litre}$) develops as a toxic reaction to several drugs or as a part of pancytopenias. Milder grades of transient neutropenia occur in many viral infections and bacterial infections like typhoid, hypersensitivity, anaphylaxis, auto-immune disorders like disseminated lupus erythematosus, and in hypersplenism. When neutropenia is caused by reduction in the formation of cells, most of the neutrophils in peripheral blood are the older forms. They show four or more lobes in the nucleus (*shift to the right*), the younger forms being particularly absent.

Reduction of neutrophil counts to below 500/cmm is associated with increased risk of several opportunistic infections. Neutropenia associated with fever is a dreaded complication in chemotherapy of malignancy, organ transplantation and others. This calls for special therapeutic intervention.

Cyclical neutropenia is a rare disorder showing periodic reduction in neutrophils at 3-4 week intervals. It is characterized by a regular 21-day cyclic fall and rise in the numbers of circulating neutrophils, monocytes, eosinophils, lymphocytes, platelets and reticulocytes. This is caused by a defect of the stem cells. During the

leukopenic phase the bone marrow shows paucity of myeloid elements. Neutropenia by itself does not cause symptoms, but it predisposes to infection when the neutrophil count falls $<500/\text{cmm}$ and persists so for >10 - 14 days.

During these episodes, infections may develop leading to oral ulceration, gingivitis, pharyngitis, lymphadenopathy and skin infections. Human granulocyte colony stimulating factor given in a dose of $3\mu\text{g}/\text{kg}$ daily subcutaneously has been found to be effective in correcting the neutropenic state. Prolonged use may predispose to the development of acute myeloid leukemia in $>10\%$ of cases.

Sometimes neutrophils migrate from the circulating pool to the marginating pool and the neutrophil count in peripheral blood falls. There is no increased tendency for infections in this condition. This is referred to as *idiopathic benign neutropenia*.

Eosinophils

Eosinophils are generally similar in morphology to neutrophils, with eosinophilic granules in the cytoplasm. The nucleus contains only two or rarely three lobes. Eosinophils develop through the same stages as the neutrophils. Distinguishing features develop at the stage of myelocyte.

Four processes are distinguishable in the development of eosinophils.

1. Differentiation of progenitor cell and proliferation in the BM.
2. Interaction between eosinophils and endothelial cells that includes rolling, migration and adhesion of eosinophils.
3. Chemoalteration which directs eosinophils to specific locations and
4. Activation and destruction.

Three cytokines—interleukin-3, IL-5 and GM-CSF are particularly involved in the development of eosinophils. Among these three, IL-5 is the most important. It is also called eosinophil differentiation factor.

Eosinophils in tissues survive for varying periods, upto 12-24 days.

Several enzymes such as aryl sulphatase, phospholipidase, acid phosphatase, beta-glucuronidase, peroxidase, and cathepsins are present in the cytoplasmic granules. The function of eosinophils has been extensively studied and their importance recognised. They phagocytose a variety of substances such as immune complexes, mast cell granules, mycoplasma, ferritin, and others. But this activity is considerably less than that of neutrophils. Eosinophils suppress allergic inflammatory processes. They play an important role in defence against parasites and in the removal of fibrin formed during inflammation.

Larval forms of parasites like filaria and schistosomes are killed by eosinophils. They kill parasites by releasing

cationic proteins and reactive oxygen metabolites into the extracellular fluid. They also secrete leukotrienes, prostaglandins and various other cytokines. Their life in peripheral blood is longer than that of neutrophils. In many conditions like hypersensitivity reactions, parasitic diseases, drug sensitivity, and polyarteritis nodosa, eosinophil counts are moderately increased (0.4 - $2 \times 10^9/\text{litre}$). Marked increase (over $3 \times 10^9/\text{litre}$) occurs in tropical eosinophilia which is common in India. Asthma, polyarteritis nodosa and helminthiasis are associated with eosinophilia. Primary hypereosinophilic syndrome and eosinophilic leukemia cause high eosinophilia, but these are rare.

Basophils

Basophils form up to 1% of the total leukocytes. They are identified by the presence of coarse basophilic granules which often overlie the nucleus which is bilobed. The granules are rich in histamine, serotonin and leukotrienes. Mast cells are related to, but distinct from basophils. Mast cells are long-lived cells which reside in tissues rather than in peripheral circulation, and they can divide further. Both basophils and mast cells participate in immediate allergic reactions such as urticaria, anaphylaxis, asthma and allergic rhinitis. Increase in basophil leukocytes (counts above $0.1 \times 10^9/\text{litre}$) is uncommon, but this is seen in myeloproliferative disorders such as chronic myeloid leukemia and polycythemia vera. Disorders like myxedema, smallpox, chickenpox, and ulcerative colitis also may be associated with basophil leukocytosis.

Monocytes

Syn: Mononuclear phagocytes: Mononuclear phagocyte system is made up of peripheral blood monocytes, their precursors in the bone marrow and tissue macrophages. Though their nomenclature indicates that they are predominantly phagocytic, they also mediate several other functions including induction of acute phase responses, regulation of hematopoiesis, activation of immune and coagulation systems, killing of microorganisms and tumour cells, and tissue repair.

The precursor of the monocyte is the monoblast which resembles the myeloblast but can be distinguished histochemically. From their sites of origin in the bone marrow the monocytes circulate in the peripheral blood for about three days and enter the tissues where they are known as macrophages. The number of tissue macrophages are several hundred times that of the circulating monocytes and their life-span is around a few months. The macrophages are seen in all tissues, but they are particularly prominent in the spleen, lymph nodes, pulmonary alveoli, liver (*Kupffer's cells*), peritoneum and skin (*Langerhan's cells*). Once the monocyte enters the tissues, it does not return to the circulation.

Mononuclear macrophages secrete several substances (numbering about a hundred) and these take part in several functions ranging from induction of cell growth to cell death. The major functions mediated by monocyte macrophages are listed below.

1. **Inflammation**—The acute phase response which is a systemic inflammatory reaction resulting from infection or injury consists of fever, tachycardia, shock and changes in the concentrations of circulating proteins such as C-reactive protein, fibrinogen interleukin-1, tumour necrosis factor and interleukin-6. These are secreted by the monocytes and they form important mediators of this response.
2. **Regulation of hemopoiesis**—Monocyte products such as granulocyte colony stimulating factor and macrophage colony stimulating factor directly stimulate cell production. Interleukin-1 and tumour necrosis factor activate T lymphocytes to produce granulocyte-macrophage colony stimulating factor and interleukin-3 which also stimulates hemopoiesis.
3. **Hemostasis**—Monocytes and macrophages can activate the blood coagulation process in response to several stimuli including bacterial endotoxin, immune complexes and complement components. Mononuclear phagocytes synthesise tissue thromboplastin which can activate the extrinsic coagulation pathway.
4. **Lymphocyte activation**—Some B- and T-lymphocytes cannot recognize free antigens themselves. Mononuclear phagocytes are capable of taking up such antigens and converting them into immunogenic fragments which are presented to B- and T-lymphocytes which are activated in turn.
5. **Microbial killing**—Mononuclear phagocytes are attracted towards an infective focus by several substances including bacterial components and endotoxins, complement components, immune complexes and collagen fragments. Once they reach the site, they remain there under the influence of a migration inhibitory factor secreted by T lymphocytes and phagocytose the microbes. After ingestion the organisms are killed.
6. **Destruction of tumour cells**—Mononuclear phagocytes infiltrate tumours and lead to lysis of tumour cells. This forms a major defensive mechanism against tumours. Tumour necrosis factor produced by the mononuclear phagocytes has been synthesized by recombinant DNA technology and it is used therapeutically.
7. **Tissue repair and remodelling**—The collagenase and elastase secreted by mononuclear phagocytes help to debride wounds. They also release substances which stimulate the proliferation of fibroblasts and new vessels.

Macrophages in tissues are quiescent under normal conditions, but in times of need they are activated by several stimuli including endotoxin, immune complexes, complement components and products of T-cells. Gamma interferon secreted by lymphocytes is an important activator of macrophages. Macrophage function is essential to life. It is impaired in immunosuppressed states, diabetes mellitus, chronic granulomatous disease and several others.

Bacterial infections such as tuberculosis, brucellosis, bacterial endocarditis and typhoid, and protozoal infections like amoebiasis may lead to moderate monocytosis (over $0.8 \times 10^9/\text{litre}$). Other causes of monocytosis are neutropenia, Hodgkin's disease, and monocytic leukemia.

LYMPHOCYTES

Lymphocytes and plasma cells are together known as **immunocytes**. Their role is to assist the phagocytes in defence mechanism and add specificity to the attack.

Lymphocytes are formed in the bone marrow and thymus during postnatal life. In the fetus, the yolk sac and liver produce lymphocytes. In the lymphopoietic tissues the stem cells undergo spontaneous division without depending on antigenic stimulation. Other lymphoid tissues found in lymph nodes, spleen, organized lymphoid tissues of the alimentary and respiratory tracts and the lymphocytes seen in blood and tissue spaces, constitute secondary lymphoid tissues. In the bone marrow the precursor of the lymphocyte is the lymphoblast. Maturation to the lymphocyte stage occurs without any distinct stages in between.

B-lymphocytes are derived from bone marrow stem cells. When activated by antigens, the B-cells proliferate and mature into plasma cells which secrete specific immunoglobulins, the antibodies.

The primordial T-cells are produced in the bone marrow and the cortex of the thymus, where they are conditioned to recognize the body's antigenic make-up. T-cell precursors migrate from the bone marrow to the corticomedullary regions of the thymus where they begin to differentiate, rearrange their variable region genes and proliferate. This process is completed in the medulla of the thymus from which the mature T-cells exit, 98% of the cells undergo apoptosis during their maturation in the thymus and only 2% emerge as functionally competent T-cells.

They are the main cells responsible for cell-mediated immunity. **Helper T-cells** (CD4+) are specific lymphocytes which instruct B-cells about specific antigens. The T-cell population also contains **suppressor cells** (CD8+) which reduce B-cell responses. The **killer cells** (K cells) cause damage to cells recognized as 'foreign'. Lymphocytes migrate to the lymph nodes and spleen through post-capillary venules. The T-cells are seen in the perifollicular

areas of the cortex of lymph nodes (paracortical areas) and in the periarteriolar sheaths surrounding the central arterioles of the spleen. The majority of lymphocytes in the thoracic duct and peripheral blood are T-cells. B-cells selectively accumulate in the subcapsular periphery of the cortex and medullary cords of lymph nodes, and germinal follicles of lymph nodes and spleen. Majority of B-cells remain for long periods in these sites.

Most of the lymphocytes in peripheral blood are small with scanty nongranular cytoplasm and a central nucleus with coarse chromatin. Larger lymphocytes which may also occur in peripheral blood are probably stimulated by antigenic challenge from viruses or foreign proteins.

T- and B-lymphocytes are not distinguishable morphologically in the smear. The large lymphocytes which form about 10%, characterised by abundant cytoplasm and reddish granules are the natural killer cells. They can destroy virus-infected cells and HLA incompatible target cells.

Cytokines

In addition to specific antibodies produced by specifically stimulated cells the cytokines constitute another type of mediators. They act as messengers both within the immune system and between the immune system and other systems of the body forming an integrated network that is highly involved in the regulation of immune responses.

B-lymphocytes

Bone marrow stem cells migrate to the gut lymphoid tissue associated with the alimentary and respiratory tracts and develop into B lymphocytes. These are concerned mainly with the production of antibodies. B-cells differentiate into plasma cells which produce the antibodies. Antibodies consist of two identical heavy chains and two identical light chains that are held together by disulphide bonds. The amino acid sequence of the constant region of the heavy chain specifically determines the class of immunoglobulins IgG, IgA, IgM, IgD and IgE, and the subclasses of IgG and the IgA. Each type of antibody can be produced as a circulating molecule or a stationary molecule. The latter which is anchored to the B-lymphocyte cell membrane acts as the B-cell receptor. It has been estimated that both B-cells and T-cell can produce about 10^{15} different antibody variable regions and T-cell receptor regions respectively. Unlike antibodies, T-cell receptors are produced only as transmembrane molecules. Peptides held by the MHC molecule are recognized by specific receptors on T-cells.

The extreme diversity of antibody production is achieved by less than 400 genes which are located on three chromosomes 14, 2 and 22. The sequence of receptors on T-cells remains unaltered during cell division whereas the B-cells can undergo further rearrangement in the

genes, their receptors, and their antibody producing capacity, in the germinal centres of the secondary lymphoid organs. This process is referred to as '*receptor editing*'.

When B lymphocytes meet an antigen presented by the MHC class I molecule, they proliferate to produce a few thousands of cells. Each B-cell is capable of producing only the same type of antibody. The term pre-B-cell denotes the immature B-lymphocyte in which immunoglobulins have not appeared on the surface. On exposure to an antigen the clone of specific B-cells proliferates rapidly and produces antibodies promptly. Primary immune response occurs on first encounter with the antigen. During this phase all the three types of cells—cytotoxic and helper T-cells and B-cells (antibody secreting plasma cells) and memory T- and B-cells proliferate.

The memory T- and B-cells enable a quantitatively superior immune response on subsequent exposure to the same antigen. The germinal centres of lymph nodes and spleen are discrete areas where B-cell responses occur. Immunoglobulin class switching of B-cells, production of memory cells and plasma cell precursors occur within the germinal centres. The final stage of differentiation of B-cell into antibody producing plasma cells occurs outside the germinal centres.

When B-cells undergo terminal differentiation into plasma cells they acquire the ability to produce and secrete large amounts of antibodies. The antibody can be directly protective if it can inhibit the binding of the micro-organisms or its toxin to the target tissue. In most instances, in addition to this effect, the antibodies also recruit other arms of the immune system for defence.

Activation of the complement cascade helps to enhance phagocytic activity of neutrophils. Natural killer cells, monocytes, macrophages and neutrophils can all function in IgG-mediated antibody dependent cellular cytotoxicity. Macrophages, eosinophils and platelets are involved in IgE mediated antibody dependent cellular cytotoxicity. If the target cell is too large for phagocytosis, the mechanisms employed include perforins (which perforate the cell wall), granzymes which destroy the cell components and reactive oxygen intermediates.

In normal adults 3-4 g of secretory IgA is produced every day, by plasma cells located under mucosal surfaces. This is transported to mucosal surface. It offers protection against adhesion by microbes on the luminal surface.

In general, plasma cells are short-lived with a half-life of only a few days, but some of them, located within the bone marrow survive for weeks.

T-lymphocytes

Formation of T-cells in the thymus occurs throughout life even when the thymus has involuted. MHC class I molecules are expressed on all nucleated cells in the body.

This allows infected cells to signal their plight to cytotoxic CD8 T-cells and establish intimate intercellular contact by presenting the complex of foreign peptides and MHC molecules to the T-cell receptors.

T-cell Function and Migration

T-cells respond to pathogens when they get contact with pathogen-derived antigens. This is achieved by the T-cell receptors recognizing the peptide or lipid antigen bound to a major histocompatibility complex (MHC) or CD-1 respectively on the surface of another cell. The dendritic cells which are derived from monocytes present in skin, epithelial surfaces and subepithelial tissues are the antigen presenting cells. These cells engulf antigens, break them down to peptides and display them on their surface with the help of MHC complexes, also known as HLA molecules. The site of engagement of the antigen presenting cell and the T-lymphocyte is called the immunological synapse. The MHC molecules help to transport intracellular antigenic material to the surface of the cell.

The T-cells are capable of detecting antigens occurring in any part of the body promptly. The dendritic cells present in various tissues and secondary lymphoid organs trap antigens produced in their territories. Naive (unstimulated) T-cells reach these lymphoid organs preferentially, being attracted by inflammatory cytokines. This is called homing. Maturing dendritic cells also home to the T-cell areas of lymph nodes. They ready their apparatus for antigen presentation and also secrete cytokines which make them attractive to T-cells which have arrived in the lymph nodes. On meeting the antigen the T-cells proliferate to produce 1000 times the number of original activated T-cells. Eventually these activated T-cells 'home' to sites of inflammation. They interact with antigen bearing tissues, parenchymal cells and leukocytes. For allergic reactions eosinophils and basophils are recruited. For inflammatory response the neutrophils and macrophages are involved. Most of the effector cells die after the antigen is cleared, but a few antigen experienced T lymphocytes persists for long-term protection as memory cells.

CD4 T-cells are mainly cytokine producing helper cells. CD8 T-cells are mainly cytotoxic killer cells. CD4 T-cells (helper) can be subdivided into two major types based on their cytokines.

Type 1 (Th₁) helper T-cell secrete interleukin-2 and interferon γ , but not IL 4,5, or 6.

Type 2 (Th₂) helper T-cells secrete IL 4,5,6 and 10, but not IL 2 or interferon γ .

Type 1 helper T-cells (Th₁ cells) facilitates cell mediated immunity including activation of macrophages and T-cell mediated cytotoxicity. On the other hand Th₂ cells help B-cells to produce antibodies.

The null cell which do not possess either T or B markers are also members of the immune system.

Interaction between T- and B-cells

There is close interaction between T and B lymphocytes at several stages of the immune response. Some of the T-cells influence B-cells for humoral responses. Leukocytes engage several sequential adhesion pathways to leave the circulation and enter tissues. Adhesion is effected with the help of selectins and integrins which are adhesion proteins. Chemokines are produced by activated endothelial cells, epithelial cells, leukocytes and several other types of cells. Chemokines direct the migration of leukocytes to the sites of antigens.

Some of the T-cells proceed to eliminate pathogens whereas others find pathogen-specific B-cells which need the help of T-cells for efficient antibody response.

The killer T-cells CD8 (T-cells) kill virus infected cells. The viruses are deprived of the cellular enzymes needed for their replication and they are also deprived of their sanctuary within the host cell. Any virus that is released is destroyed by the antibodies.

In addition to direct killing of infected cells the CD8 T-cells also produce cytokines such as tumour necrosis factor (TNF α), lymphotoxin (also known as TNF β), interferon γ and others. The interferon γ renders neighbouring cells resistant to viral infection. To a minor extent CD4 cells (both Th₁ and Th₂) can become cytotoxic on recognizing peptides presented by MHC class II molecules.

A successful immune response eliminates the inciting antigen, and once rid of the stimulus, the concerned cells go back to their pre-stimulatory state.

Plasma cell series: Plasma cells form about 2-3% of cells in the bone marrow. Though they are not usually seen in the peripheral blood, they may appear occasionally. Plasma cells accumulate in chronically inflamed tissues. Such plasma cells contain eosinophilic (acidophilic) smooth hyaline spherical cytoplasmic bodies called *Russell bodies*. These bodies are composed mainly of gammaglobulin. Plasma cells constitute the main source of antibodies. They are formed from stem cells in the bone marrow though B-lymphocytes and then migrate to other tissues. Plasma cells synthesising IgA migrate to gastrointestinal tissues while cells producing IgG and IgD go to tonsillar tissue.

PLATELETS

Platelets are formed from megakaryocytes. Ten billion platelets/L of blood are produced every day in an adult. This can be increased ten- folds in times of need (Figs 148.3 to 148.8).

Myeloid stem cells give rise to megakaryoblast which resemble myeloblast morphologically.

Fig. 148.3: Normal bone marrow × 1000. Note: Platelets escaping from the margins of the megakaryocyte

Fig. 148.4: Ultrastructure of the platelet electron microscopy

Promegakaryocytes develop from them by endoreduplication. This is the process in which nucleus divides without cell division. As the megakaryocytes mature, the capacity for endoreduplication increases. This leads to the formation of large cells resembling multinucleated giant cells containing basophilic cytoplasm and a few basophilic granules.

Mature megarkaryocytes are large cells 30-80 µm in diameter and containing 4-16 lobes in the nucleus. The cytoplasm is protruded into the sinusoids of the bone marrow and the platelets are detached and liberated into the circulation. Platelets themselves are nonmotile, but they possess intrinsic contractile activity.

The final product of thrombopoiesis is the platelet which is non-nucleated and is 1-4 µm in diameter. The central part contains red purple granules and the cytoplasm is light blue. Normal platelet count ranges from 150-300,000/cmm of blood.

Thrombopoiesis occurs under the influence of thrombopoietin which controls the proliferation and

Fig. 148.5: Morphological changes in platelet on vessel injury

Fig. 148.6: Platelet surface receptors

Fig. 148.7: Mechanism of adhesion to vessel wall

Fig. 148.8: Platelet physiology – action on fibrin to stabilize it (1) Fibrin threads (2) Activated platelets

development of megakaryocytes precursors. Thrombopoietin is a polypeptide growth factor containing 353 amino acids. Plasma levels of thrombopoietin vary inversely with the platelet mass in circulation. It acts as a megakaryocyte colony stimulating factor including the proliferation of the committed precursors. It also promotes platelet production and release.

Freshly formed platelets are non-nucleated, they contain RNA and are able to synthesize small amounts of proteins. Platelet with elevated nucleic acid content can be detected by flow cytometry. These are called 'reticulated platelets,' (RP). The RNA content can be identified by using the fluorescent dye thiazole orange, and platelet surface markers such as CD 41, and CD 61. Estimation of the proportion of reticulated platelets gives an idea of the rate of platelet production. Normal RP is 7.7%. In conditions such as immune thrombocytopenia the RP may go up as high as >20%.

Ref: (Mukherjee et al, Ind J. Haemat and BL Tras XX X1 suppl 2004 1-3).

30% of platelets are in the splenic pool. The rest are in circulation. Under normal conditions, in the absence of overt or occult bleeding, the life-span of platelets is 8-14 days. They are used up in the hemostatic process. Old and effete platelets are destroyed especially in the spleen.

Thrombopoietin (TPO) is produced mainly from the hepatocytes (50%) and sinusoidal endothelial cells of the liver. Small amounts are produced by the kidneys, brain testes and skeletal muscles. It is a polypeptide growth factor containing 353 amino acids. TPO is the primary regulator of platelet production. It supports the survival and proliferation of megakaryocyte (MKC) progenitors. In vitro TPO induces the differentiation of progenitor cells into large MKCs each of which produces thousands of platelets. TPO is a potent stimulator of platelet production and it also enhances the aggregating activity of the platelets. Fall in platelet counts leads to rise in TPO levels by 50% or more within 8 hours and reach a peak by 24 hours. Platelets have receptors for TPO and they take up TPO from the circulation. TPO levels are low in immune thrombocytopenic purpura and they are high in aplastic anaemia. TPO acts synergistically with erythropoietin to stimulate erythrocyte production.

TPO also enhances the survival and expansion of hematopoietic stem cells. It is used to stimulate stem cell production in the bone marrow and peripheral blood.

Hepatic TPO production is enhanced by inflammatory cytokines such as IL-6 and therefore platelet levels increase in infections, inflammations, chronic diseases like rheumatoid arthritis and others.

TPO has a half-life of 30 hours in circulation. Pegylation increases the half-life ten-fold. Platelet counts start rising in 3-5 days after administration of TPO and reach a peak in 10 days. TPO is available commercially

for therapeutic use as recombinant TPO. Prolonged use of TPO leads to production of antibodies which suppress endogenous TPO, thereby leading to thrombocytopenia. This can be reversed by the use of immunosuppressants.

Therapeutically TPO is indicated in thrombocytopenic states, chemotherapy for malignancy, and to improve the yield of platelets and stem cells for therapy.

Thrombopoietin Stimulating Protein

This is a novel protein moiety (AMG 531) developed recently. It is quite different from thrombopoietin. It has been tried to stimulate thrombopoiesis in immune thrombocytopenic purpura. Initial results are encouraging.

Clinical Aspects of Hematological Disorders

Pallor: Pallor of the mucous membranes and skin occurs when the hemoglobin level is below 10 g/dL. Skin colour depends also on other factors such as state of peripheral circulation and pigmentation. Mucous membrane over the soft palate is the most suitable area to assess pallor since this is least likely to be influenced by other factors. Though there is general agreement between pallor and the severity of anemia, these show wide disparity in many cases.

Jaundice: Jaundice is an important finding in hemolytic anemia. The severity of jaundice depends on the level of bilirubin in the blood and this corresponds to the severity of hemolysis. In the majority jaundice is only mild to moderate, but deep jaundice may occur in hemolytic crises. In hemolytic jaundice the serum contains unconjugated bilirubin and the urine is loaded with urobilinogen, but bile pigments are absent. In severe cases methemalbumin may be present in the serum and urine may contain hemoglobin. In fulminant cases renal failure may occur.

Hepatosplenomegaly: Many hematological disorders are associated with hepatosplenomegaly. Mild or moderate hepatosplenomegaly occurs in 10-20% of cases of nutritional anemias, 60-80% of acute leukemias, 90% of hemolytic anemias, 80% of infectious mononucleosis and practically never in idiopathic thrombocytopenic purpura. Gross splenomegaly exceeding 15 cm is seen in thalassemias, hemoglobinopathies, chronic granulocytic leukemia, lymphomas, and myelofibrosis. The liver also shows variable degrees of enlargement in these cases.

Moderate enlargement of lymph nodes occurs in acute leukemias and infectious mononucleosis. Lymphomas, chronic lymphatic leukemia, and blastic transformation of chronic granulocytic leukemia are characterized by gross lymphadenopathy.

Fever: Fever is a common nonspecific accompaniment of many hematological disorders. In anemia, when the

hemoglobin level goes below 7 g/dL, fever is common. The temperature reverts to normal on correcting the anemia. Hectic rise of temperature may accompany hemolytic crises. In all forms of leukemia fever may occur. Often this is due to infection, less commonly it may be due to the malignant process itself. Presence of fever in lymphomas is of diagnostic and prognostic importance.

Bleeding tendency: Hemorrhagic manifestations may be the primary symptom in disorders like immune thrombocytopenic purpura and hemophilia. In acute leukemia and aplastic anemia, secondary thrombocytopenia may occur resulting in bleeding. Purpuric hemorrhage into the skin, mucous membranes or tissues is commonly seen if the abnormality affects the platelets or blood vessels. In disorders of coagulation, spontaneous bleeding occurs into deep tissues and joints. Bleeding from cuts and wounds tends to be prolonged markedly.

Laboratory Investigations

- 1. **Hemoglobin estimation:** It is now accepted that this procedure should be done with internationally accepted standards by the cyanmethemoglobin method using a photoelectric colorimeter. Other visual methods are only approximate at best.
- 2. **Cell counts:** Automated instruments which give several parameters are available commercially. Their advantage is reliability of the result and reproducibility, provided the operator is skilled and the machine is kept in good condition and the laboratory is under quality control organizations. As far as possible, manual testing should be avoided.
- 3. **Reticulocyte count:** It is done directly in the wet preparation after staining with brilliant cresyl blue which is a vital stain.

Corrected reticulocyte count

This is also known as absolute reticulocytes percentage. This is a formula which is used to correct the variations of reticulocyte count in relation to total erythrocyte count or packed cell volume.

$$\text{Corrected reticulocyte count} = \frac{\text{Observed reticulocyte count} \times \text{Patient's PCV}}{\text{normal PCV for that age and sex}}$$

Reticulocyte proliferation index (RPI) is a measure of erythrocyte regeneration.

$$\text{RPI} = \frac{\text{Corrected reticulocyte count}}{\text{'Shift factor'}}$$

where the shift factor is a constant depending upon the PCV.

- 4. **Estimation of packed cell volume (PCV)**—venous hematocrit.
- 5. **The red cell indices:** These are calculated from packed cell volume (PCV), hemoglobin (Hb) and red cell count. They are MCHC, MCH and MCV.

- a. **MCHC: Mean corpuscular hemoglobin concentration.** This represents concentration of hemoglobin in the red cell. It is calculated as follows:

$$\text{MCHC} = \frac{\text{Hb in g/dL} \times 100}{(\text{g/dL}) \text{ PCV}}$$

Normal range is 32 to 36 g/dL.

- b. **MCH: Mean corpuscular hemoglobin.** It represents the average weight of hemoglobin in each cell and is calculated as follows:

$$\text{MCH} = \frac{\text{Hb in g/dL} \times 100}{(\text{pg}) \text{ RBC count in million/cmm}}$$

Normal range is from 27 to 32 pg (picogram).

- c. **MCV: Mean corpuscular volume.** It gives the average volume of red cells and is calculated as follows:

$$\text{MCV} = \frac{\text{PCV} \times 10}{(\text{fl}) \text{ RBC count in million/cmm}}$$

Normal value varies from 76-94 fl (femtolitres).

- 6. **Osmotic fragility of erythrocytes:** It is determined by estimating the hemolysis when a standard volume of erythrocytes is added to increasing dilutions of sodium chloride. Osmotic fragility is increased in spherocytosis and decreased in thalassemia.
- 7. **Peripheral blood smear:** This is the most useful single investigation which will help in diagnosis. All the cellular elements are examined systematically. Erythrocytes may be small (*microcytes*), large (*macrocytes*) or normal in size (*normocytes*). Variation of size is called *anisocytosis*. *Poikilocytosis* refers to difference in shape. The cells may be pear-shaped, elliptical, or sickle-shaped. *Schistocytes* are fragmented red cells. *Acanthocytes* (spur cells) show numerous spiny projections. Both are seen in hemolytic anemias. Burr cells show short projections on their surface. These are seen in renal failure (Fig. 148.9).
- 8. **Bone marrow examination:** It is an important and integral part of hematological examination. Bone marrow examination is absolutely necessary to establish the diagnosis of leukemias, myeloma, myelofibrosis, hypersplenism, lymphomas, aplastic anemia, megaloblastic anemia and other dyshemopoietic states. It is helpful in the diagnosis of kala-azar, histiocytosis, amyloidosis, secondary carcinomatosis, and several other conditions. Commonly used site for bone marrow aspiration and biopsy is the posterior superior iliac spine or other regions on the iliac crest. With proper techniques, in almost all cases successful aspiration can be done from this region.

Fig. 148.9: Normal blood film

The posterior superior iliac spine overlies actively cellular marrow tissue. The needle used for aspiration is the Cox needle. For trephine biopsy the Jamshidi needle or Islam’s needle is used. Suitable sizes for adult and children are available. It is better that trephine biopsy is done for the proper morphological diagnosis of the marrow which is confirmatory in lymphomas, granulomas, metastases, tumours, myelofibrosis and hypoplastic anemia. A core of marrow tissue 1½ cm long is taken and processed as tissue for histopathological studies. Imprints, touch smears and smears from blood obtained from the biopsy needle are helpful in the diagnosis of general hematological disorders such as leukemia, anemia and myeloma. Conditions such as myelofibrosis, myelodysplastic syndromes, hairy cell leukemia, lymphomas, secondaries and marrow necrosis can be diagnosed only with marrow biopsy. The biopsy material can be used for electron microscopy and immunophenotyping studies. In non-hematological conditions such as typhoid fever and miliary tuberculosis the success rate of culturing the organisms is higher with bone marrow than blood.

In extreme obesity the iliac crest may not be easily accessible. Other sites for aspiration are the manubrium sterni and body of the sternum, ribs, vertebral spines, and tibial shaft in children. These alternate sites are seldom used now due to higher risks involved and more chances for procedural failure. Failure to get marrow tissue by aspiration is called ‘dry tap’. This may be due to:

- 1. Faulty techniques
- 2. Aplasia of marrow or solid marrow as occurs in fibrosis, osteopetrosis or
- 3. Extreme cellular hyperplasia where the marrow assumes the consistency of solid tissue.

Contraindications to bone marrow aspiration include defects of coagulation, and sepsis at the site of aspiration.

APPENDIX
Normal hematological values

1. Hemoglobin	
Infants	16-18 g/dL
Men	13-16 g/dL
Women	11-14.5 g/dL
2. Red cells	
Infants	5-6 × 10 ¹² /L
Men	4-6.6 × 10 ¹² /L
Women	3.5-4.5 × 10 ¹² /L
3. PCV	
Men	40-54%
Women	35-47%
4. MCV	76-94 fl
5. MCH	27-32 picogram (pg)
6. MCHC	32-36 g/dL
7. Reticulocytes	0.2-2.5%
8. ESR	
Males	0-10 mm 1st hour (Westergren)
Females	0-20 mm 1st hour (Westergren)
9. White cells	
Infants	15-16 × 10 ⁹ /L
Adults	5-10 × 10 ⁹ /L
10. Differential leukocyte count	
Adults:	
Neutrophils	40-75%
Lymphocytes	20-45%
Monocytes	2-9%
Eosinophils	1-5%
Basophils	0.0-1%
11. Platelets	150,000-400,000 per mm ³ (1.5-4 × 10 ¹¹ /L)
12. Bleeding time	(Ivy’s method) upto 10 min
13. Coagulation time	(Lee and White method at 37°C) 5-11 min
14. Prothrombin time	12-14 sec
15. Plasma fibrinogen	150-400 mg/dL
16. Serum iron	60-160 µg/dL
17. Total iron binding capacity (TIBC) (Transferrin)	280-400 µg/dL
18. Serum ferritin	
Males	40-340 µg/dL
Females	14-148 µg/dL
19. Serum folate	6-20 ng/mL
20. RBC folate	160-640 ng/mL
21. Serum vitamin B ₁₂	100-1000 pg/mL

Complications of bone marrow puncture include prolonged bleeding, formation of hematoma and periostitis. Sternal puncture may be complicated by injury to mediastinal structures and mediastinitis. Aortic aneurysm is a contraindication for sternal puncture.

149

Anemias:
General Considerations

K.V. Krishna Das

Chapter Summary

- Clinical Aspects 984
- Investigations 985
- Management of Anemia 989

Anemia is defined as a reduction of hemoglobin levels below the normal values for the different age and sex groups. The normal values of hemoglobin for different age groups accepted by WHO are as follows:

Children	6 months to 6 years	11 g/dL and above
	6 years to 14 years	12 g/dL and above
Adult males		13 g/dL and above
Adult female (nonpregnant)		12 g/dL and above
Adult female (pregnant)		11 g/dL and above

In full health there is no racial variation in hemoglobin. In India any hemoglobin level below 12 g/dL in adult males and 11.5 g/dL in adult females should be diagnosed as anemia and investigated. In general, reduction of hemoglobin is associated with a fall in erythrocyte count and packed cell volume (PCV). In anemic subjects, hemoconcentration, as occurring in dehydration, tends to mask the severity of anemia, so also when there is increase in plasma volume as in pregnancy there is an apparent fall in hemoglobin level even though the total hemoglobin mass remains normal.

Classification: Based on erythrocyte morphology as seen in the stained blood film, anemias may be classified into microcytic hypochromic, normocytic normochromic, macrocytic normochromic, and macrocytic hypochromic (Table 149.1).

Clinical Aspects

General features: Irrespective of the etiology or type, anemic subjects develop a group of symptoms on account of reduction in hemoglobin. The severity of symptoms depends on the rapidity of fall of hemoglobin. When anemias develop slowly, the subject adapts to the lower levels of hemoglobin by reducing his physical activity and the symptoms are less pronounced. With falling levels of hemoglobin, the oxygen carrying capacity of blood diminishes. This is partly compensated by increasing the blood flow to organs by vasodilatation. The cardiac output is increased. Most of the general symptoms are attributable to the diminished oxygen carrying capacity of blood and hyperdynamic circulation. These symptoms include fatigue, disinclination to work, mental apathy, pallor, exertional dyspnea, effort angina, and cardiac failure in severe cases. Symptoms are referable to all systems. Alimentary symptoms include loss of appetite, constipation and abdominal distension. The liver is enlarged and tender due to fatty change. Cardiovascular changes include tachycardia, cardiomegaly, high volume pulse, prominent third heart sound, ejection systolic murmurs heard over the pulmonary and aortic areas and in advanced cases, signs of cardiac failure. Cardiac murmurs are produced as a result of decreased viscosity of blood and increased cardiac output. Pallor is most marked over the mucous membranes, skin, and nails. There may be greying of the hair and premature baldness. Neurological manifestations include apathy, loss of mental alertness, paresthesia over the extremities and brisk tendon reflexes. When severe anemia develops rapidly, signs resembling raised intracranial tension may be rarely encountered. These

TABLE 149.1

Classification of anemia based on erythrocyte morphology

Microcytic hypochromic anemia	Iron deficiency, thalassemias, hemoglobinopathies, and hemolytic anemia
Normocytic normochromic anemia	Aplastic anemia
Macrocytic normochromic anemia	Folate deficiency, vitamin B ₁₂ deficiency, hypothyroidism
Macrocytic hypochromic anemia (dimorphic)	This picture is due to combined deficiency of iron and folate or B ₁₂

TABLE 149.2

Classification of anemia based on etiopathogenesis

1. Dyshemopoietic (disorders of erythrocyte formation)	1. Nutritional anemias—Anemias due to deficiency of essential nutrients such as folate, vitamin B ₁₂ , proteins, vitamin C
2. Hemorrhagic	2. Hypothyroidism
	3. Sideroblastic anemia due to metabolic blocks in the synthesis of hemoglobin
	1. Acute hemorrhage, e.g., antepartum and postpartum hemorrhage, bleeding oesophageal varices, bleeding peptic ulcer, hematemesis and melena, traumatic or surgical bleeding.
	2. Chronic blood loss, e.g., due to intestinal parasites such as hookworms, whipworms and E. histolytica hemorrhoids, excessive menstrual blood loss and repeated pregnancies, chronic peptic ulcer, erosions (drug induced), cancers in the GI tract.
3. Hemolytic	Anemias developing because of increased destruction of erythrocytes—Various causes
4. Hypoplastic	Anemias developing because of decreased formation of erythrocytes—Various causes
5. Myelophthitic	Anemias developing as a result of replacement of normal erythropoietic tissue by abnormal tissue e.g. acute leukemias, lymphomas, multiple myeloma, malignant secondaries in bone marrow, myelofibrosis and storage diseases

include headache, papilledema and retinal hemorrhages. All these regress with improvement in the hemoglobin levels.

Several other criteria have also been employed for classification. Etiological classification is given in Table 149.2.

Splenomegaly occurs in many cases, and the frequency and extent depends on the type of anemia. Whereas in iron deficiency anemia 10% may show mild splenomegaly, in hemolytic anemias it is over 90%.

Diagnosis: Any patient with anemia should be approached with the aim of determining the type, severity, and cause of the disorder. Anemia may be the only apparent general feature of several underlying disorders, and attempts should be made to detect the etiology. Symptomatic treatment of anemia without identifying the cause should be avoided since in many instances a serious underlying disorder like gastrointestinal malignancy or renal failure may be missed at the early stage when effective treatment is possible.

Detailed history should include the onset, course, and duration of anemia. Periodic fluctuation in intensity is common in nutritional and hemolytic anemias. In general they are of longer duration than aplastic and myelophthitic anemias. Nutritional anemias affect several members of the same family or household. Hemolytic anemias such as spherocytosis, hemoglobinopathies, and red cell enzymopathies reveal characteristic genetic patterns.

Common bleeding foci such as hemorrhoids, menorrhagia, peptic ulcer and oesophageal varices should be excluded by interrogation and full physical examination. Rectal and pelvic examinations should be undertaken in all cases.

Investigations

Preliminary investigations: The following investigations are carried out to detect the severity and type of anemia.

Hemoglobinometry and blood counts: The standard procedure is the cyanmethemoglobin method using a reliable standard for comparison. When the hemoglobin level is below 12 g/dL full investigations should be undertaken. Absolute counts of erythrocytes, leukocytes, and platelets, and calculation of the erythrocyte indices should be done by automatic machines which are accurate.

Packed cell volume (PCV-hematocrit) is a reliable parameter which should be done in all cases. The mean corpuscular hemoglobin concentration.

$$(MCHC) = \frac{[(Hb \text{ in g/dL} \times 100)]}{PCV}$$

helps to determine the type of anemia in a borderline case and also in the follow-up of the case. Values below 27 g/dL suggest microcytic hypochromic types.

Examination of blood smear: This is the easiest and reliable method to determine the morphology of erythrocytes. Microcytic hypochromic erythrocytes are smaller than normal [normal mean corpuscular diameter (MCD) is 7.5 ± 0.3 µm] and the centre is empty with only a ring of hemoglobin taking up the stain. Considerable anisocytosis and poikilocytosis are seen. Macrocytic erythrocytes are larger with the centre also showing uniform staining. Normocytic normochromic erythrocytes are normal in size and staining. Reticulocytes appear as polychromatophilic macrocytes in Romanovsky's stained films, but when stained in the fresh state with brilliant cresyl blue the cytoplasmic reticulum is visualized.

Normal value for reticulocytes in Indian subjects is 0.5 to 2.5%. Anisocytosis, poikilocytosis, polychromasia, and reticulocytosis indicate active regeneration of erythrocytes. When erythropoiesis is very much accelerated normoblasts may appear in peripheral blood. In myelophthitic anemias normoblast may be released from the bone marrow even without active regeneration of erythrocytes. The leucocyte picture is often helpful. Neutropenia and relative lymphocytosis may suggest aplastic anemia. Presence of eosinophilia suggests helminthic infestation.

Examination of the platelets will give additional clues regarding the type of anemia and its cause. Normally-functioning platelets occur in small or medium sized clumps. Absence or considerable reduction in the platelets shows up as scanty platelets in the smear and absence of clumps.

In microcytic hypochromic anemia presence of excess platelets generally suggests blood loss. Thrombocytopenia indicates the possibility of hypoplastic anemia. In the tropics special attention should be given to detect malarial parasites in all cases, especially *P. falciparum* (Figs 149.1 to 149.14).

Red Blood Cell Distribution Width (RDW)

With the availability of automated counting machines and recording instruments in hematology, red blood cell distribution curves are provided along with the counts. A routine measurement obtained from these curves is the RDW. Depending upon the technology employed in the machine RDW can be expressed as RDW-SD or RDW-CV. The different technologies employed to count and size the red blood cells determine the shape of the RDW distribution curves (RDW-C). These denote the homogeneity or heterogeneity of erythrocyte size (i.e.) anisocytosis. Manual determination of anisocytosis by light microscopy is at best only approximate.

The values obtained by RDW-SD and RDW-CV differ slightly. The RDW is a reliable parameter to distinguish between iron deficiency anemia and other microcytic anemias. Values of RDW CV >17 are suggestive of iron deficiency. In thalassemias and anemia of chronic disease, the RDW CV is below 17. Increase in RDW is one of the early finding in iron deficiency anemia. In aplastic anemia, leukemia, and megaloblastic anemia the leukocytes also show morphological changes, which are diagnostic.

Examination of the bone marrow: Examination of bone marrow will reveal the type of erythropoiesis and the underlying cause in secondary anemias. Normoblastic hyperplasia suggests iron deficiency. Megaloblastic hyperplasia should suggest primary or secondary deficiency of folate or vitamin B₁₂. Normoblastic, but hypoplastic erythropoiesis occurs in aplastic anemia, anemia of chronic disease and others. Leukaemia, myeloma, disseminated lymphomas, parasitic infections

such as visceral leishmaniasis and several other conditions can be diagnosed by marrow examination (Figs 149.15 to 149.19).

Investigations to Detect the Etiology

1. Microscopic examination of feces for parasites and chemical examination for occult blood to identify gastrointestinal blood loss, rectal examination, proctoscopy. Repeated examination of feces may have to be undertaken to detect occult blood since bleeding from the alimentary tract may be intermittent at times. Negative results may exclude bleeding foci in most of the cases, though not in all.
2. Skiagram of the chest to detect tuberculosis.
3. Investigations for gastric lesions—barium meal, and endoscopy.
4. Studies for detecting malabsorption states.
5. Investigation of the large intestine—barium enema and endoscopy.
6. Blood chemistry—blood urea, serum proteins, serum creatinine, levels of nutrients in blood.
7. **Skeletal survey**—multiple myeloma, secondary deposits, thalassemias, and myelosclerosis produce characteristic skeletal changes. Skiagram of the skull, vertebrae, long bones, and hands are taken for this purpose.
8. **Isotope studies**
 - a. *Schilling's test* for determining the absorption of vitamin B₁₂.
 - b. Determination of life-span of red cells using ⁵¹Cr labelled erythrocytes.
 - c. Determination of ferrokinetics (absorption, utilisation, and disposal of iron) using ⁵⁹Fe.
 - d. Whole body scanning for bone marrow activity and presence of secondaries or tumours.
9. **Other imaging procedures:** Ultrasonography, CT scanning and MRI may be needed in cases where organomegaly, lymph node enlargement, collection of fluid in natural cavities or neoplasms are suspected.

Course and prognosis: This largely depends upon the type of anemia. Nutritional anemias are generally very insidious in onset and course. Periodic exacerbation results from intercurrent infection or physiological stresses like puberty, growth, or pregnancy. The disease progresses over several years and death is due to intercurrent illnesses or rarely severe anemia *per se*.

Hemolytic anemias exhibit wide variability in their course, ranging from fulminant hemolysis ending fatally within weeks to very slow chronic course with periodic exacerbations, extending over several years. Aplastic anemias have an intermediate course. The onset is within months and the course extends over months to a few years, with either recovery in a few or death within a few months in the majority of cases if left untreated. In myelophthitic

anemia the course and outcome depend entirely on the primary disorders.

Management of Anemia

The specific management depends on the etiology.

General principles: Hospitalization is advisable when the hemoglobin drops below 7 g/dL. With hemoglobin levels below 3 g/dL, severe disability occurs and cardiac failure at this stage may be fatal. In such a case emergency transfusion with packed erythrocytes to raise the hemoglobin above 5 g/dL is life-saving. When cardiac failure is present, intramuscular administration of frusemide 40 mg prior to the transfusion serves to prevent fluid overloading.

Chapter Summary

- Iron Deficiency Anemia 989
- Macrocytic Anemias 993
- Nutritional Megaloblastic Anemia (NMA) 994
- Addisonian Pernicious Anemia 995
- Congenital Megaloblastic Anemias 996
- Rarer Causes of Nutritional Anemia 996

- Anemia in Systemic Diseases 996
- Anemia of Chronic Diseases (ACD) 997

Iron Deficiency Anemia

Microcytic hypochromic anemia occurring in India is mostly due to iron deficiency. Less commonly

thalassemias and other hemoglobinopathies also produce similar morphology. In India and other developing countries, iron deficiency anemia far out numbers all the other types of anemias put together, as it constitutes 90-95% of the total. Iron deficiency anemia is one of the most widespread diseases all over the world.

Epidemiology: In India 5-6% of general population suffer from this disease. It is prevalent in 3% among men and 10-14% among women. About 10% of attendance in the general hospitals is accounted for by anemias. In specific groups like slum dwellers, plantation labourers, and pregnant women the prevalence rate is 30-50% or even more. Iron deficiency is prevalent in 30-50% of the adolescent and young adult women due to their unsatisfactory food habits and moderate or heavy blood loss during menstruation. Even though iron deficiency is mainly caused by inadequate iron intake in food, IDA is not exclusively a disease of the poor. Food fadism and other diseases which cause blood loss account for the majority of anemia cases occurring in the rich.

Causes

1. **Nutritional inadequacy:** It is present in more than 80% of cases, especially in the poorer groups. Meat, poultry and fish form good dietary sources of iron. Milk is low in its iron content. Among vegetable sources, grapes, dates, prunes, amla (gooseberry), green leafy vegetables, onions, jaggery and betel leaf are moderate sources of iron. Due to the cereal-based dietary habits, the optimum intake of dietary iron recommended by Indian Council of Medical Research (ICMR) is 20 mg for adults. Many diets do not contain the optimum amount of bio-available iron. Cooking in cast iron vessels and iron from water sources supplement iron intake to some extent. Replacement of cast iron kitchen vessels from many households has probably deprived this source of iron, though it may be small.
2. **Blood losses:** Sources of chronic blood loss are ankylostomiasis, hemorrhoids, menstrual losses, repeated pregnancies in women, and ulcerating lesions in the gastrointestinal tract. Normal menstrual blood loss is about 60 mL per period. Periods which are heavy and which occur more frequently than once a month predispose to iron deficiency. About 750 mg of iron is utilised from the mother for each pregnancy and lactation. Successive pregnancies occurring at short intervals without supplementation of iron during pregnancy and lactation are bound to deplete the iron stores of the mother.

Hookworms and other soil transmitted helminths lead to chronic blood loss from the upper intestinal region. Though most of this iron is absorbed, a small part is lost

in feces. Hence heavy infestations are bound to cause anemia. *Ankylostoma duodenale* is more pathogenic than *Necator americanus*. If nutritional status is good, anemia may not occur even with moderate worm loads, but in the majority of cases hookworms act as the most common aggravating factor in the presence of undernutrition. In many states in India hookworm infestation rates have come down considerably due to general improvement in sanitation, provision of sanitary latrines and safe drinking water. In some areas *Trichuris trichura* (whipworm) which has established as a common intestinal nematode, causes blood loss and even malabsorption states. Bleeding caused by whipworms is considerably less than that due to hookworms (see chapter 67).

Loss of iron from surface epithelium increases with *excessive sweating*. This is a significant source of iron loss in the tropics, especially in the working classes.

Iron absorption is controlled at the level of the intestinal mucosal epithelium. Excess of dietary or medicinal iron is not absorbed normally, but in the presence of iron deficiency higher amounts of iron are absorbed till the deficiency is corrected. When loss of iron from the body exceeds absorption, the tissue stores gradually become depleted. This phase is asymptomatic and when anemia develops there is considerable depletion of iron stores. So also when iron is supplied the anemia recovers first but it requires prolonged supplementation to replenish the tissue stores, usually up to one year and often, continuously. Bone marrow shows normoblast hyperplasia (Fig. 150.3).

In iron deficiency anemia (IDA) the transferrin saturation is lowered and is often below 15%. Iron is present in plasma also as ferritin. The serum levels of ferritin reflect the iron stores of the individual more reliably than either serum iron or transferrin saturation.

Normal levels of serum ferritin are:

Adult male	40-340 µg/L
Adult female	14-148 µg/L
Children	7-142 µg/L

In iron deficiency states it is below 12 µg/L. Very high levels are reached in siderosis. Normally there is stainable iron in the marrow. When there is iron deficiency this form of storage iron disappears. Absence of stainable iron in the bone marrow is a reliable evidence of iron deficiency state helps to distinguish iron deficiency anemia from hemolytic and hypoplastic anemias in which there is increase in stainable iron. Gross iron deficiency leads to depletion of the iron containing enzymes in tissues and this probably accounts for the generalized tissue effects. These are promptly restored by iron therapy even before the hemoglobin level improves. As the hemoglobin levels fall below 3 g/dL, compensatory mechanisms fail and death is usually due to cardiac failure or infection of the respiratory or gastrointestinal tract.

CLINICAL FEATURES

In addition to the general features of anemia described earlier, special features particular to iron deficiency anemia are described below.

Onset is gradual over months or years. Special features include loss of appetite; **pica**, especially for eating sand, raw cereal, or lime (CaCO_3), glossitis, sideropenic dysphagia, and koilonychia. About 10% of cases may show mild splenomegaly. Extreme pica may itself lead to further nutritional deficiency (Fig. 150.1).

The tongue is pale and small. Dysphagia takes the form of a feeling of obstruction and food sticking at the upper end of the oesophagus especially on swallowing liquids. It is called Plummer-Vinson syndrome or Kelly-Patterson syndrome. Probably dysphagia is produced by loss of afferent impulses for the swallowing reflex due to degeneration of the lining epithelial cells. Sometimes constriction, spasm, or even bands may be detected, but in general, local examination is unrewarding. In one-third cases barium swallow may reveal the narrowed area. Clinical features and the radiological abnormalities clear up easily within months of iron therapy, but in a few neurotic individuals vague symptoms may persist. There is increased incidence of post-cricoid and oropharyngeal carcinoma in these subjects, especially in women.

Nail changes are characteristic of iron deficiency anemia of long standing and in many cases these are diagnostic. The initial changes are thinning, cracking, and brittleness of the toe and finger nails, later becoming typically spoon-shaped (*koilonychia*). With correction of iron deficiency, normal nail grows and replaces the affected nail.

Alimentary system: Gastric acid is reduced, but histamine fast achlorhydria is rare. Motility of the alimentary tract is reduced and this results in constipation. Gastric secretion and gastrointestinal motility recover with treatment.

DIAGNOSIS

Clinical diagnosis of iron deficiency anemia is simple. In areas where thalassemia and other hemoglobinopathies

Fig. 150.1: Male iron deficiency anemia.
Note: Pallor: small pale tongue

occur, these have to be differentiated. Though iron deficiency is by far the most important etiological factor, latent deficiency of folate (20-40%) and/or vitamin B₁₂ (5-10%) may occur simultaneously. These become manifest as megaloblastosis, when the iron deficiency is corrected by treatment. In such cases iron therapy produces initial rise in hemoglobin, but full correction can be achieved only with supplementation of folate and/or vitamin B₁₂.

Laboratory diagnosis: The erythrocytes are microcytic hypochromic. Presence of eosinophilia usually points to a helminthic etiology and thrombocytosis to chronic or acute blood loss. Reticulocytes are mildly increased (2-3%) even before specific treatment is started, but when therapy is started their count rises to 15-30% within days and remains elevated at lower levels till anemia is corrected. The MCHC is below 27 g/dL. Red cell distribution width (RDW) is above 17. Bone marrow shows normoblastic hyperplasia with absence of stainable iron. It is not feasible, nor is it necessary to do bone marrow examination in all cases of iron deficiency anemia. The serum iron is usually below 80 µg/dL (normal 60-160 µg/dL). Transferrin levels are normal (280-400 µg/dL) or increased. Transferrin saturation is about 14-15% or less. Total iron binding capacity (TIBC) in both males and females is 340 mg/dL with the range of 250-450 mg/dL.

Estimation of serum ferritin is helpful to assess the iron stores in the body, and therefore, wherever facilities permit, this should be done. Values below 15 µg/L suggest depletion of stores. Based on the several metabolic steps undergone by dietary and transport iron, specific sophisticated tests are available. These help to distinguish anemia due to iron deficiency from anemia of chronic disease, thalassemias and others.

Free erythrocyte protoporphyrin (FEP) Elevation of FEP, mainly the erythrocyte zinc protoporphyrin (EZP) is a very sensitive index of iron deficiency. In uncomplicated iron deficiency anemia EZP levels reach 100-1000 µg/dL.

Soluble transferrin receptor (STIR) Serum levels of STIR are elevated in iron deficiency. The assay is done by ELISA-Normal serum levels of STIR range from 2.8-8.5 mg/L.

For all practical purposes the beneficial response of oral iron in correcting microcytic hypochromic anemia may be taken as a suggestive evidence of iron deficiency, retrospectively. Search for the cause of iron deficiency should be continued and this should be corrected to prevent relapse.

Complications

1. **Infections** are more common in IDA, especially those of the respiratory, gastrointestinal or urinary tracts. These are associated with higher mortality.

Tuberculosis is more common in them. Cell mediated immunity is reduced in these subjects.

2. **Chronic anemia reduces the efficiency in work** and study, and therefore, widespread nature of this disease in the community impairs efficiency for work and production. Deficiency of tissue iron and presence of anemia have been shown to lead to impairment of cognitive function of the brain and retardation of learning ability and motor skills in children. This may persist for long periods even after correction of the anemia. Reversible diminution of functional reserve of heart, muscles and other organs, has been demonstrated.

Symptomatic Iron-deficiency Anemia

Even though IDA is caused by nutritional inadequacy and gastrointestinal blood loss due to intestinal parasitism in the vast majority of patients, in a small proportion it may be the warning symptom of carcinomas, especially of the gastrointestinal tract—stomach, colon and other sites. Slowly proceeding blood loss as occurring in hemorrhagic telangiectasia, angiodysplasia of the gastrointestinal tract, hemoptysis due to bleeding into the respiratory tract as in Goodpasture’s syndrome and chronic purpura should be looked for, if an obvious nutritional cause is not forthcoming.

TREATMENT OF IRON DEFICIENCY ANEMIA

This can be considered under two heads: (1) *Correction of anemic state* and *replenishment of iron stores*, and (2) *elimination of the cause*.

Correction of anemia: Overall correction of nutrition with articles rich in iron is most important. For the poorer sections of society proper dietary advice, including indigenously available sources of food, is most important. Meat, liver, green vegetables, onions, grapes, and jaggery are good sources of iron.

Iron deficiency is corrected by the administration of **medicinal iron**. Ferrous sulphate given as 300 mg tablets thrice daily after food is ideal and least expensive. The response is evident within a week as improved well-being and activity, return of appetite, and increase in reticulo-cytes and hemoglobin. On an average the hemoglobin rises at the rate of 1% everyday. Ferrous sulphate is well tolerated in most cases but 10% of cases may show side effects such as nausea, vomiting, abdominal pain, metallic taste in the mouth, staining of the tongue (Fig. 150.2) diarrhea, and constipation. Side effects are reduced if the drug is administered after food, but absorption is better if given on empty stomach. Rarely oral iron may not be tolerated.

Other preparations are available for administration to those who show intolerance to ferrous sulphate.

Fig. 150.2: Female staining of tongue by oral iron therapy

The gastric delivery system technology (GDS) consists of the controlled release of the drug which is incorporated into a matrix with inert materials which form the outer capsule. In contact with gastric juice the outer capsule becomes semipermeable. It releases the drug slowly. The capsule floats over the gastric contents and remains for several hours in the stomach. GDS ensures good absorption of the drug with less side effects.

Iron preparations	Weight per tablet (mg)	Elemental Iron
Ferrous sulphate	300	80
Ferrous gluconate	300	40
Ferrous fumarate	200	60
Ferrous succinate	150	35

Chelated iron is available as iron choline citrate. None of the iron preparations is totally free of side effects. Iron salts have to be continued for at least six months after the hemoglobin level reaches normal with a view to replenish the iron stores. In multiple deficiency, the other nutrients also have to be supplemented.

Parenteral iron is indicated when oral medication becomes impossible because of side effects or when the anemia has to be corrected within a shorter period. Parenteral iron raises the hemoglobin by 2% everyday. The preparations are iron dextran complex, iron sorbitol complex, ferric gluconate and iron-sucrose complex. All preparations are effective, but iron dextran complex is more popular. The total dose required for correcting the iron deficiency is calculated using a specific formula and this total dose is given intravenously slowly or given by repeated intramuscular injections over a few weeks.

Formula for Calculating Total Iron Requirement

Total dose of iron required in mg
= (weight of patient in kg) × (deficiency in Hb%) × (0.66).

Intramuscular injection: Iron dextran complex is given in doses of 100 mg of elemental iron given in areas usually covered by clothing, once in 3 days till the total dose is reached. Thereafter only nutritional therapy is continued along with oral supplementation. Hemoglobin reaches normal levels in course of time when the administered iron is used up.

When a large dose is decided to be administered within a shorter period, to save the pressure on hospital beds and avoid frequent injections, intravenous route is adopted. The **total dose infusion (TDI)** is given as a slow drip in which 500-1000 mg of iron dextran complex is diluted in 5% glucose after testing for hypersensitivity with the pilot ampoule supplied by the manufacturers. The whole requirement can be administered in 2 or 3 sessions. In general only mild side effects occur, but rarely, they may be catastrophic.

Side effects of parenteral iron include fatal anaphylactic reactions, iron encephalopathy, local thrombophlebitis, tissue necrosis, pyrexia, arthralgia, arthritis, serum sickness like reactions, and pigmentation over injection sites. Anaphylaxis is more frequent with total dose infusions and the more so if oral iron is concurrently administered. It is advisable, therefore, to stop oral iron therapy for a week before parenteral iron is administered. Administration of excessive doses of parenteral iron leads to hemosiderosis.

Iron sorbitol citrate (Jectofer)

Each mL contains 50 mg of elemental iron. 30% of the injected drug is excreted in urine within 24 hours. This loss has also to be taken into consideration while calculating the total dose. The total dose of Jectofer is given as 10-20 deep I M injections.

Ferric gluconate (Globac, Efficient)

It is safer than iron dextran complex and iron sorbitol complex. Two strengths are available 62.5 mg/mL and 125 mg/mL. It is given in split doses as I V infusions, the total dose being determined before hand.

Iron sucrose (Encifer) – This is a complex of polynuclear iron (111) hydroxide in sucrose. It is available as 5 mL vials each mL containing 20 mg of elemental iron.

It can be given as slow IV injection over 5 minutes or as an infusion mixed with 100 mL N. saline and given over 15 minutes. Total dose infusion should not be undertaken. Compared to iron dextran complex injections, the newer preparations are safer and the utilization time may also be shorter.

Rarely a case of anemia with hemoglobin level below 3 g/dL may require packed cell transfusion and management for cardiac failure.

Prophylaxis

Iron has to be given prophylactically to vulnerable groups which are likely to develop iron deficiency. These include: (1) premature infants, and infants fed solely on unfortified milk formulas; (2) pregnant and lactating women; and (3) patients who had surgical operations on the stomach.

Measures to eradicate iron deficiency anemia in the community: Several attempts have been made in India to eradicate iron deficiency anemia from large sections of the population. Improvement in nutrition, elimination of helminthic parasites, provision of protected water and sanitary latrines, and prompt treatment of respiratory and gastrointestinal infections should all be taken up as a comprehensive programme to eliminate anemia at the community level. Several studies have shown that isolated programmes of deworming or nutritional supplementation are of only marginal and temporary benefit. Attempts have been made to fortify cooking salt with iron.

The problem is to incorporate a stable, at the same time absorbable form of iron in the salt without altering its cooking properties. Iron pyrophosphate has been identified as a suitable salt for this purpose. Field trials are being undertaken by the Indian Council of Medical Research and the findings are encouraging.

In many centres in India tablets containing iron and folic acid are distributed among vulnerable groups and this measure has also proved successful.

Macrocytic Anemias

These constitute about 5% of nutritional anemias seen in India. In these the red cells are larger in size. The mean corpuscular volume reaches above 110 fl or more. These cells are usually fully hemoglobinised and MCHC is normal. Mean corpuscular hemoglobin is increased. In some cases the macrocytes may also be hypochromic due to concomitant deficiency of iron (dimorphic). Common cause of macrocytosis in India is deficiency of folic acid and/or vitamin B₁₂. In the absence of these vitamins DNA synthesis is abnormal. Megaloblastosis results when DNA synthesis is impaired in the presence of normal RNA and protein synthesis. Synthesis of protein, RNA, and hemoglobin continues in the cytoplasm. When DNA synthesis is impaired, cell division is retarded but the cell grows more in between mitotic cycles and hence the megaloblasts are larger in size. As the deficiency becomes more pronounced, many early forms of erythroblasts are destroyed in the marrow, and ultimately erythropoiesis becomes almost totally ineffective.

Macrocytic anemias may be associated with megaloblastic erythropoiesis or normoblastic erythropoiesis. Macrocytic anemia with normoblastic marrow is seen when there are numerous reticulocytes in peripheral blood.

Fig. 150.3: Normoblastic bone marrow.
Note: All elements are present

Fig. 150.4: Megaloblastic bone marrow. Note: megaloblast: nuclear chromatin is loose—arrow

Other less common causes include hypothyroidism, liver disease, renal failure, and chronic infections.

Megaloblasts: The defect of DNA synthesis is most pronounced in marrow cells, but it is also present in varying degrees in all rapidly proliferating cells. The nucleus of the megaloblast has a finer reticular pattern which distinguishes it from normoblast. Megaloblastic anemia is common in nutritional deficiency of folate or vitamin B₁₂ or when the metabolic pathways of these nutrients are blocked (Figs 150.3 and 150.4).

15

Causes of Megaloblastic Anemia

I. Those caused by inadequate supply of folic acid, vitamin B₁₂ or both.

- a. nutritional deficiency
- b. increased demand such as pregnancy, infancy, infection
- c. protein-calorie malnutrition
- d. malabsorption states
- e. drugs with antifolate action e.g. phenytoin, methotrexate
- f. total gastrectomy or extensive lesions involving the stomach
- g. infestation with the tapeworm *Diphyllobothrium latum*

II. Acquired vitamin B₁₂ malabsorption in Addisonian pernicious anemia which is due to deficiency of the gastric intrinsic factor. Other rare causes include intense suppression of gastric acid using proton pump inhibitors or H₂ receptor antagonists.

Nutritional Megaloblastic Anemia (NMA)

In India this is the most common form of megaloblastic anemia and is caused by the deficiency of folic acid, vitamin B₁₂ or both. Folate deficiency is more frequent than vitamin B₁₂ deficiency in all parts of the country. In many cases there is also iron deficiency and so the blood picture is dimorphic.

Folic acid is obtained from dietary articles such as green vegetables, sprouted cereals or pulses, liver, meat, yeast and others. The daily requirement of folic acid is 0.1 mg. Excessive demand occurs during growth spurts, pregnancy and convalescence from illnesses. Folic acid is absorbed from the small intestine. Malabsorption states such as celiac disease, sprue and others lead to folate deficiency. In communities in which nutritional status is marginal, diarrheal diseases precipitate folate malnutrition. Several drugs such as phenytoin sodium, methotrexate and sulphonamides exert their therapeutic effects by interfering with the metabolic pathways in the utilisation of folate. Such drugs are liable to lead to folate deficiency on prolonged administration.

Since folate is rapidly used up by the system and body stores are relatively less compared to vitamin B₁₂, folate deficiency manifests within weeks to months of onset of dietary deficiency.

Requirement of vitamin B₁₂ (cyanocobalamin) is 1 µg/day. It is obtained mainly from animal foods such as liver and meat. Smaller amounts are obtained from milk and fermented milk products such as buttermilk and yoghurt or curds, which form an important component of Indian diets. Dietary deficiency occurs in those who are vegans i.e., those who consume only diets of plant origin excluding even dairy products. In general the serum vitamin B₁₂ levels of vegetarians are lower than those of persons consuming adequate amounts of meat products. Vitamin B₁₂ is absorbed in the distal part of the ileum in combination with intrinsic factor. Malabsorption states affecting the ileum and diseases of the stomach which is the source of intrinsic factor lead to secondary deficiency of this vitamin. In blind loop syndromes vitamin B₁₂ is avidly taken up by the bacterial flora colonising the blind loop. In fish tapeworm infection the parasite takes up vitamin B₁₂, and deficiency develops.

In normal subjects there is adequate store of vitamin B₁₂ which may last for several years and therefore dietary deficiency of the vitamin manifests clinically only after several months or even years.

Folate and cyanocobalamin are required for normal metabolic activities of almost all growing cells in the body, and therefore, widespread dysfunction of several organs systems occurs in deficiency states. Maximal effects are seen in bone marrow, epithelial cells and others. Cyanocobalamin is required for the normal metabolism of myelin and other components of the nervous system. Therefore, deficiency of this factor leads to lesions in the nervous system as well.

CLINICAL FEATURES

The onset is insidious. Pregnant women and children are more affected. In addition to the general features of anemia certain distinguishing features seen are: (1) large beefy tongue; (2) dark pigmentation over the palms, soles, face, and tongue; (3) hepatosplenomegaly and (4) mental changes and neurological involvement in vitamin B₁₂ deficiency. Neurological abnormalities include peripheral neuropathy and degeneration of the posterior columns and pyramidal tracts—subacute combined degeneration. Psychiatric disturbances and optic neuritis may occur in a few. The neurological manifestations can develop in nutritional deficiency of vitamin B₁₂ also, if the condition persists for long periods, but compared to pernicious anaemia this complication is less frequent and milder. Nutritional deficiencies of folate and /or vitamin B₁₂ may lead to hyperhomocysteinemia which, in turn, induces thrombophilia and pathological thrombosis in arteries and veins. Stroke occurring in young persons in developing countries is caused by hyperhomocysteinemia in a small proportion of cases. This risk is abolished by nutritional supplementation.

Investigations: Hemoglobin level may vary from 5 to 8 g/dL or less, MCHC is within the normal range (28-32%) while MCV is increased and may be as high as 120 fl. Macrocytosis and anisopoikilocytosis are easily recognizable. Some red cells may show punctate basophilia due to the presence of remnants of ribonucleic acid. Nuclear material may be present in erythrocytes. These are seen as *Howell-Jolly bodies* and *Cabot's rings*. Leukocytes may be normal or decreased in number. Granulocytes are larger than normal, showing increased lobulation with the average lobe count higher than 5 (*macropolycytes*). This change in leukocytes is very helpful in diagnosis when the morphology of erythrocytes is equivocal. Platelet count may be decreased at times. Platelet function may also become defective.

Bone marrow is hyperplastic due to erythroid hyperplasia. All stages of megaloblasts are present. Normoblastic erythropoiesis may also be present simultaneously. In the absence of iron deficiency, hemosiderin content of marrow is increased. Life-span of red cells is moderately decreased.

Levels of serum folate and red cell folate are diminished. The normal level of folate in serum is 6-20 ng/mL

and that in red cells is 160-640 ng/mL. Serum levels below 3 ng/mL and red cell levels below 100 ng/mL indicate deficiency of folate. Serum vitamin B₁₂ values below 100 pg/mL are indicative of deficiency.

Treatment: Overall dietary correction should be undertaken. Oral administration of 1 mg or more of folic acid daily is adequate to correct folate deficiency. Supplementation of folic acid will improve the anemia due to deficiency of vitamin B₁₂ also, but not the neurological complications. In the later stages of therapy, deficiency of iron may develop and iron may have to be given.

Vitamin B₁₂ deficiency can be rapidly corrected by intramuscular injection of 1000 µg of hydroxocobalamin. Oral doses of 1-2 µg are curative in most cases if continued over a few months.

Prevention of NMA: Oral supplementation of folates to 0.1 mg/day to growing children, and subjects receiving anti-epileptic drugs, helps to prevent folate deficiency. In pregnancy a daily dose of 0.5 mg of folic acid should be given prophylactically from the first trimester. Where megaloblastic anemia has developed 5 mg should be given orally daily throughout the pregnancy and puerperium. Infants require 1 mg of folic acid orally daily as supplement. Therapeutic administration of folates (400 µg/day) to pregnant women irrespective of their nutritional status reduces the risk of development of neural tube defects in the baby. If absorption is defective, the folic acid has to be given by IM injection in a dose of 5 mg daily for a few days.

Prophylactic oral supplementation of vitamin B₁₂ is given as 10 µg either singly or along with the other deficient factors during pregnancy and in those with marginal nutritional states. When absorption is defective, IM injection of 1000 µg is given once a week for 3 to 4 weeks.

ADDISONIAN PERNICIOUS ANEMIA

Syn: Pernicious anemia, Biermer's anemia

Etiology: Pernicious anemia (PA) is more common among the Caucasian population, but is rare in Indian subjects. It is found more often in the older age groups and only rarely before 30 years of age. It may be familial and affects both sexes. Antibodies directed against the gastric parietal cells are present in the serum in 85-90% of cases and antibodies against intrinsic factor are demonstrable in the serum as well as in the gastric juice in a smaller proportion of cases. This is an autoimmune disease. Other disorders like myxedema, Addison's disease, thyrotoxicosis, Hashimoto's disease and vitiligo which all have an autoimmune basis may occur along with pernicious anemia. The gastric mucosa undergoes atrophy resulting in the absence of intrinsic factor and gastric acid—achylia gastrica. Dietary vitamin B₁₂ is not absorbed. This leads to megaloblastic erythropoiesis. Several other tissues are also affected, particularly the nervous system. Demyele-

nation of the pyramidal tracts and posterior columns develop (see also Chapter 187). Carcinoma of the stomach develops in 4% of cases on follow-up.

CLINICAL FEATURES

The onset is insidious. In addition to symptoms of anemia, special features include soreness of the tongue, paresthesia of hands and feet, diarrhea, and yellowish tinge of skin and mucous membranes. The tongue is atrophic. Spleen is palpable in 25% of cases. Spinal cord involvement results in sub acute combined degeneration manifesting as varying combination of dysfunctions of the pyramidal tracts and posterior columns.

Psychiatric symptoms are common. These include melancholia, depression and behaviour disorders.

If left untreated, the disease follows a prolonged course, ending fatally due to severe anemia or its complications. The megaloblastic change and anemia are rapidly correctable by the parenteral administration of vitamin B₁₂ or oral administration of folate. The neurological changes tend to remain permanent once they have developed. Only vitamin B₁₂ is capable of preventing their occurrence and arresting their further progress, once they have set in. Folate does not prevent this neuropathy, in some it may even aggravate the lesion.

Laboratory findings: Erythrocytes are macrocytic with marked anisopoikilocytosis. The bone marrow is megaloblastic. In a florid case, the hemoglobin is usually below 7 g/dL. Leukopenia and thrombocytopenia are common. Gastric juice analysis shows histamine fast achlorhydria and absence of intrinsic factor (*achylia gastrica*). Serum vitamin B₁₂ is below 80 pg/mL. Serum and red cell folate are normal. Serum iron levels are elevated.

Defect of absorption of vitamin B₁₂, and its correction by addition of intrinsic factor present in normal gastric juice can be demonstrated by *Schilling's test* using radioactive vitamin B₁₂. Parietal cell antibodies which are detectable in the serum are helpful in diagnosis. Gastroscopy and biopsy confirm the diagnosis.

Therapy: In severe cases where the hemoglobin is below 5 g/dL, transfusion of packed erythrocytes may be required. Specific therapy is to give hydroxocobalamin 1000 µg intramuscularly every week till Hb level becomes normal. Reticulocyte response is noticed within 2 to 3 days of the first injection. Folic acid is contraindicated since it is known to precipitate the neurological complications, if administered alone.

Maintenance: Subjects with pernicious anemia should receive life-long supplementation of parenteral vitamin B₁₂, 1000 µg every month.

Congenital Megaloblastic Anemias

Though in the vast majority of cases of pernicious anemia the defect in intrinsic factor is an acquired one, it can be congenital in some rare cases.

Congenital intrinsic factor deficiency: In this condition the gastric histology and secretions are normal except for the absence of intrinsic factor.

Congenital deficiency of transcobalamin II (TC II) also causes megaloblastic anemia. In this condition the serum level of vitamin B₁₂ is normal, but since it is bound to transcobalamin I, it is not available for hematopoiesis.

Rarer Causes of Nutritional Anemia

Vitamin C deficiency: Normocytic normochromic anemia may occur in early cases of vitamin C deficiency. When bleeding complicates the picture, iron deficiency anemia results.

Protein deficiency: It can lead to anemia due to diminished production of erythrocytes and possibly reduced life-span of these cells. The anemia is mild, and hemoglobin levels range from 8 to 10 g/dL.

Copper deficiency: This leads to hypochromic microcytic anemia in experimental animals. Copper deficiency may occur in infants fed solely on milk or due to severe malnutrition. In adults this is not a significant clinical problem.

Anemia in Systemic Diseases

Thyroxine deficiency: This produces a mild to moderate type of anemia in 20-60% of cases. Thyroxine deficiency *per se* causes a normocytic normochromic anemia or slightly macrocytic anemia. There is mild hypoplasia of erythroid precursors.

Anemia in rheumatoid arthritis: There is mild to moderate anemia with hemoglobin levels ranging from 9 to 10 g/dL. Blood picture is usually normocytic hypochromic. Anemia may be partly due to gastrointestinal bleeding resulting from excessive ingestion of antirheumatic drugs. In addition to concomitant nutritional deficiencies, rheumatoid arthritis *per se* produces a resistant type of normocytic hypochromic anemia, which is relatively resistant to oral iron. Parenteral iron therapy results in significant improvement.

In acute renal failure: Normocytic normochromic anemia develops with reticulocytopenia and depression of erythroblasts in bone marrow. Erythropoietin levels are low.

In chronic renal failure: Severity of anemia correlates well with the glomerular filtration rate and to a lesser degree with blood urea nitrogen (BUN). Anemia is mainly due to reduction in erythropoietin levels and diminution in erythropoiesis. Blood loss and nutritional deficiency contribute in varying proportions. Hemodialysis aggravates the blood loss. When the blood urea exceeds 280 mg/dL hemolysis may develop. The anemia is

generally resistant to treatment, but erythropoietin produces marked improvement in hemoglobin level and several other parameters as well (see Chapter 179).

In chronic liver disease: There is mild anemia which may be multifactorial in origin. The factors are gastrointestinal bleeding, ineffective erythropoiesis and hemolysis. The anemia may be hypochromic or macrocytic normochromic. Usual hematinics are not very effective. Improvement may take place with improvement of liver function.

Malignant neoplasms: These cause anemia at some stage or the other during their course. Different types of anemia are encountered since multiple factors operate. These are:

1. *Iron deficiency anemia* due to gastrointestinal hemorrhage or malabsorption.
2. *Folic acid deficiency anemia* due to increased requirement of the vitamin caused by extensive tumours growths or due to chemotherapy or radiation therapy. Folinic acid therapy together with vitamin B₁₂ are helpful.
3. *Hemolytic anemia* may occur in lymphomas or ovarian neoplasms due to development of antibodies.
4. *Hypoplastic anemia* may result from bone marrow suppression caused by immune mechanisms, e.g., thymoma, lymphoma.
5. Myelophthisic anemia caused by invasion of the marrow by tumour tissue, e.g., malignant secondaries, lymphoma, myelofibrosis.

Anemia of Chronic Diseases (ACD)

Syn: Anemia of inflammation

Anemia may complicate several chronic, and at times, acute inflammatory disorders. These are not uncommon. These may masquerade as other types of anemia. Activation of the immune system by chronic and acute inflammatory disorders lead to ACD.

Causes

Chronic and acute infections- bacterial, parasitic, fungal and viral including HIV and AIDS.

1. Neoplasms: hematological malignancies and tumours of solid organs.
2. Autoimmune diseases, especially rheumatoid disease, systemic lupus erythematosus, vasculitis, sarcoidosis, inflammatory bowel disease, transplant rejection after solid organ transplantation.
3. Chronic renal diseases.
4. Other forms of chronic inflammation.

Mechanism: Immune mediated cytokines and immunocytes are activated which adversely affect iron metabolism, erythroid progenitor development, production of erythropoietin, and RBC life-span. All these factors contribute to the development of anemia. Bleeding, conditioned deficiencies of hemopoietic factors and autoimmune haemolysis aggravate the anemia. The proliferation and differentiation of the proerythroblast, erythroid BFU and CFU are impaired. Interferon-γ is one of the potent inhibitors. Stimulation by erythropoietin is inadequate to compensate for the inhibition. The response of the erythroid progenitor cells to erythropoietin is inhibited in proportion to the severity of the underlying chronic disease and inhibitor cytokines. Erythrophagocytosis (phagocytosis of RBC by macrophages) develops and this worsens the anemia by reducing RBC life-span in some cases of ACD.

Laboratory findings: The anemia is mild (Hb 6-9.5g), normocytic, normochromic or microcytic. Where iron absorption is impaired the anemia resembles IDA. In IDA serum ferritin levels are generally < 30 ng/mL. Ferritin levels are higher in ACD due to the increase in storage iron in RE cells and also the acute inflammatory reaction raising ferritin levels (Table 150.1).

A specific distinguishing test to differentiate between IDA and ACD is the level of *soluble transmembrane receptor* (STR) in serum. STR is a truncated fragment of the membrane receptor that is increased in iron deficiency when the availability of iron for erythropoiesis is diminished. In ACD the STR levels are normal. Another measurement is the determination of the ratio of the STR to the log of ferritin. Ratios above 2 suggest IDA whereas

TABLE 150.1

Shows the clinical parameters to distinguish between IDA and ACD

Parameter	ACD	IDA	Combined ACD+IDA
Iron	Reduced	Reduced	Reduced
Transferrin	Reduced	Increased	Reduced
Transferrin saturation	Reduced	Reduced	Reduced
Ferritin	Normal	Reduced	Reduced or normal
STR	Normal	Increased	Normal or increased
STR/log ferritin	<1	>2 High	> 2
Cytokine levels	Increased	Normal	Increased

ratios <1 suggest ACD. STR can be estimated easily using commercially available test kits.

Hemoglobin levels $< 8\text{ g/dL}$ double the chances of death in chronic renal failure

Treatment: Aims of treatment are

1. To raise hemoglobin up to 12 g/dL and
2. Attention to the underlying disorder

Management consists of supplementation of iron in those with iron deficiency. Iron should not be administered to those without evidence of iron deficiency, since this

may lead to the production of highly active toxic hydroxyl radicals which can worsen tissue damage. Erythropoietin is indicated in those in whom attention to the primary disease is not fully successful. The dose of erythropoietin should be adjusted to keep hemoglobin levels around 12g/dL .

Anemia of infections: Infections suppress erythropoietin production nonspecifically. Inflammatory cytokines also depresses the production of erythropoietin.

Hemolytic Anemias

K.V. Krishna Das

Chapter Summary

General Considerations	998
Autoimmune Hemolytic Anemias	1001
Secondary Hemolytic Anemias	1002
Hemolytic Disease of Newborn (HDN)	1002
Inherited Disorders of Erythrocytes	1004
Red Cell Membrane Disorders	1004
Red Cell Enzymopathies	1005
Hemoglobinopathies, Thalassemias and Thalassemia Syndromes, General Considerations	1007
Sickle Cell Disease	1008
Thalassemias	1011
Thalassemia Syndromes	1014

GENERAL CONSIDERATIONS

Normal life-span of red cells is 120 days. Old erythrocytes are removed from the circulation. Mildly deformed cells are phagocytosed in the spleen, severely injured cells are removed by the liver macrophages, and grossly damaged cells are destroyed in the circulation itself. When destruction of erythrocytes exceeds the normal rate, their life-span diminishes and compensatory hyperplasia of erythroid precursors develops. For considerable periods

this compensates and the hemoglobin level is kept up. Since the marrow can compensate by enhanced erythropoiesis upto seven times the normal rate, anemia need not follow in all cases. When hemolysis is severe and the life-span of the erythrocyte falls below 18 days, anemia is bound to develop. Rarely marrow erythropoietic activity may fail, aggravating the anemia. The term hemolytic anemia is reserved for those disorders where the anemia is caused predominantly by excessive destruction of erythrocytes.

Hemolysis occurs due to several pathogenetic mechanisms (Table 151.1).

1. A decrease in the surface area/volume ratio, e.g. hereditary spherocytosis, autoimmune hemolytic anemia, and drug induced hemolysis.
2. Defect in structure of the erythrocyte membrane, e.g. paroxysmal nocturnal hemoglobinuria (PNH) and drug induced hemolytic disorders.
3. Increased internal viscosity inside the red cell, e.g. sickle cell anemia and Heinz-body hemolytic anemia.
4. Hypersplenism.

Hemolytic anemia contributes 4% of the total anemias seen in south India. Hemolysis may occur intra-or extravascularly. Intravascular hemolysis takes place in many cases of acquired hemolytic anemias whereas in the inherited form, hemolysis is generally extravascular.

TABLE 151.1

Classification of hemolytic disorders

- 1. **Inherited hemolytic disorders**
 - a. Red cell membrane defects, e.g. hereditary spherocytosis, hereditary elliptocytosis, hereditary acanthocytosis, hereditary stomatocytosis
 - b. Red cell enzyme deficiencies, e.g. deficiencies of pyruvate kinase, hexokinase, glucose-6-phosphate dehydrogenase, and glutathione reductase.
 - c. Defects in amino acid configuration of globin chains, e.g. sickle cell anemia, and other hemoglobinopathies including unstable hemoglobins
 - d. Failure to switch over of beta or alpha globin chains in post natal life, e.g. thalassemias
- 2. **Acquired hemolytic anemia**
 - a. Immunologically mediated hemolytic anemia, e.g. incompatible blood transfusion, hemolytic disease of the newborn, autoimmune hemolytic anemia (warm antibody and cold antibody types).
 - b. Microangiopathic hemolytic anemia, e.g. disseminated intravascular coagulation, hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, mechanical causes like implantation of cardiac prosthesis and march hemoglobinuria
 - c. Caused by infections, e.g. malaria, *Clostridium welchii* infections, and bartonellosis
 - d. Caused by drugs, chemicals, and toxins, e.g. nitrofurantoin, sulphonamides, viper venom, and formic acid poisoning.
 - e. Paroxysmal nocturnal hemoglobinuria.

In intravascular hemolysis it is usually a complement mediated antigen antibody reaction. It is seen in conditions such as black water fever in *P. falciparum* malaria, and favism induced hemolysis. This may lead to the presence of hemoglobin in the plasma, methemalbuminemia and hemoglobinuria in addition to hyperbilirubinemia.

Extravascular hemolysis is generally caused by destruction of the erythrocytes in reticuloendothelial organs, particularly in the spleen. In these hyperbilirubinemia and jaundice are more prominent.

Acute massive intravascular hemolysis leads to hemoglobinuria and renal failure. Extravascular hemolysis occurs in the reticuloendothelial system and this produces hyperbilirubinemia without hemoglobinuria.

Clinical Feature

In addition to the general symptomatology of anemia, hemolysis leads to distinctive features which differ from each other in the acute and chronic forms. Chronic hemolysis leads to jaundice, hemolytic facies, chronic leg ulcers, splenomegaly, cholelithiasis, cutaneous pigmentation, and iron overload states. On the other hand, acute hemolytic episodes are characterized by sharp rise in temperature and marked prostration. They may be accompanied by hemoglobinuria, acute renal failure,

disseminated intravascular coagulation, and shock. In many cases the hemolysis is secondary to other underlying conditions such as lymphomas, leukemia, malignancy, or dyscollagenosis.

- 1. **Jaundice:** Hemolytic jaundice is generally mild, but at times this can be very severe, e.g. Rh incompatibility. The degree of jaundice and the extent of hemolysis may not always correlate.
- 2. **The facies:** It is characteristic in chronic hemolytic anemias especially thalassemia. There is enlargement of the skull with frontal and parietal bossing. The malar bones are prominent with flattening of the bridge of the nose, widely set eyes, and malocclusion of the teeth. The appearance may be mongoloid. All these changes are caused by enlargement of the marrow tissue.
- 3. **Chronic leg ulcers:** Chronic non-healing ulcers develop over the malleoli in severe hemolytic states such as sickle cell anemia and hereditary spherocytosis. These heal when the anemia improves.
- 4. **Splenomegaly:** Splenomegaly is invariably seen in all cases of hemolytic anemia though the size of the spleen may be variable. Massive splenomegaly occurs in thalassemia and this may lead to hypersplenism.
- 5. **Cholelithiasis:** Pigment stones in the biliary tree are occasional complications seen in chronic hemolysis, caused by the excessive presence of bilirubin in bile.
- 6. **Hemolytic crisis:** The course of chronic hemolytic anemias may be punctuated by acute episodes called crisis (Fig. 151.1). These are *aplastic, megaloblastic, hemolytic, sickling, and sequestration crisis*. *Aplastic crisis* is due to sudden marrow failure precipitated generally by viral infection especially parvo viruses. *Megaloblastic crisis* is produced by folate deficiency resulting from the excessive demand brought about by accelerated erythropoiesis. *Hemolytic crisis* is rare, which may develop spontaneously or may be an adverse reaction to drugs or viral infections. *Sickling*

Fig. 151.1: Hemolytic crisis: PB: Note: Anisopoikilocytosis, and presence of normoblasts-arrows

crisis occurs in sickle cell anemia when exposed to hypoxic environment. This leads to vascular occlusion of many organs such as lungs, spleen, kidney, and brain. In *sequestration crisis* sudden splenomegaly develops because of pooling of blood within the organ and severe anemia ensues rapidly.

7. **Darkening of skin and other iron overload syndromes:** Chronic hemolytic anemias lead to iron overload due to liberation of excessive iron which is taken up by the macrophages or deposited in the parenchymal cells of several organs. The absorption of iron from the GI tract is also increased in thalassemias. Repeated blood transfusion adds to iron overload. These result in hemosiderosis characterized by greyish complexion of the skin, cirrhosis of liver, diabetes mellitus, and cardiomyopathy.

Investigations: Proper laboratory investigations are necessary to establish the diagnosis of hemolytic anemia.

1. **Tests to detect the presence of hemolysis:** The direct method is to measure the red cell life-span, but this may not be available in many laboratories in India. The presence of hemolysis can be inferred by demonstrating: (a) reticulocytosis, (b) rise in serum bilirubin, (c) reduction of serum haptoglobin, and (d) increase in serum lactic dehydrogenase.
 - a. **Reticulocytosis:** Reticulocytes are demonstrated by staining with vital stains like brilliant cresyl blue or fresh methylene blue. Increase in reticulocyte count above 1.5% suggests increased erythropoiesis (Fig. 151.2). Hemolytic anemia must be suspected wherever the reticulocyte count is above 5% and this is not accountable by other causes like recent blood loss or hematinic therapy. Rarely reticulocytosis may be absent even in hemolytic states when there are antibodies against red cell precursors or bone marrow aplasia.
 - b. **Bilirubin:** Presence of unconjugated hyperbilirubinemia (above 1 mg/dL) in the absence of

primary hepatic disease strongly suggests hemolysis. The metabolic products of bilirubin like urobilinogen in the urine and stercobilinogen in feces are also increased. Presence of excess pigment in feces makes it darker—polycholia.

- c. **Serum haptoglobins:** These are alpha-2 glycoproteins which are normally present in serum at a concentration of 50-150 mg/dL. They combine with hemoglobin liberated from red cells to form complexes which are rapidly destroyed. Consequently, haptoglobin level in serum is lowered in active hemolysis.
 - d. **Serum lactic dehydrogenase level:** This is invariably elevated above the normal range (70-240 IU/mL) in hemolytic anemia. This is more marked in intravascular hemolysis.
 - e. **Bone marrow:** The bone marrow shows erythroid hyperplasia in the vast majority of cases. Megaloblastosis occurs when there is associated folate deficiency. Chronic overactivity of erythroid tissue leads to expansion of marrow volume and deformity of several bones such as the skull, facial bones, metacarpals, phalanges and others.
 - f. **Isotopic methods:** Red cell survival and the sites of hemolysis can be studied isotopically using ⁵¹Cr. The severity of hemolysis can also be established by this method.
2. **Tests to detect the cause:** History and physical examination help to reveal the cause in most of the cases. Examination of the peripheral blood film, tests for intravascular hemolysis and the demonstration of antibodies serve to identify the underlying factors.

Examination of a properly made blood film gives the most valuable clues to the etiology in most of the cases. Large number of spherocytes is suggestive of hereditary spherocytosis or immune hemolytic anemias. Gross alteration of red cell morphology and the presence of basophilic stippling, hypochromia and target cells favour the diagnosis of thalassemia and hemoglobinopathies. Schistocytes, which are fragmented erythrocytes, are seen characteristically in micro-angiopathy and mechanical causes for hemolysis. Stomatocytosis is seen in hereditary stomatocytosis and hepatic disorders. Acanthocytes are seen in abetalipoproteinemia and in chronic liver diseases. In elliptocytosis the erythrocytes are oval—hence called ovalocytes. In India no examination of blood film is complete without careful search for malarial parasites which may be the cause of hemolysis in many cases in endemic areas.

Anisopoikilocytosis, polychromasia, punctate basophilia, and Cabot's rings are suggestive of active erythropoiesis and also dyserythropoiesis which may indirectly indicate hemolysis. In hemolysis due to drug toxicity Heinz bodies can be demonstrated by suitable techniques.

Fig. 151.2: Hemolytic anemia peripheral blood x 1000 reticulocytes increased—note reticulum within erythrocytes—arrow

Intravascular hemolysis: In this condition free hemoglobin in the serum rises to 100-200 mg/dL or even more whereas the normal level is only 2-5 mg/dL.

Demonstration of antibodies by Coombs' test: The direct Coombs' test is a screening test for the detection of antibodies present on the erythrocytes. It is usually positive in immunohemolytic anemias. The indirect Coombs' test detects antibodies present in the serum.

3. **Other special tests:** Various other special tests are employed for the diagnosis of hemolytic anemias: (1) *Osmotic fragility* is increased and autohemolysis is present in spherocytosis. (2) *Sucrose-hemolysis test* and *Ham's acid serum test* are positive in paroxysmal nocturnal hemoglobinuria. (3) Detection of abnormal hemoglobins, assays for erythrocyte enzymes, demonstration of Heinz bodies, and immunological studies are all employed in specific cases.

Course and Prognosis

Prognosis in hemolytic anemias is very variable. Mild cases may extend over several years with aggravation of hemolysis during periods of stress. On the other hand acute fulminant hemolysis can be fatal. Death is due to severe anemia and shock or acute renal failure. The course of secondary hemolytic anemias depends on the primary cause.

Management

General measures: When the drop in hemoglobin is severe, it has to be restored by transfusion of packed erythrocytes. In acute intravascular hemolysis emergency transfusion is needed to avoid cardiorespiratory failure. Packed cell transfusion obviates the risk of volume overloading and also the risk of sensitisation by plasma proteins. When the hemolysis is aggravated by complement, as in paroxysmal nocturnal hemoglobinuria, washed erythrocytes should be given.

In severe hemolysis compensatory erythropoiesis leads to excess demand for hematinic factors, especially folic acid, which has to be supplemented. In general since the iron is not lost from the body iron deficiency does not occur. On the other hand many types of hemolytic anemias such as thalassemias may lead to iron overload. Hence administration of iron should not be routinely undertaken. In cases with prolonged hemoglobinuria and hemosiderinuria iron deficiency may develop and these require iron therapy.

The specific treatment of immune hemolytic anemias involves the administration of corticosteroids and immunosuppressants. Splenectomy is the treatment of choice in hereditary spherocytosis, immune hemolytic anemia refractory to medical treatment, and in the presence of hypersplenism. In enzyme deficiencies and

Causes of autoimmune hemolytic anemias	
Warm antibody type	Cold antibody type
1. Idiopathic (primary)	1. Idiopathic
2. Drugs, e.g. penicillin and methyl dopa	2. Infections by viruses e.g. EB virus and mycoplasma infection
3. Systemic lupus erythematosus and other collagen disorders	3. Drugs, e.g. stibophen
4. Lymphomas and chronic lymphatic leukemia	4. Chronic lymphatic leukemia
5. Immune deficiency states	5. Paroxysmal cold hemoglobinuria

hemoglobinopathies, splenectomy is not generally indicated.

Intravenous immunoglobulin given in a dose of 0.4 g/kg b.w daily for 3-4 days is effective in acute hemolytic episodes. This should be reserved for intractable cases since its cost is high.

Acquired Hemolytic Anemias

Autoimmune Hemolytic Anemia (AIHA)

Autoantibodies develop against the erythrocytes. The antibody may agglutinate the red cells at 37°C (*warm antibody*) or at lower temperatures (*cold antibody*). Warm antibodies generally belong to IgG class whereas cold antibodies are IgM. In the warm antibody type hemolysis takes place extravascularly in the spleen, while in the cold antibody type hemolysis occurs intravascularly or in the liver. Warm antibody type may vary in its course from mild chronic anemia to explosive and life-threatening hemolytic crisis.

Etiology: Table 151.2 lists the causes of autoimmune hemolytic anemias.

CLINICAL FEATURE

The majority of cases present symptoms like anemia, jaundice and splenomegaly. In secondary AIHA, features of the underlying disorder may be evident.

Acute massive hemolysis with shock and renal failure may develop in some cases.

Hemolytic anemia of the cold antibody type may give rise to two clinical syndromes an exposure to cold environment: (1) **Cold agglutinin syndrome**, and (2) **Paroxysmal cold hemoglobinuria**. Cold agglutinin syndrome occurs in older patients and presents with acrocyanosis, Raynaud's phenomenon, gangrene of fingertips, and a mild chronic hemolytic anemia. In paroxysmal cold hemoglobinuria, sudden hemolysis develops leading to hemoglobinuria. Paroxysmal cold hemoglobinuria is the first identified autoimmune disease

described by Karl Landsteiner, pathologist from Vienna. The antibody reacts with erythrocytes in the cold.

The *peripheral blood film* shows marked anisopoikilocytosis, polychromasia, spherocytosis, and increase in reticulocytes. *Neutrophil leukocytosis* is common. Rarely platelets may be reduced due to the development of antibodies against them (*Evan's syndrome*). The antibodies present on erythrocytes can be demonstrated by the *direct Coombs' test* and free antibodies in the serum can be identified by the *indirect Coombs' test*. The thermal characteristics are demonstrable by suitable tests.

Treatment: In secondary hemolytic anemia, treatment is directed towards the underlying cause. If blood transfusion is necessary, properly cross-matched erythrocytes should be given.

Majority of cases of primary AIHA responds to prednisolone in a daily dose of 1-2 mg/kg body weight. Once the acute episodes are controlled, the dose should be tapered off but the maintenance dose may have to be continued for prolonged periods. Methyl prednisolone in doses of 1-2 g/day given IV as infusion may prove to be superior to other steroids in some cases. In cases where steroids fail, or the maintenance dose is high, splenectomy has to be considered. If erythrocyte destruction can be demonstrated in the spleen by isotopic methods, such cases benefit promptly by splenectomy. In the others, although the response is unpredictable, 33-50% still derive benefit.

Immunosuppressive drugs like azathioprine (2-3 mg/kg body weight) cyclophosphamide (1-2 mg/kg body weight) or cyclosporine may be required, if steroids given alone are not fully effective.

In cold antibody type, if the hemolysis is mild, only general measures such as avoidance of cold may be necessary. If transfusions are necessary the blood should be warmed to body temperature before infusion. Steroids and splenectomy are less effective in this type, compared to warm antibody type of AIHA.

Secondary Hemolytic Anemias

Syn: Symptomatic hemolytic anemia

Hemolysis may develop in the course of infections such as malaria, viral hepatitis, infectious mononucleosis, and mycoplasma infection. Collagen disorders, leukemia, lymphomas, and other malignancies may be associated with immune hemolysis. Several drugs like penicillin and methyl dopa are associated with the production of antibodies and hemolytic anemias. Drugs act in several ways: (1) drugs like penicillin may act as haptens and make the erythrocyte antigenic; (2) drugs like stibophen, quinine, quinidine, INH, PAS, and sulphonamides, lead to the development of immune complexes which get attached to the erythrocytes and lead to complement-

mediated hemolysis (innocent bystander type); and (3) drugs like methyl dopa lead to production of antibodies directed against specific antigen sites in the erythrocyte and lead to hemolysis.

Rarely hemolysis may be due to physical factors. Prosthetic cardiac valves lead to mechanical injury and damage of red cells. Long marches and severe physical exertion lead to hemolysis by the same mechanism—march hemoglobinuria. Severe burns lead to extensive hemolysis.

Hemolytic Disease of Newborn (HDN)

The newborn may suffer from Rh incompatibility or ABO incompatibility if there is Rh or ABO incompatibility between the parents. If the father is Rh positive the fetus may also sometimes be Rh positive and entry of fetal erythrocytes into the Rh negative mother leads to production of anti-negative-Rh antibodies which reach the fetus and destroy its erythrocytes. A similar phenomenon may occur in ABO incompatibility as well.

RH INCOMPATIBILITY

This accounts for the vast majority of isoimmune hemolytic anemias of the newborn and manifests as jaundice on the first day of life. Among the Rh antigens 'D' is most antigenic. Fetuses with this phenotype cause more severe immunisation of the mother and greater degrees of hemolysis in the fetus. In India 8% of population is Rh negative, unlike in the West where the frequency is 15%. About 17% of Rh negative women get immunised during pregnancy if the fetus is Rh positive.

Pathogenesis

The Rh isoimmunisation occurs when an Rh negative individual receives Rh positive blood by transfusion or by other sources. When an Rh negative mother carries an Rh positive fetus there is transplacental exchange of small quantities of fetal blood into the maternal circulation during the last weeks of pregnancy and during labour. Therapeutic obstetric procedures increase this risk. The fetal cells immunise the mother and antibodies of IgG class are produced depending upon the amount of fetomaternal transfer. Usually the first born child escapes unless the mother is previously sensitised due to Rh incompatible blood transfusions during childhood or due to previous abortions. With successive pregnancies and abortion the antibody titre in the mother progressively rises. Spontaneous or induced abortions, ectopic pregnancy, amniocentesis and other similar procedures increase the risk. The maternal antibodies pass back into the fetus and lead to hemolysis of fetal erythrocytes, resulting in hemolytic disease of the newborn. Severity of hemolysis depends upon the amount of maternal antibody and the period of gestation at which the fetus is affected.

Hemolysis leads to the development of marrow hyperplasia and extramedullary hemopoiesis. Hepatosplenomegaly occurs. Hepatic function suffers and therefore hypoalbuminemia, ascites and hydrops fetalis develop. In the severe form there is congestive heart failure, impairment of placental circulation, intrauterine growth retardation and stillbirth. The excess of bilirubin resulting from excessive hemolysis is handled both by the liver and placenta during fetal life, but after birth, this bilirubin load has to be handled by the liver alone. Unconjugated bilirubin crosses the blood brain barrier when the serum levels are high. It gets deposited in neural cells when the serum level exceeds the binding capacity of serum albumin. It interferes with mitochondrial function and leads to cell death and permanent-neurological defects. Neurones in the brainstem, basal ganglia and other regions are affected most. Neurotoxicity of bilirubin may also lead to nerve deafness, seizures, athetoid movements, spasticity and death.

D-phenotypes cause maximum sensitisation and lead to most severe disease. Factors determining the extent and severity of the disease are the timing, number and extent of fetomaternal exchanges of blood. Fetal cells which are both ABO and Rh incompatible are more rapidly destroyed in the maternal circulation than purely Rh-incompatible cells. Hence the latter type is more immunogenic and it leads to clinically more serious type of disease. The unconjugated bilirubin formed by hemolysis is bound to albumin, but when the bilirubin level exceeds 20 mg/dL, the unbound bilirubin passes to the CNS and causes damage, which is most pronounced in the basal ganglia.

Clinical presentation The mild form manifests as moderate hemolytic anemia in the first days of life. Hepatosplenomegaly may be just detectable. The moderately severe form presents as *icterus gravis neonatorum*. This leads to jaundice within 24 hours of birth and this feature distinguishes it from physiological jaundice. Anemia may progress and lead to cardiac failure. Hepatosplenomegaly may be more evident. Neurological abnormalities develop in severe cases. This is known as *kernicterus* which is characterized by a high pitched cry, opisthotonus and convulsions. Sequelae include choreo-athetosis, deafness, cerebral palsy and mental deficiency which become evident as the child grows.

The severe form manifests as *hydrops fetalis*. Usually the affected baby is born dead or it dies soon after birth. Gross edema, hepatosplenomegaly, anemia and effusions into serous cavities are the common stigmata.

Investigation in a suspected case of Rh isoimmunisation: The mother's blood shows the presence of antibodies by the indirect Coombs' test. Titres above 1/64 or rising titres are indicative of risk to the fetus. Further adjuncts to diagnosis are amniocentesis and analysis of bile pigments in amniotic fluid. Unlike normal amniotic fluid which is colourless, in Rh hemolytic disease the

amniotic fluid is bright yellow and this can be quantitated spectroscopically.

Postnatal diagnosis: The baby's blood shows positive direct Coombs' test, elevated serum bilirubin, reticulocytosis, anemia and presence of large number of erythroblasts (over 10% of nucleated cells).

MANAGEMENT

Rh immunisation is a preventable disease by proper Rh typing during the prenatal check up.

Prenatal Management

1. When the mother is not immunised or the Rh antibody titre is low and static the pregnancy is allowed to continue.

The Rh-D antibody titres are estimated at the first month itself in at-risk pregnancy and repeated. If the titre exceeds 1/16 at 20 weeks or the titres double from the original value, amniocentesis is done to estimate the bilirubin level in amniotic fluid. Polymerase chain reaction (PCR) has been employed to determine the fetal genotype using amniotic cells or fetal blood or maternal plasma collected early in the second trimester.

Other investigations to be undertaken include ultrasonography, and two-dimensional Doppler studies to detect fetal ascites and hydrops. If the risk of hydrops fetalis or stillbirth before 34 weeks is high, blood transfusions have to be given to the fetus to ameliorate anemia, reduce ascites and hydrops and suppress erythropoiesis. With modern techniques, direct intravascular transfusion is possible in upto 80% of cases. The alternative is to give intraperitoneal infusion of blood.

2. If the risk of hydrops fetalis or stillbirth is high, induction of labour between 34 and 38 weeks is indicated.

Test for pulmonary maturity is carried out by estimating the lecithin sphingomyelin (L/S) ratio of the amniotic fluid. If the L/S ratio is above 2, the pulmonary surfactant will be normal and so there is no risk of acute respiratory distress syndrome in the newborn.

Postnatal Management

The principles of management include the correction of anemia, acidosis, hypoglycemia and hyperbilirubinemia. When the serum level of unconjugated bilirubin is above 20 mg/dL in term babies or 15 mg/dL in preterm babies, exchange transfusion with Rh negative group O blood is indicated. By this procedure antibody coated erythrocytes and excess bilirubin are removed, and anemia is corrected. Hemoglobin level below 14 g/dL and serum bilirubin above 3 mg/dL in cord blood are also indications for immediate exchange transfusion. Usually 150 mL/kg body weight of compatible blood is used for each exchange.

Other forms of therapy: Mild or even moderate cases can be controlled by *phototherapy* and *phenobarbitone*. Natural sunlight and fluorescent light oxidise bilirubin to biliverdin and then to nontoxic water soluble products. Phototherapy reduces indirect bilirubin level and helps to reduce the need for exchange transfusion. Phenobarbitone induces liver enzymes to conjugate bilirubin and favour its excretion.

Prevention: Rh negative mothers who are at risk are protected from getting immunised by the administration of 300 µg of anti-D gammaglobulin (Rhogam) within 72 hours of delivery or abortion, amniocentesis or rupture of ectopic gestation. Rh immunoglobulin is prepared from plasma obtained from persons with Rh D antibodies. It agglutinates and destroys the circulating fetal cells.

ABO Hemolytic Disease

In 15-20% of pregnancies ABO incompatibility occurs between the mother and fetus. IgG antibodies against fetal red cells are produced in the mother. Group O mothers produce antibodies more readily than A or B group mothers. The ABO hemolytic disease of the newborn is mild compared to Rh hemolytic disease. Further differences are: (1) the first pregnancy may be affected as frequently as subsequent pregnancies, and (2) even if one pregnancy is affected the subsequent one may escape.

The clinical features are milder compared to Rh hemolytic disease and they may subside spontaneously. Phototherapy and exchange transfusion may be required at times.

Non-Rh Hemolytic Anemias

Other alloantibodies are increasingly being recognized as causes of non-Rh hemolytic anemia. These include antibodies of the Kell system (K and K), Duffy (Fy), Kidd (JKa and Jk^b) and MNSs systems (M, N, S and S). Some women get immunised to more than one system of antigens. Next to anti-D, anti-Kell is the most common. 6-8 weeks after the recovery from the hemolytic process with treatment, hyporegenerative anemia may develop in the infant. This may require transfusion.

Inherited Disorders of the Erythrocytes

RED CELL MEMBRANE DISORDERS

Hereditary Spherocytosis

Hereditary spherocytosis is the most common inherited disorder of erythrocyte membrane. It is an autosomal dominant disorder presenting as a chronic hemolytic anemia with the presence of spherocytes in peripheral blood, intermittent jaundice, and splenomegaly. In 80% cases family history indicates hereditary involvement.

Pathogenesis: Though the exact molecular lesion in spherocytosis is yet unknown, several alterations in structure and function of the cell membrane have been noticed. These include: (1) reduction in membrane lipid; (2) increased permeability to sodium; and (3) defective phosphorylation of the membrane protein—*spectrin*. Abnormalities in membrane proteins such as spectrin, ankryn, pallidin (protein 4.2) and band 3 have been identified. The spherocytes are erythrocytes which assume a spherical shape due to inability to maintain the normal biconcave shape. Spleen destroys the defective erythrocytes. Bone marrow shows erythroid hyperplasia. In long-standing cases gall stones are common.

CLINICAL MANIFESTATIONS

In the vast majority the condition presents in the second and third decades with mild hemolytic anemia and recurrent jaundice. Occasionally it may manifest as persistent anemia and failure to thrive in infants. Many cases remain asymptomatic throughout life. Hemolytic and aplastic crises may occur from time-to-time. Extreme cases may present as neonatal hyperbilirubinemia requiring exchange transfusion.

Laboratory findings: Hemoglobin level is usually 8-10 g/dL. Reticulocyte count ranges from 5-20%. Over 30% of erythrocytes in the peripheral blood are spherocytes (Fig. 151.3). They are smaller in diameter, thicker, and appear uniformly stained with loss of the central pallor. Mean corpuscular volume is increased. The osmotic fragility is increased. Autohemolysis occurs in stored blood and this is corrected by the addition of glucose or ATP. Coombs' test is negative.

Diagnosis: Recurrent anemia, jaundice, splenomegaly, and spherocytosis should suggest this diagnosis, though spherocytosis may occur in other types of hemolytic anemias also as an acquired defect. Occurrence of spherocytosis and hemolysis in siblings or parents strengthens the diagnosis. In addition, demonstration of autohemolysis and its correction by glucose or ATP are

Fig. 151.3: Spherocytosis-PB: Note: The small densely stained RBCs-(spherocytes)-arrows

Fig. 151.4: Peripheral blood-post splenectomy
Note:Target cells-arrow

diagnostic, since these tests are specific for hereditary spherocytosis.

Treatment: Hereditary spherocytosis is functionally curable by splenectomy in almost all cases. Poor response to splenectomy or relapse suggests a wrong diagnosis or the development of accessory splenic tissue. Children have a higher tendency to develop pneumococcal and other types of septicemia after splenectomy and, therefore, splenectomy should be avoided in children below 10 years of age. In some intractable cases splenectomy may have to be done but this should be preceded by pneumococcal vaccination and prophylactic penicillin therapy when infections are likely to occur. Target cells appear in peripheral blood after splenectomy (Fig. 151.4).

OTHER RED CELL MEMBRANE DISORDERS

Hereditary elliptocytosis (HE): This is a specific autosomal dominant disorder where mild or moderately severe hemolysis occurs, but may remain unnoticed in about 90% cases. Almost all the red cells are elliptical in shape (elliptocytes) (Fig. 151.5). Diminished spectrin interactions, deficiencies or dysfunction of protein 4.1, and glycophorin deficiency have been identified.

Fig. 151.5: Ovalocytosis peripheral blood x 1000-
(elliptocytosis). Note: The oval erythrocytes

Fig. 151.6: Acanthocytes (arrow)

Treatment is symptomatic. Results of splenectomy are unpredictable.

Acanthocytosis: Acanthocytes are abnormal erythrocytes showing projections of variable width and length on their surface. They are seen in abeta-lipoproteinemia and severe liver disorders (Fig. 151.6).

Red Cell Enzymopathies

General considerations: A mature red cell cannot synthesize proteins since it has neither the nucleus nor ribosomes. It has lost its mitochondria, and therefore, it cannot generate ATP via the tricarboxylic acid cycle. It has also no ability to synthesize nucleic acids or lipids. Still it completes its full life-span of 120 days through other metabolic pathways for which it is endowed with a full supply of several enzymes. Important among them are hexokinase, glucose-P-isomerase, phosphofructokinase aldolase, triose-P-isomerase, glutathione peroxidase, glutathione reductase, glutathione synthetase, glucose-6-phosphate dehydrogenase and many others. Most enzymopathies are inherited in an autosomal recessive manner but some are sex linked or autosomal dominant. Hemolytic anemias caused by enzymopathies are also known as hereditary non-spherocytic hemolytic anemias.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY (G-6-PD)

Prevalence: The G-6-PD deficiency is prevalent in different parts of the world, commonly in the Mediterranean population. In India, the incidence varies from 1 to 20% in different ethnic groups, the highest incidence being in Naga tribals, Parsees and others. Three common variants of G-6-PD have been identified. These are G-6-PD Kerala, G-6-PD West Bengal and G-6-PD Jammu. At present over 400 isoenzymes of G-6-PD have been recognised. G-6-PD deficiency gives partial protection against falciparum malaria in female heterozygotes. G-6-PD deficiency is sex

linked recessive phenomenon which is transmitted from mother to son. The gene for G-6-PD is located on the long arm of the X chromosome. Fifty percent of the sons are affected while the heterozygous females may show only slightly lower enzyme values. The G-6-PD deficiency finds full expression in hemizygous males and homozygous females. Clinical features depend on the severity of enzyme deficiency and the racial patterns. Normal G-6-PD level is 12-18 units/mL.

Clinical Severity of G-6-PD Disorders	
Class I:	Enzyme activity is below 10% and this results in chronic hemolysis.
Class II:	Enzyme activity is below 10% but there is no chronic hemolysis, e.g. G-6-PD-B.
Class III:	Functional activity 10 to 60%. Here hemolysis occurs only after exposure to drugs or infections, e.g. G-6-PD-A.
Class IV:	Normal functional activity.
Class V:	Increased activity.
Classes IV and V are of no clinical significance.	

The Indian variant usually produces hemolysis on exposure to several drugs and infections. Drug-induced hemolysis may present as a life-threatening disorder in such subjects. Rarely neonatal jaundice may occur—icterus neonatorum.

Common Drugs Causing Hemolysis in G-6-PD Deficiency

1. Antimalarials:	Quinine, primaquine, chloroquine, mepacrine.
2. Sulfa group:	Sulfanilamide, sulfapyridine, acetylsulfanilamide, sulfacetamide, sulfafurazole, thiazosulfone, salazosulfapyridine, aldesulfone sodium, sulfamethoxypyridazine, cotrimoxazole.
3. Analgesics:	Acetanilide, acetylsalicylic acid, phenacetin, phenazone, aminophenazone.
4. Other drugs:	Furozolidone, nitrofurantoin, chloramphenicol, para-aminosalicylic acid, naphthalene, vitamin K, probenecid, quinidine, trinitrotoluene, methylene blue, dimercaprol, phenylhydrazine.

In addition several articles of food may precipitate hemolysis, e.g. Fava beans.

Clinical features: The subjects carrying the enzyme defect do not show any evidence of disease but exposure to oxidant drugs and/or infection may lead to hemolysis. Drug induced hemolysis starts 24 to 72 hours after administration of the drug. Urine is dark and jaundice may be present. Hemolysis stops when the drug is withdrawn and the hemoglobin level improves. Sometimes spontaneous arrest of hemolysis occurs even when the drug is continued. Babies with G-6-PD deficiency may develop severe icterus neonatorum.

Laboratory findings: Severe anemia may result. Red cells may show *Heinz bodies* before the onset of hemolysis. These are refractile inclusions which are seen in the erythrocyte in the wet unstained preparation. They are indistinguishable by the Romanowsky stains, since they stain uniformly with the surrounding hemoglobin. Hemoglobinuria may develop and this may result in renal failure. Reticulocytes are increased. Red cell morphology is generally normal. Estimation of the enzyme helps to establish the diagnosis. Since reticulocytes are generally rich in G-6-PD, the enzyme activity may be normal in the presence of active reticulocytosis. In such cases the enzyme assay should be repeated after the reticulocytosis has subsided.

Course: In the majority of G-6-PD deficiency patients it is a self-limiting phenomenon and it tends to subside when G-6-PD levels increase with the onset of reticulocytosis.

Therapy: Mild cases are self-limiting and demand only withdrawal of the offending drugs. In severe cases, blood transfusion may be required. Renal failure should be managed on its own merits. Subjects who are G-6-PD deficient should be informed of the condition to prevent further recurrence.

Other important inherited enzymopathies include the following:

Pyruvate kinase deficiency: This is an autosomal recessive disorder with several different mutations of the gene. It also manifests as hemolytic anemia. Splenectomy may benefit some cases.

Triose-phosphate deficiency: This leads to hemolytic anemia as well as neurological defects, cardiomyopathy and susceptibility in infection. Many cases die in childhood.

Red cell enzymopathies should be suspected in children with hemolytic anemia which is not associated with abnormalities of hemoglobin and morphological abnormalities of erythrocytes and absence of antibodies against erythrocytes.

Hemoglobinopathies, Thalassemias, and Thalassemia Syndromes

GENERAL CONSIDERATIONS

Hemoglobinopathies are among the most widespread genetic disorders seen in humans. The hemoglobin in normal individuals is made up of three components. These are HbA₁ (94-97%) HbA₂ (1-3.5%) and HbF (0-2%). During fetal life HbF is the main hemoglobin and it is replaced by HbA within the first six months of life. This transformation is under genetic control. Failure of formation of adult hemoglobin to replace the fetal hemoglobin results in thalassemias.

The hemoglobin molecule is made up of heme and globin. Chemical changes in the heme lead to the production of methemoglobin, sulphhemoglobin, and carboxyhemoglobin. The globin contains four polypeptide chains. The polypeptide chains are alpha, beta, gamma and delta. HbA₁ has 2 alpha and 2 beta, HbF has 2 alpha and 2 gamma and HbA₂ has 2 alpha and 2 delta chains. The genes for beta, gamma and delta chains are located in a closely linked cluster on the short arm of chromosome 11. Alpha and beta chains are produced on separate ribosomes in nearly equal amounts. Each polypeptide chain has a specific amino acid constitution. When the sequential order of amino acids is altered or the chain is altered by deletion or addition, abnormal hemoglobins are formed. For example, substitution of valine for glutamic acid at sixth residue of beta chain results in the formation of HbS and lysine for glutamic acid results in formation of HbC. Such alterations result in the change of electrical charge of the molecule and consequently, the electrophoretic mobility alters. This property enables these abnormal hemoglobins to be separated by electrophoresis. Abnormal hemoglobins and thalassemias are inherited as autosomal dominant trait, but their expressivity and penetrance vary considerably. This factor accounts for the very heterogenous mode of transmission. Many authors consider that inheritance of abnormal hemoglobins may clinically resemble that of autosomal recessives. Variants of Hb A have been identified.

Hemoglobinopathy in India: Several hemoglobin variants are encountered in India. These are hemoglobins D, E, F, H, I, J, K, L, M, S, Q, Norfolk, and Lepore. Of these, prevalence of hemoglobins S, E, D, J, K, and Q have been studied in detail in population groups. Hemoglobin S is found mostly in the tribals. HbE is seen in Bengal and Assam; Hb D, J, and K are seen in Punjabis and Gujaratis and HbQ is seen in Sindhis. Among these only HbS and HbE are widely prevalent. The sickle cell gene is widespread in India. In some tribal populations

the frequency is up to 45%. Hemoglobin C is not reported from India.

The cumulative gene frequency for HbS, E and D in India is 5.45. For HbS it is 4.5, for HbD it is 0.86, and for Hb E in the northern states it is 10.9 (Balgir RS JI Ass Phys India 1996:44, 1, 25-28). In Wynad district of Kerala, Kurumas, Paniyas, Adiyas and Wynad Chettys have HbS disease. The disease is mild in 52.2% of cases. Crisis occurs in 43% of cases. Splenomegaly and leg ulcers occur with a frequency of 4.3% in these tribes.

Sickle cell β^+ thalassemia has HbA levels of 20-30% whereas sickle cell β^0 thalassemia has only much lower levels of HbA and therefore the former is less severe. Sickle cell β^+ thalassemia and sickle cell HbC disease tend to be milder than sickle cell anemia.

Inheritance Pattern

If both parents carry one each HbS gene 25% of children develop SS disease and the others will be heterozygous for S. All pregnancies carry the same risk. If one parent is SS and the other is heterozygous (AS), the risk of having SS for the offspring is doubled. The study of the structure of DNA flanking the beta-globin locus has helped to classify population groups who possess the HbS gene. The genetic constitution of HbS patients in India belongs to the Asian haplotype. This is the same seen in eastern Saudi Arabia too.

Hemoglobinopathies lead to physical and chemical alterations in the function of the hemoglobin molecule depending on the site and nature of the amino acid substitution. Many lead to hemolytic anemia, e.g. HbS. Substitution of certain nonpolar amino acids within the hemoglobin molecule makes it unstable so that even in the heterozygous state it leads to hemolytic anemia. Certain substitutions lead to congenital methemoglobinemia.

Some substitutions lead to increased affinity of the hemoglobin to oxygen and this prevents the release of oxygen to the tissues. Tissue anoxia leads to polycythemia. Abnormal hemoglobins can be separated by electrophoresis in suitable buffers. In comparison with the mobility of hemoglobin A, they can be classified as slow moving, fast moving, and very fast moving types as given below.

Electrophoretic mobility at pH 8.6		
Very fast	H group	H, I, Barts
Fast	J group	J, K, No, Norfolk
Normal	A group	A, M, F
	G group	G, L, P, Q
Slow	S group	S, D, Stanville-2, Lepore
	C group	C, E, A ₂ O, F, Alexandra

Hemoglobinopathies

SICKLE CELL DISEASE

Sickle shaped red cells were first described by Harrick in 1902. Sickle cell disease is the most widespread hemoglobinopathy in India. Though nation wide epidemiological data is not available for India, it is known to be widely prevalent in many areas, particular communities being affected. Many tribal populations of Tamilnadu, Assam, Andhra Pradesh, Orissa, Madhya Pradesh, Kerala (particularly Paniyas), Maharashtra and all other states do suffer from the disease. Occurrence among high caste population in Kerala has also been reported. HbS may constitute more than 50% of the contents of the red cell.

Sickle Cell Anemia

Homozygous sickle cell disease: It leads to sickle cell anemia. In sickle cell trait the condition is heterozygous and the levels of HbS are much lower. Hemoglobin S offers partial protection against falciparum malaria (*balanced polymorphism*) accounting for the persistence and relative increase in HbS hemoglobinopathy in regions having high prevalence of falciparum malaria.

The genetic variants are:

Sickle cell anemia	homozygous S-S
Sickle cell trait	heterozygous A-S
HbS-thalassemia	heterozygosity between HbS and thalassemia
	The thalassemias may be B ⁰ or B ⁺
	HbS + B ⁰ has severe manifestations whereas
	HbS + B ⁺ give rise to milder manifestations
HbS-C disease	heterozygosity between S and C
HbS-D disease	heterozygosity between S and D
HbS with hereditary	The clinical manifestations are milder persistence of fetal hemoglobin

PATHOLOGY

Hemoglobin S is formed by the substitution of valine in place of glutamic acid in the sixth residue of the beta chain of adult hemoglobin and it is a slow-moving hemoglobin. Oxygenated HbS is normally soluble and the erythrocyte carrying it behaves normally. On deoxygenation the abnormal hydrophobic valine becomes exposed. On encountering another deoxygenated HbS molecule, polymerisation occurs at an explosive rate. Higher concentration of HbS and low pH favour

Fig. 151.7: Sickle cell anemia (HbS)
Note: (A) sickling-arrow (B) oxygenated blood

polymerisation. This leads to change of shape of the erythrocyte- *sickling*. The erythrocyte loses its deformability due to stiffening.

On reoxygenation the polymerised HbS promptly fall apart instantaneously.

The polymerisation of hemoglobin S is central to the pathogenesis of the disease. Polymerisation which occurs in anoxic environment stiffens the sickled erythrocytes, changing it from a flexible and deformable biconcave disc to an unyielding obstacle that blocks the circulation leading to the anoxic and nutritional damage to distal tissues. The polymerised HbS forms liquid crystals (tactoids) which distort the erythrocytes and make them assume the sickle shape (Fig. 151.7).

Only deoxygenated HbS polymerises. On reoxygenation the processes are promptly reversed. Organs with relatively sluggish circulation, high level of oxygen extraction and low pH such as the spleen and bone marrow are the most vulnerable to polymerisation and anoxic damage. Vaso-occlusion and tissue ischemia are caused by other factors as well, which are triggered by sickling and adhesion of erythrocytes. These include interaction between erythrocytes, endothelium, platelets, leucocytes and plasma factors. Endothelial dysfunction also plays a major role in the final outcome of vaso-occlusion. High molecular weight von Willebrand's factor favours adhesion of red cells and platelets to endothelium. Reticulocytes release free oxygen radicals which lead to endothelial damage and further changes. These pathological changes are most marked in SS disease. They are milder in HbS-β⁺ thalassemias and HbS+ persistence of HbF.

The painful episodes in the spleen and bones are caused by anoxic infarction. As a result of repeated infarcts the spleen may shrink and become functionless (autosplenectomy). In the bone marrow periodic infarction leads to fat necrosis and fat embolism and embolisation in the lungs is one of the precipitating factors for acute chest syndrome.

Normally the lung is the de-polymerising organ which protects the arterial side of the circulation from blockage by sickled erythrocytes.

Vaso-occlusion by sickle cells is a two step process that begins with adhesion of red cells to endothelium, probably in the post-capillary venules. This is followed by a propagation phase caused by accumulation of poorly deformable red cells behind the site of adhesion.

In addition to the abnormalities in sickled red cells several other factors also favour their adhesion to the endothelium. These include endothelial injury caused by release of cytokines liberated by granulocytes, thrombospondin released by activated platelets leading to adhesion, and the influence of young reticulocytes called “stress reticulocytes”. These cells express adhesive ligands that facilitate interaction between sickle cells and endothelial cells. Expression of adhesion receptors on endothelial cells is accelerated by hypoxia, thrombin, tissue necrosis factor, platelet activating factor and interleukin-1. Among the various hemolytic anemias, the vaso-occlusive component in sickle cell anemia is unique.

Life-span of the erythrocyte is reduced to 10-12% of normal. A new equilibrium with hemoglobin around 6-9 g/dL and reticulocytes forming 10-15% gets established.

Sickled cells are easily destroyed and this leads to hemolytic anemia. Factors which precipitate sickling are hypoxia, acidosis, dehydration, fever, and infections. Occlusion of the microcirculation resulting from sickling aggravates acidosis further, thereby establishing a vicious circle. Maximal lesions are seen in the heart, lungs, spleen, bone marrow, brain, and placenta. Pulmonary hypertension, demonstrable by Doppler studies is common in adults with sickle cell disease. Hemolysis seems to be the causative factor, stimulating procoagulant activity leading on to microvasculopathy and thrombosis. Primary pulmonary hypertension is also not uncommon. Presence of pulmonary hypertension confers higher mortality.

Obstruction of the microcirculation of the bone marrow leads to ischemic necrosis, marrow embolism and fibrosis. Priapism occurs due to occlusion of the corpora of the penis. This may be persistent, painful and troublesome. Retinitis proliferans may develop in children.

In HbS-thalassemia the presence of large amounts of HbF protects against sickling.

CLINICAL FEATURES

Most of the clinical features can be explained on the basis of anemia, hemolysis, obstruction to microcirculation, and siderosis of parenchymal organs. Sickle cell disease may present in different ways, with a wide spectrum ranging from subclinical cases to mild, moderate and severe manifestations. The child may appear normal at birth. The disease becomes evident after six months of age, by which time; normally adult hemoglobin takes over completely

from HbF. The defects in the synthesis of the chains are manifest by this period. Severe cases of HbS disease have higher neonatal and perinatal mortality due to pneumococcal infections. Untreated, severe cases die within 10 years. When the disease is severe, growth is retarded with delay in skeletal maturation giving rise to the characteristic picture of stunted growth, long limbs, narrow hips, and exaggerated lordosis. Anemia, mild or moderate splenomegaly, swelling of fingers and a characteristic appearance develop.

Sickling crises supervene frequently involving several organs, and untreated cases are fatal before the third decade. This extreme form is more common in negros and many tribals. In mild cases there may be only mild anemia, growth and development being normal. This variety is more common in the Middle East. In India the cases show an intermediate severity.

The splenic sequestration syndrome is characterised by sudden painful splenomegaly associated with rapid fall in hemoglobin and hypotension. This is seen more frequently in children. The condition may be fatal if left untreated. As a result of repeated infarction, the spleen may shrink and be converted into a fibrous streak. This is referred to as *autosplenectomy*. The infarcts may become calcified. The spleen becomes impalpable in sickle cell anemia by the age of 10-12 years. In other sickle cell syndromes such as S-thalassemia, S-C and S-D, the spleen remains palpable throughout life.

Acute Chest Syndrome

This is a painful pneumonia like presentation occurring in sickle cell disease. This may be due to vaso-occlusion, infection or both. Precipitating causes include infection by any organism, bone marrow embolism and atelectasis. Physical signs of consolidation or collapse may occur. X-ray may show local infiltration. If severe, respiratory failure may develop.

Renal involvement manifests as hematuria, hyposthenuria, acute nephritis, or occasionally nephrotic syndrome. **Priapism** may occur due to obstruction to corpora cavernosa. **Skeletal symptoms** are common. These include bone pain, arthralgia, backache, dactylitis, salmonella osteomyelitis, and multiple bone infarcts. **Dactylitis** is seen in young children. The femoral and humeral heads may undergo avascular necrosis. Neurovascular accidents develop due to occlusion of intracranial vessels. **Stroke** is a very disabling complication occurring in 10% of patients annually. This occurs around the age of 10-20 years and this confines them to a life of morbidity up to the age of 30. **Blindness** may develop due to repeated vitreous hemorrhages, and retinal tears and detachment. **Aplastic crisis** occur rarely and it is characterised by the rapid development of severe anemia due to marrow

hypoplasia and accelerated hemolysis usually the result of parvovirus B-19 infection. It is self limiting if the crisis is tided over.

Complications include anemia with hemoglobin levels below 6g/dL, cholelithiasis, aplastic crisis, sickling crisis, acute chest syndrome, stroke, infections by *Str. pneumoniae*, *E. coli* and gram-positive cocci, *salmonella osteomyelitis* and adverse effects of repeated blood transfusion.

Diagnosis: In endemic areas the clinical diagnosis can be easily confirmed by demonstrating the sickling phenomenon. One drop of blood is mixed with an equal volume of 2% sodium metabisulphite solution. A cover slip is applied and the edges are sealed with vaseline. After incubation at 37° for 30 minutes sickle cells are demonstrable. Sickling may occur with other hemoglobins also in some cases, e.g. HbC group and Hb Barts. Electrophoresis of Hb at pH 8.6 shows HbS as a slow-moving band.

Course and prognosis: Majority of severe cases die in childhood before reaching five years of age. Only one-fourth live up to 30 years or more. Acute splenic sequestration, chest syndrome, septicemia, meningitis, stroke and gastroenteritis account for most of the morbidity and deaths. Pregnancy carries increased risk to mother and fetus. By proper transfusions and chelation therapy the risk of stroke can be reduced to 1% annually. Proper transfusion therapy even helps to reduce the narrowing of the cerebral blood vessels. Those with lower levels of HbS develop painful crises and chest syndrome and they may live up to 40-45 years.

Cases with thalassemia with higher levels of HbF live up to 40 years or more and may have only minor episodes of crisis. Their transfusion requirements are also low.

MANAGEMENT

Aim of treatment is to prevent deterioration and avoid crisis. The hemoglobin level should be maintained around 8 g/dL with the hematocrit around 25%. Since folic acid deficiency may develop in a few cases, supplementation of 1 mg folic acid daily is beneficial. Intercurrent infections should be treated promptly. Crises have to be managed as emergencies with rest, sedation, maintenance of fluid and electrolyte balance and blood transfusions.

Blood Transfusion

Indications for blood transfusion
i. Symptomatic episodes of acute anemia and acute sequestration syndromes
ii. Prevention of recurrent strokes in children
iii. Surgery, eye complications

The aim of transfusion is to raise the general level of hemoglobin and also reduce the relative proportion of HbS to below 30%. Partial exchange transfusion may be needed during hemolytic or sickling crises if other methods fail.

In severe cases exchange transfusions and simple transfusions in milder cases are life-saving. In the case of stroke, the exchange transfusion should be adequate to lower HbS level below 30%. Follow up transfusions to prevent rise of HbS above 30% are required. Packed cell transfusions are preferable. The transfused packed cells should be sickle cell negative and preferably leukocyte depleted.

Priapism can be managed by packed cell transfusion and alpha adrenergic agonists like terbutaline. Surgery may be required in resistant cases. Iron overload occurs and this has to be treated with iron chelating agents. This is detailed on pp 1013.

Hydroxyurea (hydroxycarbamide) given in a dose of 500 mg bd orally improves the production of HbF and this helps to reduce the frequency and severity of sickling crisis. Reduction in level of neutrophils and platelets reduces the adhesion of sickled cells to vascular endothelium. The drug also reduces the frequency and severity of painful episodes, hospitalisation, chest syndrome and need for transfusions. Increasing the level of HbF is the most widely studied method to prevent sickling. In addition to hydroxyurea, 5-azacytidine, decitabine, erythropoietin, short chain fatty acid like valproic acid and others are also active in this respect.

Sickling is precipitated by cellular dehydration caused by injury to cell membrane. Substances which modulate the ion transport systems of RBC membrane have been tried. Such drugs include *clotrimazole*, and *magnesium pidolate*. Nitric oxide (NO) has shown anti-sickling activity. A drug which improves blood flow in the microcirculation is *polaxamer*, which a non-ionic surfactant co-polymer.

Bone marrow transplantation is curative in over 70% of cases and this is the only modality which is curative. Bone marrow transplantation is ideal if suitable donors are available. Transplantation of cord blood stem cells is an alternative. **Gene therapy** has been tried with success; but the progress has been slow.

Prophylactic measures: These include: (1) screening of babies born to carriers of HbS, with a view to make an early diagnosis and prevent crises, (2) detection of an affected fetus by amniocentesis, and termination of the pregnancy, and (3) genetic counselling to avoid marriage between heterozygotes.

Since pneumococcal infection leads to septicemia, meningitis and pneumonia in children with sickle cell

disease, long-term penicillin prophylaxis has been tried. Oral penicillin (penicillin V potassium) given in a dose of 125 mg bid introduced before four months of age prevents infection and reduces morbidity and mortality. *Pneumococcal infection* is common to produce crisis in sickle cell anemia and therefore antipneumococcal vaccination should be given.

Thalassemias

In normal intrauterine life fetal hemoglobin made up of alpha and gamma polypeptide chains constitutes more than 95% of the total. After birth there is a switch over to beta globin chains which are produced in progressively increasing amounts, substituting gamma chains, thereby giving rise to the transition from HbF to HbA by the age of six months. Fetal hemoglobin is not as efficient as adult hemoglobin for oxygen transport in postnatal life, though it is ideally suited for the intrauterine environment.

Thalassemias are genetic disorders in which the synthesis of normal polypeptide chains forming adult hemoglobin is suppressed. Though the adult hemoglobin level does not come up, the production of gamma chains subsides, and therefore, the absolute level of HbF falls even though its level may be proportionately higher.

Selective deficiency of one or more polypeptide chains has two consequences.

- 1. Reduction in hemoglobin leading to anemia and exaggerated erythropoiesis.
- 2. Imbalance between alpha and non-alpha chains, which is even more dangerous. In the absence of the complementary globin chains, the normally produced chains form aggregates, precipitate within the cytoplasm, damage cell membranes and leads to premature destruction of cells. In beta thalassemias where beta chains are not formed normally, alpha chains are in excess, and they precipitate in the erythroid precursors to form structures similar to Heinz bodies. True Heinz bodies contain denaturated hemoglobin (alpha 2-beta 2) whereas the precipitates in beta thalassemia contain only alpha chains with some amount of attached heme. In the ordinary case of beta thalassemia only 15-30% of cells escape destruction in the marrow. The condition manifests with varying degrees of severity. In decreasing order of severity they may be classified as *thalassemia major*, *thalassemia intermedia*, *thalassemia minor*, and *thalassemia minima*.

Thalassemia major	In this there are major clinical abnormalities with profound anemia.
Thalassemia intermedia	Anemia is not so severe as to necessitate regular blood transfusion.
Thalassemia minor	This is seen in parents of children with thalassemia major who have genetic

abnormalities and morphological abnormalities in erythrocytes but no anemia.

Thalassemia minima	This is the condition in which the person who is an obligate carrier of the abnormal gene manifests neither anemia nor abnormal erythrocyte morphology.

Another scheme of nomenclature takes into account the polypeptide chain involved. The condition is designated alpha or beta thalassemia if the synthesis of alpha chain or beta chain is depressed respectively. In some cases of beta thalassemia, the adjacent delta chain gene is also affected and this gives rise to delta-beta thalassemia.

Several genetic mechanisms have been shown to be responsible for thalassemia. These are gene deletion, gene loss due to unequal crossover, defective transcription of mRNA, unstable mRNA, and nucleotide mutation leading to premature termination of polypeptide chain synthesis. More than 100 different mutations have been identified giving rise to thalassemia, and therefore, genetically and clinically the disease has a highly varied presentation. The single nucleotide mutation produces defects in transcription, RNA splicing and modification and abnormalities of translation, in beta thalassemia either no beta chains are produced (β^0) or β chain production is only impaired (β^-). In alpha thalassemia there are two main abnormal forms. In alpha+ thalassemia there is deletion of only one alpha chain gene, and therefore, some amount of alpha chains are produced. In α^0 thalassemia both alpha chain genes are deleted and therefore there is no alpha chain formation. In the homozygous state only gamma chains are produced. The gamma chains combine with each other to form Hb Barts (γ^4). In the heterozygous form some alpha chains are produced. Excessive production of beta chains without corresponding production of alpha chains leads to formation of tetramers of beta chains Hb-H (β^4). Interaction of the genes for abnormal hemoglobins and thalassemia gives rise to heterozygous states showing the characteristics of both. Homozygous thalassemia presents as a severe hemolytic anemia, whereas in the heterozygous state beta-thalassemia is asymptomatic or only mildly symptomatic. It is beta thalassemia which is most commonly seen in India.

BETA THALASSEMIA MAJOR
Syn: Cooley's anemia

Also known as homozygous beta thalassemia, this is the most severe form of thalassemia, and is reported from all parts of India. In homozygous β^0 thalassemia, there is no synthesis of beta chains, while in homozygous β^+ thalassemia, beta chains are present, but only in small

amounts. In most cases the formation of gamma chains is also reduced.

Pathogenesis: Due to the absence of beta chain synthesis, the alpha chains which are in excess are precipitated to form inclusions within the erythroid precursors. These alpha globin inclusions lead to impairment of erythroid cell replication, membrane function, migration from bone marrow, and red cell survival. Such cells are selectively destroyed in the bone marrow. Erythropoiesis becomes ineffective and this, in turn, stimulates further erythropoiesis.

The relative excess of alpha chains determines the clinical severity. In those cases in which production of gamma chains continues, some of the alpha chains combine with them to form fetal hemoglobin and such cases are clinically less severe.

Hyperplasia of erythroid marrow leads to skeletal changes, thalassemic facies, increased cardiac output, hyperdynamic heart failure, arthralgia and recurrent fractures. Because of diversion of a major part of the cardiac output to the marrow and consequent hypoperfusion of other parts, muscular development is poor.

There is considerable increase in absorption of iron from the intestines and together with iron introduced by blood transfusion, iron-overload results. On an average 19-21 mg of iron accumulate every day from both sources. The body stores of iron may reach 40-60 g or above. This leads to deposition of iron in several organs such as liver, pancreas, spleen, gonads, heart muscles and others. These organs develop hemosiderosis and dysfunction. Secondary diabetes, hypogonadism and skin pigmentation may develop. Cardiac dysfunction and intractable cardiac failure set in later and this is a major cause of death in those cases which live up to adolescence or more. Serum ferritin is raised to very high levels and this indicates the tissue iron load.

By transfusion of 250 mL erythrocytes 250 mg of elemental iron is introduced into the recipient. The end organ manifestations of iron overload include hepatic cirrhosis, cardiac failure, diabetes mellitus, hypopituitarism and hepatocellular carcinoma. These shorten life expectancy in the same manner as hereditary hemochromatosis. Cirrhosis occurs in β thalassemia when the hepatic iron concentration rises above 15 mg/g (0.268 μ mol/g) dry weight.

CLINICAL FEATURES

The child is quite normal at birth and for the first few weeks or months of life, but anemia appears and gradually increases from the 6th to 24th week. Gross hepatosplenomegaly causes protuberance of the abdomen (Fig. 151.8). The limbs are thin. Overgrowth of malar bones, depression of the nasal bridge, protrusion of the upper row of teeth, and bossing of the frontoparietal regions

Fig. 151.8: Boy aged 4 years. Thalassemia major
Note the gross splenomegaly

contribute to the *classic thalassemia (chipmunk) facies*. There is increased susceptibility to infection. Intercurrent infection may be the presenting complaint, anemia being detected incidentally. Anemia and hepatosplenomegaly increase with time. The hemoglobin level is generally 3-4 g/dL on presentation. Erythrocytes are hypochromic and microcytic with the presence of anisopoikilocytosis, schistocytes, *target cells*, basophilic stippling, and normoblasts (see Fig. 149.10). Presence of target cells in large numbers is suggestive of the diagnosis. Other features indicating hemolysis are the presence of Howell-Jolly bodies, Cabot's rings, and reticulocytosis. Leucocyte count is generally normal but in some cases leukemoid blood picture may occur. Osmotic fragility of red cells is decreased. Marrow is hypercellular with marked erythroid hyperplasia. "Hair-on-end" appearance on skull X-ray and thinning and widening of metacarpal shafts indicate enlargement of marrow tissue. Primary pulmonary arterial hypertension develops in the majority of cases. Main endocrine disturbances include retardation of growth, hypogonadism, osteopenia and osteoporosis. These lead to bone pains and fractures.

Diagnosis: Thalassemia should be looked for in all children showing persistent or progressive anemia, hepatosplenomegaly, and the characteristic facies. Positive family history strengthens the diagnosis. Microcytic hypochromic anemia unresponsive to iron therapy and the presence of numerous target cells and other evidences of hemolysis are strongly suggestive of thalassemia.

The diagnosis is established by estimating the fetal hemoglobin level which forms even up to 80% of the total.

Fetal hemoglobin is easily estimated by alkali denaturation test. Hemoglobin A is considerably diminished. Hemoglobin A₂ may be increased in most of the cases though it can be normal at times. Normal level of hemoglobin A₂ in adults ranges from 1.8-3.2%. The abnormal hemoglobins are identified by electrophoresis in paper, cellulose acetate or starch block, using appropriate buffer solutions. Further identification is done by studying the polypeptide chains. Genetic characterisation is facilitated by gene mapping and DNA splicing techniques or chain synthesis studies using reticulocytes. In iron deficiency anemia which is the commonest cause for hypochromic microcytic anemia in India HbA₂ levels are subnormal. The red cell distribution width (RDW) is small unlike as in iron deficiency anemia in which the RDW is above 17.

Course and prognosis: Children do not survive without adequate blood transfusions. With passage of time hemosiderosis eventually develops. Damage to several organ systems manifests as delayed puberty and maturation, diabetes, cirrhosis of liver, and heart failure. Cardiac failure is the result of accumulation of iron in the myocardium and the increased demands caused by anemia. The majority of patients succumb before the age of 20 years. Ferritin levels below 2000 ng/mL indicate better prognosis. Rise in levels of tissue iron in the liver and the heart is associated with poorer prognosis. *Magnetic susceptibility* is a non-invasive method to measure the iron content of the liver. This investigation is not available in India at present.

In addition to the damage done by tissue iron, non-transferrin bound serum iron is highly toxic since it catalyses the formation of reactive oxygen and leads to tissue damage.

MANAGEMENT

Blood transfusion is the mainstay of therapy. If Hb level is maintained above 10.0 g/dL all the time by regular transfusions, erythroid hyperplasia is suppressed. If the treatment is started early, skeletal deformities are prevented and growth and development continue normally. **Hypertransfusion** is the use of packed red cell transfusion in doses adequate to keep the Hb above 10 g/dL. This method helps to ensure near-normal growth, physical and mental development and sexual maturity. Splenomegaly, cardiac failure, infective episodes, bone marrow hyperplasia and hypogonadism can be prevented. The average requirement of packed cells is 200 mL/kg/year. If hypertransfusion is started around 3 years of age, bony deformities can be prevented and near-normal growth ensured. If the programme is started after 4 years, the catch-up growth may not be complete. Even in ideally transfused subjects the growth lags behind the ideal due to the ill-effects of iron overload.

Supertransfusion programmes aim at keeping the hemoglobin level above 14 g/dL. This allows the bone marrow volume to shrink further. Growth pattern also becomes normal. When the hemoglobin rises, intestinal absorption of iron is reduced.

Refinements in transfusion techniques include the following:

- Proper compatibility testing of ABO and RhD, and matching for other components of Rh system and Kell system
- Use of packed cells within 7 days of collection-This ensures longer survival
- Phenotypically matched donor
- Use of leucocyte depleted packed red cells – this reduces the incidence of non-hemolytic transfusion reactions
- Use of washed packed red cells-this reduces allergic reactions caused by plasma proteins and
- Transfusion of neocytes, which are young red cells selectively harvested and transfused. They have longer in-vivo survival and therefore the number of transfusions and total annual quantity of packed cells are reduced

Iron chelation therapy should be started when the serum ferritin levels reach >2000 ng/mL.

Iron Chelating Agents

These are employed to mobilise tissue iron from iron stores and eliminate it in urine. The original drug **desferrioxamine** is in use for over five decades. It has to be given parenterally preferably as continuous subcutaneous infusion lasting for 8-12 hours at night over the abdominal wall or other regions. Infusion pumps are available. The dose is 1.5-2 g (up to 12g) daily.

Infusions are given 5-6 times a week. Prior administration of 100 mg vitamin C increases the mobilisation of iron and its excretion. The drug is available as Desferal in vials and the daily injection costs Rs. 200-500.

Though generally safe, the adverse effects include local pain and visual and auditory impairment. Posterior capsular cataract may develop in some and it is essential to monitor vision to avoid toxic damage.

Patients with β thalassemia have fewer cardiac related complications, iron overload, and better survival when the serum ferritin is kept below 2500 μ g/L or hepatic iron concentration is kept below 15 mg/g dry weight.

Oral iron chelating agent: l-2-dimethyl-3-hydroxypyrid-4-one (**Deferiprone**) is a good chelator of iron. It is available as 0.5 g tablets and it is given an hour before food. The total dose is up to 100 mg/kg body weight, the average being 2-3 g/day. In short-term studies the drug is safe. Concurrent administration of vitamin C enhances iron excretion. This drug chelates iron selectively without leading to the loss of calcium, zinc and magnesium. Toxic

side effects include agranulocytosis, arthralgia, arthritis and drug induced lupus erythematosus. Daily elimination of iron in urine may reach up to 36 ± 19 mg, if the drug is given daily in a dose of 100 mg/kg body weight. The commercial preparation is Deferiprone. The drug is available as Kelfer, 250 and 500 mg tablets.

Long-term observations on this drug show that even though it eliminates iron, accumulation of hepatic iron is not prevented to the same extent as desferrioxamine. Deferiprone removes myocardial iron effectively. When regular therapy with desferrioxamine is not possible due to economic reasons and lack of facilities, deferiprone is the next best alternative. This drug is also expensive, a day's treatment costing more than Rs. 60.

A newer iron chelating agent is a *tridentate orally active iron chelator (1cL 670)* which is still under trial. When given in a dose of 20 mg/kg body weight it is effective and well tolerated.

Splenectomy is indicated if transfusion requirements exceed 250 mL/kg of packed cells annually.

Bone marrow transplantation (BMT): Allogenic BMT done early in the disease before iron accumulation develops, is effective in curing the disease in over 80% of cases when followed up for 3 years or more. If the procedure is done after siderosis of the liver has started, the cure rates are lower. Facilities for BMT are available on a limited scale in India. The cost is around Rs. 6-10 lacs or more.

Attempts have been made to increase the production of gamma chains, with a view to increase the content of fetal hemoglobin. Drugs such as 5-azacytidine, cytarabine and hydroxyurea have been shown to increase the production. At present these methods have not gained universal acceptance, though individual cases they may show benefit.

Thalassemia Syndromes

In a population where genes for abnormal hemoglobins and thalassemia are present, random mating gives rise to offspring carrying both the abnormal genes. Such double

heterozygosity may lead to HbE thalassemia, HbS thalassemia, and so on. The term thalassemia syndrome is used to include these double heterozygote conditions as well as the classic homozygous thalassemia. The double heterozygote states present with milder manifestations compared to thalassemia major. In such subjects the presence of abnormal hemoglobin as well as the elevation of fetal hemoglobin can be demonstrated by suitable tests.

Lepore Hemoglobins

Lepore hemoglobins are formed when normal alpha chains combine with chains consisting of the N-terminal residues of delta chain and G terminal residues of beta chains. Three variants of Hb Lepore have been identified. In the homozygous state, clinical picture is that of Cooley's anemia, the hemoglobin consisting of 75% HbF and 25% Hb Lepore.

Hereditary Persistence of Fetal Hemoglobin (HPFH)

In this condition the gene for HbF persists beyond the neonatal period, resulting in the production of large amounts of HbF throughout life. The hematological picture varies. In homozygous subjects, HbF constitutes 100% and in heterozygotes it forms about 25%. Except for slight morphological abnormalities of erythrocytes, the clinical picture is almost normal. It is important to distinguish them from thalassemia syndromes which have different courses and prognosis.

Prevention: Considerable progress has been achieved in the treatment and prevention of thalassemia. Chorionic biopsy and amniocentesis done during pregnancy help to make accurate prenatal diagnosis in the fetus at risk. Such pregnancies can be terminated. This is done on a wide scale in many countries where thalassemias are rampant.

Other hemoglobinopathies: Several other hemoglobinopathies have been described from time to time in India. Except HbE these are less common and hence not described in this book. The student should refer to larger monographs for further details.

Anemias Characterized by Defective Erythrocyte Production

K.V. Krishna Das

Chapter Summary

Sideroblastic Anemias 1015
 Paroxysmal Nocturnal Hemoglobinuria (PNH) 1016
 Aplastic Anemia 1017
 Special Forms of Aplastic Anemia 1019

Sideroblastic Anemias

Anemias may result from impaired red cell production due to disorder in the synthesis of heme. The term sideroblast denotes an erythroblast containing one or two stainable iron granules in the cytoplasm. When such stainable iron granules are present in the erythrocyte, it is called *siderocyte*. Even under normal conditions a few of these iron granules may be seen lying free in the cytoplasm without relation to any particular organelle within the cell. But under pathological conditions, iron granules accumulate in the mitochondria and they appear in the form of a perinuclear ring in the late erythroblasts and such cells are called *ringed sideroblasts*. Sometimes pathological non-ringed sideroblasts occur, with excess of free iron granules in the cytoplasm.

Sideroblastic anemias form a heterogeneous group of inherited or acquired disorders characterised by anemia of variable severity, microcytic erythrocytes in peripheral blood and ringed sideroblasts in the bone marrow (Fig. 152.1). Ringed sideroblasts are erythroblasts with large perinuclear Prussian blue positive granules made up of amorphous iron deposits in the mitochondria. The inherited form (hereditary sideroblastic anemia) may occur as an isolated congenital disorder arising from a new mutation, or an autosomal defect, but in most cases it follows an X-linked pattern of inheritance. In many cases the first enzyme required for heme biosynthesis i.e., 5-aminolevulinate synthase which is controlled by a gene located in the X-chromosome is defective.

The acquired form occurs in later life as a clonal disorder in most cases without any obvious etiological factor but some may be drug induced or disease related.

Fig. 152.1: Sideroblastic anemia: Bone marrow × 1000 note ringed sideroblasts (arrow)

In all sideroblastic anemias the synthesis of heme is defective even though the delivery of iron to the mitochondria is normal.

The inherited variety responds to pharmacological doses of pyridoxine.

Etiology: Sideroblastic anemia may be hereditary or acquired. The hereditary form shows a sex-linked inheritance manifesting in males and being transmitted by females. It manifests as a microcytic hypochromic anemia resistant to iron therapy. It follows a benign course.

The acquired form is seen in elderly subjects. In the majority of cases there is no detectable cause but known causes include rheumatoid disease, malignancy, myelosclerosis, chronic myeloid and lymphatic leukemias, acute leukemia, myeloma, polycythemia vera, myxedema, pyridoxine deficiency (nutritional and that induced by antituberculous drugs like INH), alcoholism, lead poisoning, ingestion of drugs like chloramphenicol, cycloserine and rifampicin, and erythrocytic porphyria.

Diagnosis should be suspected when a patient with microcytic hypochromic anemia fails to respond to adequate iron therapy. Diagnosis is established by the demonstration of ringed sideroblasts in the bone marrow stained for iron by Prussian blue reaction. Siderocytes may be seen in peripheral blood (Fig. 152.2).

Fig. 152.2: Sideroblastic anemia peripheral blood $\times 1000$. Note: Siderocytes (RBC containing iron pigment)-arrow Prussian blue stain

Course and prognosis: In secondary causes, prompt clinical improvement occurs on removal of the primary cause. The idiopathic form may be resistant to all forms of therapy. Some cases of idiopathic sideroblastic anemia progress to acute myeloid leukemia and, therefore, this may be considered as one of the preleukemic conditions.

Treatment: The primary cause, if identified, should be rectified. In the presence of overt pyridoxine deficiency small doses of pyridoxine (5-10 mg) are effective. Rarely even in the idiopathic variety large doses of pyridoxine given orally (100-500 mg/daily) are beneficial and, therefore, this should be given a trial. Concomitant folate deficiency should be corrected by oral folic acid 5 mg/day. In resistant cases symptomatic relief can be achieved with regular transfusion of packed erythrocytes.

Paroxysmal Nocturnal Hemoglobinuria (PNH)

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal stem cell disorder which leads to complement mediated haemolysis, deficiency and defect in hematopoiesis, and with a tendency to develop aplastic anemia later. Both sexes are affected. Though more common in middle age, all age groups may be affected. The name is derived from the fact that intravascular hemolysis being at night and hemoglobinuria occur more frequently in the morning intermittently. In addition to hemoglobin, hemosiderin is also present in urine. In PNH a clone of abnormal erythrocytes proliferates and co-exists with other normal erythrocytes. The erythrocyte membrane is abnormal, and several proteins are missing. The genetic defect is somatic mutation of the X-linked gene for phosphatidylinositolglycan protein A (GP1A). This protein is required for the production of glycerylphosphatidylinositol (GPI), which acts as an anchor which tethers several proteins to RBC surface, which protects the red-cell membrane from complement mediated damage. Biosynthesis of GPI is disrupted and this results in the

PNH phenotype. The biosynthetic defect always affects the transfer of glucosamine from UDP-N acetyl glucosamine on to phosphatidyl inositol. PNH is a unique disorder in which an abnormal clone or small number of abnormal clones expand to replace the whole hematopoietic stem cell pool, but they have no malignant potential as evidenced by normal processes and absence of invasion and metastasis.

Other proteins implicated in the pathogenesis of PNH include decay-accelerating factor (CD55) and CD59, absence of which will result in complement mediated red cell lysis.

Absence of complement regulatory protein leads to abnormal sensitivity to complement and results in complement mediated hemolysis. The surface abnormalities can be demonstrated by flow cytometry. The granulocytes also show complement mediated lysis whereas lymphocytes do not. Platelets show increased prothrombinase activity and this results in thrombotic tendencies. The erythrocytes undergo autohemolysis through the complement-mediated pathway with consequent reduction in complement levels.

Clinical Features

The condition presents as chronic anemia with or without jaundice, and splenomegaly.

Abdominal pain, dysphagia due to esophageal spasm, erectile failure and lethargy are attributable to intravascular hemolysis and the presence of haemoglobin in the plasma. Hemolytic episodes may be acute paroxysms or may be chronic. Hemolytic episodes may be precipitated by infections, drugs or transfusion of whole blood. Hemolysis leads to fall in serum levels of nitric oxide and this may be a direct reason for many of the symptoms. Haptoglobin efficiently combines with, and removes free haemoglobin from plasma. In PNH when intense haemolysis occurs the capacity of haptoglobin is exceeded and free hemoglobin circulates. Free hemoglobin is a scavenger of nitric oxide (NO). This avidly combines with nitric oxide NO and the fall in NO levels results in smooth muscle dysfunction and leads to symptoms in an acute paroxysm.

Venous thrombosis occurs in about 50% of cases. The intra-abdominal veins including the hepatic vein, and cerebral veins show predilection.

Other complications may develop during the course of the illness. These include aplastic crises and iron deficiency anemia due to loss of hemosiderin in urine. Presence of hemosiderin in urinary deposit can be demonstrated by Prussian blue staining.

Diagnosis of PNH is confirmed by **Ham's test** and **sucrose lysis test**. In the Ham's test the serum is acidified. PNH erythrocytes undergo accelerated hemolysis compared to normal, since acidification activates complement. PNH cells also show lysis in solution of sucrose. The gold standard diagnostic test is the analysis of GPI- linked molecules on the surface of hemopoietic cells by flow

cytometry. Absence of the CD55, CD59 and other antigens on these cells is diagnostic. Based on the number of missing antigens and their decrease, PNH can be graded as PNH I, PNH II, and PNH III in increasing order of severity.

Prognosis: Survival is 65% at 10 years and 48% at 15 years after diagnosis. Complication rate for pancytopenia, thrombotic events and myelodysplasia is 15%, 25% and 5% respectively when assessed at 8 years after diagnosis. Age above 55 years and occurrence of complications worsen the prognosis. Five percent may progress to develop acute leukemia. 15% may undergo spontaneous remission.

Treatment: In mild cases treatment is supportive with avoidance of offending agents. If hemolysis becomes active and anemia develops, transfusion of washed erythrocytes is given to tide over the crisis. Whole blood transfusion may precipitate a fresh bout of hemolysis due to the introduction of complement in transfused blood. In acute hemolysis corticosteroids may be beneficial. Androgens produce benefit in some. Anticoagulant therapy is indicated if thrombotic complications occur. Life-long anticoagulation may be necessary in a few. Eculizumab, an antibody with high affinity for C5 complement can reduce the hemolytic episodes as shown by clinical trials. Further studies are continuing.

Ref: Peter Hillmen et al The New Eng. J Med. 2006: 355, 1233-43.

Severe form of PNH is an indication for bone marrow transplantation.

Aplastic Anemia

Definition: Anemia resulting from failure to produce the formed elements of blood by the bone marrow is called aplastic anemia (AA). Morphologically in the vast majority of cases, the bone marrow is hypocellular or even totally acellular. Generally all the formed elements are affected though at times the affection may be selective.

Incidence: Aplastic anemia is a rare disorder contributing to 1-2% of the total number of anemias. Males suffer twice as many as females. The disease is primary (idiopathic) in over 75% of cases, in the rest it is secondary to known causes (Table 152.1).

PATHOPHYSIOLOGY

In this disorder the proliferation and differentiation of hemopoietic stem cells are deranged.

- 1. Loss of pluripotent stem cells.
- 2. Dysfunction of progenitor cells.
- 3. Defects in the microenvironment of the marrow.
- 4. Abnormalities of humoral regulators of hematopoiesis.
- 5. Autoimmune inhibition of hematopoiesis

TABLE 152.1 Causes of aplastic anemia	
Primary:	Acquired idiopathic Congenital (Fanconi's)
Secondary:	Chemicals and toxins including drugs
1. Agents which regularly produce bone marrow hypoplasia	
a. Anti-cancer drugs (busulphan, cyclophosphamide, and others)	
b. Ionizing radiations	
c. Benzene and its derivatives	
These damage the stem cell and arrest mitosis. If the damage is not severe, withdrawal of the drug is curative.	
2. Agents that occasionally produce bone marrow hypoplasia: chloramphenicol, sulphonamides, phenylbutazone, gold, thiouracil, anticonvulsants, antidiabetic agents, insecticides, industrial solvents, hair dyes, and several others	
These are not dose related. Many have an immunological basis. Withdrawal of the drug may not improve the marrow aplasia.	
3. Infections: Viral hepatitis (HCV), human parvovirus B19, chickenpox, miliary tuberculosis.	
4. Pregnancy	
5. Thymoma (autoimmune)	
6. Paroxysmal nocturnal hemoglobinuria (PNH)	
7. Systemic disorders such as chronic renal failure, hypothyroidism, and Addison's disease	
8. Autoimmune diseases such as systemic lupus erythematosus	
9. Hemophagocytosis syndrome	

In over 70% of cases, autoimmune processes lead to destruction of hemopoietic stem cells by autoreactive T-cells via Fas ligand in a HLA-DR restricted manner. It is also possible that basic stem cell defects may coexist since AA is more frequent in myelodysplastic syndrome and acute myeloid leukemia. The immune process may be triggered by factors such as viral infection, chemicals or drugs.

The marrow is reduced in volume; often it is yellow due to increase in fat. It is difficult to obtain a specimen and dry taps are common. In an ordinary case all the formed elements are reduced. Megakaryocytes, myeloid elements, and erythroblasts are progressively wiped out resulting in thrombocytopenia, neutropenia, and anemia as the disease evolves. The marrow shows pancytopenia. Unlike as in leukemias there are no abnormal infiltrating cells. There is no increase in reticulin. MRI may reveal the replacement of bone marrow by fat tissue.

In the final stage all cells are uniformly reduced. Due to reduction in granulocytes, the lymphocytes, plasma cells, and other reticuloendothelial cells may appear to be relatively increased.

CLINICAL FEATURES

The disease is insidious in onset. The peak age groups are 10-25 and above 60 years. Symptoms are slow in

onset, taking 1-2 months for manifestation. Sometimes bleeding and infection may set in early. Symptoms are due to the consequences of pancytopenia. Varying grades of anemia develop and often it is severe. Hemorrhagic manifestations occur due to thrombocytopenia. Common presentations are purpura, ecchymosis, epistaxis, bleeding from the gums, gastrointestinal bleeding, and vaginal bleeding. Bacterial infections occur due to neutropenia. These present with fever or other localised infections.

Hematological features: The erythrocytes, granulocytes, and platelets are all reduced, reticulocytes may be absent. In some cases granulocytes may be present in small numbers, but the young forms are considerably reduced. Erythrocytes are normocytic and normochromic with uniform size and shape. The bone marrow shows aplasia or hypoplasia. Stainable iron in the marrow may be increased.

Diagnosis: The picture of peripheral pancytopenia with aplastic bone marrow confirms the diagnosis. Bone marrow biopsy is essential in all cases, since it helps to rule out conditions like acute leukemia, myelodysplastic syndromes, lymphomas, multiple myeloma, and myelofibrosis which may superficially resemble aplastic anemia. Peripheral pancytopenia with normocellular or hypercellular marrow should suggest the possibility of aleukemic leukemia, sideroblastic anemia, dyserythropoietic states, myelodysplastic syndromes and paroxysmal nocturnal hemoglobinuria. Acute myeloid leukemia may be mistaken for aplastic anemia in the initial stages, but presence of splenomegaly is suggestive. Hypoplastic MDS is diagnosed by the presence of cytopenias, hypocellular bone marrow and definite dysgranulopoiesis and dysmegakaryopoiesis in addition to dyserythropoiesis. In AA the marrow is uniformly hypoplastic (Fig. 152.3) whereas it may not be so in MDS. The proportion of CD34+ cells is below 0.3% in AA whereas it is normal (0.5 to 1%) or higher in MDS.

Paroxysmal nocturnal hemoglobinuria (PNH) may lead to clinical AA, this has to be distinguished by appro-

priate tests such as demonstration of hemosiderinuria, Ham's acidified serum test, sucrose lysis test and demonstration of the PNH clone. Some cases of PNH present initially as aplastic anemia, their true nature becomes evident only later during the course.

Differential diagnosis includes thrombocytopenic purpura, agranulocytosis and hemolytic anemia with aplastic crises. In immune thrombocytopenia, the marrow shows increase in the number of megakaryocytes. In agranulocytosis only the granulocyte precursors are diminished. Other elements are normal. In hemolytic anemia with aplastic crises, erythroid precursors are selectively depressed. Pure red cell aplasia has to be distinguished from aplastic anemia. Death is due to severe anemia, bleeding or infection.

Course and prognosis: The course is variable in aplastic anemia and the course may extend for periods ranging from a few months to even years. Severe cases have particularly grave prognosis and the median survival is less than 4 months. Early response to therapy is a favourable sign. About 80% of nonresponding patients die within 3-4 months. Life can be prolonged for several years by proper substitution therapy.

The criteria for assessing severity are given below:

1. Marrow with cellularity below 25% of normal or cellularity below 50% of normal with less than 30% made up of hemopoietic cells.
2. Two of three of the abnormal peripheral blood values:
 - a. granulocytes below $0.5 \times 10^9/L$,
 - b. platelets below $20 \times 10^9/L$, or
 - c. anemia with reticulocytes corrected for hematocrit less than 1%.

MANAGEMENT

This consists of: (1) withdrawal of the offending agents; (2) supportive measures to compensate for the pancytopenia and prevent complications; and (3) positive attempts to restore bone marrow activity. Supportive measures include transfusion of blood or packed red cells, platelets, and granulocytes. The patient should be isolated and care should be taken to prevent cross infection from attendants and endogenous infections by the commensal flora. Infection should be diagnosed early and treated with bactericidal antibiotics.

Effective treatment of primary aplastic anemia consists of two modalities

1. Immunosuppression and
2. Bone marrow transplantation or peripheral blood stem-cell transplantation.

Both are effective in about 70% of cases. Cases which do not respond to immunosuppression may be benefitted by subsequent bone marrow transplantation (BMT).

Fig. 152.3: Aplastic anemia – Bone marrow. Note: (1) Reduction in cellularity (2) Increase in fat spaces and (3) arrow points to a spicule of bone

Immunosuppression : This is the first line of treatment. Antithymocyte globulin (ATG) causes effective immunosuppression. This is the treatment of choice – Both horse ATG and rabbit ATG are available, depending on the source of production.

ATG contains polyclonal IgG₁ antibodies specific to interleukin-2 receptor, which is present on activated lymphocytes. ATG reacts with T-cells, B-cells, NK cells, monocytes macrophages and dendritic cells. It acts on neutrophils and platelets and reduces their levels in blood. Cell migration, adhesion and apoptosis of immunocytes are modulated by ATG to produce profound immunosuppression. This leads to greatly increased susceptibility to infection. The dose is 40 mg/kg/bw IV infusion slowly for 4-14 days or till the lymphocyte count dropped to 200/cmm. Immediate side effects include rigor, rash and dyspnea. Serum sickness like reaction may develop. This is controlled by corticosteroids. Lymphopenia, neutropenia and thrombocytopenia develop later. Infections are common, occurring in about 80%. These have to be anticipated and managed.

Patient has to be nursed with strict aseptic precautions. Adjuvants to ATG include hydrocortisone or methyl prednisolone initially given IV, later replaced by oral corticosteroids. Cyclosporine, given in a dose of 3-4 mg/kg bw orally acts synergistically.

When ATG is not available immunosuppressants like cyclosporine or high dose cyclophosphamide can be given, but success rate is slightly less. Complete response is defined as normalisation of hemoglobin, neutrophil count above 1500/cmm and platelets above 150,000/cmm.

The cost of a course of ATG is around Rs. 150-200000. The Indian experience on the treatment of aplastic anemia using ATG is given in Table 152.2.

ATG manufactured in India is much less expensive than other brands.

Bone marrow transplantation (BMT)- Transplantation of HLA compatible donor marrow is effective in 50-60% of cases of severe AA, especially if the recipient is below 40 years of age. Long-term survival is achieved in those who get successful graft.

Peripheral blood stem cell transplant can be done with success and it is being increasingly used. Whereas severe cases respond only to immunosuppression therapy or BMT, milder cases can be kept reasonably active and asymptomatic by supportive therapy and immunosuppression with high dose cyclophosphamide 0.5-1g/m² body surface once a month. Previously, nonvirilising semisynthetic androgens such as oxymethalone in doses of 2-3 mg/kg bw orally for three months were used. This did produce clinical and hematological benefit in 50-60% of cases, though complete response was not achieved in all patients. Corticosteroids have been used, but at present these modalities are not employed if immunomodulation therapy and/or stem cell restitution is available.

Vast majority of mild and moderate cases respond partially, to reach symptom-free state, and they are able to lead almost normal lives. Some of them get cured on long-term follow up. Therefore the prognosis in such cases has to be guarded.

Secondary aplastic anemia may respond to the treatment of the primary condition and appropriate use of hematopoietic cytokines.

Points to remember

1. AA is not uncommon in India
2. Precise diagnosis of the type and possible mechanism is essential for proper management
3. Severe AA is as fatal as acute leukemia, if untreated. Immunosuppressive therapy, appropriate replacement of blood cell components and marrow transplantation are highly successful.

Special Forms of Aplastic Anemia

The term constitutional aplastic anemia is used to denote congenital, genetic, or familial aplastic anemias.

Fanconi's Anemia

Syn: Congenital pancytopenia

In this syndrome congenital abnormalities like hyperpigmentation, absence or hypoplasia of the thumbs and radii, strabismus, mental retardation, deafness and dwarfism are seen. Pancytopenia and bone marrow hypoplasia develop by the age of 5-10 years. Untreated, the mortality is high (Fig. 152.4).

Fanconi's anemia (FA) is an autosomal recessive disorder characterised by developmental abnormalities, bone marrow failure and cancer predisposition; especially squamous cell carcinoma and acute myeloid leukemia.

It is usually lethal by the age of 20 years. The underlying defect in Fanconi's anemia is not fully known. Cultured fibroblasts from these patients show increased generation time and increased cell death. More than 8 groups of FA have been distinguished genetically (termed FA-A to H), each carrying a distinct genetic lesion. Germ

TABLE 152.2

Showing Indian experience in the treatment of aplastic anemia

Therapy	Response in ordinary cases	Response in severe AA
ATG alone	40.2%	30.6%
ATG + cyclosporine	68.5%	58.7%
Cyclosporine alone	28.3%	16.2%

Ref: Agarwall MB ATG (Thymogam) - The Indian experience; Haemato-oncoscan 2005, published by Bombay Hospital-Mumbai 2005

Fig. 152.4: Fanconi's anemia, boy aged 12
Note hypoplastic thumb left hand

Fig. 152.5: Bone marrow pure red cell aplasia
Note the reduction in erythrocyte precursors

line mutations in six different genes have been identified. Cell lines established from FA patients show two unique characteristics

1. Accumulation of broken and mishapen chromosomes that originate from DNA replication.
2. Increased sensitivity to the action of DNA cross linking agents like mitomycin-C which trigger chromosomal abnormalities.

Leukopenia and thrombocytopenia precede pancytopenia. Fetal hemoglobin level is elevated.

The diagnostic laboratory test is the chromosomal breakage analysis using metaphase preparations of phytohemagglutinin stimulated peripheral blood lymphocytes. Spontaneous chromosome breakages are demonstrable in up to 70% of lymphocytes and 25-50% fibroblasts. Such an abnormality is not present in Diamond-Blackfan syndrome. Prenatal diagnosis is possible by chromosome breakage studies done by chorionic villus sampling at 9-12 weeks gestation, amniocentesis at 16 weeks or by fetal blood sampling done later.

Treatment

Anabolic Steroids

Mild cases may benefit by the administration of anabolic agents such as oxymethalone 2-3 mg/kg bw given orally for 2-3 months. Adverse side effects such as virilisation and fluid retention may develop. Blood component therapy may be required for symptom relief. Bone marrow transplantation from HLA matched normal donors is curative. Umbilical cord blood is a good source of stem cells for transplantation.

PURE RED CELL APLASIA

This is a rare form of aplasia selectively affecting the erythroid precursors, reticulocytes and red cells; the other formed elements and their precursors being normal. Usually the onset is insidious. If red cell aplasia supervenes on hemolytic states where the life-span of the

red cell is considerably shortened the onset is much more rapid and the condition is more serious. This is what happens in sickle cell anemia and other acquired or inherited hemolytic anemias when aplastic crises develop as a result of parvovirus B19 infection.

The patient presents with severe anemia without any bleeding tendencies or infective episodes. Reticulocytes are very low, often absent. Bone marrow shows pure aplasia of the erythrocyte progenitors (Fig. 152.5). Most cases are transient and they recover spontaneously or with treatment. Some follow a prolonged course and end fatally.

Etiology: Majority of cases are immune mediated and various autoimmune mechanisms have been postulated. Antibodies against erythroblasts and erythropoietin may develop and selectively suppress and destroy them. T-cells may produce selective cytokines inhibiting erythroid precursors or leading to their lysis. Another mechanism is loss of MHC class 1 expression on the erythroid progenitor cells which become increasingly susceptible to destruction by NK-T lymphocytes. Autoimmune PRCA may be primary (idiopathic) or secondary. Secondary PRCA may be due to:

- a. Infections —parvovirus B19, AIDS
- b. Autoimmune diseases like rheumatoid disease and systemic lupus erythematosus
- c. Neoplasms such as thymoma, lymphoma or carcinoma
- d. PRCA may be a preleukemic or pre myelodysplastic manifestation and
- e. PRCA may be drug induced

Prolonged use of erythropoietin in chronic renal failure may lead to development of neutralising antibody against erythropoietin, by about one year after the start of therapy. These cases present as PRCA. Treatment with corticosteroids, other immunosuppressant and IV immunoglobulins is successful.

Occasionally ABO incompatibility between donor and recipient of bone marrow transplantation or stem cell transplant can lead to antibody mediated PRCA.

PRCA has to be differentiated from aplastic anemia, in which all the blood cell precursors are affected. Early stages of myelodysplastic syndrome may produce diagnostic difficulty. In MDS, dysplasia is evident in all cell lines.

Management: Transient cases are self-limiting in prolonged anemia with evidence of parvovirus infection and immunological processes, steroids, immunosuppressants such as cyclosporine or mycophenolate mofetil are beneficial. In intractable cases intravenous immunoglobulin in a dose of 0.4g/kg bw for 6-8 days is effective. In those with thymoma, thymectomy is curative. In those with other underlying disorders, treatment of the primary disease relieves the PRCA as well.

RED CELL APLASIA IN CHILDREN

Syn: *Diamond-Blackfan anemia, Congenital hypoplastic anemia, Chronic congenital aregenerative anemia, Erythrogenesis imperfecta.*

This is a form of congenital anemia developing in infancy or in early childhood. The children develop normocytic anemia (at times macrocytic) caused by selective aplasia of erythroid precursors beyond the stage

of pro-erythroblasts, and reticulocytopenia. Leucocyte and platelet counts and their precursors are generally normal. 75% of cases are sporadic, 25% show inheritance patterns. Both dominant and recessive inheritance has been identified. Chromosomal abnormalities, mainly involving chromosomes 19 and 13 (translocation or deletions) have been reported. Congenital abnormalities occur in about 30%. These include short stature, atrial or ventricular septal defects, urogenital abnormalities, facial abnormalities and others. Fetal hemoglobin level may be increased.

Management consists of symptomatic measures in mild cases. Severe cases require bone marrow or stem cell transplantation.

Transient Erythroblastopenia of Childhood (TEC)

This is an acquired form of PRCA in previously healthy children. TEC occurs in children older in age than Diamond-Blackfan anemia even though the majority is below one year of age. Possible causes include viral infections, or autoimmune mechanisms as in adults. The condition is generally benign with spontaneous recovery within 4-8 weeks. Management is symptomatic.

Blood Transfusion

K.V. Krishna Das

Chapter Summary

General Considerations	1021
Blood Group Systems	1022
Blood Bank Procedures	1023
Indications for Transfusion	1024
Hazards of Transfusion Therapy	1025
Cord Blood Transfusion	1027
Blood Substitutes	1027
Stem Cell Transplantation	1027

General Considerations

Transfusion medicine has become a major speciality encompassing several subspecialties such as immunohematology, blood banking, component preparation, genetic studies and so on. Many of the present day state-of-the-art technologies such as complicated cardiac surgery, other major surgical procedure, traumatology, organ transplantation, cancer chemotherapy, management of haematological and immunological disorders, prenatal and neonatal interventions and several

15

others owe their existence and development to sound transfusion medicine practices. The present day problems of transfusion transmitted infections including AIDS have given further impetus to the growth of this speciality.

Blood Group Antigens

The outstanding landmark in the history of blood transfusion is the discovery of human *ABO blood group system* in 1900 by Landsteiner. He differentiated human blood into four distinct groups on the basis of two antigens A and B.

Following the discovery of the ABO system in 1900. Landsteiner and co-workers described further blood group systems. The human MN and P antigens were described, but those systems seemed to have only little clinical importance. In 1937, Landsteiner and Wiener discovered the rhesus factor by a new method.

Subsequent workers have identified several other antigens present on the red cell surface and these form the basis of blood grouping.

On the basis of different antigens about 15 different red cell blood group systems are known with wide distribution in different radical groups. These are ABO, MNSs, P, Rh, Lutheran, Kell, Lewis, Duffy, Kidd, Diego, Yt, Xg, Ii, Dombrack, and Cotton system. Except Xg system which is determined by genes on the X chromosome all the others are determined by genes located on autosomes.

Among all the different blood group antigens ABO system and Rh system are the most important in clinical transfusion practice. The others which are less prevalent assume importance when dealing with hemolytic states developing in multiply transfused individuals and while cross-matching blood for patients who may require life-long transfusion therapy.

Antibodies

Two types of antibodies against red cell antigens occur. These include:

- 1. **Naturally occurring antibodies:** which develop even without external antigenic stimulus, e.g. anti-A and anti B. These antibodies which are present in the serum are directed against antigens which are not present on the red cells of the same individual.
- 2. **Immune or acquired antibodies:** These develop as a result of immunisation by a red cell antigen which is foreign to the same individual. These develop as a result of mismatched transfusion or pregnancy, e.g. Rh antibodies, ABO antibodies. All red blood cell antigens are capable of stimulating antibody production, but some such as Rh antigen are more powerful than others.

In addition to red cell antigens other immunising antigens such as tetanus toxoid, TAB vaccine,

pneumococcal vaccine and others which contain substances closely mimicking A and B antigen do stimulate the production of immune anti-A and anti-B antibodies. These assume clinical importance in persons who have been repeatedly immunised against infections.

Naturally occurring red cell antibodies belong to IgM class and they react best at temperature below 37°C. In contrast immune antibodies are mainly IgG or IgM and their optimal temperature for reaction is 37°C. Immune antibodies produced early during the process of immunisation are IgM class, whereas the antibodies produced long-term are IgG. IgM does not cross the placenta whereas IgG readily crosses it.

Antibodies are detected in the laboratory by four types of tests:

- 1. Saline agglutination
- 2. Agglutination in colloid solutions-albumin
- 3. Tests using enzyme treated cells
- 4. Indirect antiglobulin test (Coombs')

Complete antibodies are detectable by saline agglutination. Incomplete antibodies are detectable by the other three methods. The various immune antibodies behave differently in the various tests. Their detection and cross-matching in their presence involve very delicate and highly developed laboratory techniques.

Blood group systems form the cornerstone of transfusion medicine. The study of blood groups help to:

- 1. Perform blood banking
- 2. For anthropological studies
- 3. Performance of medicolegal investigations in paternity disputes, and
- 4. To correlate with prediction of diseases. Several diseases show associations with particular blood groups (Table 153.1).

TABLE 153.1
Distribution of ABO blood groups in the Caucasian population and Indians

Blood group	Caucasian	Indian
O	47%	40%
A	42%	22%
B	8%	33%
AB	3%	5%

Blood Group Systems

ABO system: This comprises of the four main blood groups A, B, AB and O designated according to the presence or absence of A or B antigens on the red cell surface. In the O group there is neither A nor B antigen. In addition to the presence of the antigen on the red cell surface, in the natural state itself the plasma contains antibodies against the A or B antigen that is not naturally present in the same individual (Table 153.2).

TABLE 153.2

Antigens and antibodies present in each of the four main groups of the ABO system		
Blood group	Antigen in red cell	Antibodies in plasma
O	Nil	Anti-A, anti-B
A	A	anti-B
B	B	anti-A
AB	A and B	Nil

The formation of the A and B antigen is controlled by three allelic genes A, B and D located on the long arm of chromosome 9. The A and B genes are codominant. O gene is an amorph (i.e.) it has no effect on antigenic structure. Another gene, the H gene controls the formation of a precursor H substance which is present in the serum. Action of A and B genes leads to the formation of A and B antigen and in the process the H-substance is consumed. The O genes does not act on the H substance therefore O group individuals have higher levels of H-substance in the serum. Conversely AB group individuals have the lowest levels of H-substance. Very rarely some O group subjects not possessing the H-substance in the serum develop antibodies against H-substance as well. There are several subgroups of A, among which A₁ and A₂ are important. 80% of A group subjects possess A₁ and 20% possess A₂. Correspondingly AB subjects also fall into the subgroups A₁B and A₂B. Compared to A₁, A₂ cells react only weakly with the antiserum. It is therefore necessary to use strong antisera which will agglutinate both A₁ and A₂ cells in order to detect A₂ subtypes. Rarely A₂ subgroups persons may produce anti-A₁ antibody which can destroy transfused A₁ cells.

The Bombay blood group: O group individuals normally possess serum antibodies against A and B antigens only. O group individuals who have antibodies against H-substance are designated as the Bombay blood group, being described first by H.M. Bhatia and his colleagues from the Blood Group Reference Centre, Bombay.

Secretors are individuals who secrete these blood group substances or antigens in the body secretions (80%) whereas non-secretors are those who do not secrete blood group antigens in body secretions (20%). For purposes of testing saliva is examined (Table 153.3).

TABLE 153.3

The specific ABH substances present in the saliva of secretors	
ABO group of red cells	Soluble antigen in saliva
O	H
A	A and H
B	B and H
AB	A, B and H

Rhesus system (Rh system): Next in importance to the ABO system are the Rh antigens. The Rh antigens (C, c, D, d, E and e) are inherited through three closely linked allelic genes C or c, D or d and E or e, located on chromosome 1. One set of three genes is inherited from each parent giving rise to various combinations of genotypes e.g. CDE/CDE or CDe/CDe. The antigens produced by the genes are given similar notations. All the genes except d express their corresponding antigens, while 'd' being an amorph, there is no 'd' antigen.

Among these antigens the presence or absence of D antigen is most important and Rh+ and Rh-ve are decided by the presence or absence of 'D' antigen.

Among caucasians 85% are Rh positive and 15% are Rh-ve. Among Indians 4-10% (average 7) are Rh -ve. A study from Bangalore in 2001 gave the prevalence of Rh +ve as 94.25% and Rh -ve as 5.75%.

Unlike the ABO blood groups antibodies to the missing Rh-antigens do not occur naturally, but Rh-ve persons can be allo-immunised to produce anti-Rh antibodies on challenge with the foreign Rh antigen obtained either through transfusion or during pregnancy, See Rh hemolytic disease pp 1002.

Leukocyte groups: HLA antigens are present on the surface of granulocytes and lymphocytes. ABO antigens may be present on lymphocytes and possibly, granulocytes, in very small quantities.

Platelet groups: ABO, HLA-A, HLA-B, and HLA-C are present on platelet surface in addition to several other platelet specific antigens. Platelet antibodies may be detectable in multitransfused persons and these shorten the life-span of transfused platelets.

Lewis system: These antigens are glycosphingolipids which are produced in the plasma and are absorbed to the red cell surface. There are two subtypes Le-a and Le-b. Though they are independent systems, often they interact with other systems. This system does not lead to hemolytic diseases of the newborn.

Ii blood group system: This system consists of two antigen I and i. At birth the neonatal red cells are rich in i antigen and are low in I. There is a gradual change over from i to I antigen up to the age of 2 years. In some persons this change over may not take place and i antigen predominates. In hemoglobinopathies and dyshemopoietic states also, the red cells may contain more of i antigen.

MNS system: This system is made use of for anthropological and genetic studies and for medicolegal purposes. This group is not generally responsible for hemolytic anemia.

Blood Bank Procedures

These include: (1) Collection of blood, (2) preservation of blood, (3) separation of components, (4) cross-matching, and (5) monitoring the adverse reactions.

At present blood is collected in citrate phosphate dextrose with adenine (CPD A₁) solution. In this medium the blood can be stored for 35 days.

ABO and Rh groupings may be done by slide method, tube method, or tile method using specific known antisera and red cells. Detection of incomplete antibodies in the serum and red cells is done by the indirect Coombs' test and direct Coombs' test respectively.

Indirect Coombs' test: This is used for detecting the presence of incomplete antibodies in the serum, e.g. Rh antibodies or antibodies in autoimmune hemolytic anemia. The test serum is incubated with saline washed O group Rh positive cells for one hour at 37°C, washed, and a 2% suspension of the sensitised washed red cells is made. One drop of washed cell is mixed with one drop of Coombs' serum and examined for agglutination by microscopy. A positive test indicates the presence of antibody in the test serum.

Direct Coombs' test: It is done to find out whether the cells are already sensitised by an incomplete antibody *in vivo*. The washed red cells are suspended in saline and one drop of Coombs' serum is added to one drop of red cell suspension. Agglutination indicates that the cells are already sensitised by the antibodies *in vivo*.

Indications for Transfusion (Table 153.4)

- 1. Replacement of whole blood—Sudden loss of 30% of the blood volume (1.5 L) demands urgent replacement.
- 2. Specific components are indicated under special circumstances when there is selective deficiency of these components.

Examples

Anemia	Packed erythrocytes
Thrombocytopenia	Platelets
Fibrinogenopenia	Fibrinogen
Hypogammaglobulinemia	Gammaglobulin
Hypoalbuminemia	Albumin
Deficiency of clotting factors	Coagulation factor concentrates

Many of the coagulation factors are produced by recombinant DNA technology at present.

Present policy is to separate blood into its components such as erythrocytes, plasma, coagulation factor concentrates, platelets and fibrinogen and give them selectively when indicated. These components are useful for specific indications. Whole blood is given mainly for replacement of extravasated blood. Plasma fractions are coagulation factor concentrates, immunoglobulins, and albumin. In many situations specific component therapy is more effective and safer than whole blood. Component therapy serves to raise the missing coagulation factor rapidly and predictably with a small volume of the concentrated material. In many cases the exact dose to be transfused can be calculated so that the coagulation factor level can be raised to the desired level and maintained for long periods depending on the specific requirement.

Collected whole blood retains all the stable coagulation factors for 7 days. The labile factors disappear rapidly and only 30% of factors V and VIII will be present in stored blood. RBC maintains their oxygen carrying capacity for 7-10 days, after which the oxygen dissociation curve shifts to the left due to reduction in the levels of diphosphoglycerate. Platelets lose their viability rapidly, unless stored under special conditions. Granulocytes undergo degeneration and become non-functional after 24 hours (Table 153.5).

The term '**massive transfusion**' refers to the transfusion equal to the patient's blood volume within 24 hours.

At present donor blood is collected in polythene bags. By using appropriate bags a single unit of blood can be fractionated into packed red cells, platelet concentrates and plasma. From the plasma further preparations such as cryoprecipitate, fibrinogen and coagulation factors are produced. Erythrocyte fraction is also processed further.

Erythrocyte Preparations

- 1. Packed cells with or without the buffy coat
- 2. Partially packed red cells
- 3. Washed red cells
- 4. Frozen red cells
- 5. Leukocyte-poor and platelet-poor red cells

TABLE 153.4

Blood components: Use and abuse		
Component	Indications	Abuse
Red cells	To increase oxygen carrying capacity in anemic patients	a. as a volume expander b. to improve general "well-being"
Platelets	To control or prevent bleeding associated with deficiencies in platelet number or function	a. Routine treatment of immune thrombocytopenic purpura b. Prophylactically in other conditions
Fresh frozen plasma	As a replacement of clotting factors when specific deficiency is demonstrated	As a simple volume expander

TABLE 153.5

The storage requirements and shelf-life of blood products

Blood product	Storage specification	Shelf-life
1. Red cells	2-6°C	35 days
2. Frozen red cells (reconstituted)	2-6°C	24 hours
3. Washed red cells	2-6°C	6 hours
4. Granulocyte concentrates	Room temperature	24 hours
5. Platelet concentrates	Room temperature with agitation	5 days
6. Fresh frozen plasma	-20-40°C	12 months
7. Cryoprecipitate	-20-40°C	12 months

Platelets: These are frequently used to tide over periods of thrombocytopenia occurring during anti-cancer chemotherapy, naturally occurring disease such as thrombocytopenia and thrombocytopathy and to prevent excessive bleeding during and after surgery on thrombocytopenic individuals.

The original method was to concentrate platelets by centrifugation of freshly collected blood. This preparation has the disadvantage of lower yield of platelets and presence of excessive amounts of leukocytes and plasma. Moreover several donors have to be recruited for optimal therapy.

Present method is to separate platelets by apheresis in a cell separator from a single donor. On an average 5×10^{11} platelets are removed in each sitting. Platelets lose their ability to aggregate if stored at refrigerator temperature. They can be stored at room temperature for up to five days with constant shaking in order to facilitate gas exchange. Infused platelets may remain viable in the system for short periods. Presence of antibodies directed against class I HLA antigens on platelet surface, or specific antiplatelet allo-antibodies developing as a result of repeated transfusions result in rapid destruction of transfused platelets.

This can be avoided to some extent by making the platelet concentrate as pure as possible without admixture of leukocytes. Another method is to expose the platelet concentrate to ultraviolet light, which inhibits lymphocyte function while sparing platelet function.

Indications for Platelet Transfusion

- 1. Prophylactic in bleeding thrombocytopenic patients when the platelet count is < 50000/cmm
- 2. In head injury when platelet count is < 100000/cmm
- 3. ITP when other measures do not help to bring up the platelet count and arrest bleeding
- 4. ITP with pregnancy when the maternal and fetal platelet counts are low

- 5. In cancer chemotherapy when iatrogenic thrombocytopenia is likely
- 6. In leukemia patients when platelets count is < 20000/cmm.

Platelets can be administered as platelet concentrates obtained by apheresis using a cell separator from single donor or as platelet rich plasma (PRP). 1 unit of PRP raises the platelet count by 5000-10000/cmm. 1 unit of platelet concentrate obtained by apheresis is equivalent to 6-8 units of PRP.

Fresh frozen plasma (FFP): This is prepared from fresh blood by separating and freezing the plasma within 6 hours. It can be stored at -20°C or below for up to one year. The volume of one unit of FFP is 200-250 mL. It contains mainly factors V and VIII, but other factors as well. It is indicated for bleeding in multiple coagulopathies, liver disease, DIC, and bleeding due to massive blood transfusion as a first time therapy.

Cryoprecipitate: This is prepared from single donor plasma, by controlled precipitation from fresh plasma, at 4°C. It is rich in factors VIII, von Willebrand's factor, factor XIII, fibrinogen and fibronectin. Before transfusion it is thawed at 30°C. 1 mL of cryoprecipitate contains 10 units of factor VIII compared to 1 unit/mL in FFP. The dose of cryoprecipitate is 1 unit for every 10 kg body weight.

Plasmapheresis: In this process only plasma is removed from the donor. Plasmapheresis can be used as a therapeutic measure to treat circulatory overload, hyperviscosity syndromes, or for removal of circulating immunoglobulins and immune complexes. This method is also employed to obtain high titre immune globulins from suitable subjects.

Hazards of Transfusion Therapy

Febrile reactions: These are caused by pyrogenic substances present in the material or in the infusion set. Sometimes these indicate bacterial contamination.

Allergic manifestations: Allergic reactions like urticaria and edema may occur due to antigen antibody reactions.

Bacterial contamination: If the blood is heavily infected, severe reactions set in even with the introduction of a small quantity of blood. Shock may ensue which may be followed by disseminated intravascular coagulation (DIC).

Mechanical complications: Circulatory overloading, air embolism, thrombophlebitis and pulmonary embolism may develop if the infusion is not carefully supervised.

Metabolic complications: These develop due to citrate toxicity, potassium toxicity, toxic substances eluted from synthetic containers, and vasoactive substances, especially after massive transfusion.

Hemolytic reactions: These reactions usually develop due to the presence of incompatible antibody in the recipient's plasma which cause destruction of donor red cells. Less commonly potent antibodies such as anti-A or anti-B present in donor plasma may react with the homologous antigens present in the recipient's red cells and provoke hemolysis.

Hemorrhagic reaction: This complication may be encountered after massive transfusions using stored blood.

Immune reactions: Various types of immunological reactions may develop varying in severity from fatal to mild symptoms. Among this, hemolytic reactions due to transfusion of incompatible blood or hemolysed blood are the most common. This manifests with pain in the back, dyspnea, and circulatory collapse. At times persistent hypotension may be the only finding. In severe cases jaundice, hemoglobinuria, and anuria develop within 24 h. Renal failure may be fatal. Rarely DIC may follow ABO incompatibility.

Non-hemolytic reactions: These may vary from simple allergic reactions to fatal anaphylaxis. Antibodies to drugs such as penicillin may be present in the donor's blood causing allergic reactions in the recipient.

Transmission of disease: Several diseases are transmitted by blood. These are hepatitis viruses (virus B, hepatitis C and others), cytomegalovirus, EB virus, syphilis, brucellosis, malaria, trypanosomiasis, and acquired immunodeficiency syndrome (AIDS). HCV seropositivity among blood donors in Punjab was 0.78% and that of HBs Ag was 1.7%. The infectivity of *T. pallidum* is lost on storing the blood at 4°C for five days or more. Detection of infection in the donor should exclude him from blood donation. Most of the blood banks in India insist on tests for syphilis, viral hepatitis and AIDS. Recent reports from several parts of India show a downward trend in the prevalence of hepatitis B and C, HIV and syphilis.

occasions at 5 days interval when estimated at 14-180 days after the transfusion.

3. Other viruses: Human T-cell lymphotropic virus (HTLV) I and II, cytomegalovirus (CMV).
4. Parasitic infections: Malaria, trypanosomiasis, toxoplasmosis, babesiosis.
5. Bacterial infections: *Yersinia enterocolitica*, *Staph. epidermidis*, *Bacillus cereus*, syphilis and others.
T. pallidum can remain viable in refrigerated blood for up to 5 days.

The risk of infection from needle stick injuries to medical personnel handling infective blood is given below:

HIV	3/1000
HBV	30%
HCV	1.2-10%

The rates are much higher if infected blood is transfused.

Apart from extreme care in selecting donors, proper methods to sterilise the equipment are absolutely essential to avoid microbial contamination of the blood and blood products and infection of the medical and laboratory personnel. Common norms to be followed include:

1. Proper handwashing before and after handling every patient.
2. Use of protective gloves.
3. Use of mask and eye-protectors when blood or body fluids are likely to splash.
4. Handling all infective fluids and tissues with the same precautions as for blood, e.g., semen, vaginal and cervical secretions, amniotic fluid, cerebrospinal fluid, other aspirated fluids, saliva, tissues and organs including the cornea.

Disinfection

Most of the disinfectants available in India are capable of destroying almost all microbes including HIV, if used properly. Since blood and tissue fluids will protect the microbes embedded within them, they have to be properly cleaned before applying the chemical disinfectant. The following disinfectants are amply effective in the recommended dosage.

1. Chlorine releasing compounds.
2. Iodine compounds—povidine iodine 1% strength.
3. Ethyl alcohol 70% (denatured spirit)
4. Cetrime (Savlon) 1/1000 solution.
5. Dichloroxylenol (Dettol) 1.5% solution.

Gamma Irradiation of Blood

Transfusion associated graft-vs-host disease is a rare immunological complication caused by the presence of immunocompetent T-lymphocytes in the donor blood. Gamma irradiation of blood and blood products prevents this complication.

Transfusion Transmitted Diseases

1. **Viral infections**
 - a. Human immunodeficiency virus HIV I and HIV II.
Data from Delhi gave seroprevalence for HIV rate as 0.71 to 0.77% for blood donors. In Trivandrum the seroprevalence of HIV is 0.2%. In Punjab it was 0.26%.
2. **Hepatitis viruses**

All the hepatitis viruses HBV, HCV, delta virus, HAV, HGV and HEV can be transmitted. HBV and HCV are clinically the most important in this group. The approximate risk for transfusion associated hepatitis in India for HBV is 0.07% and for HCV is 0.04%. Transfusion associated hepatitis (TAH) should be diagnosed if there is elevation of SGPT levels in the recipient to 1.5 times the normal value or more, on two

Hemosiderosis: In subjects receiving repeated transfusions iron overload may occur leading to deposition of iron in reticuloendothelial and parenchymal tissue. Usually this complication is seen in persons who have received 100 units or more of blood.

Each unit of 250 mL of erythrocytes introduces 250 mg of elemental iron into the recipient. The end organ manifestations of iron overload include cirrhosis, hepatocellular carcinoma, cardiac failure, diabetes mellitus and hypothyroidism.

Autotransfusion: This is the use of blood collected from the patient for use at a subsequent occasion such as selective surgery. Several units of blood can be collected from the patient at regular intervals preceding the surgical procedure, to be used at the time of need. Stimulation of erythropoiesis by erythropoietin and nutritional supplements helps to increase the yield of blood. Autotransfusion is safe and it is free from several of the drawbacks of external blood.

Any reaction occurring in the patient within 48 h of transfusion should be reported to the blood bank. Whenever there are good grounds for suspecting any untoward reaction the transfusion should be discontinued, and the patient should be monitored. The blood sample should be taken for tests.

CORD BLOOD TRANSFUSION

Use of blood collected from the umbilical cord after delivery as a source of stem cells has become an established procedure within the past 15 years. Cord blood contains large number of granulocyte-macrophage progenitor stem cells, sufficient enough to re-populate marrows of irradiated subjects. This has paved the way for organised cord blood banking. There are several blood banks undertaking storage and delivery of cord blood, all over the developed countries. In India there are a few privately-owned cord blood banks. Cord blood can be cryopreserved in the viable state for many years. The services provided include:

1. Use of cord blood as a source of stem cells and
2. Preservation of the cord blood indefinitely for long periods, for use in the same individual if a need for stem cells arises. The donor is charged for this service.

Uses of Cord Blood

1. Allogenic transplant
2. Autologous transplant
3. As a source of pluripotent stem cells for reconstitution and repair of damaged tissues such as the heart, after myocardial infarction.

The immunological properties of cord blood stem cells differ from those of adult marrow or peripheral blood.

Cord blood contains a higher proportion of T-cells expressing (C D 45 R A +/ C D 45 R A O-) and

CD 62 L+. These cells are immunologically naive and therefore graft versus host disease is less common. The chemokine receptor C C R5 expressed by Th-1 T lymphocytes is less abundant in cord blood T-cells compared to adult T-cells.

Cord Blood Banking

Pregnant women are recruited as donors after obtaining informed consent, and excluding common communicable diseases. Blood is collected from the placental side of the severed umbilical cord either in utero before the delivery of the placenta or ex-utero after its delivery. Long-term storage is done under temperatures below -180°C and released for use on demand after proper cross-matching.

Indications for Cord Blood Transfusions

- a. Stem cell replenishment in hematological malignancies—acute leukemias, chronic myeloid leukemia and myelodysplastic syndrome.
- b. Non-malignant conditions—aplastic anemia, thalassemias, hemoglobinopathies, immunodeficiency states.

Advantages of cord blood are its availability, lower incidence of graft versus host disease (GVHD) and good success rate even if mismatched for two antigens. The waiting period for transplantation is also shorter. Disadvantages are the higher infection rates with cord blood stem cells, compared to preparations from bone marrow or peripheral blood from adult donors.

Future strategies for improving the service include:

1. Pooling of cord blood
2. Cord blood expansion using cytokines which stimulate stem cell proliferation
3. Combining cord blood and haplo-identical bone marrow transplants
4. Non myeloablative or reduced intensity conditioning regimen.

BLOOD SUBSTITUTES

Several attempts have been made from time-to-time to find out substitutes for blood, (i.e.) fluid media which can transport oxygen from the lungs to the tissues and remove carbon dioxide. Perfluorocarbon compounds have the property to transport oxygen and carbon dioxide and these are under study. Hemoglobin solutions have also been studied for this purpose. It may not be long before blood substitutes are available for clinical use on a wider scale.

STEM CELL TRANSPLANTATION

Stem cells are capable of pluripotent differentiation when exposed to the appropriate chemical or biological influences, both in vivo and in vitro. Such cells are present in several tissues in the body such as the bone marrow,

peripheral blood, skin, periodontal ligament of teeth sockets and others. When transplanted, these cells can reconstitute the cell population of several organs such as the hemopoietic tissue of bone marrow, myocardium, neural tissue, immunocytes, periodontal ligament and others. Stem cells have the unique property of self-perpetuation (i.e.) a proportion of the stem cell pool remain in the pluripotent phase without differentiation, and these proliferate and help to perpetuate these primordial capabilities, without decline.

Sources of stem cells include bone marrow, peripheral blood, umbilical cord blood, fetal organs and artificially produced human embryos in vitro. Active research is going on in several countries on the potential use and production of stem cells.

Mainly stem cells are used for haematological disorders such as aplastic anemia, leukemia, myeloma, thalassemias, hemoglobinopathies, congenital immunodeficiency

syndromes, inherited disorders of metabolism and for repopulating the marrow after intensive chemotherapy for malignancies.

Stem cells have been used for the treatment of non-haematological diseases as well. There include:

1. Intra-coronary infusion of stem cells for restoration of function of ischemic myocardium.
2. Restoration of periodontal tissues
3. Reconstitution of immunocytes
4. Generation of neural precursors- using stem cells derived from adult human skin
5. Amyotrophic lateral sclerosis
6. Diabetes mellitus and several others

Creation of human embryos for purposes of organ donation and stem cell production are matters involving ethical issues and therefore this matter is under discussion and debate.

Acute Myelomonocytic Leukemia 1041

Erythroleukemia 1041

Acute Megakaryocytic Leukemia 1041

Transient Myeloid Disorders of Infancy 1042

General Considerations

Definition: Leukemias are a group of neoplastic disorders affecting mainly the leukopoietic tissues in the body and characterised by the presence of leukocytosis, immature leukocytes in the peripheral blood and proliferation of these immature cells in the bone marrow resulting in the

suppression of normal tissue. The abnormal cells infiltrate several organs in the body. Considerable information has accrued over the past decade in understanding the molecular basis of and cellular characteristics which lead to leukemic transformation. Genetic abnormalities transform precursor stem cells into potential leukemia cells. The disease process starts in the bone marrow or lymphatic tissue depending on the cell type and the peripheral blood is flooded with abnormal cells at some stage of the disorder. Less commonly erythroid precursors, plasma cells, or megakaryocytes may be involved.

Leukemias may be broadly grouped into two—acute and chronic leukemias. Acute leukemias affect younger age groups more frequently. They run a rapid course and the peripheral blood and bone marrow show the presence of large number of blast cells. If left untreated, these are fatal within weeks or months. Chronic leukemias generally affect the older age groups, they run a more protracted course, and terminate life within 2-3 years of onset.

TABLE 154.1

Frequency of leukemias in adults seen in India	
	Percent
Chronic myeloid leukemia	25-30
Acute myeloid leukemia	20-25
Acute lymphatic leukemia	20-25
Other varieties of leukemia	1-2
Chronic lymphatic leukemia	1-2

Leukemias account for 0.15-0.6% of the total medical admissions in many general hospitals in India.

It is to be noted that chronic lymphatic leukemia is less common in India and the neighbouring countries when compared to West (Table 154.1).

Classification of leukemias: Acute leukemias being heterogenous, several parameters have been employed for classification. These include morphology, histochemistry, cell surface and cytoplasmic immunological markers and cytogenetic and immunogenetic studies.

It is important to classify the disease precisely since the clinical behaviour, course, prognosis and response to treatment differ in the different types (Table 154.2).

In over 80% of cases of ALL and AML non-random chromosomal abnormalities are usually present. Leukemias have been classified by several authors based on different criteria. At present the *French, American British, (FAB) classification* is one of the accepted systems for acute leukemia (Table 154.2). Acute myeloid leukemia is classified on the degree of maturation and differentiation of the abnormal cell. Acute lymphatic leukemia is classified on the basis of cell size, nuclear chromatin pattern, nuclear shape, nucleoli, amount and basophilia of cytoplasm, and extent of cytoplasmic vacuolisation.

Etiology and pathogenesis: Leukemias are multicentric in origin. An abnormal stem cell undergoes mutation and proliferates in a disorderly and unrestrained manner so as to fill the marrow, spill into the peripheral blood, and infiltrate almost all organs in the body. The clone of malignant cells proliferates by division but fails to differentiate and hence immature forms persist in the marrow and peripheral blood. Though the exact stimulus for the mutation is not clear in an individual case, several factors are known to induce leukemia in experimental animals and humans.

1. Genetic factors are important as evidenced by the increased incidence of leukemia in mongolism and Fanconi's anemia.
2. RNA viruses such as the retrovirus and DNA viruses such as Epstein-Barr virus may induce leukemogenic changes in cells.
3. Exposure to ionising radiation (accidental and therapeutic) and long-term use of drugs and chemicals

TABLE 154.2

Classification of neoplasia involving leukocytes	
1. Acute leukemias	
Acute myeloid leukemia (AML) French, American, British (FAB) Classification. Differentiation of the immature cells forms the main criteria.	
Subclass	Type of cell
M ₀	Undifferentiated by light microscopy
M ₁	Poorly differentiated
M ₂	More differentiated
M ₃	Dysplastic promyelocytes
(acute promyelocytic leukemia)	M ₃ h-hyper granular PML M ₃ v-inapparent or fine granules M ₃ a-less hypergranular blasts
M ₄	Both granulocytic and Monocytic
M ₄	Eo-Myelodysplastic eosinophils
M ₅	Monocytic differentiation M ₅ a-predominantly blasts M ₅ b-differentiation into promonocytes and monocytes
M ₆	Myeloblasts with dysplastic erythroid precursors
M ₇	Megakaryoblastic
Acute lymphatic leukemia (FAB):	
When stained with Wright's stain three types—L1, L2 and L3 can be distinguished morphologically	
L1	The blast cells are small and there is no appreciable variation in size and shape. The nuclear chromatin is smooth and the nucleoli are indistinct.
L2	The blast cells vary in size with prominent nucleoli and a variable amount of cytoplasm.
L3	The cells are deeply basophilic with vacuolated cytoplasm. Immunological markers and other cytochemical markers help to identify the cell precisely.
Different hematological cancers can be distinct at the molecular level even though they may appear similar morphologically. This is true for acute and chronic leukemias and lymphomas. Acute lymphatic leukemias can be broadly grouped into three	
1. Precursor B lymphoblastic leukemia 2. Precursor T lymphoblastic leukemia 3. Burkitt lymphoma or leukemia	
In addition there are acute leukemias of ambiguous lineage. These are:	
1. Biphenotypic acute leukemias 2. Undifferentiated acute leukemias	
The availability of immunological probes like monoclonal antibodies, techniques like flow cytometry and DNA microarray analysis have enabled the sub-typing of acute leukemias and lymphomas based on immunological markers such as CD positivity (cluster group of differentiation). This has helped to devise specifically effective therapy with less of side effects.	
2. Chronic leukemias	
Chronic myeloid leukemia (CML)	
Chronic lymphatic leukemia (CLL)	
Hairy cell leukemia (variant of CLL)	
Prolymphocytic leukemia (variant of CLL)	
Plasma cell leukemia	
Chronic myelomonocytic leukemia	
Sézary syndrome: (leukemic phase of mycosis fungoides)	

which depress bone marrow (benzol, chloramphenicol and cytotoxic drugs such as alkylating agents and cyclophosphamide) have been incriminated to be leukemogenic by clinical, experimental and epidemiological observations.

4. Occurrence of cases in close relatives or in successive generations and in clusters in closed communities have strengthened the role of environmental factors in leukemogenesis.
5. Diseases like multiple myeloma and lymphomas transform into acute myelogenous leukemia in some cases. It is likely that the development of leukemia is the total effect of the environmental factors on the genetically predisposed individual. The clone of leukemic cell multiplies in exponential rates. The cell cycle time is generally longer for leukemias than for many other tumours (AML 80-84 h, CML 120 h).

The role of oncogenes in the causation of malignancies has been established (see chapter 6). Several leukemias show chromosomal abnormalities which point to their basic role in leukemogenesis. The formation of proto-oncogenes, their activation to form oncogenes by translocation, and the production of the malignant clone have all been studied. Diagnostic and prognostic information is obtained by chromosomal studies of almost all hematological malignancies especially in chronic myeloid leukemia and myelodysplastic syndromes.

Pathophysiology: The underlying defect in acute leukemia is the unregulated proliferation of primitive cells without undergoing differentiation. The transformation into a leukemic cell may occur at any point in the maturation and differentiation of the pluripotent stem cell. Both ALL and AML are unicellular in origin, and this abnormal cell proliferates to form a clone of malignant cells which populate the marrow and other tissues. AML may develop at any stage of development of the myeloid stem cells (CFU-S). If the malignant transformation takes place at the early stage, both erythroid and granulocytic series are involved (M6). Similar CML originating from a very primitive precursor which has the capability of differentiating into lymphoid or myeloid cell lines, can develop lymphoid blast crisis during transformation. If it occurs at a later stage of development after formation of the committed granulocyte macrophage progenitor (CFU-GM) only the myeloid and monocyte series are involved (M1-M6). In acute lymphatic leukemia the committed myeloid progenitor cells (CFU-C) are normal and the leukemic cells are superimposed on the normal hematopoietic cells. In acute leukemia the bone marrow contains both abnormal and normal cells, the latter being considerably suppressed, so that with eradication of the malignant cells, the remaining normal cells can repopulate the marrow. In contrast, in CML almost all the cells in the bone marrow are abnormal.

General symptomatology: Symptoms differ between acute and chronic leukemias. These are summarised in Table 154.3.

Diagnosis of leukemias: Acute leukemia should be suspected in all cases of rapidly developing anemia, prolonged fevers, hepatosplenomegaly, lymph node enlargement, hemorrhagic tendency, local tumour formation, neurological manifestations, and other bizarre clinical presentations. Acute lymphatic leukemia may be mistaken for rheumatic or rheumatoid arthritis in children. Early diagnosis is possible only if the clinical suspicion is strong.

It is not uncommon for acute myeloid leukemia to present with atypical features initially. Local tumour formation (also known as granulocyte sarcomas) without or with blood and bone marrow abnormalities is a rare presentation. Granulocytic sarcomas may develop in acute myeloid leukemia, and less commonly in chronic myeloid leukemia or other myeloproliferative disorders. They can be typed histologically into mature, immature (intermediate) or blastic types according to the cell composition. They may involve any tissues.

As the disease evolves, characteristic bone marrow and blood picture become evident. Aleukemic leukemia cutis is such a condition in which the skin lesion appears as an induration, nodule or tumour caused by leukemic cell infiltration, blood and bone marrow remaining normal.

Acute lymphatic leukemia is more common to produce local lesions in the bone.

Serum uric acid is elevated during the active phase of leukemias. Uric acid levels are elevated further during treatment with cytotoxic drugs due to rapid cell destruction.

Since early institution of treatment is more effective in curing the disease, specific investigations should not be delayed. Rarely leukemias may be brought out by routine investigations in asymptomatic individuals. This is more so for chronic myeloid leukemia.

Clinical diagnosis has to be followed up with hematological confirmation.

Peripheral blood film examination: The diagnosis of acute leukemia is suggested by the presence of blast cells, which are the precursors of leukocytes. Blast cells are characterised by deep blue non-granular cytoplasm and a rounded or oval nucleus showing pale stained inclusions—the nucleoli—which vary in number from 2 to 5. Though some idea about the nature of the blast can be obtained by morphology, further identification is done by cytochemical and immunological methods (Figs 154.1, 154.2, 154.9 and 154.10).

Peroxidase and *Sudan black* are stains which detect the presence of lysosomes containing the primary granules of the neutrophilic and monocytic series. *Terminal*

TABLE 154.3

Differences between acute and chronic leukemias		
	Acute leukemia	Chronic leukemia
Age group	More in the first and second decades but can occur in all age groups	Mostly in the 4th, 5th and 6th decades but even young children may be affected rarely
Sex ratio	M:F is 2:1	M:F is 1:1
Duration of symptoms	Weeks to months	Several months to one year
Presenting complaints	Anemia, fever, infections, hemorrhagic tendencies or complications, especially neurological	Vague symptoms, loss of weight, mass in the abdomen, or lymph nodular masses
Organomegaly	Liver, spleen and lymph nodes are moderately enlarged in 70-80% of cases	Moderate to gross splenomegaly is the rule in CML. Moderate to gross lymphadenopathy occurs in CLL.
Blood picture	Total leukocyte count is moderately elevated ($15-30 \times 10^9/\text{litre} = 15-30,000/\text{cmm}$), Blast cells form 10-90% of the total. Platelets are often reduced	Total leukocyte count is grossly elevated, $15-25 \times 10^{10}/\text{L}$ (150-250,000/cmm)
Bone marrow	Shows depression of erythroid cells, myeloid cells and megakaryocytes, and infiltration by the abnormal cells. Blast cells form more than 30% and may be even up to 90%	CML shows increase in myeloid cells, especially myelocytes, metamyelocytes, and neutrophils, infiltration by small lymphocytes is seen in CLL. Erythroid and megakaryocytic precursors show variable cellularity.
Chromosomal studies	Different patterns in different subtypes	Ph chromosome is demonstrable in over 95% cases of CML.
Course and prognosis	Untreated, fatal within weeks to six months due to infections, hemorrhage, anemia or other complications	Untreated, CML has a median survival of 18-24 months, CLL has a generally more prolonged course
Response to treatment	Spontaneous remissions have rarely been reported. With modern treatment, over proportion of 90% of cases go into remission and 60-70% get complete cure. Acute lymphatic leukemia in children gives the best results	With modern chemotherapy a small CML is cured With bone marrow transplantation at the ideal-time cure rates exceed 50%. CLL follows a variable course with chemotherapy

Fig. 154.1: ALL peripheral blood $\times 1000$.
Note: The blast cell (arrow)

Fig. 154.2: AML peripheral blood $\times 1000$ myeloblast with Auer's rods (arrow)

deoxynucleotidyl transferase (TdT) is seen most commonly in ALL, occasionally in the blastic phase of CML and rarely in AML (Table 154.4).

Cytological differentiation and immunophenotyping are important since the treatment, complications, and

prognosis are different. Even with a battery of tests 5-10% of acute leukemias may defy final identification initially. Follow-up helps to reveal their true type.

Bone marrow examination is mandatory in all cases. Presence of blasts in excess of 30% of the total cells in

TABLE 154.4

Differences between lymphoblasts and myeloblasts		
	Lymphoblasts	Myeloblasts
Number of nucleoli	1-2	2-5
Accompanying cells	Lymphocytes and non-granular cells	Promyelocytes, myelocytes and neutrophils
Peroxidase staining	Negative	Promyelocytes, myelocytes and neutrophils are positive; early blasts are negative
Sudan black staining	Negative	Positive
PAS staining (periodic acid Schiff)	Coarsely positive	Finely positive
TdT (terminal-deoxytransferase)	Generally positive	Generally negative

Note: Many more histochemical and immunological markers are available for precise diagnosis. Figures 154.1 to 154.3 and 154.9 to 154.11

the marrow confirms the diagnosis of acute leukemia. Elevation above 5% should be noted with suspicion.

In the case of chronic leukemias, diagnosis is easy by examining the blood film, since the cells show typical differentiating features. In chronic myeloid leukemia, neutrophils, and myelocytes predominate in the peripheral blood. In chronic lymphatic leukemia mature lymphocytes predominate.

Though the vast majority of leukemias show leukocytosis, in 10-20% the count may be normal or low even though immature cells are present. These are termed as **subleukemic leukemias**. When there are no abnormal cells in the peripheral blood, the term **aleukemic leukemia** is used. Bone marrow is hypercellular in most cases and shows infiltration by abnormal cells irrespective of the leukocyte count in peripheral blood.

Leukemias have to be differentiated from leukemoid reactions which are less common.

Leukemoid Reaction

Leukemoid reaction is a non-neoplastic reactive leukocytosis characterised by the presence of immature cells of all stages in peripheral blood. This may involve the myeloid, lymphatic, or other cell types. Children are affected more frequently than adults.

Causes

1. Acute infections like pneumonia, septicemia, whooping cough, chickenpox, infectious mononucleosis, diphtheria, and meningitis.
2. Chronic infections like tuberculosis, and amebic liver abscess.
3. Hemolytic crisis and massive hemorrhages.
4. Metastatic carcinoma involving the bone marrow especially from neuroblastoma, lungs, thyroid, prostate and others.
5. Other hematological malignancies, e.g. multiple myeloma, myelofibrosis, and Hodgkin's disease.
6. Toxic states like eclampsia, burns, and mercury poisoning.

The blood picture is myeloid in pneumonia, meningitis, diphtheria, tuberculosis, amebic liver abscess, metastatic malignancies, multiple myeloma, post hemorrhagic states and hemolysis. Lymphoid picture occurs in whooping cough, chickenpox, infectious mononucleosis, and tuberculosis. Monocytic reaction rarely occurs in disseminated tuberculosis. Eosinophilic picture occurs in amebiasis, melanomatosis, and invasive stages of helminthiasis. The bone marrow is normal with accelerated leukopoiesis in leukemoid reaction unlike as in leukemia. Total leukocyte counts may vary widely and overlap with those of leukemia. Liver and spleen are not usually enlarged. **Leukocyte alkaline phosphatase is increased in leukemoid reaction whereas it is low in chronic myeloid leukemia.**

Treatment of the underlying disorder corrects the blood picture also.

Congenital Leukemia

This is leukemia presenting within the first month of life. Almost always it is acute non-lymphatic leukemia. Chromosomal disorders such as Down's syndrome, Turner's syndrome, trisomy 13, monosomy 7, mosaic trisomy 9, and abnormalities of chromosome 11 have a higher incidence of congenital leukemia.

PRINCIPLES OF TREATMENT OF ACUTE LEUKEMIAS

Management of leukemia requires the coordinated efforts of the physician, oncologist, radiotherapist, clinical psychologist, and blood bank officer. The services of a well-equipped laboratory are absolutely essential for proper work-up of the case and follow up. The prime requirements expected of the general physician is to detect leukemias early and arrange treatment for them under the specialist team. Attempting to treat cases of leukemia single-handed in general hospitals will lead at best only to less satisfactory results. In the following description, only principles of diagnosis and management are given,

omitting precise practical details. Monographs on the subject should be consulted for more practical information.

When the disease is clinically evident the tumour load is heavy and the malignant tissue proliferates rapidly. At this stage it is essential to reduce the tumour load within a short time by the use of intensive chemotherapy. This phase is called **“induction of remission”**. The patient is deemed to have achieved remission when the clinical and hematological abnormalities (both blood and bone marrow) have disappeared. Even at this stage, although tumour cells are not demonstrable by the usual laboratory techniques, 10^5 - 10^6 tumour cells persist in the body which are capable of proliferating and re-populating the bone marrow and blood. This is the common cause for relapse.

Consolidation: After the induction and cranial prophylaxis another course of chemotherapy, meant to decrease the leukemic burden and to avoid the development of resistance is given, employing a different combination of drugs.

Many tissues in the body such as the brain, meninges, CSF cisterns, and testes act as sanctuaries for the leukemic cells since the systemically administered drugs do not freely reach them. The residual leukemic tissue in the brain and CSF is destroyed by drugs like methotrexate or cytosine arabinoside introduced intrathecally or intravenously in high doses. This constitutes **neuroprophylaxis**.

Testicular involvement occurs in 10-15% of ALL cases before the onset of therapy. This usually clears up with chemotherapy. Next to the central nervous system, testis is the most frequent sanctuary site where leukemic cells proliferate. Though overt testicular leukemia is treated by local irradiation, at present there is no consensus regarding testicular prophylaxis.

The present schedules of chemotherapy do not eradicate the leukemic cells completely. Hence **maintenance therapy** is given after the achievement of remission to prevent the surviving cells from proliferating and leading to relapse. Maintenance therapy is generally given for varying periods after which it could be withdrawn. During maintenance, regular short intensive regimen as given for induction are included in many treatment protocols. These pseudoinduction regimens are given to ensure that the leukemic cells do not reach significant numbers. It is possible that if the leukemic cell population is kept low, immunological defences of the host will eliminate them.

Maintenance therapy is more commonly employed for acute lymphatic leukemia. For acute myeloid leukemia, the success depends more on the effectiveness of induction therapy.

A modern approach to the problem of eradicating the residual leukemic cells is the use of monoclonal immunoglobulins which selectively destroy the malignant

TABLE 154.5

Drugs used for the treatment of acute leukemias

1. *Antimetabolites*
Methotrexate
Cytosine arabinoside
6-mercaptopurine
6-thioguanine
2. *Antimitotic drugs*
Vincristine
3. *Antibiotics*
Daunorubicin (Daunomycin)
Doxorubicin (Adriamycin)
Rubidazole
Bleomycin, Mitomycin
4. *Enzymes*
L-asparaginase
5. *Alkylating agent*
Cyclophosphamide
6. *Corticosteroids*
Prednisolone

cells. Monoclonal antibodies have been employed therapeutically and diagnostically in clinical situations rarely. Their greater use is for the removal of leukemic cells from harvested marrow before transplantation.

The total duration of treatment is generally limited to 5 years since the majority of patients attain freedom from the leukemic process by this period. Many of those who remain in the first remission without relapse achieve long-term survival (above 10 years) and cure, though a few may relapse even after this interval. In those in whom relapse occurs, survival is considerably shortened. Relapses are treated on the same lines as initial induction. If relapse occurs the therapeutic modality of choice is marrow transplantation. If this is not available, the next best is chemotherapy. Tables 154.5 and 154.6 give the details of drugs used to treat acute leukemias.

Supportive treatment: Infections are very common in the active phase of acute leukemia, especially during the induction phase, because of impairment of cellular and humoral defence mechanisms. They account for 80% of deaths during induction and remission. The common infective agents include the pyogenic cocci, gram-negative bacilli, *Pseudomonas aeruginosa*, anaerobes, *candida spp.*, *aspergillus* and the herpes viruses. Relatively avirulent organisms such as *Mycoplasma pneumoniae*, *Pneumocystis carinii* and *Cryptococcus neoformans* become invasive and account for many deaths. The risk of tuberculosis flaring up during treatment with corticosteroids is also high. Fulminant infections are seen most frequently during the stage of induction. Bacterial infections are common when the neutrophil count is below 1000/cmm. Reduction of absolute neutrophil counts below 500/cmm is dangerous, unless prompt antimicrobial therapy is instituted. Infection may be nosocomial or endogenous from the flora inhabiting the alimentary tract.

TABLE 154.6

Mechanism of action and toxic side effects of anti-leukemic drugs

Drugs	Mechanism of action	Adverse side effect
1. Vincristine (Oncovin)	Mitotic inhibitor	Alopecia, leukopenia, peripheral neuropathy, and myelopathy
2. Daunorubicin Doxorubicin (Adriamycin) Rubidazole Hydroxydoxorubicin	Binds DNA and inhibits mitosis	Alopecia, leukopenia, cardiomyopathy as a sequel. Doxorubicin cardiomyopathy is dose dependent and is more frequent when the total dose exceeds 550 mg/m ² . It leads to oxidative stress and cellular injury which can be demonstrated by myocardial biopsy studies. Often it occurs after long latent periods, even up to 20-40 years. Echocardiographic studies show reduction in ejection fraction. Slow administration of the drug as IV infusion over a period of 48-96 hours reduces cardiotoxicity. Antioxidants such as probucol are being tried as protective drugs.
3. L-asparaginase 4. 6-Mercaptopurine 6-Thioguanine Cytosine arabinoside Methotrexate	Deprives the cells of asparagine Inhibit purine or pyrimidine synthesis or inhibit incorporation into DNA	Hypersensitivity, hepatic dysfunction, pancreatitis Ulceration of mouth and GI tract, leukopenia
5. Cyclophosphamide	Alkylating agent, cross-links DNA and impairs RNA formation	Alopecia, leukopenia, marrow aplasia, pigmentation, hemorrhagic cystitis, pulmonary fibrosis. Second neoplasms on follow-up.
6. Corticosteroids 7. All transretinoic acid	Mechanism of action not clear Induces differentiation in acute promyelocytic leukemia	Several toxic effect, see Chapter 5.
8. Interferons	Immunomodulation	Several adverse effects.

NB: All the cytotoxic drugs, irrespective of their type, are capable of producing marrow aplasia and this effect is cumulative. This is probably the most serious toxic effect which limits the total dose. Till the advent of stem cell transfusion therapy intended to repopulate the marrow with normal cells, intense cytotoxic chemotherapy could not be given in eradicated doses due to toxicity on the host. With the support of stem cell transfusion and judicious use of cytokine growth factors it is possible to give more intensive chemotherapy and achieve higher cure rates at present. Specific monoclonal antibodies are also being introduced in selected cases.

Note: Drugs are usually given in combination cyclically or as continuous dosage. The selection, dose, and sequence of administration of these drugs depend on the type of leukemia. The dosage is usually calculated in terms of body surface area (which can be read off from nomograms using the height and weight), and this is more reliable than determining the dose on the basis of body weight. Combination of different drugs and intermittent administration has served to reduce the dosage and toxicity of each drug, and improve the effectiveness by optimal action at the appropriate phases of the cell cycle. Over the past four decades several collaborative studies have been conducted and evidence based protocols have been formulated for different subtypes of leukemia. It is important to follow the protocols strictly. Breaking the protocol, or use of individual drugs at random results in sub-optimal outcome. Studies on the management of leukemias are continuing.

Several methods have been employed to prevent such infections.

These include

1. the provision of an isolated sterilized environment,
2. reverse barrier nursing to avoid infection from the attendants,
3. provision of sterilized articles for food and drink,
4. special care of intravenous lines and injection sites, and
5. prophylactic use of antimicrobial drugs like cotrimoxazole and nystatin with a view to sterilise the gut flora.

Prophylactic antimicrobial drugs are started prior to the induction of remission and are continued during

the phase of leukopenia. Systemic infection should be anticipated when there are early symptoms like fever and rigor or any local lesions such as furuncles, cellulitis, or ulcers. A combination of powerful bactericidal antibiotics should be instituted early, after taking blood and bacteriological specimens from the nose, throat, mouth, anus, and genitalia for culture and sensitivity studies. Superficial candidiasis is treated by administering nystatin 500,000 units every 6 h orally and more serious fungal infections by amphotericin B in a dose of 1 mg/kg body weight intravenously or fluconazole. Antiviral drugs such as vidarabin 5 mg/kg/day or acyclovir 5 mg/kg/day intravenously every 8 h may be given for treating

herpes and other viral infections. *Pneumocystis carinii* infection responds to cotrimoxazole in a daily dose of 9-12 g given in divided doses.

Delay in starting antimicrobial therapy results in heavy mortality and hence it is necessary to start treatment on clinical grounds, even before bacteriological evidence is obtained. The advent of newer antimicrobial agents has been a great help in treating these patients. Blood component therapy.

Chemotherapy induced thrombocytopenia and anemia are promptly reversed by transfusion of platelets and packed red cells. Coagulant factors may be needed as and when bleeding tendencies develop.

Use of colony stimulating factors such as G-CSF and GM-CSF help to reconstitute the neutrophil and macrophage population early, shorten the period of dangerous neutropenia and risk of severe infections. Adverse side effects of colony stimulating factors include worsening of autoimmune disorders, inflammation of ocular structures and allergy.

Other supportive measures include red cell transfusions for anemia, platelet transfusions for hemorrhage, and whole blood to correct blood loss.

Hyperuricemia may lead to secondary gout and renal failure during treatment. Prompt use of allopurinol 100 mg thrice daily orally during the initial phases of treatment helps to keep the uric acid levels normal. Adequate hydration and maintenance of urine output of at least two litres daily help to minimise the risk of nephropathy.

Prognosis: Leukemia is invariably fatal if untreated. Modern treatment has helped to prolong useful life in the vast majority of cases of acute leukemias and in about 50-60% of cases to bring about cure. Best results are obtained in acute lymphatic leukemia in children. Those who are not curable by chemotherapy are subjected to bone marrow transplantation (BMT) which is curative in more than 2/3 of the cases. Stem cell transplantation is a more readily available alternative to repopulate the marrow.

At present management of acute and chronic leukemias is a highly evolved procedure, requiring the services of specialised equipment and trained teams who have experience of treating these patients. If treatment is done in such units, the results are excellent. No physician should undertake to treat them if these facilities are not available. Moreover, administration of corticosteroids or individual drugs instead of well-defined treatment protocols serve to alter the clinical and hematological picture, produce problems in diagnosis and worsens the prognosis. In India treatment of leukemias is undertaken in several centres.

During the past decade several protocols for treating acute leukemias have been developed by international teams. At present more and more aggressive chemo-

therapeutic combinations are being employed, each major centre using its own protocol depending on the availability of the drugs, cost, facility for supportive services and availability of marrow or stem-cell replacement. In general, over 95% of acute leukemias must go into remission and at least 70% should get long-term cure.

The Favourable Prognostic Factors

1. Initial leukocyte count below 20,000/cmm,
2. Platelet count above 100,000/cmm,
3. Absence of organomegaly, i.e. lymph nodes, spleen, and liver are impalpable,
4. Null cell (common ALL) leukemia, promyelocytic leukemia
5. Absence of complications,
6. Absence of mediastinal lymphadenopathy in acute lymphatic leukemia,
7. Younger age groups,
8. Institution of proper therapy from the beginning, and
9. Availability of trained teams for management and BMT.

The Unfavourable Prognostic Factors

1. Older age groups,
2. Initial leukocyte count above 20,000/cmm,
3. Thrombocyte count below 100,000/cmm,
4. Organomegaly,
5. Presence of complications,
6. T-cell acute lymphatic leukemia, and
7. Presence of mediastinal lymph nodes in lymphatic leukemia.

Cases which fall in the poor-prognosis group are given more intensive induction regimen using a larger number of drugs and early bone marrow transplant.

Bone Marrow Transplantation (BMT)

BMT has been employed as a therapeutic modality in several diseases for over four decades, to reconstitute stem cells in conditions where there is deficiency, (e.g. aplastic anemia and immunodeficiency states) or abnormality of the patient's own stem cells (e.g. leukemias and thalassemia). The success of this procedure and availability of BMT in several centres in many parts of the world have established its place in treatment. The pioneer in initiating BMT was ED Thomas who reported success of this procedure in 1959. Later he was awarded the Nobel Prize for his work. Stem cells are obtained from several sources—bone marrow, peripheral blood and cord blood. They have the potential to repopulate the marrow and differentiate into appropriate mature cells.

The indications and ideal time to perform BMT have also been defined. Unlike as in other solid organ transplants, there is no need for a major surgical procedure

since the stem cells collected from the donor reach their location in the bone marrow when injected intravenously. Within a few weeks of marrow donation, the donor's marrow fully regenerates so that there is no organ-loss for the donor. The marrow to be transfused may be homologous or allogenic (derived from another person with non-identical genetic status), isologous or syngenic (derived from identical twins with the same genetic status) or autologous (marrow recovered from the patient on an earlier occasion and transplanted later). Selection of the donor depends upon the compatibility of the HLA complex. Theoretically a single stem cell can repopulate the entire marrow. The genes for the HLA complex are closely linked on chromosome 6 and they are inherited as haplotypes. Thus two siblings have a one-in-four chance of being HLA identical. Transplantation between HLA identical persons does not evoke a graft versus host disease (GVHD). In selecting donors siblings are the most suited, next only to identical twins.

PRINCIPLES IN BMT

Conditioning Regimen

Ablation of the recipient's marrow cells: This is done by the administration of cyclophosphamide 50 mg/kg bw daily for 4 days along with total body irradiation of 800-1500 rads. This regimen destroys all the hemopoietic cell lines in the patient, including most of the leukemic cells. Several other regimens are used by different centers for ablating the patient's marrow. The present trend is to use less aggressive regimen to ablate the recipient's marrow since such regimen are associated with better success rates and survival.

Infusion of donor marrow: About 750 mL of marrow withdrawn from the HLA matched donor by multiple punctures under anesthesia is prepared for infusion and administered IV at a dose of $2-6 \times 10^6$ donor marrow cells per kg bw.

In the vast majority, the recipient's marrow increases in cellularity within two to four weeks. Thereafter all the hematopoietic cells, plasma cells, tissue macrophages and immunological cells are derived from the transplanted marrow.

Though in principle BMT appears to be simple, elaborate equipment, facilities to control infection of the recipient during the pre-transplant preparation and during the leukopenic phase before the donor marrow proliferates, need for powerful antibiotics, and hyperalimentation during the critical period, make BMT a highly specialised and very expensive procedure which can be undertaken only in advanced institutions where trained teams are available. Several institutions undertake BMT in India. The approximate cost is Rs. 10 to 12 lacs (\$ 22000).

An immunological complication that develops in all successful transplants is graft versus-host disease

(GVHD), if the donor happens to be other than an identical twin. The immunocompetent T lymphocytes in the donor marrow derived from the stem cells proliferate and attack recipient's tissues and give rise to the clinical picture of GVHD. GVHD may be acute or chronic. Acute GVHD occurs within 1-2 months of BMT. The incidence ranges from 10-80% depending upon the initial disease and technique of preparation of bone marrow. Main targets of attack of GVHD are the immune system, skin, GI tract, liver and brain. Profound immunosuppression occurs as a result of GVHD, leading to fatal infections. Selective epithelial damage occurs in the target tissues.

Chronic GVHD occurs after about 3 months or persists for more than 100 days. Two stages may be recognised in the pathogenesis. First step is activation of donor T lymphocytes by recipient tissues. Second step is the production of cytokines by the activated T-cells, recruitment of more cells and mounting the immune response in the host's tissues.

Administration of immunosuppressants, particularly methotrexate, and cyclosporine helps to suppress GVHD by inhibiting donor T-cell activation. Corticosteroids and cyclosporin inhibit the synthesis of interleukin. Methotrexate blocks cell proliferation. After varying periods these drugs can be discontinued. Newer immunosuppressants such as tacrolimus and mycophenolate mofetil are also useful.

The occurrence of GVHD is associated with more complete eradication of the leukemia clone and therefore, better long-term results. Cases that survive successful management of GVHD have longer leukemia-free survival.

Other fatal complications include graft rejection, severe infections, pulmonary complications including acute respiratory distress syndrome and interstitial pneumonia, and iatrogenic problems. Availability of growth promoting factors such as GM-CSF has enabled earlier reconstitution of recipient's neutrophils and macrophages, thus reducing infections and mortality. The mortality in the post-transplant period is 30-40% and the main causes are infection, marrow failure or GVHD. Refinements in techniques have given better results and lower failure rates.

A major offshoot of this procedure is the employment of autologous marrow transplant. This is the procedure in which bone marrow of the patient is harvested prior to administration of aggressive chemotherapeutic regimen and infused back after chemotherapy is administered. This helps to repopulate the marrow after ablating cancer tissue. The harvested marrow is treated with monoclonal antitumor antibodies which help to remove the intrinsic malignant cells contained in it. This procedure is called purging the marrow. Use of autologous marrow obviates the problem of donors and GVHD.

Peripheral Stem Cell Transplantation

Another modality that is more popular is stem cell transplantation. Peripheral blood normally contains stem cells which can be used to repopulate marrow after chemotherapy. The stem cell pool is allowed to proliferate under stimulation by appropriate colony stimulating factors (GM-CSF or G-CSF) and the harvested stem cells are infused into the patient instead of bone marrow.

Cord blood is a rich source of pluripotent stem cells. They are less likely to mount immunological reactions. Cord blood stem cell infusion is becoming more popular.

Prophylactic use of fluconazole and ganciclovir ensure prophylaxis against fungal and cytomegalovirus infections respectively.

Indications for BMT

- 1. Acute and chronic leukemias, myelodysplastic syndrome.
- 2. Multiple myeloma.
- 3. Lymphomas which have relapsed after initial chemotherapy.
- 4. Aplastic anemia, radiation injury, paroxysmal nocturnal hemoglobinuria.
- 5. Hemoglobinopathies, thalassemias.
- 6. Immunodeficiency states—severe combined immunodeficiency, Wiskott-Aldrich syndrome, Chédiak-Higashi syndrome, chronic granulomatous disease.
- 7. Other genetic disorders such as malignant osteopetrosis, Gaucher’s disease, infantile metachromatic leucodystrophy and X-linked adrenoleucodystrophy.

Results of BMT in Different Diseases

See Table 154.7.

Acute Lymphatic Leukemia
Syn: Lymphoblastic leukemia—ALL

This type of leukemia which is more common in children, arises from lymphoid tissue. About 75% cases are null cell type, 20-25% T-cell type and a few are B-cell type. Maximum incidence is in the first two decades. There is also a peak in the fourth and fifth decades. Male to female ratio is 2:1.

CLINICAL FEATURES

The presenting features are fever, pallor, lymphadenopathy, and bleeding tendencies. Some cases present with neurological involvement. These take the form of meningitis, cranial nerve palsies, focal neurological deficits, convulsions, or coma. About 20% present with arthralgias and arthritis resembling rheumatic or rheumatoid arthritis. Moderate lymphadenopathy,

TABLE 154.7 Gives the present indications for BMT and survival rates		
Indication	Timing	Approximate long-term survival
ALL	Second relapse	70%
AML	First relapse	70%
CML	Within 1 year of diagnosis, while in CML phase	70%
CLL	Variable	50%
Multiple myeloma	Stage I	66%
	Stage II	33%
Poor prognosis lymphomas	Failure of initial or second course of treatment	Over 50%
Hemoglobinopathy, Thalassemia	As early as possible	Over 80%
Severe aplastic anemia	As early as possible	Over 60%
Note: There are several other conditions in which BMT is an accepted treatment modality at present. A complete list is not attempted in this table. Autologous stem cell transplantation is done for almost all indications given in Table 154.8. Supportive stem cell transplantation given along with intensive cancer chemotherapy has improved the curability of several malignant diseases.		

TABLE 154.8 Gives the present status of autologous stem cell replacement	
Curative potential	Diseases
Certain	Acute leukemias, Aggressive NHL, Relapsed Hodgkin's disease

More than 30000 autologous and more than 15000 allogenic stem cell transplants are done annually, world-wide. Ref: Copelan EA. hematopoietic stem cell transplantation N Engl J Med 2006. 354:17, 1813-1826.	

especially the posterior cervical and mediastinal groups, mild hepatosplenomegaly (spleen 2-5 cm), and pallor are detectable on physical examination. Bone involvement is more common.

Ophthalmoscopic examination reveals pallor of the optic disc, venous engorgement, hemorrhages, and exudates. Vitreous hemorrhage and subconjunctival hemorrhage may occur in severe cases.

T-cell leukemia is more serious since it is less responsive to therapy. It is characterised by higher total leukocyte count and enlargement of mediastinal lymph nodes. There are reports that the frequency of T-cell lymphatic leukemia is higher in India. A subgroup of ALL, especially in adults shows Ph¹ chromosome positivity on karyotyping. Probably these arise from a very early totipotent stem cell which has the capacity to develop towards the myeloid cell line as in chronic myeloid leukemia. Ph¹ positive ALL has a poorer prognosis compared to Ph¹ negative ALL.

Laboratory findings: Normocytic normochromic anemia may be seen. Total leukocyte count is moderately elevated (20-30,000/cmm) (Fig. 154.3) but sometimes it may go up to 100-200,000/cmm. Lymphoblasts may form 5 to 95% of the total. Platelets are reduced. Bone marrow shows infiltration by lymphoblasts.

TREATMENT

Remission is induced by a combination of vincristine, prednisolone and L-asparaginase. Several other drugs such as doxorubicin (adriamycin), etoposide and cytosine arabinoside are also used for induction in high-risk cases (Tables 154.6 and 154.9). Newer modalities and treatment protocols are still being developed.

About 95% of children and 90% of adults respond to this regimen and achieve complete remission. Poor prognostic factors include the following:

- 1. Age < 1 and > 10 years
- 2. Male sex
- 3. Presence of mediastinal mass in X-ray
- 4. Presence of organomegaly involving the spleen, liver, lymph nodes and other organs
- 5. Laboratory features
 - a. Total leukocyte count exceeds 50,000/cmm
 - b. Blasts are of T-cell phenotype, which do not express CD 34 or CD 10 with a hypodiploid, diploid or near diploid karyotype.
 - c. Presence of Ph¹ chromosome.

Remission is consolidated by giving 1 or 2 doses of the drugs used in the induction regimen.

Fig. 154.3: ALL bone marrow × 400. Note: Replacement by lymphoblasts

Maintenance: Methotrexate in a dose of 15 mg/m² as a single weekly dose and 6-mercaptopurine in a total dose of 600 mg/m²/week divided into daily doses are given orally. Vincristine 1.5 mg/m² is given intravenously every month. Maintenance therapy has to be continued for 2 years.

Neuroleukemia

Neuroleukemia occurs in 50% of ALL and 10-12% of AML cases, if neuroprophylaxis is not given along with initial therapy.

Pathological lesions include infiltration by leukemic cells, hemorrhage, and demyelination. In addition, drug toxicity, and occlusion of cerebral microcirculation due to leukostasis add to the total neurological picture. When the leptomeninges are infiltrated, CSF shows the presence of a large number of blast cells, rise in protein and increased pressure, and this may be mistaken for meningitis. Neuroleukemia may manifest during remission, or this may even be the presenting symptom in some.

Clinical features may be those of meningitis, raised intracranial tension with papilledema, stupor, coma, focal neurological symptoms like convulsions or paralysis, cranial nerve palsies, spinal cord or spinal root compression, or intracranial hemorrhage. Sometimes hyperviscosity syndrome develops because of very high

leukocyte counts above $200 \times 10^9/L$ (200,000/cmm). Symptoms of cellular hyperviscosity include auditory and visual disturbances, ataxia, headache, profound lethargy, and coma. Leucapheresis relieves these symptoms dramatically (Fig. 154.4).

Neuroprophylaxis: It is started along with induction regimen and is a must in acute lymphatic leukemia. Intrathecal methotrexate in a dose of $10\text{--}12 \text{ mg/m}^2$ should be given twice a week for a total of 6 doses. A single dose should not exceed 15 mg. An alternative is cytosine arabinoside 50 mg intrathecally given twice a week for 6 doses.

CNS involvement should be diagnosed when the CSF cell count exceeds 5/cmm with or without the presence of blast cells. Cytospin studies and flow cytometry help to identify abnormal cells more accurately.

Treatment of established neuroleukemia is less effective. Cranial or craniospinal irradiation combined with intrathecal methotrexate or cytosine arabinoside is the method of choice. Intrathecal drugs may cause chemical meningitis or neuromyolytic accidents. Cranial irradiation may give rise to cerebral irritation, rise in intracranial pressure, somnolence or convulsions. Children who have received more than 2000 cGy to the cranium may develop impairment of intellectual performance on long-term follow-up. Therefore, it is the present consensus to limit the dose to 1800 cGy or even lower. Many centres have abandoned cranial irradiation. Drugs such as methotrexate when given intravenously in high doses reach the CSF in therapeutic concentrations.

At present, results in the management of the primary disease are very good. But neuroleukemia once it occurs, worsens the prognosis for long-term survival. Therefore, prevention of this complication has an important place in overall management.

Fig. 154.5: Testicular leukemia. Boy aged 2 years with acute lymphatic leukemia. Note: The enlarged testes

Testicular Leukemia

The testes may be enlarged, firm and tender, or the involvement may be clinically inapparent. Affection of the testes may occur before, during, or after the induction therapy. Testicular involvement leads on to relapse. Treatment of testicular lesion is by irradiation with 1000–2000 rads over a period of 2–10 days. Prophylactic irradiation of the testes has been tried in some centres, but the high incidence of sterility limits its routine application (Fig. 154.5).

Treatment of Relapse

Reinduction can be achieved by the same regimen as for the initial presentation. After achieving remission a second time the possibility of bone marrow transplantation should be explored since the chances of long-term survival with medical therapy are less in such cases. With the improvement in the results of bone marrow and stem cell transplantation, these modalities are considered even earlier.

Acute Myeloid Leukemia

Syn: Acute non-lymphocytic leukemia—ANLL

Acute myeloid leukemia arises from a common precursor stem cell and it is subdivided into seven types—M1 to M7. Ref: (Table 154.2). Risk factors include exposure to

ionizing radiations, benzene and cytotoxic chemotherapy, especially alkylating agents. Cigarette smoke is a common cause of benzene exposure. AML blast cells develop from normal blasts which have undergone genetic damage. Marrow blasts are protected by the marrow stroma from apoptosis induced by chemotherapy.

AML shows various cytogenetic abnormalities. WHO has proposed the **WHO classification of AML**, based on genetic abnormalities. This helps to select the best therapeutic approach and to assess the prognosis. Cytogenetic markers help to categorise the therapeutic response in AML as *favourable*, *intermediate* or *adverse*. The myeloid blast cells have surface markers CD33 or CD13.

All age groups are affected, though the second and third decades show a higher incidence. Both sexes are equally affected.

CLINICAL FEATURES

The disease presents with progressive anemia, fever and focal or general infections or hemorrhages (Fig. 154.6). Usual sites of infection are the gums, mouth, throat, skin, perianal regions, genitalia, and the respiratory tract. In many cases lymphadenopathy and hepatosplenomegaly may be absent. Atypically the disease may present with affection of unusual sites. Sites of extramedullary involvement include:

- 1. Bilateral or unilateral retro-orbital masses producing exophthalmos (Fig. 154.7).
- 2. Breasts—uniform or localised enlargement occurs in one or both sides (Fig. 154.8).
- 3. Skin—nodular or diffuse lesions. *Chloromas* are cutaneous manifestations of myeloid leukemia. They appear as reddish blue thickening of the skin. On pressing out the blood from the area a greenish hue is noticeable for a few seconds due to the presence of myeloperoxidase.
- 4. Bones—diffuse osteoporosis or localised tumours affecting the long bones.

Fig. 154.7: AML female retro-orbital tumours

Fig. 154.8: AML female tumour breasts

Fig. 154.9: AML P B × 500. Note myeloblast arrow

Fig. 154.6: AML female sub-conjunctival hemorrhage

Acute Promyelocytic Leukemia (APML) (M3)

About 15-20% of AML fall under this group. The predominant cells are promyelocytes with coarse granules in the cytoplasm. In addition to the general features of acute leukemia, APML is characterised in most cases by major bleeding tendency, caused by disseminated intravascular coagulation.

In APML there is translocation between chromosomes 15 and 17 (L 15:17). The genes for retinoic acid receptor (RAR) alpha on chromosome 15 fuses with the promye-

Fig. 154.10: AML: Bone marrow is replaced by myeloblasts

locytic leukemia gene (PML) on chromosome 17, resulting in the formation of PML-RAR fusion product. All trans retinoic acid acts at this fusion product and normalises it.

APML responds very satisfactorily to initial treatment with all-trans retinoic acid (isotretinine-ATRA) which is the treatment of choice at present. The dose is 45 mg/m² body surface per day for 15 days, once in three months as maintenance therapy. The remission induced by this therapy tends to be short lived, and therefore, it has to be followed up by chemotherapy.

Acute Myelomonocytic Leukemia (M4)

It shows a high proportion of monoblasts and monocytes. Hypertrophy and infection of gums are prominent features. Neuroleukemia is more common in this group (Fig. 154.11).

Erythroleukemia (Deguglielmo's Syndrome) (M6)

In this variety abnormal erythroid precursors proliferate. Erythroleukemia forms 5-7% of all acute nonlymphatic leukemias. It presents as progressive anemia, hepato-splenomegaly, and the presence of numerous erythroblasts in peripheral blood. Marrow shows gross hyperplasia of erythroblasts, many of which have a superficial resemblance to megaloblasts (hence termed megaloblastoid). As the condition progresses, numerous myeloblasts also appear in peripheral blood.

Fig. 154.11: Acute monoblastic leukemia peripheral blood. Note monoblasts (arrow)

Acute Megakaryoblastic Leukemia (M7 Type) (M7)

This may occur rarely. The cells may be indistinguishable from the other types of AML. Histochemical staining for platelet peroxidase and electron microscopy helps to identify the abnormal cells as megakaryoblasts. The histological appearance of the marrow is similar to that of myelofibrosis with presence of increased amounts of bone marrow reticulin.

Bone marrow or stem cell transplantation should be considered on achieving first remission.

TREATMENT OF AML

Except for APML the induction regimen consists of daunorubicin, and cystosine arabinoside (Table 154.10).

Induction therapy: The most popular regimen is the 3+7 combination of daunorubicin 45 mg/m² or 60 mg/m² / I V for 3 days and standard dose cytarabin 100 mg/m² by continuous infusion for 7 days. This combination produces severe neutropenia and when the neutrophil count falls below 0.5 × 10⁹ cells/L fatal infections may occur. Therefore, in order to achieve good results proper germ-free environment and prophylactic antimicrobial therapy are essential. Judicious use of colony stimulating factors such as GM-CSF and G-CSF helps to reduce the duration and severity of drug induced leukopenia. Availability of these cytokines has helped to plan more aggressive and curative chemotherapeutic regimens. Other induction regimens employ idarubicin or mitoxantrone

TABLE 154.10			
Treatment schedule for acute myeloid leukemia (3 + 7 regimen)			
	Dose	Route	Frequency
Daunorubicin	45-60 mg/m ²	Intravenous	Daily for 3 days
Cytosine arabinoside	100 mg/m ²	continous IV infusion or push doses 8-hourly	for 7 days
6-Thioguanine	100 mg/m ²	Oral	Given 8-hourly
or			
6-Mercaptopurine	100 mg/m ²	Oral	Daily

instead of daunorubicin. Therapy related AML is more resistant to treatment.

The induction of remission and its maintenance depends mainly on the effectiveness of initial inducing regimen. The value of maintenance regimen is not as clearcut as in the case of acute lymphatic leukemia. Therefore, many centres do not follow a continuous maintenance regimen.

Neuroprophylaxis may be indicated for acute myelomonocytic leukemia even though the incidence of neuroleukemia is much less compared to acute lymphatic leukemia. BMT has to be considered earlier than in the case of acute lymphatic leukemia.

Transient Myeloid Disorder of Infancy

Transient myeloproliferative disorder or transient leukemia of infancy may occur in the first few weeks of life. It is always associated with Down’s syndrome or trisomy 21. Infants with these disorders have leukocytosis, often with blast cells in peripheral blood, exceeding that in the bone marrow. Most often the blast cells are of megakaryocytic or erythroid lineage and are clonal. Hepatosplenomegaly, pericardial and pleural effusion and liver involvement are common. Majority show spontaneous remission. In 30% myelodysplastic syndrome or acute myeloid leukemia may develop.

- Chronic Myelomonocytic Leukemia 1046
- Chronic Myeloid Leukemia in Infants and Children 1047
- Chronic Lymphatic Leukemia (CLL) and Its Variants 1047
- Hairy Cell Leukemia 1050
- Prolymphocytic Leukemia 1050

Chronic Myeloid Leukemia (CML) and Its Variants

Chronic myeloid leukemia also known as chronic *granulocytic leukemia*, is the most common type of Chronic leukemia affecting adults in India. It forms 30% of the total leukemias. It is clinically characterised by gross overproduction of granulocytes. The disease is rare (less than 5% of total) below the age of 5 years. Maximum

incidence is in the age group 40-60 years, men are affected more often than women (3:2). Neutrophilic leukemia forms more than 95% of the total, though rarely eosinophils and basophils may be the affected cells.

Etiology: Chronic myeloid leukemia is a neoplastic disorder arising from the malignant transformation of a single hematopoietic stem cell. Over 95% of CML shows a constant chromosomal abnormality in the myeloid, erythroid and megakaryocytic cells. This abnormal chromosome known as the *Philadelphia chromosome* (Ph¹) is formed by the reciprocal translocation of the long arms of chromosome 22 and chromosome 9. CML arises from a single pluripotent hematopoietic stem cell which acquires Ph¹ chromosome carrying the BCR-ABL fusion gene which confers a proliferative advantage over normal cells and thus allow the Ph¹ carrying cells to proliferate at the expense of other hematopoietic cells. CML cells also live longer since they resist apoptosis.

Ph¹ chromosome: This chromosomal abnormality was identified in 1960 but only in 1973 that it was attributed to 9:22 translocation which involves a reciprocal translocation of genetic material (containing proto-oncogene C-abl, from chromosome 9 to chromosome 22, at the break point of the bcr locus) resulting in the fusion gene bcr-abl which encodes for an abnormal tyrosine

Fig. 155.1: CML karyotype showing Ph¹ chromosome

kinase with abnormally increased activity. There is clonal expansion of the stem cells with bcr-abl probably due to reduced adhesion of progenitor cells to stromal elements, as a result of which the stem cells escape the physiological inhibition. Even though the specific cellular disturbances involved are not fully known it is certain that bcr-abl is directly involved in the pathogenesis as evidenced from animal experiments. Philadelphia chromosomes are demonstrable in the dividing cells from the marrow as well as in the circulating cells. Myeloid, erythroid, and megakaryocytic, cell lines show Ph¹ chromosome (Fig. 155.1).

What causes the mutation in human beings with CML is not known, viruses, radiation, and toxic chemicals are all implicated.

Molecular Pathogenesis of CML

Molecular consequence of t (9;22) (q 34; q 11) translocation is the creation of the fusion gene bcr-abl which encodes for an abnormal tyrosine kinase that mediates an unregulated signal transduction. Depending on the site of breakpoint in the bcr gene the fusion proteins may vary in size from 185 kd to 230 kd. Nearly all patients with CML express 210 kd bcr-abl fusion protein. Fusion proteins of different sizes can be related to different outcomes. 190 kd-bcr-Abl protein has greater tyrosine kinase activity and is a more potent oncogene, than 210 kd protein.

As a consequence of increased tyrosine kinase activity the bcr-abl protein can phosphorylate several substances, thereby activating multiple signal transduction cascades affecting growth and differentiation of cells. Since the bcr-abl signal is constitutive, these cells escape the normal constraints of growth, and become leukemic. On the basis of this findings remission in CML can be defined as hematologic, cytogenetic (disappearance or reduction of Ph¹ chromosome) and molecular (disappearance of bcr-abl gene). Modern PCR assays enable quantitative monitoring of bcr-abl messenger RNA transcripts

Fig. 155.2: CML: PB × 1000. Note neutrophil myelocyte (arrow) Basophil (arrow head)

Fig. 155.3: CML: Bone marrow × 400. Note myeloid hyperplasia. All the elements are present

periodically. This is used for assessing prognosis and predicting cure.

Pathology: There is gross increase in granulocytes and their precursors in the blood and marrow. The bone marrow is filled with granulocytes, myelocytes, metamyelocytes and promyelocytes (Figs 155.2 and 155.3). Blasts are less than 5% in the chronic phase but can increase in the accelerated and blast phase. Erythroblasts are usually decreased. Megakaryocytes are normal in number or may be increased. The spleen is grossly enlarged and the liver is moderately enlarged. All organs show infiltration by myelocytes and a smaller number of promyelocytes. When blastic transformation occurs the percentage of blast cells increases in the marrow and peripheral blood. The diagnostic finding in the peripheral blood is the gross leukocytosis with the total leukocyte count often exceeding 50,000 to 100,000/cmm or more and the differential count showing 40-50% neutrophils, 20-30% myelocytes, 10-30% metamyelocytes, 5-10% promyelocytes, an occasional blast and the rest constituted by basophils, lymphocytes and monocytes. Basophil count is increased in CML during the chronic phase and remains elevated even when the patient responds to treatment. Platelet count is increased or

Fig. 155.4: CML: Gross splenomegaly in males aged 34 and 46 without gross impairment of general health

normal. Mild anemia may occur. In an occasional case the peripheral smear may show only leukocytosis with mature neutrophils. This is called *chronic neutrophilic leukemia* or *Emil-Weil's CML*.

Serum proteins are elevated with increase in gamma globulin. Leukocyte counts exceeding 300,000 cmm may give rise to cellular hyperviscosity syndrome. The serum uric acid is high due to more rapid cell turnover. Basal metabolic rate is increased. **Leukocyte alkaline phosphatase score (LAP score)** is low or absent in more than 90% in the chronic phase. Serum vitamin B₁₂ and B₁₂ binding capacity are elevated due to increase in transcobalamin I and II.

CLINICAL FEATURES

The disease is insidious in onset and it is almost impossible to assess the duration of illness when the patient comes up for examination. Some asymptomatic cases are picked up by routine blood tests. Majority of patients present with the feeling of a mass and dull ache in the abdomen caused by splenomegaly. The spleen is grossly enlarged in over 95% of cases (Fig. 154.4). Splenic size correlates reasonably well with the total leukocyte count. Gross splenomegaly is associated with episodes of splenic infarction which present as painful episodes. Some cases reveal bone tenderness. Pallor, exertional dyspnea, and tachycardia may occur due to moderate or severe anemia. Hypermetabolism leads to loss of weight, lassitude and night sweats. With progress of the disease the abdomen becomes distended due to huge splenomegaly and moderate hepatomegaly. Nutritional deficiencies, cachexia and intercurrent infections complicate the picture. When the leukocyte count is high, the ocular fundus shows hyperemia of the disc, venous engorgement and occasionally hemorrhages.

Complications

Several complications may occur from time-to-time. These are infections, malnutrition, anemia, trauma, infarction of the spleen and secondary gout. Thrombotic tendencies due to high leukocyte counts, consequent leukostasis and

associated thrombocytosis, develop resulting in venous thrombosis and priapism. Hemorrhagic complications may also occur because of the defective platelet function despite a normal or high platelet count.

Most of the CML patients present in the chronic phase with very few blasts in the peripheral blood and marrow and after a variable period of months to years enter the more serious and inescapable complication of **blastic transformation** (blast crisis). A range of additional non-random chromosomal changes occur including duplication of Ph chromosome and trisomy 8. Multiplication or deletion of tumour suppressor genes such as p16 and p53 occur with variable frequency. Probably these contribute to the blastic transformation. Blastic transformation is heralded by unresponsiveness to conventional treatment and the development of severe anemia, fever, infections, lymphadenopathy, bleeding tendencies and rapid deterioration of general health. In 75% of cases, the blast transformation is into myeloid (AML) and in 25% lymphatic (ALL). Extramedullary tumours consisting of myeloblasts may develop especially in the bones, lymph node and skin. These are called **granulocytic sarcomas**. The peripheral blood count and the proportion of blast cells increase, the blasts cells forming more than 20 to 30%. Thrombocytopenia develops as well. In the blastic stage the prognosis is that of AML, but response to therapy is less satisfactory than primary AML. The lymphatic blast crisis responds better to treatment than the myeloid type. Successful chemotherapy in blast phase converts the clinical and blood picture to that of CML. A few patients may develop secondary myelofibrosis even during the chronic phase.

Diagnosis

CML should be considered in the diagnosis when there is moderate to massive splenomegaly in the presence of reasonably good general health. A very high total leukocyte count and the blood smear examination confirms the diagnosis. Presence of thrombocytosis and basophilia are supporting evidences. Low or absent leukocyte alkaline phosphatase score almost confirms the diagnosis. When the diagnosis is in doubt, demonstration of the Ph¹ chromosome by karyotyping or FISH (fluorescent *in situ* hybridization) is diagnostic of CML. In addition, highly sensitive and specific molecular probes are now available to detect the presence of bcr-abl in peripheral blood or bone marrow leukocytes. This helps to diagnose and monitor therapy. PCR testing of peripheral blood RNA is so sensitive as to detect one Ph⁺ cell in 10⁶ cells. For clinical purposes bone marrow examination and genetic studies are not mandatory.

Differential Diagnosis

Other causes of splenomegaly such as myelofibrosis, portal hypertension, chronic malaria, leishmaniasis, and hemolytic anemias should be considered in the differential

diagnosis Leukemoid reactions should be excluded. Leukocyte alkaline phosphatase score is low in CML, whereas in leukemoid reactions it is high. Idiopathic myelofibrosis may pose some difficulty to be distinguished from CML. Myelofibrosis is characterised by gross splenomegaly, only modest elevation of the total leukocyte count (15,000 to 30,000) and is characterised by a leuko-erythroblastic blood picture. Teardrop shaped erythrocytes are characteristic. Bone marrow is scanty and trephine biopsy reveals fibrosis.

Course and Prognosis: Chronic myeloid leukemia runs a relentless course to end fatally in all cases. Unlike as in acute leukemia, medical therapy does not bring about predictable cure. Untreated, the average period of survival used to be 2-3 years in the early 1990s. Treatment given early in the disease brings about clinical relief and clears the blood picture, but the disease is not eradicated, and therefore, relapse is the rule. About 20% patients survive up to 10 years. Death is due to blastic transformation, infection, hemorrhage or rarely drug toxicity. Presence of Ph¹ chromosome confers a better prognosis. Ph¹ positive cases do better and live longer with an average period of survival of 4 years whereas Ph¹ negative cases invariably run a downhill course and die within one year. Ph¹ chromosome negative cases have been termed as *atypical CML*, and most of these occur in children.

Bone marrow transplantation brings about cure in the vast majority who survive the procedure. With the introduction of the specific tyrosine kinase inhibitor, Imatinib the disease undergoes clinical, hematological and even molecular remission. Symptoms are completely abolished and quality of life improves.

Treatment: Since conventional medical therapy does not eradicate the disease, the aim is to relieve symptoms and bring about clinical and hematological normalcy. The high leukocyte count and organomegaly subside completely with treatment and the patient becomes asymptomatic though a few abnormal cells and the Ph¹ chromosomes persist.

Drugs

Imatinib (Gleevec)

The *inhibition of tyrosine kinase* activity is the most effective therapy for CML if bone marrow transplantation is not available. The signal transduction inhibitor (STI 571), imatinib selectively inhibits the fusion protein tyrosine kinase of the bcr-abl gene. It has been approved for use in CML patients as first line therapy. It is given in doses of 400 mg orally as single dose for adults continuously for an indefinite period. At times, upto 800 mg can be given daily. It is still not clear how long the treatment has to be continued. Within weeks of starting therapy the leukocyte counts, the abnormal cells and splenomegaly come down and full clinical normalcy is

restored. The median survival has also improved. Complete cytogenetic response at 12 months was 69% and at 60 months was 87%. Blast crisis develops in 7% even while on treatment. Overall median survival at 60 months in those who were put on imatinib from the start was 89%.

Cessation of therapy promptly brings back the leukocytosis and abnormal blood picture. 60-80% show full clinical response with 68% showing cytogenetic clearance in the chronic phase. Real time PCR measures the ratio of BCR-ABL transcripts to BCR transcripts. This helps to monitor recovery at the molecular level.

Imatinib may produce response in accelerated and blastic phase as well, even though the results are poorer. In such cases the duration of response is also shorter. Adverse side effects include peripheral and periorbital edema, muscle cramps, joint pains, neutropenia, elevated liver enzymes and rarely, congestive heart failure. Resistance to imatinib has been recorded. Administration of hydroxyurea in doses of 1-2 g orally daily in combination with imatinib restores the clinical effects of the latter. Combination therapy with two tyrosine kinase inhibitors is also under evaluation.

Imatinib mesylate is finding its use in several other neoplasms where the tyrosine kinase receptor is expressed prominently. The present cost of imatinib therapy is Rs. 300 /day.

Dasatinib (Bristol-Myers Squibb) is an ABL kinase inhibitor that differs from imatinib in that it combines to both the active and inactive conformations of the ABL kinase domain. In imatinib resistant cases and in those who are intolerant to imatinib, dasatinib given orally in doses ranging from 15-240 mg/day leads to hematological and cytogenetic response. Major adverse effects include reversible myelosuppression and non-malignant pleural effusion.

Nilotinib (Novartis) – This is a new orally active aminopyrimidine-derivative tyrosine kinase inhibitor which is more potent than imatinib in vitro against CML. In doses starting from 50 mg oral daily and worked up to 1200 mg od or 400-600 mg bd, this drug is effective during the chronic phase, accelerated phase and blastic phase in diminishing effectiveness. Adverse effects include myelosuppression, transient direct hyper-bilirubinemia and rashes.

Hydroxyurea (hydroxycarbamide) This used to be the drug of choice for over 5 decades for the treatment of CML before the advent of interferon alpha and imatinib.

The dose varies from 0.5-2 g daily orally in divided doses. It brings about a steady fall in total leukocyte count with reduction in the immature cells within 1-2 months. The mechanism of action is inactivation of the enzyme ribonucleotide reductase with consequent inhibition of cellular DNA synthesis leading to cell death in the

S-phase. Adverse side effects include gastrointestinal upsets, marrow suppression, skin pigmentation, alopecia and ulceration in the feet. These regress on stopping the drug. The cost of treatment is Rs. 70/day.

Busulphan (myeleran): This is an alkylating agent belonging to the group of sulphur mustards. It is given orally in the dose of 2-8 mg/day. Blood counts are done at weekly intervals. By 2-3 weeks the total leukocyte count starts falling. At this stage, the dose is reduced and continued till the total leukocyte count falls below 10,000/cmm. At this stage the splenomegaly also disappears. In the majority of cases, this is achieved when the total dose reaches 200-220 mg of busulphan. Once the leukocyte count falls below 10,000/cmm busulphan is withdrawn to avoid marrow suppression. Further treatment is indicated when the total leukocyte count goes above 50,000/cmm. Busulphan is effective in over 75% of cases to give symptomatic relief. Relapses also respond to busulphan, but with the passage of time the response becomes less satisfactory and the duration of clinical remission progressively shortens.

Adverse side effects include bone marrow aplasia, allergic manifestations, and pigmentation resembling Addison's disease, (Fig. 155.5) but without the endocrine abnormalities. Rarely busulphan produces extrinsic alveolitis and interstitial pulmonary fibrosis (busulphan lung). This is an absolute contraindication for further busulphan therapy. The use of busulphan has been stopped in preference to hydroxyurea or imatinib. Treatment with busulphan costs Rs. 500/month.

Interferon Alpha (IFN alpha)

IFN was the first line of therapy for all patients with CML before the advent of imatinib. It has to be given by subcutaneous or intramuscular injection daily for a period of two years or more in a dose of 3 to 9 million units IM daily for 4 to 6 weeks initially and later at lower doses for long periods. Adverse effects include 'flu' like

syndrome, anorexia, diarrhea, weight loss, polyneuropathy, psychosis and others. The drug is costly (Rs. 1500/day). The exact duration of therapy is not yet defined.

Sustained disappearance of Ph occurs only in 5-10%. Better results are achieved by combination of IFN with cytarabine. IFN alpha is not used routinely for CML at present.

Management of Hyperviscosity State

Leukapheresis using a cell separator may be temporarily beneficial in hyperviscosity state and may be required when the total leukocyte count exceeds 300-400,000/cmm. The procedure may also bring about temporary hematological remission.

Bone marrow transplantation (BMT): Since this is the only predictable curative modality of treatment at present, it should be considered as early as possible after diagnosis. BMT done in the chronic phase of the disease, and in younger subjects, gives the best results with cure rates well above 70%. The procedure related mortality is a major deterrent in opting for this form of therapy. At present the cost of BMT in India is Rs.10 to 15 lacs. BMT done during the accelerated or blastic phase is less successful and more risky.

Variants of CML

EOSINOPHILIC LEUKEMIA

In this disorder the patients present with marked eosinophilia often above 100,000/cmm with the clinical picture of chronic myeloid leukemia. The blood shows eosinophils, eosinophil myelocytes and occasional neutrophil myelocytes. In a few cases Ph¹ chromosome may be found.

CHRONIC BASOPHILIC LEUKEMIA

This clinically resembles CML, but there is gross increase in basophils. A few neutrophils may be present. Ph¹ chromosome may or may not be present.

CHRONIC MONOCYTIC LEUKEMIA

This term is used to denote the condition in which the monocytes are also considerably increased in addition to the blood picture of CML.

CHRONIC MYELOMONOCYTIC LEUKEMIA

This entity which is considered as one of the myelodysplastic syndromes is seen in patients over the age of 50 years and the clinical picture resembles that of refractory anemia with excess of blasts (RAEB). Blood shows absolute elevation of monocytes (2×10^9 litre or more), many of them being atypical. The spleen enlarges

1046 Fig. 155.5: CML female pigmentation due to myeleran therapy

Fig. 155.6: Juvenile CML in blastic crisis.
Note: The gross lymphadenopathy (arrow)

progressively. The main difference from AML (M2, M4 and M5) is that the count of promyelocyte + blasts in the marrow is less than 30%. Over one-third of the cases develop AML on follow-up.

CHRONIC MYELOID LEUKEMIA IN INFANTS AND CHILDREN

In children only less than 5% of leukemia is formed by CML. There are two types.

1. Ph¹ positive CML, which has the same biological behaviour and response to therapy as adult CML, and;
2. Ph¹ negative CML which is more frequent. These may occur at any age, between 2 months to 9 years, though the peak incidence is between 1 and 2 years. This is termed *juvenile CML*.

Juvenile CML

Juvenile CML is characterised by the proliferation of myelocytes in bone marrow, peripheral blood and tissues. Both sexes are equally affected. They show marked enlargement of spleen and liver. The peripheral blood shows increase in myelocytes and monocytes, but the total leukocyte count may be lower than that in adults. Platelets are often reduced. There is increase in fetal hemoglobin which may form upto 85% of the total. The disease runs a more rapid course and ends fatally within one year of diagnosis (Fig. 155.6).

A diagnostic feature is the finding that, on *in vitro* cultivation of peripheral blood stem cells stimulated by GM-CSF, only colonies of monocytes are produced whereas in Ph¹ positive CML, both myelocytes and monocytes are produced. There is suggestion that juvenile CML may be more akin to acute myelomonocytic leukemia.

Treatment: The response to conventional drugs is less satisfactory. Cytosine arabinoside and 6-mercaptopurine

are found to be partially effective. Isotretinoin given orally in a dose of 100 mg/m² daily is reported to produce durable improvement in clinical and laboratory parameters. The newer drugs and BMT have to be employed when indicated.

Chronic Lymphatic Leukemia (CLL) and Its Variants

This is the most common type of leukemia occurring in adults in the west, but in India, this is much less common. In the Mongoloid and Chinese races also the incidence is very low. Chronic lymphatic leukemia is a neoplasm arising usually from a clone of B lymphocytes, occurring usually above the age of 45 years, characterised by the presence of excessive number of mature looking lymphocytes in the bone marrow and peripheral blood, and organomegaly due to infiltration by lymphocytes. In around 2% of cases the neoplastic cells are of T-cell origin and this is termed T-cell prolymphocytic leukemia (PLL). *The modern trend is to include chronic lymphatic leukemia and its variants such as hairy cell leukemia and prolymphocytic leukemia along with primary lymphatic malignancies. This is so, because there is considerable overlap in the cell characteristics and clinical manifestations.*

CLL is now considered to be two related entities, both originating from antigen stimulated mature B-lymphocytes which either avoid death through the intercession of external signals or die by apoptosis, only to be replaced by proliferating precursor cells. The monoclonal populations of B-cells shows CD19, CD5 and CD23 markers and have reduced levels of IgM, IgD and CD 79b which is, the phenotype of mature B-cells. Pathological features of lymph nodes resemble those of small cell lymphocytic lymphoma. Antigenic stimulation and presence of pro-CLL activating factors have been identified. These cytokines help the CLL cell to proliferate and avoid apoptosis. CLL cells are highly dynamic with brisk proliferation rates and reduced apoptosis (0.1 to 1% of the clone/day). The size of the spleen and lymph nodes bear some relationship to the proliferation rate.

At present early treatment is advised, newer modalities of therapy are being tried.

Pathology: Most of the cases are B-lymphocyte type, though rarely T-lymphocytes may be involved. These cells proliferate. The lymph nodes are enlarged and histologically resemble diffuse well-differentiated lymphoma. Liver, spleen and bone marrow show varying degrees of lymphocytic infiltration. Progressive replacement of the normal bone marrow leads to compensatory hyperplasia of the yellow marrow, but finally the bone marrow fails. Lymphocytes may infiltrate other organs and the skin. At times monoclonal paraproteins of the kappa or lambda type are produced by the tumour cells even without antigenic stimulation.

Normal immune mechanisms of the host are impaired since the abnormal immunocytes are functionally incompetent. Other autoimmune disorders like hemolytic anemia, autoimmune thrombocytopenia, rheumatoid disease and Guillain-Barre syndrome may occur in association with chronic lymphatic leukemia.

CLINICAL FEATURES

Males are affected twice as frequently as females. Most of the patients are above 50 years. The disease is rare in younger individuals. The onset is insidious with fatigue, tiredness and vague ill health, and on many occasions, the disease is revealed by routine physical examination and/or blood examination in asymptomatic subjects. Clinically, two forms of the disease can be identified – benign and aggressive forms. In about 80% of cases, the disease presents with painless lymphadenopathy. The nodes are moderate to large in size, rubbery in consistency, discrete, and are most prominent in the neck and axillae. Tonsils may be enlarged considerably. Enlargement of the lacrimal and salivary glands is known as *Mikulicz's syndrome*, but this presentation is more common with *lymphoma*. Anemia develops due to marrow infiltration by lymphocytes replacing the erythroid series, auto-immune hemolysis, hypersplenism, vitamin B₁₂ or folic acid deficiency or even iron deficiency and blood loss.

Spleen is moderately enlarged (5-10 cm) in 75% of cases and in 10% splenomegaly may be the only sign in the absence of lymphadenopathy. Splenic enlargement can lead onto hypersplenism and associated clinical problems. Cutaneous involvement presents as nodules, or diffuse infiltration producing a picture of erythroderma (*homme rouge*). Some have an exaggerated cutaneous response to mosquito bites. Immunodeficiency due to poor T-cell function and hypogammaglobulinemia contribute to recurrent infections of the respiratory and urinary tracts. Intractable pruritus is a distressing feature.

Diagnosis

The disease should be suspected from the clinical findings. Diagnostic finding in peripheral blood is the marked leukocytosis ($50-200 \times 10^9/L$ or 50,000-200,000/cmm) consisting almost totally of small mature lymphocytes. The cells are uniform in type and blasts are usually not seen except in the later stages (Fig. 155.7). The total leukocyte count does not bear a direct relationship to the tumour load. Many lymphocytes are ruptured and these are termed *smudge cells* or *basket cells*. The bone marrow is replaced by lymphocytes which form 90-95% of the total cells. Pseudohyperkalemia can occur due to severe leukocytosis (Fig. 155.8).

Differential diagnosis includes other causes of lymphocytosis like viral infections – the lymphocytosis in such infections is not persistent, the patients are

Fig. 155.7: Peripheral blood film chronic lymphatic leukemia. Note: Mature looking lymphocytes

Fig. 155.8: Bone marrow chronic lymphatic leukemia. Note: Infiltration by lymphocytes

younger, the clinical setting is different and the cells are not monoclonal. Low grade small lymphocytic B-cell lymphoma comes in the differential diagnosis, since the lymph node histology is similar; the distinction is basically made by clinical evaluation. CLL is associated with blood lymphocytosis and marrow lymphocytosis with or without lymphadenopathy. Whereas lymphoma is primarily associated with lymphadenopathy but marrow and blood lymphocytosis are uncommon except in late stages when these organs are involved. Prolymphocytic lymphoma closely mimics CLL but the cells here are larger. Hairy cell leukemia can be differentiated by the larger size of the lymphocytes and the electron microscopic hairy projections on the cells (Fig. 155.9). Waldenström's macroglobulinemia is another condition to be differentiated from CLL.

A system of *clinical staging* has been accepted since it correlates with the response to treatment and survival.

Course and Prognosis

In the Caucasian races, the disease follows a slow and progressive course, remaining asymptomatic for several years, and ultimately ending fatally because of infection, bone marrow failure, cachexia, or iatrogenic complica-

Fig. 155.9: Hairy cell leukemia (1) electron microscopy (2) blood film

tions. In general, patients with stages I, II and III disease survive for 150, 101 and 71 months respectively. Stage III and IV do not show any significant difference in survival. Though acute lymphoblastic or even acute myeloid leukemia may occur terminally in a few cases, unlike chronic myeloid leukemia terminal blast crisis is much less common. CLL can transform to an aggressive large B-cell high grade lymphoma at any point in the course of the disease and this is called **Richter's syndrome**.

Staging of Chronic Lymphatic Leukemia (Rai 1975)

Stage 0	Lymphocytes 15×10^9 /litre or more in peripheral blood and 40% or more in the bone marrow. No enlargement of lymph nodes, spleen or liver. Hemoglobin is above 11 g/dL and platelet count is over 100×10^9 /L
Stage I	Features as in Stage 0, but with enlarged lymph nodes
Stage II	As in stage 0, but with enlarged spleen, liver or both. Lymph nodes may or may not be enlarged
Stage III	As in stage II, but with hemoglobin less than 11g/dL
Stage IV	As in stage III, but with platelet count below 100×10^9 /L

In 1981 Binet suggested an alternate three stage classification considering total lymphoid mass. Stage A having less than three areas of lymphoid enlargement, Stage B having three or more areas of lymphoid enlargement. The advanced form of stage C includes all patients having anemia and thrombocytopenia.

The aggressive form is more common in Indians. This type follows a more rapidly progressive course, punctuated by episodes of infection. Death occurs within 2-3 years in the advanced stages, in the majority of cases. Since the total leukocyte count does not bear a direct relation to the tumour load, this is not useful in prognosis. High leukocyte count by itself is not an indication for starting

therapy. In general the following are the indications for starting treatment:

1. Anemia
2. Thrombocytopenia
3. Disease related symptoms
4. Markedly enlarged spleen
5. Disfiguring or symptomatic lymph node enlargement
6. Blood lymphocyte doubling time less than 6 months
7. Prolymphocyte transformation and
8. Richter transformation. Treatment helps to allay symptoms and relieve suffering and hence treatment is indicated in all symptomatic cases though it is not clear whether it prolongs life.

A subgroup of CLL is present in which the leukemic cells show deletion of chromosome 13q14 and also contain mutated immunoglobulin heavy chain variable (VH) region genes. This subgroup has a better prognosis. It is seen in 50% of cases of CLL. Other conditions where the gene situated at 13q14 is deleted include non-Hodgkin's lymphoma and multiple myeloma. Trisomy 12 confers a poor prognosis to CLL.

TREATMENT

Although it is customary in the west to withhold treatment till the disease reaches stages III or IV, in Indian subjects treatment may have to be started earlier, depending on the progress and extent of the disease. Specific treatment is with **chlorambucil** (*Leukeran BW*) started usually with 2 to 4 mg per day continuously till the total leukocyte count becomes normal and the morphological lesions disappear. An alternate dosage schedule is 0.4 mg/kg/body weight of total dose divided into 4 equal doses and given on days 1 through 4. This cycle can be repeated every two to 4 weeks. Cyclophosphamide 50-100 mg/day can be used instead of chlorambucil. Corticosteroids, given in cycles, enhance the effect of alkylating agents. Optimal improvement occurs in 1-2 years, though the neoplasm is not eradicated. Combination chemotherapy has been beneficial in resistant cases. The usual combination is cyclophosphamide, doxorubicin, vincristine and prednisolone.

Fludarabine which is a nucleoside analogue given in a dose of 25 mg/m² body surface area IV daily for 5 days every 28 days is effective in bringing about higher response rates and longer remissions especially in chlorambucil resistant cases. The drug is expensive. Another nucleoside analogue, **Cladribine** also is equally effective. Pentostatin which is a purine analogue and Alemtuzumab which is a monoclonal antibody are occasionally used in patients refractory to common drugs.

Infective episodes demand prompt treatment with antibiotics. Immunoglobulin can be given prophylactically in doses of 50-100 mg/kg/bw periodically to reduce the frequency and severity of bacterial infections.

Leukapheresis has been found to be beneficial in removing the leukemic cells and thereby reducing the

tumour load in intractable cases and also to reduce leukostasis.

The role of bone marrow or stem cell transplantation has not been definitely established. Results and evidence based guidelines have not yet become clear.

Monoclonal antibodies especially campath-1H has been tried in relapsed and refractory CLL. The response rate is around 40%.

Combination Therapy

- A. Fludarabine 25 mg/m²/day plus cyclophosphamide 250 mg/m²/day given IV for 3 days.
- B. Fludarabine 24 mg/m²/day plus cyclophosphamide 150 mg/m² given orally for 5 days repeated at 4 week intervals for six course has given better mission rates and quality of life, compared to others drug schedules.

Ref: D. Catovsky, et al. Assessment of fludarabine plus cyclophosphamide for patients with chronic lymphocytic leukemia (The CRF CLL 4 trial) a randomised controlled trail. The Lancet 2007;370:230-39.

Hairy Cell Leukemia

Syn: Leukemic reticuloendotheliosis

This is a variant of chronic lymphatic leukemia and is rare. It is seen in the age group 40-80 years and males are affected four times more common than females. Presents with massive splenomegaly, anemia, relative lymphocytosis, more often with a low total leukocyte count, often pancytopenia is present. The B-lymphocytes are larger than that in CLL and show the characteristic fine hairy projections which can be detected in peripheral smear and bone marrow, but best brought out by electron microscopy.

The cytoplasm shows a number of villi which give the hairy appearance. The diagnostic histochemical test for hairy cells is *acid phosphatase staining reaction resistant to the action of tartarate*. Bone marrow is infiltrated heavily and it is difficult to aspirate and often a dry tap is obtained. Marrow biopsy and imprint smears show the hairy cells.

Treatment: In the early stages corticosteroids are useful. The disease responds best to splenectomy. Other drugs include pentostatin (Deoxycoformycin, Nipent-Parke Davis), a purine analogue and Cladribine (2-Chloro-deoxyadenosine-Leustatin-Ortho Biotech) which produce lasting remissions.

Dose: Pentostatin - 4 mg/m²/week for three weeks, then once in 2 weeks for 6 weeks followed by once a month for 6 months, given intravenously.

Cladribine is given in doses of 0.1 mg/kg/bw by continuous IV infusion for 5 days every month. Alpha interferon given in doses of two million units/m² thrice a week used to be the treatment of choice. It is most probably only palliative.

Prolymphocytic Leukemia

This is a rare variant of CLL, seen in males above the age of 60 years and showing gross splenomegaly and a very high white cell count, often above 400 × 10⁹/L. Lymphadenopathy is rare. The characteristic cell is the large lymphocyte showing a prominent nucleolus. The course is rapidly downhill and prognosis is poor.

Myelodysplastic Syndrome

K.V. Krishna Das

Chapter Summary

- General Considerations 1050
- Clinical Features 1051
- Management 1052
- Pre-leukemia 1053
- Leukoerythroblastic Blood Picture 1053

General Considerations

Myelodysplastic syndromes (MDS) comprise a group of heterogenous hematopoietic disorders affecting predominantly the elderly age groups. The overall general disease incidence is 4 per 100,000 people, but in the age group above 60 it may go upto 30 or more per 100000.

In India the disease affects relatively younger persons, median age group being 45 years, children also may be affected rarely.

The term MDS covers a range of neoplastic disorders of hemopoietic tissues in which the progeny of transformed stem cell gradually expands and replaces normal marrow cells. The hallmark of MDS is ineffective hematopoiesis evidenced by peripheral cytopenias despite a normo- or hypercellular bone marrow. Clinically and hematologically five distinct conditions can be included under this term. These are given below (FAB) classification.

1. Refractory anemia (RA)—which do not respond to nutritional supplements.
2. Refractory anemia with ring sideroblasts—presence of excess of ring sideroblasts in bone marrow (RARS) (see Fig. 149.18).
3. Refractory anemia with excess of blasts—1-4% in peripheral blood and 5-20% in bone marrow (RAEB).
4. Refractory anemia with excess blasts in transformation—5% blasts in peripheral blood and 20-30% in bone marrow (RAEB-E).
5. Chronic myelomonocytic leukemia (CMMOL).

PATHOGENESIS

MDS results from the expansion of an abnormal clone of stem cells, with concomitant suppression of normal hemopoiesis. The main pathological processes include:

- a. Augmented apoptosis leading to ineffective hematopoiesis and peripheral cytopenias and
- b. Transformation to acute myeloid leukemia (AML)

MDS originates in the pluripotent stem cells and involves all myeloid cell lines and in some cases, possibly lymphoid cells as well.

The cells produced by the abnormal clone do not mature normally, and are also functionally abnormal. They survive poorly in the blood and bone marrow. The final outcome is the development of pancytopenia. The precise abnormality varies from patient-to-patient. The clonal evolution is characterised by increasing chromosomal abnormalities, progressively increasing malignant characteristics in the bone marrow and the final evolution into AML with the appearance of large number of blast cells. It is difficult to define where MDS ends and AML begins though several attempts have been made to define the condition as far as possible. Several newer criteria have been added to modify the FAB classification.

One popular scheme is the WHO classification which identifies 8 classes. Scoring systems which quantify the risk of development of AML and prognostic factors which modify treatment schedules have been made. The International Prognostic Scoring System (IPSS) which is well accepted, takes into account three parameters (see Table 156.2).

(1) Percentage of blasts in the bone marrow (2) karyotype and (3) number of cytopenias. The total score 0-2.5 is taken to help in predicting the risk of progression and survival MDS is characterised by regular chromosomal

abnormalities. Interstitial deletions involving the long arm of chromosome 5 are among the most common cytogenetic finding. The clinical and hematological features, response to treatment and prognosis depend to a great deal on the cytogenetic abnormalities.

The common chromosomal abnormalities include trisomy 8, monosomy 5 or 7, loss of y and interstitial deletion of the long arm (q) of 5,7,11 and 20. Deletion of bands q13 to q5 of chromosome 5 is the most frequent abnormality. Patients with this type of deletion show particular features and hence this is even known as 5-q syndrome. This is seen more in elderly females. Oncogene mutations are reported in MDS—ras mutation in upto 40% of cases and p53 mutations in 5-10%. Activation of ras oncogene plays a part in the pathogenesis, even though its clinical significance is not yet clear. Cases with N-ras mutation have higher mortality.

MDS has a great predisposition to develop into acute myeloid leukemia. This transition may be insidious or rapid. In some cases there may be clinical similarity but they can be distinguished by clinical features and investigations.

The hematological findings include macrocytic anemia, normal or raised platelet counts, erythroid hypoplasia and mononuclear megakaryocytes in the marrow. The features of MDS vary depending on the genetic defect.

CLINICAL FEATURES

MDS affects the older age groups more, though children may also be affected at times. The disease presents insidiously as cytopenias affecting the erythroid, myeloid and megakaryocyte cell lines, resulting in anemia, leukopenia and thrombocytopenia. The presenting features are those of refractory anemia, recurrent infections, and hemorrhage. Organomegaly (liver, spleen and lymph nodes) is rare, or if at all present, mild compared to AML. The bone marrow is cellular and shows evidence of defective maturation (i.e.) dysplastic changes in all cell lines. The morphological abnormalities include arrest of maturation, nuclear division without cytoplasmic division and other changes. In over 90% of cases chromosomal changes are demonstrable. The erythrocytes may be macrocytic. Neutrophils may show Alder-Reilly and Pelger Huët anomalies (Figs 156.1 and 156.2). In Pelger-Huët anomaly the granulocytes in peripheral blood show rod, dumbbell, peanut or spectacle like nuclei, with coarse chromatin. This abnormality may be inherited or acquired. There is no gross disturbance of function.

Though it is difficult to distinguish MDS from AML in borderline cases, in the majority this distinction can be made by clinical and laboratory parameters (Table 156.1). RA and RARS generally show only less than 1% of blast cells in peripheral blood. Their median survival is over 50 months.

RAEB and RAEB-E show about 5% blast cells in peripheral blood. Their median survival is 5-12 months.

Fig. 156.1: Alder-Reilly anomaly neutrophils: heavy azurophilic granules in some neutrophils—(arrow), monocytes and lymphocytes—Functional significance not clear

Fig. 156.2: Peripheral blood smear Pelger-Huët abnormality neutrophils: Note: The absence of segmentation of neutrophils—arrow points to bilobed nucleus—Functional significance is not clear

Prognosis depends on the type of MDS 50% of cases die within one year of diagnosis due to marrow failure. About 30% develop AML. Groups 3, 4 and 5 show a greater tendency to evolve into AML. Prognosis also depends on the type of chromosomal abnormalities. Prognostic scoring systems based on bone marrow blasts, karyotype and severity of cytopenias are available. Primary MDS has to be distinguished from treatment related MDS (t-MDS), also known as secondary MDS, which may follow radiotherapy or chemotherapy for malignancies such as lymphomas, myeloma and carcinomas.

MANAGEMENT

Management of MDS can be divided into two broad categories (Tables 156.3 and 156.4)
A. For those with low and intermediate- 1 risk
B. For those with intermediate- 2 and high risk
Since the pathogenesis of these two groups is different, treatment goals are also different.

Main aims are:
1. To improve hematopoiesis and correct the cytopenias
2. To improve survival and
3. To delay the transition to AML.
For FAB classes 1 and 2 monitoring and occasional blood transfusion may be the only treatment required over prolonged periods.
Several treatment strategies have been evolved at present. These include single agent chemotherapy with cytosine arabinoside, 5-azacytidine, topotecan, oral idarubicin and hydroxyurea. Combination chemotherapy with or without hemopoietic growth factors is used in some cases. Anti-cytokine therapy using the following combination is found to benefit some (Table 156.4).
Pentoxifylline 800 mg tds
Ciprofloxacin 500 mg bid
Dexamethasone 4 mg qid
A small proportion go into cytogenetic remission. Antithymocyte globulin (ATG) given to selected cases brings about remission in 40% of cases. Supportive

TABLE 156.1 Showing the differences between MDS and AML		
	Myelodysplastic syndrome (MDS)	Acute myeloid leukemia (AML)
1. Age group	More in the older age groups	All age groups
2. Course	More protracted	More acute
3. Hepatosplenomegaly	Rare	More common
4. Peripheral blood studies	Cytopenias and morphological abnormalities. Blasts rare—usually below 5%.	Presence of blasts more frequent, demonstrable invariably
5. Nonspecific hematological phenomena	Red cell enzymopathies, low levels of neutrophil alkaline phosphatase, raised fetal hemoglobin levels, altered blood group antigens, positive Ham's tests	Rare
6. Bone marrow	Blasts less than 30% in many cases much liver dysplasia present	30% or more
7. Chromosomal studies	Abnormality in 90%	Variable
8. Prognosis	Depends on the type	Uniformly bad
Note: Though in the majority of cases these features help to distinguish MDS from AML, in a borderline case this distinction can be made only by prolonged observation.

1.5-2.0	Intermediate – 2
>2.5	High

TABLE 156.4

Relation between IPSS risk groups and disease progression			
Risk group	Probability for AML%	Median time for AML to develop years	Median survival years
Low	19	9.4	5.7
Intermediate-1	30	3.3	3.5
Intermediate-2	33	1.1	1.2
High	45	0.2	0.4

measures include packed cell transfusions, use of growth factors G—CSF and G—MCSF and erythropoietin and control of infections.

Thalidomide and linalidomide have been employed with good response. Thalidomide, in a dose of 400 mg/day has given good response in low risk patients.

Bone marrow transplantation or stem cell transplantation may be necessary in many cases, to effect cure.

Further reading- Hematology today 2005 edited by M B Agarwal – XIth National CME in hematology and hemato-oncology, Mumbai. Myelodysplastic syndromes by Hussain I. Saba pp 175-192.

PRE-LEUKEMIA

Four undermentioned groups of conditions fall under this category since they may develop into acute myeloid leukemia on follow-up.

1. Well-defined hematological disorders such as polycythemia vera, idiopathic myelofibrosis, paroxysmal nocturnal hemoglobinuria, Fanconi’s anemia, idiopathic sideroblastic anemia, multiple myeloma, and lymphomas. CML invariably transforms into AML or ALL if the patient lives long enough.
2. Genetic disorders like Down’s syndrome.
3. Primary malignancies such as those of the breast or ovaries when treated with cytotoxic drugs or immuno-suppressants.
4. The myelodysplastic syndromes.

Long-term exposure to several drugs used in cancer chemotherapy, especially the alkylating agents, is associated with the development of second cancers, among which AML is frequent.

It is not clear whether prophylactic therapy will prevent the emergence of acute leukemia and thereby change the natural history and therefore the treatment is symptomatic.

Leukoerythroblastic Blood Picture

This is the simultaneous presence of the precursors of both myeloid and erythroid series of cells in peripheral blood (Fig. 156.3).

It is also characterised by abnormal RBC, WBC and platelet morphology. RBCs appear pear-shaped or distorted. Nucleated red cell precursors occur. WBC count is elevated, with immature cells like myelocytes, promyelocytes and even myeloblasts suggesting a leukemoid reaction. Platelets are generally normal, but they may be reduced or increased or may be larger size. All these are the result of hematopoiesis occurring outside the marrow (extramedullary hematopoiesis) in foci such as the spleen, liver and even lymph nodes, consequent to marrow fibrosis, or infiltration by inflammatory or neoplastic tissue. The condition should not be mistaken for leukemia.

The developing cells proliferating in the extra medullary sites enter the blood stream prematurely without passing through the normal tissues which prevent immature precursors and defective cells from entering the circulation. Normally the spleen destroys and removes deformed erythrocytes from circulation. In the absence of normal

Fig. 156.3: Leukoerythroblastic picture
M—Myeloid cell, E—Erythroblast

splenic function leukoerythroblastic blood picture may result.

The causes of leukoerythroblastic blood picture include:

1. Primary idiopathic myelofibrosis
2. Secondary myelofibrosis
3. Infections like tuberculosis, HIV, fungal infections
4. Radiation
5. Associated with polycythemia, chronic myeloid leukemia, lymphoma, myeloma, hairy cell leukemia
6. Marrow infiltration
 - a. Carcinoma breast
 - b. Carcinoma lung
 - c. Carcinoma prostate

- d. Neuroblastoma
- e. Sarcoidosis

All the conditions other than primary idiopathic myelofibrosis can be called myelophthisic. In all these conditions there are three processes occurring in varying grades (1) proliferation of fibroblasts in the marrow space, (2) extramedullary hematopoiesis (myeloid metaplasia) and (3) ineffective erythropoiesis. Similar blood picture can some times occur when a normally functioning marrow is under stress due to acute hemorrhage, hemolysis or DIC. When megaloblastic anemia is treated with large doses of vitamin B₁₂ and folate there is severe erythroid hyperplasia the immature cells pass out of the normal marrow in large numbers.

Agranulocytosis (Severe Neutropenia)

P.K. Sasidharan, K.V. Krishna Das

Chapter Summary

General Considerations 1054
Clinical Features 1055
Diagnosis of Neutropenia 1055
Treatment 1055

GENERAL CONSIDERATIONS

Agranulocytosis (severe granulocytopenia) refers to decrease in absolute neutrophil count below 500/cmm. Though the term indicates absence of granulocytes (especially neutrophils), for practical purposes neutrophil counts below 500/cmm should be taken as agranulocytosis and remedial measures have to be instituted. Severe neutropenia of this level will predispose to life threatening infections. It can occur due to various causes such as chemotherapy with anticancer drugs, hypersensitivity to other drugs in common use, infections, bone marrow failure, irradiation by ionizing radiations and at times, without an obvious underlying cause.

It should be remembered that almost all drugs can cause severe neutropenia, and hence this risk should be anticipated when introducing any new drug. Some drugs have a predilection to cause agranulocytosis.

Drug induced agranulocytosis: Pathogenesis: In the majority of cases it is caused by immunological

mechanisms, where the antibody coated granulocytes are preferentially removed by the reticuloendothelial system. It may also be due to direct effect on bone marrow as in the case of anticancer drugs. Two clinical patterns are usually seen. Sometimes it can occur even with first dose administration or on intermittent administration, but the agranulocytosis occurs abruptly. In the second pattern as exemplified by drugs like phenothiazines, prolonged administration leads to a gradual reduction of neutrophils. Often this neutropenia recovers when the drug is withdrawn or sometimes the neutrophil count can get stabilised at a lower level even when the drug is continued. It is to be noted that no drug is completely free from this

Major Causes of Neutropenia

- a. Drug induced
- b. Infections; viral hepatitis, enteric fever, tuberculosis, HIV
- c. Septicemias
- d. Acute leukemias
- e. Myelodysplasias
- f. Aplastic anemia
- g. Bone marrow infiltration/metastasis
- h. Autoimmune destruction
- i. B₁₂ or Folate deficiency
- j. Hypersplenism
- k. Radiation

Note: Though several conditions lead to neutropenia, many of them do not lead to agranulocytosis.

Drugs causing Neutropenia

1. Cytotoxic and anticancer drugs
2. Immunosuppressants
3. Antithyroid drugs- propylthiouracil, methimazole, carbimazole
4. Anticonvulsants- Phenytoin, carbamazepine
5. Antihypertensives-methyldopa, captopril
6. NSAIDs: indomethacin, ibuprofen, gold salts
7. Antibiotics-chloramphenicol,sulfonamides, rifampicin
8. Diuretics, acetazolamide, hydrochlorothiazide
9. Others: dapsone, quinine, interferons, allopurinol,

form of toxic reaction. All antineoplastic drugs are capable of producing severe neutropenia if administered in sufficient dosage and this is due to direct impairment of cell production. History of drug ingestion may not be forthcoming in 20% of cases.

CLINICAL FEATURES

Irrespective of the cause, the risk of infections is maximum when the absolute neutrophil counts fall below $500/\text{mm}^3$. The neutropenia may be asymptomatic when the counts are above $1000/\text{mm}^3$ and also when it is acute in onset or of brief duration. When neutropenia is chronic, monocytosis may occur and might compensate for the risk of infections. The sources of infection in such patients are usually gums, throat, tonsils, lips, tongue, genitalia, perianal regions, genitourinary tract, gut, skin and lungs and the organisms are the usually suspected ones from these respective sites from which infection spreads. In the hospital settings they can have infection by unusual organisms and even by drug resistant ones. Usual signs and symptoms which suggest an infection may be absent in neutropenic patients owing to the absence of inflammatory mediators and hence a careful search for infections at these sites is mandatory.

Serious pneumonia can present with only minimal or even absence of chest signs, no sputum or only non purulent sputum and minimal or no infiltrates on X-ray chest. Signs of inflammation may be absent at sites of skin infections and if ulcers are present they may be covered with grayish black offensive exudates. The surrounding skin may be red and necrotic without any tendency to localise the lesion and since these infections are not contained locally, they get disseminated very fast and hence empirical broad spectrum antibiotic treatment is warranted without delay. Clinical features are basically those of the primary disorder causing neutropenia, and those due to neutropenia which can predispose to severe bacterial and some fungal infections. The patient may present with high fever, chills and rigor, sore throat or only extreme prostration without fever.

Diagnosis of Neutropenia

Total neutrophil counts below $1000/\text{cmm}$ should alert the physician. Counts below $500/\text{cmm}$ indicate serious neutropenia. Whenever any unusual symptom develops in a patient who can potentially have neutropenia, or when

Fig. 157.1: Agranulocytosis bone marrow: Note: The absence of myelocytes promyelocytes and neutrophils

very low neutrophil counts are documented bacteriological samples are collected from the appropriate sites for culture and sensitivity and broad spectrum antibiotics are started without waiting for the culture reports. Culture report might help to modify the regime in a given patient or at least help to plan empirical treatment in future.

Agranulocytosis has to be differentiated from acute aleukemic leukemia, aplastic anemia, infectious mononucleosis, Vincent's angina and thrush. Bone marrow study is mandatory when the cause is not obvious, especially when it is a bicytopenia or pancytopenia.

Examination of peripheral blood reveals leukopenia with absence of neutrophils or presence of only a few old neutrophils with multilobed nuclei. Young forms with less than three lobes in the nuclei are rare or absent. This should suggest depression of leukopoiesis. Bone marrow examination shows suppression of neutrophil precursors (Fig. 157.1).

Treatment

At the earliest clinical suspicion all potentially offending drugs should be withdrawn. Otherwise treatment depends on the cause of neutropenia; and treatment of infection by powerful bactericidal antibiotic combinations. Empirical broad spectrum antibiotic therapy should be started without delay whenever infection is suspected. A useful combination is gentamicin, ciprofloxacin and metronidazole all given intravenously. Other drugs that may be considered for use are cefotaxime, ceftazidime, ceftriaxone, imipenem, and amikacin. Severe neutropenia in selected situations are benefited by recombinant granulocyte colony stimulating factor (GCSF) or granulocyte macrophage colony stimulating factor (GM-CSF) but the routine use of these drugs especially to prevent infections is not recommended, except in the setting of potentially toxic anticancer chemotherapy. Prognosis depends on the cause, prompt diagnosis and intervention. Drug induced agranulocytosis is a preventable disease if it is remembered that all drugs, including even apparently safe drugs are capable of producing this complication.

Plasma Cell Dyscrasias

K.V. Krishna Das, Mathew Thomas

Chapter Summary

Multiple Myeloma 1056

Variant Forms of Myeloma 1060

Smouldering Multiple Myeloma 1060

Plasma Cell Leukemia 1060

Nonsecretory Myeloma 1060

Osteosclerotic Myeloma
(POEMS Syndrome) 1060

Amyloidosis 1060

These include a group of disorders mainly characterized by: (1) uncontrolled proliferation of antibody producing cells, and (2) secretion of a structurally homogenous gammaglobulin or its polypeptide chains—the ‘M’ component.

Traditionally, multiple myeloma, Waldenström’s macroglobulinemia, heavy chain diseases, benign monoclonal hypergammaglobulinemia, and amyloidosis are included in this group, though Waldenström’s macroglobulinemia and heavy chain diseases are actually lymphoid dyscrasias.

Characteristic protein abnormalities form the hallmark of these disorders.

myeloma proteins may be biclonal. Any of the immunoglobulins—IgG and its subclasses, IgA, IgM, IgE, and IgD, or their light chains-kappa or lambda—may be produced in large amounts. The abnormal immunoglobulins are produced without antigenic stimulation and the normal immunoglobulins are reduced. Hence infections are common. Rarely abnormal immunoglobulins may not be secreted—*non-secretory myeloma*.

Evolution of Myeloma

First step is the emergence of a limited number of clonal plasma cells. This is the stage of monoclonal gamopathy of undetermined significance (MGUS). This is not detected clinically. Annually 1% of these develop multiple myeloma or other related malignant diseases. With the progression of MGUS into myeloma, complex genetic events occur in the abnormal plasma cells and bone marrow micro environment. These include angiogenesis, suppression of cell mediated immunity, and development of paracrine signalling loops involving cytokines such as IL-6, and vascular endothelial growth factor. The resultant interactions of myeloma cells, bone marrow stromal cells and micro vessels contribute to the persistence of the tumour and its resistance to drugs. Asymptomatic cases may become symptomatic in two to three years.

Pathology: There is gross hyperplasia of the plasma cells and these almost fill the bone marrow, eroding into bone and leading to pathological fractures. Myelomatous bone disease represents an imbalance between bone resorption and formation as a result of increased osteoclastic activity and reduction of osteoblastic activity. The plasma cells produce osteoclast activating factors which are cytokines including IL-1 β , TNF β and possibly IL-6. Osteolysis occurs in the proximity of the abnormal plasma cells. A vicious cycle of myeloma cells activating osteoclasts and the osteoclasts in turn stimulating plasma cells through the cytokine IL-6 which is a potent myeloma growth factor, is established. Proliferation of the plasma cells may take a diffuse pattern (*myelomatosis*) or may be localized and nodular (*myeloma*).

Multiple Myeloma

Syn: Myelomatosis

This is the most common disorder among the group of plasma cell dyscrasias. Myeloma is a malignant tumour arising from the plasma cells. The tumour may arise unicentrically or multicentrically from the bone marrow or as localized tumours in other sites.

Genetics of myeloma Many cases show a 14q 32 translocation (1gH translocation). The immunophenotype in myeloma is characterized by CD₃₈⁺⁺, CD₁₃₈⁺, CD₅₆⁺, CD₂₀[–] and FMC7.

Myeloma is a clonal disorder arising from one abnormal clone of plasma cells, secreting only the same type of immunoglobulin-monoclonal myeloma. Rarely

The plasma cells show abundance of cytoplasm, with foamy vacuoles and many of them may be multinucleated (*myeloma cells*). Signs of nuclear immaturity may be evident. Due to increased cell turnover serum uric acid level is elevated. Primary type of amyloidosis occurs in 10% cases. In over 60% of cases the light chains appear in urine in demonstrable amounts. These are called *Bence Jones proteins*. The Bence Jones proteinuria, amyloidosis, and hyperuricemia lead to renal damage resulting in renal failure. The light chains are toxic to renal tubules. Mobilization of calcium from bones causes hypercalcemia, hypercalciuria, and nephrocalcinosis.

Hyperviscosity syndrome may develop due to the presence of abnormal immunoglobulins. The signs of hyperviscosity include weakness, anorexia, impairment of cerebral circulation leading to neurological deficits, and retinal abnormalities. This is more pronounced in IgA myeloma.

Invasion of the bone marrow by plasma cells may cause myelophthisic anemia, leukopenia, and thrombocytopenia. In the majority of cases, plasma cells occur in small numbers in peripheral blood and can be demonstrated in the buffy coat. In a few, large number of plasma cells and plasmablasts (showing nucleoli) appear in the peripheral blood when the condition may be termed *plasma cell leukemia*. At autopsy several organs show infiltration by myeloma cells, but clinical abnormality may not be detectable in many. Chromosomal changes have been detected in myeloma though they are not quite specific or universal as in CML.

CLINICAL FEATURES

This disease is more frequent in the middle and older age groups majority of cases being between 50 and 70 years. It is more common in males. The onset is insidious with symptoms of vague ill-health, back pain, aches and pains, arthralgia and progressive anemia. In the majority of cases diagnosis is made on routine investigation for anemia, raised ESR, bone pains or pathological fractures, localized tumours, or recurrent bacterial and viral infections. In the more advanced cases all evidences of myelophthisic anemia may be present. 20% of cases are asymptomatic and detected by routine laboratory work-up during health checks.

Bone changes: Vertebrae, sternum, ribs, skull, and clavicles show characteristic osteolytic changes (Fig. 158.1). Localised bony or soft tissue swellings may be detectable over these sites. In some, the disease presents abruptly with the onset of pathological fractures in an otherwise healthy subject. In about 3% of cases the osseous lesion is confined to a single bone, without evidence of generalised marrow involvement. Vertebral compression may result in reduction in height of the individual and compressive myelopathy.

Other neurological manifestations develop due to demyelination, amyloid peripheral neuropathy, paraproteinemia neuropathy, carpal tunnel syndrome, and rarely cranial nerve palsies.

Splenomegaly occurs in 20%, hepatomegaly in 40%, lymphadenopathy and involvement of organs like thyroid, adrenal, ovaries, testes, lung, pleura, pericardium, skin, and others in a smaller proportion of cases. Infections like pneumonia and herpes zoster are more common due to immunodeficiency state.

Renal failure may present as insidious onset of azotemia, which is made out on investigation, or it may occur acutely with renal shut down due to tubular obstruction. Contrast radiography (IVP) may precipitate renal failure due to dehydration. Aggressive chemotherapy is also associated with the development of uric acid nephropathy.

Hematology: Normocytic normochromic anemia may be present and neutropenia and thrombocytopenia may develop later. In addition to thrombocytopenia, qualitative platelet defects occur. These include abnormalities of adhesion, aggregation and platelet factor 3 release. Inhibitors of coagulation factors may develop. Hyperviscosity develops as a result of increase in paraproteins. This manifests as bruising and bleeding tendency. In 5% of cases cryoglobulins occur as part of the paraproteins. Such patients may manifest Raynaud's phenomenon. The peripheral blood smear shows marked rouleaux formation which reflects the high ESR. Plasma cells may be seen in small numbers. Presence of numerous plasma cells suggests *plasma cell leukemia*. In some cases plasma cell precursors (plasmablasts) are seen in peripheral blood and bone marrow.

DIAGNOSIS

Myeloma should be suspected in any elderly person presenting with vague rheumatic symptoms, pains, and deformity over the spine. Neurological symptoms, pathological fractures, unexplained anemia, and recurrent infections should alert the physician to the possibility of myeloma. Investigations are absolutely essential to diagnose the condition and assess the extent of the disease. Presence of a very high ESR (often above 100 mm in 1 h) should suggest the possibility of myeloma, if other more common causes can be excluded.

Urine examination: Over 50% of cases show *Bence Jones proteinuria*. Bence Jones proteins are made up of light chains which cross the glomerular filter. On heating acidified urine above 80°C, the protein precipitates and on continuing heating it redissolves above 90°C. Another method for detection is to add an equal volume of 5% sulphosalicylic acid which precipitates the proteins.

Immunoelectrophoresis of urine reveals the type of protein. Though Bence Jones proteins are very suggestive of myeloma, other conditions such as combined light

Fig. 158.1: X-ray skull showing punched out areas

chain nephropathy, lymphomas, leukemias and congenital renal tubular defects may also be associated with this abnormality.

Radiology: X-rays of the skull, long bones, pelvis, ribs, and vertebrae reveal characteristic punched out lesions. One or several vertebrae may be affected. The bone lesions are usually localized. Despite the bone lesions plasma alkaline phosphatase is normal (Fig. 158.1).

Bone marrow examination is diagnostic: Material aspirated from any site is usually diagnostic, but in case of doubt aspiration must be done from an area of radiological abnormality. Normally the proportion of plasma cells ranges from 2 to 10%. Rarely it may rise even up to 20%. In myeloma the number of plasma cells is considerably increased (> 10%) and the plasma cells show morphological abnormality (Fig. 158.2).

Some plasma cells show multinucleation and cytoplasmic vacuoles. These are called myeloma cells. Plasmablasts possess nucleoli. Increase in plasma cells due to myeloma has to be distinguished from reactive plasmacytosis in which plasma cells are increased. Several conditions give rise to reactive plasmacytosis. These include chronic infections like tuberculosis, amyloidosis and secondary neoplasms. In this condition the plasma cells do not generally exceed 10% of the total. Morphological abnormalities are not produced. The secondary plasmacytosis resolves on removing the cause.

Diagnostic Criteria for Myeloma

- 1. Plasma cells in the marrow more than 10%
- 2. Presence of monoclonal proteins in the serum or urine
- 3. Evidence of end organ damage. This may include
 - a) hypercalcemia
 - b) renal insufficiency
 - c) anemia and
 - d) bone lesions (CRAB)

Fig. 158.2: Plasma cells in bone marrow

Electrophoretic studies: Demonstration of paraprotein by electrophoresis and determination of the immunoglobulin type by immunoelectrophoresis or diffusion techniques help to confirm the diagnosis and type the myeloma.

Serial measurement of the paraprotein level helps to assess progress since its level reflects the tumour load. 75% show IgG, 25% IgA and 1% IgD. In younger patients the proportion of IgD myeloma is slightly more. IgD myeloma is more often associated with hypercalcemia and renal failure. Bence Jones myeloma is also more common in the younger age group. Assessment of renal function by blood urea, creatinine, uric acid and glomerular filtration rate are essential to indicate the prognosis and plan therapy. Table 158.1 gives the clinical staging for assessing the prognosis and which is of help to plan therapy.

Differential diagnosis of multiple myeloma includes multiple bony secondaries from carcinoma of the prostate, adrenals, breast, thyroid, and other organs. In this condition, the protein abnormalities are absent or only minimal. Biopsy from these sites may be required to confirm the diagnosis. Eosinophilic granuloma of bone or other lipidoses like Hand-Schüller-Christian disease and Niemann-Pick disease may produce multiple lytic lesions in the skull.

Genetic analysis helps to differentiate Waldenström’s macroglobulinemia from multiple myeloma.

TABLE 158.1

Staging of myeloma		
Criteria	Stage 1	Stage III
Hemoglobin	above 10 g/dL	below 8.5 g/dL
Serum calcium	below 12 mg/dL	above 12 mg/dL
X-ray of bones	normal or sparse lesions	advanced lytic lesions
M-components		
IgG	below 5 g/dL	above 7 g/dL
IgA	below 3 g/dL	above 5 g/dL
Urinary		
M-component	below 4 g/24 h	above 12 g/24h

Benign monoclonal gammopathy is a rare disorder in which paraproteins are increased to high levels, but often lower than that in myeloma. Normal immune mechanisms are not suppressed. The stage of the disease can be assessed by the laboratory values.

Stage II is intermediate between stage I and III. Subclass A indicates normal and B indicates impaired renal function based on serum creatinine levels. In A it is < 2 mg/dL and in B it is > 2 mg/dL.

Course and prognosis: The disease runs a chronic course extending over a few years, but relentlessly progresses to death. Blood urea level above 80 mg/dL (13 mmol/L), hemoglobin below 7 g/dL, and hypoalbuminemia are bad prognostic factors. Cases with blood urea above 80 mg/dL rarely survive a few months. Complications include painful pathological fractures, anemia, hypercalcemia, recurrent bacterial infections and renal failure.

Prognosis varies with the different types of myeloma and treatment administered. At present chemotherapy and radiotherapy are only palliative. Bone marrow transplantation is curative in a smaller proportion when compared to leukemias. Younger patients do better. Median duration of remission with palliative treatment is 2 years. Less than 10% of cases may survive 10 years. Even this small group ultimately succumbs to the disease.

TREATMENT

Melphalan

The drug freely available at low cost is melphalan which is an alkylating agent (phenylalanine mustard). This is the most time honoured specific drug. Several dosage schedules have been used. One of the standard regimens is to give melphalan 8 mg/m² and prednisolone 60 mg/m² orally after breakfast for 4 consecutive days repeated once in 4 weeks. If the response is not satisfactory the dosage of both the drugs should be increased by 20%.

40% of cases get remission with reduction of myeloma protein by 75%, Bence Jones proteinuria by 95% and reduction of bone marrow plasma cells below 5%. Maintenance therapy has to be given by repeating the course. High dose melphalan therapy may even give cure in a small proportion of cases. Various dosage schedules and combinations using melphalan are in vogue at present.

Bone Resorption Inhibiting Agents

The bisphosphonates-pyrophosphate analogues—suppress osteoclastic activity and indirectly myeloma cells as well. The different members of this group of drugs vary in their therapeutic potential and possibly mode of action as well. Etidronate is the least effective, but the later analogues are definitely beneficial by reducing vertebral and other fractures, bone pains, plasma levels of paraproteins and

also serum calcium. Several preparations are available. These include etidronate, clodronate, pamidronate, ibandronate, zolendronate and alendronate in the ascending order of therapeutic potency. They have to be given under supervision. Alendronate is highly effective. The drug is expensive.

It is now clear that patients who have bone lesions, with or without hypercalcemia benefit by the addition of bisphosphonate. Bisphosphonates may lead to osteonecrosis of the jaw. Treatment consists of withdrawal of bisphosphonates and antibiotics to treat infection.

Thalidomide (α -N phthalimido glutarimide) which is a derivative of glutamic acid has produced very good results in myeloma. When given orally it is readily absorbed. Its main actions are anti-TNF α activity, anti-angiogenesis activity and immunomodulation. It inhibits IL6, IL12 and IFN α . It reduces expression of intracellular adhesion molecules. Different doses have been tried. The drug has been used singly, and in combination with dexamethasone in a dose schedule of thalidomide 200 mg oral on days 1-28 and dexamethasone 40 mg/m² oral on days 1-4, 9-12 and 17-20. This produces favourable response in 65-70% of newly diagnosed cases and 50% in relapsed cases. Adverse effects include teratogenicity, somnolence, peripheral neuropathy, constipation and others. Thalidomide is also effective in advanced myeloma. A newer analogue of thalidomide, lenalidomide is an amino substitute variant which is more potent with less side effects.

Other drugs which can be combined with thalidomide include cyclophosphamide and melphalan. Studies are going on to identify the best regimen.

Resistant Cases

If the response to standard drugs is unsatisfactory, a combination of vincristine, doxorubicin and dexamethasone may be successful.

Dose: Vincristine 0.4 mg/day, and doxorubicin 9 mg/day, are given as continuous IV infusion through a central venous catheter for 4 days, along with oral administration of 40 mg dexamethasone on days 1, 9 and 17 of each 28-day cycle. About 30-40% of resistant cases do respond. High dose dexamethasone and methyl prednisolone (2 g given IV once a week) are very potent drugs which suppress myeloma, in combination with other drugs.

Newer drugs include **bortezomib** (velcade) which is a proteasome inhibitor which inhibits nuclear factors and also induce apoptosis. It is given in a dose 1.3 mg/m² I V over 3-5 minutes on days 1, 4, 8 and 11. Cyclically every 21 days. The results are encouraging in relapsed and resistant cases. This drug is very expensive.

Bone marrow transplantation (BMT): Allogenic or autologous BMT is an accepted and very useful therapeutic modality employed, when the myeloma is not amenable to chemotherapy. With the present state of technical

advancement, persons up to 65-70 years can be considered for successful engraftment. At present less aggressive bone marrow ablative regimen to the recipient is being tried in several centres (mini transplant). The post-BMT complications are less severe. With the use of modern immunosuppressive drugs results are quite encouraging.

Stem Cell Transplantation

Autologous stem cell transplantation preceded by high dose chemotherapy is beneficial.

Tandem transplantation in myeloma. In this procedure a second autologous stem cell transplant is given after the patient has recovered from the first. The rates of cure are better than single transplants.

Supportive Measures

Infections have to be treated promptly with antibiotic combinations. **Hyperuricemia** has to be prevented by the oral administration of allopurinol 100 mg tid.

Renal complications of hyperuricemia can be avoided by hydrating the patient, alkalinising the urine by the administration of sodium bicarbonate, and ensuring a daily urine output of at least 2 litres by the use of frusemide in small doses. Hemodialysis may be required to tide over acute renal failure. Dangerous **hypercalcemia** may occur. Management of hypercalcemia is given in section 11. Chapter: 99.

Hyperviscosity syndrome is treated by plasmapheresis using a blood cell separator. Administration of thiols inhibits the synthesis of myeloma proteins. Bleeding and fractures demand symptomatic treatment in addition. Spinal cord compression demands immediate laminectomy and irradiation to the spine.

Treatment of localized myeloma: Local irradiation in a dose up to 4000 cGy gives rapid pain relief and helps to clear the lesions. This has to be accompanied by chemotherapy.

Extramedullary plasmacytomas may occur, most commonly in the upper respiratory tract, gastrointestinal tract and other regions.

Localized plasmacytomas in soft tissues have to be removed surgically, and the patients have to be followed up for several years to watch for the development of multiple myeloma.

Variant Forms of Myeloma

SMOULDERING MULTIPLE MYELOMA

This condition presents with the following features.

- 1. Abnormal monoclonal protein in excess of 3 g/dL in serum.
- 2. Presence of abnormal plasma cells in excess of 10% in bone marrow.

Bence Jones proteins may be present in urine. Levels of normal immunoglobulins may be decreased. Many of them follow a prolonged benign course which may resemble benign “monoclonal gammopathy”. Risk of developing florid myeloma is 51%, 66% and 73% at 5, 10 and 15 years respectively. Management consist of close follow-up every 4-6 months.

PLASMA CELL LEUKEMIA

In this condition the peripheral blood plasma cells form more than 20% of nucleated cells or absolute count of plasma cells exceed 2000 cmm. If the presentation of the plasma-cell disorder is with the leukemic phase it is called primary plasma cell leukemia, and if this phase develops during the course of multiple myeloma it is termed secondary.

NONSECRETORY MYELOMA

One percent of multiple myelomas fall under this category. In this condition the plasma cells may produce the abnormal protein, but do not secrete it into the plasma. The presence of monoclonal protein within the plasma cells can be confirmed by immuno-peroxidase staining or immunofluorescence studies.

OSTEOSCLEROTIC MYELOMA (POEMS SYNDROME)

This produces osteosclerotic shadows in skiagrams and accounts for 3-5% of all the myelomas. The lesion may be single or multiple. This is a rare condition in which the number of plasma cells in bone marrow is below 5% but bone biopsy may show localized plasmacytomas. The components of this syndrome include:

Polyneuropathy, mostly demyelination, motor disability

- Organomegaly—liver, spleen, lymph nodes
- Endocrinopathy—gynecomastia, atrophic testes
- Monoclonal protein abnormality, and
- Skin changes—pigmentation, hypertrichosis.

The major disability is due to a chronic inflammatory polyneuropathy. Bone marrow shows only less than 5% of plasma cells. Diagnostic finding is the presence of plasmacytoma on histology of the bone lesion. Treatment consists of local irradiation over the affected bone.

Amyloidosis

Virchow coined the term amyloid in the mid 19th century. Amyloidosis consist of a large group of diseases in which misfolding of the extracellular proteins has a major role. This dynamic process which occurs in parallel with, or as an alternative to physiological folding, generates insoluble toxic protein aggregates that are deposited in tissues as bundles of β short fibrillar protein. These consist

TABLE 158.2

Characteristics of systemic amyloidosis			
Type	Fibril composition	Precursor protein	Clinical spectrum
Primary AL	Monoclonal immunoglobulin light chains	Lambda or kappa light chain	Cardiomyopathy, hepatomegaly, proteinuria, macroglossia, autonomic dysfunction, orthostasis, ecchymosis, shoulder pad sign, carpal tunnel syndrome (CNS not affected, peripheral and autonomic nervous system are affected)
Familial ATTR	Transthyretin	Abnormal transthyretin	Mid-life onset of peripheral and autonomic neuropathy, myopathy, vitreous opacities.
Secondary AA	Amyloid A protein	Amyloid A protein	Underlying inflammatory disease, hepatosplenomegaly renal failure

of strands of polypeptides arranged in zig-zag manner. The unique feature of amyloidosis is the capacity of these proteins to acquire more than one conformation. Amyloidosis is characterized by the extracellular deposition of amyloid which appears as a homogenous eosinophilic material in several tissues. Amyloidosis may be primary or secondary. The amyloid fibrils in primary amyloidosis are fragments of immunoglobulin light chains. Lambda light chains predominate over kappa light chain in the ratio of 2:1. Different proteins make up the amyloid fibrils in reactive (secondary) and familial amyloidosis.

Clinical Classification (Table 158.2)

- 1. *Primary*: without any detectable underlying cause or associated with myeloma
- 2. *Secondary*
 - a. Chronic infections- tuberculosis, bronchiectasis
 - b. Rheumatoid disease
 - c. Lymphoma and other neoplasms
- 3. *Heredo-familial mediterranean fever*
- 4. *Local amyloidosis*—skin, joints, tendons, nerves, and other structures
- 5. *Senile amyloidosis*

Modern biochemical classification is based on the nature of precursor plasma proteins that form the fibril deposits:

AL amyloidosis: immunoglobulin light chain related (AL)

Familial amyloidosis: transthyretin-associated (ATTR)

Secondary amyloidosis: Amyloid A protein (AA)

Primary amyloidosis is a plasma cell dyscrasia related to multiple myeloma. Clonal plasma cells in the BM produce immunoglobulins that are amyloidogenic.

Familial Amyloidosis

This consists of a group of autosomal dominant diseases in which a mutant protein forms amyloid fibrils beginning in mid-life. The most common form is caused by mutant

transthyretin (ATTR). Other genetic and environmental factors may play a role in the phenotypic expression of this disease.

Secondary Amyloidosis

These are due to amyloid formed from serum amyloid A (SAA) which is an acute phase protein produced in response to inflammation. There are several SAA proteins, out of which at least four different molecular forms take part in the formation of amyloid.

Clinical Features

Systemic amyloidosis: Clinical features depend on the tissues involved. Since the kidneys are affected most frequently in secondary amyloidosis, 60% cases present with nephrotic syndrome. Proteinuria results from damage to the glomeruli and also toxicity of SAA oligomers or profibrils. The rest may be asymptomatic. The common cause of death is chronic renal failure.

The heart is affected in 80-90% of cases of primary amyloidosis and this results in restrictive and congestive cardiomyopathy, cardiac failure, and arrhythmias. Sudden death may occur (Table 158.3).

Gastrointestinal involvement: Macroglossia may interfere with deglutition and respiration. Involvement of the intestines produces diarrhea, malabsorption, intestinal obstruction, and gastrointestinal bleeding.

Liver is commonly involved in both types of amyloidosis. The organ is enlarged and firm but functional derangement is not marked. *Spleen* is commonly enlarged and firm in secondary amyloidosis. *Adrenal gland* is affected in secondary amyloidosis and this leads to hypofunction of the gland.

Respiratory tract: Amyloid deposition may occur in the respiratory passages or in the lung parenchyma.

Nervous involvement: Common presentations are peripheral neuropathy and carpal tunnel syndrome. Primary cerebrovascular amyloidosis may occur in which

TABLE 158.3

Common sites of involvement in amyloidosis

Primary amyloidosis	Secondary amyloidosis
Heart	Kidney
Tongue	Spleen
Gastrointestinal tract	Liver
Skeletal and visceral muscles	Adrenal cortex
Nerves	Lungs
Joints, tendons	Other organs
Liver	
Skin	
Lungs	

Note: Considerable overlap may occur between the two forms.

amyloid deposits occur in the arteries and arterioles as well as adventitia of the veins and venules. This weakens the vessel wall and accounts for some cases of hemorrhagic stroke. Autonomic neuropathy affecting several organs is common.

Localized amyloidosis: Nodular masses of amyloid may occur in and around joints and tendons, particularly around the glenohumeral joints. Large deposits may occur giving rise to the “*shoulder pad sign*”.

Arthralgia and arthritis resembling rheumatoid arthritis may occur. Affection of the skin manifests as lichenoid plaques, nodules, or purpura around the orbits.

In 80-90% of persons above the age of 80 years amyloidosis of the heart may occur (*senile cardiac amyloidosis*).

Amyloid purpura occurs rarely over the chest above the nipple line, neck and eyelids. Amyloid fibrils bind to factor X and lead to factor X deficiency and purpura.

Diagnosis: Amyloidosis is confirmed by biopsy of appropriate tissues. The rectal mucosa is commonly involved in primary amyloidosis, and therefore, rectal biopsy is a rewarding procedure. Renal biopsy is usually positive when there is proteinuria. Amyloid deposits can be demonstrated in the gingival mucosa when gums are

clinically abnormal. Electron microscopy of urine and synovial fluid may reveal amyloid fibrils.

Tests to Identify the Type of Amyloid

AL amyloid: Immunofixation electrophoresis of urine and serum, bone marrow biopsy with immune histochemical staining for lambda and kappa light chains. Amyloid deposits are identified on the basis of their apple green birefringence under polarized light microscope after staining with Congo red. Under the electron microscope amyloid fibres appear as rigid non-branching fibrils 7.5-10 nm in diameter.

Familial ATTR: Serum isoelectric focussing for abnormal transthyretin, or DNA based test for mutant transthyretin gene.

Secondary AA: Elevated concentration of serum amyloid A protein, immunohistochemical staining of tissue for AA protein. Normal level of SAA fragments in blood is < 4 mg/dL. Severity of amyloidosis and prognosis correlate with blood levels of SAA.

Prognosis: Systemic amyloidosis is always fatal if untreated. Death is due to renal or cardiac failure within 1-2 years of diagnosis. Progress of amyloidosis can be arrested and the lesions may even regress with treatment of the underlying condition. AL amyloidosis (primary) has the worst progress with a median survival of 1-2 years. Patients with ATTR amyloidosis may survive up to 15 years and the prognosis for secondary amyloidosis depends upon the underlying condition.

Therapy: Treatment of the underlying cause is instituted wherever a cause can be detected. Cytotoxic drugs like melphalan are sometimes beneficial in primary and reactive amyloidosis, but not in all cases. For all forms specific therapy directed to the organs affected is essential. For primary amyloidosis chemotherapy is needed. Deflunisal is effective in familial amyloidosis. Eprosinate inhibits amyloid deposition in tissues. It delays renal damage. The dose is 800-2400 mg oral daily. Liver transplantation helps cases with familial amyloidosis. Bone marrow transplantation has been tried with varying success.

Malignant Disorders of Lymphoid Cells

Lymphomas

GENERAL CONSIDERATIONS

These are malignant tumours arising from lymphoid tissue. In general, lymphomas remain confined to lymph nodes and other lymphoid structures in their early stages. Lymphomatous cells in varying numbers are seen later in the bone marrow and the peripheral blood. On the other hand lymphatic leukemias which are also primary malignancies of the lymphatic cells start in the marrow or in the lymph nodes and become disseminated from the beginning, even though lymph nodes and other lymphoid organs do show lesions simultaneously. Lymphatic leukemia and its variants are described in chapter 155.

Lymphomas may start unicentrically or multicentrically. They have been classified broadly into *Hodgkin's lymphoma* (HL) and *Non-Hodgkin's lymphoma* (NHL). *Hodgkin's lymphoma* is characterized by the presence of *Sternberg-Reed cells* which are absent from the latter. The course, prognosis and response to treatment are different in the two types.

In many instances lymphomas arise *de-novo* at sites not conventionally included under the lymphoreticular system, such as the brain and several other solid organs. These may remain so for long periods without manifesting any tendency for generalized spread and behaving like local tumours.

Etiology: As in the case of leukemias, several possibilities have been postulated. These include genetic predisposition, viral infections, immunological factors, long-term toxicity to drugs like cyclophosphamide, and exposure to irradiation and chemicals. There are many reports of lymphomas occurring in clusters in closed ethnic groups, and showing a seasonal prevalence. These phenomena suggest a common environmental factor.

Epidemiology: Lymphomas form 1.9% of all cancers in many general hospitals in India. Among the lymphomas 35-43% is HL and the rest is NHL. Lymphatic malignancies formed 4.3% of all cancer cases seen in Tata Memorial Hospital, Mumbai.

(Ref: Biswas et al, JAPI: 2006. 54, 24-33).

Lymphomas have been the object of intensive studies by oncologists and hematologists and based on the various parameters such as cell morphology, cytology, cytochemistry, immune markers, chromosomal characteristics, gene variation and biological behaviour, the classification, specific diagnosis, management protocols and follow-up have all assumed great importance just as in the case of leukemias.

Management of lymphomas is an equally complex exercise requiring sophisticated facilities for diagnosis and treatment. Newer and newer observations lead to changes in classification and management strategies. Only basic principles are given in this chapter.

HODGKIN'S DISEASE

SYN: HODGKIN'S LYMPHOMA

Pathology: Hodgkin's disease (HD) generally arises unicentrically and spreads to other lymphatic tissues by contiguity and later to non-lymphatic organs as well.

The pathological hallmark is the presence of **Reed-Sternberg's cells** (RS cells) which are large multinucleated cells with the nuclei being arranged in mirror image fashion in histological slides (Fig. 159.1). A causal association between EB virus infection and EBV positive subgroup of HD has been identified.

Fig. 159.1: Bone marrow Hodgkin's disease.
Note: The Reed-Sternberg's cell (arrow)

They are clones of neoplastic B-lymphocytes which originate from the germinal centres of lymphoid organs. They appear as modified germinal centre B-lymphocytes that have escaped apoptosis. They show rearrangement of the immunoglobulin variable region (V) genes. RS cells produce cytokines which promote their own growth and are also responsible for the systemic manifestations of the disease. In general RS cells form only 1% of the cell population even though they constitute the malignant tissue.

The rest of the tissue is made up of lymphocytes, macrophage and granulocytes, especially eosinophils.

The lymph node architecture is destroyed and replaced by abnormal tissue. Four histological patterns have been recognized.

Rye (1965) Classification

This classification arrived at by consensus, held its pride of place until recently. Now newer and more elaborate classifications have been introduced. The Rye classification is based on general morphology of the tissue and the cell types.

1. **Lymphocyte predominant (10%):** There is predominance of lymphocytes with a few RS cells. Nodular and diffuse patterns are recognisable. This has the best prognosis. Nodular variety of lymphocyte predominant HD is of B-cell origin.
2. **Nodular sclerosis (30-40%):** In this form the tumour is arranged as nodules which are encircled by collagenous bands extending from the capsule. A variant of the RS cells, the lacunar cell—may be present. Mediastinal lymph node enlargement is more common.
3. **Mixed cellularity (20-30%):** There are numerous RS cells and moderate number of lymphocytes.
4. **Lymphocyte depleted (10-20%):** The pattern may be reticulate or diffuse fibrosis. In the former, there is dominance of RS cells and depletion of lymphocytes. In the latter, the lymph node is replaced by disorderly connective tissue containing a few lymphocytes and a few RS cells.

The nodular sclerosis type maintains its distinct histology throughout whereas the other types may progress to one or the other or show overlap when followed up. In India mixed cellularity type is more frequent than nodular sclerosis. The prognosis becomes progressively worse as one moves from the lymphocyte predominant type to the lymphocyte depleted types.

Newer Classifications

Different newer classifications have come in. HD has been broadly classified as two distinct entities (a) nodular lymphocyte predominant and (b) the classic HD which is further divided into four subtypes 1-4.

CLINICAL FEATURES

Hodgkin's disease may be encountered at any age, but it is more common in the second decade. Males are affected twice as frequently as females. The majority of patients come in an advanced stage, the disease having been present for more than six months.

The most frequent symptom is painless asymmetrical circumscribed enlargement of the lymph nodes, which are rubbery in consistency. In over 75% cases, cervical groups are affected. Axillary, mediastinal and inguinal groups are involved less frequently. Involvement of the retroperitoneal lymph nodes is not uncommon. The lymph nodes reach moderate to large sizes. They do not soften, breakdown, or ulcerate.

Moderate splenomegaly occurs in over 50% of cases and hepatomegaly in a smaller number. These organs are firm and nontender. Hepatocellular or obstructive jaundice may occur.

Constitutional symptoms occur in the majority of cases in the later stages. Pel-Ebstein fever consists of a few days of high swinging pyrexia followed by an afebrile period. Though Pel-Ebstein type of fever has come to stay as a classic feature of Hodgkin's disease, in the vast majority the typical form is not seen. Fever is commonly due to concomitant infection, but less commonly it is due to the malignant process itself. The patient rapidly loses weight and develops toxemia. Sweating, intractable pruritus, and anemia develop in many cases.

Alcohol induced tenderness over the lymph nodes and bone is described as a diagnostic feature, but in Indian subjects it is rare. Horner's syndrome may occur due to pressure on the cervical sympathetic chain. Spinal root and cord compression and development of lymphoma in the CNS are neurological complications. Opportunistic infections such as *Herpes zoster*, *M. tuberculosis*, *cytomegalovirus*, *cryptococci* and *Candida sp.* are common.

Investigations: There may be normocytic normochromic anemia. In the advanced stage when the bone marrow is infiltrated, myelophthisic anemia develops. Mild

eosinophilia may occur frequently. In the advanced stage lymphopenia develops.

Bone marrow involvement is seen in 10-20% of cases and this is best demonstrated by trephine biopsy. As the disease progresses the immunologically competent T lymphocytes progressively diminish and this coincides with the development of anergy to tuberculin. With achievement of remission the cell-mediated immunity recovers. Humoral immunity may be normal.

Bone involvement is accompanied by hypercalcemia, hyperphosphatemia, and raised alkaline phosphatase levels. Hyperuricemia may develop. Hepatic alkaline phosphatase is raised. Serum copper is elevated during the active stages and it falls during remission. Serum LDH is elevated and it is an indicator of the tumour burden.

Several other advanced investigations such as cytochemistry, immunological tests, molecular procedures and imaging modalities such CT scan, MRI and PET studies are undertaken for full evaluation of the extent, type of tumour, and prognostic information.

Clinical staging (Ann Arbor Conference, 1971): This is based on the extent of the disease at the time of presentation.

- Stage I: Lymph node involvement in one anatomical lymph node region (I) or in a single extralymphatic organ (I_E).
- Stage II: Involvement of two or more lymph nodal regions, confined to the same side of the diaphragm (II) or localized involvement of an extralymphatic organ and one or more lymph node regions on the same side of the diaphragm (II_E).
- Stage III: Involvement of lymph nodes above and below the diaphragm (III) which may also be accompanied by splenomegaly (IIIs).
- Stage IV: Extensive disease involving nodes on either side of the diaphragm and involvement of extralymphatic tissues such as bone marrow and liver.

Each stage is further classified as B or A depending upon the presence or absence of constitutional symptoms. The important constitutional symptoms are:

- 1. Fever above 38°C and night sweats and
- 2. Loss of 10% or more of body weight within six months.

In group B the prognosis is worse compared to group A both from the point of remission and duration of survival.

Staging procedures: Since the choice of initial therapy depends on the stage, full investigation should be undertaken in all cases before deciding the therapeutic schedule. It has been established beyond doubt that proper staging and institution of appropriate therapy from the beginning are most important in bringing about a favorable outcome.

Investigation of a Case of Lymphoma

1. Full clinical examination.
2. Radiology of the chest to reveal mediastinal nodes and pulmonary involvement.
3. Complete hematological investigations.
4. Ultrasonography to detect masses of glands in the abdomen and hepatosplenomegaly.
5. Bone marrow trephine biopsy.
6. Liver function tests and liver biopsy if liver is enlarged and shows ultrasonographic changes.
7. CT scan of abdomen and chest to detect enlarged masses and wherever indicated MRI.
8. Isotopic liver scan to detect lymphomatous involvement.
9. Radio-isotopic scintigraphy of lymphnodes
10. Radio-isotopic bone scan, especially in stages III and IV.

Staging laparotomy which was a regular procedure in early stage HD has now been abandoned since the necessary information can be obtained by imaging procedures. In addition systemic chemotherapy is more commonly employed in all stages.

Diagnosis: All cases presenting with chronic local or general lymphadenopathy in which a distinct cause cannot be established should be subjected to lymph node biopsy without delay. When several groups of nodes are affected, an entire node which is moderately enlarged should be selected for biopsy.

Differential diagnosis: All other causes of lymph node enlargement such as leukemias, tuberculosis, syphilis, filariasis, secondary carcinomatosis, HIV infection, nonspecific lymphadenopathy, toxoplasmosis, sarcoidosis, and pseudolymphoma have to be excluded.

Drugs like streptomycin and phenytoin produce a type of immunoblastic lymphadenopathy (pseudolymphoma) clinically resembling lymphoma. Withdrawal of the drugs results in resolution of the node.

Treatment

Stages I and II: The treatment of choice is to give radiotherapy given up to a total dose of 4000-4500 cGy in four weeks. A total dose not below 4000 rads is curative in 90% of cases. Improved high voltage radiotherapy techniques allow safe irradiation of all lymph nodes above or below the diaphragm by upper mantle or inverted Y fields (Fig. 159.2).

Stages III and IV: These patients are treated with cyclical chemotherapy. The most popular combination is MOPP and this consists of

	Dose	Days
Mustine hydrochloride	6 mg/m ² I V	1 and 8
Oncovin (Vincristine)	1.5 mg/m ² I V	1 and 8
Procarbazine	100 mg/m ²	1 to 14
(Natulan-Roche)	oral	
Prednisolone	40 mg/m ²	1 to 14
	oral	

Fig. 159.2: Diagram showing mantle for radiotherapy

The 14-days treatment is followed by 14 days rest and the cycle is repeated. Usually 6 courses are given. There are many other effective regimens which use different drug combinations.

A more popular chemotherapeutic regimen consists of doxorubicin, bleomycin, vinblastine and dacarbazine (ABVD).

At present all stages of HD are given chemotherapy. For stages I and II it is short course chemotherapy preceding irradiation and for the higher stages it is the full course.

Prognosis: Approximate five-year survival rates reported from the west are:

	below 20 yrs (%)	21-40 yrs (%)	above 40 yrs (%)
Stages			
IA and IIA	94	93	78
IB and IIB	93	83	45
III and IV—A and B	80	61	22

Histologically lymphocyte predominant types show the best prognosis. Circumscribed lesions have a better prognosis than diffuse lesions. Results in Indian series are not so encouraging as these figures suggest.

In India only about 25% of cases are in stages I or II when initially diagnosed.

Other adverse prognostic factors include:

1. Age above 45 years.
2. Presence of B symptoms
3. Mediastinal width exceeding 45% of thoracic width in the skiagram.

4. Presence of extranodal disease.
5. Involvement of bone marrow.
6. PCV below 25% and ESR above 50 mm/hr.

Relapses are managed by the same or alternate schedules of chemotherapy. In resistant cases two regimens can be combined. At present more aggressive drug combinations are being used in poor-prognosis cases and relapsed cases. This has been made possible due to the availability of supportive services during the phase of neutropenia. Autologous bone marrow transplantation and stem cell transplantation have helped to institute almost curative chemo-radiotherapy.

Long-term risks: 1% of patients treated for HD may develop acute myeloid leukemia which is resistant to therapy. The risk of second malignancies is higher in treated HD patients than in the general population. Several types of second malignancies have been reported. Other complications include reversible azoospermia caused by chemotherapy, serious infective complications in splenectomized patients, amenorrhea and cumulative cardiotoxicity caused by daunomycin and related drugs. The cardiotoxicity may manifest as cardiac dysfunction even several years after recovery from the malignancy.

Advances in investigations and therapeutic modalities introduced during the past decade have made the results of therapy and prognosis much better in India as well. Institution of therapy in special institutions has helped to improve the results. Wherever possible, treatment should be undertaken in such tertiary care centres.

Non-Hodgkin's Lymphoma (NHL)

Majority of these are B cell neoplasms, though T cell NHL also occurs. Unlike Hodgkin's lymphoma, the clinical picture is more variable. Extranodal involvement is more common, so also involvement of the blood and bone marrow. The disease often starts multicentrically.

Classification

Classification of NHL has undergone considerable modification from time-to-time. Rappaport (1966) gave the histological classification as mainly 1) Nodular and 2) diffuse types. Luke and Collins based their classification on morphology and immunological characteristics.

Newer classifications have come in such as Kiel, International Working Formulation (IWF), Revised European and American lymphoma (REAL) group and WHO. Modern classification takes into account the clinical schema classifying the disease into

1. Indolent lymphoma/leukemias (with survival times measured in years, if untreated)
2. Aggressive lymphomas (survival measured in months) and

3. Highly aggressive lymphomas and leukemias (survival measured in weeks)

Each type is further subdivided into B and T cell types and also the histological pattern. For further details, refer to Hiddemann W. et al, Blood 1996; 88: 4085-4089.

The Kiel classification, which is also in vogue, makes a distinct subdivision into low grade and high grade lymphomas, the former being composed of relatively small cells, whereas the latter is composed of larger and more rapidly proliferating cells. Different institutions follow a combination of histologic, immunologic (B-cell, T-cell, etc.) and behavioral factors (Kiel) to group the lymphomas for statistical and therapeutic purposes.

Non-Hodgkin's lymphomas occur in all regions. Certain types show geographic differences, e.g. Burkitt's lymphoma is seen in Africa mainly. Kaposi's sarcoma is a cutaneous lymphoma in some cases triggered by viral infections especially AIDS.

Co-existence of NHL with Other Hematological Disorders

Diffuse well differentiated lymphoma may merge imperceptibly with chronic lymphatic leukemia and Waldenström's macroglobulinemia. Histological picture of the lymph nodes is similar in these conditions. Acute lymphatic leukemia, especially in children, presents with lymph node involvement, indistinguishable from diffuse poorly differentiated lymphoma. Histiocytic lymphomas are relatively uncommon, but when they occur, the histiocytes may phagocytose erythrocytes causing hemolytic anemia.

Majority of non-Hodgkin's lymphomas are monoclonal B-cell tumours and paraproteins of IgM or IgG classes may be demonstrable in many cases. T cell NHL presents especially with mediastinal lymph node enlargement in children.

CLINICAL FEATURES

Majority of cases occur in the second to fifth decades. The duration of illness ranges from weeks to months. More than 70% of the cases are in advanced stages at presentation.

The disease begins as asymmetric painless progressive lymphadenopathy, involving one or several lymph node regions. The cervical, axillary, inguinal, mediastinal, abdominal, and other groups of nodes may be affected. The nodes are firm, variable in size from a few to several centimeters, and are matted in the later stages. Pressure on neighbouring structures may lead to mediastinal syndrome, Horner's syndrome, and lymphedema.

Enlargement of the tonsils and Waldeyer's ring may lead to obstruction to breathing and swallowing. Liver and spleen are moderately enlarged in the majority of cases.

Mesenteric and retroperitoneal lymph nodes may be enlarged.

Systemic manifestations include early onset of fever, weight loss, and night sweats in about 30% of cases. Anemia and infections are also more common.

Comparison between Hodgkin's and Non-Hodgkin's lymphoma		
	HL (Percentages)	NHL
Lymphadenopathy	93	89
Fever	69	29
Abdominal masses	—	16
Cough and dyspnea	20	25
Skin lesions	3	15
Pruritus	14	3
Pleural effusion	6	17
(Based on 120 cases)		

Involvement of other organs: Though several organs are affected in the advanced stages of NHL, sometimes extra-nodal involvement may be the presenting symptom. Involvement of the skin leads to nodular or diffuse lesions. Intense pruritus is an early and intractable symptom in a few. Brain, spinal cord, and meninges are affected in many cases. Gastrointestinal tract, liver, lungs, respiratory tract, pleura, and bone may be the seat of primary lymphoma. Hemorrhagic pleural effusion may occur (Fig. 159.3).

Laboratory Findings

Hematology: Moderate normocytic normochromic anemia may occur in the advanced stages. The leukocyte picture is generally unremarkable but in a few cases lympho-sarcoma cells are detectable in the circulation. These cells resemble large lymphocytes with lobed or folded nuclei and may show nucleoli. The condition is termed lymphosarcoma leukemia.

Fig. 159.3: Female orbital lymphoma

Autoimmune hemolytic anemia develops in a few cases. Infiltration of the marrow results in myelophthistic anemia. Bone marrow involvement is common in stage IV NHL.

Biochemistry: Paraproteins of IgM or IgG class may be detectable in a few cases. Serum uric acid is moderately elevated in the advanced stages. Hepatic involvement is characterized by rise in alkaline phosphatase and transaminases. Obstructive jaundice results from pressure of lymph nodes at the porta hepatis.

Staging procedures are the same as for HD.

NHL is generally advanced even on first presentation.

Prognosis: Well-differentiated nodular lymphocytic lymphomas have the best prognosis and many may survive 5 years or more. Diffuse undifferentiated lesions have poorer prognosis. Extensive disease and advancing age are unfavourable prognostic factors. Females have a better prognosis than males. Prolonged survival and cure have been achieved in many cases with intensive chemotherapy.

Leukemic transformation may occur in a few cases and these behave like acute lymphoblastic leukemia.

Death is due to progressive disease, infections, liver failure, profound anemia, bone marrow failure, or drug toxicity.

TREATMENT

Stages I and II respond to radiotherapy as for HD. In the other stages chemotherapy is advocated. At present chemotherapy is given even in the earlier stages.

Single drug regimen: Continuous or intermittent therapy with chlorambucil or cyclophosphamide has been reported to give good results in patients with localized nodular and diffuse well-differentiated lymphoma. Except under special circumstances such as advanced age and general debility this is seldom followed at present.

In the vast majority of cases the disease is widespread on presentation, combination therapy is followed.

Combination therapy with cyclophosphamide, vincristine, and prednisolone (COP), as in the case of stages II and IV Hodgkin's disease, has been tried with remission rates upto 55-60%. A remission rate of 60% is obtained with MOPP regimen. In more advanced cases, adriamycin and bleomycin have been included (BACOP regimen) with remission rates upto 80%. Local irradiation with 4000-5000 cGy to control massive local disease and systemic chemotherapy give better remission rates in diffuse poorly differentiated lymphoma.

Combination chemotherapy consisting of cyclophosphamide, doxorubicin, vincristine and prednisolone (CHOP) is used most frequently in the aggressive types of NHL due to its better efficacy and predictable results.

Monoclonal antibodies developed against specific CD 20 cells-rituximab (mabthera) is used to target specific

CD 20⁺ B cells which occur in several forms of NHL. The dose is 375-500 mg/m² on day-1 of the cycle. The results are considerably better.

Total body irradiation of 15 rads twice a week for 5 weeks (total 150 rads) has been used as an alternative.

Neuroprophylaxis as for acute leukemia has been advocated in stages III and IV NHL. At present depending on the type of cell and its biological behaviour, several combination chemotherapy protocols are available. These have to be given only in special treatment facilities. The modern drugs are very expensive, but when given properly, results are good.

Support by transfusion of platelets and use of growth factors have helped to tide over the leukopenic and thrombocytopenic periods. Stem cell transplantation or BMT done after chemotherapy is quite successful since these permit more aggressive and intensive regimen without causing fatal bone marrow aplasia. At present the results of treatment of NHL are being bettered. The ideal therapeutic modality is still not established.

The overall survival and disease free survival among new cases of lymphoma reported from Tata Memorial Hospital Mumbai (2006) resulting from doxorubicin based chemotherapy at five years are 62% and 50% respectively. Rituximab improved remission rate to 72%.

BURKITT'S LYMPHOMA

This lymphoma is more prevalent in Africa showing a geographical localization to areas with altitude below 1700 m and high rainfall, which are also holoendemic for malaria. Stray reports are available from all parts of the world, including several from India. Epstein-Barr (EB) virus infection is a cofactor in the development of Burkitt's lymphoma (BL), the other factor being chronic stimulation of the reticuloendothelial system by malaria.

Histology: Histology of the lesion is diagnostic and the tumour is made up of uniform type of lymphoblast-like cells, 10-25/μm in size with rounded nuclei and nucleoli. Phagocytic macrophages with large pale cytoplasm are uniformly distributed among the dark staining cells giving the appearance referred to as the "starry sky" appearance. Chromosomal abnormalities have been observed, the most frequent being a translocation between 8 and 14 (t,(8,14)(q24,q32).

Clinical features: The African cases are seen predominantly in children, mostly in the age group of 3-5 years. Multicentric tumours arise which grow rapidly affecting the jaw, salivary glands, neck, abdominal viscera, long bones and central nervous system. Spread to bone marrow and lymph nodes and the leukemic phase are uncommon.

Burkitt's lymphoma, as reported from other parts of the world affects older age groups. Lymph node and

marrow involvement is more common. Antibodies to EB virus are less pronounced.

Course and prognosis: The disease is rapidly fatal if untreated. The African cases respond dramatically to cyclophosphamide in large doses or combination chemotherapy. Response is less dramatic in cases described from other parts of the globe.

Other Rare Forms of Lymphocyte Tumours

ANGIOIMMUNOBLASTIC LYMPHADENOPATHY

This is the result of an immunological disorder seen in patients taking drugs for various conditions. The pathological process suggests a borderline between a reactive condition and a neoplasm.

Histology: The lymph node shows loss of normal architecture, pleomorphic cellular infiltrate consisting of immunoblasts, plasma cells, neutrophils and histiocytes, and proliferation of small blood vessels.

Clinical features: The disease starts as an acute or subacute illness characterized by fever, sweating, weight loss, generalized lymph node enlargement and hepatosplenomegaly. Unlike malignant lymphomas, these patients show rise in polyclonal immunoglobulins, especially IgM. If left untreated, many cases end fatally due to infective complications or supervening malignancy. The prognosis in individual cases is unpredictable.

Treatment is effective in one-third of the cases. Corticosteroids, alkylating agents, and combination chemotherapy have all been employed with variable results.

HYDANTOIN-LINKED LYMPHOMA

Syn: Pseudolymphoma

Diphenyl hydantoin may produce an allergic response characterized by fever, rash, generalized lymphadenopathy and even splenomegaly resembling angioimmunoblastic lymphadenopathy. The condition remits fully within months of drug withdrawal (Fig. 159.4).

MYCOSIS FUNGOIDES

This term has been loosely used by different workers. The consensus is to limit the term to the group showing a classical histological picture. Mycosis fungoides and Sézary's syndrome are T cell non-Hodgkin's lymphomas. These are all rare diseases.

Fig. 159.4: Hydantoin linked lymphoma

Clinical features: The onset of the disease may be as a lesion resembling pruritic erythroderma, psoriasis, seborrheic dermatitis, eczema, nonspecific exfoliative dermatitis, lichenoid dermatitis, or neurodermatitis. After several years, plaque formation or tumour formation starts. In some cases the lesions directly start as tumours which may ulcerate. The skin is red and diffusely thickened. Later the nails may be affected and they may be lost.

The course of the disease is variable. Tumour-like lesions do worse than lichenoid lesions. Advancing age worsens the prognosis. Median survival period is 5 years from diagnosis.

SÉZARY SYNDROME

This is the leukemic phase of mycosis fungoides. It is rare and is characterized by intense pruritus, erythroderma, and later on enlargement of the liver, spleen and lymph nodes. Skin shows diffuse infiltration by typical *Sézary's cells*. These cells are seen in good numbers in the peripheral blood.

Treatment: The condition responds to alkylating agents like chlorambucil or cyclophosphamide singly. Combination therapy as for NHL has been found beneficial in advanced lesions. Superficial irradiation with rays of low penetrance and surface application of mustine hydrochloride (HN_2) 10 mg dissolved in 60 mL water brings about remission in a good number of cases. Intensive electron beam therapy or photochemotherapy with psoralens and long-wave ultraviolet light are other modalities employed.

Chapter Summary

- Primary Myelofibrosis 1070
- Polycythemia Rubra Vera (PRV) 1072
- Essential Thrombocythemia 1073

The term myeloproliferative syndrome was coined by William Dameshek in 1951. Myeloproliferative disorders are clonal hematopoietic stem cell disorders that result in overproduction of one or other of the blood cells. Myeloproliferative disorders include primary idiopathic myelofibrosis, polycythemia rubra vera (PRV), essential thrombocythemia and chronic myeloid leukemia (CML). They arise from a common precursor stem cell which can proliferate and differentiate into any one of these types. In these disorders there is a clonal proliferation of one or more cellular elements in the marrow like RBC, WBC, platelets or fibroblasts. They may show a tendency to transform into one or other type when followed up. All these have some phenotypic similarity. Around 30% of cases of PRV develop myelofibrosis but myelofibrosis transforming to PRV is rare. All these disorders show a higher tendency to transform to acute leukemia if followed up for long periods.

Ref: The myeloproliferative disorders. Peter J Compbell et al N. Eng J, Med 2006, 355 2452-2466

The JAK2 V617 F mutation Janus Kinase 2 (JAK2) which is a cytoplasmic tyrosine kinase is critical for instigating intracellular signalling by the receptors for erythropoietin, thrombopoietin, interleukin 3, granulocyte colony stimulating factor (GCSF) and granulocyte macrophage colony stimulating factor (GMCSF). JAK2 binds to erythropoietin receptors in the endoplasmic reticulum and aids in their expression on the surface. The JAK2 mutation in myeloproliferative disorders (MPD) is acquired and it is common to all the MPD.

JAK2 mutation occurs in more than 95% of cases of polycythemia vera (PV), and in 50-60% of cases of essential thrombocythemia (ET) and idiopathic

myelofibrosis (IMF). The JAK2 mutation is the first genetic marker associated with the pathogenesis of MPD and it has acquired importance in both diagnosis and follow up. The causative role of this mutation in the pathogenesis of MPD is established. The JAK2 mutation explains many of the cardinal features of MPD and it can be compared to the role played by BCR-ABL in chronic myeloid leukemia. **Cooperating mutations:** Leukemic transformation of MPD reflects the acquisition of additional mutations. One such is V617F positivity in MPD, which may even predate JAK2 mutation. The V617F somatic mutation in the JAK2 gene causes the substitution of phenylalanine for valine at position 617. Patients with 20q deletion are almost exclusively V617F positive. Mutant JAK2 protein activates multiple downstream signalling pathways with effects on gene transcription, apoptosis, the cell cycle and differentiation. Testing for JAK2 V617F mutation is now widely available and it promises to simplify the diagnostic work up. JAK2 and V617F can be identified by allele specific PCR assay, pyrosequencing, restriction enzyme digestion and real time PCR. The JAK2 mutation is also assuming importance in classification of MPDs.

Primary Myelofibrosis

(Chronic idiopathic myelofibrosis, agnogenic myeloid metaplasia, or myelofibrosis with myeloid metaplasia)

It is characterized by fibrosis of marrow without any other obvious primary cause for it. As a consequence there is massive splenomegaly due to extramedullary hematopoiesis and a characteristic leukoerythroblastic blood picture. The etiology of this disorder is not known and there are no specific cytogenetic abnormalities although abnormalities like 20q-, 13q- and trisomy 1q are often encountered. Marrow fibrosis is associated with overproduction of transforming growth factor β and thrombopoietin. The marrow is initially hypercellular with an excess of megakaryocytes which may be releasing the cytokines for proliferation of fibroblasts and as the disease

progresses the marrow becomes fibrosed and is difficult to aspirate.

Causes of Myelofibrosis

Secondary myelofibrosis
Infections e.g. tuberculosis, fungal infections
Lymphoma (NHL)
Hodgkin's disease
Acute leukemias
Chronic myeloid leukemia
Polycythemia rubra vera
Systemic mastocytosis
Systemic lupus erythematosis
HIV infection
Hypoparathyroidism
Primary myelofibrosis (Idiopathic)

CLINICAL FEATURES

Most patients are over the age of 50 years, and they usually come to medical attention for anemia and symptoms due to splenomegaly which is often massive even at presentation. Other modes of presentation include fatigue, tiredness, weight loss, night sweats and sometimes low grade fever due to the hypercatabolic state. Anemia and splenomegaly are detected during physical examination. Many patients are asymptomatic and come to attention due to accidentally detected splenomegaly or abnormal blood counts during a routine examination. The anemia is due to replacement of the hematopoietic tissue and also due to ineffective erythropoiesis or hypersplenism. The large spleen can give rise to abdominal fullness and early satiety. Splenic infarcts occur with severe abdominal pain. Sometimes portal hypertension may develop. Mild hepatomegaly is also common due to extramedullary hematopoiesis. Other sites for extramedullary hematopoiesis include lymph nodes, pleura (resulting in pleural effusion) or peritoneum (leading to ascites) or in paraspinal or epidural spaces with resultant spinal cord or nerve root compression.

Diagnosis

The erythrocytes show marked aniso and poikilocytosis with polychromasia and characteristic 'tear' drop cells. Most patients have leukocytosis at presentation with a leukoerythroblastic blood picture (Fig. 160.1). WBC count can be normal or sometimes decreased, due to hypersplenism. Thrombocytosis can occur in some, but others may have normal or even decreased platelet counts. Megakaryocytic fragments may be seen in peripheral blood.

Bone marrow aspiration often results in dry tap. Trephine biopsy of the bone marrow reveals dysplastic megakaryocytic hyperplasia, osteosclerosis and dilatation

Fig. 160.1: PB myelofibrosis. Note: The teardrop cell (arrow). Normoblast (arrow head)

of marrow sinusoids with intravascular hematopoiesis. Foci of extramedullary hematopoiesis can be demonstrated in the spleen, liver and rarely lymph nodes. Radiographs of bones show osteosclerosis with obliteration of marrow cavity. Changes are most markedly seen in the vertebrae, shafts of long bones of the extremities, ribs, clavicles, and pelvis. Serum uric acid is increased. Leukocyte alkaline phosphatase is high.

Hyperuricemia and secondary gout can occur due to the hypermetabolic state.

Prognosis is good in most cases and they can be managed with supportive measures for more than 10 years but the survival is shorter than that for PRV and essential thrombocythemia. With advanced age, anemia, and WBC counts more than 30000 and blasts in peripheral blood, the survival may be much less (1-2 years). Survival is not directly proportional to the degree of splenomegaly. The common disease-related cause of death is leukemic transformation which usually occurs after 10 years.

Treatment: Treatment is mainly supportive or palliative, with supplementation of folic acid and at times, pyridoxine. Androgens have been used to correct the anemia. Erythropoietin (EPO) may help sometimes, but the anemia is usually due to ineffective erythropoiesis and hypersplenism and this may not respond to EPO. Hydroxyurea given in doses of 500 mg three times a day is used to control leukocytosis, thrombocytosis and organomegaly. Packed red cell transfusions may be given to correct severe anemia. Splenectomy may be required when the splenomegaly causes disabling symptoms or when there is severe hypersplenism. Splenectomy will be followed by rebound thrombocytosis and progressive hepatomegaly. Allopurinol can be used in doses of 100 mg tid oral to control hyperuricemia. Glucocorticoids are sometimes useful when there are co-existing autoimmune phenomena.

Thalidomide given in doses of 100-800 mg daily produces benefit in anemia and thrombocytopenia. Bone marrow transplantation may be beneficial in 50-60% of young patients.

Polycythemia Rubra Vera (PRV)

Syn: Erythremia, Vaquez's disease, Osler's disease, Cryptogenic polycythemia

The word "polycythemia" indicates excess of cells-mainly erythrocytes. In adult men hemoglobin level > 17 g/dL or PCV $> 50\%$ can be taken as abnormal. In females the corresponding values are hemoglobin level above 16 g/dL and PCV above 45%. Polycythemia may be true or apparent. In true polycythemia there is increase in red cell mass. Apparent polycythemia occurs when there is an acute reduction in plasma volume following severe dehydration, as happens in diarrhea, vomiting, use of diuretics, capillary leak syndromes and in severe burns. Polycythemia may be primary or secondary. The latter is more common. When polycythemia occurs in the absence of any physiological stimulus or without a pathological increase in EPO it is called as *polycythemia rubra vera* (PRV). This is one of the myeloproliferative disorders.

Secondary polycythemia occurs mainly due to increased amounts of erythropoietin (EPO) secreted as a physiological response to hypoxic stimulus, or abnormal secretion of EPO from the kidneys or from ectopic foci. Rarely the erythroid progenitors in the bone marrow may respond in an exaggerated manner to normal levels of EPO. All these constitute secondary polycythemia.

Causes of Secondary Polycythemia**I: Erythropoietin mediated (EPO)-hypoxia driven**

1. Chronic lung diseases
2. Chronic carbon monoxide exposure (including cigarette smoking)
3. Right to left cardiac shunts
4. High altitudes above 2500 m
5. Hypoventilation syndromes including extreme obesity
6. Sleep apnea
7. Dysfunction of the respiratory centre
8. Renal artery stenosis
9. High affinity Hb (autosomal dominant) with defective oxygen unloading in the tissues e.g.
10. Defective oxygen delivery by erythrocytes having deficiency of 2,3 diphosphoglycerate (DPG).

II: Pathologic Erythropoietin production

- A. *Malignant tumours producing excessive erythropoietin*
 1. Hepatocellular carcinoma
 2. Renal cell cancer
 3. Cerebellar hemangioblastoma
- B. *Non-malignant conditions*
 1. Uterine leiomyoma
 2. Renal cysts
 3. Hydronephrosis
 4. Adrenal tumours
 5. Atrial myxoma
 6. Post-renal transplantation

III: Miscellaneous causes

- a. Androgen abuse, erythropoietin abuse
- b. Familial polycythemia (AD)

Pathogenesis of PRV

There is clonal expansion of multipotent hematopoietic stem cells resulting in overproduction of phenotypically normal RBCs, WBCs and platelets without physiologic stimulus. The erythropoietin independent proliferation of pleuripotent stem cells, occurs possibly due to an aberrant signal transduction pathway. JAK_2 gene is a signal transduction molecule which influences several cytokine receptors including receptors for erythropoietin (EPO). Mutations of the JAK_2 gene (V617 F mutation) confers increased tyrosine kinase activity, allowing the erythroid precursors to grow even in the absence of EPO. The total red cell mass (RCM) is increased to > 36 mL/kg bw in men and > 32 mL/kg bw in women. V617 F mutation can be demonstrated by allelic specific PCR in peripheral blood nucleated cells. By an unknown mechanism there is suppression of proliferation of the normal stem cells and hence the formed elements in the patients represent the progeny of the transformed clone. The bone marrow is apparently normal, but there is increase in number of all cellular elements. Two phases of the disease can be seen. The initial one is of cellular proliferation. The latter is one of cytopenias with ineffective hematopoiesis, marrow fibrosis, and hypersplenism.

CLINICAL FEATURES

Usually it occurs in people above 40 years. Most often the disorder is picked up by noticing the eye congestion or an abnormally high hemoglobin and PCV on routine blood testing. Early symptoms are vague. These include lassitude, loss of concentration, dizziness, vertigo, tinnitus, heaviness of head or headaches, and visual disturbances. A symptom that is more specific for PRV is pruritus exacerbated by water contact (aquagenic pruritus). Sometimes they may present with the complications like vaso-occlusive diseases. These include digital ischemia, TIA, stroke, myocardial infarction, deep vein thrombosis with or without pulmonary embolism, Budd-Chiari syndrome and portal vein thrombosis. Easy bruising, epistaxis and gastrointestinal hemorrhage due to peptic ulceration may be the presenting symptoms. Hypermetabolic state can give rise to weight loss, fatigue, night sweats or hyperuricemia with features of secondary gout or even renal calculi.

On examination there is congestion of eyes and ruddy complexion and palmar erythema may be obvious in fair skinned individuals. Systolic hypertension may be present. Splenomegaly is the suggestive physical finding that helps differentiation from secondary causes. While evaluating them look also for features of the known secondary causes for polycythemia.

Features that support the diagnosis of PRV

1. Polycythemia without any known secondary cause
2. Splenomegaly
3. Elevated white blood cell count $> 12 \times 10^9/L$
4. Increased basophil count
5. Thrombocytosis $> 400 \times 10^9/L$
6. Elevated serum uric acid levels
7. Elevated leukocyte alkaline phosphatase levels
8. Elevated serum vitamin B₁₂ and vitamin B₁₂-binding protein levels.

Diagnosis

Clinically polycythemia is suspected based on symptoms and signs. Estimation of Hb, PCV and red cell count confirms the diagnosis. The features that suggest PRV are given in box above:

Presence of JAK2 is highly suggestive of polycythemia vera in patients with erythrocytosis.

In those with massive splenomegaly at times the hematocrit values may be normal due to pooling of blood in the spleen. In such cases estimation of red cell mass may be needed to differentiate PRV from primary myelofibrosis. Bone marrow study is not often required unless myelofibrosis or leukemic transformation is suspected. Leukocyte alkaline phosphatase is increased in many. Elevated levels of vitamin B₁₂ and vitamin B₁₂ binding protein may be present.

Course and Prognosis

Prognosis is good and the majority live more than 10 years after diagnosis; some live up to 20 years or more. Thrombotic complications occurring in vital tissues may contribute to morbidity and mortality. Death may occur due to fatal thrombosis or hemorrhage, and due to leukemic transformation into acute myeloid leukemia or unrelated causes. Secondary myelofibrosis may develop in some on follow-up.

TREATMENT

Aims of management include reduction of the red cell mass and thrombocytosis to normal levels, avoidance of thrombotic complications and reassuring the patient about the relatively benign nature of the disease. Management is primarily aimed at preventing the thrombotic complications by maintaining the Hb less than 15 g/dL (PCV45%) in males and less than 14 g/dL (PCV42%) in females. This is achieved by repeated venesections (300-400 mL) weekly in the initial stages, sufficient to induce a state of iron deficiency, and thereafter, done less frequently (once in 3 months). Anticoagulants and aspirin are relatively contraindicated in these patients for the control of thrombotic tendency. Allopurinol is given in doses of 100 mg tid to control hyperuricemia. Hydroxyurea (also known as hydroxycarbamide) has been used to control the splenomegaly, and thrombocytosis. But chemotherapy is not the preferred method of choice to

reduce the red cell mass. If there is severe thrombocytosis (levels above 500000/cm) anagrelide can be used to lower platelet levels. The dose is 0.5 mg/daily, the drug is expensive and not freely available in India. Interferon α has been tried with good results.

Essential Thrombocythemia

Syn: Primary (idiopathic) thrombocytosis, hemorrhagic thrombocythemia, megakaryocytic myelosis

It is a clonal disorder of unknown etiology with variable cytogenic abnormalities. There is primary proliferation of megakaryocytes in the marrow, producing apparently normal platelets but having some functional abnormalities which can predispose to either thrombosis or hemorrhage. Physiological thrombocytosis, mediated by thrombopoietin usually occurs as a response to infections, chronic inflammatory disorders, connective tissue disorders, post hemorrhagic states, iron deficiency anemia, in association with some malignancies or after splenectomy. Thrombocytosis occurring in the absence of any physiologic stimulus by thrombopoietin is called essential thrombocytosis or essential thrombocythemia. This is a myeloproliferative disorder. Apparently normal looking platelets are seen on the peripheral smear, no specific platelet function defects have been documented in spite of the bleeding tendency which may develop at times. Bone marrow biopsy usually shows megakaryocyte hyperplasia. Clonal abnormalities of the Janus kinase 2 gene (JAK₂) are demonstrable in some cases. This abnormality is seen also in polycythemia rubra vera and primary myelofibrosis.

Causes of thrombocytosis

- a. Reactive
 1. Iron deficiency anemia
 2. Infections
 3. Chronic inflammatory disorders
 4. Collagen vascular disorders
 5. Post hemorrhagic
 6. Post splenectomy
- b. Neoplastic thrombocytosis
 1. Chronic myeloid leukemia
 2. Polycythemia rubra vera
 3. Myelofibrosis
 4. Essential thrombocythemia

CLINICAL FEATURES

It is an uncommon disease seen in adults and older individuals. Patient may present with arterial or venous thrombosis at different sites. These include cerebrovascular accidents, ischemic heart disease, cortical vein thrombosis or digital ischemia and gangrene (Fig. 160.2). Hemorrhagic manifestations like mucocutaneous bleeding, easy bruising, epistaxis or GI hemorrhage may occur. Thrombotic complications are more common in

Fig. 160.2: Digital gangrene on the foot due to venous thrombosis in essential thrombocythemia

patients above 60 years of age and those with previous episodes of vascular complications. Hemorrhage is more common in those with extreme thrombocythemia. More often the disorder is identified when very high platelet count ($> 600,000$) is reported on routine investigations for other conditions. Physical findings are usually unremarkable, but sometimes mild splenomegaly may be seen. Diagnosis is established by the presence of sustained elevation of platelet counts, usually above 600,000/cmm without any underlying cause. In patients with

thrombocytosis presence of JAK2 suggests possibility of MPD. Patients without a MPD are V617F negative. Essential thrombocythemia patients with V617F mutation are more sensitive to hydroxycarbamide (but not to anagrelide) than patients who are V617F negative.

The course of the disorder is generally benign but occasionally they can have serious complications caused by thrombosis or hemorrhage. The prognosis or survival is good- rarely the disease may transform into megakaryocytic leukemia or polycythemia rubra vera.

Treatment: Asymptomatic patients below 45 years of age with platelet counts below 400000/cmm are having only low-risk. Such patients can be kept under observation without active treatment. Treatment is indicated only when the platelet count goes very high or if clinical features are attributable to the elevated platelet count. Hydroxycarbamide is effective in reducing the platelet count when given in doses of 1-2 g/day orally. Interferon α , in doses of 25 million units/week given subcutaneously as divided doses and tapered off to 8.5 million units/week is effective in bringing down the platelet count. Anagrelide given in a dose of 0.5 mg daily is an alternative. Both these drugs are more expensive. Low dose aspirin (100 to 150 mg oral daily) may have to be used to prevent thrombotic tendencies.

Chapter Summary

Functions of the Spleen 1074
Splenomegaly 1075
Hypersplenism 1075
Tropical Splenomegaly Syndrome 1075
Hyposplenism 1076

Functions of the Spleen

The spleen is made up of collections of lymphocytes in the white pulp performing an immune function, and reticuloendothelial cells in the red pulp performing

phagocytic function. The normal spleen weighs 120-200 g.

White pulp: It serves the following immunological functions:

1. Antibodies to circulating antigens are produced. A major function is to cull wornout, damaged or potentially dangerous cells from the blood stream. Antibodies are produced in the germinal centres of the white pulp. Milieu of the germinal centre provides specific conditions for initiating and halting the production of highly specific clinically protective antibodies by B-lymphocytes. Fc receptors help the phagocytic cells to identify the IgG-coated cells from

all others. The spleen removes spherocytes, parasitized erythrocytes and distorted erythrocytes.

- Probably a factor which increases neutrophil chemotaxis and phagocytosis (*tuftsin*) is produced. Absence of this factor is possibly responsible for the increased susceptibility to infection in asplenic subjects.

Red Pulp: It serves the following functions:

- Phagocytic functions — The cells of the red pulp remove effete red cells, antibody coated cells, and bacteria. Splenic phagocytes remove the nuclear remnants such as *Howell-Jolly bodies* from erythrocytes. This is known as “*pitting*”. Presence of numerous erythrocytes containing Howell-Jolly bodies should indicate the absence of splenic function. In the splenectomized subject, macrophages of the liver, lymph nodes and bone marrow take over most of the culling function.
- Removal of nuclear remnants, Heinz’s bodies and others from erythrocytes.
- The spleen acts as a reservoir for the formed elements of blood and these are released into the general circulation in times of stress. About 1/3 of the total platelet pool is stored in the spleen. Normal life-span of the platelets is only 9 days and out of this 1/3 is spent in the spleen. Splenectomy leads to thrombocytosis which may persist for several weeks, sometimes even up to years.
- Hematopoiesis occurs in the spleen normally in fetal life. When there is impairment of normal marrow activity the spleen takes up extramedullary hematopoiesis.

Splenomegaly

Various conditions lead to splenomegaly in the tropics. Size of the enlarged spleen is variable and when gross, the spleen may fill almost the whole abdomen. An enlarged spleen can sequester up to 25 to 30% of the total red cell mass. In splenomegaly, since the plasma volume is increased and red cells are sequestered, dilutional anemia results. Massive splenomegaly from any cause leads to secondary effects on the hemopoietic tissues known as hypersplenism.

Etiology: Some of the common causes of splenomegaly are listed below.

- Chronic infections:** Malaria, leishmaniasis, trypanosomiasis, disseminated tuberculosis, brucellosis, and systemic mycotic infections. In these conditions the spleen is considerably enlarged and generally firm in consistency.
- Acute infections:** Septicemia, enteric fever, viral hepatitis, infectious mononucleosis, infective endocarditis, exanthemata, relapsing fevers, and typhus. The spleen is moderately enlarged and often soft.

- Venous congestion:** Portal hypertension and chronic right-sided heart failure. In portal hypertension spleen enlarges considerably.
- Hematological neoplasia:** Leukemias, lymphomas, polycythemia vera, and myelofibrosis.
- Reactive splenomegaly with reticuloendothelial hyperplasia:** Hemolytic anemias, megaloblastic anemia, thalassemias and hemoglobinopathies, myelophthisic conditions, tropical splenomegaly, and acquired hypogammaglobulinemia.
- Granulomatous disorders:** Felty’s syndrome, systemic lupus erythematosus, sarcoidosis, and berylliosis.
- Infiltrative disorders:** Lipid storage disease, amyloidosis, histiocytosis-X, and gargoylism.

HYPERSPLENISM

This condition is characterized by the occurrence of anemia, leukopenia, and thrombocytopenia (pancytopenia) in a patient with moderate or massive splenomegaly of any etiology. The bone marrow is active and hypercellular. When the splenic size is increased there is increased pooling of blood in an environment with relatively decreased availability of nutrients, but full of phagocytes. This leads to exaggerated sequestration and destruction of cells. In other words it is an exaggeration of its normal function. In addition there may be humoral factors depressing cell maturation as well. The cytopenia recovers promptly on splenectomy.

Causes of Hypersplenism

All causes of moderate to massive splenomegaly like portal hypertension, lymphomas, tropical splenomegaly syndrome, myelofibrosis, hemolytic anemias, and chronic infections may lead to this situation.

Treatment: If the pancytopenia is severe, splenectomy is indicated, but the prognosis depends on the original cause of splenomegaly.

Tropical Splenomegaly Syndrome

The condition is characterized by persistent splenomegaly without any other cause in some residents of malaria endemic areas of tropical Africa and Asia. Probably it is due to an abnormal immunological response to repeated malarial infections. Malarial parasites are not seen in blood, liver or spleen but there is lymphocytic infiltration of splenic sinusoids and they show high titers of IgM Malarial antibody. Anemia and sometimes pancytopenia may occur due to the hypersplenism.

Treatment: Those in endemic areas should receive chemoprophylaxis with proguanil and those who migrate to non-endemic areas should receive antimalarial treatment.

HYPOSPLENISM

This term denotes the condition that develops after splenectomy or after splenic atrophy; Alterations of cellular and humoral immunity may develop.

Causes of Hyposplenism

- 1. Asplenia
 - i. Congenital- may be associated with fatal cardiovascular anomalies
 - ii. Splenectomy
- 2. Splenic atrophy
 - i. Infarction
 - ii. Injury
 - iii. Irradiation

Splenic atrophy is common in sickle cell disease. Rarely ulcerative colitis, Crohn’s disease and adult celiac disease may be associated with splenic atrophy.

Diagnosis: The hematologic features include presence of large number of target cells and Howell-Jolly bodies. Moderate leukocytosis and thrombocytosis are present.

Diagnosis is based on clinical suspicion and hematological features. History of splenectomy and absence of splenomegaly by physical examination and ultrasonogram help to confirm the diagnosis.

Complications: Splenectomy predisposes to infection by capsulated organisms like *Streptococcus pneumoniae*, *Haemophilus influenzae*, and meningococci. Children are more susceptible. Protozoal infections such as malaria, babesiosis and toxoplasmosis are also more common.

Management: Asplenic patients should receive bactericidal antibiotics active against pneumococci and H influenzae, at least at the first sign of infection. Prophylactic vaccination is mandatory.

Platelets 1076

Coagulation 1078

Natural Inhibitors of Coagulation 1078

Coagulation Pathways 1079

Fibrinolysis 1080

General Clinical Considerations 1081

Laboratory Investigations in Hemorrhagic Disorders 1081

Normal Hemostasis

Clotting of blood is one of the host defence mechanisms which, when accompanied by inflammation and repair responses, helps to protect vascular integrity and preserve life.

Hemostasis (arrest of bleeding) takes place in two distinct stages—(1) primary hemostasis and (2) secondary hemostasis.

Primary hemostasis occurs within a few seconds after injury to blood vessels and it involves the platelets which form the platelet plug. This helps to stop bleeding occurring from capillaries, small arterioles and venules. Secondary hemostasis involves the plasma coagulation factors which help to form a stable fibrin clot and strengthen the primary hemostatic platelet plug. This may take a few minutes. This is important in the larger blood vessels. It prevents recurrence of bleeding. Both primary and secondary hemostasis are closely linked and inter-related. For example plasma coagulation is accelerated by activated platelets and products like thrombin formed by plasma coagulation reaction can induce further platelet activation.

Primary hemostasis consists of platelet adhesion, granule release and platelet aggregation.

PLATELETS

Platelet adhesion: When there is an injury to the vessel wall, platelets start adhering to the collagen fibrils of the vascular endothelium within seconds. This occurs with

the help of glycoprotein receptors (Gp) on the platelets and von Willebrand's factor (vWF) in the vascular endothelium.

Platelet activation: When agonists like epinephrine, collagen or thrombin binds to the platelet surface receptors they get activated. Thromboxane A₂ (TXA₂) is formed from arachidonic acid which is released from membrane phospholipids with the help of an enzyme cyclo-oxygenase. TXA₂ stimulates platelet activation and secretion further. Aspirin and non steroidal anti-inflammatory drugs inhibit cyclo-oxygenase.

Platelet aggregation: When activated, the platelets secrete several of their granule contents into plasma, which include ADP, serotonin, calcium, fibronectin, platelet derived growth factor (PDGF) and platelet factor 4. Released ADP binds to the glycoprotein receptors on the platelet surface. The receptors, in turn, get activated and change the conformation of the Gp II b/III a complex so that it binds fibrinogen, thereby linking the adjacent platelets and aggregating them. These aggregated platelets form the platelet plug (see Figs 148.5 to 148.8).

Once the optimum amount of clot has been formed, further extension is arrested by the antithrombic substances and the fibrinolytic enzyme plasmin, which is generated locally. Plasmin helps to remove excess of fibrin by converting it into soluble fibrin degradation products (FDP). Normal hemostasis is a well balanced system brought about by the close interaction of the vascular platelet factor, coagulation, and fibrinolysis. This can be achieved only in the presence of normal vessel walls, adequate number of functioning platelets, sufficient quantities of functional coagulation proteins, and a normal fibrinolytic mechanism (see page 979).

In peripheral blood the normal platelet count is 150-400,000/cmm. Platelets are disc-shaped non-nucleated bodies, 1.5-3 µm in diameter.

Ultrastructure of platelets—The surface of platelets is made of three layers—the glycoprotein layer, phospholipid layer and inner layer. The glycoprotein layer contains receptors for the binding of von Willebrand's factor and fibrinogen. Defects in the glycoprotein layer lead to abnormalities of adhesion and aggregation. The matrix of the platelet is made up of the sol-gel zone and the organelle zone. In the sol-gel zone the cytoplasm shows fibre systems in various stages of polymerization. These fibre systems help to maintain the shape and also account for the contractile apparatus of the platelets. The organelle zone shows various bodies—the alpha granules, dense granules and lysosomes. The alpha granules contain several secreted proteins, von Willebrand's factor, fibrinogen, fibronectin, thrombospondin, coagulation factor V, high molecular weight kininogen, platelet factor 4, beta thromboglobulin, platelet derived growth factor

(PDGF), albumin and histidine-rich glycoproteins. The dense granules contain calcium, pyrophosphate, serotonin, and adenine nucleotides. All these substances are released into plasma when the platelets are activated. Deficiency of alpha granules and dense granules lead to platelet dysfunction (see Fig. 148.4).

Platelet function requires the presence of specific receptors on the platelet surface, which interact with proteins in the plasma including those secreted by the platelets (see Fig. 148.7).

Platelets can produce many of the factors taking part in the coagulation cascade, in addition to concentrating them on their surface.

These processes collectively known as **contact interactions** consist of several processes. Platelet adherence is mediated by the interaction of platelet glycoprotein Ib/1x with endothelial von Willebrand's factor under high shear conditions, and by platelet glycoprotein Ia/IIb binding to collagen under low shear rates. Upon stimulation, adherent platelets recruit more platelets into the growing thrombus by three distinct mechanisms:

1. Platelets concentrate clotting factors on their surface and favour thrombin generation. Thrombin activates further platelets.
2. The activated platelets liberate ADP from their granules and activate further platelets.
3. Activated platelets generate thromboxane A₂ which also activates further platelets.

Activation of platelets by an agonist also activates the glycoprotein IIb/IIIa receptor conformationally. This receptor, also known as integrin binds to fibrinogen.

Fibrinogen is essential for platelet aggregation. Normal inactive platelets do not bind fibrinogen. Once activated by ADP, epinephrine or thrombin, fibrinogen receptors manifest on the surface and bind to fibrinogen. The contractile proteins of the platelets consist of actin and myosin. These help in changing shape, locomotion and extrusion of the contents to the surface.

Apart from mediating primary hemostasis (which includes the retraction and contraction of the injured vessel, and plugging of the injured vessel by platelet plug) the platelets take part in coagulation as well—this is referred to as procoagulant activity. **Platelet procoagulant activity** is mediated by the following mechanisms.

1. Protection of the coagulation factors on the platelet surface from the action of plasma inhibitors and secretion of several coagulation factors.
2. Activation of factors X, XII, and XI.
3. Platelet factor 4 antagonises heparin and other inhibitors of coagulation.

Antigenicity of Platelets

The glycocalyx layers on the external membrane of the platelets contain a series of complex glycoproteins

numbered I to X. These express several polymorphic antigenic determinants on their surfaces. These are termed platelet specific antigens (HPP, PIA I or HPAI). These antigens lead to antibody formation resulting in post transfusion purpura and neonatal autoimmune thrombocytopenia purpura (NAITP).

Coagulation

Coagulation: Nomenclature of the coagulation proteins has been accepted internationally.		
Factor	I	Fibrinogen
Factor	II	Prothrombin
Factor	III	Tissue thromboplastin
Factor	IV	Calcium ions
Factor	V	Proaccelerin-labile factor
Factor	VII	Stable factor-Proconvertin
Factor	VIII	Antihemophilic globulin (AHG, AHF)
Factor	IX	Plasma thromboplastin component (PTC), Christmas factor
Factor	X	Stuart-Prower factor
Factor	XI	Plasma thromboplastin antecedent-PTA
Factor	XII	Hageman's factor
Factor	XIII	Fibrin stabilising factor.

The numerical order does not represent the sequence of activation. In addition to the above, several other factors such as prekallikrein (PK) and high molecular weight kininogen (Kin) and several cytokines are involved in the activation of coagulation factors at several steps in the intrinsic pathway. The activated factors are represented with suffix “a”.

Molecular Basis of Blood Coagulation

All the proteins and cellular components taking part in coagulation remain in the circulation as inactive precursors. The coagulation factors are present in optimal amounts required for their efficient action. Thus fibrinogen is present in the concentration of 10 µmol/L where as factor VIII is present only in 0.2 nmol/L.

These are rapidly activated by enzymatic cleavage of one or more peptide bonds. The enzymes concerned with blood clotting are similar to digestive protease enzymes. Since the former group acts intravascularly, precise control and regulation are necessary to moderate their actions. The cascade process of blood coagulation is initiated and maintained on surface membranes of stimulated cells. Platelet surface membrane provides this critical venue for blood clotting *in vivo*. As the coagulation process proceeds, inhibiting factors such as antithrombin III, protein C and protein S are also activated and these help to arrest the coagulation process.

All the coagulation proteins are synthesised mainly in the liver. Endothelial cells including those of hepatic blood vessels secrete von Willebrand's factor polymers. von Willebrand's factor (vWF) is concerned with platelet-

vessel wall and platelet-platelet interactions. It is absent or defective in von Willebrand's disease. Factor VIII molecules form ionic bonds with vWF polymers which provide a carrier for them in the circulation and also prevent their destruction.

Factors II, VII, IX and X are produced in the liver and these are termed vitamin-K dependent factors since this vitamin is necessary for making them functional. Thrombin is produced from prothrombin and it converts soluble fibrinogen to fibrin which consists of insoluble polymers.

Natural Inhibitors of Coagulation

Antithrombin III (AT III): This is present in normal plasma and endothelial cell surfaces. It combines with thrombin and inactivates it. Heparin combines with the lysine residue of AT III and this product is more potent in inactivating thrombin. Hence AT III used to be known as heparin cofactor. AT III has got other activities as well. These include inhibition of the procoagulant factors such as IXa, Xa, XIa, XIIa, VIIa, tissue factor, plasma kallikrein, HMWK and plasmin.

Deficiency of AT III may lead to thrombotic tendencies. AT III has also antiplasmin activity.

Protein C, a vitamin K dependent protein synthesized in the liver is the key component in a physiologically important anticoagulant system. Protein C circulates in plasma as an inactive precursor which is rapidly converted into activated protein C (APC) on contact with thrombin which is bound to thrombomodulin receptors on vascular endothelial cells. APC selectively degrades factors Va and VIIIa. By inactivating these factors it controls the conversion of factor X to Xa and that of prothrombin to thrombin, thereby inhibiting the coagulation cascade.

Inherited abnormalities of factor V also known as factor V Leyden has a glutamine instead of arginine in position 506. Factor V Leyden is resistant to the section of APC. In the white population the frequency of this genetic defect is 2-15%. In India also this abnormality is present as a cause of thrombophilia. Activated protein C, antithrombin III and tissue factor pathway inhibitor (TFPI) dampen coagulation, enhance fibrinolysis and remove microthrombi. APC proteolytically inactivates factors V a and VIII a, and decreases the synthesis of plasminogen activator inhibitor -I (PAI-I).

Protein C deficiency may be inherited as an autosomal dominant. Such individuals suffer from recurrent venous thrombosis and even fatal pulmonary thromboembolism. Infants who are homozygous for protein C deficiency develop neonatal purpura fulminans. This is characterized by generalized macrovascular thrombosis. In addition to quantitative deficiency, functional abnormalities of protein C may occur as genetic defects. Resistance to APC has

been reported to occur as an inherited disorder. Sepsis reduces the levels of protein C, Protein S, ATIII, and TFP-I.

Protein S—This is also a vitamin K dependent plasma protein synthesized by the liver, which acts as a co-factor for activated protein C and this complex takes part in inhibiting coagulation cascade. Protein S exists in two forms in plasma-free and combined forms. The former is the functionally active one. Action of protein S is not fully understood. Inherited protein S deficiency leads to thromboembolic complications. Individuals who develop thromboembolic complications due to abnormalities of protein C or protein S require life-long anticoagulant therapy.

Blood coagulation occurs under two main groups of circumstances. The commonest event requiring the coagulation process to be initiated is trauma or any event that leads to disruption of a blood vessel. The extrinsic pathway is triggered and this results in prompt coagulation and arrest of bleeding. Another pathway known as the intrinsic pathway becomes operational when blood clots inside vessels or *in vitro* spontaneously. Though these two distinct processes start off differently, after the few initial steps both proceed through a common pathway. Both the processes are complementary to each other.

In 1977 a vitamin K-dependent protein circulating in bovine plasma was identified by Prowse and Eonou. The human counterpart of this protein was identified in 1984. Its structure is broadly similar to that of factors VII, IX and X and also protein C. It was named **protein Z**. It acts as a co-factor to form protein dependent proteinase inhibitor (ZPI) which inhibits the action of factor Xa.

Protein Z is synthesised in the liver. Normal levels range from 2-3 mg/L in plasma. Association between protein Z deficiency and ischemic stroke has been suggested (Protein Z and thrombosis. The Lancet; 2001, 337, 900-901).

Coagulation Pathways

The mechanism of coagulation can be considered under two heads for purposes of description, even though in real-life the whole process proceeds as a smooth continuous cascade like process.

1. Primary or extrinsic pathway end
2. Accessory or intrinsic pathway

The main pathway resulting in clot formation is the primary or extrinsic pathway. Regardless of path chosen, the final steps are the formation of prothrombinase complex which converts prothrombin to thrombin, which in turn converts fibrogen to fibrin. Fibrin is the ultimate product which forms the clot. On injury to the vessel wall, tissue factor (TF) combines with circulating factor VIIa to form extrinsic tenase. Initially this converts factors IX

to IXa and X to Xa simultaneously Factor IXa combines with factor VIIIa to form intrinsic tenase. Factor Xa with factor Va form prothrombinase complex. The intrinsic tenase also converts more of factor X to Xa.

Factor IXa is also formed from the accessory pathway with the help of factors XIIa, XIa, prekallekrein and high molecular weight kininogen (HMWK).

The combined actions of the intrinsic and extrinsic tenase and the prothrombinase, complex lead to an explosive burst of the enzyme thrombin (factor IIa). Enzyme thrombin cleaves fibrinogen to yield the fibrin clot.

Enzyme thrombin also activates factor XIII which further stabilizes the fibrin.

The next step is to terminate the activated coagulation process so that excessive clot formation will be prevented and only optimum clot will be formed. This is achieved by inhibition of the procoagulant enzyme complexes. This involves antithrombin III which inhibits thrombin and factor IXa, Xa, XIa, XIIa factor VIIa- tissue factor, plasma kallikrein and HMWK. Protein C and protein S inhibit factors Va, VIIIa. The termination phase serves to limit the coagulation process and prevent excessive clot formation (Fig. 162.1).

Thrombin

This is the key effector enzyme for converting fibrinogen into fibrin. The most crucial event in the coagulation process is the generation of thrombin from prothrombin by thromboplastin which is also known as prothrombinase. Thrombin has other actions as well.

1. Activation of platelets
2. Conversion of fibrinogen into fibrin network
3. Feedback amplification of coagulation factors.

Phosphatidylserine is a negatively charged phospholipid required for the assembly of the tenase and prothrombinase complexes. In platelets under normal conditions phosphatidylserine is present in the inner layer leaflet of the plasma membrane. When platelets are activated this phosphatidyl serine is translocated from the inner to the outer layer of the plasma membrane. In the tenase and prothrombinase complexes all the participating proteins, namely,

- a. The enzyme factor IXa and Xa
- b. The cofactors VIIIa and Va
- c. The substrate factors X and prothrombin show affinity to the phospholipid surface. The enzymes and substrates are vitamin K dependent.

Calcium binding is necessary for the molecular reactions. Antagonists of vitamin K lead to defective binding of calcium and loss of ability to interact with the phospholipid membrane. This is the mechanism of action of vitamin K antagonists employed therapeutically.

Fig. 162.1: Overview of hemostasis. Note: The term extrinsic and intrinsic 'tenase' indicate their enzymic activity

In experimental mice, lack of tissue factor, factor V and prothrombin leads to death *in utero*. Deficiency of factor VII leads to death from bleeding, shortly after birth. Deficiency of factor VIII and IX are compatible with normal growth and development, but such animals develop hemophilia like disease later on.

Polymerization of fibrin is limited by the inhibition of factors XIIa, XIa, IXa and Xa, and thrombin by anti-thrombin III (heparin cofactor) present in blood and endothelial cell surfaces. At this stage the other inhibitors of coagulation—protein C and protein S—also come to play their roles in limiting further thrombosis.

Fibrinolysis

This is the process by which fibrin polymers are lysed by the enzyme plasmin derived by partial proteolysis of the zymogen-plasminogen which is adsorbed to fibrin polymers. The main fibrinolytic components of plasma are plasminogen, alpha-2 antitrypsin, tissue plasminogen activator (tPA) and urinary type plasminogen. The

formation of plasmin-resistant stable fibrin clot is the ultimate result in the coagulation process.

Coagulation factor XIII acts on fibrin to convert it into polymerized form which is resistant to plasmin. Tissue plasminogen activator facilitates the conversion of plasminogen to plasmin. Plasminogen activators are derived from the lysosomes of disrupted endothelial and tissue cells. These bind to fibrin polymers and convert fibrin-bound plasminogen into plasmin.

Plasmin remains bound to fibrinogen and degrades it into soluble fragments—the fibrin degradation products (FDP). D-dimer is also produced in excess. In addition to splitting fibrin, plasmin is also capable of splitting fibrinogen and factors V and VIII. Fibrinolysis is inhibited by plasminogen activator inhibiting type I (PAI-I) and increased plasma concentrations of factor VII, fibrinogen and von Willebrand's factor. PAI-I is produced by vascular endothelium. It is also seen on platelets. Increase in PAI-I occurs in syndrome X which is associated with diabetes mellitus and increased tendency to atherosclerotic vascular occlusions.

GENERAL CLINICAL CONSIDERATIONS

In general, primary hemorrhagic disorders are rare, in the majority of cases abnormal bleeding is due to secondary causes, either localized (surgical conditions) or generalized, e.g. hepatic failure, renal failure and anticoagulant overdose. In any patient who gives a history of easy bruising or excessive bleeding from childhood, a congenital hemostatic defect is likely. The acquired form starts at a later age. Even in congenital defects which are mild, clinical onset may be delayed.

Congenital Hemorrhagic Disorders are Characterized by

1. Purpura, ecchymosis, hematoma, or spontaneous bleeding from multiple sites or following minor trauma.
2. Excessive bleeding after trauma or minor surgery.
3. Bleeding into joints, gums, and mucous membranes of the gastrointestinal and the genitourinary tracts.
4. Positive family history in many cases.
5. History of previous episodes of hospitalization and blood transfusions to control the hemorrhage.
6. Abnormality involving one or only a few coagulant factors.

On the other hand, acquired hemorrhagic tendencies set in at a later age, may be temporary and may reveal deficiencies of multiple coagulation factors.

Broadly the hemorrhagic disorders can be divided into two groups.

1. **Purpuric disorders:** These affect the process of primary hemostasis, i.e. platelet and/or vascular functions are abnormal. These are characterized by bruising, ecchymosis, and bleeding from mucous membranes, especially of the gastrointestinal and genitourinary tracts. Bleeding starts soon after injury and it is brisk initially. It is relieved by local pressure. The capillary resistance test (*Hess' test*) is positive. Bleeding time is prolonged. Unless there is severe thrombocytopenia (less than 20000/cmm), coagulation time is not prolonged.
2. **Coagulation defects:** These may be congenital or acquired. In the majority of cases the primary coagulation disorders are congenital. They are characterized by deep tissue bleeding, bleeding into joints, progressive deformity of joints, prolonged coagulation time, and normal bleeding time and a negative Hess-test. If the platelets and capillaries are normal, post-traumatic bleeding stops temporarily to be followed by prolonged and gradually increasing bleeding, which may even threaten life.

LABORATORY INVESTIGATIONS IN HEMORRHAGIC DISORDERS

A. Screening tests

1. *Platelet count* and morphology.

2. *Prothrombin time* (to test the extrinsic coagulation pathway).
3. *Partial thromboplastin time* (to test the intrinsic coagulation pathway).
4. *Thrombin time* to test the common coagulation pathway.

A *stained blood film* should show clumped and single platelets at the rate of 1 for 20-25 erythrocytes. Absence of clumping may suggest thrombasthenia.

B. Further tests for platelet function

1. *Bleeding time (Ivy):* Prolongation beyond 12 minutes is definitely abnormal. In dysfunction of platelets and capillaries, the bleeding time is prolonged. Common causes of prolongation of the bleeding time are thrombocytopenia (platelet count below 100,000/cmm), thrombopathies, von Willebrand's diseases and scurvy.
2. *Hess tourniquet test:* Appearance of more than 30 spots (when examined with a hand lens) within a circle of 2.5 cm diameter is considered a positive test. Hess' test is positive in thrombocytopenia, thrombocytopathy, and diseases of the capillaries. This test is less reliable than the bleeding time and hence abandoned in many centres.
3. *Platelet aggregometry:* This is an *in vitro* test to determine the ability of the platelets to aggregate in platelet-rich plasma. This phenomenon can be studied spectrophotometrically or using an aggregometer. Platelet aggregation in response to ADP, epinephrine, collagen or thrombin is absent in thrombasthenia.

Interpretation of findings on platelet aggregation

Normal	Thrombocytopenias von Willebrand's disease
Absent	Thrombasthenias, especially Glanzmann's disease
Diminished	Disorders of platelet release reaction and afibrinogenemia.

4. *Tests for platelet adhesion:*

C. Tests for coagulation

Clotting time (coagulation time-Lee and White): 1 mL blood is drawn into each of three clean dry test tubes and clotting time for each test tube at room temperature is noted and the values are averaged. Normally clotting occurs in 5-7 min. Prolongation beyond 10 min is abnormal. Clotting time is prolonged in hemophilia, Christmas disease, presence of circulating anticoagulants, hypofibrinogenemia, and secondary deficiencies of coagulation factors. Clotting time is prolonged only when the defect is gross, and therefore, it is not reliable when the disorder is mild.

Clot retraction: When kept at room temperature the clot retracts and the serum separates within two hours. When the platelet number is grossly deficient or platelet function

is defective, clot retraction is impaired. Normally the serum expressed measures 55-65% of the total quantity of blood.

Prothrombin time (Quick's): This test evaluates the production of thrombin and fibrin polymers by the extrinsic coagulation pathway. Prothrombin time is prolonged whenever factors VII, X or V, prothrombin, or fibrinogen are reduced to levels below 30% of normal. Normal prothrombin time is 10-12 seconds. In order to standardize the test results and avoid inter laboratory variations, internationally standardized thromboplastin is used and the results are expressed as International Normalized Ratio (INR).

Partial thromboplastin time (PIT): Activated partial thromboplastin time (APTT) measures the time required for the formation of thrombin and fibrin polymers by the intrinsic pathway. Normal APTT is 35 sec. Value of APTT rises whenever the levels of one or more of the coagulation factors other than factor VII is reduced below 30% of the normal. When the common pathway is impaired both PTT and APTT are prolonged.

Substitution Test and Factor Assays

Identification of deficiencies of coagulation factors is done by estimating APTT in the patient's plasma and repeating the test with added plasma with known defects, till APTT is corrected. Assay of factors XII, XI, IX and VIII-C, prekallikrein, and high molecular weight kininogen is done by modified APTT test.

Thrombin time: This helps to identify abnormalities in the quantity and quality of fibrinogen. It is prolonged in hypofibrinogenemia and dysfibrinogenemia. Normal level of fibrinogen in plasma is 150-400 mg/dL.

Estimation of fibrin degradation products (FDPs): Increase in FDPs in serum and urine indicate increased fibrinolysis.

Euglobulin lysis time: This indicates the amount of fibrinolytic activity in the serum, and therefore, it is an indirect indication of plasmin activity. In disseminated intravascular coagulation (DIC) and primary hyperfibrinolytic states, euglobulin lysis time is shortened and serum levels of FDPs are increased.

D-dimer Elevated levels of D-dimer in plasma are more specific indicators of thromboembolic episodes followed by fibrinolysis. D-dimer is the fibrin fragment in plasma which is a marker of fibrin formation and reactive fibrinolysis. Normals levels of D-dimer in plasma is < 500 ng/mL.

Rusven (Russels viper venom) clotting time is employed to assay factor X and also for the detection of lupus anticoagulant.

At present test kits are available from many sources, and therefore, these tests can be done even in moderately equipped laboratories.

Detection of Circulating Anticoagulants

In conditions where the abnormality of coagulation is due to deficiency of one or more of the clotting factors, addition of 10-30% by volume of normal plasma corrects the abnormal laboratory tests.

In conditions where circulating anticoagulants or antibodies to coagulation factors are present, substitution with normal plasma fails to correct the abnormality, until very large quantities are added.

Automated testing machines are available for performing coagulation tests and platelet function tests. If properly serviced and calibrated using standard specimens, they are reliable and more accurate than manual methods.

Platelet and Vascular Disorders

K.V. Krishna Das, Mathew Thomas

Chapter Summary

- General Considerations 1083
- Immune Thrombocytopenic Purpura (ITP) 1083
- Neonatal Thrombocytopenia 1087
- Secondary Thrombocytopenia 1087
- Thrombocytopathies 1088
- Anaphylactoid Purpura 1089
- Hereditary Hemorrhagic Telangiectasis 1090
- Antiplatelet Drug Therapy 1091

General Considerations

The term purpuric disorder is applied to a hemorrhagic state characterized by bleeding into the skin in the form of dot like purpura, ecchymosis, or deep hemorrhages, and often associated with bleeding from the mucous membranes of the mouth, nose, gastrointestinal tract, uterus, and urinary tract. Purpuras are caused by primary disorders of blood vessels or thrombocytopenia or thrombocytopathy. Purpura has to be distinguished from macular rashes. The former does not blanch on pressure whereas the latter does. Palpable purpura occurs in vasculitis, e.g. Henoch-Schönlein syndrome (Table 163.1).

When the platelet count falls below 100,000/cmm (1010/L) it is designated as thrombocytopenia. Even at this level mild bleeding tendency may start, but bleeding becomes pronounced when the platelet count falls below 50,000 per cmm. Severe bleeding occurs when the platelets fall below 20,000 per cmm. The severity of the bleeding does not always correlate with the degree of thrombocytopenia. Bleeding may be spontaneous or may follow minor trauma. Purpuric bleeding usually stops within 24 hours either spontaneously or on local compression.

Causes of thrombocytopenia: Thrombocytopenia may result from either diminished production or increased destruction of platelets. In some both may operate. It may also occur in disseminated intravascular coagulation and massive transfusion of stored blood.

TABLE 163.1

Causes of thrombocytopenia

- A. **Diminished production of platelets**
 - 1. Aplastic anemia
 - 2. Selective hypoplasia of megakaryocytes or inhibition of platelet production by antibodies
 - 3. Dyshemopoietic states, e.g. megaloblastic anemia
 - 4. Myelophthistic conditions, e.g. acute and chronic leukemia, lymphoma, myelofibrosis, disseminated carcinoma, and multiple myeloma
 - 5. Heavy alcoholism (ethanol leads to inhibition of megakaryocytes)
- B. **Increased destruction**
 - 1. Idiopathic (immune) thrombocytopenic purpura
 - 2. Chronic or acute secondary immune thrombocytopenia following viral infections, systemic lupus erythematosus, lymphomas, and chronic lymphatic leukemia, acquired hemolytic anemias, AIDS and others.
 - 3. Drugs like sedormid, quinine, quinidine, para aminosalicylic acid, sulphonamides, rifampicin, stibophen, digoxin, streptomycin, alpha methyl dopa, heroin, carbimazole, chloramphenicol, tetracycline, mesantoin, troxidone, and phenylbutazone
 - 4. Sequestration of platelets, e.g. splenomegaly, giant hemangioma, arteriovenous fistulae, disseminated intravascular coagulation.
- C. Dilutional thrombocytopenia, e.g. transfusion of massive quantities of stored blood poor in platelets

Immune Thrombocytopenic Purpura (ITP)
Syn: Idiopathic thrombocytopenic purpura

This is one of the common hemorrhagic disorders seen in clinical practice in India. In the vast majority of cases antibodies develop which coat the platelets and lead to their destruction in the reticuloendothelial system in the spleen, liver, bone marrow and other sites. These antibodies are demonstrable by direct or indirect methods. Though the exact antigenic stimulus for production of the antibodies is not clear, it is seen that they are directed against many of the components of the platelets. Most of the autoantibodies are directed against epitopes on

glycoproteins on the platelet surface. The antibody-coated platelets are sequestered in the spleen, liver, bone marrow and other reticuloendothelial organs, and selectively destroyed by macrophages. The antibodies are produced in the spleen and bone marrow. They are IgG in 70%, IgM in 5% and IgG and IgM in 20% of cases. In the circulation they are attached to the platelets. Most of the auto-antibodies are directed against epitopes on glycoproteins on the platelets surface. Life-span of the platelets is reduced and the reduction is inversely related to the amount of platelet associated IgG.

There is compensatory increase in platelet production brought about by increase in the number of megakaryocytes to 3-5 times the normal, but platelet destruction exceeds the regeneration and ultimately the platelet count falls. The antibody has also action in inhibiting the production and release of platelets from megakaryocytes and in some cases platelet production may be suppressed. In the bone marrow many megakaryocytes are seen to possess hyaline cytoplasm and entire margins, indicating absence of platelet production. In small doses the antibodies lead to platelet dysfunction. In larger doses they lead to platelet destruction. Many of the platelets formed under stress are larger than normal. These megathrombocytes have the same diameter as red cells. They have reduced life-span which is inversely proportional to their diameter. Presence of antibodies may also contribute to their morphological abnormality.

CLINICAL FEATURES

Idiopathic thrombocytopenic purpura (ITP) may occur at any age, but younger subjects are affected more. The disease may present as the acute and the chronic varieties. In chronic ITP duration of the disease exceeds three months. Acute ITP is more common in children whereas the chronic variety is more common in young women. Both sexes are equally affected below the age of 12 years, but after that age females are affected about four times more frequently than males.

In many cases of ITP in children, purpura may be preceded by an upper respiratory infection or other specific diseases like measles or mumps. Viral infections trigger the formation of antiplatelet antibodies. The acute form is characterized by rapid onset of bleeding from the gums, purpura, ecchymosis, and bleeding into deeper tissues. Majority of these patients seek medical help within 1-2 weeks of onset. In the chronic form the onset is insidious and the course is prolonged over several weeks or months, sometimes even years, before they seek medical help. Periods of exacerbations and remissions occur. In women one of the common presentations is menorrhagia and intermenstrual bleeding. The menorrhagia tends to be severe and in some cases blood loss may be considerable so as to necessitate blood transfusion.

Fig. 163.1: Female purpura over legs

Due to this complication ITP tends to be more severe in women than in men. Subdural hematoma may occur in chronic ITP.

Physical examination reveals the typical purpuric spots and ecchymosis, particularly over the limbs, chest, and sometimes over the neck. Areas of pressure by clothing or minor trauma of rubbing as in the axillae and thighs show more purpuric spots. Spontaneous bleeding is seen from the mouth, nose, urinary tract and genital tract in women. In severe cases hemorrhagic bullae develop in the mucous membrane of the mouth. The extravasated blood undergoes clotting. Hematemesis and melena may occur. Ordinarily the bleeding stops within a few days either spontaneously or with treatment. Retinal bleeding occurs in severe cases. Bleeding into the central nervous system may present as spontaneous subarachnoid hemorrhage or cerebral hemorrhage. Central nervous system bleeds are likely when the platelet counts fall below 20,000/cmm. As a rule, there is no palpable splenomegaly. Presence of moderate or marked splenomegaly should suggest the possibility of leukemia, systemic lupus or other disorders (Figs 163.1 and 163.2).

Laboratory investigations: Platelet count is reduced in all cases. It may be below 20,000 per cmm in severe cases. Under light microscopy the platelets appear normal, except for the presence of a few large forms—the *megathrombocytes* (Fig. 163.3). The presence of megathrombocytes indicates disordered thrombopoiesis and possibly the effect of antibodies. Though there is no

Fig. 163.2: Purpura over the palate

Fig. 163.3: PB ITP megathrombocytes

gross impairment of platelet function, the antibody leads to impairment of platelet release reaction which can be demonstrated *in vitro*. The hemorrhagic manifestation is mainly due to thrombocytopenia, it is aggravated by platelet dysfunction as well. Bleeding time is prolonged whereas the whole blood clotting time is normal. Clot retraction is deficient if the platelet count is below 50,000/cmm. Hess' test is positive. Examination of the bone marrow is basically normal but it may show increased number of megakaryocytes. Many of them have hyaline cytoplasm, entire margins and are devoid of budding activity. In over 75% of cases antiplatelet antibodies can be demonstrated by direct or indirect tests. The degree of anemia is proportional to the blood loss which may be visible externally or deep into tissues.

Differential diagnosis: This includes allergic purpura, drug induced thrombocytopenia, systemic lupus erythematosus, acute leukemias, aplastic anemia, thrombocytopathies, vascular disorders, HIV infection and septicemias. Systemic lupus erythematosus may clinically present as thrombocytopenic purpura for a considerable period of time before other florid features develop.

Presence of mild or moderate splenomegaly should suggest the possibility of acute leukemia, lupus erythematosus, or hemolytic anemia. Sometimes ITP may be associated with other autoimmune disorders such as hemolytic anemia (*Evan's syndrome*). Rarely ITP may coexist with autoimmune thyroid diseases.

Course and prognosis: Acute ITP runs a short course and may remit spontaneously in a few of the cases. It may result in serious bleeding with rapid development of anemia. Fulminant cases may be fatal if untreated. Death is due to severe blood loss or bleeding into vital organs such as the brain. Platelet counts below 10,000/cmm, hematuria, retinal hemorrhages and signs of meningeal irritation are grave prognostic signs. Mortality is about 2-3% in large series.

Among the acute ITP cases, 7-28% go into the chronic form. In the chronic form periods of remissions and exacerbations alternate and the patient suffers only minor disability. Infections, menstruation, or drugs like aspirin may precipitate bleeding episodes. Menstrual and intermenstrual blood loss in women may be severe and even life-threatening and they seek medical help earlier due to this factor. During pregnancy the bleeding episodes may aggravate in many cases, though in some cases the condition may remit. Risk of intra-uterine death of fetus and perinatal fetal loss are high.

TREATMENT OF ITP

All treatment modalities available at present are only supportive or palliative. Therefore, prolonged treatment may have to be given in chronic ITP. Acute ITP may remit and relapse and therefore treatment also may have to be repeated. Rest in bed is essential to reduce the severity of bleeding. If blood loss is severe blood transfusion is indicated. Platelet transfusions have been satisfactory in some cases, but when antibody titre is high the transfused platelets are also destroyed rapidly.

Corticosteroids form the mainstay of treatment in the acute stage. Prednisolone given orally in the dosage of 1 to 2 mg per kg body weight (about 40 mg in divided doses) brings about relief within hours. The effect is brought about by immediate inhibition of macrophage function and a long-term effect on antibody production. The dose is reduced after the first or second week, when clinical severity comes down. Steroids can be withdrawn when the platelet count returns to normal. In fulminant ITP

hydrocortisone or its analogues are given intravenously in a dose equivalent to 100 mg every 8 hours. In resistant cases methylprednisolone given IV in a dose of 1 g daily for a few days may bring about remission. Steroids should be withdrawn only gradually to avoid exacerbation. In many cases the remission is permanent.

Immunoglobulin given in a dose of 0.4-0.8 g/kg IV daily for 4-6 days brings about rapid relief in 60-70% of cases. IVIG helps to raise the platelet counts rapidly. In many cases it is life-saving and may help to avoid emergency splenectomy. The preparation—*Sandoglobulin* (Sandoz, NJ) is ideal. The daily dose is 0.4-0.5 g/kg bw. It is given IV as a 3-4% solution daily for 6 days consecutively. As the condition improves gammaglobulin is repeated in smaller doses at 1-6 week intervals. Heavy expense and non-availability of the drug limit its widespread use.

In large doses, immunoglobulin may increase the viscosity of blood and thereby increase the risk of myocardial infarction and strokes in susceptible individuals.

Plasmapheresis may be employed as an emergency measure to remove antibodies from the plasma.

Chronic ITP: As in the case of acute ITP steroids are started on a moderate dose and withdrawn on getting remission. Corticosteroids are reintroduced in a dosage necessary to maintain clinical remission, if the platelet count falls on their withdrawal. Steroids are effective in 50-60% of cases.

The clinical benefit and rise in platelet count are not uniform in all cases. Though it is ideal to raise the platelet count above 100,000/cmm, often it may not be possible and therapy has to be aimed at clinical improvement. More emphasis should be given to the clinical condition than to the absolute platelet count alone (Fig. 163.4).

Splenectomy: Since the spleen is the major source of production of antibody and also platelet destruction,

removal of the spleen produces dramatic benefit in over 75% of cases. Following are the indications for splenectomy.

1. Acute ITP non-responsive to corticosteroids or immunoglobulin—emergency splenectomy is indicated, especially if there is a danger of intracranial bleeding.
2. Chronic ITP in which the bleeding recurs frequently on reduction of steroid dosage below 15 mg/day.
3. Exacerbation during pregnancy or when pregnancy is to be allowed in a case of chronic ITP requiring moderate or high doses of corticosteroids.

Soon after splenectomy the platelet counts shoot up and severe thrombocytosis may lead to thrombotic episodes in the postoperative period. In such cases antiplatelet drugs and heparin may be necessary. The platelet count gradually returns to normal over weeks and remains so in most cases. In some cases small doses of corticosteroids may be required even after splenectomy. In general, splenectomy is effective in 80% of cases. Splenectomy is not undertaken in children below the age of ten years due to the risk of severe infections. Appropriate immunizations are indicated in splenectomized patients. Accessory spleens occur in about 10% of cases. If these are left behind, these impair the effectiveness of splenectomy. Accessory or persistent splenic tissue can be confirmed by radionuclide scan.

Immunosuppressants: Cyclophosphamide in a dose of 1-2 mg/kg or azathioprine in a dose 1-4 mg/kg are effective adjuvants when used along with corticosteroids. They are contraindicated in pregnancy. Vincristine in a dose of 1 mg/m² once a week given for three to four weeks helps to bring about remission in intractable cases. Mycophenolate mofetil may be used in resistant cases of ITP.

Alternate drugs: *Danazol*, an androgen with only low virilizing activity, commonly used in gynecological practice, when given in doses of 100-300 mg/day brings about clinical improvement in 50% of cases. After control of the acute episode the drug may be given as a maintenance dose for 2-3 months. It probably enhances suppressor T cell function and reduces antibody levels. It acts synergistically with corticosteroids.

Anti-Rh-D immunoglobulin (Rhogam) when given in a dose of 25 µg/kg IV on two consecutive days is effective, especially in Rh-D positive individuals. This may be tried as a cheaper substitute for IV immunoglobulin. Anti Rh-D leads to immune hemolysis and this secondarily overloads the phagocytic cells, thereby reducing the phagocytosis of antibody coated platelets.

Dapsone causes oxidative hemolysis and this process overloads the phagocytic cells, thus rendering them less effective to destroy antibody coated cells. In dose of 50-100 mg/day given orally it can be used for maintenance

Fig. 163.4: ITP figure female long-term steroid therapy striae

therapy. About 50% of mild chronic ITP patients respond favourably.

Rituximab (Mabthera) which is an anti-CD20 monoclonal antibody, eliminates B lymphocytes that produce platelet antibodies. It has been found to be useful in resistant cases with severe symptoms. The drug is very expensive.

Neonatal Thrombocytopenia

In women suffering from ITP IgG antibodies cross the placenta to reach the fetus. The neonate may develop thrombocytopenia and bleeding. Common manifestations include bleeding from the umbilical stump and ecchymosis. The majority of infants recover spontaneously. The risk of fetal bleeding during vaginal delivery is high. During delivery or soon after, the fetus may die from intracranial bleeding. Maternal platelet count below 100,000/cmm and/or fetal platelet count below 50,000/cmm are associated with high risk of intracranial bleed during vaginal delivery. In severe cases intravenous hydrocortisone 2-3 mg/kg body weight and platelet transfusions are necessary to tide over the crisis. Judicious use of immunoglobulin will help to tide over a crisis if other measures fail. Since the risk of intracranial bleeding is high during vaginal delivery, cesarean section is indicated if the platelet count in the fetus is below 50,000/cmm or the maternal platelet count is below 100,000/cmm. Neonatal thrombocytopenia may develop even when the mother is in remission.

Neonatal Alloimmune Thrombocytopenia

It is a rare fetomaternal incompatibility in which maternal IgG antibodies directed against fetal platelets reach the fetus transplacentally. The mother is clinically normal. In most children the platelet count is low at birth, it declines further during the first 48 hours of birth, to reach a nadir below 10,000/cmm in almost 50%. Hemorrhagic manifestations develop in 90% of cases. Neonatal alloimmune thrombocytopenia follows a benign course in 90% of cases and spontaneous recovery is the rule. Recurrence rate in subsequent pregnancies is 50%. Central nervous system bleeding may occur in 15% of cases, it may be intracerebral or rarely subarachnoid.

Treatment: Corticosteroids, transfusion of maternal platelets and immunoglobulins have been tried with good results. Treatment of choice is the transfusion of maternal platelets, washed free from antibody—containing plasma and suspended in A B blood group plasma. Intravenous immunoglobulin therapy should be tried in cases resistant or not fully responding to corticosteroids.

Anti-D immunoglobulin is a less effective alternative. It is given in doses of 25 µg/kg IV on two consecutive days.

ITP and Pregnancy

50% of women develop mild asymptomatic gestational, thrombocytopenia during term. If the platelet counts go below $70 \times 10^9/L$ in early gestation, ITP is the probable diagnosis.

Mild or moderate asymptomatic cases are monitored without intervention. If the platelet count goes down further and symptoms occur, treatment is on the same lines as ITP.

Women with ITP should be counselled regarding the risks before they opt to become pregnant. There is higher risk for both the mother and the fetus. Aggravation of bleeding tendency in the mother and risk of fetal loss has to be anticipated. These patients should be monitored every month. Corticosteroids can produce adverse side effects.

Splenectomy should be delayed up to the second trimester in order to avoid abortion. Drugs like vinca alkaloids and cyclophosphamide are teratogenic. Azathioprine is possibly safe. IV IG is safer and may have to be used more frequently in order to raise maternal platelet counts above 30000 throughout pregnancy and above 50000 during labour. Platelet transfusions may have to be given to maintain these levels. Cesarean section should be undertaken based on the obstetric indications, in order to avoid trauma to fetal head during delivery.

Pre-eclampsia (PE) is associated with thrombocytopenia in 15% of cases. In addition, some women with PE develop microangiopathic hemolysis and liver dysfunction—known by the **acronym HELLP** (hemolysis, elevated liver-enzymes, low platelet) counts. If severe, plasma exchange may be needed. In the ordinary cases the platelet abnormality clears after delivery.

Secondary Thrombocytopenia

Thrombocytopenia may develop as part of the clinical picture in acute leukemia, aplastic anemia, myelodysplastic syndromes, systemic lupus erythematosus, AIDS, viral hemorrhagic fevers and several virus infections. In these the major clinical manifestations are those of the primary condition.

Drug induced thrombocytopenia may be a result of toxic damage to the bone marrow. In this case, the thrombocytopenia is a manifestation of marrow hypoplasia. Drugs may lead to immune mediated thrombocytopenia. Heparin, sedormid, quinine, vancomycin and others may lead to immunologically mediated platelet destruction. The antibodies can be demonstrated by flow cytometry, or ELISA.

In **drug-induced thrombocytopenias**, very often other signs of drug toxicity may be evident but thrombocytopenia may be the sole manifestation at times. The drug or its metabolites act as haptens which bind

noncovalently with albumin or other serum proteins in the plasma to form complete antigens. Antibodies are produced which combine specifically with the protein-bound haptenic drug or its metabolites to form antigen-antibody complexes. These are absorbed on to the platelet glycoproteins such as IIb/IIIa fibrinogen receptor or glycoprotein 1b/1x (vWF receptor or both).

In some cases, e.g. quinine the thrombocytopenia may be accompanied by other phenomena such as immune neutropenia and disseminated intravascular hemolysis. They activate complement and this leads to complement-mediated lysis of platelets in the circulation. If the amount of antibody coating the platelets is small, such platelets are destroyed by the macrophages of the spleen and liver. Drug induced thrombocytopenia is generally severe. Since presence of the drug or its metabolites is essential to perpetuate the immune mechanism, withdrawal of the drug relieves the thrombocytopenia promptly. In severe cases platelet transfusions are required. Corticosteroids help to arrest platelet destruction by inhibiting macrophage function in the spleen and liver.

Thrombocytopenia occurring as an isolated abnormality in otherwise healthy persons.

Thrombocytopenia detected on routine platelet count may remain asymptomatic in many cases. Sometimes congenital thrombocytopenia may occur. Asymptomatic thrombocytopenia may precede myelodysplastic states or immune mediated diseases like SLE for considerably long periods.

Congenital thrombocytopenia is rare. Commonly it is associated with morphological abnormalities such as giant platelets.

Pseudothrombocytopenia

This is a falsely low platelet count due to platelet agglutination caused by the anticoagulant EDTA used during blood collection, with the frequency of 1/1000 samples.

Thrombocytopathies

These are conditions associated with functional defects of platelets. Platelet counts are normal or even increased in many. The defects may be either congenital or acquired. A classification of thrombocytopathies is given in the Table 163.2.

Thrombopathies are common, though many may be asymptomatic.

Storage Pool Disease

This disease is inherited as an autosomal dominant. In this condition there is no store of ADP in the granules of the platelets and so ADP is not released for further aggregation and platelet functions.

TABLE 163.2

Classification of thrombocytopathies

I. Hereditary conditions

1. Storage pool disease
2. Wiskott-Aldrich syndrome
3. Albinism
4. Hermansky-Pudlak syndrome
5. Hereditary thrombasthenia (Glanzmann's disease)
6. May-Hegglin anomaly
7. Bernard-Soulier syndrome

II. Acquired

1. Drug effects—anti-inflammatory drugs e.g. aspirin, phenylbutazone, indomethacin, other NSAIDs, dextran, clofibrate, dipyridamole, beta-lactam antibiotics and antihistamines, clopidogrel.
2. Uremia, hepatic failure, scurvy
3. Paraproteinemias—myelomatosis, Waldenström's macroglobulinemia
4. Articles of food such as excess of ginger, garlic and onion

Bleeding disorder associated with *albinism* and **Wiskott-Aldrich syndrome** is also due to deficiency of nucleotides in the platelets. *Wiskott-Aldrich syndrome* which is inherited as a sex linked recessive is usually associated with bleeding from various sites, thrombocytopenia, overwhelming infection, eczematous dermatitis and a tendency to develop lymphomas.

In **Hermansky-Pudlak syndrome** there is lack of storage of adenine nucleotides and a deficiency of serotonin. The associated hemorrhagic disorder is clinically mild.

HEREDITARY THROMBASTHENIA

Hereditary thrombasthenia (Glanzmann's disease) is a rare autosomal recessive disorder occurring in both sexes. The platelet membrane glycoproteins Gp II b/IIIa are deficient or defective. The platelets do not bind fibrinogen and cannot aggregate. Bleeding manifestations are purpura, epistaxis, bleeding from wounds and cuts, menorrhagia and excessive bleeding during delivery. The characteristic laboratory finding is the failure of platelets to aggregate in presence of ADP, adrenaline, noradrenaline, thrombin or 5-hydroxytryptamine. Platelet adhesion and clot retraction also are poor. There is deficiency of fibrinogen on the platelet, and it does not bind to the platelet surface membrane. Therefore aggregation is not initiated. Bleeding may be mild or sometimes severe. Platelet transfusion may be required to arrest bleeding.

Diagnosis: Clinical suspicion can be strengthened by examining a stained blood film. Normally platelets should be seen in clumps. In thrombasthenia the platelets are seen singly in large numbers, without any tendency to form clumps.

Morphological abnormalities of platelets such as larger size may suggest immunological and functional abnormalities. Diagnosis is confirmed by studying platelet aggregation. Positive family history may be obtained in the majority of cases.

The May-Hegglin anomaly: In this anomaly, a mild bleeding disorder is associated with basophilic and pyroninophilic inclusion bodies in the leukocytes and an abnormality of the megakaryocytes. Thrombocytopenia may develop. Megathrombocytes may be seen in peripheral blood.

BERNARD-SOULIER SYNDROME

This is a rare autosomal recessive disorder which may lead to mild or severe bleeding. This is characterized by the presence of larger platelets in peripheral blood which fail to adhere to vessel wall. The abnormality is in the surface glycoprotein coat. The platelets have deficient or defective glycoprotein Gp Ib/Ix complex. They cannot bind to vWF and therefore platelet adhesion to vascular endothelium is defective.

Paraproteinemias

Platelet dysfunction may develop in Waldenström's macroglobulinemia and myeloma. The abnormal protein in circulation may coat the platelets and lead to dysfunction resulting in disorders of adhesion, aggregation and release reaction.

Acquired disorders of platelet function: Drugs such as aspirin, clopidogrel and sulphinyprazole inhibit platelet activities and they are used as antiplatelet drugs. Several drugs and articles of food produce platelet dysfunction, sometimes leading to mild or even moderate bleeding tendency. These are used as antiplatelet drugs.

Other drugs such as NSAIDs, beta-lactam antibiotics and antihistamines and articles of food such as *ginger, onion, garlic* and fish oils may give rise to purpura.

Except thrombocytopenia, drug induced thrombopathies rarely give rise to serious generalized bleeding tendency in normal subjects. In persons who have congenital or acquired defects of hemostasis more serious bleeding manifestations develop. Withdrawal of the drug for a week may be essential if surgery or similar procedures are to be undertaken. The platelet defect can be compensated by platelet transfusions. Recently DDAVP (arginine vasopressin) has been reported to reverse the platelet abnormality.

Platelet adhesiveness is diminished in scurvy and this factor also contributes to the hemorrhagic tendency.

Metabolic disorders: The bleeding diathesis in uremia is partly attributable to defects of platelet function. Several

abnormalities may be seen. These defects are reversible when the metabolic abnormalities are corrected. In liver failure also variable platelet defects may be encountered.

VASCULAR PURPURAS (NON-THROMBOCYTOPENIC PURPURA)

These are a group of heterogenous disorders characterized by bruising and spontaneous bleeding from small vessels. In these the bleeding is due to abnormality in the capillaries. Except for a prolongation of bleeding time, other tests may be normal.

The number and function of platelets are usually normal, though occasionally platelet dysfunction may co-exist. The defects may be hereditary as in *Ehlers-Danlos syndrome* or acquired as in *scurvy*.

ANAPHYLACTOID PURPURA Syn; Henoch-Schönlein syndrome, Hypersensitivity angiitis, Rheumatic purpura

This is an immune complex disease caused by type III hypersensitivity reaction similar to that of rheumatic fever and acute glomerulonephritis. This is an acute small vessel leucocytoclastic vasculitis. This is not a primary hematological disorder. It belongs to the group of vasculitic disorders, described in Section: 12. This particular entity is described here since, often it is mistaken for thrombocytopenic purpura clinically. Although the cause is unknown, IgA has a pivotal role in the pathogenesis of HSP. Among the two subclasses of IgA-(IgA₁ and IgA₂) only IgA₁ is involved in HSP. IgA₁ is deposited in vessel walls and renal mesangium. The IgA₁ molecules are altered so that they aggregate into macromolecular complexes which activate the alternate pathway of complement and then deposit in the renal mesangium.

Histology shows vasculitis involving the small blood vessels. This syndrome is more common in children but occasionally it may be seen in young adults. Males predominate. In a small proportion of cases there is history of preceding B-hemolytic streptococcal infection 10 to 20 days prior to the onset of purpura. Other precipitating causes are allergic reactions to drugs and food materials. In many there may be no evidence of a precipitating cause (Fig. 163.5).

Clinical features: A purpuric rash develops acutely over the skin of the extensor surface of the forearms, elbows, buttocks, and legs distally. The lesions may be urticarial, blotchy, and pruritic. Only rarely lesions develop over the trunk and face. Cutaneous purpura in the distal parts of the body is the essential feature. Joint lesions occur in 75%, gastrointestinal involvement occurs in 50-75%, and renal involvement occurs in 40-50%. They share many of the features of IgA nephropathy.

Fig. 163.5: Pitted lesions persisting after relief of anaphylactoid purpura

Abdominal symptoms such as colicky pain and vomiting are usual. Hematemesis and melena may develop in severe cases.

Involvement of joints is common and many large joints are affected. Polyarthralgia, polyarthritis, and peri-arthritis may occur. Hematuria, albuminuria, edema, and hypertension are indicative of renal involvement which may develop in 10 to 30% of cases. The renal lesions may manifest as acute glomerulonephritis. Some of the cases may develop acute renal failure. A small proportion develops persistent and progressive renal lesions. Diagnosis is clinical. There are no pathognomonic laboratory tests. Serum IgA levels are raised in 50% of cases. Blood shows neutrophil leukocytosis. Mild eosinophilia may occur at times. Tests of platelet and capillary function are usually normal. HSP is a self-limited disease. In a third, recurrence may occur. Majority of patients recover completely but recurrence may occur on exposure to the allergen.

Treatment: Symptomatic treatment is adequate in most of the cases since the condition is self-limiting in the majority. Prednisolone 1 mg/kg per day gives symptomatic benefit. Steroids should be withdrawn after a short course. Antispasmodics relieve abdominal pain. Steroids have no effect on the skin lesions. If streptococcal sore throat is evident, a course of penicillin is indicated. For persistent nephritis IV pulse dose is methylprednisolone (30 mg/kg for 3 consecutive days followed by oral corticosteroids may help to arrest the nephropathy. Immunosuppressive drugs like azathioprine and cyclophosphamide have been employed when the glomerulonephritis proves to be resistant to steroid therapy. Response to therapy is unsatisfactory.

Drug induced vascular purpura: Exposure to drugs like penicillin, sulphonamides, atropine, phenacetin, aspirin, and sedatives may produce vascular purpura.

Senile purpura: This condition occurs as a chronic disorder of thin elderly people above the age of seventy

years. Purpuric and ecchymotic spots occur on the extensor surfaces of the forearms which arise spontaneously or after unnoticed trauma. The purpura is due to traction injury to the small capillaries of the dermis due to loss of dermal collagen and subcutaneous fat. No therapy is effective in this condition. It is important to distinguish this benign disorder from other diseases which may require therapy.

Hereditary Hemorrhagic Telangiectasia

Syn: Rendu-Osler-Weber syndrome

This hereditary bleeding disorder is transmitted as an autosomal dominant and affects both sexes. Endoglin is a transferring growth factor B (TGFB) receptor which is normally present abundantly on endothelial cells. TGFB is member of a family of dimeric polypeptide growth factors. TGF regulates the proliferation and differentiation of cells, embryonic development, wound healing and angiogenesis. Endoglin is mutated in patients with hereditary hemorrhagic telangiectasia. Multiple telangiectasia are found in the tongue, nasal mucosa, face, lips, conjunctiva, mucous membrane of the gastrointestinal tract, kidneys, solid organs and over other parts of the skin. Any of these sites may bleed recurrently since the vessels are fragile. Smaller lesions on exposed parts lead to cosmetic problems and bleeding. Larger ones lead to bleeding, embolic manifestations and high output cardiac failure. At the sites of bleeding there is increased fibrinolytic activity (Fig. 163.6).

Ocular complications include bleeding from the conjunctiva, retinal hemorrhage and retinal detachment. Neurological hepatic and pulmonary complications may develop. These include cerebral or subarachnoid hemorrhage, development of mycotic aneurysms, hepatic cirrhosis, portal hypertension, biliary disease and pulmonary arteriovenous fistulae. Primary pulmonary hypertension occurs in 15%.

High output cardiac failure, embolization and digital clubbing may follow. As age advances, the number of

Fig. 163.6: Woman with telangiectasia oral cavity and tongue. Note: The telangiectasias (arrow)

lesions increases and bleeding becomes more marked. Diagnosis is made from the typical telangiectasis, bleeding episodes, and the family history.

Treatment: Local pressure and application of thrombin help to arrest bleeding. Cauterization and surgical treatment of arterio-venous fistula are of limited value but may be required at times. Hematinic therapy is indicated to prevent anemia. Antifibrinolytic drugs have been tried with benefit.

Symptomatic purpura: Several infections cause purpuric manifestation.

1. **Bacterial infections:** Meningococcal septicemia, bacterial endocarditis, leptospirosis and the gram-negative septicemias.
2. **Viral infections:** Measles, influenza, hemorrhagic fevers, and smallpox.
3. **Rickettsial infections:** Typhus and spotted fevers.
4. **Protozoal infections:** Falciparum malaria.

Bleeding is caused by the direct injury to the vascular endothelium by the infecting agent, bacterial embolism, or due to vasculitis as in bacterial endocarditis. The toxins of infective agents inhibit thrombopoiesis and also accelerate platelet destruction. Other factors like thrombocytopenia and diffuse intravascular coagulation may also be contributory.

Antiplatelet Drug Therapy

Antiplatelet drugs to prevent thrombosis of the coronary, cerebral and peripheral arteries widely employed. Antiplatelet drugs acting at different levels of platelet activation are available at present. On many occasions they are used

singly. Often they are combined in order to improve the efficacy. All of them lead to some degree (often minor) of hemorrhagic tendency.

Aspirin	blocks synthesis of thromboxane A2
Ticlopidine and clopidogrel	inhibits ADP binding to receptor on platelets irreversibly
Glycoprotein IIb/IIIa antagonists	blocks aggregation in response to all agonists by preventing cross-linkage of fibrinogen-mediated activity

Different types of glycoprotein IIb/IIIa receptor antagonists are available. These include:

Abciximab	a monoclonal antibody against IIb/IIIa receptor. It blocks receptor action and also blocks the binding of vitronectin to its receptors on endothelial cells. It inhibits platelet aggregation and the template bleeding time.

Synthetic inhibitors	
Eptifibatide	This is a heptapeptide
Tirofiban	These are non-peptides
Lamifiban	
All inhibit IIb/IIIa receptors.	

Combination of different antiplatelets drugs produce enhanced activity than using a single drug.

This type of different combinations of anti-platelet drugs improves the success rate of stenting in coronary and other arteries and prevents postangioplasty thrombosis.

Defects of Coagulation

Mathew Thomas, K.V. Krishna Das

Chapter Summary

- Hemophilia-A 1091
- Christmas Disease 1095
- von Willebrand's Disease 1095
- Vitamin K Deficiency 1096
- Circulating Anticoagulants 1096
- Pathological Fibrinolysis 1097

Inherited Disorders

HEMOPHILIA-A (Factor VIII Deficiency)

Hemophilia comprises of two clinically indistinguishable coagulation defects-hemophilia A due to deficiency of factor VIII, and hemophilia B due to deficiency of factor IX—both inherited through the X-chromosome. The pathogenesis and basic defects in the two conditions are

different; therefore treatment schedules are also different. Hemophilia is the most common among the inherited coagulation defects. The disease is worldwide in distribution. In India it forms two thirds of all the inherited coagulation defects. About 25-50% of cases may not give any family history and it is presumed that in them the disease arises due to spontaneous mutation either in the patient or his mother. The clinical picture varies widely in affected subjects.

Prevalence of hemophilia in the developed world is around 6/10000 population. India should have about 50000 patients with severe hemophilia. In addition about 1300 new patients will be added each year.

Hemophilia is transmitted as a sex-linked recessive disorder and the genetic defects is located in the X-chromosome. The gene locus for factor VIII is at the tip of the long arms of X chromosome at Xq-24q tcr. It consists of 186 kilobases and has a molecular weight of 267000. It constitutes 0.1% of the bulk of the X-chromosome. Factor VIII gene is very susceptible to undergo abnormalities such as deletion, mis-sense mutation and non-sense mutation. Due to the variability of genetic abnormalities hemophilia is a heterogeneous disorder varying in severity and clinical behaviour. In about 50% of hemophiliacs factor VIII C is below 5% of normal. In the others the level ranges from 5-20%. It is transmitted by females who act as carriers, but it manifests almost exclusively in males. Half of the daughters of female carriers possess the trait and half of the sons suffer from the disease. Male hemophiliacs pass the trait to all their daughters but their sons are not affected. Carriers of hemophilia (A and B) have only 50% of the normal levels of factor VIII/or factor IX respectively. Clinically they have no bleeding, but they have decreased coagulability. This may even protect them against fatal ischemic heart disease. They may show higher bleeding tendencies when exposed to anti-platelet drugs.

The basic defect is deficiency, defective function or absence of factor VIII. Levels of factor VIII as low as 0.2 units/ml of plasma ensures adequate coagulation activity. The bleeding tendency depends to a great deal on the levels of factor VIII in the plasma.

When the level of factor VIII falls below 30% of normal, bleeding tendencies start. Spontaneous bleeding occurs only when the level falls below 5%. In a severe case, there may be no detectable factor VIII C during episodes of bleeding (Table 164.1).

Factor VIII molecule: This is a protein of large molecular size $1.5-2 \times 10^6$ daltons. Factor VIII is synthesized primarily by the hepatocytes, but kidneys, sinusoidal endothelial cells and lymphatic tissue can also synthesise small amounts. Its half-life in circulation is 12 hours in adults. It circulates in plasma as a covalent complex with von Willebrand's factor (vWF) which is synthesized by

TABLE 164.1

Shows the relationship between the levels of factor VIII and clinical severity

Mild hemophilia	5-40% of normal factor VIII levels (i.e.)	0.05-0.4 u/mL.
Moderate	1-5%	0.01-0.05 u/mL
Severe	< 1%	< 0.01 u/mL

endothelial cells. vWF forms the major bulk of the circulating factor VIII complex. It used to be known as factor VIII related antigen (VIII RAG) since it could be precipitated by heterologous antisera developed in animals. Combination of vWF with factor VIII helps to increase the synthesis, protect factor VIII from proteolysis and concentrate factor VIII coagulant activity at the required site. Factor VIII has to be released from vWF to enable it to take part in the process of coagulation and form the complex consisting of factor VIIIA, IXa and phospholipid. Factor VIIIA accelerates the rate of cleavage of factor X through IXa. Activated factor VIII is short-lived.

CLINICAL FEATURES

The bleeding tendency is noticed early in life. Sometimes the umbilical stump may bleed. Though bleeding can occur from any site, the common presentations are hematomas, deep tissue bleeding, hemarthroses, or hematuria. Bleeding may be spontaneous, may follow trivial trauma or undue physical exertion. Following cuts or wounds, bleeding is arrested initially, but may start soon and proceed unchecked, leading to fatal blood loss. The extravasated blood does not clot for long periods. Recurrent painful swelling of the knees when the child walks should suggest the possibility of hemophilia.

Bleeding into joints occurs frequently in moderate and severe cases. The knees, ankles, elbows, shoulders, and hips are commonly affected. Bleeding may be spontaneous or follow unaccustomed exertion. The joints show features of acute inflammation. Repeated hemorrhage into joints and deep tissues lead to crippling ankylosis and contractures. Chronic synovitis is seen in 10% of hemophiliacs in India. 64% of such patients showed the presence of HLA B₂₇ and this is statistically significant. Bleeding can occur in the central nervous system in severe cases (Fig. 164.1).

The disease shows remissions and exacerbations. Physical exertion, infections, trauma, or psychological stress lead to exacerbations. With the passage of time the severity and frequency of bleeding diminishes. Death may result from uncontrolled blood loss or bleeding into vital organs.

Diagnosis: Hemophilia should be suspected from the history, evidence of heredity, and from the prolonged

Fig. 164.1: Male: Hemophilial arthritis knees

coagulation time or APTT. Clinical hallmarks are joint and muscle hemorrhages, easy bruising and prolonged potentially fatal hemorrhage following trauma or surgery, but no excessive bleeding after abrasions or minor cuts. Bleeding time, platelet count, and prothrombin time are normal but PTTK (APTT) is prolonged. Assay of factor VIII helps to establish the diagnosis and assess the severity. Factor VIII assay also helps to monitor replacement therapy.

Hemophilia has to be differentiated from Christmas disease, von Willebrand’s disease and acquired coagulopathies.

TREATMENT

Rest in bed is essential during a bleeding episode. The inflamed joint should be splinted and cooled with ice packs. Sedatives like diazepam or phenobarbitone or analgesics like dextropropoxyphene may be used to relieve insomnia and pain. Local measures to stop the bleeding include pressure, adrenaline packs, and local dressing with fibrin-foam or thrombin. Bleeding sites from gums, tooth-sockets, or nose should be plugged with adrenaline packs. Aspiration of joint should be done only after AHG is administered. Early mobilization prevents ankylosis.

The mainstay of the treatment is administration of factor VIII concentrate. Factor VIII is available as cryoprecipitate or as freeze dried AHG. Cryoprecipitate contains factor VIII (both factor VIII: vWF and factor VIII: C portions), fibrinogen and fibronectin. The dose is determined by the severity and site of bleeding. The aim is to elevate factor VIII levels to 50% or above. The usual dose is to administer 1 pack for every 10 kg body weight as IV infusion and repeated 12-hourly, for 2 days, and thereafter, depending upon the requirement. To prepare for major surgery and in life-threatening hemorrhage, factor VIII level should be raised to 100% and factor VIII preparations are ideal.

Freeze dried AHG is available from several laboratories. Factor VIII is prepared from human blood and by recombinant DNA technology. Each vial contains 250 to 1000 units and the shelf-life is 18 months. In the ordinary case the initial dose should be 250-1000 units depending on the severity of the bleeding. Larger initial doses are more effective. The half-life of administered AHG is 10-12 hours. The total dose of AHG required to elevate the AHG level to the desired level is given by the formula.

Percentage increase in factor desired × weight in kg

2

The whole quantity has to be given as an IV push dose or a rapid infusion, after dissolving the freeze dried preparation in the diluent. Correction of the bleeding tendency occurs immediately and this persists for 8-12 hours. The dose has to be repeated 8-12 hourly.

1 mg of AHG ≡ 15 units of factor VIII. Infusion of 1 unit/kg bw of AHG will raise the plasma level by 0.02 unit/mL (2%). For minor bleeds the factor VIII level should be raised to 0.3 unit/mL of plasma and for major bleeds it should be raised above 0.5 unit/mL. This level has to be maintained for 36-48 hours till hemostasis is firmly established (Table 164.2).

In febrile and actively bleeding patients, the half-life of AHG will be considerably shorter.

TABLE 164.2 Showing dosage of factor VIII			
Condition	Initial dose U/kg	Repeat doses U/kg	Total duration of therapy
Life/limb-threatening bleed	50	25-30 every 8-12 h or 3-4 U/kg/bw as IV infusion	14-21 days
Intracranial bleed			
Major tissue bleed			
Major surgery			
Hemarthrosis	20-30	20 every 12 h	1-2 days
Hematomas – not life-threatening	20-30	20 every 12 h	Do
Dental extraction, minor surgery	20	20 every 12 h	1-2 days

The factor VIII level in whole blood is 0.3 unit/mL and in (fresh frozen plasma it is 0.8 unit/mL.

In cryoprecipitate factor VIII level is 6-8 units/mL. One unit of cryoprecipitate is 15 mL. Several units may be required for a moderately severe patient. All available commercial preparations of factor VIII have to be free from HIV, HBV and HCV. Still it is advisable to immunize hemophiliacs against hepatitis B. The cost of AHG is around Rs. 5-6/unit and it can be obtained from the office bearers of Hemophilia Society which has branches in several places in India.

Other Supportive Measures

Antifibrinolytic drugs like epsilon-aminocaproic acid (EACA) given in doses of 24 g daily orally have been used along with AHG to prevent dissolution of the clots formed as a result of therapy. EACA should be avoided in urinary bleeding due to the risk of clotting of blood in the urinary tract with the production of urinary obstruction and clot colic.

Mild cases of hemophilia with factor VIII activity of 10% or above respond to 1-deamino-8-D arginine vasopressin (DDAVP). The functional levels of AHG and vWF increase 3-5 times. The dose is 0.3 µg/kg/IV slowly. Though expensive, and not freely available in India, DDAVP provides a reasonably good alternative for the management of mild hemophiliacs. DDAVP can be used prophylactically as a nasal instillation. It helps to reduce the bleeding episodes and the requirement of AHG.

Inhibitors of Factor VIII

20-52% hemophiliacs receiving factor VIII repeatedly, develop antibodies which neutralize factor VIII activity and thereby make further treatment ineffective. Plasma from such patients inactivates factor VIII in normal subjects as well. The level of inhibitors can be assayed and expressed as Bethesda units. Genetic mutation in which there is absence of endogenous factor VIII predisposes to the development of anti-factor VIII antibodies more readily when replacement therapy is given. Less commonly antibodies to AHG may occur *de novo* as part of an immunological disorder such as systemic lupus erythematosus.

Management of Patients with Antibodies to Factor VIII

1. Higher doses of factor VIII may be given – 100 units/kg/bw.
2. Use of porcine factor VIII- as a temporary measure.
3. Factor VIII bypassing activity- (a) use of prothrombin complex concentrates (PCC) (b) infusion of recombinant factor VIIa, which directly activates factor X, thus bypassing factor VIII action.

4. Removal of antibodies by plasma exchange or protein A sepharose affinity column.
5. Use of immunosuppressant drugs.

Recombinant factor VII (Novo seven) is the treatment of choice for severely bleeding patients with factor VIII antibodies. Factor VII activates factor X directly and bypasses the inhibitor induced defect.

Prophylaxis: All hemophiliacs should carry identification cards showing their blood groups to enable emergency treatment without delay. They should be made aware of the nature of the disease and its management. Children should attend ordinary schools but avoid games and strenuous physical training. Special care should be taken to avoid all trauma. Intramuscular injections and anti-platelet drugs should be avoided in all hemophiliacs. Dental care should be instituted to avoid dental caries and the need for extractions.

The modern approach is to prevent bleeding into joints by early administration of AHG. The patient or his near relative is instructed to identify bleeding episodes and self-administer AHG early at the first sign of bleeding or joint pain. This prevents further bleeding and joint deformity which is the most disabling complication (home care programme). Administration of factor VIII at least 2-3 times a week will help to maintain AHG levels above 0.01-0.02 units/mL and this serves to avoid spontaneous bleeding into joints and tissue spaces.

In developed countries all hemophilia patients are provided with adequate amounts of AHG with a view to prevent painful episodes of bleeding and permanent disability.

Prognosis: The ultimate prognosis depends on the severity of the disease, facilities for early diagnosis and specialized management and the availability of factor VIII concentrates. If diagnosed early and joint bleeding is avoided, these patients can lead to near-normal life under supervision. If early diagnosis is missed and repeated joint bleeds occur, permanent or remediable deformities may result. The development of antibodies to AHG gives rise to serious problems in subsequent management. In general, more than 2/3 of the patients can be managed with general measures, moderation of activities and limited use of factor VIII or cryoprecipitate. Mortality is generally due to uncontrolled external bleeding or bleeding into vital organs, such as the brain.

Prenatal diagnosis of hemophilia is possible by estimating factor VIII in fetal blood obtained by fetoscopy. Fetuses in the first trimester of pregnancy can be subjected to genetic analysis and the diagnosis established. Affected pregnancy can be aborted. Carrier females can be detected by VIII assay. Such females show only half the VIII activity expected for the level of vWF.

Future prospects: With effective replacement therapy all surgeries can be performed on hemophiliacs. Effective

home care programmes help to prevent disability and ensure quality of life.

Implantation of genetically altered fibroblasts which are capable of producing factor VIII have been tried successfully. Such grafts secrete factor VIII for long periods.

Christmas Disease
Syn: Hemophilia B

This is also a X-linked recessive disease, caused by deficiency or abnormality of factor IX. Transmission is similar to that of hemophilia. Factor IX is a 415 aminoacid serine protein, synthesized in the liver. It is the largest among the vitamin K dependent proteins. Plasma concentration of factor IX is 50 times that of factor VIII and its half-life is 24 hours. Factor IX gene is located in the long arm of chromosome X at Xq27. The gene for factor IX is smaller and less complex than that of factor VIII. More than 2100 mutations of the gene have been identified.

Preliminary coagulation tests are similar to those of hemophilia. Frequency is 1/4 of that of hemophilia A. The diagnosis can be confirmed by demonstration of reduced levels of factor IX. Fifty percent of daughters of carrier females are carriers. Carriers of hemophilia B have lower levels of factor IX activity compared to normals. Normal level of factor IX activity is 1 unit/mL. Levels less than 0.1 unit/mL indicate severe disease. The clinical spectrum resembles that of hemophilia, and it varies depending on the levels of factor IX. Inhibitors to factor IX develop only in 1.5-3% of cases.

Treatment: Factor IX can be administered as the concentrate, prothrombin complex concentrates, recombinant factor VII (Novo seven), or fresh frozen plasma. Since the distribution volume of factor IX in the tissues is twice the plasma volume, the dose of factor IX for therapy should be twice that of factor VIII. This has to be administered as IV bolus twice a day.

von Willebrand's Disease
Syn: Pseudothrombophilia

von Willebrand's disease (vWD) is a primary vascular hemostatic defect, transmitted as an autosomal dominant, affecting both sexes. Next to hemophilia this is the most frequent inherited hemostatic defect. vWF is encoded by a gene spanning 178 Kb of genomic DNA of chromosome 12. More than 250 mutations of the vWF gene have been identified. vWF is synthesized by endothelial cells and megakaryocytes and secreted into plasma and subendothelial extracellular matrix.

Functions

- 1. It acts as an adhesion protein and helps in the formation of the platelet plug.
- 2. It forms a non-covalent complex with factor VIII in plasma thereby protecting it from inactivation and clearance.

Laboratory tests for VW disease show prolonged bleeding time, reduced levels of factor VIII, reduced levels of vWF antigen and reduction of ristocetin cofactor.

The basic defect is reduction of the amount of subendothelial factor VIII: vWF polymers or the presence of abnormal or inadequately polymerized subendothelial factor VIII: vWF. Normal vWF contains multimers of varying molecular sizes ranging from 850,000 to 12 million daltons. Von Willebrand's factor is normally secreted from endothelial cells as extra large polymers of a peptide bound by disulphide bonds. In the plasma the peptide bonds are cleaved by a metalloproteinase enzyme. This results in the formation of dimers of 176 kd and 140 kd fragments. This protease enzyme is inactive in circulation unless it is unfolded by high shear force or other factors. Inhibition of this enzyme and abnormal configuration of this enzyme leads to abnormalities of function of vWF. The defective vWF leads to impairment of platelet adhesion to sites of vascular injury. There is also impairment in function of factor VIII leading to defects of coagulation, even despite normal factor VIII levels. Depending on the genetic defect the disease has been divided into three types.

Genetic Transmission of von Willebrand's Disease

Phenotype	Mechanism	Transmission
1 (1)	Partial quantitative deficiency of vWF and factor VIII	Autosomal dominant (AD)
2 (A)	Defect in platelet dependent vWF and lack of large multimers	AD
2 (B)	Heightened platelet dependent vWF functions associated with lack of large multimers	AD
2M	vWF functions and multimers reduced	AD
2N	Defective vWF binding to factor VIII	AD
3	Severe or complete deficiency of vWF and moderately severe factor VIII deficiency	Autosomal recessive

CLINICAL FEATURES

These are similar to that of ITP, i.e. excessive post-traumatic bleeding, menorrhagia, and mucosal bleeding, especially from the nose, gums, gastrointestinal tract, and genitourinary tract. Bleeding time is prolonged. Platelet counts are normal in Types I and IIA, but may be

moderately decreased in II B. In those with factor VIII C levels below 1% of normal, manifestations of a coagulation defect may also be prominent. Bleeding manifestations are most marked in homozygous type IIA which is rare.

Diagnosis of the specific defect of factor VIII : vWF is made by electrophoresis. Another *in vitro* test is to determine the capacity of plasma to aggregate platelets in the presence of the antibiotic-ristocetin. Ristocetin partially neutralizes negative charges on factor VIII: vWF polymers to induce platelet aggregation.

This phenomenon is called ristocetin cofactor activity. Ristocetin cofactor activity is diminished in types I and II A disease.

In patients with type I or II A vWD, the diminution of ristocetin cofactor activity correlates with the defective platelet adhesion to subendothelium *in vitro*. But in type II B disease this is not so. In type II B the factor VIII: vWF polymers are abnormally formed and these are incapable of inducing platelets to adhere to vascular endothelium. But even in the presence of small amounts of ristocetin, these abnormal polymers present in platelet poor plasma attach to platelets and induce aggregation *in vitro*.

In homozygous type II A vWD patients with severe bleeding tendency, endothelial polymerization of factor VIII: vWF monomers is defective and only small factor VIII: vWF polymers are present in plasma. In these patients bleeding time is prolonged and plasma levels of factor VIII : vWF antigen, ristocetin cofactor activity, and factor VIII: C are extremely low. Being heterozygous, the majority of cases of vWD have only mild bleeding tendency.

Factor VIII: C is also reduced in the plasma of majority of patients with vWD. Unlike hemophilia in which the synthesis of factor VIII : C is diminished, in vWD, though factor VIII: C is synthesized, it is not transported effectively in the systemic circulation without adequate levels of polymerized factor VIII : vWF. Further, factor VIII : C molecules which enter the circulation unbound to VIII: vWF polymers are rapidly removed.

Treatment: Cryoprecipitate infusions arrest bleeding promptly and these are employed to arrest bleeding episodes and to prepare the patient for surgery. The largest factor VIII : vWF polymers in the cryoprecipitate get deposited on the injured subendothelial surface and this favours platelet adhesion and hemostasis. The therapeutic effect lasts only for 4 hours and hence cryoprecipitate has to be repeated. Lyophilized factor VIII preparations are not as effective as cryoprecipitate as they do not contain the largest plasma factor VIII:vWF polymer forms.

In type I vWD where synthesis of factor VIII : vWF within the endothelial cells is normal, infusion of **deamino-8-D arginine vasopressin** (DDAVP) causes

release of VIII: vWF polymers from endothelial cells. DDAVP attaches itself to vasopressin receptors on the endothelial cells and helps in releasing factor VIII: vWF polymers. Both factors VIII and vWF can be temporarily raised. Optimal dose is 0.3 µg/kg bw IV. If given intranasally the dose is 300 µg in adults and 150 µg in children. The concentration of factor VIII and vWF are doubled or quadrupled within 10-30 minutes of IV use and 60-90 minutes of intranasal use. Side effects include facial flushing, headache and arterial thrombosis. In heterozygous type II A and II B and homozygous type II A vWD, DDAVP is not very effective.

Acquired vWF Disease

vWF is excessively cleaved by increase in concentration of the metalloprotein ADAMTS 13 which is produced in valvular heart diseases such as aortic stenosis, VSD and PDA. Reduction or absence of large multimers of vWF causes bleeding from mucus membranes and skin.

Correction of the cardiac defect abolishes the bleeding as well. Acquired vWF does not respond to DDAVP or replacement of coagulation factors.

Vitamin K Deficiency

Vitamin K is essential for the production of functional prothrombin, factor VII, factor IX and X in the liver. In the absence of vitamin K, the blood contains nascent non-functional forms of these factors. Nascent nonfunctional forms of protein C also exist in the circulation in vitamin K deficiency. Since the body stores are small, deficiency of vitamin K leads to hypoprothrombinemia within two weeks. Clinically it manifests as ecchymoses, bleeding from injection sites, bruises, gum bleeding, hematemesis, melena, or hematuria. Both the prothrombin time and activated partial thromboplastin time are prolonged. Administration of vitamin K in a dose of 5-10 mg stops the bleeding promptly within 1-2 days. Either the oral water-soluble preparation or parenteral forms may be used. Natural preparations are preferable, being more effective. If blood loss is severe or response to vitamin K is inadequate, fresh blood transfusion or fresh frozen plasma is also indicated. See also Chapter 30.

Circulating Anticoagulants

Sometimes hemorrhagic manifestations develop on account of the presence of anticoagulants in the circulation. Many of these anticoagulants are antibodies to fibrinogen and the other specific clotting substances like factors VIII, IX, V, X, XI, and XIII. Antibodies may develop due to repeated transfusions, or as part of an immunological disorder like SLE, rheumatoid disease, or generalized penicillin allergy.

Flow chart 164.1: Sequence of events in accelerated fibrinolysis

Clinical features are similar to those of the primary coagulation disorders with the exception that replacement therapy may be ineffective as long as the antibody persists in the circulation. This can be overcome by giving large doses of the missing factor and removal of the circulating antibodies by plasmapheresis or by immunosuppressant therapy.

Other rare coagulation disorders: Several other inherited deficiencies of coagulation factors exist, though they are rare. These include deficiencies of fibrinogen and defects in the composition of fibrinogen, deficiency of prothrombin, factors XII, X and XI and XIII. These crop up infrequently and may be mistaken for the more common hemorrhagic disorders. Diagnosis is by specific laboratory tests. Therapy consists of the administration of fresh frozen plasma, specific factors if available or prothrombin complex concentrate.

Pathological Fibrinolysis

Healthy individuals may show minor variations in fibrinolytic activity without any deleterious effects, but gross increase in fibrinolytic activity causes hemorrhage. Excessive fibrinolysis may be a primary phenomenon or develop as a consequence of disseminated intravascular coagulation (DIC).

Causes of Excessive Fibrinolysis

- a. *Obstetric causes:* Abruptio placentae and amniotic fluid embolism.
- b. *Surgical causes:* Gastrectomy, lung resection, nephrectomy, prostatectomy, cardiopulmonary bypass, splenectomy, and pancreatectomy.
- c. *Medical causes:*
 - i. Liver diseases such as cirrhosis of liver.
 - ii. Leukemias, especially in acute leukemia and chronic granulocytic leukemia.
 - iii. Anaphylactic shock.
 - iv. Autoimmune diseases such as systemic lupus erythematosus.

Pathogenesis: Fibrinolytic activity may be enhanced as a result of excessive release of plasminogen activator or reduction in the inhibitor. The sequence of events is given in Flow chart 164.1.

Clinical features: The clinical features depend on the predominant mechanism. If thrombocytopenia is also pronounced, capillary bleeding predominates. If coagulation mechanism is defective the bleeding is more serious. The severity and clinical presentation may vary from case-to-case.

Diagnosis: Normal bleeding time, slightly prolonged clotting time, and poor quality of the clot should suggest the possibility of excessive fibrinolysis. Primary fibrinolysis has to be distinguished from disseminated intravascular coagulation (DIC). In primary fibrinolysis, platelet count is normal and this distinguishes it from DIC in which platelet count is reduced. It is important to distinguish these two conditions since treatment is different (Table 164.3).

TABLE 164.3		
Differentiation between DIC and primary fibrinolysis		
Tests	Acute DIC	Primary fibrinolysis
Platelet count	Decreased	Normal
Bleeding time	Prolonged	Normal
Clot retraction	Defective	Clot is dissolved
Red cell fragmentation	Present	Absent
Clotting time	Prolonged	Prolonged slightly
Prothrombin time	Prolonged	Prolonged
Activated partial thromboplastin time	Prolonged	Slightly prolonged
Euglobulin lysis time	Shortened	Shortened
Fibrin split products (FDP) estimation	High titre	High titre
D-dimer levels	Raised	Raised
Thrombin time	Prolonged	Prolonged

Laboratory tests: The tests for fibrinolysis are:

1. Euglobulin lysis time for detecting the presence of increased levels of circulating plasminogen activator.
2. The detection of excess of fibrin degradation products (FDP) by immunological methods.
3. D-dimer levels in plasma are elevated. D-dimer is the fibrin fragment in plasma which is a marker of fibrin formation and active fibrinolysis.
4. Circulating levels of plasminogen which will be low in fibrinolysis.

Treatment: Primary fibrinolysis can be readily controlled by the use of antifibrinolytic agents.

Commonly used antifibrinolytic agents are epsilon-aminocaproic acid (EACA) and tranexamic acid which are synthetic amino acids, and aprotinin (Trasylol) which is a polypeptide. Both EACA and tranexamic acid bind reversibly to plasminogen and thereby block its binding to fibrin and fibrinolysis. Aprotinin inhibits the action of trypsin, chymotrypsin, plasmin and tissue kallikrein. By inhibiting kallikrein it indirectly blocks the activation of factor XII and thereby prevents the initiation of both coagulation and fibrinolysis. Activity of aprotinin is expressed as kallikrein inactivation units (KIU).

When given orally, EACA is rapidly absorbed and a single oral dose is effective for 4 hours. It is contraindicated in advanced renal disease. For immediate effect, 5

to 10 g is given intravenously in the first hour followed by 2 g hourly for the next 2 to 3 hours. This is then followed by oral therapy with 4 g every 4 hours. The total dose in 24 h should not exceed 30 g. Since the drug is excreted by the kidneys, its concentration in urine is higher than in plasma. Aprotinin (Trasylol) used for reducing intra operative blood loss in cardiac surgery may lead to serious nonfatal cardiovascular events and renal toxicity.

In disseminated intravascular coagulation (DIC), fibrinolysis occurs as a defence mechanism helping to remove the clots formed, and inhibition of fibrinolysis is harmful since it may lead to widespread thrombosis. Administration of EACA should not be undertaken without concurrent heparin therapy if the distinction between primary fibrinolysis and DIC is not clear. Thrombotic complications, particularly renal cortical necrosis may develop when EACA is used alone in patients with DIC.

Dose of tranexamic acid is 20-25 mg/kg bw orally bd or tds. The parenteral dose is 0.5 to 1 g IV tds or also as an infusion.

Aprotinin is used mainly as an intraoperative infusion to reduce surgical blood loss. The dose is 0.5-1 million units given over 10 minutes, repeated in doses of 0.2 million units till the bleeding is arrested.

Since aprotinin inhibits pancreatic trypsin and chymotrypsin it is also useful in acute pancreatitis.

165

Therapeutics of Anticoagulants

Mathew Thomas, K.V. Krishna Das

Chapter Summary

Heparin 1099

Oral Anticoagulants 1100

Direct Thrombin Inhibitors (DTI) 1101

Anticoagulants inhibit the coagulation pathway in one or other step, thereby preventing thrombus formation. They are indicated in the prevention and treatment of thromboembolic disease.

Indications

- Recurrent venous thromboembolism,
- Ischemic heart disease
- Cerebral venous thrombosis,
- Prevention of thromboembolism in atrial fibrillation
- Implantation of prosthetic heart valves, arterial conduits
- Recurrent pulmonary embolism
- Follow-up therapy after thrombolysis

Available drugs

1. Heparin and its derivatives which are given parenterally.
2. Oral anticoagulant drugs—coumarins and indanediones.
3. Thrombin inhibitors

HEPARIN

Heparin is present naturally in mast cells and the liver, but in health there is no free heparin detectable in plasma. Commercially available heparin is produced from animal lungs. Standard heparin (SH) is a mixture of compounds with molecular weights ranging from 2000-20000 (mean 5000) and their anticoagulant activity is also variable. By physico-chemical methods low molecular weight heparin (LMWH) having molecular weights ranging from 2000-10000 is produced e.g. Dalteparin sodium.

SH and LMWH show difference in their actions and chemical effects.

Action

Heparin inhibits coagulation both *in vitro* and *in vivo*. SH acts mainly through the medium antithrombin III (AT III) which acts as cofactor. AT III is part of the natural defence mechanism of the body against thrombosis. The major ultimate actions of heparin are to inhibit the formation of thrombin from prothrombin and aggregation of platelets caused by thrombin. Heparin produces a conformational change in AT III. This accelerates and augments the effects of AT III against thrombin and factor Xa about 1000 folds. SH binds to plasma proteins and platelets in varying degrees and therefore its action is less consistent when compared to LMWH which has more bioavailability. LMWH acts more as anti-factor Xa and this effect is 2-4 times that of SH. LMWH is more expensive than SH, still its advantage in special situations makes it the drug of choice in cardiovascular and neurovascular indications.

Indications

1. As prophylactic and curative in venous and arterial thromboembolic disease. The anticoagulant effect is rapidly achieved by parenteral administration of heparin. Simultaneously oral anticoagulants are also started. The latter takes 2-3 days for their effect to be established. By this time the heparin is withdrawn and anticoagulation is continued for prolonged periods, depending on the indication.
2. Disseminated intravascular coagulation: heparin inhibits the widespread intramuscular thrombotic process and thus arrests the vicious circle from developing.

Side effects: These include bleeding from the gastrointestinal and urinary tracts, intracranial bleeding, thrombocytopenia and purpuric bleeding, allergic manifestations, alopecia, osteoporosis and prolonged administration. Heparin leads to thrombocytopenia by an immune mechanism, on repeated administration.

Preparation: Vials—5000-25000 units (1000 units/mL to 5000 units/mL) 1 mg is approximately 100 units.

Dose

1. 5000-10000 units every hour or as IV infusion 20000 units, diluted in 5% glucose solution or normal saline, run over 12-24 hours. The dose and rate of administration depend on the indications and degree of anticoagulation desired.
2. Repeated deep IM or sub-adipose injections of 2000-10000 units 6th hourly.

The dose is titrated by keeping the clotting time 2-3 times the normal. A more reliable parameter is the activated partial thromboplastin time (APTT) which should be maintained at 1½-2 times the normal.

Dose for small adults and children

15-25 units/kg/bw IV infusion continuously or 2.5 units/kg/bw every 12 h by sc injection is quite effective.

In general the doses required to prevent venous thrombosis are considerably less in comparison to those required for arterial thromboembolism (2000 units once or twice a day v/s 5000-10000 units 6h).

Low molecular weight heparin

Note: LMWH has distinct advantages over SH. These are:

1. Smaller dose and longer duration of action.
2. Once or twice a day administration.
3. More consistent clinical effects.
4. Less chance of thrombocytopenia.
5. No need to have regular laboratory monitoring when given in the usual dosage.
6. Can be given as outpatient therapy and at home.

Preparation: Solution containing 2500 iu/mL-4 mL ampoules.

Dose: 2000-5000 units given SC once or twice a day.

Antidote to Heparin**Protamine Sulphate**

This is available as 5 mL ampoules, each mL $\equiv$ 10 mg.

Dose: Protamine sulphate 1% solution given IV neutralizes heparin and rapidly reverses its effect. 1 mg protamine sulphate for every 100 units (1 mg) of heparin is given as the last dose. If given after 3-4 h of the last dose of heparin, only smaller amounts of protamine are needed. It is effective in neutralizing dalteparin as well. Adverse effects include allergy, flushing and hypotension.

HEPARIN INDUCED THROMBOCYTOPENIA (HIT)

It is an immunologically mediated adverse drug reaction characterized by platelet activation, thrombocytopenia and a high risk of thrombotic complications. It is characterized by the paradox in which thrombosis occurs in a thrombocytopenic patient who is anticoagulated. HIT is caused by heparin- dependent IgG antibodies that activate platelets. Platelet derived micro particles are formed which are highly procoagulant. Two clinical syndromes have been identified and HIT type I and HIT-type II.

HIT type I: This occurs in 20% of patients. It is not antibody mediated. These patients develop thrombocytopenia within the first four days of starting therapy. Despite continuance of heparin the platelet count recovers.

HIT type II is mediated by IgG. It is associated with mild to severe symptoms, fall of platelet count to < 50% of normal and thrombotic tendencies. Clinical features correlate with the type of heparin, its dose and route of administration. Acute thrombotic events include occlusion of peripheral arteries, mesenteric artery, ischemic heart disease, cerebrovascular accidents and deep vein thrombosis, pulmonary embolism and venous limb gangrene. Systemic features like fever and chills develop. Heparin induced platelet agglutination test (HIPA) is positive. ELISA test detects heparin-PF4 complexes.

Management

Thrombotic complications have to be reversed. Heparin and LMWH are contraindicated. Warfarin is contraindicated since it may lead to deep vein thrombosis and limb gangrene. Ancrod which is obtained from defibrinating snake venom has been used with success. Danaparoid sodium is a mixture of low molecular weight glycosaminoglycans such as heparan sulphate, dermatan sulphate and chondroitin sulphate. It specifically inhibits platelet aggregation caused by HIT. The dose is 2250 units I V as a loading dose, followed by 400 units/hour for four hours. Other thrombin inhibitors such as lepirudin, argatroban and bivalirudin are also useful.

Note: The association of physicians of India has published Consensus Development Recommendations for the role of LMW. Heparins in the prophylaxis of venous thromboembolism - an Indian perspective: Supplement to JAPI. January 2007. www. japi. org

Guest editor: Rajiv Prakash

Oral Anticoagulants

The two classes of drugs in this group are the coumarins and indanediones. They are effective when given orally, but they do not possess any anticoagulant activity *in vitro*.

Mode of Action

They prevent the activation of vitamin K-dependent coagulation factors, i.e. VII, IX and X in the liver. When given orally they are well absorbed and peak serum levels are obtained in 2-3 hours. They are concentrated in the liver which is their main site of action. Their action is slow, taking 2-3 days for maximal effect, but once established, the anticoagulant effect persists for 4-7 days even after withdrawal of the drug.

Coumarin Group of Drugs

Warfarin Sodium

Preparations: When given orally it is absorbed rapidly. Its half-life is 15-70 hours. Tablets of 1 mg, 2 mg, and 5 mg, are available.

Therapy is started with a loading dose of 10-15 mg daily along with heparin. The dose is tapered off daily to 3-5 mg/day in order to maintain the prothrombin time as 2 to 3.5 times the control value, or international normalized ratio (INR) as 2-3 depending upon the underlying indication.

Indanediones

The commonly used drug in this class is Phenindion.

This is an effective anticoagulant. When given orally it is rapidly absorbed. Its half-life is 5-10 hours.

Preparations: Tablets 10 mg, 25 mg, and 50 mg

Dose: The initial loading dose is 200-300 mg/day. It is rapidly tapered off daily to 100 mg and later to 50 mg daily. The maintenance dose is around 50 mg in order to maintain optimal anticoagulation.

Oral anticoagulants are contraindicated in pregnancy, lactation.

Side effects: Hemorrhagic manifestations—gastrointestinal, urinary and intracranial.

Drug interactions: Oral anticoagulants produce several important drug interactions which lead either to enhancement or blunting of their effects.

Drugs which enhance anticoagulants effects

1. Sulpha drugs, clofibrate, ethacrynic acid, nalidixic acid. The anticoagulant is displaced by these drugs from its plasma protein binding sites and therefore the anticoagulant activity is enhanced.
2. Further depression of vitamin K related clotting factors by quinine, quinidine, thyroxine.
3. Anabolic steroids—impairment of hepatic function.

Drugs which impair the anticoagulant action

Barbiturates, phenytoin, haloperidol, griseofulvin and rifampicin will cause microsomal enzyme induction in the liver and rapid destruction of the anticoagulant.

TABLE 165.1

Showing the properties of available DTIs

Parameter	r. Hirudin	Bivalirudin (HIRULOG)	Argatroban (NOVASTAN)	Ximelagatran and melagatran (EXANTA)	Dabigatran
Route of administration	IV, SC	IV	IV	xymelagatran po melagatran oral IV and SC	Oral
Plasma half-life	IV-60 mts SC- 120 mts	25 mts	45 mts	Oral 3-5 hrs IV and SC-2-3 hrs	12 hrs 50-225
Dose	15 mg per day for 8-12 days	-	-	ximelagatran 24 mg bd x 7-12 days oral melagatran 3 mg/day SC	50-225 mg bd for 6-10 days
Main site of clearance	Kidney	Kidney, liver other sites	Liver	Kidney	Kidney

Since oral anticoagulants are administered over long periods for prophylaxis and treatment of life-threatening conditions, it is important to elicit drug history which should suggest drug interactions.

Antidote to Oral Anticoagulants

The first step is to withdraw the anticoagulant. If the prothrombin time is only 3 times the normal this measure is enough. If the PTT is further prolonged, *phytomenadion* (Vitamin K₁) 5 mg given by slow IV injection corrects the hemorrhagic tendency within a few hours. If the condition is life-threatening or the hepatic function is unsatisfactory, concentrates of factors II, IX, X and VII have to be given. If the concentrates are not available, fresh frozen plasma is infused, approximately 1000 mL for an adult.

Other Anticoagulants

Fondaparinux: It is a synthetic anticoagulant with anti-Xa activity. The effect is similar to that of heparin. The dose is 50-100 mg daily to be given by subcutaneous injection. Monitoring is not required.

Direct Thrombin Inhibitors (DTI)

Thrombin is inhibited by low molecular weight heparin directly. DTIs can inhibit thrombin bound to fibrin or

fibrin degradation products in addition to free thrombin. By inhibiting thrombin, DTIs exert an indirect antiplatelet effect as well. DTIs include recombinant hirudins, lepirudin or bivalirudin, argatroban, xymelagatran, melagatran and dabigatran (Table 165.1).

Overdose of these drugs can be managed by either hemodialysis or administration of activated prothrombin complex concentrates.

Indications

- 1. Acute coronary syndromes with and without precutaneous coronary interventions
- 2. Myocardial infarction
- 3. Non-valvular atrial fibrillation
- 4. Prevention of venous thromboembolism in patients undergoing major orthopedic surgery
- 5. Recurrent deep venous thrombosis
- 6. Heparin induced thrombocytopenia

Guidelines for Correcting Over Dose of Anticoagulants

The target INR to be achieved is given below:	INR
Moderate bleeding, with high risk of thrombosis	2-2.5
Serious bleeding with moderate risk of thrombosis	1-1.5
Serious or heavy bleeding with low risk of thrombosis	1.0

166

Disseminated Intravascular Coagulation, Microangiopathic Hemolytic States

K.V. Krishna Das, Mathew Thomas

Chapter Summary

Disseminated Intravascular Coagulation (DIC) 1102
Microangiopathic Hemolytic States 1103
Thrombotic Thrombocytopenic Purpura (TTP) 1104
Hemolytic Uremic Syndrome (HUS) 1104

Disseminated Intravascular Coagulation (DIC)

Syn: Defibrination syndrome, consumption coagulopathy

Pathogenesis: This is an example of consumptive thrombohemorrhagic disorders in which excessive consumption of the factors needed for hemostasis leads to their depletion in circulation resulting in widespread hemorrhagic tendency. All the components—platelets, fibrinogen and coagulation factors are consumed. Widespread thrombosis develops leading to the occlusion of the microcirculation in several organs. The capacity of the system to replenish the coagulation factors and platelets is exceeded and this leads to their reduction in circulating blood.

The basic pathophysiology consists of:

1. Systemic formation of fibrin due to increased generation of thrombin
2. Simultaneous suppression of physiological anticoagulant mechanism, and
3. The delayed removal of fibrin as a consequence of impaired fibrinolysis.

Several cytokines act as procoagulant mediators. Prominent among them is interleukin-6. All major physiological anticoagulants such as antithrombin III, protein-C and tissue factor-pathway inhibitor are to be affected in DIC.

Formation of widespread thrombi in different situations triggers off excessive secondary fibrinolysis

which results in the formation of large amounts of the degradation products of fibrin and fibrinogen, detectable in plasma and urine. These in turn also act as anti-thrombotic agents which tend to aggravate the hemorrhagic tendency. Initially the acceleration of fibrinolysis is a protective mechanism, but when it becomes excessive it is harmful.

DIC is triggered off by the liberation of large amounts of thromboplastic substances into the circulation.

Common causes of Disseminated Intravascular Coagulation (DIC)

1. Obstetric: Abruptio placentae, intra-uterine fetal death, septic abortion, and amniotic fluid embolism.
2. Infections: Falciparum malaria, gram-negative septicemia, meningococcemia, septic shock, rickettsial infections, viral infections and several others.
3. Malignant disease: Diseases of prostate, breast, lung, pancreas and others.
4. Hematological malignancies: Acute promyelocytic leukemia.
5. Mismatched blood transfusion with hemolytic transfusion reaction.
6. Cavernous hemangioma.
7. Miscellaneous: Trauma, fat embolism, burns, hypothermia, viper bites, and scorpion bite.

CLINICAL FEATURES

There is a wide spectrum of presentation ranging from chronic mild bruising and bleeding tendencies as is seen in intrauterine fetal death, to fulminant bleeding from sites of injections, mucous membranes, tissue spaces and vital structures as is seen in acute DIC. In many cases DIC is a primary disorder. In others such as burns and septicemia DIC occurs as a complication. DIC is a very frequent complication of the sepsis syndrome and shock.

Laboratory findings: Diagnostic findings are reduction in platelets, fibrinogen, and factors II, V and VIII. The prothrombin time and partial thromboplastin time are prolonged.

Fibrin degradation products (FDP) are markedly increased in blood and urine. Euglobulin lysis time is

increased due to excessive fibrinolysis. D-dimer levels are increased in blood. Normal levels of D-dimer in plasma is < 500 ng/mL.

Normal fibrinogen in plasma is 150-400 mg/dL

Diagnostic Criteria

- A. Presence of the triggering factor
- B. Laboratory diagnosis
 1. Platelet count below 100,000 and rapidly falling further.
 2. Clotting time, prothrombin time and APTT are all prolonged.
 3. Increase in FDP levels and D- dimer in plasma.
 4. Coagulation inhibitor levels reduced.

Differential diagnosis: DIC has to be distinguished from primary hyperfibrinolytic states, thrombocytopenias, vasculitis, microangiopathic hemolytic states, septicemias and overdose of therapeutically administered anticoagulant and fibrinolytic drugs. Severe hepatic failure may resemble DIC clinically.

Prognosis: Mild chronic cases subside promptly when the primary cause is attended to. Fulminant DIC is fatal due to bleeding and dysfunction of vital organs. Prompt recognition of the condition and management are needed to save life.

Management—Principles

1. Identify the underlying causes and correct them.
2. Restore normal hemostasis by blocking the activation and excessive consumption of the coagulation factors and platelets.

This is achieved by the administration of heparin in moderate doses (i.e.) 300-500 unit/kg bw as continuous infusions. Indication of heparin

1. Chronic DIC of malignancy,
2. Dermal necrosis due to vascular occlusion and
3. Retained dead fetus with hypofibrinogenemia.

Heparin can act only in the presence of normal levels of AT III which is also deficient. AT III has to be administered if the level is below 70% of normal. A dose of 11units/kg/bw produces rise in plasma AT III level to 80% or more, at which level it is effective. AT III is replaced by giving AT III concentrates containing 120-250 units/day for 2-3 days, given as IV infusions.

Once this level is reached, maintenance is continued with half this dose given at 4-6 hours intervals.

3. If the plasma levels of coagulation factors and platelets are deficient, replacement of these components with fresh frozen plasma is indicated under close supervision. The dose in 15 mL/kg bw. Cryoprecipitate which contains the coagulation factors is very effective. It is indicated when the plasma fibrinogen

level is < 80 mg/dL. Usually 6 units are required. This raises the blood fibrinogen levels to 100 mg/dL or more. Platelet concentrates are required when there is thrombocytopenia.

Antifibrinolytic drugs are generally contraindicated, since fibrinolysis automatically comes down, once the DIC is corrected.

4. The general condition of the patient and the dysfunction of vital organs have to be managed on appropriate lines.

MICROANGIOPATHIC HEMOLYTIC STATES

Microangiopathic Hemolytic Anemia (MHA)

This comprises thrombotic thrombocytopenia purpura (TTP), hemolytic uremic syndrome (HUS), chemotherapy induced microangiopathic hemolytic anemia, malignant hypertension and the HELLP syndrome (hemolysis, elevated liver enzyme levels and a low platelet count occurring in association with pre-eclampsia).

1. Formation of microthrombi initiated and perpetuated by platelet adhesion and aggregation in the microcirculation of vital organs with the consequent development of thrombocytopenia and organ dysfunction, and
2. Development of microangiopathic hemolytic anemia, which results from damage to erythrocytes traversing the platelet thrombi and adhesion to endothelium of the affected vessels. The hallmark of microangiopathic hemolytic anemia is the presence of fragmented and damaged erythrocytes in circulation (schistocytes) at least two in a high power field (Fig. 166.1).

Unlike as in DIC, there is no gross alteration in the process of coagulation and fibrinolysis. The serum levels of prothrombin and fibrinogen are near-normal and *in vitro* tests of coagulation are normal.

Pathogenesis: The condition is triggered off by events which alter platelet adhesiveness to endothelium and also

Fig. 166.1: Blood smear –schistocytes in microangiopathic hemolytic anemia (arrow)

damage the capillary endothelial cells. The common precipitating factors are gastrointestinal infections, sepsis, malignant diseases, immune complex disease, vasculitis, malignant hypertension and others. The common feature of microangiopathic hemolytic anemia seems to be endothelial damage which causes adhesion and aggregation of platelets, the formation of thrombin and the impairment of fibrinolysis. In both TTP and HUS, aggregates of platelets form and these reversibly obstruct the capillaries of various organs, leading to fluctuating ischemia and at times, infarction.

TTP: The major pathogenic factor in TTP is the activation of platelets by large multimers of vWF leading to the formation of disseminated platelet thrombi. Normally large vWF multimers are cleaved into smaller fragments by the protease enzyme known as ADAMTS13 (an acronym for a disintegrin and metalloprotease with thrombospondin-1-like domain). In TTP this enzyme level is only < 5% of normal.

HUS: Activation of platelet glycoprotein IIb and IIIa and adhesion to fibrinogen under high shear forces lead to their deposition in microvessels and these microthrombi occlude the circulation. This is the main pathogenic factor in HUS. The pathogenesis of TTP and HUS are different.

THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP)

The main lesions are in the brain, kidneys and other organs. It is a multisystem disease characterized by fever, fluctuating central nervous system abnormalities, renal failure and thrombocytopenia. In many cases there may be overlap of symptoms between TTP and HUS. Peak incidence is in the third decade of life and females are more affected.

The characteristic symptom complex includes;

1. Microangiopathic hemolytic anemia
2. Thrombocytopenia
3. Neurological lesions
4. Renal lesions and
5. Fever.

The hemorrhagic manifestations include petechiae, ecchymosis, gastrointestinal bleeding, hematuria or epistaxis. More than 80% of cases show hemolysis and thrombocytopenia. The neurological features include headache, confusion, delirium, coma, convulsions and focal neurological deficits. Renal manifestations occur in 80% of cases. These include proteinuria, varying grades of hematuria and renal failure. Abdominal pain and tenderness along with nausea and vomiting may be mistaken for gastroenteritis.

Untreated, the mortality is high, reaching upto 75%.

Laboratory findings: The hemoglobin is reduced, often to 7 g or less. Thrombocytopenia is demonstrable and it may persist for 7-20 days. There is no constant relationship between the severity of thrombocytopenia and the clinical picture. Microscopic, or rarely macroscopic hematuria may occur. Lactic dehydrogenase (LDH) in serum is grossly elevated. LDH is derived from ischemic and necrotic vascular cells and not mainly from lysed erythrocytes.

Coombs' test is negative. Osmotic fragility is normal.

Prognosis: The mortality may reach upto 75% if the condition is not recognized and managed properly.

Treatment: In addition to attention to the causative event, and appropriate supportive measures, plasma exchange is done using 1-1.5 times of the patient's predicted plasma volume. FFP is used, starting with 30 mL/kg bw on the first day, thereafter 15 mL/kg daily till the platelet count rises above 150,000/cmm. Plasma LDH levels help to monitor progress and recognize relapse early.

Recurrence: At times, TTP may relapse. Drugs such as glucocorticoids, cyclophosphamide, vincristine and monoclonal antibodies such as rituximab have been employed to prevent relapse.

Hemolytic Uremic Syndrome (HUS)

In this condition renal endothelial injury is the primary event. HUS may follow two clinical patterns—diarrhea associated and non-diarrhea associated. The exotoxins of shigella and *E. coli* (particularly verotoxin of *E. coli* 0157:H7) are the triggering factors in the former group.

In the diarrhoea associated group intraluminal platelet thrombi and fibrin occlude glomerular capillaries and afferent arterioles. In the other group thrombi are seen in the arterioles and small arteries. Unlike TTP, vWF multimers do not play a major role in the pathogenesis. LDH levels are grossly elevated.

Major occlusion of the capillaries may lead to necrosis of glomeruli and tubules. Late complications such as hypertension and end-stage renal disease may follow.

Clinical features: HUS is more common in children and the illness starts abruptly after an episode of diarrhea or upper respiratory tract infection. Sixty percent of patients develop acute renal failure which resolves with treatment. About 10% go to the chronic stage. Laboratory findings include evidence of renal failure, microangiopathic hemolytic anemia and thrombocytopenia. Mortality ranges from 10-20%. In adults mortality is higher.

Treatment: In many, supportive measures may be the only form of therapy required. Infusion of fresh frozen plasma, plasma exchange, corticosteroids and anti-platelet drugs have been employed with considerable benefit.

Thrombophilia

K.V. Krishna Das, Mathew Thomas

Chapter Summary

Definition 1105

Definition

This term denotes an abnormally increased tendency to undergo thrombosis *in vivo* either spontaneously or due to trivial reasons. Venous system is affected more often. This is a pathological state caused by several inherited and acquired abnormalities. Broadly the causes may be grouped as below:

1. *Increases in hemostatic components*
e.g. increase in coagulation factors VIII, VII, fibrinogen. A mutation in the 3' untranslated region of the prothrombin gene G to A at position 20210 (PT 20210 A) is associated with increased plasma levels of prothrombin.
2. *Abnormalities of coagulation factors to*
e.g. factor V Leyden which is resistant to activated protein C
3. *Reduction or absence of natural inhibitors of coagulation*
e.g. AT III deficiency, protein C and protein S deficiency
4. *Abnormal metabolites in the system*
e.g. hyperhomocysteinemia. This leads to venous and arterial thrombosis
5. *Presence of coagulant factors in the circulation*
e.g. (a) tumour metabolites in several cancers leading to migrating and recurrent phlebothrombosis
(b) antiphospholipid antibody syndrome
6. Endothelial factors which favour thrombosis.

Pregnancy is associated with a five-fold risk of venous thromboembolism caused by venous stasis, rise in factors II, VII and X and decreased fibrinolysis. Obesity is a predisposing factor for venous thrombosis. The risk of venous thrombosis in the various thrombophilic conditions is given below.

	Risk of venous thrombosis
AT III deficiency	70%
Protein C deficiency	33%
Protein S deficiency	17%

Patients with antiphospholipid antibody syndrome have several complications during pregnancy.

Patients with thrombophilia are candidates for long-term anticoagulant therapy.

Venous thrombosis is 3-6 times more frequent in women taking oral contraceptives (OC). Those drugs raise the levels of prothrombin, factor VII, VIII and X and also fibrinogen. Oral contraceptives also confer an acquired resistance to activated protein C. Venous thrombosis is more common in the young, whereas arterial thrombosis is also more frequent in older age groups. Previous history of myocardial infarction and concurrent tobacco smoking are associated with higher risk. Persons undertaking long haul flights in aircrafts develop predisposition to venous thrombosis.

Antiphospholipid Antibody Syndrome (APAS)

Note: see Section: 12, Chapter 106.

DEEP VEIN THROMBOSIS (DVT)

Risk of deep vein thrombosis can increase when patients with thrombophilia are exposed to temporary risk factors such as surgery or trauma.

Quantitative risk of DVT in thrombophilic conditions compared to normals

Factor V Leyden	7 fold in heterozygotes 80 fold in homozygotes
Factor II G 20210 A	2.8 fold
Antithrombin III deficiency	8 fold
Protein C deficiency	7 fold
Protein S deficiency	8 fold
High clotting factor levels	
Factor VIII > 150 Iu/ dL	4.8 fold
Factor IX > 129 Iu/ dL	2.8 fold
Factor XI > 121 Iu/ dL	2.2 fold

mild hyperhomocysteinemia	2.7 fold
Pregnancy and puerperium	2-14 fold

Ref: Paul A Kyrle and Sabine Eichin Deep vein thrombosis
The Lancet 2005 365 1163-1174

Management of Acute DVT:
Dose of Anticoagulant

LMWH (enoxaparin) 40 mg daily or daltaparin 50000 units.

In patients undergoing major orthopedic surgery—Fondaparinux 2.5 mg daily, started 6 hours after surgery is an effective alternate to LMWH.

Long-term prevention is by warfarin therapy, given in doses to keep INR at 2-3. The duration of prophylaxis depends upon the underlying condition, varying from a few months to life-long.

Chapter Summary

- Development of the Kidneys and Urinary System 1108
- Structure of the Kidney 1109
- Functions of the Kidney 1111

Development of the Kidneys and Urinary System

Nephrogenesis starts from the 4th week of intrauterine life. Three sets of excretory organs are formed in mammalian embryos from the intermediate mesoderm. They are the pronephros, mesonephros and metanephros. The pronephros and mesonephros are tubular structures that involute before birth. Only the caudal portion of the mesonephric duct which opens into the cloaca persists. Metanephros is the direct precursor of the adult kidneys. Nephrons, the excretory units of the kidneys, develop from metanephros. Collecting system of the kidneys develop from the ureteric bud which starts as an outgrowth of the mesonephric duct close to its entrance to the cloaca (Fig. 168.1).

The ureteric bud penetrates the metanephric tissue (blastema) and is appears as a cap moulded over its blunt end. The ureteric bud dilates and splits into branches. These develop ultimately into the collecting ducts, minor and major calyces, the renal pelvis ureter and the trigone of bladder. The metanephric blastema differentiates into the glomeruli, proximal convoluted tubule, loop of Henle and the distal convoluted tubule and renal interstitium. Nephrogenesis is complete at 36 weeks of intrauterine life. The number of nephrons does not increase once the development is complete. At birth the kidneys have a lobulated appearance (Fig. 168.2). During infancy the lobulation disappears as a result of further growth of the nephrons.

The development of urinary bladder and urethra starts with the formation of a membrane called the urorectal septum. This membrane divides the cloaca into two compartments: The dorsal rectal compartment and ventral urogenital compartment. The urogenital compartment

Fig. 168.1: Schematic diagram showing relationship of cloaca, ureteric bud, pronephros, mesonephros and metanephros

Fig. 168.2: Lobulated appearance of kidney

communicates with the allantois. The caudal portion of the mesonephros forms the urogenital sinus. The urinary bladder develops from the urogenital sinus and allantois. The trigone of the bladder develops from the ureteric bud.

Fig. 168.3: Cut section of kidney showing cortex, medulla, renal pelvis and upper part of ureter

Structure of the Kidney

The kidneys are paired bean shaped organs situated in the retroperitoneum on either side of the vertebral column against the psoas major muscle. Each kidney weighs about 120-170 gram, and is about 12 cm in length, 6 cm in breadth and 3 cm in thickness. At the concave medial border of each kidney, there is a slit-like aperture—the hilum. The renal artery, renal vein, nerves, lymphatic and the expanded funnel shaped renal pelvis pass through the hilum. Surrounding each kidney is the tough fibrous capsule, the perinephric fat and perirenal fascia (Gerota's fascia). The kidneys play a major role in maintaining the internal environment (milieu interior).

The cut section of the kidney reveals an outer dark zone – the cortex and the inner pale zone, the medulla (Fig. 168.3).

Corticomedullary distinction can be clearly made out. The cortex is 2-3 cm thick. It is divided into an outer cortex and juxtamedullary cortex. The cortex contains the glomeruli, proximal and distal tubules, blood vessels and interstitium.

The medulla is divided into outer and inner parts. The outer medulla adjacent to the cortex is divided into an outer stripe and inner stripe (Fig. 168.4).

Fig. 168.4: Subdivisions of renal parenchyma

Fig. 168.5: Arrangement of cortical and juxtamedullary nephrons

The medulla consists of the limbs of the loop of Henle, collecting tubules, vasa-recta and interstitium. There are about 8-18 pyramid like projections in the medulla with their base adjacent to the cortex. The apex of each pyramid is called the papilla. The collecting ducts open into the papilla. Each renal papilla is surrounded by the minor calyx, which receives the urine from the collecting ducts. 3-5 minor calyces open into the major calyx, which join to form the renal pelvis.

Nephron is the functional unit of the kidney and consists of renal corpuscle or glomerulus and a system of tubules called proximal tubule, loop of Henle and distal tubule. The spatial arrangement of different parts of the nephron in the different zones of the renal parenchyma plays an important role in their function. There are mainly 2 types of nephrons – cortical and juxtamedullary nephrons (Fig. 168.5). The juxta-medullary nephrons are near the corticomedullary junction and have long loops of Henle which turn back in the inner medulla. Cortical nephrons have short loops of Henle which turn back in the outer medulla.

The glomerulus consists of the central mesangial frame work surrounded by a specialized capillary net work. This globular structure is encircled by the Bowman's capsule all around except at the vascular pole. The afferent arteriole enters the glomerulus at the vascular pole and divides into the capillary net work. This network of capillaries reunites and form the efferent arteriole which leaves the glomerulus. The blood is filtered and the ultrafiltrate moves through the basement membrane into the Bowman's capsular space. The mesangium is the central skeletal frame work of the glomerulus. The mesangium consists of the mesangial cells and the matrix. The mesangial cells contain contractile elements like actin, and myosin which enable them to regulate the ultrafiltration. The macrophage derived cells in mesangium exhibit reticuloendothelial function and remove the trapped macromolecules. The wall of the capillary loop is lined by endothelial cells. The endothelial

Fig. 168.6: Electron microscopy of the glomerulus

cell cytoplasm is stretched into thin sheets completely encircling the lumen. On electron microscopy, fenestrations are seen in this thin sheet of endothelial cell cytoplasm. Outside the endothelium is the glomerular capillary basement membrane and a layer of specialized visceral epithelial cells called podocytes. The basement membrane consists of a central dense layer called lamina densa with two less dense layers on either side, lamina rara interna on the endothelial side and lamina rara externa on the epithelial side. It is made up of collagen and negatively charged sialoglycoproteins (Fig. 168.6).

Podocytes are specialized visceral epithelial cells. They resemble an octopus with a central nucleus and numerous cytoplasmic prolongations. The divisions and subdivisions of these cytoplasmic prolongations

interdigitate with the neighbouring podocytes. The term podocyte is derived on account of the presence of the foot processes which are in contact with the basement membrane. The space between two foot processes has a slit pore membrane. The slit in this membrane is the ultimate ultrafiltration barrier which permits only substances with less than 60 daltons to pass through. The whole glomerular capillary network is surrounded by the Bowman's capsule. The parietal epithelial cells line the outer surface of the Bowman's capsule. The space between the visceral and parietal cell layers is the urinary space. The urinary space communicates with the lumen of the proximal tubule (Fig. 168.7).

The renal tubules consist of a long tubular system with 3 main segments, which differ in their structure and functions. They are the proximal tubule, loop of Henle and distal tubule. The proximal tubule consists of a convoluted and a straight portion. The glomerular basement membrane continues as the basement membrane of the proximal tubule. The proximal tubule is lined by a single layer of columnar cells with prominent brush border on the luminal side. These cells contain several mitochondria and are metabolically very active and highly oxygen dependent. Thus this region is very vulnerable to ischemic injury. The capillary net work arising from the efferent arteriole surrounds the proximal tubule. Loop of Henle, is a hairpin like segment of the tubule which connects the proximal and distal tubules. It consists of the descending limb, the bend and the ascending limb. The descending limb and the 'U' bend of the loop of Henle is lined by a single layer of flat cells with clear cytoplasm. Cortical nephrons have short loops of Henle with short thin descending limbs. The 'U' bends stop short at the outer stripe of the medulla. The juxtamedullary nephrons have long thin descending and ascending limbs

Fig. 168.7: Glomerular capillary filtration barrier

with the 'U' bend reaching deep into the inner medulla. A portion of the ascending limb is thick and it is called the thick ascending limb. The thick ascending limb is lined by columnar cells and it has specialized function. At the junction of the ascending limb and the distal tubule, the glomerulus, afferent and efferent arterioles and the distal tubule are close together to form the juxtaglomerular apparatus.

The juxtaglomerular apparatus (JGA) consists of macula densa at the initial part of the distal tubule, the afferent and efferent arterioles of the parent glomerulus and the glomerular mesangium at the vascular pole (Fig. 168.8).

The modified smooth muscle cells of the afferent arteriole contain renin stored as granules. The macula densa consists of specialized cells in the tubular wall at the junction between thick ascending limb of loop of Henle and distal tubule. These long and narrow cells have densely packed large nuclei (macula densa). The structural organization of JGA suggests a regulatory function. The macula densa senses the composition of the tubular fluid reaching it. This information is used to regulate the release of renin from the modified smooth muscle cells of the afferent arteriole.

The distal tubule is the continuation of the thick ascending limb of loop of Henle. The lining cells of the distal tubule are cuboidal with microvilli on the luminal side. Unlike proximal tubular cells, they do not have brush

border. The collecting ducts are formed by the union of several distal tubules. They pass through part of the cortex and the whole length of the medulla to open into the calyces through slit like openings into the renal papillae. The lining cells of the collecting ducts are of two types – the principal cells and intercalated cells. The principal cells are simple polygonal cells. The intercalated cells are of two types: Alpha (Type A) and Beta (Type B) cells. Alpha cells secrete acid and beta cells secrete bicarbonate.

The renal interstitium increases in volume progressively from cortex to medulla. The interstitium contains fibroblasts with many lipid droplets especially in the medulla. These are called lipid laden interstitial cells. They produce prostaglandin and vasodilatory hormones called *medullipin*. The peritubular fibroblasts secrete *erythropoietin*. The interstitium also contains dendritic cells of macrophage origin.

The kidney receives about 20% of the cardiac output and each gram of renal tissue receives 3.5 to 4 mL of blood every minute. Near the renal sinus, the renal artery divides into 6-8 interlobar arteries. At the junction between cortex and medulla they divide into numerous arcuate arteries which run along the corticomedullary junction. Interlobular arteries arise perpendicularly from the arcuate artery and traverse the renal cortex. The afferent arterioles arise from the interlobular arteries. The afferent arterioles divide to form the glomerular capillary network and reform as the efferent arterioles. They break up to form the peritubular capillary plexus or vasa recta and ultimately form the interlobular veins, arcuate veins, interlobar veins and renal veins.

Functions of the Kidney

Kidneys are important in maintaining the internal milieu. Major functions of the kidney include excretion of nitrogenous waste products, maintenance of acid base, electrolyte and water balance. Kidney also functions as an endocrine organ. It produces chemicals with which have endocrine and paracrine functions. The formation of urine contributes to the excretory and metabolic functions of the kidney.

The glomeruli filter about 120 mL ultrafiltrate from nearly 1500 mL of blood every minute. The ultrafiltrate contains all the solutes such as glucose, sodium, potassium, calcium, phosphate, bicarbonate, small molecules such as urea, creatinine, uric acid and amino acids. The ultrafiltrate flows from the Bowman's space through the urinary pole into the proximal convoluted tubule (PCT). About 60-70% of water and solutes are reabsorbed from PCT. Glucose, bicarbonate, amino acids and phosphate are completely reabsorbed. The proximal tubule is capable of reabsorbing large amounts of fluid. As the fluid reabsorption is iso-osmotic, the concentration of the fluid and osmolality do not change. The proximal

Fig. 168.8: Juxtaglomerular apparatus

tubular cell is also involved in the metabolism and elimination of metabolites like ammonium, drugs and toxic chemicals. The proximal tubule is particularly vulnerable to injury by toxins which reach in high concentrations.

The thin portion of the descending and ascending parts of the loop of Henle are freely permeable to water and urea. Since the medullary interstitium is maintained hyperosmotic (1100-1200 mOsm/kg water), there is reabsorption of water and urea from the tubular fluid. Consequently the osmolality of the tubular fluid progressively increases as the fluid moves down the thin portion, reaching a maximum of approximately 1200 at the 'U' bend of the loop. The thick ascending limb of loop of Henle is impermeable to water. There is an active chloride pump which helps to remove chloride and sodium from the tubular fluid into the interstitium. Approximately 20–25% of the sodium filtered by the glomerulus is reabsorbed in this segment without reabsorption of water. Thus the tubular fluid leaving this segment is always hypotonic with osmolality of 50-100 mOsm/kg. So, this segment is also called the *diluting segment*.

In the distal tubule, reabsorption of sodium in exchange for potassium occurs and is regulated by aldosterone. In the distal tubule, ammonia (NH_3) is converted to ammonium NH_4 by H^+ in secreted into the tubule. This segment is permeable to water and the permeability is partly regulated by the anti-diuretic hormone (ADH). ADH completely controls the water reabsorption in the collecting duct. In the presence of ADH, water transport channels called *aquaporin 2 channels* are inserted into the tubular cell membrane. Thus the cell becomes freely permeable to water and reabsorption occurs resulting in formation of smaller volumes of concentrated urine. In the absence of ADH, the aquaporin channels are stored inside the cell and the cell wall becomes impermeable to water. Thus larger volumes of dilute urine are formed.

The kidney functions as an endocrine organ. It produces hormones with local and systemic effects.

The main hormones are

1. Renin-angiotensin
2. Metabolites of Vitamin D
3. Erythropoietin
4. Prostaglandins
5. Kallikrein – Kinin system

Angiotensinogen is an alpha globulin produced by the liver and which circulates in the plasma. This is converted by the renin which is released by the modified smooth muscle cells of the afferent arterioles into *angiotensin I*. This in turn is converted by the angiotensin converting enzyme (ACE) to *angiotensin II* which is a powerful

vasoconstrictor. It is a trophic hormone for the zona glomerulosa of the adrenal cortex stimulating the release of aldosterone. By selective action of angiotensin II on the smooth muscle cells of the afferent and efferent arterioles, the glomerular filtration can also be regulated by the juxtaglomerular apparatus (JGA). This interaction between the tubule and the glomerulus is called the tubuloglomerular feed back. The renin angiotensin system controls the blood pressure and electrolyte balance through the coordinated effects on the heart, blood vessels and kidney.

Vitamin D obtained from different sources is converted to 25 hydroxy vitamin D in the liver. This is further converted to 1, 25 dihydroxy vitamin D in the proximal tubular cells of the kidney. This conversion is under the influence of parathormone which is the rate limiting factor. The most active biological product which acts as a hormone is 1, 25 dihydroxy vitamin D. Renal osteodystrophy may occur in chronic renal disease due to inadequate formation of active vitamin D. Administration of conventional or even high doses of vitamin D may be ineffective in such patients. Administration of 1, 25 dihydroxy vitamin D is therapeutically effective.

Erythropoietin is a glycoprotein with a molecular weight of 36,000 produced mainly by the interstitial cells of the kidney and to a lesser extent by the liver. Erythropoietin is secreted in response to hypoxia. It stimulates the proliferation of committed stem cell precursors in the bone marrow and induces differentiation as erythroblasts. Deficiency of erythropoietin causes regenerative anemia in chronic renal failure. Recombinant human erythropoietin is now used for the management of anemia in chronic renal failure.

Vasodilator prostaglandins produced in the renal medulla play an important role in autoregulation of renal blood flow. Even in times of hypotension and early shock they help to maintain glomerular blood flow and filtration. Nonsteroidal anti-inflammatory drugs (NSAIDs) which suppress prostaglandins render the kidney susceptible to hypoperfusion and damage even with mild or transient hypotension. These drugs should be avoided especially in those with compromised renal blood flow and when other nephrotoxic drugs are concurrently used.

The renal kallikrein-kinin system also produces renal vasodilatation and plays important roles in renal hemodynamics and excretory function. They are important in the pathogenesis of essential hypertension. In addition to the primary renal hormones already listed, kidney is also acted upon by other hormones like parathormone, prolactin, estrogen, progesterone, aldosterone, ADH, growth hormone and several others. Kidney also plays a key role in the metabolism of hormones like insulin.

Clinical Approach—
Evaluation and Investigations

Jacob George

Chapter Summary

Symptomatology in Renal Disease 1113

Clinical Syndromes in Nephrology 1113

Investigations in Renal Disease 1114

SYMPTOMATOLOGY IN RENAL DISEASE

An underlying renal disease may be suspected if a patient presents with any of the following symptoms:

1. *Oliguria*: The urine output is less than 400mL/24 hours. This is usually seen with renal failure, though some cases of renal failure may be non-oliguric.
2. *Anuria*: The urine output is less than 50 mL/24 hours and may be seen with severe renal failure, total urinary obstruction, bilateral renal artery occlusion, acute cortical necrosis, rapidly progressive glomerulonephritis, etc.
3. *Edema* can occur with acute nephritis, nephrotic syndrome, renal failure, etc. Periorbital edema is more often seen in renal edema rather than cardiac edema as patients with cardiac failure have orthopnea and hence have more of dependent or pedal edema (Fig. 169.1).

Fig. 169.1: Acute glomerulonephritis: woman 30 years
Note: Puffiness of face and moderate edema

4. *Hematuria* can signify a pathology occurring anywhere in the genitourinary tract and may be due to a urological problem. Cola colored urine is however more often seen with glomerular diseases.
5. *Anorexia, nausea and vomiting* may signify underlying renal failure.
6. *Dysuria, frequency and urgency* should raise the possibility of a lower urinary tract infection.

CLINICAL SYNDROMES IN NEPHROLOGY

A constellation of symptoms, signs and abnormal investigation results can constitute a renal syndrome. The following are some of the syndromes often seen in nephrology practice:

1. *Acute nephritic syndrome* (acute glomerulonephritis): This is characterized by varying combinations of edema, hypertension, hematuria and oliguria. Acute postinfectious glomerulonephritis, IgA nephropathy, lupus nephritis and membranoproliferative nephritis can present with this syndrome.
2. *Nephrotic syndrome* is associated with massive edema, proteinuria exceeding 3.5 gm/1.73 m², hypoalbuminemia, hypercholesterolemia and lipiduria. Minimal change disease, focal segmental glomerulosclerosis, membranous nephropathy, diabetic nephropathy, amyloidosis and other systemic diseases can present with this syndrome (Fig. 169.2).
3. *Rapidly progressive glomerulonephritis*: There is a doubling of serum creatinine within a period of weeks to months with associated glomerular hematuria or RBC casts in urine. Post-infectious glomerulonephritis, Goodpastures syndrome, lupus nephritis and vasculitis can present with this syndrome.
4. *Acute renal failure* is characterized by a rapid fall in glomerular filtration rate (GFR) with accumulation of nitrogenous waste products and can be seen in prerenal, renal and obstructive causes.
5. *Chronic renal failure* is associated with a gradual but often progressive decline in GFR of more than 3 months. There can be various signs and symptoms in this disorder which are however individually

Fig. 169.2: Nephrotic syndrome boy

nonspecific so that several of these patients can present to various other specialities of medicine. The term chronic kidney disease (CKD) is used to represent chronic involvement of kidney with normal or subnormal kidney function lasting for over 3 months.

6. Other syndromes include *urinary tract infections, urinary tract obstruction, nephrolithiasis, hypertension*, renal tubular disorders, etc. which are covered in detail in the subsequent chapters.

Investigations in Renal Disease

Investigations in renal diseases are intended to diagnose the type of renal involvement, quantify the severity, identify the underlying etiology, plan management strategies as well as predict the outcome. Investigations start with routine urinalysis and more sophisticated tests are done as needed.

Urine Examination

This is the most rewarding investigation in renal disease. It is essential, therefore, that the clinician familiarises himself with all the tests and their critical interpretation. Fresh urine collected directly in a clean container is examined macroscopically and is subjected to biochemical and other tests. The centrifuged deposit is examined under the microscope. Gram staining of the deposit, cytology and urine culture is undertaken depending on the indication.

The first voided sample in the morning is usually preferred for routine test. For estimating urinary loss of proteins, electrolytes and for calculating creatinine clearance, 24-hour urine is collected in appropriate containers with preservative. If collection and transport of the 24-hour urine sample is difficult, timed samples for 4, 6 or 12 hours is collected. In females, the labia are

separated and in males, prepuce is retracted during micturition to ensure a clean catch specimen. For microbiological culture, urine is collected directly into the culture bottle after cleaning the genitalia with water. Since this procedure may not always be practical in children, suprapubic aspiration of bladder may be necessary to get an uncontaminated sample.

A detailed urinalysis includes numerous tests from which the appropriate ones are chosen.

1. **Volume** is determined by accurate 24 hour urine collection.
2. **Colour:** Normal urine is amber coloured. The color can vary widely in normal persons depending on the concentration or dilution of urine. Presence of substances like bilirubin, blood, drugs, dyes or other coloring agents impart different colours.
3. **Odour:** Normally, freshly passed urine is odourless. On standing, a pungent ammoniacal odour develops due to splitting of urea to ammonia. In urinary infections even freshly passed urine may be foul smelling. Excretion of substances such as metabolites or other malodorous substances may impart characteristic smells to the urine, e.g. fruity odour of acetone.
4. **Turbidity:** Turbid urine may occur in pyuria, chyluria, or hematuria. Amorphous phosphate may precipitate on standing and lead to turbidity, which disappears on adding acetic acid. *Chyluria* has a milky appearance due to fat droplets which clears on addition of ether or chloroform. In pyuria, centrifugation of the urine leaves the supernatant clear.
5. **Reaction / pH:** The pH of urine ranges from 4.5 to 8.0. Strongly alkaline urine may denote infection with urea splitting organisms such as proteus, or renal tubular acidosis. Estimation of the pH of urine is important in the diagnosis and management of urinary tract infections, renal calculi and others.
6. **Specific gravity and Osmolality:** Specific gravity (sp.gr.) and osmolality are indirect indicators of the solute content of urine. Normal sp.gr. of urine may vary from 1002 to 1030. Sp.gr. increases during water deprivation, presence of excessive solutes, excessive fluid losses, and in some cases of acute glomerulonephritis. Increase in specific gravity may occur due to presence of sugar, proteins or radiographic contrast dyes in urine. Sp.gr. is low in the diuretic phase of acute tubular necrosis, diabetes insipidus, during clearance of edema and in normal subjects after excessive fluid intake. In chronic glomerulonephritis where the tubules lose their capacity to concentrate and dilute the urine the specific gravity becomes fixed around 1010 (isosthenuria). This is approximately the specific gravity of protein free plasma. Osmolality indicates

the amount of osmotically active particles and it is expressed as milliosmoles/kg. Normal urine osmolality can vary from 50 to 1200 mOsm/kg.

7. **Water deprivation test:** This assesses the concentrating capacity of the kidney and is employed in polyuric states. On withholding fluids for a period of 6-8 hours normally the hourly urine output falls and the kidneys produce concentrated urine with a specific gravity of 1022 or more. In diabetes insipidus the concentrating power of the kidney is lost and therefore large volumes of dilute urine with sp.gr. less than 1004 are passed. If the diabetes insipidus is due to reduced production of vasopressin (central diabetes insipidus), injection of vasopressin will correct the urine volume and concentration. In nephrogenic diabetes insipidus where the renal tubules are unresponsive to vasopressin, this does not happen.
8. **Water loading test:** This tests the diluting ability and is rarely done in clinical practice. The patient is given one litre of water to drink within 20 minutes. A normal person excretes 80% of this water within 4 hours and the specific gravity of at least one sample should be around 1002. A normal test suggests that the ability of the kidney to dilute the urine is preserved. Apart from primary renal disorders, which impair the excretory capacity of the kidney, deficiency of glucocorticoids (Addison's disease) leads to impairment of diluting function.
9. **Proteinuria and albuminuria:** Proteinuria and albuminuria are not synonymous terms. Normally, urine may contain upto 150 mg proteins in 24 hours. In health, two-thirds of the urinary proteins is constituted by protein of tubular origin, particularly the *Tamm-Horsfall mucoprotein*. This protein is secreted into the tubular lumen by the distal tubular cells and it forms the basic ingredient of urinary casts. Proteins derived from plasma namely albumin, immunoglobulins, light chains and beta-2 microglobulin constitute the remaining third. Albumin may constitute only upto 10 mg in 24 hours. Such small amounts of albumin are not detectable by the usual side room tests. Specific dipstick tests or radioimmunoassays are needed for detecting albumin in such small quantities.

In glomerular diseases, the proportion of albumin lost in urine increases. In addition, small quantities of lipoproteins may also be present. Proteinuria may result from renal disorders, lesions in the urinary tract or extra renal causes like cardiac failure and fever. Gross proteinuria associated with the presence of casts is invariably due to renal disease. Presence of blood in urine gives rise to considerable amounts of protein in urine and this has to be excluded before attributing proteinuria to a primary renal lesion.

Selectivity of proteinuria can be used to assess the extent of glomerular damage and predict response to drugs such as corticosteroids in diseases like nephrotic syndrome. The ratio of IgG excretion to albumin forms the basis for identifying selectivity. In highly selective proteinuria, more of albumin and less of IgG are excreted, suggesting milder glomerular damage and good response to steroids. If the proportion of IgG is high, it suggests greater damage and poorer therapeutic response. A *globulin albumin ratio of <0.1% suggests highly selective proteinuria. Gross proteinuria, above 3.5 g in 24 hours or 2 g/m² body surface occurs in nephrotic syndrome.* Serial quantitative estimation of urinary proteins helps to monitor the progress of nephrotic syndrome and other renal diseases. Proteinuria can be assessed from a spot urine sample by estimating the protein – creatinine ratio. A value of 3.5:1 indicates a 24-hour urinary protein of 3.5 g. Estimation of this ratio is useful in children and in situations where an accurate 24-hour urine collection is difficult. In about 50% patients with multiple myeloma, light chains of immunoglobulins called *Bence Jones protein* is detected in urine. It may also be seen in other conditions like macroglobulinemia, lymphoma, leukemia, amyloidosis and other malignancies. The dipstick test does not detect Bence Jones protein. Immunoelectrophoresis of urine is the ideal method to detect and quantify Bence Jones protein.

Several terms are used to denote specific types of proteinuria.

Fixed proteinuria: >1 g/24 hours mostly of glomerular origin and mainly albumin.

Tubular proteinuria: <1g/24 hours mostly proteins other than albumin.

Overflow proteinuria: light chains of myeloma.

Orthostatic proteinuria: This occurs only when the patient assumes erect posture.

Physiological proteinuria: (transient proteinuria) This may occur transiently even in normal persons after heavy exertion.

Among the pathological proteinurias approximately $\frac{2}{3}$ rd is of glomerular origin and $\frac{1}{3}$ rd is of tubular origin.

10. **Reducing substances:** Presence of glucose in urine often suggests a diagnosis of diabetes mellitus. Rarely, glucose may appear in urine in the presence of normal blood sugar and this occurs in renal glycosuria. **Glucose oxidase test** is specific for glucose and can be used in test stripes for rapid detection of glucose.
11. **Other biochemical tests:** Specific tests are available for detection of ketone bodies, bile pigments, bile salts, urobilinogen and others. Other tests which

Fig. 169.3: Urinary sediments

are occasionally employed include urinary electrolytes, urea, creatinine, uric acid, calcium, amino acids, phosphates, oxalate, metabolites of hormones, drugs or toxic substances.

12. **Microscopic examination:** This is done to study the formed elements consisting of various cells, casts, crystals, lipid droplets, micro-organisms and parasites. The cells are derived from blood or may be acquired from any part of the urinary tract (Figs 169.3 to 169.6).

Erythrocytes: Presence of more than 2 erythrocytes in every high power field should suggest microscopic hematuria. Gross hematuria occurs in acute glomerulonephritis, infections, tumours, renal infarction, ulceration in the urinary tract, bleeding disorders and others.

Leucocytes: Neutrophils constitute the majority. They are numerous in urinary tract infections, urologic disorders and in patients with interstitial nephritis. Lymphocytes may appear in urine in smaller numbers. Eosinophils also may occur

Fig. 169.4: Waxy cast

particularly in acute interstitial nephritis or athero-embolic renal diseases.

Renal tubular cells: These can be differentiated from leucocytes only by transmission electron microscopy.

Fig. 169.5: White blood cell cast

Fig. 169.6: Urinary sediments crystals

Urothelial cells: These may be present in small numbers. The cells are derived from the urinary tract. Excessive number of vaginal squamous cells should suggest contamination during collection of urine.

Cancer cells from malignancy of the urinary tract or renal carcinoma can be identified by special stains.

Casts: Casts are elongated and cylindrical shaped moulds formed in the lumen of the distal tubules where aggregation and gel formation of Tamm-Horsfall glycoprotein occurs. The casts may be hyaline, granular or cellular. *Hyaline casts* contain mainly Tamm-Horsfall protein and they may be seen even in normal urine. They have low refractive index and hence they are visible under dim lighting. *Granular casts* contain either fine or coarse granule like substances. These granules may represent ultrafiltered protein or degenerating cells. Normal urine may show only a few fine granular casts. *Waxy casts* are large and refractile with clean-cut edges (Fig. 169.4). *Broad casts* are formed in the dilated tubules of the surviving hypertrophied nephrons in

chronic kidney disease. *Fatty casts* contain lipids and are characteristic of nephrotic syndrome. *Pigment casts* may contain hemoglobin, myoglobin, bilirubin or other pigments. *Cellular casts* may contain erythrocytes, leucocytes, and renal epithelium in varying numbers.

Crystals: Various types of crystals are seen in the urine and can be identified by their characteristic morphology (Fig. 169.6). Normal urine may contain several crystals depending on the concentration and pH. Under abnormal conditions such as gout, oxaluria and urolithiasis specific crystals may be present in large numbers and may even suggest the diagnosis. Presence of cystine, leucine, isoleucine and other amino acid crystals occurs in metabolic errors and in hepatic failure. These are always pathological.

Gram-staining and acid-fast staining are done with centrifuged deposit of fresh urine. If there is likely to be delay in transport to the laboratory, the urine should be preserved with boric acid to give a final concentration of 1.8%. Conventional Ziehl-Neelsen staining can identify AFB in urine. *Mycobacterium smegmatis*, which is also acid fast may be seen as a contaminant in males.

Phase contrast microscopy helps to identify dysmorphic (abnormal) and isomorphic (normal) erythrocytes. This helps to identify the site of bleeding. Dysmorphic erythrocytes such as crenated or budding forms and acanthocytes suggest glomerular disease. Bleeding from sites below the renal parenchyma show normal erythrocytes.

Scanning or transmission electron microscopy can be used to distinguish between leucocytes and tubular epithelial cells in the urine sediment.

13. **Culture:** A clean catch midstream specimen of urine is generally satisfactory for microbiological examination. Urinary catheterization should not be routinely performed for this purpose due to risk of introducing infection. In addition to routine culture, quantitative determination of the colony count helps to decide whether the organisms exist as contaminants or as active invaders. Bacterial counts below 10^4 colony forming units (CFU/mL) of urine is suggestive of contaminants whereas those above 10^5 /CFU/mL is in favour of active infection. For doing colony counts and to facilitate culture, dipsticks coated with the culture media are available commercially. These can be directly inoculated by immersion to the urine and incubated straight away.
14. **Hematological tests:** Hemoglobin and packed cell volumes are often low in patients with chronic renal disease. Patients with nephrotic syndrome who develop contraction of plasma volume may have high hemoglobin and PCV. Polymorphonuclear

leucocytosis occurs when there is acute infection. High ESR often above 100 mm should suggest the possibility of lupus erythematosus, other forms of dyscollagenoses, renal tuberculosis or myeloma. In chronic renal failure, the erythrocytes are normocytic and normochromic. This is due to deficiency of erythropoietin. In addition to this mechanism, several other factors may also contribute to the development of anemia.

Biochemical Tests

Investigations of the blood and urine are necessary to assess the renal function. These tests also help to determine selectively the functions of the different parts of the nephron.

Blood urea (BU) or blood urea nitrogen (BUN): Urea is the principal end product of nitrogen metabolism. It is excreted by the kidney and it accounts for 50% of total urinary solutes. Amount of urinary urea is primarily determined by dietary protein intake and it depends upon the amount of urinary flow. Urea is filtered, reabsorbed and secreted by the tubule. Normal blood urea is 20-40 mg/dL and BUN is 10-20 mg/dL. Blood urea nitrogen is approximately 50% the value of blood urea. Blood urea or BUN gives an approximate estimate of the glomerular filtration rate (GFR). In addition to changes in GFR, several other factors like the state of hydration, urine flow rate and protein intake alter the serum levels of BU or BUN. Hence blood urea level or BUN is a less reliable parameter of glomerular filtration compared to creatinine.

Serum creatinine and creatinine clearance: Creatinine is the end product of muscle breakdown and is normally excreted by the kidney. The normal level of serum creatinine is 0.8-1.3 mg/dL (70-113 μmol/L). Creatinine is filtered by the glomerulus and is not reabsorbed from or secreted into tubular lumen in large amounts. Therefore, for all practical purposes, the clearance of creatinine closely reflects the GFR. The normal creatinine clearance is 115 ± 15 mL/min. The clearance of a substance is the amount of plasma that is completely cleared of the substance in unit time and can be calculated from the formula:

$C = UV/P$

- Where C = Clearance of the substance in mL/min.
U = Concentration of the substance in the urine (mg/dL)
V = Volume of urine formed (mL/min)
P = Concentration of the substance in plasma at that time (mg/dL)

Given the 24-hour urinary creatinine in mg/day and serum creatinine in mg/dL, the clearance can be calculated at the bedside as follows:

Creatinine clearance =

$$\frac{24\text{-hr urinary creatinine (mg)} \times 5}{\text{Serum creatinine in mg/dL} \times 72}$$

(This is derived from the formula: Clearance = UV/P)

e.g. If 24 hour urinary creatinine is 1200 mg and serum creatinine level is 1.0 mg/dL.

Creatinine clearance =

$$\frac{1200 \times 5}{1.0 \times 72} = 83.66 \text{ mL/min}$$

The creatinine clearance reduces with age even though the serum creatinine levels remain within normal range. This is due to the reduction in muscle mass which occurs with age. It is possible to calculate the creatinine clearance from serum creatinine, age and body weight using the following formula (Cockcroft-Gault formula):

Creatinine clearance =

$$\frac{(140 - \text{age in years}) \times \text{body wt (kg)}}{72 \times \text{Serum creatinine (mg/dL)}} = 83.66 \text{ mL/min}$$

Note: for females, multiply by 0.85, because the creatinine clearance is only 85% of this value in females.

This formula helps to calculate the approximate creatinine clearance at the bed side, particularly for adjusting drug dosages. There is a fixed relationship between serum creatinine and creatinine clearance in the same person. When the creatinine clearance falls to 50% the serum creatinine doubles. Therefore, serial estimations of serum creatinine can give an approximate idea about creatinine clearance. For example, if the creatinine clearance is 120 mL/minute and the serum creatinine is 1.2 mg/dL, when the creatinine clearance comes down respectively to 60mL/min, 30mL/min and 15 mL/min. the corresponding values of serum creatinine would be 2.4, 4.8 and 9.6 mg/dL in the same patient. Therefore, if the relationship between serum creatinine levels and the corresponding creatinine clearance is known, it will be possible to estimate the creatinine clearance by serial monitoring of serum creatinine alone.

Cystatin C: This is an endogenous substance produced at a constant rate by all nucleated cells and is removed only by glomerular filtration. It is possible to estimate the GFR by measuring cystatin C blood level. This test eliminates the need for 24-hour urine collection.

Serum electrolytes: Estimation of serum sodium, potassium, bicarbonate and pH helps to assess acid base status and renal function.

Serum cholesterol and lipids are elevated in some types of nephrotic syndrome and in chronic renal failure.

Uric acid: Hyperuricemia may be the cause or result of renal failure. High serum uric acid level can itself produce renal damage. In renal failure caused by hyperuricemia, the excretion of uric acid (spot sample) exceeds that of creatinine.

Serum calcium levels are low in chronic renal failure. Secondary hyperparathyroidism may cause bone changes.

Fig. 169.7: Plain X-ray abdomen: right renal area showing branched radio-opaque stag-horn calculus

In advanced cases, tertiary hyperparathyroidism may develop, resulting in elevation of serum calcium and metastatic calcification. Serum phosphorus levels are increased in acute and chronic renal failure.

Radiological Investigations

- a. **Plain X-ray of the abdomen** to include kidney, ureter, bladder and urethra (KUB) taken after suitable bowel preparation gives a good picture of the kidney and urinary tract. For getting a good skiagram, it is better to ensure proper bowel movement, if necessary by giving anti-flatulents like activated carbon and laxative for the previous 2 days and asking the patient to be ambulant so as to avoid excess of gas in the intestines.

Abnormalities of size, presence of calculi and calcification can be seen (Fig. 169.7). The bipolar length of the normal kidney is about the width of 3 ½ lumbar vertebrae. The left is about 1 cm longer and is situated higher than the right. In health, the two kidneys do not differ in length by more than 2 cm. An atrophic kidney may be smaller than its normal counter part. Tumours may lead to enlargement. In addition, bone changes occurring in the spine and pelvis can be seen. Tumours of the kidney may give rise to larger renal shadows. Hydronephrosis and polycystic kidney, though palpable as abdominal masses, may not be seen in the plain X-ray picture. Larger tumours, polycystic kidneys and hydronephrosis may give indirect evidences of their presence such as the displacement of gas-filled bowel.

- b. **Ultrasonography:** This has become the most popular and easily available imaging procedure for the preliminary assessment of the excretory organs. This is an investigation of choice for assessing renal size and the presence of obstruction, tumour, cysts, and calculi. Moreover, ultrasonography being noninvasive

Fig. 169.8: Ultrasonogram showing stone in renal pelvis (arrow) Note the 'acoustic' shadow due to the stone

is used more and more extensively. Ultrasonography is not useful for assessing renal function (Fig. 169.8).

- c. **Intravenous urography (IVU):** Intravenous urogram helps to assess the renal structure, anatomy of the collecting system and function by using radio-contrast agents, which contain iodine. These agents are selectively concentrated and excreted by the kidneys. Originally, hyperosmolar agents like meglumine and iothalamate were used. At present safer and non-ionic low osmolar agents like, iohexol, iopamidol and ioxglate are used. They produce adverse side effects only infrequently. Hypersensitivity to iodine is an absolute contraindication for IVU. Risk of renal failure is high in impaired renal function, concurrent use of other nephrotoxic agents, multiple myeloma with proteinuria and those with and diabetic nephropathy. The risk of contrast nephrotoxicity can be reduced by good hydration with intravenous saline and agents like N-acetyl cysteine (Fig. 169.9).

A plain X-ray of the abdomen is taken for comparison. Then films are taken at 5, 10, 20 and 30 minutes after administration of the contrast agent intravenously and a final picture after complete micturition.

Points to be noted on the IVU are summarized below

1. Time of initial visualization of the renal outlines. This depends upon renal circulation and glomerular filtration.
2. Time for maximum opacification of kidneys and visualisation of pelvicalyceal system. This depends upon the excretory function of the kidneys.
3. Size, shape and presence of negative contrast (stones, tumours, etc.) in the pelvicalyceal system.
4. Flow of the dye along the ureters, their size and presence of obstruction.
5. Time taken for the renal and pelvicalyceal shadow to disappear. This is usually complete within 20-30 minutes and this gives an idea about the efficacy of the drainage system, as well as vascularity of the kidneys.
6. Size and shape of the bladder, presence of filling defects caused by calculi, tumours or enlarged prostate and completeness of bladder emptying, as is seen in the post-micturition film.

Fig. 169.9: Intravenous urogram showing right renal area with sloughed papilla appearing as a rounded shadow in the middle calyx—arrow (from a case of analgesic nephropathy)

Several modifications of the IVU have been devised. These include:

- a. **Minute sequence pictures.** When pictures are taken every minute for the first five minutes, delay in appearance of nephrogram on one side, decrease the size of the kidney, higher concentration of the contrast in the collecting system and delayed drainage on the same side are all suggestive of unilateral renal artery stenosis.
- b. **Diuretic urogram** is performed by administration of a diuretic in cases with upper ureteric ballooning or obstruction to confirm or rule out obstruction. A functional obstruction of the pelvi-ureteric junction is relieved by the use of diuretic whereas the ballooning persists if there is a mechanical block.
- c. **Infusion urogram** is undertaken in the presence of renal failure and delayed pictures are taken at intervals of 6 hours upto even 96 hours to delineate the urinary tract in some cases of obstructive uropathy.
- d. **Retrograde pyelography** is the procedure by which the ureter is catheterized and the pelvicalyceal system is visualized by direct instillation of radiographic agent.
- e. **Cystourethrography** helps in studying the bladder, urethra, and vesicoureteric junction.
- f. **Micturating cystogram:** X ray is taken while the patient passes urine after introducing radiopaque contrast into the bladder. This helps to visualize the urethra, identify lesions such as posterior urethral valve or other obstructions and to establish the presence of vesicoureteric reflux (Figs 169.10A and B).
- g. **Aortography** performed by injecting dye into the aorta delineates clearly the aorta, renal arteries and the renal vascular pattern. Selective angiography can be done after catheterizing the renal arteries. Renal venograms can be obtained by injecting the dye into the renal veins (Fig. 169.11).
- h. **Isotope renography** helps to assess renal perfusion and excretory function. It is particularly useful to diagnose renovascular hypertension, assess individual kidney function, renal scarring and to confirm pelvi-ureteric junction obstruction. The radiopharmaceutical agents include technetium labeled DTPA (diethylene triamine penta acetic acid) (Fig. 169.12). Diuretic renogram is performed after administering frusemide and helps to differentiate between organic and functional ureteric obstruction. The functional obstruction clears after diuretic. Captopril renogram is performed after administration of 12.5 mg captopril

Figs 169.10A and B: A. Cystourethrogram: AP view showing bladder filled with dye before patient tries to pass urine. Note that there is no filling of the ureters. B. Oblique view of the same case when the patient (child) is passing urine. Note the flow of urine through the urethra and simultaneous filling of both ureters and the dilated renal pelvis and calyces (Grade V vesicoureteric reflux)

Fig. 169.11: Abdominal aortogram showing aorta and both renal arteries. Note the narrowing of proximal left renal artery (arrow) and post-stenotic dilatation

Fig. 169.13: DMSA scan showing scar in the upper pole of left kidney (arrow)

Fig. 169.12: DTPA renogram showing retention of radiopharmaceutical in the renal pelvis of right kidney (From a case of congenital pelviureteric obstruction)

Fig. 169.14: CT scan showing bilateral enlarged kidneys due to numerous cysts of varying sizes in both kidneys (arrows). (Autosomal dominant polycystic kidney disease)

orally and it helps to identify renal artery stenosis. The radiopharmaceutical DMSA (dimercapto succinic acid) is concentrated in the renal parenchyma and it is used to identify scars in the parenchyma (Fig. 169.13).

- i. **CT scan** helps to delineate the structural and morphological abnormalities in the kidney, details of tumour, and the relationship to other organs. In the vast majority of cases, CT scan will give adequate information (Fig. 169.14).
- j. **MRI** is employed at times. The advantages are a clear delineation of the corticomedullary junction and better visualization of the renal artery, vein and inferior vena cava.

Renal Biopsy

Renal tissue can be obtained by closed needle biopsy. The tissue is processed for histology, microbiological studies, electron microscopy and for immunofluorescence microscopy. Histological diagnosis is necessary for

determining the management and prognosis of several renal disorders like acute glomerulonephritis, nephrotic syndrome, lupus erythematosus, amyloidosis, and transplant rejection. Since clinical pattern of several different pathological entities may be similar, the ultimate diagnosis in many diseases has to rest on renal biopsy.

Serological Tests

These have to be done in selected cases depending on the clinical picture to confirm the diagnosis. These include ANA, Anti-dsDNA, ASO Titre, Complement (C3 and C4) levels anti-neutrophil cytoplasmic antibodies (pANCA and cANCA), Anti-GBM antibodies, screening for hepatitis viruses (esp. HCV and HBV) and HIV.

Urologic Investigations.

Urological investigations such as cysto-ureteroscopy help to visualize the urinary tract and enable endoscopic procedures.

Membranoproliferative Glomerulonephritis 1130

Acute Nephritic Syndrome

R. Kasi Visweswaran

Acute nephritic syndrome is characterized by hematuria, red blood cell casts, proteinuria, oliguria, hypertension, fluid retention and sometimes, renal failure.

Common Causes

1. Post-streptococcal acute glomerulonephritis
2. Other post-infective acute nephritic syndromes following staphylococcal, pneumococcal, and viral infections.
3. Focal glomerulonephritis and membranoproliferative glomerulonephritis.
4. Collagen disorders, especially systemic lupus erythematosus and polyarteritis nodosa.
5. Miscellaneous group: Henoch-Schönlein syndrome, infective endocarditis, hypersensitivity angitis, hemolytic uremic syndrome and early stages of Goodpasture's syndrome.

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Pathogenesis and pathology: Poststreptococcal acute glomerulonephritis is a common form. It is an example

of immune-complex mediated glomerulonephritis. Following streptococcal infection, the streptococcal antigens stimulate the production of antibodies. The antigens and antibodies combine to form immune complexes. These get deposited in tissues, particularly in the kidney and initiate acute inflammatory reaction in the glomerulus. The kidneys are enlarged. The Glomeruli are swollen and show proliferation of the endothelial cells. Glomerular tuft is infiltrated by polymorphonuclear cells. Immune complex deposits can be demonstrated as electron dense deposits when seen under electron microscopy. These can also be demonstrated by immunofluorescence staining which shows a granular pattern of distribution of immune complexes in the glomeruli.

Clinical features: The illness starts about 2-3 weeks after streptococcal infection of the skin, throat or respiratory tract. It is more common in children but can occur in any age. In India the most common precipitating cause was infected scabies or other skin infections. Both sexes are affected. The onset is often abrupt with puffiness of the face, oliguria, reddish smoky-urine, hypertension and edema. Small outbreaks may occur in closed communities due to the presence of nephritogenic strains of streptococcus. Severity of the disease is variable. Mild cases may go unnoticed (subclinical type). Severe cases present acutely with life-threatening complications like hypertensive encephalopathy, acute left ventricular failure or uremia. Majority of cases of poststreptococcal glomerulonephritis in children are self limited and more than 90% recover completely without complications or sequelae. After a week or so of the oliguric phase, diuresis starts. Though gross hematuria and casts disappear promptly, proteinuria and microscopic hematuria may persist for up to 6 months. In most cases, the blood pressure returns to normal with recovery. Some cases may require anti-hypertensive drugs.

Investigations

Urine examination: The urine volume is reduced, it is reddish-brown and contains protein. At this stage, the specific gravity is normal or raised. Numerous red cells

are seen. The presence of red cell casts indicates active glomerulonephritis.

Blood chemistry is altered depending on the severity of the disease and the presence of renal failure. During the oliguric phase, biochemical features of renal failure may be evident. The ASO titre is elevated above 200 Todd units and in many cases hemolytic streptococci may be obtained by culture of the skin lesion or throat swab. Levels of C3 complement are low in 95% of cases in the first two weeks of illness, C5- or C9 are also low. Classical pathway complement components C1, C4 and C2 are usually normal. This indicates that the alternate pathway is activated.

Diagnosis: Any patient presenting with abrupt onset of puffiness of face, oliguria, hematuria, hypertension and edema should be investigated to exclude acute nephritic syndrome.

Differential Diagnosis of Acute Glomerulonephritis

1. Angioneurotic edema
2. Nephrotic syndrome
3. Membranoproliferative glomerulonephritis (MPGN)
4. Chronic renal failure with acute exacerbation.

Angioneurotic edema involving the face may occur in children. This may superficially resemble acute glomerulonephritis. In angioneurotic edema, puffiness is asymmetrical. Often there is pruritus and other signs of allergy. The blood pressure is not elevated and urine is normal.

Nephrotic syndrome may present with edema of the face, though edema is more prominent in the dependent parts. The long duration, less dramatic onset, and urinary findings should suggest the diagnosis. The blood pressure is normal in the majority of cases of nephrotic syndrome.

MPGN with nephrotic syndrome may have an onset similar to acute nephritis but with massive proteinuria, hypertension, hematuria and renal failure. MPGN is more common in children and it may occur due to various causes, including streptococcal infection. 20-30% present as acute nephritic syndrome, whereas the others follow the nephrotic pattern. Majority progresses to persistent nephritic state and renal failure. The complement levels of both classical and alternate pathways are reduced in Type I MPGN whereas in Type II MPGN only C3 complement is lowered. Renal biopsy is indicated in order to confirm the diagnosis in all cases where the course is atypical. Chronic renal failure may present with acute exacerbations due to causes such as infection, electrolyte imbalance or cardiac failure. Though clinically they may suggest acute nephritic syndrome, the long history, urinary findings such as isosthenuria, presence of granular casts and evidence of uremic features should suggest the diagnosis.

Fig. 170.1: Renal biopsy poststreptococcal glomerulonephritis: Note enlargement of the glomeruli, increase in cellularity and occlusion of capillary lumen, polymorphonuclear infiltrates

Diagnosis is confirmed by urinary findings and biochemical examination of blood. Etiological diagnosis is made by estimating serum complement levels, isolation of the organisms, estimation of ASO titer and renal histology. Reduction in serum complement levels and demonstration of the pattern of immune complex deposition in histological specimens by immunofluorescence microscopy are diagnostic of the different types of immune mediated glomerulonephritis. Poststreptococcal glomerulonephritis is usually associated with coarse granular immune deposits. In conditions like Goodpasture's syndrome, linear ribbonlike immune deposits are seen along the glomerular basement membrane.

Renal biopsy is not routinely indicated in all cases of acute post-streptococcal glomerulonephritis especially in children. It is indicated under the following conditions: (1) failure to recover promptly, (2) persistence of hypertension, azotemia and hematuria and (3) possibility of systemic diseases like vasculitis and collagen diseases (Fig. 170.1).

Course and prognosis: In 90% of children recovery is uneventful and complete even though the proteinuria and microscopic hematuria may persist for a few weeks or months. Some children develop nephrotic syndrome or chronic glomerulonephritis. Advanced irreversible renal failure may develop in 2-5% of cases in the acute phase. During recovery any intercurrent infection may precipitate transient exacerbation of the clinical and urinary abnormalities. In adults uneventful recovery occurs only in 50%. In the rest, acute renal failure, hypertension, nephrotic syndrome or chronic glomerulonephritis progressing to renal failure develop in varying proportions.

Management: Since in the vast majority of patients, acute nephritic syndrome is self-limiting, only fluid restriction and close observation are required. As in the case of acute renal failure, bed rest, maintenance of fluid and electrolyte balance and adequate nutrition with carbohydrate and fat calories form the basic principles of therapy.

Complications arising during the course of the disease, such as hypertensive encephalopathy, cardiac failure with pulmonary edema, hyperkalemia and uremia demand active intervention.

The hypertension occurring in acute nephritic syndrome is often self-limiting and in most cases does not require any long-term treatment. If the diastolic blood pressure is over 90 mmHg and hypertensive complications are imminent, hydralazine, methyldopa, nifedipine, amlodipine or atenolol have to be used in adequate doses. If blood pressure rises rapidly or hypertensive encephalopathy occurs, parenteral labetalol or nitroglycerine has to be given. Nifedipine administered through buccal mucosa helps to bring down the blood pressure rapidly and smoothly. The blood pressure can be maintained by the same drug or other drugs given orally. If convulsions continue in spite of antihypertensive therapy more aggressive measures to control the convulsions may be needed. Pulmonary edema is to be treated on the usual lines of left ventricular failure. Sedation with diazepam 10 mg given intravenously, oxygen inhalation, frusemide in large doses (100-200 mg IV) and slow intravenous injection of aminophylline are helpful. If the diuretics do not bring about diuresis, pulmonary congestion can be effectively relieved by physiological venesection by applying tourniquets to the proximal parts of the limbs to prevent venous return. Dialysis or ultrafiltration should be employed to remove the excess of fluid in these cases. A course of penicillin is indicated if there is active infection by streptococcus.

SPECIAL TYPES OF ACUTE NEPHRITIC SYNDROME

Goodpasture's Syndrome

This is a typical example of anti-GBM-antibody mediated glomerulonephritis. Antibodies against the glomerular basement membrane (GBM) and pulmonary capillary basement membrane are produced. These attach to the respective basement membranes and set up inflammatory reaction. In the glomerular capillary basement membrane the antibody appears as a linear deposit on immunofluorescence microscopy. This stands out in sharp contrast to the granular deposit of immune complexes seen in post-streptococcal acute glomerulonephritis. Renal histology shows proliferation of the epithelial cells of the Bowman's capsule giving rise to the appearance of crescents. The disease presents with pulmonary symptoms such as

hemoptysis and features of acute glomerulonephritis. The prognosis is generally unfavorable. Large doses of corticosteroids and immunosuppressive drugs have been tried but the results are not uniformly good.

Other Conditions

Systemic lupus erythematosus, polyarteritis nodosa, Henoch-Schönlein syndrome, and infective endocarditis may give rise to acute nephritic syndrome during their course. Other evidences of the underlying disease are generally present. Treatment is for the primary disorder. Renal manifestations also usually subside when the primary condition resolves. In lupus and Henoch-Schönlein purpura, the renal lesion may persist in many and lead to renal failure later. Renal involvement is a major factor deciding long-term prognosis in these disorders.

Nephrotic Syndrome

Ramdas Pisharody, M. Sreelatha

Definition

Nephrotic syndrome (NS) is a condition characterized by heavy proteinuria of $>3.5 \text{ g/1.73m}^2$ body surface area in 24 hours, often associated with hypo-albuminemia, edema, hyperlipidemia and a hypercoagulable state.

ETIOLOGY

NS can be due to primary (idiopathic) glomerular diseases, or may be secondary to a large number of identifiable diseases (Table 170.1).

PATHOPHYSIOLOGY

The glomerular filtration barrier consists of 3 layers: fenestrated endothelial cells, the GBM and epithelial slit diaphragms. Movement of molecules across this barrier depends on the size, electrical charge, configuration, shape and deformability of the molecule. The structural integrity of GBM and glomerular hemodynamics are the other factors controlling the filtration. Under normal conditions, the GBM has an electronegative charge and this repels the negatively charged albumin molecules. Thus, leakage of albumin is prevented. In minimal change disease (MCD), there is loss of the negative charge of GBM allowing more of albumin to be filtered. This is known as *charge selective proteinuria*. In most other glomerular diseases, there is structural damage to GBM leading to alteration in the size selective barrier function. Thus, all substances below a particular molecular size are filtered. This is known as *non-selective proteinuria*.

Hypoalbuminemia is a cardinal feature of NS. This is due to urinary loss of albumin and albumin catabolism in

TABLE 170.1

Etiology of NS

1. Primary glomerular diseases (Idiopathic NS)
1. Minimal change disease (MCD)

2. Focal segmental glomerulosclerosis (FSGS)

3. Membranous nephropathy (MN)

4. Membranoproliferative glomerulonephritis (MPGN)

5. Mesangioproliferative glomerulonephritis (Mes. PGN)

6. IgA Nephropathy
2. Secondary nephrotic syndrome
1. Infections

Bacterial: Post streptococcal glomerulonephritis, infective endocarditis, shunt nephritis, syphilis, tuberculosis, chronic bacterial infections

Viral: Hepatitis B, hepatitis C, cytomegalovirus, Epstein Barr virus, HIV

Protozoal: Quartan malaria, toxoplasmosis

Helminthic: Schistosomiasis, trypanosomiasis, filariasis

2. Neoplasms

Solid tumours: Lung, colon, stomach and breast, leukemia, lymphoma

3. Drugs: Penicillamine, gold, mercury, nonsteroidal anti-inflammatory drugs (NSAIDs), captopril, probenecid, trimethadione, alpha-interferon, lithium

4. Multisystem diseases: Systemic lupus erythematosus (SLE), mixed connective tissue disease (MCTD), dermatomyositis, rheumatoid arthritis (RA), Henoch Schonlein purpura (HSP), mixed cryoglobulinemia, sarcoidosis, light chain and heavy chain diseases, amyloidosis

5. Heredo-familial and metabolic diseases: Diabetes mellitus, myxedema, Graves' disease, Fabry's disease, congenital nephritic syndrome, Charcot-Marie-Tooth syndrome, Hurler's syndrome, familial nephrotic syndrome, lipoprotein glomerulopathy

6. Miscellaneous: Pre-eclampsia, malignant nephrosclerosis, chronic allograft nephropathy, obesity, reflux nephropathy, Castleman's disease, Kimura disease.

the proximal tubule. Hepatic albumin synthesis is increased in nephrotic patients. Along with albumin several other plasma proteins are also lost in urine. These include IgG, erythropoietin, complement, thyroxine Vit D binding globulins, some of the procoagulant factors and also anticoagulant factors like antithrombin III. This predisposes the patients with nephrotic syndrome to repeated infections, hypothyroidism, anemia and thrombosis.

Generalized edema and facial puffiness are the cardinal symptoms of nephrotic syndrome. Effusions into serous cavities occur. The severity of edema depends on severity of proteinuria, duration of disease, type of glomerular disease, dose of diuretic and intake of salt and fluid by the patient. Oliguria due to renal hypoperfusion is common especially in the acute phase. The edema formation in nephrotic syndrome is explained by the ‘underfill and overfill’ hypothesis. In the ‘underfill’

hypothesis the hypoalbuminemia and decreased plasma oncotic pressure cause underfilling of the vascular system. Fluid accumulates in the interstitial space. The rennin-angiotensin-aldosterone system is stimulated causing further salt and water retention and aggravation of edema. In ‘overfill’ hypothesis there is primary reabsorption of sodium and chloride by the renal tubules with resultant edema. This is further aggravated in the setting of reduced GFR (Flow chart 170.1).

Hyperlipidemia is common in NS with marked elevation of plasma LDL, VLDL, intermediate density lipoproteins (IDL) and lipoprotein-a (Lp(a)) and lowering of HDL concentration. LDL and VLDL increase as a result of increased synthesis in liver and this is linked to lipoprotein synthesis. The urinary loss of lipoprotein lipase, an enzyme involved in degradation of lipids contributes to an increase in VLDL. HDL levels are lowered due to losses in urine. Hyperlipidemia not only leads to early atherosclerosis but also contributes to the progression of renal disease. Hyperlipidemia reverts to normal when nephrotic syndrome undergoes remission. *Dietary restriction does not improve the lipid abnormalities in nephrotics.* Lipid lowering therapy is indicated only if the course of nephrotic syndrome is prolonged or if the patient has steroid resistant nephrotic syndrome. Statins are preferred as lipid lowering agents in nephrotic syndrome.

Minimal Change Disease

This disease first described in 1913 was called “*Lipoid Nephrosis*” or “*Nil Disease*”. It constitutes 80-90% of nephrotic syndrome in children under the age of 10 and

Flow chart 170.1: Showing the pathogenesis of edema

about 20% of primary NS in adults. The male: female ratio is 3:2 in children and 1:1 in adults. The exact pathogenesis is not known. Immunological injury with involvement of both cell mediated and humoral immune mechanisms are responsible.

The cardinal clinical feature of MCD is generalized edema. Facial edema is noted first. Edema becomes clinically evident when more than 5 liters of fluid accumulate in the interstitial compartment. Since the intravascular volume is low or normal, the patients are not dyspneic or orthopneic except when they have serous effusions. Usually there is no hypertension, hematuria or renal failure. Reversible acute renal failure may occur due to acute tubular necrosis caused by extreme intravascular volume contraction; diuretic (frusemide) induced acute interstitial nephritis, renal vein thrombosis or severe renal interstitial edema.

Ideally all adults with nephrotic syndrome should be subjected to renal biopsy before starting treatment. However, a patient with nephrotic syndrome may be given a course of treatment with corticosteroids before considering renal biopsy in the absence of hematuria, hypertension and renal failure. Biopsy should be done if response to steroids is inadequate and more powerful drugs are to be used.

The renal biopsy is essentially normal on light microscopy (Fig. 170.2). Immunofluorescence (IF) studies show absence of immune deposits in MCD. Faint mesangial staining for IgM and component C1q may be encountered in variants of MCD. These are catagorized as 'IgM mesangial nephropathy', and 'C1q nephropathy', respectively. The only structural abnormality seen under electron microscopy (EM) is the extensive effacement of foot processes of the podocytes (Fig. 170.3).

Fig. 170.2: The glomeruli appear normal under light microscopy in minimal change disease. Note the normal cellularity, open capillary lumen, normal capillary wall and normal Bowman's capsule

Fig. 170.3A: Line drawing showing normal capillary loop

Fig. 170.3B: Line drawing showing effacement of foot process in minimal change disease

MANAGEMENT

General treatment measures for the control of edema include, fluid restriction, low sodium diet and rest in recumbancy. Rest helps to mobilize the fluid from the extracellular to the intravascular compartment. Aggressive diuretic therapy is avoided since it may precipitate intravascular volume depletion, hypotension and acute tubular necrosis. If the patient has very low intravascular volume, intravenous administration of plasma or IV albumin with frusemide will help to temporarily improve the intravascular volume and make the diuretic more effective. Human albumin is given as a 20% solution

100-200 mL IV as slow infusion until the plasma albumin rises above 2.5 g/dL or diuresis is established. Other temporary measures to relieve resistant edema include standing neck deep in water for about one hour in the morning and evening (head-out water immersion) and graded pressure elastic stockings. Both procedures result in increase in the interstitial fluid hydrostatic pressure causing movement of fluid from the extravascular to the intravascular compartment.

The diet should be of normal protein with low fat. Salt and water should be restricted. The total allowance of fluid should be 400-600 mL less than the previous 24-hours urine volume so as to effect a weight reduction of 400-600 g/day. Long-term anticoagulation is required in those who had episodes of venous thrombosis or even a single episode of arterial thrombosis.

Specific Treatment

The drug of choice for the treatment of minimal change disease (MCD) is corticosteroid. The accepted guidelines for the treatment of the first attack are as follows.

Prednisolone 60 mg/m²/day (maximum dose 80 mg per day) is given as a single morning dose for a period of 4-6 weeks. If the patient goes into remission, the dose is reduced to 40 mg/m² on alternate days and continued for 4-6 weeks. The dose is then tapered stepwise every 2 weeks and discontinued by 8-12 weeks. About 80% of adults and 95% of children undergo complete remission of proteinuria within 6-8 weeks. In some adults the response may be delayed up to 16 weeks even on full dose of daily steroids.

Depending on the response to steroids, the nephrotic patients can be classified as *primary responder*, *frequent relapser*, *steroid dependent* and *steroid resistant*. The term *steroid response* is defined as reduction of proteinuria to less than 4 mg/kg/day (<200 mg/day) for 3 consecutive days. Early responder is one who goes into remission within 4 weeks of standard steroid therapy. Late responder is one who undergoes remission within 16 weeks. The term persistent remission indicates sustained remission for 18-24 months. The term relapse indicates occurrence of proteinuria of more than 3+ for 3 consecutive days even without edema or more than 1 g per day after achieving remission. If two or more relapses occur within 6 months or more than three relapses occur in a year, it is termed frequent relapse. The term infrequent relapse indicates occurrence of less than 2 in 6 months or less than 3 in a year. Steroid dependence is defined as the occurrence of relapse within 2 weeks of stopping steroids or while tapering steroids on at least 2 consecutive occasions. In primary steroid resistance there is no response in spite of 16 weeks of full dose daily steroids. The term secondary steroid resistance indicates the condition in which a primary responder fails to respond during a subsequent relapse despite 16 weeks of full dose steroids.

In adults with MCD, 40% are frequently relapsing, 30% steroid dependent and 10% steroid resistant. Patients with frequently relapsing NS and steroid dependent NS must be treated with a combination of low dose steroids and cytotoxic drugs like cyclophosphamide (2-3 mg/kg/day) or chlorambucil (0.1-0.2 mg/kg/day) given for 12 weeks. Cyclosporin in doses of 5-6 mg/kg/day may be considered if response to steroid is inadequate. It is expensive and withdrawal may be associated with relapse. Levamisole is used as an adjunct to low dose maintenance steroids in children with frequently relapsing NS. Steroid resistant MCD occurs in less than 7% of children and 15% of adults. They should be treated with antiproteinuric drugs like angiotensin converting enzyme inhibitors or angiotensin receptor blockers. Progression of MCD to renal failure is rare. Spontaneous remissions may occur in 25% of cases on long-term follow-up.

Focal Segmental Glomerulosclerosis (FSGS)

FSGS accounts for 30% of nephrotic syndrome in adults and 50% of all steroid resistant cases. Most cases of FSGS eventually develop kidney failure over a period of 10 to 20 years. When end stage renal disease occurs within 3 to 5 years, it is termed malignant FSGS.

Classification of FSGS

- Primary (idiopathic) FSGS
- Familial FSGS
- Secondary FSGS
 1. Due to glomerular maladaptation and reduced nephron number
 - Reflux nephropathy
 - Oligomeganephronia
 - Obesity
 - Unilateral renal agenesis
 - Sickle cell disease
 - After removal of one kidney
 2. HIV associated nephropathy
 3. Heroin induced nephropathy
 4. Secondary to focal proliferative GN
 5. Treatment with palmidronate, interferon and sirolimus.

Pathogenesis of FSGS

The pathogenesis of focal segmental glomerulosclerosis is poorly understood. Injury to the visceral epithelial cell (podocyte) in the glomerular tuft is an important factor. A circulatory factor which increases the permeability of the glomerular filter leading to sclerosis has been identified. The same factor is responsible for the recurrence of original disease in the transplanted kidney in some cases of FSGS. HLA associations and aberrations of single genes have been identified in familial forms of FSGS.

Fig. 170.4: Diagram showing focal and segmental glomerular involvement

Note: 3 out of 7 glomeruli are affected. They show sclerosis involving < 50% of the glomerular capillary tuft

Pathology

In 'classic FSGS', sclerosis is focal involving < 50% of the glomeruli and segmental involving < 50% of the glomerular tuft (Fig. 170.4). The remaining part of the glomerular tuft and the other glomeruli are normal (Fig. 170.5). If the biopsy sample does not contain adequate number of glomeruli, the diagnosis of FSGS may be missed. Two important clues in the biopsy favour the diagnosis. They are abnormally enlarged glomeruli, presence of interstitial fibrosis and tubular atrophy. Immunofluorescence study may show nonspecific IgM deposits. Under EM there is foot process effacement in sclerotic and nonsclerotic glomeruli. Depending on histological variations, FSGS is subclassified as (a) classic (b) collapsing (c) cellular (d) tip lesion and (e) peri hilar FSGS.

Adverse prognostic factors are elevated serum creatinine, hypertension at the onset, massive proteinuria exceeding 10 gm/day, steroid non-responsiveness, persistent nephrotic state, cellular lesions and interstitial scarring involving more than 25% of the biopsy tissue.

Clinical Features and Treatment

Most patients present with sub-nephrotic or nephrotic proteinuria. Nearly half of the patients have microscopic hematuria, hypertension or elevated serum creatinine at presentation. Treatment is with steroids given in daily

Fig. 170.5: Light microscopy of focal and segmental glomerulosclerosis showing a segment (< 50%) of glomerular capillary tuft showing sclerosis (arrows) and the remaining part of the glomeruli remaining normal

doses of 1 mg/kg body weight for at least 6 months. Steroid response rate is only 30%. In resistant cases, immunosuppressive drugs like cyclosporine have to be added. ACEI and ARB have anti-proteinuric effect and are useful in steroid resistant cases.

Recurrence of FSGS in the transplanted kidney may occur in 30-40% of patients. Recurrence often occurs within 3 months of transplantation. Secondary FSGS may occur when there is loss of more than 70% of the functioning nephrons. The remaining nephrons hypertrophy and hyperfilter and undergo progressive damage.

Membranous Nephropathy

Membranous nephropathy (MN) is the most common cause of adult-onset NS accounting for about 50% of the cases. In children the frequency is 5-7%. The peak incidence is in 4th and 5th decades of life. Male to female ratio is 2:1.

Causes of Membranous Nephropathy

1. Idiopathic MN
2. Secondary MN

Infections: Hepatitis B, Hepatitis C, syphilis, *Plasmodium malariae*, leprosy, filariasis, chronic suppurative infections.

Neoplasia: Solid tumours: Colon, lung, rectum, sarcomas, lymphomas, leukemias.

Drugs: Penicillamine, gold, mercury, probenecid, lithium, NSAIDs.

Autoimmune disorders: Systemic lupus erythematosus, rheumatoid arthritis, mixed connective tissue disease,

Fig. 170.6: Membranous nephropathy. Note thickened capillary wall due to immune deposits on the subepithelial side of the BM. Over growth of BM between the deposits as spikes

autoimmune thyroiditis, sarcoidosis and dermatitis herpetiformis.

Miscellaneous: Renal transplantation, diabetes mellitus, Sjögren's syndrome, renal vein thrombosis, bullous pemphigoid.

Pathophysiology

The characteristic histologic abnormality under light microscopy is diffuse global capillary wall thickening in the absence of significant glomerular hypercellularity (Fig. 170.6). The capillary wall thickening is due to subepithelial immune deposits and overgrowth of the basement membrane around it. This is best demonstrated with silver-methanamine staining as 'spike and dome' appearance (Fig. 170.7). It shows diffuse granular capillary wall staining for IgG and C3. Clq staining is uncommon. Electron microscopy demonstrates the typical subepithelial immune deposits. Tubular basement membrane staining for IgG or complement and occurrence of mesangial dense deposits under EM suggest the possibility of secondary MN.

Clinical Features and Natural History

NS is of insidious onset. Hypertension and microhematuria are present in 30-50% cases. Most patients present with normal or slightly decreased renal function. The adverse prognostic factors in MN are male gender, age >50 years, severity of NS, persistence of NS for >6 months, low GFR at presentation, significant

Fig. 170.7: Diagram showing the processes in the basement membrane thickening

tubulointerstitial damage, crescents and segmental sclerosis. Of these, persistence of the nephrotic state for over 6 months is the most serious adverse factor. Women, children and young adults have relatively better prognosis. About 30% of patients undergo spontaneous remission, 30% progress to renal failure and 30% have variable degrees of proteinuria, but stable renal function. Ten percent die of non-renal causes. Rarely, spontaneous remission may occur after 36-48 months.

Treatment

Low risk patients with normal renal function and proteinuria < 4 g/day require only blood pressure control and anti-proteinuric measures. ACEI or ARBS are the drugs of choice since they act in both ways. Medium risk patients with normal or near normal renal function and proteinuria between 4-8 g/day are treated with the 'Ponticelli regimen'. This consists of pulse doses of IV methyl prednisolone 1 g/day for the first 3 days of every month for 6 months and daily oral methyl prednisolone 0.4 mg/kg/day or prednisolone 0.5 mg/kg/day in the first

month. During the next month, chlorambucil 0.2 mg/kg/day is given in place of prednisolone. Oral prednisolone and chlorambucil are used every alternate month for 6 months. More patients attain remission or remain with stable renal function with this regimen. Cyclophosphamide in a dose of 1.5-2.5 mg/kg/day can be used as an alternate drug instead of chlorambucil. Alternatively, cyclophosphamide and prednisolone are given simultaneously for 6 months.

High risk patients who have deteriorating renal function and/or proteinuria >8 gm/day should be treated with prednisolone and immunosuppressants. Cyclosporin is given in a dose of 4-5 mg/kg/day for a period of 6-12 months.

All the patients should be given supportive treatment with dietary protein restriction, control of hypertension, hyperlipidemia, and use of ACEI or ARBS as anti-proteinuric agents, oral anticoagulant therapy is also used as primary prevention for venous thrombosis in high-risk patients with serum albumin < 2 g/L. Immunosuppressive therapy is not indicated in patients with serum creatinine >4.5 mg and in those with severe chronic changes in biopsy.

Membranoproliferative Glomerulonephritis (MPGN) (Mesangio-capillary GN)

MPGN is common in children between ages of 8-16 years. There is an equal proportion of males to females.

Causes of MPGN

- I. Idiopathic MPGN → Type I, II, III
- II. Secondary MPGN:
 - Infection: Hepatitis B and C, chronic deep seated abscesses, infective endocarditis, shunt nephritis, malaria, schistosomiasis.
 - Rheumatologic diseases: SLE, scleroderma, Sjögren's syndrome, sarcoidosis, essential mixed cryoglobulinemia.
 - Malignancy: carcinoma, lymphoma, leukemia.
 - Inherited disorders: Deficiencies of α_1 antitrypsin and complements C2 and C3.

Pathogenesis

Type I MPGN is an immune complex disease but specific antigens have not been identified. The immune complex formed leads to inflammation through complement activation and proliferation of mesangial cells, endothelial cells and infiltration by inflammatory cells. In MPGN Type II, the pathogenesis is related to IgG auto-antibodies known as C3 nephritic factor (C3 NeF) which is directed against the enzyme C3 convertase. In the alternate

1. Visceral epithelial cell
2. Basement membrane
3. Interposition of mesangium between endothelial cell and basement membrane—causing thickening a capillary wall. Basement membrane is not thickened
4. Mesangial cell invading capillary wall
5. Fenestrated capillary endothelial cell cytoplasm
6. Endothelial cell
7. Increase in number of mesangial cell
8. Increase in mesangial matrix

Fig. 170.8: Line drawing showing interposition of mesangium between basement membrane and endothelium in MPGN

pathway of complement activation, C3 NeF mediates C3 breakdown leading to persistent activation of complement cascade. Hypocomplementemia is a characteristic feature of all types of MPGN. In Type I, C3 is used up for immune complex formation, and in Type II, it is continuously broken down by C3NeF.

Histology shows glomerular hypercellularity with 'double contour' appearance of GBM due to mesangial overgrowth and interpositioning in the subendothelial space of the capillary wall (Fig. 170.8). The glomeruli are enlarged and there is lobular accentuation. The proliferation is typically uniform and diffuse in idiopathic MPGN. In a few patients, crescents involving >50% of glomeruli are seen. On immunofluorescence, IgG, IgM and C3 are present on the capillary wall and mesangium.

Type II MPGN also known as 'Dense Deposit Disease', is characterized by thickening of the basement membrane due to deposition of highly refractile and eosinophilic intramembranous deposits. These deposits give the appearance of a 'string of sausages'. Immunofluorescence (IF) shows C3 deposits on the capillary wall. Type II MPGN is rarer than Type I, accounting for 15-25% of all MPGN cases. Type II MPGN may show crescentic glomerulonephritis and chronic tubulointerstitial changes on biopsy (Table 170.2).

TABLE 170.2

Differences between Type I and Type II MPGN

Type I	Type II
Mainly nephrotic presentation	Nephritic presentation more common
C3 NeF in 20%	C3 NeF in 70-80%
Terminal nephritic factor +ve in 30%	Terminal nephritic factor – Not present
Circulating immune complex in 60-70%	Circulating immune complex in 30-40%
Classical pathway of complement activation	Alternate pathway of complement activation
Recurrence in graft 30%	Recurrence in graft 100%

Type III MPGN shows, in addition to subendothelial and mesangial deposits, numerous subepithelial deposits as well.

Clinical Features and Natural History

MPGN constitutes 10 to 15% of NS in childhood and adolescence. Patients present with combined features of acute nephritic and nephrotic syndrome. It usually presents with edema, hypertension, hematuria and renal insufficiency. Respiratory tract infections may precede MPGN in 50% of patients. Persistent hypocomplementemia is the hallmark of MPGN. Partial lipodystrophy is sometimes seen in patients with complement deficiency and MPGN.

Course and Prognosis

Usually MPGN has a downhill course. The prognosis of Type II disease is worse compared to that of Type I.

Clinical remissions are very rare in Type II and patients reach ESRD by 8-10 years from onset.

Treatment

A third of patients with Type I MPGN may have spontaneous remission, a third has progressive disease and the rest show a waxing and waning clinical course without full recovery. Drug treatment offers only limited success.

Guidelines for the Treatment of MPGN

In children with non-nephrotic proteinuria and normal renal function, a trial of prednisolone 1mg/kg on alternate days is given for 3 months. If the renal function is abnormal, steroids may have to be continued for a longer period.

In adults, no specific treatment is recommended, but the patient is kept under periodic follow-up. If renal failure is present, aspirin 325 mg daily may be given for 6-12 months. ACEI and ARB help to reduce proteinuria.

Tubulointerstitial Nephritis

A. Vimala

Chapter Summary

- Introduction 1131
- Classification 1132
- Pathogenesis and Pathology 1132
- Acute Tubulointerstitial Nephritis 1133
- Chronic Tubulointerstitial Nephritis 1133

Introduction

Tubulointerstitial nephritis (TIN) includes a spectrum of diseases of different etiologies that primarily involve the interstitium. This is different from the changes occurring in the interstitium secondary to glomerular disorders. The patient can present with acute or chronic

interstitial nephritis. Many forms of tubulointerstitial injury may result from exposure to drugs or other nephrotoxic agents and infections.

Classification

Tubulointerstitial nephritis may be broadly classified as acute and chronic (Table 171.1).

Pathogenesis and Pathology

The pathogenetic mechanism in acute and chronic TIN is the same. Lethal or sublethal injury to renal cells leads to expression of new local antigens, inflammatory cell infiltration, and activation of proinflammatory and chemoattractant cytokines. These cytokines are produced by inflammatory cells such as macrophages and lymphocytes and also by the renal cells such as proximal tubular cells, vascular endothelial cells, interstitial cells and fibroblasts. The outcome can be acute or chronic TIN. The histopathology of acute TIN is shown in Figure 171.1. The interstitium shows inflammatory cell infiltrate. In chronic TIN there is tubular atrophy, interstitial scarring and fibrosis (Fig. 171.2). Glomeruli are normal in primary TIN till advanced stages of the disease.

Fig. 171.1: Acute interstitial nephritis in renal biopsy. Note: Interstitial edema with infiltration with eosinophils and some cells even in the lumen of renal tubules. No glomeruli are seen in this high power view. They appear normal in acute interstitial nephritis

TABLE 171.1

Causes of tubulointerstitial nephritis	
1. Acute tubulointerstitial nephritis	
Drugs	
•	Nonsteroidal anti-inflammatory drugs [NSAIDs] nimuselide, ibuprofen, diclofenac, indomethacin, Cox2 inhibitors
•	Antibiotics – rifampicin, penicillins, sulfa drugs
•	Diuretics – thiazide, frusemide
•	Anticonvulsants – phenytoin, valproate
•	Miscellaneous – indinavir, captopril, allopurinol
Infections	
•	Spirochetes: leptospirae
•	Bacterial: acute bacterial nephritis
•	Viral: cytomegalovirus [CMV], Hantavirus, HIV
•	Fungal: histoplasmosis
•	Parasitic: lymphatic filariasis
•	Immunologic diseases – Lupus erythematosus, Goodpasture's syndrome, Sjögren's syndrome, acute transplant rejection
2. Chronic tubulointerstitial nephritis	
•	Analgesic nephropathy, cyclosporin nephrotoxicity
•	Drugs: lithium, tacrolimus
•	Heavy metals: lead, cadmium, mercury
•	Obstructive nephropathy, nephrolithiasis, reflux nephropathy
•	Immunologic diseases: lupus erythematosus, Sjögren's syndrome, amyloidosis
•	Primary glomerulopathies, sarcoidosis, vasculitides such as - antineutrophil cytoplasmic antibody vasculitis and Wegener's granulomatosis
•	Chronic transplant nephropathy
•	Neoplasia: myeloma, leukemia
•	Sickle cell anemia
•	Atherosclerotic kidney disease (ischemic) - cholesterol microembolism
•	Metabolic diseases: hypercalcemia, cystinosis, hypokalemic nephropathy, hyperoxaluria
•	Genetic disorders: Alport's syndrome, medullary cystic disease
•	Miscellaneous: Balkan endemic nephropathy, Chinese herbal/Aristolochia nephropathy and other toxins.

Clinical consequences of functional disturbances of interstitium is shown in Table 171.2.

TABLE 171.2

Clinical consequences of TIN	
Functional disturbance	Clinical consequence
Damage to proximal tubule	Type II renal tubular acidosis (RTA), Fanconi's syndrome (phosphaturia, renal glycosuria, aminoaciduria, bicarbonaturia and RTA
Damage to distal tubule	Type I renal tubular acidosis, salt wasting, hypokalemia
Damage to medullary tubules and vasculature	Polyuria, isosthenuria
Obstruction to tubules	Reduction in GFR

Fig. 171.2: Chronic interstitial nephritis in renal biopsy. Note: The glomerulus is near an area of interstitial scar and shows segmental area of sclerosis (arrow). There is scarring and tubular atrophy. Some tubules are relatively normal

Acute Tubulointerstitial Nephritis

Acute renal failure is the most common presentation of acute tubulointerstitial nephritis. Renal failure is usually non-oliguric but rarely can present with anuria. Patients commonly present with rash, fever, arthralgia, arthritis, eosinophilia, eosinophiluria, and elevated immunoglobulin E (IgE) levels. Renal involvement can be subtle and the only manifestation may be hematuria or Fanconi's syndrome. Urinalysis may show microscopic hematuria and/or sterile pyuria with or without eosinophils. Proteinuria is usually less than 2 g in 24 hours. Nephrotic syndrome does not occur. Renal biopsy is required to make a definite diagnosis. Withdrawal of the offending agent usually results in complete recovery. In some patients renal failure persists for many weeks before improvement occurs.

Acute Tubulointerstitial Nephritis Caused by NSAIDs

Pathogenesis NSAIDs block the cyclooxygenase pathway and hence cause preferential conversion of arachidonic acid to leukotrienes. This will activate helper T cells, release various inflammatory mediators like cytokines and result in inflammation of the interstitium.

All NSAIDs including specific Cox2 inhibitors can result in TIN. This should be differentiated from hemodynamically mediated ARF which is more common in patients with renal impairment.

Clinical features include rash, fever, arthralgia, arthritis, eosinophilia and eosinophiluria. Patients may have nephrotic proteinuria due to glomerular involvement. Renal biopsy is diagnostic and may show granulomas. Spontaneous recovery occurs within weeks to months of withdrawal of the drug. Topical preparations of these drugs should be stopped as they can be absorbed. Relapse may occur with subsequent administration.

Treatment – If the renal function is markedly deranged, dialysis support is given till recovery occurs. If renal failure persists for more than 2 to 3 weeks after stopping the drug, a short course of steroids may be tried.

Antibiotic-induced Acute TIN

This is usually observed during antibiotic treatment and occurs after initiation of antibiotic therapy. Renal failure develops along with rash, eosinophilia, and eosinophiluria. Sterile pyuria, hematuria, and proteinuria usually <1 g/day occurs. Nephrotic range proteinuria is very rare. Renal biopsy may show eosinophils in the interstitium.

Rifampicin: Intermittent therapy with rifampicin is associated with TIN. It occurs when the antibiotic is reintroduced after an interval. Usually it presents with flu-like syndrome such as fever, arthralgia, skin rash, flank pain, hypertension and oliguria. Some patients may have circulating anti-rifampicin antibodies and immunoglobulin G (IgG) deposits along the tubular basement membranes.

Acute TIN Caused by Miscellaneous Agents

Infections by spirochetal, viral, bacterial and fungal infections may be occasionally associated with acute TIN. Pathogenetic species of leptospirae - *L. interrogans* is a common cause of ARF in several parts of India.

Leptospirosis: ARF in leptospirosis is due to multiple causes. Hypoperfusion of the kidneys from hypovolemia is the most common cause. Leptospirae can traverse the glomerular capillaries, enter the interstitium and cause TIN. The renal failure is usually reversible and it does not progress to chronicity.

Hantavirus, CMV, and HIV are associated with acute interstitial nephritis. In HIV disease, acute interstitial nephritis is usually observed in conjunction with glomerular disease (i.e., focal segmental glomerulosclerosis). Parenchymal invasion by the virus is not always present and other characteristic features such as eosinophilia and fever, are usually absent.

Acute bacterial nephritis: This is due to direct bacterial infection of the kidneys. Patients present with high grade fever, rigor loin pain and anuric renal failure. Kidneys are enlarged and palpable. Ultrasonography shows large kidneys, but CT scan and MRI are diagnostic. It shows micro-abscesses in the medulla. Patients improve with appropriate antibiotic therapy.

Chronic Tubulointerstitial Nephritis

The chronic form is an insidious disease which progresses slowly. Clinical presentation may be as anemia, and /or bone disease. Children may present

TABLE 171.3

Differences between interstitial and glomerular diseases		
Clinical feature	Interstitial disease	Glomerular disease
Edema	Usually absent till late	Edema early
Blood pressure	Normal or low	High
Anemia	Disproportionate to decline in GFR	Proportional to decline in GFR
Bone disease	Rickets / osteomalacia	Not common
Neuromuscular symptoms	More common	Not common
Nephrotic proteinuria	Absent	Pathognomonic
Hematuria	Rare	Dysmorphic RBCs / RBC casts
WBCs in urine	Sterile pyuria, pus cell casts	Usually absent

with failure to thrive, growth retardation and rickets. Evaluation for anemia or rickets may reveal elevated renal parameters.

The differentiating features between glomerular and interstitial disease is shown in Table 171.3.

Analgesic Nephropathy

Analgesic nephropathy is the most common category of chronic interstitial nephritis worldwide. There is higher incidence in women in the sixth and seventh decades of life. This disorder occurs with long-term ingestion of combinations of phenacetin, aspirin, and caffeine or phenacetin-acetaminophen or NSAIDs and acetaminophen. In its most severe form, it is associated with papillary necrosis. The amount of phenacetin-acetaminophen combination required to cause chronic interstitial nephritis has been estimated to be at least 5-6 kg over many years . Clinically, patients with analgesic nephropathy present with renal insufficiency, modest proteinuria, sterile pyuria, and anemia. Diagnosis can be supported by history of heavy analgesic use and features of chronic interstitial nephritis. Microcalcifications at the papillary tips may be demonstrated on CT. It is often associated with uroepithelial malignancies and eventually progresses to end stage kidney disease. Extrarenal manifestations include psychosis, accelerated atherosclerosis, and acid peptic disease. Treatment is supportive and includes discontinuation of analgesic use.

Cyclosporin- and tacrolimus-induced nephropathy:

Chronic tubulointerstitial nephritis is associated with long- term use of cyclosporin. Most kidney transplant recipients have a stable course with mild impairment of renal function, up to 10% of heart transplant recipients develop progressive renal insufficiency and eventually require dialysis. Patchy striped interstitial fibrosis on renal biopsy is diagnostic.

Lead nephropathy: The major consequence of chronic lead poisoning is chronic tubulointerstitial disease usually in the third to fourth decades of life. This is an occupational hazard in painters, welders, smelters and battery workers. The diagnostic triad is chronic TIN, gout and hypertension.

Chinese herb nephropathy and TIN due to drugs from alternative systems of medicine:

Chinese herbal medicines used for weight reduction containing aristolochic acid can produce chronic TIN. Renal biopsies show severe interstitial fibrosis. Some drugs from alternate systems of medicine contain unknown quantities of various heavy metals or other toxic substances which may lead to chronic TIN.

Miscellaneous causes like obstructive uropathy, atherosclerotic kidney disease, cholesterol microembolic disease and metabolic disorders are other causes of chronic TIN.

Chapter Summary

Introduction 1135

Uncomplicated Urinary Tract Infection 1135

Complicated Urinary Tract Infection 1136

Investigations 1136

Introduction

Urinary tract infection (UTI) is a common problem in the community. It is more common in women of childbearing age and in older individuals. Normally, colonization of bacteria in the urinary tract is prevented by numerous defense mechanisms. The flow of urine, the presence of mucus coat in the stratified squamous epithelium, the high concentration of urea in the urine, osmolality, lack of nutrients like glucose in the normal urine and certain normal ingredients like Tamm Horsfall protein prevent the adherence of bacteria to the urothelium. When any of these defense mechanisms are defective, bacteria may adhere to the urothelium, colonise and cause bacteriuria. Depending on the virulence of the organism, manifestations of UTI vary.

UTI is defined as the presence and multiplication of bacteria in the urinary tract. Since contamination of urine with peri-urethral flora occurs, urine collection must be meticulous.

Significant bacteriuria is defined as the presence of 10^5 or more colonies of the same organism per mL of urine in females. In males, since the chances of contamination is less likely, presence of even 10^4 or more of same organism per mL of urine is taken as significant.

Rarely infections of urinary tract without bacteriuria may occur in pyogenic renal abscess, perinephric abscess, prostatitis or infection of renal cysts.

Urinary tract infection may be uncomplicated or complicated, upper or lower. The clinical features, diagnosis, treatment and prognosis vary depending on the organism, site of infection and structural and functional integrity of the urinary tract.

Uncomplicated Urinary Tract Infection

This term denotes the occurrence of infection in a normal urinary tract, unassociated with diseases like diabetes mellitus, analgesic abuse and immunosuppression or recent urological interventions. Females in the reproductive age are more often affected. 80% of the infections are due to *E. coli*. The colonisation of vagina and urethra occurs from the perianal region. They ascend to the bladder and from there to the upper tract. Factors predisposing to infection in women of child bearing age include migration of bacteria from the peri-urethral region to the bladder during sexual intercourse. The use of spermicidal jellies may alter the normal vaginal flora and predispose to infection. Some women have genetically determined increase in the number of receptors for *E. coli* in the urothelial cells. In addition, bacterial fimbriae and production of bacterial products enable adherence of bacteria to the urothelium.

Acute Bacterial Cystitis

This is the most common type of urinary infection in females. In addition to *E.coli*, *Staph. saprophyticus* infection may be encountered in few cases. The typical symptoms are dysuria, increased frequency, urgency, voiding small volumes of urine and lower abdominal and suprapubic pain. The urine may be foul smelling and blood stained. Systemic symptoms like fever, loin pain and tenderness may be absent and does not lead to renal damage.

Urethral Syndrome

These patients have symptoms similar to cystitis, but without significant bacteriuria. This is because the common organisms that produce urethral syndrome like *Ureaplasma urealyticum*, *Mycoplasma hominis*,

lactobacilli and other microaerophilic bacteria do not grow in the conventional cultures.

Urethritis and Vulvovaginitis

The combination of urethritis with vulvovaginitis occurs in sexually transmitted infections like *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Herpes simplex virus*, *Candida* or *Trichomonas* infection. The onset of symptoms is gradual and is often mild in severity. The patient may have foul smelling vaginal discharge and dysuria for a long time. The sexual partners may also have lower urinary symptoms.

Acute Pyelonephritis

This is due to infection of the upper urinary tract. Pathologically the kidneys are swollen. Microscopically they show focal inflammatory reaction with neutrophil and monocyte infiltration, tubular damage and interstitial edema.

It presents characteristically with constitutional symptoms such as high grade fever, chills and rigor, headache, nausea and vomiting. Local symptoms include flank pain, loin tenderness and burning micturition. In severe cases, gram-negative septicemia, shock and renal failure may supervene.

Complicated Urinary Tract Infection

In this condition, there is pre-existing anatomical or functional abnormality of the urinary tract or presence of systemic diseases like diabetes. UTI occurring in males is invariably complicated.

Factors associated with complicated UTI are:

- 1. Diabetes mellitus
- 2. Pregnancy
- 3. Nephrolithiasis
- 4. Neurogenic bladder
- 5. Urinary tract obstruction
- 6. Renal failure
- 7. Vesico-ureteric reflux
- 8. Foreign body in the urinary tract
- 9. Renal transplant recipient
- 10. Instrumentation of urinary tract.

Investigations

Urinalysis: The urine may be turbid, blood stained and foul smelling. The pH of the freshly voided urine depends on the pathogenic bacteria. *E.coli* and *klebsiella* infections cause acid urine. *Proteus* infection causes alkaline urine. Mild proteinuria may be present. Urine microscopy often shows pus cells and pus cell casts. A clean catch

midstream urine specimen is taken before starting treatment. If such specimens are difficult to obtain as in small children a suprapubically aspirated bladder urine specimen is used for culture. Hemogram, blood glucose and renal function tests are done in all cases.

Ultrasonography is performed routinely for all patients since in 5% of patients structural abnormalities are detectable. Such patients require more detailed evaluation. Imaging during the acute phase is necessary mainly to rule out conditions like pyonephrosis, abscesses, perinephric lesions, urinary tract obstruction or presence of air in parenchyma or collecting system. Repeat ultrasonogram done 3-6 weeks after cure of infection helps to identify renal scars.

Other investigations include plain X-ray abdomen to rule out stones or calcifications. Intravenous urography is done to localise calculi in the calyces or pelvis, delineation of the collecting system, obstruction to the drainage system and the presence of papillary necrosis. Medullary sponge kidney, scars developing in reflux nephropathy and congenital abnormalities like cysts and others can be visualized. In addition, the IVU also gives reliable information about renal functional parameters. Computed tomography is required in selected cases to identify small renal abscess, minimal pelvicalyceal dilatation and detection of air and small radiolucent calculi. Isotope renography using Technetium (⁹⁹Tc) labelled dimercaptosuccinic acid (DMSA) is useful to detect severe parenchymal infections and scars. Scans using ⁹⁹Tc labelled diethylenetriamine penta-acetic acid (DTPA) are useful to study the vascularity, function and obstruction to the upper tract. The other investigations which are useful are micturating cystourethrography to rule out vesicoureteric reflux (VUR), urodynamic studies to assess the bladder pressure, sphincter tone, and cystoscopy to visualize the bladder.

Cystoscopy is indicated in older patients with severe hematuria in order to exclude bladder cancer. Patients with recurrent or persistent unexplained frequency and dysuria who have sterile urine also require this investigation.

Treatment

Regimen is shown in Table 172.1.

Relapsing infection is defined as recurrence of symptoms and bacteriuria with the same organism within three weeks of treatment. The urine culture at the end of treatment is usually negative. Relapse indicates failure to eradicate the organism. Such patients have to be investigated further and carefully followed up. Patients given single dose therapy may harbor the organisms in the periurethral area

Reinfection is defined as infection with a different organism after 7-10 days of treatment. This is more common than relapse. Reinfection with the same bacterial

TABLE 172.1

Treatment of bacterial urinary tract infection				
Condition	Common pathogens	Associated conditions	Treatment schedules	Duration
Uncomplicated acute cystitis in women	<i>E.coli</i> , <i>Staph.saprophytics</i> , <i>Proteus mirabilis</i> , <i>Klebsiella pneumoniae</i>	Nil	Trimethoprim + sulphamethoxazole, fluoroquinolones	3 days
Uncomplicated acute pyelonephritis in women	<i>E.coli</i> , <i>Klebsiella</i> <i>Staph.saprophyticus</i>	Nil	Amoxycillin, nitrofurantoin, cephalosporins	7 days
Complicated acute cystitis in women	<i>E.coli</i> , <i>Staph. saprophyticus</i> , <i>Proteus mirabilis</i> , <i>Klebsiella pneumoniae</i>	DM, symptoms > 7 days, recurrent UTI	Trimethoprim + sulphamethoxazole, fluoroquinolones	7 days
Complicated acute cystitis in pregnancy	<i>E.coli</i> , <i>Staph. saprophyticus</i> , <i>Proteus mirabilis</i> , <i>Klebsiella pneumoniae</i>	Pregnancy	Amoxycillin, nitrofurantoin, cephalosporins	7 days
Complicated UTI	<i>E.coli</i> , <i>Klebsiella</i> , <i>Proteus</i> , <i>Pseudomonas</i>		Oral amoxycillin, fluoroquinolones, cephalosporins (as out patient)	14 days
Complicated UTI	<i>E.coli</i> , <i>Klebsiella</i> , <i>Proteus</i> , <i>Pseudomonas</i>	Severe infection, pregnacy	Parenteral antibiotics – ampicillin, aminoglyco- sides, fluoroquinolones, cephalosporins (as inpatient)	14 days
Acute urethral syndrome	Urea plasma urealyticum Mycoplasma hominis	Sexual activity Non-gonococcal urethritis 'Dysuria-pyuria'	Doxycycline	5 days

Note : Fluoroquinolones are to be avoided in pregnancy

species can occur if the organism persists in peri-urethral area or in the fecal reservoir.

Chapter Summary

- Introduction 1137
- Types of Renal Stones 1138
- Clinical Features 1138
- Diagnosis 1139
- Management 1139

Introduction

Renal stone disease occurs worldwide and has been recognised as a medical problem even from the BC era. Urine contains various solutes dissolved in water. The concentration of urine changes depending on the amount of water and the solutes. When the concentration of solutes in urine increases, it reaches a state of saturation. Saturation is the point at which the water and the minerals dissolved in the urine are in equilibrium and precipitation does not occur below this level. Further increase in solute load leads to supersaturation. Supersaturation is the level beyond which addition of further solute invariably results in crystallisation. The stage between saturation and supersaturation is the metastable zone. In this stage, crystallisation occurs if other factors are favorable.

The term nephrocalcinosis suggests calcification of renal parenchyma. Nephrocalcinosis may be cortical or medullary. Nephrolithiasis is defined as the occurrence of stones in the collecting system of the kidney. Nephrocalcinosis and nephrolithiasis may coexist. Often nephrolithiasis starts by the aggregation of crystals on a nidus. The Nidus can be glycoprotein matrix, injured epithelium, foreign body or another crystal. Once such a nidus is formed and the urine saturation remains in the metastable zone or it is supersaturated, aggregation of crystals occurs over the nidus and the crystal grows in size to form a stone. There are inhibiting factors in normal urine which prevent stone formation.

The natural inhibitors include citrate, Tamn–Horsfall protein, glycosaminoglycans, nephrocalcin and uropontin.

Deficiency of natural inhibitors in urine is an important factor contributing to formation of urinary stones. Stone disease is more common in adults, particularly males. It shows variability in incidence from region to region. The geographical peculiarities and quality of drinking water in areas with arid climate favor stone formation. This stone belt includes areas of northwestern part of India, Pakistan, Afghanistan, Iran, Iraq and Turkey, eastern Europe and the Middle East countries. Idiopathic renal lithiasis accounts for 60-80% of stone disease. The inherited tubular or enzymatic abnormalities constitute only less than 1% of the stone forming population. Etiologic classification of urolithiasis is shown in Table 173.1.

Types of Renal Stones

Renal stones can be broadly classified into *radiopaque* and *radiolucent stones*. The commonest radiolucent stone is uric acid stone. Less common radiolucent stones include xanthine and hypoxanthine stones. Radiopaque stones constitute the majority of renal stones. All calcium

TABLE 173.1

Etiologic classification of urolithiasis

1. Hypercalcemic states
 - i. Primary hyperparathyroidism
 - ii. Immobilization
 - iii. Hypervitaminosis D
 - iv. Neoplasia
 - v. Milk alkali syndrome
 - vi. Sarcoidosis
2. Uric acid lithiasis
 - i. Idiopathic uric acid stones
 - ii. Gout
 - iii. Myeloproliferative disorders
 - iv. Acidic urine and oliguric states
3. Idiopathic renal lithiasis
 - i. With hypercalciuria
 - ii. Without hypercalciuria
 - iii. Hyperuricosuria
 - iv. Hyperoxaluria
 - v. Hypocitraturia
 - vi. Increased urine alkalinity
4. Renal tubular syndrome and enzyme abnormalities
 - i. Distal renal tubular acidosis
 - ii. Carbonic anhydrase inhibitors
 - iii. Hyperoxaluria
 - iv. Cystinuria
 - v. Xanthinuria
5. Drugs
 - i. Triamterene
 - ii. Acyclovir
 - iii. Indinavir
 - iv. Sulphonamides

Secondary Nephrolithiasis

1. Cystic renal diseases
2. Urinary diversion procedures
3. Stents, suture materials
4. Catheters

containing stones are radiopaque. Hypercalcemia, hypercalciuria, hyperoxaluria, hyperuricemia, hypocitraturia, high protein intake and low liquid intake are the risk factors for calcium stones. It is also common in those consuming large volumes of carbonated beverages. Stones are more common in persons with urinary tract infection and in those taking drugs like triamterene, acyclovir, indinavir and sulpha drugs. For unknown reasons, it is more common among vasectomized individuals and in hypertensives.

Clinical Features

Patients may remain asymptomatic and stones may be detected incidentally on X-ray or during ultrasound examination. The most common symptom is colicky pain often associated with macroscopic or microscopic hematuria. Increased WBC excretion may be seen in many cases of stone disease. The pain due to stone in renal

pelvis is often abrupt in onset, intense in severity, intermittent and radiates from groin to loin. The colic due to mid-ureteric stone is characterized by radiation to testes or labia. Bladder stone are usually associated with frequency, strangury, urgency or dysuria. The lower urinary symptoms are due to irritation of the trigone of the bladder by the stone. The patient may experience dull dragging suprapubic or perineal pain as well. Interrupted urinary stream may occur if the stone is moving freely in the bladder or partially impacted in the lower urinary tract. General symptoms like sweating, nausea and increased frequency also occur. Stone can cause obstruction, secondary infection, pyonephrosis and renal failure. Anuria may occur when the obstruction is bilateral and complete or if the urethra is totally blocked. When a patient presents with a history of not passing even a drop of urine, total obstruction should be ruled out by appropriate procedures. Even in the most severe forms of glomerulonephritis or tubular necrosis the urine output may be at least a few milliliters in 24 hours. Strangely a person with partial obstruction to urinary system will present with polyuria rather than oliguria. This is due to associated tubular abnormality resulting from the back pressure due to obstruction.

In secondary urolithiasis, infection or obstruction appear to be the primary cause of stone formation. Infection with bacterial organisms that produce urease, results in the breakdown of urea to ammonia resulting in liberation of bicarbonate. Thus the urine is alkalinized. Alkaline urine favours the precipitation of calcium, magnesium and ammonium phosphate resulting in triple phosphate stones (*struvite stones*). These stones are less radiodense than pure calcium oxalate stones. They are often laminated and have branched or staghorn configuration. The stones that are formed in the dilated collecting system due to partial obstruction often contain phosphate. *Cystine stones* occur in cystinuria. It is a genetic disorder of amino acid metabolism with autosomal recessive inheritance. Abnormal transport of the amino acids – cystine, ornithine, arginine and lysine (COAL) results in increased urinary excretion and stone formation. In homozygous individuals, cystine stones are more common. These stones are moderately radiopaque and appear homogenous. They are usually large and surrounded by smaller satellite stones.

Primary hyperoxaluria is an inherited disorder of glyoxalate metabolism resulting in increased urinary excretion of oxalate. Two types of enzyme abnormalities are recognized. Type I (glycolic aciduria) due to deficiency of peroxisomal alanine glyoxalate aminotransferase (PAGA) and Type II (L glyceric aciduria) due to deficiency of D glyceric dehydrogenase. Both enzyme disorders results in hyperoxaluria, stones, nephrocalcinosis and renal failure. Oxalate stones are extremely radio-dense and non-branching.

Diagnosis

In nephrolithiasis and urolithiasis, metabolic or secondary causes for stone formation should be excluded. The recognition of stone forming risk factors is also important.

Laboratory evaluation includes urinalysis, urine culture and determination of antibiotic sensitivity. If urine culture is sterile, fasting urine pH is done to assess acidification ability of the kidney. A 24 hours urine chemistry of calcium, phosphorus, uric acid, oxalate, cystine, citrate and creatinine are also assessed to rule out hypercalciuria, hyperuricosuria, hyperoxaluria and hypocitraturia. Other investigations include estimation blood urea, serum creatinine, serum calcium, phosphorus, uric acid, sodium, potassium, chloride, and bicarbonate. Ultrasound examination of kidneys and urinary system not only detects the presence of stones but also the site of obstruction if any. Ultrasound examination is the most useful investigation to detect the presence, severity and site of obstruction due to stone. It is non-invasive and can be performed repeatedly. Plain X-ray abdomen for kidney, ureter, bladder and urethra (KUBU) will detect the radio-paque stones. Intravenous urography (IVU) helps to assess the renal function apart from detecting the radiolucent stones as filling defect and the level of obstruction. Biochemical analysis of stone helps to plan treatment. CT scan abdomen may be used as needed. Once the diagnosis is made the activity of the stone is assessed by the criteria in Table 173.2.

Management

Management of stone depends on the position, size, symptoms and the ‘activity’. When a patient presents with acute or severe colicky pain, the management includes hydration and administration of analgesics, antispasmodics and relief of obstruction. Often the small calculi in the urinary tract are washed off, if the urine flow rate is

TABLE 173.2	
Classification of the ‘activity’ of stone	
1.	Surgically active stones Stone associated with colic, obstruction, infection or bleeding
2.	Indeterminate metabolic activity All stones which are not surgically active are initially classified as indeterminate metabolic activity
3.	Metabolically active stones Evidence of new stone formation or stone growth within one year
4.	Metabolically inactive urolithiasis No evidence of stone formation or growth in one year of follow-up
5.	Secondary urolithiasis

increased with oral or intravenous fluid administration combined with antispasmodics and diuretics. The general measures for the medical management of stone disease include.

Dietary Modification

The fluid intake is increased so that the urine volume is more than 2.5 litres in 24 hours. High fluid intake is encouraged to reduce the recurrence or growth of urinary stone. Animal proteins, dietary sodium, oxalate rich foods such as leafy vegetables, spinach, rhubarb, chocolate and nuts, carbonated beverages and excessive vitamin C intake should be avoided. Normal calcium intake should be encouraged. Patients with hypercalciuria benefit from treatment with thiazide diuretic combined with potassium citrate. Thiazides decrease calcium excretion in urine. The administration of citrate or citrus fruits is also beneficial in patients with hypocitraturia. Hyperuricosuria is commonly encountered in patients with stone disease. If hyperuricemia and uricosuria are present, allopurinol 200-300 mg a day combined with potassium citrate is given so as to maintain an alkaline urine pH. Long-term alkalinisation of urine helps to dissolve uric acid stone by increasing its solubility. High protein intake in the form of red meat is avoided in such cases. In stone disease with hyperoxaluria, in addition to dietary modifications, oral calcium citrate is used to bind citrate in the gut. Oral pyridoxine is also beneficial. In cystinuria alkalinisation of urine, reduction of dietary sodium and meat combined with measures to increase the urine output to more than 3 liters per day may help to reduce recurrence rate. D-penicillamine, captopril or Vit. B₆ may also be useful. In infection related stones treatment of infection and modi-

fication of urine pH (acidification if initial pH is alkaline and vice versa) and long-term antibiotic prophylaxis are beneficial.

For those with family history of stones, bone disease, gout, chronic UTI and nephrocalcinosis, more extensive investigations are required. The presence of a silent stone detected by X-ray or ultrasonogram alone is not an indication for aggressive investigation and / or treatment. A surgically active stone which is not passed spontaneously or with hydration or following various modalities of minimally invasive nature may be considered for surgical removal. The minimally invasive procedures for stone powdering and removal include:

- 1. **Extracorporeal shock wave lithotripsy (ESWL):**
It is useful for small stones less than 2.5 cm in diameter, stones in the renal pelvis and those in the upper third of the ureter. The stones are powdered or pulverized using shock waves administered from outside the body and directed to the stone.
- 2. **Ureteroendoscopy for stone in ureter:**
In ureteroendoscopy an ultrasound probe is passed 'through the cystoscope and sound energy is used to pulverize the stone. Usually a stent is also placed to enable the smooth passage of the stone fragments.
- 3. **Percutaneous nephrolithotomy (PCNL)** is another procedure whereby the stones are approached through the loin through an ultrasound guided nephrostomy. This procedure is usually undertaken if there is significant hydronephrosis and the stone is sufficiently large and incapable of passing through the ureter.
Open surgical methods are used only if other minimally invasive procedure fail or are not possible. A systematic approach in the diagnosis and management of stone disease helps to avoid long-term renal complications like the kidney failure and infections.

Kidney in Systemic Diseases

M. Thomas Mathew

Chapter Summary

- Diabetic Nephropathy (DN) 1141
- Systemic Lupus Erythematosus (SLE) 1142
- Rheumatoid Arthritis (RA) 1143
- Sjögren's Syndrome (SS) 1143
- Progressive Systemic Sclerosis (PSS) 1143
- Mixed Connective Tissue Disease (MCTD) 1143

- Polyarteritis Nodosa (PAN) 1143
- Churg-Strauss Syndrome 1143
- Microscopic Polyarteritis 1144
- Wegener's Granulomatosis (WG) 1144
- Henoch-Schönlein Purpura (HSP) 1144
- Mixed Cryoglobulinemia 1144
- Takayasu's Arteritis 1144

Amyloidosis 1145

Multiple Myeloma 1145

Renal Lesions Associated with Neoplasia
1146

Tumour Lysis Syndrome 1146

Kidneys are often involved in many metabolic, immune mediated, infective, neoplastic and congenital diseases. Kidney involvement may be the predominant manifestation or it may be a minor part of the systemic illness. A brief outline of the renal involvement in important systemic diseases affecting the kidney is given below. The student should also refer to the appropriate chapters where the diseases are described in detail.

DIABETIC NEPHROPATHY (DN)

The renal involvement in diabetes can be related to duration of diabetes, glycemic control, genetic susceptibility, atherosclerosis, hypertension and pattern of hyperlipidemia. Diabetes mellitus is the leading cause of End Stage Renal Disease (ESRD). Most cases of Type 1 (IDDM) and Type 2 (NIDDM) diabetes mellitus eventually develop diabetic nephropathy and to ESRD over the course of many years. Hyperglycemia is the most important factor inducing glomerular and mesangial injury through different mechanisms like formation of advanced glycation end products (AGE), activation of protein kinase-C (PKC) and generation of reactive oxygen species (ROS). The most common lesions involve the glomeruli and include capillary basement membrane thickening, expansion of the glomerular mesangium and increased secretion of mesangial matrix leading to diffuse or nodular sclerosis of the glomeruli. This is the hallmark of diabetic nephropathy. Exudative lesions like capsular drops, formation of fibrin caps and hyalinosis or arteriosclerosis of afferent arterioles are also seen. Slight increase in urinary albumin excretion called 'microalbuminuria' can be measured only by sensitive methods and is the earliest clinical manifestations of involvement of kidney in diabetes. In healthy normal adults, urinary albumin excretion in 24 hours is less than 30 mg/day (20 microgram/minute). Microalbuminuria is diagnosed when at least 2 out of 3 urine samples examined within a 6 weeks period shows more than 30 mg/24 hrs. The range for microalbuminuria is 30-300 mg/24 hours. When urinary albumin excretion is > 300 mg, it can be detected by the conventional laboratory tests for albumin or by 'albustix'. It is established that those with microalbuminuria have increased risk of developing overt diabetic nephropathy, renal failure and cardiovascular complications in future. The urine sample for microalbuminuria should be collected only when the diabetic state

is well controlled, hypertension is controlled, and the patient has no urinary infection.

The course of diabetic nephropathy often pass through five different stages. Any one who is having clinical diabetes is already in:

Stage I: Soon after the onset of diabetes, the kidney size enlarges (nephromegaly), renal blood flow increases, GFR increases. Blood pressure is typically normal at this stage. This is the stage of hypertrophy and hyperfunction. Tight control of diabetes arrests of progression to the next stage.

Stage II: Once diabetes has been present for more than 5 years or more, patient may pass on to a stage of incipient latent diabetic nephropathy which is characterized by reversible microalbuminuria of >30 mg/24 hrs particularly when the diabetic and hypertensive states are poorly controlled, or the patient undergoes physical exertion. This is the stage of intermittent microalbuminuria. In this clinically silent stage, there is thickening of glomerular and tubular basement membrane, expansion of mesangial matrix and increase in blood pressure. The illness may progress to stage III within 5-7 years.

Stage III: This stage typically occurs 10-15 years after the onset of the diabetic state and it is characterized by the progression of microalbuminuria to "overt" proteinuria or macroalbuminuria, i.e. with urinary albumin excretion of at least 300 mg/24 hours, corresponding to overt proteinuria of >500 mg/24 hours. Patient may become nephrotic and the blood pressure is elevated. The natural history of the disease is progressive with gradual fall in GFR. Histologically, there is diffuse or nodular glomerulosclerosis as well as arteriosclerosis and tubulointerstitial fibrosis.

Stage IV: In the next 4-5 years, progression to advanced nephropathy takes place. This stage is marked by nephrotic range of proteinuria (>3.5 g/24 hr), overt hypertension and rapid fall in GFR with elevated urea and creatinine, the stage of Kimmelstiel-Wilson syndrome.

Stage V: In another 1-3 years' time, the disease progresses further to end stage renal disease (ESRD) with severe hypertension and cardiac failure requiring dialysis or renal transplantation.

More than 60% of patients with diabetic nephropathy also have diabetic retinopathy and neuropathy—the so called "triopathy" of the microvascular complication of diabetes. Patients may also have other renal and genitourinary manifestations of diabetes. These include tubular proteinuria, fluid-electrolyte disorders, hypercalciuria, hyperkalemia, hypoaldosteronism, type IV distal renal tubular acidosis (RTA), papillary necrosis, emphysematous pyelonephritis, xanthogranulomatous pyelonephritis and others.

Treatment

Tight glycemc control with strict diet, insulin and oral antidiabetic drugs is the mainstay in the prevention and treatment of diabetic nephropathy. Normalization of blood pressure is equally important and is achieved by using a combination of angiotensin-converting enzyme inhibitors (ACE-I) and angiotensin-receptor blockers (ARBs). Lipid lowering agents, diuretics and antioxidants also help in retarding the progression of nephropathy. It is prudent to avoid high protein diet in overt nephropathy or ESRD. The average nonvegetarians and all vegetarians may continue to take their ‘normal’ protein intake. Once patient develops ESRD, renal replacement therapy should be initiated. Kidney transplantation is preferable to dialysis therapy because of the risk of infection and vascular access problems due to the atherosclerotic vessels in these patients. In most of the nephrology centers in India, diabetic nephropathy accounts for a major portion of the work load and renal replacement services. Combined pancreas – kidney transplantation achieves the best medical rehabilitation.

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

(See also Section 12, Chapter 108)
Renal involvement occurs in over two-third of patients with SLE. Although the immunologic abnormalities of lupus can virtually affect any organ system, renal involvement is a major cause for morbidity and mortality. Renal involvement is extremely diverse ranging from asymptomatic urinary findings to nephrotic syndrome or fulminant renal failure.

The pathogenesis of SLE is complex and multifactorial. Immunologic dysregulation leads to production of autoantibodies to nuclear and other cellular antigens. The term “lupus nephritis” or “lupus glomerulonephritis” is commonly applied to the many patterns of glomerular involvement in SLE. This includes mesangial lesions, membranous patterns and proliferative lesions. The World Health Organization (WHO) has classified lupus nephritis on the basis of histopathology for proper diagnosis and uniformity in the management.

Modified WHO Classification of Lupus Nephritis

Class I	Normal Glomeruli (by LM, IF, EM)
Class II	Pure mesangial alteration a. Normal by LM, mesangial deposits by IF, EM b. Mesangial hypercellularity and deposits by IF, EM

Class III	Focal segmental glomerulonephritis a. Active necrotizing lesions b. Active and sclerosing lesions c. Sclerosing lesions
Class IV	Diffuse glomerulonephritis (severe mesangial, endocapillary or mesangiocapillary proliferation or with crescents)
Class V	Diffuse membranous glomerulonephritis a. Pure membranous b. Associated with sclerosis c. Associated with focal or segmental proliferative lesions
Class VI	Advanced sclerosing glomerulonephritis
LM – Light Microscopy, IF – Immunofluorescence, EM – Electron microscopy	

The clinical presentation varies from mild or moderate proteinuria, microhematuria and telescoped urinary sediments or with hypertension and renal insufficiency. Class I and II often present with significant proteinuria. Class III may present with nephrotic syndrome and moderate renal failure. The most active form of lupus nephritis is the Class IV group. They present as nephritic syndrome with hematuria, hypertension and moderate to severe renal failure. Class V and Class VI present with nephrotic syndrome, hypertension and renal failure.

Diagnosis

Apart from the clinical diagnostic criteria of SLE, the presence of LE cells, ANA, Anti-dsDNA and hypocomplementemia and the renal histology as per the WHO classification are helpful in diagnosis, prognosis and treatment.

Treatment

The general recommendations for treatment of lupus nephritis are guided by the activity of lupus and the classification as per WHO. In general, Class I and mostly Class II do not require any specific aggressive treatment apart from general measures for SLE. Often symptomatic treatment is given for the systemic manifestations. For Class III and IV, prednisolone in a dose of 1-1.5 mg/kg/day alone or in combination with cyclophosphamide 2 mg/kg/day is given for a period of 4 to 6 weeks or till remission is achieved. Thus the drugs can be given on alternate days for another 4 to 6 weeks. A more effective and safe method of administering cyclophosphamide is to give 0.5-0.75 g/m² as an IV infusion in 500 mL of normal saline over 4 hours. The infusion may be preceded by a bolus dose of ondansetron 4 mg in order to prevent vomiting. This should be followed by 20-40 mg frusemide IV in order to reduce the toxic effects of cytophosphamide. Such ‘pulse’ doses cyclophosphamide are given at

monthly intervals for 6 doses, and 3 monthly intervals thereafter for 6-9 more doses. The blood counts are monitored before and 5 days after each pulse dose. Plasmapheresis has been tried in severe cases of lupus nephritis. Plasma exchange involving one plasma volume daily for 7-10 days has been recommended. Other immunosuppressive drugs like cyclosporine, azathioprine, and mycophenolate mofetil, thromboxane antagonists and IV gammaglobulin have all been used. In spite of treatment, 20-30% of patients of Class III and IV progress on to ESRD and require renal replacement therapy. Often SLE becomes quiescent with the development of ESRD and recurrence of nephritis is not common after renal transplantation.

Rheumatoid Arthritis (RA)

(see also Section 12 Chapter 105)

Kidney involvement is uncommon in rheumatoid arthritis. However, in 10 to 20% of patients, there could be direct involvement or the kidneys could be affected by the treatment given for RA. The changes resulting directly due to RA are membranous glomerulonephritis, mesangial proliferative nephritis, diffuse proliferative nephritis or necrotizing vasculitis. Renal amyloidosis (AA type) may develop secondary to the chronic inflammatory state due to RA. Drugs used in the treatment of RA like NSAIDs, methotrexate azathioprine, cyclosporine, and others can indirectly produce kidney damage. Treatment is usually symptomatic, but in a rare patient with renal insufficiency steroids or cyclophosphamide may be useful.

Sjögren's Syndrome (SS)

(see also Section 12 Chapter 105)

Distal renal tubular acidosis, Fanconi's syndrome, impaired urinary concentrating ability, interstitial nephritis, nephrogenic diabetes insipidus, hypercalciuria and nephrolithiasis may occur in 20 to 25% of patients. Urinary tract infection is more common especially in women who have vaginal sicca symptoms. Some patients may progress to chronic renal failure due to interstitial fibrosis or glomerular sclerosis. Use of steroids and immunosuppressive drugs in the early stages, followed by symptomatic treatment and renal replacement therapy when the patient is in ESRD are advocated.

Progressive Systemic Sclerosis (PSS)

(see also section 12 Chapter 107)

Kidney involvement is the most common cause of death in PSS and is present in 40 to 70% of cases. The renal blood vessels are predominantly involved with marked intimal thickening, intimal cell proliferation and fibrinoid necrosis which are indistinguishable from malignant hypertension. There is slowly progressive renal insuffi-

ciency accompanied by hypertension and moderate proteinuria. However, manifestation such as acute renal failure with or without malignant hypertension (scleroderma renal crisis) is not uncommon. There is no specific treatment. However, energetic management of hypertension with ACE inhibitors and renal replacement therapy will be required in ARF or if the patient goes on to ESRD. In spite of advanced renal failure, ACE inhibitors are the drug of choice in scleroderma renal crisis.

Mixed Connective Tissue Disease (MCTD)

(see also Section 12 Chapter 107)

Mixed connective tissue disease has overlapping clinical manifestation of SLE, polymyositis, systemic sclerosis and the presence of a distinctive antibody profile. Kidney disease occurs in approximately 25% of patients with MCTD. It may be clinically silent or mild consisting of proteinuria or haematuria. Serious kidney involvement is common in children. Membranous or focal proliferative glomerulonephritis is common. Malignant hypertension can be a presentation with proliferative vasculopathy similar to the vasculopathy seen in systemic sclerosis. Some patients may end up with ESRD or may develop renal involvement due to treatment with NSAIDs. There is no specific treatment. Patients with hypertension will require antihypertensive medication including ACE inhibitors.

VASCULITIDES

The kidneys may be involved in systemic vasculitis in different ways. Refer also to Section 12 Chapter 108.

Polyarteritis Nodosa (PAN)

Renal involvement is seen in more than 80% of patients. The glomerular lesions are those of ischemia with collapse of the glomeruli and fibrinoid necrosis. Renal infarctions may be seen because of the ischemia produced by vascular blocks and necrosis. Diagnosis is based on anemia, raised ESR, leukocytosis and supportive clinical features. Definite diagnosis can be made by angiography or tissue biopsy.

A combination of steroids in dose of 2 mg/kg/day and cyclophosphamide in doses of 1 to 2 mg/kg body weight is given for 4-6 weeks and tapered off gradually over 6-12 months. Hypertension has to be controlled adequately.

Churg-Strauss Syndrome

Churg-Strauss syndrome is a granulomatous vasculitis affecting small arteries especially of the lungs and marked by eosinophilic tissue infiltration. cANCA is positive in these patients. Renal involvement is less

common and may consist of granulomatous nephritis and focal necrotizing granulomatosis. Treatment is with corticosteroid and cyclophosphamide.

Microscopic Polyarteritis

Renal involvement is common and it manifests with proteinuria, hematuria and RBC casts. Hypertension is usually mild. The most striking feature is rapidly progressive renal failure. When extrarenal features are inconspicuous or missing it is called *renal-limited vasculitis*. Renal histology shows involvement of small vessels in the form of polymorphonuclear infiltration, fibrinoid necrosis and extravasation of erythrocytes. Glomeruli show focal necrotizing lesions and there may be variable degree of crescent formation. Endocapillary proliferation is uncommon. Immunofluorescence shows scanty deposits of immunoglobulins and complement (pauci-immune glomerulonephritis).

Treatment is similar to PAN, consisting of steroids and cyclophosphamide. Plasma exchange has been shown to be of benefit in some patients. Intravenous immunoglobulins and monoclonal antibodies directed against CD4 or CD52 have been used in patients who are resistant or intolerant to the conventional treatment.

Wegener's Granulomatosis (WG)

(see Section 14, Chapter 143)

Renal involvement occurs in 85%. GFR is reduced in about half of the cases at the onset of the disease. cANCA is positive in 90-95% and is sensitive and specific. Prominent features include hematuria, variable degree of proteinuria and progressive renal insufficiency.

Renal histology is that of diffuse or focal necrotizing glomerulonephritis. Crescentic glomerulonephritis may be seen in patients presenting with rapidly progressive renal failure. Immunofluorescence shows a lack of immune deposits and electron microscopy may show scattered electron-dense deposits in capillary walls. The prognosis of untreated WG is dismal, and 1-year survival may be <20%. Treatment with prednisolone 1 mg/kg/day and cyclophosphamide 2 mg/kg/day is effective. Steroid dose is reduced after 6 weeks and may be discontinued once clinical remission is achieved. Cyclophosphamide should be continued in the same dose for at least 1 year after achieving quiescence of disease activity. Plasma exchange may be tried in patients who do not respond quickly to conventional therapy and dialysis undertaken for renal failure.

Henoch-Schönlein Purpura (HSP)

(see also Section 15, Chapter 163)

Renal involvement is seen in 50-80% of cases, and is usually apparent within 4 weeks of diagnosis. The findings

include gross or microscopic hematuria, proteinuria and rarely rapidly progressive renal failure. Nephrotic syndrome is seen in 50% of cases. The most striking histopathological lesion in the kidney is segmental mesangial proliferation. The degree of proliferation is variable and may be associated with glomerular capillary tuft necrosis and crescent formation. HSP is a leucoclastic vasculitis. The renal lesions resemble IgA nephropathy. Predictors of renal involvement are available. HSP is usually a benign condition with an overall mortality rate of 10% on 10 years follow-up. If the renal functions are normal 5 years after the onset of clinical symptoms, the chances of progressive renal failure are less. However, poor prognostic factors include older age, acute nephritic syndrome with renal failure and persistent nephrotic range proteinuria. Treatment is symptomatic. Steroids or immunosuppressive agents are unhelpful in altering the course of renal disease. Patients with rapidly progressive renal failure in association with crescentic glomerulonephritis may be benefited by intensive plasma exchange along with immunosuppressive drugs and dialysis.

Mixed Cryoglobulinemia

This condition is characterized by the presence of cold agglutinins in blood. They are a mixture of monoclonal IgM and polyclonal IgG in the circulation which precipitate in cold and give rise to clinical symptoms like purpura, necrotizing skin lesions, arthralgias, hepatosplenomegaly and Raynaud's phenomenon.

Renal disease is seen in about 50% of cases and is more common if circulating cryoglobulin concentration exceeds 1 g/dL. Clinical features may be precipitated by dehydration or exposure to cold and include nephrotic syndrome (30%), asymptomatic proteinuria (30%), acute nephritic syndrome (20-30%) and acute renal failure (5%). Light microscopy shows endocapillary proliferative glomerulonephritis and infiltration by monocytes. Crescents may be seen in a few glomeruli. Large eosinophilic PAS- positive deposits are seen within the capillary lumen (intraluminal thrombi). There is uneven thickening of the GBM. Vasculitis is observed in 33% of cases. Treatment includes IV pulse doses of methyl prednisolone (500-1000 mg/ day for 3 days) followed by a combination of oral prednisolone (30-60 mg/day) and cyclophosphamide (2 mg/kg/day). In patients with crescentic glomerulonephritis with rapidly deteriorating renal function plasma exchange may be required to bring down cryoglobulin levels.

Takayasu's Arteritis

Various patterns of arterial lesions have been described. In India, the main seat of pathology is found in abdominal aorta and renal arteries as compared to Japan where aortic

arch and its branches are involved more frequently. Presentation with renovascular involvement is common with hypertension, chronic renal failure, congestive cardiac failure, stroke or limb ischemia. General features of toxemia like fever, malaise, arthralgias, anemia are not common in Indian patients. There is no specific treatment. Glucocorticoids or other immunosuppressive drugs are tried for cases with arterial inflammation during acute phase. Strict control of hypertension is the mainstay in treatment. Stenotic lesions of most arteries can be treated by angioplasty, stenting and by surgical correction.

Amyloidosis

(See also Section 15)

Amyloidosis is characterized by deposition of abnormal protein consisting of immunoglobulins or its fractions. Amyloidosis occurs in two forms AL and AA types. The fibrils consist of immunoglobulin light chains in AL and serum amyloid A in AA. Besides amyloid it includes light and heavy chain deposition disease, cryoglobulinaemia and fibrillary glomerulonephritis. Amyloidosis involves the kidney among several other organs as well. Kidney is involved in over 80% of the patients. Other organs like liver, spleen, lymph nodes, heart and others are also involved. The amyloid associated with chronic hemodialysis and Alzheimer's disease usually does not involve the kidneys. The involvement of kidney is commoner in AL amyloidosis as compared to AA variety. The renal presentation is with proteinuria progressing to nephrotic syndrome. Relatively low frequency of hypertension and enlargement of the kidney are the hallmark of amyloid renal disease. Progression to renal failure is slow and the severity of primary disease or the intervening complications decide the outcome. Some patients may present with amyloid deposition in the renal tubules and present as tubular syndromes like diabetes insipidus and renal tubular acidosis. Diagnosis can be made by renal biopsy. Demonstration of green birefringence in biopsy tissues stained with congo red and examined under polarized light is diagnostic. Abdominal fat biopsy and rectal biopsy are also useful. There is no satisfactory treatment of this condition. AL variety of amyloidosis may show regression with treatment of the primary disease. Both dialysis and renal transplantation are not very rewarding because often the involvement of extrarenal organs decide the outcome of the disease.

Multiple Myeloma

(See also Section 15, Chapter 158)

Almost 50% of patients have overt renal insufficiency at some time during the course of the disease. In many instances, renal disease may be the first indicator of multiple myeloma. Virtually, all parts of the renal

parenchyma can be damaged by light chain deposition. Symptomatology varies widely.

1. *Glomerular involvement*
 - a. Amyloid, type AL
 - b. Granular light chain deposition disease
 - c. Fibrillary glomerulopathies
2. *Tubulo-interstitial involvement*
 - a. Fanconi's syndrome
 - b. Acute tubular necrosis or tubulopathy
 - c. Cast nephropathy (myeloma kidney)
 - d. Tubulointerstitial nephritis
3. Vascular lesions
4. Asymptomatic Bence Jones proteinuria
5. Hypercalcemic nephropathy
6. Hyperviscosity syndrome
7. Pyelonephritis
8. Neoplastic cell infiltration
9. Obstructive nephropathy.

The common urinary abnormality is the detection of light-chains or Bence Jones proteinuria, in 65-100% of patients. Proteinuria may rarely precede the development of systemic symptoms of myeloma by a few months. The quantity of protein excreted often exceeds 3 g/day and these patients may be misdiagnosed to have nephrotic syndrome. Acute renal failure occurs in some patients even in the absence of pre-existing renal insufficiency. Precipitating factors of ARF include hypercalcemia, dehydration, increased plasma viscosity, hyperuricemia, radio-contrast administration and infection. The pathogenetic mechanism is thought to be intratubular obstruction by casts due to precipitation of myeloma proteins. In some cases of multiple myeloma, the acute renal failure may be irreversible.

Slowly progressive chronic renal failure occurs often in light chain and IgD myeloma associated with Bence Jones proteinuria. Hypertension and hematuria are rare and non-light chain proteinuria is mild. Renal histology shows dilated tubules containing "fractured glassy eosinophilic casts" surrounded by multinucleated giant cells. There is widespread tubular atrophy, interstitial fibrosis and inflammation. On immunofluorescence, the casts exhibit kappa or lamda chains beside immunoglobulins, Tamm-Horsfall protein and complement. Tubular defects involving both proximal and/or distal segments may occur in myeloma and sometimes precede it. Secondary amyloidosis occurs in 6-15% of myeloma patients, leading to proteinuria and nephrotic syndrome. Presence of renal insufficiency shortens the survival of patients with multiple myeloma.

The main principles of prevention of ARF are maintenance of adequate hydration, vigorous control of hypercalcemia and hyperuricemia, and avoidance of potentially nephrotoxic drugs. The specific treatment using standard chemotherapeutic regimen with melphalan and prednisolone ameliorates renal lesions in more than

50% of the patients. In those with severe renal failure, improvement in renal function has sometimes been observed with peritoneal dialysis or plasmapheresis, both of which can remove significant amounts of light chains. Only 50% of myeloma patients survive for over 1 year on maintenance dialysis. Renal transplantation is considered on rare occasions when the tumor growth is well controlled and the myeloma state is in prolonged remission.

Renal Lesions Associated with Neoplasia

Lymphoreticular malignancies, solid tumours of the lung, gastrointestinal tract, breast and ovary lead to mild proteinuria or even nephrotic syndrome. Renal lesions may antedate the diagnosis of the primary malignancy. The treatment is directed towards the primary tumour and symptomatic management for the nephrotic syndrome.

Minimal change disease is common in Hodgkin's lymphoma. Crescentic glomerulonephritis has been reported in non-Hodgkin's lymphoma. Other types of renal involvement like focal segmental glomerulosclerosis, membranous or membranoproliferative

glomerulonephritis have been described. Kidney may also be involved by direct infiltration in leukemias and lymphomas. The presentation could be with hematuria, proteinuria or might even manifest as ARF. Treatment is symptomatic and supportive. Dialysis may be required to tide over the crisis in ARF.

Tumour Lysis Syndrome

The tumour lysis syndrome is a complication of cancer chemotherapy in extensive rapidly growing and sensitive tumours due to rapid breakdown of tumour tissue. This results in the release of large quantities of cellular products into the circulation. The blood concentrations of uric acid, xanthine, phosphate and potassium increase very rapidly due to large scale cell destruction. The subsequent filtration and the intratubular precipitation of these substances result in ARF. This condition can be prevented by good hydration in order to ensure urine flow rate of about 120 mL/hr. Alkalinization of urine and use of allopurinol before commencing cancer therapy and maintaining the same during the treatment period helps to reduce renal failure. Patients may require dialysis to tide over the crisis if ARF develops.

175 The Kidney and Hypertension

S. Krishnakumar, Jacob George

Chapter Summary

- Introduction 1146
- Renal Parenchymal Hypertension 1147
- Renovascular Hypertension 1147

Introduction

There is a close interrelationship between the kidney and hypertension. Normally, the kidneys influence the blood pressure by several mechanisms and several kidney diseases produce hypertension. Hypertension *per se* can also cause kidney disease or worsen kidney damage. Thus hypertension can be caused by kidney

disease and hypertension can involve and damage the kidney. The primary determinants of blood pressure are blood volume and the peripheral vascular resistance, and both are influenced by the kidney. Salt and water retention can increase the blood volume resulting in hypertension in several kidney diseases. In addition, the peripheral vascular resistance is influenced by several hormones produced by the kidney. Renin, which is secreted from the kidney can cause vasoconstriction. The renal medulla may produce certain vasodilatory lipids, and their deficiency in renal disease could contribute to hypertension.

Secondary hypertension accounts for less than 5% of all hypertensive patients. The most common cause of

secondary hypertension is either a renal parenchymal disease or a renovascular disease. Endocrine diseases also cause secondary hypertension. Even in essential hypertension, the kidneys play an important role.

RENAL HYPERTENSION

Renal hypertension could be due to renal parenchymal disease or renovascular disease.

Renal Parenchymal Disease

Renal parenchymal disease can initiate and sustain hypertension. At the same time, hypertension can accelerate the progression of renal disease. The various mechanisms by which the kidney produces hypertension are shown in Table 175.1.

TABLE 175.1
Mechanism of hypertension in renal disease
1. Salt and water retention (seen in acute nephritis, renal failure, etc).
2. Activation of renin angiotensin aldosterone system.
3. Reduced renal (vasodilator) medullary lipids.
4. Stimulation of sympathetic nervous system due to increased renal afferent activity in renal parenchymal disease.

The common causes of renal parenchymal hypertension are shown in Table 175.2.

TABLE 175.2
Causes of renal parenchymal hypertension
1. Acute glomerulonephritis.
2. Diabetic nephropathy.
3. Chronic glomerulonephritis.
4. Reflux nephropathy (chronic pyelonephritis).
5. Polycystic kidney disease.
6. Hemolytic uremic syndrome
7. Collagen disorders
8. Pre-eclampsia.

Hypertension resulting from renal parenchymal disease may be of recent onset or long standing. Common causes of recent onset of hypertension include acute glomerulonephritis, hemolytic uremic syndrome, scleroderma renal crisis and pre-eclampsia. Such patients are more prone for complications such as hypertensive encephalopathy and may need hospitalization at comparatively lesser levels of hypertension than those with long standing hypertension. When a patient presents with hypertension, some clinical clues which point to renal hypertension should be looked for Table 175.3.

Investigations

TABLE 175.3
Clinical clues to suspect renal parenchymal hypertension
1. Age < 30 or > 55 years.
2. History of edema/hematuria/oliguria.
3. Palpable kidneys.
4. Difficult-to-control hypertension (three or more anti-hypertensive medications).
5. Hypertensive neuroretinopathy (striate hemorrhage/soft exudates).
6. Hypertensive encephalopathy.

Such patients are investigated to ascertain the cause. The relevant investigations include the following:

Significant proteinuria will be present in glomerulonephritis, diabetic nephropathy and reflux nephropathy. Microhematuria/granular casts are seen in glomerulonephritis. Hemoglobin may be low in chronic kidney disease, hemolytic uremic syndrome and Goodpasture’s syndrome. The erythrocyte sedimentation rate may be raised in vasculitis, SLE or multiple myeloma. Blood urea and serum creatinine may be elevated. Ultrasound of kidney may show enlarged echogenic kidney in acute glomerulonephritis or small irregular echogenic kidneys with loss of corticomedullary differentiation in chronic glomerulonephritis and chronic tubulointerstitial nephritis. Serological tests like ASO titre, C₃ and C₄ level, ANA and ANCA may be requested when warranted. Renal biopsy helps to confirm the nature and identify the underlying kidney disease, gives an idea regarding prognosis and helps in deciding the management.

Treatment

Although in essential hypertension a blood pressure less than 140/90 may be considered adequate, in secondary hypertension due to renal parenchymal disease, the aim is to bring the blood pressure below 130/80 mm Hg or even below 125/75 if there is associated proteinuria. A lower blood pressure retards the progression of renal disease and could delay the onset of end stage renal disease. Often two or more antihypertensive drugs may be needed. If the glomerular filtration rate is below 30 mL/mt, thiazide diuretics are ineffective and loop diuretic may be needed to control salt and water retention. Angiotensin II converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), beta blockers and calcium channel blockers are usually used. If ACEIs or ARBs are used, serum creatinine and serum potassium should be monitored at least twice weekly for the first two weeks after the drug is initiated and thereafter once in 4-6 weeks. If the serum creatinine rises more than 20% of baseline soon after initiation, or if hyperkalemia develops these drugs have to be withdrawn.

RENOVASCULAR HYPERTENSION

TABLE 175.4

Clinical clues for suspecting renovascular hypertension

1. Onset of hypertension before 35 and after 55 years of age.
2. Requirement of 3 or more antihypertensive drugs.
3. Systolodiastolic renal bruit/femoral bruit.
4. Asymmetric blood pressure recording in the limbs.
5. Evidence of generalised atherosclerosis like coronary artery disease, peripheral vascular disease, cerebral infarcts etc.
6. Worsening of renal function following exposure to ACEIs or ARBs.
7. 'Flash' pulmonary edema.
8. Malignant hypertension/hypertensive neuroretinopathy.
9. Chronic smokers/diabetics.

Renovascular hypertension develops when the blood supply to the kidney is impaired. This may be either due to unilateral renal artery stenosis which is usually a renin dependent hypertension or due to bilateral disease which is more often due to salt and water retention. The common causes of renovascular hypertension are atherosclerotic renovascular disease, aortoarteritis (Takayasu's arteritis) and fibromuscular dysplasia. Rare causes are coarctation of aorta, dissecting aortic aneurysm and external compression of the renal artery by tumours or lymph nodes.

The clinical clues to suspect renovascular hypertension is given in Table 175.4.

CLINICAL FEATURES

Altherosclerotic renovascular disease is suspected in those having evidence of generalised atherosclerosis like thickened vessel walls, absent peripheral pulsations, associated carotid or femoral bruits and those with coronary artery disease. It predominantly affects the proximal renal arteries and the ostia. Takayasu's arteritis occurs in those below 40 years of age and is prevalent in all parts of India. It is similar to reversed coarctation and the upper limb pulsations may be decreased where as the lower limb pulsations are normal. The ocular fundus may show a wreath like appearance of the retinal vessels near the optic disc. Fibromuscular dysplasia is seen in young females and is mostly seen in the Western countries. Renal failure is rare and the renal artery shows a characteristic beaded appearance on angiogram. Occurrence of sudden onset of pulmonary edema ("flash pulmonary edema") points to the presence of bilateral renovascular disease. Such patients have a sudden worsening of renal function or drop in urine output when ACEIs or ARBs are used.

Often when flash pulmonary edema occurs, the clinician

should suspect bilateral renovascular disease and proceed with further investigations. Today with the availability of angioplasty or stenting the results of treatment are highly rewarding.

Investigations

Urinalysis is relatively normal with no significant proteinuria or urinary sediments. When mild degrees of proteinuria occur, it represents the action of angiotensin II on the glomerular capillary permeability. The hemogram and renal function test are unremarkable. Rise of urea or creatinine when the patient is treated with ACEI or ARBs is a strong indicator of bilateral renovascular disease. Ultrasound examination of abdomen may reveal a smaller sized kidney in unilateral renovascular disease. However the cortical echotexture and corticomedullary differentiation are normal. Ultrasound duplex scan combines pulsed doppler with B mode scanning. Colour Doppler helps to identify the origin of the renal arteries. The peak systolic velocity is proportional to the degree of stenosis. Criteria for diagnosis are peak systolic velocity of 2.5 standard deviations more than the normal range and ratio of change of velocity to that recorded in the aorta (RAR) of more than 3.5. This suggests a degree of stenosis of 60 to 99%. This test is highly sensitive. A high resistivity index (>80%) suggests poor diastolic flow and indicates poor response to intervention. Although, it is a good screening test, it is highly operator dependent. Rapid sequence intravenous urogram was used as a screening test. A size difference of >1.5 cm between the affected and normal kidneys, delayed appearance of nephrogram and increasing concentration on subsequent films on the affected side are suggestive of unilateral renal artery stenosis. This test is seldom employed now because more reliable tests such as isotope renogram are available.

Isotope renogram: In this test ⁹⁹Tc (Technetium) DTPA is administered and the transit of the radio pharmaceutical through the kidney and urinary system is recorded by a gamma camera. Delay and decrease in the uptake of the DTPA and delay in excretion are the usual findings on the side of renal artery stenosis, compared to the normal side.

In captopril renography 25 mg of captopril is administered one hour before the test. The uptake and excretion of the isotope are delayed further compared to the study without captopril suggesting a fall in the GFR due to captopril on the side of renal artery stenosis. Captopril renography has a sensitivity of 90% and hence it is a good screening test. Selective catheterization of renal veins and measurement of the renin levels from each side and aorta will help to identify the side of disease. Renin levels will be high on the affected side and low on the normal side. This is an invasive test. It may be useful to predict response to angioplasty and revascularization of the renal artery.

Captopril test: Administration of captopril 25 mg further elevates renin secretion from the affected kidney. Measurement of basal levels of PRA and after captopril stimulation helps to diagnose renal artery stenosis.

Renal angiogram is the gold standard for diagnosing renal artery stenosis. This will demonstrate the stenotic area, post stenotic dilatation and a gradient across the stenosis. Digital subtraction angiography and spiral CT has the advantage of using lesser contrast. Magnetic resonance angiography (MRA) using gadolinium can be used especially in those with renal failure as there is no risk of contrast nephrotoxicity. Therapeutic procedures like balloon angioplasty or stenting can also be undertaken in the same session as angiography.

Table 175.5 summarises the diagnostic test in renovascular hypertension.

MANAGEMENT

There are three types of management for renovascular hypertension.

- 1. **Medical management:** This includes use of anti-hypertensive medication, antiplatelets and statins. Beta blockers, calcium channel blockers and occasionally diuretics are used. ACEIs and ARBs are the drug of choice in unilateral renovascular hypertension but should be used cautiously, especially in those with associated involvement of the other kidney with frequent monitoring of serum creatinine and serum potassium. It would be safer to withdraw them if the serum creatinine increases by more than 20% soon

TABLE 175.5	
Diagnostic tests in renovascular hypertension	
1.	Screening tests

b.	DSA
c.	MRA
d.	Spiral CT
3.	Tests suggesting response to intervention.
a.	Captopril test
b.	Renal vein renin assay.

after its introduction. Medical treatment should be advocated in the elderly, those unfit for angioplasty or intervention and in those unlikely to benefit from intervention procedures.

- 2. **Percutaneous transluminal angioplasty:** This can be used with or without stenting. They are most useful in fibromuscular dysplasia and when stenosis involves the distal renal artery. It can also be tried in patients who have unilateral or bilateral renovascular narrowing. It is relatively less invasive, compared to the surgical revascularisation procedures.
- 3. **Surgical revascularisation procedures:** These include endarterectomy, aorto-renal bypass, spleno-renal anastomosis or hepatorenal bypass. The revascularization is done using either saphenous vein as grafts or prosthetic grafts. It may be useful in patients in whom the lesion is likely to progress, as in high grade stenosis (75-99%) with kidney size more than 7.5 cm. It should be performed only in centers with experience in vascular surgery.

176

Pregnancy and Medical Disorders

Jacob George

Chapter Summary

- Diabetes Mellitus 1150
- Hypertension 1150
- Pre-eclampsia/Eclampsia 1151

- Pregnancy and Renal Diseases 1152
- Acute Renal Failure (ARF) in Pregnancy 1153
- Acute Pyelonephritis 1154
- Acute Fatty Liver of Pregnancy 1154
- Systemic Lupus Erythematosus (SLE) 1154

Pregnancy is a physiological state and a safe outcome is often the rule. However, medical complications can occur either due to occurrence of pregnancy in a patient with a pre-existing illness or development of a new medical disease during pregnancy. The commonly encountered medical problems during pregnancy are diabetes mellitus, hypertension, acute renal failure, chronic kidney disease, liver dysfunction, urinary tract infection, and systemic lupus erythematosus.

Diabetes Mellitus

(see also Chapter 91)

When diabetes occurs *de novo* during pregnancy, it is called gestational diabetes mellitus. In pre-gestational diabetes, mellitus pregnancy supervenes on type 1 and type 2 diabetes mellitus. The prevalence of pre-gestational diabetes is lower (0.1-0.3%) than gestational diabetes mellitus (2-5%). Some patients may develop impaired glucose tolerance during pregnancy. A decrease in insulin sensitivity and a failure to achieve a higher insulin production are mainly responsible for gestational diabetes mellitus. Those with gestational diabetes mellitus have a six fold increased risk of developing type 2 diabetes mellitus subsequently.

Screening for diabetes in pregnancy is important as uncontrolled diabetes can affect both maternal and fetal health. Hyperglycemia in first trimester is associated with fetal anomalies and miscarriages. In later pregnancy, hyperglycemia causes large for gestational age infants, macrosomia (birth weight > 90th percentile), shoulder dystocia, birth injuries and neonatal hypoglycemia. There is also an increased risk of maternal hypertension and pre-eclampsia.

Risk Factors for Gestational Diabetes Mellitus

1. Body Mass Index (BMI) > 25 kg/m²
2. Waist hip ratio > 1
3. Family history of diabetes
4. Age > 25 years
5. Multiparity
6. Ethnic predisposition

In those at risk, screening with 50 g glucose challenge test at the first prenatal visit and then at 24th and 32nd weeks is recommended. In those without risk factors, screening once between 24th and 28th week is adequate. If the test is positive, a 3-hour oral glucose tolerance test with 100 g glucose should be performed after 10 hours fasting. The diagnostic values for venous plasma in 3 hour oral 100g GTT are

FBS	≥ 95 mg/dL
1 hr	≥ 180 mg/dL
2 hr	≥ 155 mg/dL
3 hr	≥ 140 mg/dL

Two abnormal values are needed for diagnosis.

Management

Dietary management is on the same lines as for non-pregnant women. Extra calories and proteins should be provided to fulfill the needs of the fetus also. It is safer to start insulin early. Oral hypoglycemic agents are avoided as most of them can cross the placental barrier and affect the fetus. Pregnancy is a state of relative insulin resistance. So, maternal nutrients are shunted to the developing fetus and the normal range of blood glucose is lower by approximately 20%. The target fasting blood sugar should be between 60-95 mg/dL and 2 hours postprandial should be less than 120 mg/dL. At fasting blood sugar levels of more than 95 mg/dL the risk of macrosomia is more. Since blood sugar should be kept in the normal range, frequent self-monitoring is recommended.

Generally, spontaneous delivery is desirable. However, with presence of maternal hypertension, history of previous stillbirth, poor metabolic control and macrosomia, delivery is planned around 37-38 weeks of gestation. If fetal weight is greater than 4 kg, cesarean section is done. The fetal loss and perinatal mortality are higher in diabetic compared to non-diabetics pregnancies.

Hypertension

(see also Chapter 123)

Hypertension is a major problem during pregnancy. The guidelines for diagnosis and management of hypertension are different in pregnant subjects compared to the general population. As there is no clear-cut dividing line between normal and abnormal blood pressure during pregnancy, certain arbitrary BP levels have been established for clinical purposes. The Committee on Terminology of the American College of Obstetricians and Gynecologists suggested any one of the following criteria for the diagnosis of hypertension in pregnant women.

1. A sustained rise of 30 mmHg or more in systolic BP;
2. A sustained rise of 15 mmHg or more in diastolic BP;
3. A sustained systolic BP of 140 mmHg or more and;
4. A sustained diastolic BP of 90 mmHg or more.

“Sustained” refers to elevated BP observed on two different occasions, at least six hours apart. To apply the above criteria, the BP in the prepregnant state or soon after conception must be known. Since these BP readings are often not available, the diagnosis of pregnancy-induced hypertension becomes difficult. To overcome this difficulty, it is also suggested that the upper limit of normal diastolic BP should be taken as 75 mmHg in midtrimester and 85 mmHg in last trimester. The clinical classification of the hypertensive disorders of pregnancy recommended by the committee of the American College of Obstetricians and Gynecologists is shown in Table 176.1.

TABLE 176.1

Hypertensive disorders of pregnancy

1. Pregnancy-induced hypertension (pre-eclampsia / eclampsia).
2. Chronic hypertension of whatever cause.
3. Chronic hypertension with superimposed pre-eclampsia.
4. Late or 'transient' hypertension.

1. **Pregnancy Induced Hypertension (PIH) - Pre-eclampsia/eclampsia:** Pre-eclampsia is characterised by a constellation of signs and symptoms including new onset of hypertension after 20 weeks of gestation, proteinuria, edema and occasionally complicated by coagulation and liver function abnormalities. The term pre-eclampsia is used synonymously with pregnancy induced hypertension (PIH). Several factors may predispose to the development of pre-eclampsia. These include primigravida, extremes of age, multiple pregnancy, hydatidiform mole, diabetes, polyhydramnios, fetal anomalies, hydrops fetalis and family history of pre-eclampsia/eclampsia.
2. **Chronic hypertension of whatever cause:** This group includes those patients with essential or secondary hypertension who subsequently become pregnant. Those who have hypertension before twenty weeks of pregnancy are more likely to fall into this group.
3. **Chronic hypertension with superimposed pre-eclampsia:** Almost three quarters of those with severe hypertension develop superimposed pre-eclampsia in the second-half of pregnancy. Pre-eclampsia in this group is often more severe than those without pre-existing hypertension.
4. **Late or transient hypertension:** This group includes those who develop hypertension in the last trimester or immediate puerperium which normalises by the tenth postpartum day.

PRE-ECLAMPSIA/ECLAMPSIA

Pregnancy induced hypertension is a multisystem disease characterised by vascular endothelial dysfunction and damage. Placenta plays a central role in the pathogenesis and shows evidence of hypoperfusion, ischemia and scars. Various theories have been proposed on its pathogenesis including the role of superficial placentation, immune maladaptation, and reduced angiogenic factors. Normally, during pregnancy, the decidua part of spiral arteries are invaded by the cytotrophoblast and there is loss of muscle layer and endothelium of blood vessels. This results in failure of the blood vessels to respond to vasomotor stimuli. Thus the vascular supply of the placenta is transformed from a high pressure, low flow system to a low pressure, high flow system. In PIH, the trophoblastic invasion is partial and the preservation of the muscle

layers makes the vessels sensitive to vasomotor stimuli. Thus the high pressure low flow system persists leading to reduced placental blood flow and generalized endothelial damage with multi-organ involvement. Plasma volume is found to be significantly decreased in patients with PIH compared to pregnant women with normal BP. The salient pathological changes in the kidneys include enlargement of the glomeruli with no increase in the number of cells. The endothelial cells are swollen and fill up the capillary loops. These changes have been termed 'glomerular capillary endotheliosis.'

Diagnosis

Pre-eclampsia is suspected clinically by noting blood pressure elevation after 20th week of pregnancy. This may be associated with headache, epigastric or right upper quadrant abdominal pain and visual abnormalities such as scotoma, cortical blindness or spasm of retinal arterioles. Symptoms like epigastric discomfort and visual disturbances may precede the development of generalized convulsions. If convulsions occur, it is termed eclampsia. Examination of urine reveals proteinuria. The important hematologic abnormalities include rise in hematocrit and hemoglobin due to hemoconcentration and thrombocytopenia. Blood levels of aspartate aminotransferase, alanine aminotransferase and lactic dehydrogenase enzymes may be elevated, but they return to normal within ten days of delivery. The normal values for blood urea nitrogen (BUN) (8 mg/dL equivalent to blood urea of 17 mg/dL) and serum creatinine 0.4 mg/dL during pregnancy are markedly lower than the pre-pregnant levels. This is because of an increase in glomerular filtration rate. In pre-eclampsia if BUN or creatinine levels are equal to pre-pregnant values, it indicates impaired renal function. Similarly, serum uric acid is low (2.5 mg/dL) and elevation of serum uric acid to > 4.5 mg/dL indicates pre-eclampsia. Thus hyperuricemia helps to distinguish women with pre-eclampsia from those with chronic hypertension. Presence of hypertension before conception or detection of hypertension before 20 weeks of gestation is suggestive of pre-existing hypertension and not pre-eclampsia. Pre-eclampsia is uncommon in multiparous women. The blood pressure usually decreases dramatically following delivery. Severe pre-eclampsia has to be distinguished from acute fatty liver of pregnancy, thrombotic microangiopathy, glomerulonephritis or systemic lupus erythematosus.

Management

- Regular antenatal check up should include the following:
- i. To limit maternal weight gain to less than 12.5 kg.
 - ii. Control of blood pressure. The blood pressure should be maintained below 125/75 in the second trimester and 135/85 in the third trimester.

- iii. Aggressive salt restriction and diuretic therapy should be avoided since they will cause further reduction of intravascular volume.
- iv. The pre-eclamptic woman is hospitalized early and encouraged to rest on the left lateral position.
- v. Fetal growth parameters are monitored clinically and by ultrasound scans.

The fetal prognosis improves by judicious and deliberate pre-term delivery and the care given in a good premature nursery. The chances of survival of the infant improve by judicious pre-term delivery. Delivery should be planned by 37th week in mild cases and by 34th week in more severe cases. Antihypertensive treatment should be instituted if diastolic blood pressure exceeds 84 mmHg in the second trimester and 94 mmHg in third trimester. If the fetal maturity and weight are satisfactory at the time of detection of hypertension, labour may be induced. Depending on the facilities in the premature baby unit, labor is induced when the fetal weight is 1.5-1.8 kg. Prescription of antihypertensive drugs to hypertensive pregnant women should be done with caution.

Centrally-acting alpha-2 receptor agonists, e.g. methyldopa; vasodilators, e.g. hydralazine; beta adrenergic blockers, e.g. atenolol; combined alpha-beta receptor blocking agents, e.g. labetalol and calcium channel blockers, e.g. nifedipine are safe. Angiotensin-converting enzyme inhibitors (ACEI) and angiotensin II receptor antagonists are not safe. Diuretics are generally avoided. In case of hypertensive emergency, hydralazine is given IV/IM in doses of 10-50 mg every 4-6 hours or orally in doses of 25-50 mg tid or qid. Labetalol given orally in doses of 100-200 mg bd or in doses of 20-80 mg IV bolus every 10 minutes or 0.5 to 2 mg/min as infusion is a good alternative. Sodium nitroprusside is avoided since thiocyanate levels in blood increase, leading to cyanide toxicity and reduction in placental blood flow. This increases the risk to fetus.

Once pre-eclampsia is confirmed, the expectant mother is hospitalized and the condition is assessed as mild, moderate or severe. In mild and moderate PE, if pregnancy is close to term (36 weeks or later) and fetal maturity is acceptable, delivery should be induced. If the period of gestation is less than 36 weeks, the mother is closely observed and parameters like blood pressure, urine output, proteinuria, optic fundi, neurologic status, blood urea, serum creatinine, serum uric acid, lactic dehydrogenase, platelet count and aspartate amino transferase are monitored. Attainment of fetal lung maturity is the most important factor which influences the decision for pre-term delivery. Fetal lung maturity can be assessed by estimation of lecithin/sphingomyelin ratio. The normal ratio is > 3.5:1. If the ratio is > 2:1, it indicates adequate lung maturity for induction of labour.

Convulsions can be arrested and further occurrence prevented by the timely use of parenteral magnesium

sulphate. Dose of magnesium sulphate is 4 g given as IV injection of 20 mL of 20% solution given over 5 minutes. This is followed by deep intramuscular injection of 10 mL of 50% solution on the buttock. This can decrease risk of eclampsia. The loss of patellar jerk is the earliest warning sign of impending magnesium toxicity. Administration of magnesium sulphate is often continued for 24 hours postpartum. It acts at the neuromuscular junction. Long-term use of diazepam as an anticonvulsant is not favourable for the fetus, since it may cause hypotonia, drowsiness and apnea for several hours after birth.

Those who develop pre-eclampsia may be predisposed to endothelial injury and they have an eight-fold increase in the risk of cardiovascular disorders, hypertension and stroke in later life. They have also an increased risk of dyslipidemia, insulin resistance, anemia and lung diseases.

Rollover test is a simple, nonspecific, noninvasive test performed between 28 and 32 weeks. It can be used to detect patients at risk of PE. The blood pressure is recorded repeatedly 15 minutes after the subject assumes lateral recumbent posture till consistent readings are obtained. Then she rolls over to the supine position and blood pressure is checked after one minute. Any increase in diastolic blood pressure of more than 20 mmHg indicates as positive test. A negative test indicates less likelihood of developing PE.

Antiplatelet agents like aspirin have a prophylactic role in high risk individuals even though it cannot be recommended as routine prophylaxis. Low dose aspirin therapy may be used in the following situations: (1) A positive family history of pregnancy induced hypertension, (2) previous history of pre-eclampsia, (3) teenage pregnancy, (4) pregnancy above the age of 35 years, (5) pre-existing renal disease with hypertension, (6) multiple pregnancy, (7) Rh negative mother, diabetic mother and (8) a positive roll-over test.

The syndrome of hemolysis, elevated liver enzymes and thrombocytopenia (HELLP syndrome) has been recognized as a complication of pre-eclampsia and eclampsia. It's frequency is 0.1%. The typical hepatic lesion associated with HELLP syndrome is periportal or focal parenchymal necrosis, in which large hyaline deposits of fibrin-like materials can be seen in the sinusoids. Renal dysfunction is also common. Prompt induction of delivery within 24 hours of the diagnosis is the treatment of choice. Delay in delivery may lead to high maternal and fetal morbidity and mortality.

PREGNANCY AND RENAL DISEASES

Renal diseases may develop *de novo* in pregnancy or a latent renal disease may manifest during pregnancy. Pregnancy may supervene on pre-existing overt renal

disease. When proteinuria is first discovered after the twentieth week of pregnancy, the differential diagnosis is between pre-eclampsia and underlying renal disease. Proteinuria, hypertension, edema and renal insufficiency occur in both settings. Elevated serum uric acid out of proportion to the severity of renal insufficiency suggests the diagnosis of pre-eclampsia. Presence of glomerular capillary endotheliosis is specific for pre-eclampsia.

Kidney diseases during pregnancy can affect both the mother and fetus. Women with moderate or advanced renal failure generally have anovulatory cycles or amenorrhea. If they conceive, the outcome is unfavorable. Women with mild renal failure (serum creatinine < 2.3 mg/dL) can conceive and go through the pregnancy successfully. The overall fetal outcome depends on the degree of renal functional impairment, degree of control of hypertension and severity of proteinuria on conception.

Generally, pregnancy does not influence the natural course of renal disease adversely if renal function is well preserved and the blood pressure is normal at conception. Those with lupus nephritis, IgA nephropathy, membranous glomerulopathy or focal and segmental glomerulosclerosis may have further deterioration of the original disease during pregnancy or puerperium. The important risk factors are nephrotic range proteinuria, hypertension and impaired renal function. Renal disease complicated by pregnancy must be considered as “high risk” pregnancy and managed by an experienced team of nephrologists and obstetricians.

Acute Renal Failure (ARF) in Pregnancy

Acute renal failure may complete pregnancy rarely. The frequency has been brought down by improved prenatal care, better management of maternal complications and decrease in illegal abortions. The incidence of ARF in pregnancy has a bimodal pattern. The causes in the first trimester are:

- Illegal abortion practices induced by crude methods
- Nephrotoxic abortifacients
- Dehydration due to hyperemesis gravidarum
- Shock due to bleeding
- Urinary infection and
- Septicemia.

During the third trimester, ARF results from

- Severe pre-eclampsia/eclampsia
- HELLP syndrome
- Abruptio placentae
- Postpartum hemorrhage
- Hypotension
- Intrauterine death
- Amniotic fluid embolism and
- Disseminated intravascular coagulation.

Multiple factors may operate in the same patient and result in severe ARF. Bilateral renal cortical necrosis occurs more frequently in women with placental abruption. Pre-existing nephrosclerosis, renal ischemia, and disseminated intravascular coagulation predispose to development of renal cortical necrosis.

Idiopathic postpartum acute renal failure, follows an apparently normal pregnancy and manifests usually between one day to several weeks after delivery. The onset is a “flu-like” illness followed by rapidly developing renal failure. The blood pressure is usually normal. Congestive cardiac failure and convulsions may occur in some cases. The cause of the syndrome is not clear. Retained placental fragments, oral contraceptives, oxytocin, ergot alkaloids, prostaglandin deficiency and immunologic basis have all been incriminated. Circulating large multimers of von Willebrand’s factor (vWF) lead to platelet aggregation and thrombosis in renal circulation, resulting in renal damage. The management consists of bringing the blood pressure to normal and supportive measures. The renal function may not recover fully. Specific measures include plasmapheresis done daily or on alternate days for the initial 2 weeks. Plasmapheresis helps to remove the toxins and vWF multimers.

Management of Acute Renal Failure in Pregnancy

The general management of acute renal failure in pregnant and nonpregnant subjects is essentially similar. Prerenal factors are corrected. In case of blood loss, the appropriate quantity is replaced under supervision. In case of established renal failure, early or prophylactic dialysis is advocated since the uremic toxins cross the placenta and reduce the chances of fetal survival. The choice of dialysis therapy is individualized and both peritoneal and hemodialysis can be undertaken. Excessive fluid shifts during dialysis should be avoided. If the fetus is viable, it should be delivered as soon as the maternal condition improves. The neonate will have higher blood levels urea and creatinine at birth leading to osmotic diuresis. This should be recognized and managed with prompt hydration.

Urinary Tract Infections

Asymptomatic Bacteriuria

Asymptomatic bacteriuria is characterized by absence of urinary symptoms in spite of significant bacteriuria. Because of the anatomical and functional changes in the urinary tract and increased urinary excretion of amino acids, protein, calcium, glucose and vitamins during pregnancy, asymptomatic bacteriuria may occur in 5-10% of all pregnancies. It is more common when pre-existing conditions like diabetes mellitus, sickle cell disease, renal

diseases, multiparity, low socioeconomic background or hypertension are present. Although asymptomatic bacteriuria may be a relatively benign disorder not requiring active treatment in nonpregnant subjects, 30-50% of pregnant women with asymptomatic bacteriuria develop symptomatic urinary tract infection. Asymptomatic bacteriuria may be associated with increased incidence of pre-eclampsia, premature delivery, anemia and low birth weight. Therefore, routine screening of all pregnant mothers during the first trimester for bacteriuria is advocated. If detected, any one of the following antibiotics should be administered orally for 14 days.

Amoxycillin 500 mg 8 h, ampicillin 500 mg 6 h, cephalexin 500 mg 6 h or cefixime 200 mg 12 h.

The patient should be followed up with urine cultures every month till delivery. In women in whom asymptomatic bacteriuria is difficult to eradicate, continuous antibiotic therapy during pregnancy and detailed investigations to rule out urinary tract obstruction in the postpartum period are warranted.

Acute Pyelonephritis

Symptomatic renal parenchymal infection with fever, rigor, chills, loin pain and pyuria may occur in about 1% of all pregnancies. Severe infections may lead to renal cortical abscess, renal carbuncle, sepsis, shock and fetal loss. Those with asymptomatic bacteriuria, having previous episodes of urinary tract infections or congenital abnormalities of the urinary tract are more prone to develop acute pyelonephritis. The patient should be hospitalized and prompt treatment instituted. Urine and blood samples should be sent for culture, and treatment with intravenous fluids, antipyretics and antibiotics started. In severe infections, antibiotics which reach high concentrations in the renal parenchyma and which have no adverse effects on the fetus should be started immediately, e.g. amoxycillin 500 mg 8 h or cefotaxime 1g 6 h or ceftazidime 1 g 6 h IV. When the fever is controlled for 48-72 hours, antibiotics have to be continued orally for a total period of three-weeks to ensure eradication of infection. During follow-up, urinalysis and cultures are essential. Tetracycline should be avoided during

pregnancy. Co-trimoxazole should not be given near term because of the risk of kernicterus in the newborn. Aminoglycosides may cause ototoxicity and hence they should be avoided.

Acute Fatty Liver of Pregnancy

This occurs in the third trimester and is characterized by rapid development of jaundice, bleeding, seizures and hepatic encephalopathy. Serum bilirubin and liver enzymes are elevated but the serum alkaline phosphate is usually normal. More than 50% of these patients develop acute renal failure. The cause of ARF may be prerenal and hemodynamic factors as in the hepatorenal syndrome. The mortality is high due to hepatic rather than renal failure. Prompt delivery usually improves the liver function. The subsequent pregnancies may be normal.

Systemic Lupus Erythematosus (SLE)

(see also Chapter 106)

This increases the risk both to the mother and the fetus. The effect of gestation on lupus and the effect of lupus on gestation are variable. If the disease is not active for at least one year prior to conception and renal functions are normal, the chances for uneventful pregnancy are good and postpartum aggravation of lupus activity is unlikely. If the woman had active lupus at the time of conception or the symptoms develop during pregnancy for the first time, the outcome may be unfavorable. Flare up of lupus occurs during pregnancy, especially in those having thrombocytopenia and hypertension, but the episodes are usually mild to moderate. In about 10% of patients, there is exacerbation of lupus activity postpartum leading to acute renal failure. For this reason, the dose of steroids may be increased prophylactically after delivery and tapered off over the next three months.

The autoantibodies may cross the placenta and result in repeated abortions. In particular, the presence of antiphospholipid antibodies considerably worsens the fetal outcome. Such patients require special therapy for successful outcome. The presence of antinuclear antibodies may lead to the lupus syndrome in the neonate characterized by transient skin rash, pancytopenia and transient heart block.

Chapter Summary

General Considerations 1155

Clinical Features 1156

Diagnosis 1156

Management 1156

GENERAL CONSIDERATIONS

Obstruction of the urinary tract (obstructive uropathy) may occur anywhere between the renal tubule and the urethral meatus. The impedance to the normal flow of urine results in complex structural and functional changes in the kidneys and urinary tract. Based on the site of obstruction, it can be classified as intrarenal and extrarenal. The extrarenal obstruction may be upper urinary tract obstruction (obstruction above vesicoureteric junction VUJ) or lower urinary tract obstruction below the VUJ. Urinary obstruction may be unilateral or bilateral, complete or partial, acute or chronic and may be caused by extraluminal or intraluminal causes.

Obstructive uropathy is defined as the structural and functional changes in the urinary tract that impede the normal flow of urine. Changes in the kidney secondary to the obstruction of the urinary tract are termed obstructive nephropathy. The terms hydronephrosis and hydroureterosis denote only dilatation of the drainage system and does not mean obstruction.

Causes of Urinary Tract Obstruction**A. Upper urinary tract obstruction**

1. Causes in the lumen
 - Crystals and stones
 - Sloughed renal papillae
 - Blood clots
2. Causes in the wall
 - Functional - Pelviureteric junction (PUJ) or vesicoureteric junction (VUJ) obstruction
 - Tumours (transitional cell carcinoma)

- Infections (tuberculosis)
 - Strictures (tuberculosis, radiation, other granulomas)
3. Causes outside the wall
 - Retroperitoneal fibrosis
 - Pelvic tumours – fibroid, carcinomas of uterus, cervix, ovary and prostate
 - Radiation sequel
 - Lymph nodes
 - Crohn's disease
 - Aneurysm of abdominal aorta
 - Aberrant arteries
 - Retrocaval ureter
- B. Lower urinary tract obstruction**
1. Causes in the lumen
 - Stones
 - Blood clots
 2. Causes in the wall
 - Urethral stricture
 - Posterior urethral valve
 - Phimosis, paraphimosis, meatal stenosis
 - Carcinoma of bladder
 - Trauma
 - Functional causes – neurogenic bladder
 - Anticholinergic drugs
 - Levodopa
 3. Causes outside the wall
 - Prostatic enlargement,
 - Infiltrating pelvic malignancies.

Pathophysiology

When the urinary system is obstructed, changes occur in both glomerular and tubular function. The GFR declines progressively depending on whether the obstruction is complete or partial, unilateral or bilateral and acute or chronic. Abnormalities in tubular function include impairment of concentrating and acidifying function. If the obstruction is relieved within 1-2 weeks, there is normalization of glomerular and tubular functions. Chronic obstruction for more than 12 weeks results in irreversible destruction of renal parenchyma. **1155**

In such cases, functional recovery may be incomplete even after relief of obstruction. Eventually, the nephrons and renal parenchyma are replaced by extracellular matrix. When prolonged obstruction is relieved, there is temporary inability to concentrate urine or reabsorb solutes. This leads to polyuria, salt wasting and hypokalemia. This may last for variable periods. This is referred to as '*post-obstructive diuresis*'. Pathologically, marked thinning of cortex occurs over many months with atrophy of tubular structures, obliteration of nephrons, progressive sclerosis and fibrosis of the renal parenchyma.

CLINICAL FEATURES

The clinical manifestations depend on the site, degree and duration of obstruction. Pain is a common presenting symptom and is due to distension of the bladder, collecting system or renal capsule. Pain is more severe in acute, compared to chronic obstruction. The location and quality of pain often help to determine the site of obstruction. Obstruction at pelviureteric junction causes colicky pain in the loin. Mid-ureteric obstruction usually produces sudden lumbar pain with radiation from loin to groin. In lower ureteral obstruction the pain radiates to the ipsilateral testicle, labia or inner part of the upper thigh. Distension of the bladder with stretching of the trigone leads to frequency, strangury and radiation of pain to tip of the penis. In lower urinary obstruction, the patient often complains of poor stream, intermittency, hesitancy, urgency, precipitancy, dribbling, nocturia or urinary incontinence. Urinary obstruction predisposes to resistant urinary infection. Infection can be eradicated only when the obstruction is cleared. In a chronically obstructed urinary system infection with proteus group of organisms and secondary stone formation are common. In neonates and children with posterior urethral valve, secondary vesico-ureteral reflux may occur and lead to progressive renal damage. Obstruction due to calculi or neoplastic lesions may lead to hematuria. Complete lower urinary tract obstruction, bilateral ureteric obstruction or obstruction to a single functioning kidney leads to anuria. In partial obstruction, the urine output may be normal or even increased.

One or both kidneys may be enlarged and palpable depending on the site of obstruction. In the case of lower

tract obstruction, the distended bladder may be palpable and tender. Enlarged prostate is identified by rectal examination. In females, pelvic examination is required to detect local malignancy. Hypertension may occur in some cases due to salt and water retention or renin release.

Proteinuria, hematuria, pyuria and bacteriuria may be present. Rarely urine examination may be 'normal'. In chronic obstruction, the specific gravity of urine is less than 1.010. Bilateral obstruction is associated with features of renal failure. There is impaired excretion of acid and potassium and this leads to type IV renal tubular acidosis (hyperchloremic hyperkalemic metabolic acidosis).

Diagnosis

Diagnosis is often made by history and physical examination. After the preliminary evaluation including urinalysis, urine culture, hemogram, assessment of renal function and electrolytes, imaging studies are undertaken. Ultrasonography detects dilatation of the urinary tract in almost all cases. Other investigations include X-ray of the abdomen for KUB, intravenous urogram, retrograde pyelogram, CT Scan and magnetic resonance imaging. Non-contrast enhanced helical CT is now used as the primary imaging modality for assessment of acute flank pain. Isotope renography with IV frusemide (diuretic renogram) is helpful in the diagnosis of obstruction in patients with good renal function.

Management

This depends on the site and cause of obstruction and the degree of renal impairment. In acute obstruction, rapid intervention helps to salvage the kidney.

Methods used for relief of obstruction include—

- Urethral catheters or suprapubic cystostomy for urethral obstruction: Relief of obstruction should be gradual in chronic obstructive lesions.
- Cystoscopy and passage of retrograde ureteral catheter or nephrostomy for upper urinary obstruction.

These procedures are undertaken with appropriate antibiotics. Specific therapy is decided depending in the cause of obstruction after the patient is stabilized. Relief of obstruction and further management of the causative lesions is the realm of the urologist.

Chapter Summary

- Definition 1157
- Epidemiology 1157
- Classification 1157
- Pathogenesis 1158
- Clinical Features 1158
- Investigations 1159
- Management of ARF 1160

Definition

Acute renal failure (ARF) is defined as a potentially reversible rapid decline in the excretory function of the kidney which develops over hours to days leading to retention of nitrogenous waste products and the consequent clinical complications. ARF occurs due to various etiological factors.

Epidemiology

ARF complicates the clinical course of upto 5% of all hospital inpatients and nearly 30% of Intensive Care Unit (ICU) admissions. The annual incidence of adult ARF in the general population is 200 /million.

Classification

ARF can be classified based on epidemiology, etiology or pathophysiology.

Epidemiologic Classification

- 1. Community Acquired ARF (CAARF)
- 2. Hospital Acquired ARF (HAARF)
ARF acquired in the community behaves differently in its etiology, severity and outcome from that acquired in hospitals. Generally, CAARF has a better outcome and lower mortality compared to HAARF - 15% Vs 25%.
The common causes of CAARF include gastro-enteritis, diarrheal disease, viperine snake envenomation, leptospirosis, herbal toxins, falciparum malaria, copper sulphate poisoning, obstructive nephropathy and others.

The etiology varies from place to place depending on local characteristics. Most cases of HAARF result from pre-renal factors. Sepsis, postsurgical ARF and iatrogenic factors such as nephrotoxic drugs are important causes in the hospital setting.

Pathophysiologic Classification

- 1. Prerenal
- 2. Intrinsic renal
- 3. Postrenal

Prerenal	Decreased extra-cellular fluid volume Low cardiac output Impaired renal autoregulation Alteration in systemic to renal vascular resistance ratio
Intrinsic renal	Acute tubular necrosis Glomerular diseases Interstitial nephritis Vascular (macro-and microvascular) causes
Postrenal	Ureteric obstruction Bladder neck obstruction Urethral obstruction

Pre-renal Causes of ARF

Prerenal ARF is the most common form. The term ‘pre-renal’ is used when renal dysfunction is caused by decrease in renal perfusion. Restoration of renal perfusion results in rapid recovery of renal function in the early stages, before irreversible changes develop. Prerenal ARF occurs in diseases associated with reduction in extracellular fluid volume as is seen in gastrointestinal fluid loss (vomiting, diarrhea), burns, hemorrhage, third space fluid sequestration or excessive renal fluid losses. Conditions associated with a reduction in the ‘effective arterial blood volume’, seen in low cardiac output states such as myocardial, pericardial or valvular diseases, pulmonary hypertension and others, account for many cases. Other causes include drugs interfering with the autoregulation of renal blood flow and GFR such as COX

inhibitors and ACE inhibitors. Systemic to renal vascular resistance ratio is altered when there is systemic vasodilatation or intra-renal vasoconstriction. This may occur in sepsis, anesthesia and anaphylaxis leading to prerenal failure.

ARF may be broadly classified into medical ARF, surgical ARF, obstetric ARF

Intrinsic Renal Causes of ARF

The most common cause of intrinsic ARF is ‘acute tubular necrosis’ (ATN). ATN may be caused by ischemic or nephrotoxic injury. However in a large number of cases the cause is multifactorial. Conditions which cause prerenal failure may lead to renal ischemia and ATN. Substances toxic to the renal tubule are called tubular nephrotoxins, e.g. aminoglycosides, radiocontrast media, heme pigments and others. The hallmark of ATN is structural damage to the tubular cell, which regenerates over a few weeks with recovery of renal function.

Other intrinsic renal causes of ARF include acute glomerulonephritis, rapidly progressive glomerulonephritis, acute vasculitides, hemolytic uremic syndrome, malignant hypertension, acute cortical necrosis, acute allergic interstitial nephritis, acute pyelonephritis, intratubular obstruction due to heavy crystalluria and paraproteinemias. Rarely acute bilateral occlusion of renal arteries or veins by thrombosis or embolism leads to ARF.

Postrenal ARF

About 5% of cases of ARF are due to urinary tract obstruction. Obstruction at the bladder neck is the most common site. Ureteric obstruction causes ARF either when it is bilateral or it is a solitary functioning kidney. It is important to recognize obstruction since early correction leads to complete recovery.

Further discussion in this chapter will be confined to ATN which comprises more than 2/3 of all cases of ARF.

ARF used to be classified depending on the etiological setting from which renal failure develops. However this approach has been abandoned because of the advantages of the other classification systems.

Pathogenesis

The traditional views have given place to modern concepts

Pathogenetic mechanisms in ATN	
Traditional view	
Hemodynamic factors:	
Renal vasoconstriction mediated by humoral and neural mechanisms	
Tubular factors:	
Tubular obstruction	
Back leak of tubular fluid	
Modern concept	
Cellular mechanisms play the major role	

The following mechanisms have been postulated to explain the pathogenesis of renal failure in ATN.

1. *Tubular obstruction*: Intraluminal debris, cast formation or interstitial edema arising out of tubular necrosis results in renal tubular obstruction. Tubular obstruction, in turn, raises the intraluminal pressure which leads to reduction of GFR in ATN.
2. *The back leak theory*: Due to the disruption of the integrity of the renal tubular epithelium, the glomerular filtrate leaks back into the interstitium, leading to retention of fluid and waste products.
3. *Hemodynamic theories*: Hypovolemia, whether absolute or relative and sustained renal vasoconstriction results in a reduction of GFR. Cardiovascular baroreceptors and the sympathetic nervous system are activated. The vasopressor mechanisms such as renin-angiotensin-aldosterone system, vasopressin, and other vasopressors including endothelin are stimulated. All these factors act together to sustain the blood pressure, the cardiac output and cerebral perfusion. But in the kidney, intrarenal hemodynamics is deranged by the overplay of the vasopressors. This results in afferent arteriolar constriction, efferent arteriolar dilatation and decreased permeability of the glomerular membrane, all leading to reduction in GFR.
4. *Cellular mechanisms*: Several cellular and subcellular mechanisms have been identified in the renal tubular cells. Cytoskeletal injury, loss of cell polarity, impaired cell-cell and cell-matrix interactions, necrosis and apoptosis lead to the development of ATN. In addition to ischemia, reperfusion injury results in free radical induced oxidative stress, release of pro-inflammatory cytokines and reduction in nitric oxide, further perpetuating the injury.

Recovery and repair mechanisms are also mediated by growth factors which are released locally.

Clinical Features

- **Prerenal failure.** The most important symptom which draws the attention of the clinician to renal failure is oliguria. Patients commonly present with symptoms related to hypovolemia, including thirst, dizziness, and orthostatic hypotension. Evidence of excessive fluid loss through gastrointestinal tract, hemorrhage, sweating or renal losses may be present. Patients with advanced cardiac failure and renal hypoperfusion may present with signs of cardiac failure.
- **Intrinsic renal failure.** ATN should be suspected in any patient presenting after a period of hypotension secondary to hemorrhage, sepsis, drug overdose, or surgery. About 30% of patients with ATN may remain non-oliguric, especially those with nephrotoxic injury caused by drugs or radiocontrast agents. A careful

search for exposure to nephrotoxins should include a detailed history of all current medications and any recent radiocontrast administration. Allergic interstitial nephritis should be suspected with recent drug ingestion, fevers, rash, and arthralgias. Nephritic syndrome of hematuria, edema and hypertension point to glomerular etiology of ARF.

- **Postrenal failure.** Postrenal failure usually occurs in older men with prostatic obstruction, main symptoms being urgency, frequency hesitancy and obstruction to flow of urine. In women, the common causes include gynecologic conditions like prolapse, carcinoma cervix or irradiation of pelvic structures. Renal calculi and papillary necrosis present with flank pain and hematuria.

The most important part of the physical examination is the assessment of cardiovascular status and the state of hydration. Regular recording blood pressure helps to

identify hypovolemia early. Postural hypotension is the earliest sign of hypovolemia. Severe congestive cardiac failure (CHF) may cause hypotension without hypovolemia (Flow chart 178.1).

Investigations

- **Urinalysis:** Urinalysis is important in the initial evaluation of ARF. The daily urine output is usually low in about 2/3rd of the patients whereas in the remaining third, it may be normal or even increased. Reddish brown or cola-colored urine is present in patients with acute glomerulonephritis or in the presence of myoglobin or hemoglobin in the plasma. Presence of RBCs and RBC casts are very suggestive of acute glomerulonephritis. The presence of WBCs or WBC casts may denote pyelonephritis or acute interstitial nephritis. Presence of eosinophils in urine

Flow chart 178.1: Diagnosis of acute renal failure

suggests arterial embolic disease, or drug-induced interstitial nephritis. Presence of granular muddy-brown casts is suggestive of tubular necrosis.

- Complete blood cell counts and peripheral smear. These tests may be useful, and the peripheral smear may show schistocytes in conditions such as hemolytic uremic syndrome or thrombotic thrombocytopenic purpura.
- *Blood urea and serum creatinine:* Increase in the levels of blood urea and creatinine is the hallmarks of renal failure, the rate of rise of urea and creatinine is more important for confirming the diagnosis and follow-up. In prerenal failure, the rate of rise of urea is higher than that of creatinine. The proportion of urea to creatinine is usually 20 :1.
- *Urinary electrolytes:* The fractional excretion of sodium (FENa) is commonly used as an indicator of tubular integrity. The formula for calculating the FENa is given below:

$$\text{FENa} = (\text{U}_{\text{Na}}/\text{P}_{\text{Na}}) / (\text{U}_{\text{Cr}}/\text{P}_{\text{Cr}}) \times 100$$
 where, U and P represent Urine and Plasma, Na = sodium and Cr = creatinine.
 The FENa helps to differentiate oliguria caused by prerenal failure from that caused by established acute tubular necrosis. In prerenal failure the FENa is usually less than 1% whereas in ATN, it is greater than 1%. Exceptions to this rule are ATN caused by radiocontrast nephropathy, severe burns or ATN following diuretic use.
- *Ultrasound examination:* Renal ultrasonography is useful for detecting intrinsic renal disease and ruling out chronic renal failure and obstructive uropathy. Doppler studies can detect thromboembolic or renovascular disease.
- *Serologic tests:* These tests are very informative if ordered judiciously even though they are expensive. Tests such as antinuclear antibody, ANCA, cryoglobulins, and hepatitis serology markers are helpful when ARF is suspected to be due to systemic vasculitis.

Renal biopsy: This is the diagnostic investigation when other tests are inconclusive. It is particularly useful in conditions like RPGN and for distinguishing between acute glomerulonephritis and interstitial nephritis.

Management of ARF

Principles of management of ARF

1. Treatment of the underlying cause
2. Maintenance of fluid and electrolyte balance
3. Maintenance of nutritional status.
4. Monitor for life-threatening complications
5. Renal replacement therapy when indicated

Treatment of the Underlying Cause

The cornerstone in the management of ARF is the treatment of the underlying cause. The most important factor determining the outcome is the severity of the underlying disease. For example ARF complicating sepsis in the ICU setting has a mortality of up to 70%. On the other hand, ARF following snake envenomation and leptospirosis have a mortality of only around 30-40% even though they are severe and they need dialysis support.

Prerenal ARF improves with restoration of renal perfusion, by appropriate fluid therapy. The use of vasodilators and ionotropes help to restore renal perfusion in congestive heart failure.

In postrenal ARF, relief of obstruction is the crucial factor influencing recovery of renal function. Specific therapy of the underlying cause of obstruction such as prostatic enlargement ensures recovery.

Maintenance of Fluid and Electrolyte Balance

Hypovolemia potentiates and exacerbates all forms of ARF. In many forms of ARF, correction of hypovolemia may be the only treatment required. Fluid replacement should be undertaken carefully to avoid fluid overload and pulmonary edema. Therefore accurate determination of a patient's fluid volume status is essential. Loss of skin turgor, dryness of the mucous membranes and postural fall in blood pressure are reliable clinical parameters of volume depletion. Fluid intake-output chart and daily weight monitoring are essential to detect changes in the fluid volume status promptly. Monitoring of central venous pressure is indicated especially when there is severe volume depletion, clinical signs are equivocal and the patient is oliguric or anuric. In established ARF diuretics do not influence the final outcome. They are used to convert oliguric to nonoliguric ARF in order to facilitate easier fluid management.

Hyperkalemia and acidosis are the most serious and life-threatening disturbances in the acute setting. The treatment depends on the degree of hyperkalemia and the changes seen on the electrocardiogram. Calcium gluconate 10 mL of a 10 percent solution given slowly IV is cardioprotective and temporarily reverses the neuromuscular effects of hyperkalemia. Potassium can be temporarily shifted into the intracellular compartment by intravenous administration of 10 units of soluble insulin and 25g of glucose. Inhalation of beta agonists such as salbutamol or IV administration of sodium bicarbonate achieves the same purpose. Elimination of potassium is achieved by using ion-exchange resins like sodium polystyrene sulfonate and diuretics. Sodium polystyrene sulfonate is given orally (25 to 50 g mixed with 100 mL of 20 percent sorbitol) or as an enema (50 g in 50 mL of 70 percent

sorbitol and 150 mL of tap water). If these measures do not control the potassium level, dialysis should be initiated. Acidosis is corrected by giving IV or oral sodium bicarbonate if the serum bicarbonate level is less than 15 mEq per L or the pH is less than 7.2. Intractable acidosis requires dialysis for correction.

Maintenance of Nutritional Status

Acute renal failure is a catabolic state and therefore, patients need nutritional support. The total daily caloric intake should be 30 to 45 kilocalories/kg bw. Most of this should be derived from a combination of carbohydrates and fats. In patients who are not on dialysis, protein intake should be restricted to 0.6 g/kg per day. Patients on dialysis need a daily protein intake of 1 to 1.5 g/kg body weight. Fluid administration is based on the urine output, body temperature and ambient temperature in all forms of ARF. Fluid restriction is crucial in the management of oliguric renal failure. In non-oliguric renal failure, the fluid administration can be more liberal. Since the levels of potassium and phosphorus may go down in non-oliguric renal failure, they have to be monitored and supplemented.

Life-threatening Complications

Several life threatening complications may develop which require prompt management including renal replacement therapy. These complications are:

- Volume overload
- Hyperkalemia ($K^+ > 6.5$ mmol/L or it is rising)
- Acid-base imbalance, mainly metabolic acidosis
- Symptomatic uremia (pericarditis, encephalopathy, bleeding diathesis, nausea, vomiting, pruritus)
- Severe azotemia (If BUN > 100 mg/dL or creatinine > 5 mg/dL).

Renal Replacement Therapy

The principal methods of renal replacement therapy (RRT) are intermittent hemodialysis (IHD), continuous veno-venous hemofiltration (CVVH), and peritoneal dialysis (PD). Each has advantages and limitations.

IHD is widely available and is the most efficient way to remove solutes and fluids. Dialysis-associated hypotension is an adverse factor, particularly in patients who are critically ill.

CVVH is the technique of choice in patients who are hemodynamically unstable. In this hypotension does not occur. It is more expensive and it is available only in a few centers. CVVH achieves patients on better control of uremia and clearance of solutes. Since the procedure is continuous, patients on CVVH are able to remove larger fluid volumes. This is an added advantage for patients on parenteral nutrition and multiple infusions.

Peritoneal dialysis is relatively inexpensive and widely available. It does not lead to hypotension. It has been widely used in managing ARF, with good results.

Chapter Summary

Definition and Staging	1162
Etiology	1162
Natural History and Progression	1163
Clinical Manifestations	1163
Diagnosis	1166
Management	1166

Chronic kidney disease (CKD) is an important public health problem affecting more than 10% of the general population. CKD is an important risk factor progressing to end stage renal disease (ESRD), cardiovascular disease and premature mortality. Management of ESRD is expensive and beyond the reach of many sections of the population in developing countries. CKD is a silent disease and if not detected and treated early, may progress

to ESRD. Hence, it is important to identify CKD early and institute measures to retard its progression.

Definition and Staging

Chronic kidney disease is defined as either kidney damage or GFR <60mL/min/1.73m² for ≥3 months. Kidney damage is defined as pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies.

CKD is characterized by kidney damage characterized by structural, functional or pathological abnormalities in the kidney associated with abnormalities in the composition of urine and/or blood of more than 3 months duration. Anomalies in the imaging tests and decrease in the GFR may be demonstrable. If the GFR is less than 60 mL/min/1.73 m² body surface, persisting for more than 3 months, this by itself can constitute CKD.

Stages of Chronic Kidney Disease

Stage	Description	GFR (mL/min/1.73m ²)
1.	Kidney damage with normal or increased GFR	≥ 90
2.	Kidney damage with mild decrease in GFR	60-89
3.	Moderate decrease in GFR	30-59
4.	Severe decrease in GFR	15-29
5.	Kidney failure	< 15 or dialysis

The present concept of CKD was put forth by the K-DOQI (Kidney Disease Outcomes Quality Initiative) in 2002. Over the years, there has been a shift in nomenclature from *chronic renal failure* to *chronic kidney disease*. Chronic renal failure is defined as a condition where there is a permanent and irreversible impairment of renal function persisting over a period of three months or more. Kidney damage is defined as structural or functional abnormalities of the kidney. The markers of kidney damage include persistent abnormalities in urine tests such as proteinuria, microalbuminuria or microscopic hematuria or abnormalities in the blood such as rise in urea or creatinine. Presence of abnormalities in imaging tests like ultrasound, IVP or CT scan, such as small echogenic kidneys, hydronephrosis or polycystic kidneys even without reduction of GFR in early stages constitutes CKD. The GFR may decrease eventually.

Staging

Stage 1 CKD represents kidney damage when GFR is normal or high. This includes patients with albuminuria or those with abnormal imaging studies.

In stage 2 CKD, there is evidence of kidney damage with mild decrease in GFR (60- 89 mL/min/1.73 m²). In the absence of kidney damage, this level of GFR *per se*, does not constitute CKD.

Stage 3 CKD includes patients with moderate decline in GFR (59-30 mL/ min/ 1.73 m²). All patients with GFR of less than 60 mL/min/1.73 m² are classified as having CKD irrespective of whether kidney damage is present or not. This is the stage where serum creatinine starts to rise. Majority of patients still remain asymptomatic. Nocturia and polyuria are early symptoms that may appear at this stage.

In stage 4 CKD, the fall in GFR is severe (29-15 mL/ min/1.73 m²). Overt uremic symptoms like loss of appetite, nausea, anemia and recurrent infections occur during this stage.

Stage 5 CKD is the stage when GFR is less than 15 mL/ min/ 1.73 m². At this stage the patient usually requires dialysis or other forms of renal replacement therapy.

GFR is the best measure of overall kidney function in health and disease. GFR can be affected by chronic kidney disease which reduces the number of nephrons. Hemodynamic factors affect single nephron GFR and they result in fall in the GFR. The normal GFR of a young adult is around 120-130 mL/min/1.73 m². Normal values in women are 8% lower from those of men at all ages. Above the age of 30 years, GFR declines at the rate of approximately 1 mL/min/1.73 m² per year.

Normal range and variability of GFR

Age (sex)	Mean GFR ± SD (mL/min/1.73 m ²)
1 week (males and females)	40.6 ± 14.8
2-8 weeks (males and females)	65.8 ± 24.8
>8 weeks (males and females)	95.7 ± 21.7
2-12 years (males and females)	133.0 ± 27.0
13-21 years (males)	140.0 ± 30.0
13-21 years (females)	126.0 ± 22.0

Etiology

The causes of CKD are broadly classified as given below.

Glomerular Diseases

Primary—Focal segmental glomerulosclerosis (FSGS), IgA nephropathy, membranoproliferative glomerulonephritis (MPGN).

Secondary—Diabetes, systemic lupus erythematosus (SLE).

Tubulointerstitial diseases—Reflux nephropathy, obstructive uropathy.

TABLE 179.1

Distribution of CKD in different geographical regions in India and the USA

	Chandigarh	Chennai	Indian CKD registry	USA
Diabetes	24	30	27.5	33
Hypertension	13	11	15.5	21
Chronic glomerular disease	37	21	19.3	19
Chronic tubulointerstitial disease	14	31	8.6	4
Cystic (ADPKD) disease	3.5	2.3	2.0	6

Vascular diseases—Hypertensive nephrosclerosis, ischemic nephropathy.

Cystic diseases—Autosomal dominant and recessive polycystic kidney disease (ADPKD and ARPKD).

Heredofamilial—Alport’s syndrome.

Diseases in the transplant -Chronic allograft nephropathy.

Age, ethnicity and distribution of renal diseases may be different in various geographical regions. Diabetes and hypertension are the two most important causes of CKD world wide. In the developing countries chronic glomerulonephritis and chronic interstitial nephritis are relatively more common than in the developed countries (Table 179.1).

FSGS, IgA nephropathy, reflux nephropathy and congenital anomalies of the urinary tract lead to CRF usually before the age of 40 years. Diabetes, hypertensive nephrosclerosis, ischemic nephropathy, multiple myeloma, analgesic nephropathy and systemic vasculitis are more common above the age of 55 years.

NATURAL HISTORY AND PROGRESSION OF CKD

Many diseases can initiate kidney injury and lead to progression. Reduction in the number of functioning nephrons lead to hypertrophy and increased glomerular filtration by the surviving nephrons. Glomerular hyperfiltration initially maintains GFR but later, the overworked nephrons succumb to the increased workload and lead to proteinuria, which causes further damage to the glomeruli and the tubulo-interstitium. The extent of tubulo-interstitial damage is an important factor determining disease progression. Hypertension which is present in over 90% of cases of advanced CKD leads to further progression of the disease, if not controlled. Hyperglycemia also causes structural and functional changes in the glomeruli leading to progressive renal

failure. Progressive destruction of nephrons leads to several adaptive mechanisms which enable the remaining nephrons to maintain body homeostasis. Though these adaptive changes are beneficial, later, they lead to maladaptive consequences. For example, early in the course of renal failure, loss of nephrons result in reduction of phosphate excretion and lead to hyperphosphatemia. This causes a fall in serum calcium due to its binding to the excess phosphorus. Hypocalcemia stimulates PTH which results in reduction of tubular reabsorption of phosphate and increased phosphorus excretion. This helps to normalize serum phosphate levels. With progressive loss of nephrons, higher and more sustained levels PTH develop leading to secondary hyperparathyroidism with all its adverse consequences. The nature of the primary kidney disease and its activity also dictates the progression. The rate of progression of glomerular diseases is faster than that of tubulo-interstitial diseases (Table 179.2).

CLINICAL MANIFESTATIONS OF CKD

Renal impairment is associated with a variety of signs and symptoms that are collectively referred to as the uremic state. The symptomatology may involve any system of the body. However, there is no correlation between the development of symptoms and the severity of renal disease. The early stages of CKD are usually asymptomatic and are detected only on investigations.

Edema

Most of the glomerular diseases are associated with edema. In chronic glomerular disorders, development of intermittent edema and hematuria indicates disease activity. In disorders that are not primarily due to glomerular disorders, as in most tubulointerstitial diseases, edema appears late.

Hypertension

Hypertension is the most common manifestation and it may appear early during the course of renal disease (90% in glomerular and 30% in tubulointerstitial diseases). If untreated, it leads to further damage. Rarely, uncontrolled hypertension can lead to precipitous and irreversible reduction in GFR. Hypertension is also an independent risk factor for cardiovascular morbidity.

Cardiovascular Manifestations

Cardiovascular manifestations include left ventricular hypertrophy (LVH) due to hypertension and anemia, ischemic heart disease, congestive cardiac failure due to fluid overload and myocardial dysfunction due to uremia (uremic cardiomyopathy). Electrolyte disturbances,

TABLE 179.2

Factor affecting the onset, progress and course of CKD	
Increased susceptibility to kidney damage Older age Family h/o CKD Reduced kidney mass Low birth weight Racial factors	Directly initiate kidney damage Diabetes mellitus Hypertension Autoimmune diseases Systemic infections Urinary tract infections Urinary stones Lower urinary tract obstruction Drug toxicity
Progression factors These cause worsening of kidney damage and faster decline in kidney function after initiation of kidney damage Higher level of proteinuria Uncontrolled hypertension Poor glycemic control in diabetics Smoking Non-compliance with treatment	End stage factors increase morbidity and mortality in kidney failure Late referral Lower dialysis dose Temporary vascular access Anemia Low serum albumin level

particularly hyperkalemia can lead to bradycardia, syncope and cardiac arrhythmias. Other manifestations include premature atherosclerosis, vascular calcification due to secondary hyperparathyroidism and pericarditis. Pericarditis presents with chest pain. Loud pericardial friction rub is audible on auscultation. Sometimes, fibrinous pericarditis may lead to pericardial effusion and cardiac tamponade. CKD is a major risk factor for cardiovascular disease and even mild impairment of renal function can lead to cardiovascular morbidity and mortality. Conversely, compromise in cardiac function worsens renal function too.

Gastrointestinal Manifestations

The GI manifestations like anorexia, nausea, vomiting, dyspeptic symptoms, constipation or diarrhea usually appear in Stage 4 CKD (GFR between 15 and 30 mL/min). The symptoms are mainly due to gastrointestinal mucosal ulcerations. Uremic stomatitis with dry mucous membranes, multiple small oral ulcers and parotitis are seen in advanced uremia. Rarely, gastrointestinal hemorrhage may occur. ‘**Uremic fetor**’ describes the ammoniacal odor occurring in patients with advanced renal failure and it is due to the hydrolysis of urea in saliva by bacterial urease. Intractable hiccoughs may occur in advanced uremia. Severe abdominal pain and paralytic ileus may occur as a result of hypokalemia. Ascites may occur in advanced renal failure.

Neuropsychiatric Manifestations

Paresthesias, sensory or motor peripheral neuropathy, pruritus, restless legs syndrome and bladder dysfunction are the neurologic manifestations. Subtle to gross behavioral abnormalities such as anxiety, depression, personality changes and disturbances of sleep are the psychiatric manifestations. Flapping tremor (asterixis) and myoclonic jerks are features of uncontrolled uremia. Rarely, convulsions and coma may occur. When a patient is initiated on dialysis, abrupt and rapid removal of urea from the blood may lead to higher concentration of urea in the brain since it does not cross the blood-brain barrier rapidly. This leads to cerebral edema and transient neuropsychiatric manifestations, collectively called ‘**dialysis disequilibrium syndrome**’. This can be prevented by adjusting the initial few sessions of dialysis so as to achieve very gradual fall in blood urea. Patients on long term dialysis may develop features of dementia and this is attributed to aluminum intoxication which may occur due to intake of aluminum containing antacids or through the water used for dialysis. This is no longer a major problem at present because of water treatment which involves removal of contaminants like aluminium in dialysis water and withdrawal of use of aluminum hydroxide as a phosphate binder.

Cutaneous Manifestations

The characteristic sallow complexion in renal failure is due to pallor and the deposition of yellowish brown

urochrome pigment. Recurrent skin infections, dry scaly skin with severe itching, rashes, erythema, vesicles and ulcerations are common. Cutaneous calcification in association with secondary hyperparathyroidism contributes to the severe itching. Pruritic hyperkeratotic papular eruptions or **Kyrle's disease** occurs in diabetics. In stage V CKD, precipitation of urea on the surface of the skin gives rise to '**uremic frost**'. Bleeding into the skin and mucosa may occur as a result of platelet dysfunction. Nail changes include pitting, burrowing and '**half and half**' nails. In half and half nail, the distal half of the nail is pink or brown and the proximal half is white or pale. The conjunctival deposition of calcium leads to redness and gritty feeling in the eye also called the '**uremic red eye**' while deposition of calcium as a band in the lamina propria of the cornea leads to '**band keratopathy**.'

Hematological Manifestations

Anemia is common in chronic kidney disease. It appears when the GFR is below 50 mL/min (Stage 3 CKD) and progressively worsens as GFR declines further. Symptoms appear much later, (stage 4 CKD). Usually the anemia is normocytic normochromic. The most important cause is decreased secretion of erythropoietin (EPO). Other factors, apart from EPO deficiency which contribute to renal anemia include the following.

1. Circulating uremic toxins - bone marrow resistance to the effect of EPO.
2. Reduced RBC survival (120 days to 80 days) probably due to mild hemolysis.
3. Platelet dysfunction - Bleeding, including occult gastrointestinal blood loss.
4. Iron deficiency.
5. Hyperparathyroidism – bone marrow suppression or fibrosis.
6. Folic acid deficiency.
7. Chronic inflammation.
8. Aluminum toxicity (rare).

Prolonged anemia can lead to worsening of renal function and lead to left ventricular hypertrophy and increased myocardial oxygen demand. Disturbances in the coagulation system and platelet dysfunction are common in advanced uremia. Platelet dysfunction occurs due to factors like retention of uremic toxins, nitric oxide and hyperparathyroidism.

Skeletal Abnormalities - Renal Osteodystrophy

As renal failure progresses, hyperphosphatemia, hypokalemia and secondary hyperparathyroidism develop leading to skeletal abnormalities. Renal tubular defects

and altered vitamin D metabolism also contributes to skeletal changes of renal osteodystrophy. Stunting of growth, bone deformities and rickets occur due to end organ resistance to hormones as a result of circulating uremic toxins. Adults with advanced CKD manifest with high turnover bone disease (due to hyperparathyroidism), low turnover bone disease (due to vitamin D deficiency or aluminum toxicity) or adynamic bone disease (due to excessive suppression of PTH). Skeletal deformities are more pronounced especially in children. These manifest even before there is significant reduction of GFR. This is called **non-uremic renal osteodystrophy**. This is caused by renal tubular acidosis and disturbances in Vitamin D metabolism. With advancing renal failure, bone disease and growth retardation become more evident. Short stature is an important feature of chronic kidney disease of childhood. Uremic toxins and end-organ resistance to growth hormone/insulin like growth factor have been implicated. Prolonged use of corticosteroids may also contribute to growth retardation. Children with advanced chronic renal failure caused by chronic tubulointerstitial and glomerular diseases also develop severe rickets with deformities (**Uremic renal osteodystrophy**). In adults, the most common skeletal disturbance is hyperparathyroid bone disease (osteitis fibrosa) characterized by increased osteoclastic bone resorption. This is known as high turnover bone disease. Typical radiographic features include subperiosteal resorption in the phalanges, 'salt and pepper' pattern in the skull, vascular calcifications in peripheral arteries like radial and femoral arteries and osteosclerosis (**rugger jersey spine**). Large osteoclastic tumours may be seen (**brown tumours**) in the skeleton around weight bearing areas. A rare and unusual syndrome in patients with severe osteitis is **calciophylaxis**. This is due to extra-osseous calcium deposition in soft tissues. It manifests as painful violaceous mottling of the skin followed by progressive gangrenous ulcerations at the fingers, toes and ankles. **Osteomalacia** is the second pattern of bone disease seen in chronic kidney disease. Vitamin D deficiency and/or aluminum intoxication occurring in those receiving long-term hemodialysis aggravate this condition. It is characterized by severe bone pain, recurring fractures and proximal myopathy. In some cases, a mixed pattern of hyperparathyroidism and osteomalacia may be found. In addition, adynamic bone disease is being increasingly recognized. It is a histological diagnosis showing lack of bone formation and resorption. It is probably due to excessive suppression of PTH by calcium supplements and Vitamin D therapy.

Respiratory Manifestations

Patients with advanced kidney disease may develop dyspnea due to pulmonary edema, pleural effusion or severe metabolic acidosis. Flash pulmonary edema occurs

in patients with renovascular diseases due to accelerated hypertension. **‘Uremic lung’** may be seen radiologically as a butterfly shadow in the area of the hilum and this is due to noncardiogenic pulmonary edema associated with increased pulmonary capillary permeability and exudation of proteinaceous fluid into the alveoli. Uremic serositis may present as pleurisy with associated pleural friction rub or underlying hemorrhagic pleural effusion.

Other Manifestations

In early CKD due to chronic tubulointerstitial diseases, hyperchloremic metabolic acidosis with a normal anion gap is common. As the renal failure advances, high anion gap metabolic acidosis supervenes. Chronic metabolic acidosis has deleterious effect on the bone and several organ functions. Chronic malnutrition is common and it is caused by anorexia, nausea, poor dietary intake and vomiting. **Sexual dysfunction** is also common in both sexes. In males, it manifests as decreased libido, erectile dysfunction and azoospermia. In females, reduction of libido and menstrual irregularities are common. Patients with CKD are more prone to develop infections due to immunocompromised state. Infection tends to persist longer.

Diagnosis

Often CKD may go unnoticed until renal failure is advanced. Strong clinical suspicion and appropriate investigations are essential for early diagnosis. The diagnosis is established by demonstrating decreased GFR or markers of kidney damage. Estimation of serum creatinine and a creatinine clearance are usually used for this purpose. Though several formulas are available for calculating creatinine clearance, (CrCl) the most widely used one is Cockcroft-Gault formula:

$$\text{CrCl for males} = \frac{(140 - \text{age}) (\text{weight in kg})}{72 \times \text{serum creatinine (mg/dL)}}$$

Note: For females multiply the figure by 0.85

Markers of kidney damage include proteinuria, hematuria or abnormalities of urinary sediment. Since elevation of serum creatinine occurs only when GFR is below 50% of normal, early detection of CKD depends on the other markers.

Detection of more than 5 erythrocytes per high power field in a freshly voided specimen of urine indicates significant microscopic hematuria if present on repeated examinations. Presence of dysmorphic RBCs and acanthocytes in urine usually indicates pathology in the glomerulus. Coexistence of proteinuria and cellular casts points to renal parenchymal disease. Urinary specific

gravity and osmolality may be relatively fixed at around 1010 and 290 respectively, signifying the inability of the kidneys to concentrate or dilute urine.

Low serum calcium, high serum phosphorus with high serum alkaline phosphatase is often seen in advanced kidney disease. Serum bicarbonate is often reduced as a result of metabolic acidosis. High anion gap is due to decreased ammonium ion production and decreased excretion of hydrogen ions. Serum levels of sodium are usually normal until renal failure is very advanced. The ability of the kidney to maintain serum potassium homeostasis is preserved till the patient is in stage IV CKD. Hyperkalemia may set in early in patients consuming excessive potassium in diet and those taking potassium sparing diuretics, ACE inhibitors or angiotensin receptor blockers (ARBs).

X-ray of the skeleton may show features of renal rickets in children or osteomalacia, osteitis fibrosa or osteosclerosis in adults.

Presence of smaller kidneys detected by ultrasound imaging suggests long standing kidney disease. The exceptions to this rule include diabetes mellitus, multiple myeloma, polycystic kidney disease and obstructive uropathy. Demonstration of scarring of the kidneys may be the earliest indicator of parenchymal damage in diseases like reflux nephropathy. Asymmetry of the kidneys on ultrasound examination may be an indicator of underlying renovascular disease. Calcification and stone disease may be demonstrated by plain X-ray KUB or by ultrasound. Doppler imaging of the kidneys and renal blood vessels helps to detect renovascular disease early.

MANAGEMENT OF CHRONIC KIDNEY DISEASE

All patients require conservative management in the early stages. When the patient approaches Stage V CKD, renal replacement therapy has to be introduced.

The general management consists of:

- 1. Treatment of reversible causes.
- 2. Preventing or slowing the progression of the renal disease.
- 3. Treatment of the complications of renal dysfunction.
- 4. Identification and adequate preparation for renal replacement therapy.

Reversible Causes of Renal Dysfunction include the Following

- a. Exacerbation of original renal disease,
- b. Decrease in renal perfusion,
- c. Hypotension,
- d. Infections,
- e. Use of drugs which reduce GFR,
- f. Nephrotoxic agents,

- g. Urinary tract obstruction,
- h. Accelerated hypertension,
- i. Malnutrition, hypoalbuminemia, anemia,
- j. Congestive cardiac failure, hepatic failure and
- k. Persistent metabolic abnormalities such as hyperuricemia, hypercalcemia and hypokalemia

Preventing or Slowing the Progression of the Renal Disease

Hypertension, hyperfiltration, hypertrophy, proteinuria and dyslipidemia contribute to glomerulosclerosis and tubulo-interstitial damage.

The blood pressure should be maintained below 130/80 mm Hg by appropriate drug therapy. Administration of angiotensin converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) slows the progression of chronic renal failure, particularly in those with proteinuria. This therapy is most effective if it is initiated early, before the serum creatinine level exceeds 1.5 to 2 mg/dL (132 to 176 μ mol/L).

ACE inhibitors and ARBs should be used with caution since they can cause decline in renal function and hyperkalemia. Strict glycemic control is mandatory for slowing the rate of progression. Other general measures include weight reduction, cessation of smoking, alcohol misuse and avoidance potentially nephrotoxic drugs or agents.

The progression of CKD can be slowed down by instituting measures for:

1. **Control of hypertension:** Antihypertensives should be used to achieve blood pressure less than 130/80 in patients with CKD and to < 125/75 in those with proteinuria of 1 g/day.
2. **Control of diabetes.**
3. **Diet modification:** Protein intake should be restricted to < 0.8 g /kg/day to reduce the nitrogenous load on the kidney. Salt intake should be restricted to < 5 g/day. The fluid intake should be adjusted to avoid edema. Phosphorus restriction to < 800 mg/day is recommended to reduce hyperparathyroidism.
4. **Control of hyperlipidemia:** In addition to diet control, statins should be used in doses of 10-20 mg/daily to maintain serum cholesterol below 200 mg%.
5. **Reduction of proteinuria:** ACEI and ARB's prevent progression of renal disease both by reduction of blood pressure, proteinuria and by their anti-inflammatory actions. These agents should be used early in the course of the disease, before the serum creatinine goes above 1.5 mg/dL. In some patients with renovascular disease, the renal functions may deteriorate and should be monitored.
6. **Control of hyperuricemia, hyperphosphatemia and metabolic acidosis.**

7. **Life style modification:** This consists of dietary measures, exercise programmes, control of obesity, cessation of smoking and alcohol.

Treatment of the Complications of Renal Dysfunction

The complications include disorders of fluid and electrolyte balance, hyperkalemia, metabolic acidosis, hyperphosphatemia, anorexia, nausea, vomiting, fatigue, hypertension, anemia, malnutrition, hyperlipidemia, bone disease and pericarditis.

Fluid and salt balance — Even though sodium and intravascular volume are usually maintained till the GFR falls below 15 mL/min they are unable to cope up with rapid fluctuations in fluid and electrolytes. Treatment is by restriction of dietary sodium and fluids combined with administration of a loop diuretic. Salt intake is restricted to 2-4 g per day. Single large doses of frusemide (200 - 500 mg) or torsemide (30-100mg) daily are necessary. Those with CKD and salt wasting state require additional salt intake.

Treatment of Hyperkalemia

Hyperkalemia develops in patients with CKD who are oliguric or those with increased dietary potassium intake. Use of potassium sparing diuretics, ACEI, ARB's, NSAIDs or beta blockers tend to increase serum potassium. Patients with hyporeninemic hypoaldosteronism (especially diabetics) develop hyperkalemia early in the course of their disease. Hyperkalemia can be controlled by avoidance of the offending drugs, salt and K⁺ restriction, use of diuretics and potassium binding resins. Hyperkalemia above 6 mmol/L is an emergency warranting aggressive treatment.

Treatment of Metabolic Acidosis

Metabolic acidosis is common in stages 4 and 5 CKD. This is treated by administering sodium bicarbonate in doses of 0.5-1 mmol/kg/day so as to maintain serum HCO₃ above 22 mmol/L. As an alternative, Shohl's solution which contains a buffered pair of sodium citrate and citric acid can be used. One mL of Shohl's solution provides 1 mmol of bicarbonate. Severe metabolic acidosis is however, difficult to correct without dialysis.

Treatment of Renal Osteodystrophy

Along with dietary phosphate restriction to < 800 mg/day, oral phosphate binders like calcium acetate or non-calcium based phosphate binders like sevelamer are used. These help to reduce phosphate absorption from the gut. In patients who have increased serum

parathormone levels and/or hypokalemia in spite of correction of hyperphosphatemia, 1,25, dihydroxy vitamin D supplementation is indicated.

Treatment of Anemia

The main causes of anemia in CKD include a combination of poor dietary intake of iron, blood loss and erythropoietin deficiency. The initial step is detailed work-up to diagnose the cause. This includes screening of body iron stores and for sources of blood loss. Patients with iron deficiency should be given preferably, parenteral iron preparation to correct iron deficiency. Parenteral iron is usually administered IV or IM as iron dextran or iron sucrose complex. Once the iron levels are corrected, most patients with advanced CKD require erythropoietin in doses of 50-200 iu/kg/ week. The hematocrit has to be maintained at 36% (Hb 11 to 12 g/dL) by adjusting the dose. Correction of anemia improves the quality of life and improves functions of vital organs.

Treatment of Dyslipidemia

Hyperlipidemia causes progression of renal disease and therefore it should be managed aggressively. Early and judicious use of statins such as atorvastatin or simvastatin in doses 10-20 mg oral at bed time is necessary to maintain

serum LDL levels <100 mg/dL. Patients with elevated triglyceride levels need gemfibrozil in addition.

Treatment of Malnutrition

Patients with CKD are usually malnourished. This is due to poor intake of food, hypercatabolic state and the pro-inflammatory effects of uremia. In addition, protein restriction contributes to muscle wasting. The calorie intake should be 30-35 Calories/kg bw/day. The serum albumin levels should be maintained >3.5 g/dL.

Treatment of Uremic Bleeding

Platelet dysfunction is the usual cause of bleeding in CKD. Usually this is asymptomatic and no specific therapy is needed. In patients with overt manifestations or those undergoing invasive procedures, the administration of desmopressin (dDAVP), cryoprecipitate and or dialysis is recommended to correct the bleeding manifestations.

Renal Replacement Therapy (RRT)

RRT (dialysis or renal transplant) is needed in patients with stage V CKD (GFR < 15 mL/mt) or in those with severe uremic manifestations like diuretic resistant fluid overload, severe hyperkalemia, resistant metabolic acidosis, pericarditis or uremic encephalopathy.

Chapter Summary

- Hemodialysis 1169
- Peritoneal Dialysis 1170
- Continuous Ambulatory Peritoneal Dialysis 1171
- Newer Forms of Dialysis 1171
- Kidney Transplantation 1171

When the kidneys fail and life cannot be sustained any more, therapies tailored to replace all or most of the functions of the kidney are essential. They constitute renal

replacement therapy (RRT). In chronic kidney disease, a sustained reduction in GFR below 5%, is termed as end stage renal disease (ESRD). This warrants treatment with maintenance dialysis or kidney transplantation. In acute renal failure, life is supported by any one of the forms of dialysis till kidney function recovers.

Dialysis

There are broadly two forms of dialysis namely: (1) peritoneal dialysis and (2) hemodialysis. Either of them can be used as a short-term measure in ARF patients (acute

Fig. 180.1: Hemodialysis machine

Note: Blood tubings connected to the patient circulating blood through the artificial kidney and returning to the patient. The 2 cans in the base of the unit contain acetate and bicarbonate concentrate

dialysis) or as a long term option in ESRD (chronic dialysis).

HEMODIALYSIS

Principles

Hemodialysis is the modality of extracorporeal purification of blood using an artificial filter. At its simplest, blood and dialysate are pumped into a dialyser using a dialysis machine. The dialysate is a solution of specially treated water, sodium, potassium, magnesium, calcium, chloride and dextrose with bicarbonate as buffer. Its constitution is akin to plasma water except that potassium levels are usually kept low. A semipermeable membrane separates the blood from the dialysate. During the passage through the dialyser, diffusion occurs across the membrane depending on the concentration gradient. Diffusion is maximised by maintaining high flow rates of blood and dialysate in a countercurrent manner Fluid can be removed from the blood compartment by exerting a transmembrane pressure. The modern dialysis machines are equipped with electronic devices to monitor blood flow, dialysate flow, temperature and conductivity of dialysate, ultrafiltration rate and to detect blood leak into the dialysate or air in the blood circuit (Fig. 180.1).

Blood is drawn into the extracorporeal circuit and returned to the patient through a vascular access. Arteriovenous shunt or cannulation of major veins (femoral , internal jugular or subclavian) are used for

TABLE 180.1		
Definite indications for dialysis in ARF		
Clinical indications include, anuria of >48 hours, fluid overload, pulmonary edema, metabolic encephalopathy, uremic bleeding or pericarditis. The biochemical indications are		
Blood urea	≥	150 mg/dL
Daily rise of urea	>	50 mg/dL
S creatinine	≥	7 mg/dL
Daily rise of S creatinine	>	1 mg/dL
S sodium	<	125 mmol/L
Daily fall of sodium	>	8 mmol/L
S potassium	>	5.5 mmol/L
Daily rise of potassium	>	1.0 mmol/L
S bicarbonate	<	15 mmol/L
Daily fall of bicarbonate	>	5 mmol/L.

temporary vascular access. For permanant access, an arteriovenous fistula or graft is created.

Indications for Dialysis in ARF

In acute renal failure, the objective of dialysis is to prevent complications such as fluid overload, encephalopathy, hyperkalemia, hypokalemia, metabolic acidosis and other life-threatening complications. This serves to gain time for the recovery of kidney functions. Dialysis is usually initiated early in the course of the illness. Definite indications for dialysis in ARF are shown in Table 180.1.

The duration and frequency of dialysis is determined by the catabolic state of the individual which is reflected by the rate of change of the biochemical parameters, hemodynamic status of the individual and general well being. Short daily dialysis and slow low efficiency extended dialysis (SLEED) are some of the modifications of conventional hemodialysis in ARF.

Hemodialysis in ESRD

Chronic maintenance hemodialysis (MHD) in ESRD should be carefully planned in advance. The patient and the family should be appraised of the eventual need for dialysis sufficiently early. Other forms of dialysis and transplantation should also be discussed. If the patient opts for MHD and is clinically suitable, a permanent vascular access (A-V fistula) is created and allowed to mature. An AV fistula is usually created between the radial artery and cephalic vein at the wrist (Fig. 180.2) or occasionally between brachial artery and cephalic vein in the cubital fossa. Dialysis should be initiated when GFR falls below 15 mL/min or if the patient is symptomatic. The duration and frequency of dialysis is prescribed taking into account

Fig. 180.2: AV fistula at wrist

the body mass index of the individual, nutritional status, occupation and comorbidities such as cardiac and vascular disease. Ideally 4 hours dialysis should be done thrice weekly in adults. The patient should be periodically evaluated for adequacy of dialysis, general well-being, bone disease, calcium-phosphorus balance, nutritional status and anemia. Most patients on dialysis require treatment with antihypertensive medication. Other supportive measures include erythropoietin with parenteral iron for correction of anemia, water soluble vitamin supplements, phosphate binders and active form of vitamin D₃ for treating bone disease.

The 10 years survival in young patients exceeds 80% if they are initiated into maintenance dialysis early. In those above 55 years, the 5 years survival is below 20%. In India, financial constraints seriously impair the long term results.

Factors Determining Dialysis Efficacy

The important factors that determine the efficacy of dialysis are:

- Blood flow rate
- Dialysate flow rate
- Membrane permeability and surface area and
- Length of a dialysis session and frequency of dialysis.

In conventional dialysis, blood flow is usually kept at 200-400 mL and dialysate flow at 500-800 mL per minute. Different types of dialysers are available, the most widely used are the hollow fibre dialysers. The membranes used in the dialysers are made of processed cellulose or synthetic polymers such as polysulphone (PS), polyacrylonitrile (PAN) or poly methyl-methacrylate (PMMA). Generally the synthetic membranes have higher permeability. The surface area of the membranes varies between 0.8 to 1.6 m². Dialyser efficiency is usually measured by its ability to clear urea (urea clearance), remove water (ultrafiltration rate {UFR}) and clear larger molecules like vitamin B₁₂ (B₁₂ clearance). Conventional dialysers have urea clearance of 300 to 500 mL / minute and UFR of 5-10 ml/mm of Hg of transmembrane pressure. High efficiency and high flow dialysers can

achieve urea clearances of > 700 mL/minute. They have higher UFRs and they also clear larger molecular weight solutes. However, when using high flux dialysers the machines need to be more sophisticated.

Dialysis Adequacy

Adequacy of dialysis is assessed by the clinical improvement and objectively determined by biochemical indices. The most widely used index is the Kt/V where K is the efficiency to clear a substance, it is the duration of dialysis and V is volume of distribution of the substance in the body. The recommended Kt/V urea per dialysis session is 1.3. A four hour session of dialysis using a conventional dialyser and blood and dialysate flow rates of 200 and 500 mL per minute respectively often achieves this Kt/V in an average adult patient. Other measures of dialysis adequacy are urea reduction ratios (1- post dialysis serum urea/pre dialysis serum urea). Time averaged concentration of urea calculates the average urea between the beginning of two successive dialysis sessions. Assessment of the quality of life (QOL) measured by specific questionnaire is also an important measure of adequacy.

Complications of Maintenance Hemodialysis

Hypotension, pyrogen reactions, first use syndrome and dialysis disequilibrium are the common acute complications. Rapid removal of urea during the initial dialysis sessions may cause symptoms due to brain edema as a result of concentration gradient of urea between brain and blood. This is referred to as **disequilibrium syndrome**. This can be prevented by deliberately giving shorter and less efficient dialysis sessions initially. First use syndrome develops in some patients when a new artificial kidney membrane is used. It does not occur during reuse. Vomiting, headache, muscle cramps, hemolysis and bleeding are less frequent adverse effects. Patients with cardiovascular disease may develop hemodynamic instability, angina, acute coronary events, arrhythmias and sudden death.

Long-term complications of MHD include metabolic bone disease, neuropathy, dialysis dementia, chronic subdural hematoma and amyloidosis.

PERITONEAL DIALYSIS

Peritoneal dialysis (PD) was first done in 1936 for a patient of acute renal failure. The peritoneal membrane with its underlying capillary bed acts as the semipermeable membrane across which exchange occurs by diffusion between blood and dialysate. The peritoneal dialysate is a sterile solution of water with its solute concentration similar to that of plasma water. The buffer used is lactate

and dextrose is used as an osmotic agent to facilitate ultrafiltration.

Acute intermittent PD is performed by introducing a rigid or soft cannula into the peritoneal cavity using a trocar. Fluid exchanges of 500 mL to 2L are given at a time. The fluid is allowed to dwell in the peritoneal cavity for 30-45 minutes and drained off under strict sterile precautions. This process is repeated. Each exchange takes about 1 hour. 20 such exchanges constitutes one session of acute PD and is particularly effective in children where the ratio of peritoneal surface area to body surface is greater. PD is advantageous in hemodynamically unstable patients and in those with multiple organ failure.

Complications include infection, bleeding, perforation of hollow viscera, and blockage of the cannula. Disequilibrium is uncommon in PD, as the solute exchange is slow. PD may be inadequate in hypercatabolic patients.

CONTINUOUS AMBULATORY PERITONEAL DIALYSIS (CAPD)

Introduced in the 1980's CAPD has become a viable option for about 10% of ESRD patients world wide. The principles of CAPD are the same as that of IPD, except that the fluid is permitted to dwell for 3-4 hours during each exchange. A permanent silicon catheter (Tenckhoff catheter) with 2 cuffs is placed in the peritoneum surgically through a subcutaneous tunnel. One of the cuffs is positioned just before the entry of the perforated end of the catheter into the peritoneum. The other cuff is positioned in the subcutaneous tissue just deeper to the skin exit site of the catheter. The exit site is fashioned suitably below and lateral to the umbilicus. The composition of PD fluid is similar to that for IPD except that the containers (bags) are made of non-leachable plastic material. Single or double bags with appropriate connecting and transfer sets are used. A titanium adapter is usually used to connect the catheter to the transfer set in order to minimise infection. Sufficient training of the patient or a bystander to the techniques is essential to avoid infection which is the most serious complication. .

CAPD involves 3-4 exchanges per day for an average adult. Individual prescriptions vary depending upon the clinical condition of the patient, the transport characteristics of the peritoneal membrane and the type and concentration of PD fluid. Dialysis is taken to be adequate if the Kt/V is 2 for adults.

Indications of CAPD

CAPD is a suitable option for patients with cardiovascular disease, poor vascular access, those living away from centres of hemodialysis facility, and those who prefer home-dialysis. It is the preferred option for small children and elderly patients. The advantage of CAPD is the relative freedom of mobility, better rehabilitation and

quality of life, preservation of renal function and lesser need for EPO to manage anemia. Disadvantages include cost, need for clean and adequate space, self reliance and likelihood of progressive ultrafiltration failure due to change in peritoneal permeability. Complications of CAPD include peritonitis, blockage of catheter, hernias, and metabolic complications such as worsening of hyperglycemia, dyslipidemia, hypocalcemia, bone disease and obesity. Other rare but dreaded complications include loculation of PD fluid and sclerosing peritonitis. Life expectancy with CAPD is similar to that of MHD patients.

NEWER FORMS OF DIALYSIS

In order to meet the demands of acutely ill patients in the ICU setting with ARF, newer forms of dialysis have come into vogue. They are collectively called as **continuous renal replacement therapy** (CRRT). Using the principles of ultrafiltration and convective transport through highly permeable and low resistance dialysers, solute removal and fluid removal are achieved in a more physiological way, continuously (as in the kidney) to suit the hemodynamically unstable, hypercatabolic patients in the ICU. Vascular access is through a double lumen venous cannula in a central vein. Various modes used include hemofiltration, slow continuous hemodialysis and hemodiafiltration. Advantages include hemodynamic stability, removal of large volumes of fluid, thereby facilitating good nutritional supplementation and ease of performance at the bed side. Disadvantages include continuous anticoagulation and its problems, manpower for close monitoring and increased cost.

Kidney Transplantation

This is currently the best and finite option for patients with ESRD. The kidney can be procured from live donor or brain dead vegetative subjects (cadaver donor). The first successful kidney transplantation was performed in 1955 by Joseph Murray at the Peter Bent Brigham Hospital, Boston, Ma, USA, using an identical twin as a kidney donor and the recipient survived for 38 years with a functioning graft.

The most important barrier to transplantation of human organs is the immune response mounted by the recipient against the donor organ. Life long immunosuppression is required. The median survival in live related donor kidney transplantation with matched donors is 24 years and in unmatched live donors it is 18 years. In cadaver transplant the median survival is 14 years in ideal situations.

Any healthy adult can be a renal donor. Donor and recipient have to be ABO compatible and it is desirable that they are also matched to the best possible extent for

Fig. 180.3A: Renal transplantation: Position of the transplanted kidney (arrow) in the iliac fossa extraperitoneally (right or left side)

the HLA antigens. The recipient serum should not cross react with donor lymphocytes. (Lymphocytotoxic antibodies). The donor renal artery is anastomosed with internal iliac artery of recipient's (end to end), donor renal vein to external iliac vein of recipient, and donor ureter into the recipient's urinary bladder (Figs 180.3A and B). Donor selection and recipient preparation goes a long way for success in transplantation.

The donor kidney along with a portion of the ureter and the vascular pedicle is removed surgically and transplanted into the iliac fossa of the recipient. The vascular anastomosis is done after the kidney is perfused with cold isotonic solutions and the ureter is implanted into the native bladder. The native kidneys of the recipient are not removed unless there are specific indications. Usually brisk diuresis occurs after transplantation. Rarely graft function can be delayed due to acute tubular necrosis. This is more common with cadaver donors.

Complications of Renal Transplantation

Graft rejection: There are essentially three types of rejection: Hyperacute rejection resulting from performed lymphocytotoxic antibodies, acute rejection due to sensitization to donor HLA antigens and chronic rejection

- 1. External iliac artery
- 2. Internal iliac artery
- 3. Arterial anastomosis (internal iliac artery to renal artery end to end)
- 4. Ureter
- 5. Anti-reflux anastomosis of ureter into bladder
- 6. External iliac vein
- 7. Venous anastomosis (renal vein to external iliac vein-end to side)
- 8. Transplanted kidney

Fig. 180.3B: Vascular anastomosis in renal transplantation and implantation of the ureter

due to low grade humoral and cell mediated immune response against the graft. Acute rejections are reversible with treatment, but hyperacute rejection is irreversible resulting in graft loss immediately after transplantation. Chronic rejection can be retarded with treatment. Current therapy minimises acute rejection episodes and targets at decreasing chronic graft loss.

Surgical complications include *artery and vein thrombosis, ureteric obstruction or leaks, wound dehiscence, lymphoceles and urinomas*. Current refined surgical techniques have minimised these complications to a large extent.

Other complications after renal transplantation include opportunistic bacterial, viral and fungal infections, malignancy, adverse effects of drugs, diabetes mellitus, metabolic bone disease and cardiovascular morbidity.

In countries with high incidence of infective complications, and economic constraints, the survival after successful transplantation is lower compared to developed economics with subsidised health care delivery.

Chapter Summary

Vulnerability of Kidneys 1173
 Mechanisms of Drug Induced Renal Damage 1173
 Common Drugs Implicated in Renal Damage 1174
 Adjustment of the Dosage of Drugs in Renal Failure 1175
 Drugs and Dialysis 1176

Since the kidneys are involved in the excretion of several drugs or their metabolites, avoidance of certain drugs or modification of dosage may be needed in renal disease. In addition, as more and more drugs are introduced for various disorders, the risk of drug induced kidney disease will increase. It is important to know why the kidneys are affected by some drugs, the mechanisms of injury and principles of modification of dosage in renal dysfunction.

Vulnerability of Kidneys

The kidneys are highly vulnerable to the effect of drugs and toxins. The blood flow to the kidneys is nearly 20% of the cardiac output. Since the kidneys weigh about 300 g, the blood flow per gram of renal tissue is 3.5-4.0 mL/min/g. Thus, the kidneys are among the most vascular organs in the body. This results in drugs and toxins attaining high levels in the kidney. This load is exaggerated in the renal cortex, which gets 90% of renal blood flow. Substances that are filtered by the glomeruli reach the tubules and their concentration increases in the tubules because of selective water reabsorption. Some drugs such as gentamicin, which are reabsorbed by the proximal tubule reach the tubular cell in very high concentrations. Urinary concentration by countercurrent mechanism, high metabolic activity of the tubular cells, tubular secretion and precipitation of drugs in tubules depending on the concentration and pH are the other

important reasons for the high vulnerability of the kidneys.

Mechanisms of Drug Induced Renal Damage

Drug induced damage accounts for 5-20% of acute renal failure and above 20% of chronic renal disease. In many instances it may go off unrecognized. A high index of suspicion is necessary for early identification of drug induced renal damage. The various mechanisms of cell injury due to drugs are:

1. Direct interaction of drug with tubular cell membrane.
2. Insertion into the lipid components of the cell membrane.
3. Transportation into the cells and
4. Blockade of cytoplasmic metabolic events.

Renal damage due to drugs may be broadly classified as follows:

1. Prerenal:
 Volume depletion, e.g. diuretics.
 Increased catabolism, e.g. steroids.
 Vascular occlusion, e.g. oral contraceptives.
 Loss of renal autoregulation—non-steroidal anti-inflammatory drugs (NSAIDs), angiotensin converting enzyme inhibitors (ACEIs).
2. Immune mediated damage:
 Acute interstitial nephritis, e.g. rifampicin, penicillin, allopurinol.
 Allergic vasculitis, e.g. thiazides, penicillamine
 Glomerular damage, e.g. NSAIDs, gold salts and penicillamine.
3. Direct toxicity:
 Acute tubular necrosis.
 Papillary necrosis.
4. Obstructive uropathy:
 Retroperitoneal fibrosis, e.g. practolol, methyldopa, methisergide, hydralazine.
 Urinary tract obstruction.

Papillary necrosis, e.g. NSAIDs, acetaminophen.
Tubular blockade due to crystalluria, e.g. sulphonamides, acyclovir.

COMMON DRUGS IMPLICATED IN RENAL DAMAGE

The most common drugs extensively used clinically causing nephrotoxicity include NSAIDs, ACEI, angiotensin receptor blockers (ARBs) and radiocontrast agents. This combination is referred to as “**internist’s nephrotoxic quartet**”.

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs produce renal damage in different ways.

- a. **Hemodynamically mediated renal failure:** This is the most common mechanism. All NSAIDs including selective Cox II inhibitors lead to the inhibition of protective vasodilatory intrarenal prostaglandins. Therefore under conditions of reduced renal perfusion loss of renal autoregulation occurs which may lead to renal failure. Patient groups at risk are the elderly, those with dehydration, underlying renal disease, decreased effective circulatory volume and use of other nephrotoxic drugs. Patients with hemodynamically mediated renal failure present with oliguria, bland urine sediment and raised serum creatinine. Recovery usually occurs following timely withdrawal of the drug.
- b. **Nephrotic syndrome:** Nephrotic presentation may occur after several weeks to months of therapy particularly in elderly women. Renal biopsy reveals foot process fusion under electron microscopy along with interstitial edema and patchy infiltration with T lymphocytes. This may suggest a delayed hypersensitivity reaction to the drug. Recovery often occurs following withdrawal of the drug.
- c. **Hyperkalemia:** This is secondary to hyporeninemic hypoaldosteronism and is seen usually when NSAIDs are used along with ACEI, potassium sparing diuretics or potassium supplements.
- d. **Papillary necrosis:** It follows the intake of large quantities of NSAIDs over a short period. Ingestion of 1-3 kg of paracetamol over a period of 3 years or the total ingestion of 2-8 kg of phenacetin over 8-10 years along with other analgesics can induce analgesic nephropathy. Papillary damage is due to the very high concentration of the drug established at the papillary tip.
- e. **Salt and water retention:** Edema occurs as a result of salt and water retention. This worsens pre-existing hypertension and congestive cardiac failure and this can lead to resistance to the action of diuretics.

Aminoglycoside induced renal failure is commonly seen in clinical practice. The important risk factors for aminoglycoside nephrotoxicity include extremes of age, volume depletion, concurrent use of other nephrotoxic agents, hypokalemia, hypomagnesemia, sepsis and liver disease. The dose, duration and frequency of administration of the drug determine the pattern and severity of damage. Patients usually present with non-oliguric renal failure 7-10 days after the initiation of therapy. Sometimes the manifestations of renal failure appear only after the completion of the course of antibiotic.

Aminoglycosides produce renal damage by acting as a direct tubulotoxins. They are freely filtered at the glomerulus and reabsorbed at the proximal convoluted tubule. The drug accumulates in the proximal tubule and can be seen under the electron microscope as ‘*myeloid bodies*’. These cells undergo necrosis, and clinically manifests as tubular dysfunction and renal failure. Aminoglycoside toxicity is often dose related.

In all groups of patients, especially in those at higher risk of developing nephrotoxicity, the baseline renal function should be checked and serum creatinine monitored every three days during and after drug administration. In the elderly and in those with preexisting renal dysfunction, the dose should be adjusted to the creatinine clearance as discussed below. At the earliest evidence of renal dysfunction the drug should be discontinued. In most cases, recovery occurs following drug withdrawal, but in those with established renal failure, dialysis support will be required.

ACE Inhibitors

ACEI are increasingly used now in the treatment of hypertension, congestive cardiac failure and in the prevention of progression of diabetic nephropathy. ACEI can produce hemodynamically mediated acute renal failure in a selected group of patients, e.g. bilateral renal artery stenosis, renal artery stenosis in a solitary kidney, moderate to severe congestive cardiac failure, volume depletion and pre-existing renal insufficiency. The efferent arteriolar tone, intraglomerular pressure and glomerular filtration rate (GFR) are modulated by angiotensin II. Administration of ACEI under these circumstances leads to relaxation of the efferent arterioles and a subsequent drop in the intraglomerular pressure and GFR. Although in most instances the renal failure is reversible, ACEI can produce irreversible renal failure, especially when there is underlying renal parenchymal disease. ACEI can also produce hyperkalemia when used in conjunction with potassium sparing diuretics, beta-blockers or potassium supplements. Captopril can produce nephrotic syndrome (membranous nephropathy). Careful use of these drugs with monitoring of renal function and serum potassium levels and avoiding the use of these drugs in the high-risk group can prevent renal toxicity to a large extent.

Radiocontrast Agents

Renal failure associated with radio contrast agents is reported as the third most common cause of in-hospital renal failure. Conventional contrast agents are hyper-osmolar, a property contributing to their toxicity. Ionic contrast agents are especially toxic. Maximum reduction in renal function is usually noticed 48 hours after injection of the contrast. Patients can present with transient renal dysfunction or severe renal failure requiring dialysis. A persistent nephrogram 24 hours after contrast administration is another finding in radio-contrast related renal failure. Risk factors precipitating radio-contrast nephropathy are pre-existing renal insufficiency, dehydration, elderly age, severe congestive heart failure, multiple myeloma. Concurrent use of other nephrotoxic agents, repeated exposure to radiocontrast agents and high dose of ionic contrast agents. Although uncomplicated diabetes as such is not a risk factor, those with diabetes and renal involvement are affected more.

Exact mechanism of contrast mediated renal damage is not clear. The two proposed mechanisms are renal hypoperfusion and direct tubular toxicity. Urine osmolarity tends to be high with a low fractional excretion of sodium suggesting prerenal failure. This may be due to intense intrarenal vasoconstriction mediated by renin, angiotensin II, intracellular smooth muscle calcium, adenosine and endothelin.

There is no specific treatment. In most cases it is reversible. The risk can be reduced by using minimum dose of non-ionic contrast agent, avoiding multiple radiocontrast injections and avoiding dehydration prior to, and during the procedure. Administration of half normal saline starting 12 hours before and up to 12 hours after the dye injection is probably the most effective measure to reduce radiocontrast nephrotoxicity. N Acetyl cysteine given in a dose of 600mg twice daily before and after contrast has been shown to be useful in some cases. The urine output must be maintained at around 100 mL per hour before and after the procedure.

Adjustment of the Dosage of Drugs in Renal Failure

Renal disease can affect the absorption, bioavailability, distribution, metabolism and excretion of some drugs. Pharmacologically active metabolites of drugs may accumulate in renal failure causing adverse reactions, e.g. nitrofurantoin when administered in renal failure can cause peripheral neuropathy and anesthetic agents like morphine can cause respiratory depression. Drug excretion by the kidneys depends on glomerular filtration, tubular secretion and tubular reabsorption. These may be altered in renal failure. Thus, dose modification may be necessary in renal disease. The necessity and degree of dose reduction depends on the class of drug. The goal of drug

modification would be to maintain efficacy while avoiding drug accumulation and adverse reactions. This is achieved by the following methods:

1. **Using dosage nomograms:** This is based on knowledge of the creatinine clearance. This may either be estimated using 24 hours urine collection or calculated from serum creatinine using the Cockcroft and Gault formula. For patients with acute renal failure and/or end stage renal disease, the creatinine clearance must be assumed to be < 10 mL/mt.

The dose for the level of creatinine clearance for individual drugs can be read from the nomogram. Although the method is simple, the disadvantage is that different people behave differently and the nomogram may not be applicable to all individuals alike.

2. **Adjusting the loading dose and altering the maintenance dose:** If ECF volume is normal, the loading dose in renal failure is usually the same as that for a normal person, except in the case of digoxin where only 50-75% of the normal loading dose is required. For aminoglycosides 75-80% of the normal loading dose may be sufficient. In those with edema or ascites, a higher loading dose may be required. The maintenance dose is adjusted either by decreasing the individual dose or by increasing the dosage interval. In the case of gentamicin, the daily maintenance dose can be roughly calculated by the formula:

$(5 \text{ mg/kg body wt.} \div \text{serum creatinine}),$

or

By the 'rule of 8'—i.e. – frequency of administration may be 8-hourly if serum creatinine is 1 mg%, 16-hourly if serum creatinine is 2 mg, and 24-hourly if serum creatinine is 3 mg and so on.

It is prudent to monitor drug levels to ensure therapeutic levels while avoiding toxicity.

(Table 181.1 for dose modification of commonly used drugs in renal failure).

Special Group of Drugs and Dose Modification in Renal Failure

1. **NSAIDs:** Due to their inhibitory effects on vasodilatory prostaglandins, their use could result in a further fall in GFR and hyperkalemia. Of the NSAIDs sulindac has less chances of renal failure.
2. **Diuretics:** As most of the diuretics have to reach the lumen of the tubule for their action, efficacy may be affected in renal failure. Thiazide diuretics are generally ineffective when the creatinine clearance is less than 25 mL/mt. Loop diuretics are mainly secreted into the lumen in the proximal tubule through the organic anion transporter. In renal failure, high doses are required to overcome the competing action by other organic anions. So, high

TABLE 181.1

Drug dose adjustment in renal failure				
Drug	Normal dose	In mild renal failure (SCr.2-4 mg%)	Moderate renal failure (4-8 mg%)	Severe renal failure (>8 mg%)
Gentamicin	1.5 mg/kg q8h	1.5 mg/kg q12h	1 mg/kg q12h	1 mg/kg q24h
Amikacin	7.5 mg/kg q12h	7.5 mg/kg q24h	5 mg/kg q24h	5 mg/kg q24.4h
Cefazolin	1 g q6h	1 g q12h	1 g q24h	500 mg q24h
Cefotaxime	1-2 g q6h	1 g q8h	1 g q12h	500 mg-1 g q24h
Ceftazidime	1-2 g q6h	1 g q12h	1 g q24h	500 mg-1 g q24h
Crystalline penicillin	10-20 L q6h	10-20 L q6h	10-20 L q6h	10-20 L q8 h
Ampicillin	500 mg q6h	500 mg q6h	500 mg q6h	500 mg q12h
Ciprofloxacin	200 mg q12h	200 mg q12h	200 mg q12h	200 mg q24h
Vancomycin	500 mg q6h	500 mg once in 3 days	500 mg once in 5 days	500 mg once in 7 days
INH	300 mg OD	300 mg OD	200 mg OD	200 mg OD
Ethambutol	10 mg/kg OD	10 mg/kg OD	5 mg/kg OD	5 mg/kg OD
Rifampicin	450-600 mg OD	450-600 mg OD	450 mg OD	450 mg OD
Methyldopa	250-600 mg O8h	250-500 mg O8h	250-500 mg O12h	250-500 mg OD 12 h
Enalapril	2.5-10 mg OD	2.5-10 mg OD	2.5-10 mg OD	2.5-10 mg OD
Digoxin	0.25 mg OD	0.125 mg in 36 h	0.125 mg in 48 h	0.125 mg in 48 h

doses of oral loop diuretics are used. When parenteral administration is needed, high dose of frusemide IV or continuous infusion is more effective.

3. **ACE inhibitors:** Generally, it is better to be cautious in using ACEI in those with serum creatinine of > 3.5 mg%. If ACEI are used, periodic monitoring of renal functions and serum potassium are needed. Withdrawal of the drug may be necessary if serum creatinine or potassium increases steadily.
4. **Beta blockers:** Dose reduction may be needed in advanced renal failure. They should be used cautiously as they can produce hyperkalemia particularly when used with ACEI and or potassium sparing diuretics.
5. **Antibiotics:** Aminoglycosides require significant dose reduction with renal failure as well as increased dose interval. Most of the cephalosporins also require dose reduction and/or increase in interval. Vancomycin has prolonged blood levels in renal failure and this needs to be given only once in five days for moderate renal failure and once a week in severe renal failure.
6. **Antituberculous drugs:** Most of the antituberculous drugs with the exception of rifampicin require dose reduction. Dose of ethambutol is reduced to 5 mg/kg in severe renal failure and INH to 200 mg daily. Pyrazinamide is preferably avoided in severe renal failure. As rifampicin is metabolized by the liver, dose reduction is not usually required.

Thus, knowledge of drug modification in renal failure is vital to the proper management of a patient with renal disease. At the same time, it is important to periodically monitor renal functions when drugs with

potential deleterious effects are used in patients with renal disease.

Drugs and Dialysis

The dialyzability (dialytic clearance) of the drugs depends on its volume of distribution, molecular size and protein binding. Generally, protein bound drugs are less dialyzable, e.g. secobarbitone, amylobarbitone and other short acting barbiturates. The non-protein bound drugs such as, e.g. phenobarbitone and other long acting barbiturates are dialyzable. Drugs with lower molecular size and less protein binding are more dialyzable. Such drugs (barbiturates, certain antibiotics) should preferably be administered in the post-dialysis period to ensure therapeutic levels. In the case of poisoning/overdose by non-dialyzable drugs, their removal from the body is possible by charcoal hemoperfusion.

Some antibiotics are dialyzable and hence a booster dose at the end of each dialysis will be required to achieve therapeutic blood levels, e.g. aminoglycosides. In patients who are on long-term dialysis it is preferable to administer most drugs after dialysis. The property of dialyzability of drugs can be exploited in the management of poisoning/overdose with these drugs. Hemodialysis is more effective than peritoneal dialysis in drug elimination for most dialyzable drugs.

Since the kidneys are highly vulnerable and drugs can adversely affect the kidney function the clinician must try to understand the basic pharmacology and pharmacokinetics of these drugs and use appropriate drugs with conventional or modified dose, depending on the level of renal function. This may help to reduce the incidence of drug induced renal disease to a large extent.

Nervous System: General Considerations

S.R. Chandra, P.K. Mohan

Chapter Summary

General Considerations 1178
Functional Organization of the Central Nervous System 1179
Motor System 1179
Extrapyramidal System (EPS) 1182
Cerebellar System 1183
Sensory System 1184

General Considerations

The central nervous system is a highly differentiated organ in the body. Compared to its relative size in other animals, human brain is relatively the largest, most of the matter being the highly expanded frontal cortex. Neurons constitute only less than 5% of the total number of cells in the cerebral grey matter. The rest of the cells are astrocytes and other glial cells that support the neurons. The function of any portion of the brain depends upon three factors 1. where the input comes from 2. where its output goes and 3. what kind of processing is performed on the information received by the circuitry in the particular area.

The nervous system is composed of two parts: (1) The central nervous system (CNS) and (2) the peripheral nervous system (PNS). The CNS consists of the brain and the spinal cord. The PNS includes the cranial and spinal nerves. The autonomic nervous system (ANS) although functionally a separate system, is central and peripheral.

The adult human brain weighs 1250-1400 g and the spinal cord about 30 g in health. The brain develops from ectoderm. Parts of the central nervous system develop in the first twelve weeks of intrauterine life. Infections in the mother or toxic damage during this period may lead to congenital damage to the central nervous system. The cranial end of the neural tube develops into the brain and the caudal portion develops into the spinal cord. The brain and spinal cord are effectively protected by the skull and vertebral canal respectively. Within the bony structures, the dura mater, and the arachnoid mater invest the brain

and spinal cord. The dura mater is attached to the bony structures at the the entry or exit of blood vessels and nerves.

The space between the arachnoid mater and the pia mater investing the brain is called subarachnoid space and it contains the **cerebrospinal fluid** (CSF) which is secreted by the choroid plexuses in the lateral, third, and fourth ventricles. The CSF thus formed in the ventricles escapes into the subarachnoid space through the apertures on the roof of the fourth ventricle (*foramina of Magendie and Luschka*) to circulate around the brain and spinal cord. It is returned into the dural venous sinuses through the arachnoid villi. More than three times the volume of the total CSF is produced daily for circulation. When suspended in the cerebrospinal fluid, the weight of the brain is only 50g. The total quantity of CSF is 130-150 ml in an adult. It provides a cushioning effect and a proper chemical milieu for nerve cells. The normal pressure of CSF in the lumbar subarachnoid space is 50-150 mm of water when the individual lies quiet on his side. Maneuvers such as straining, coughing, sneezing, and compression of the jugular veins lead to obstruction of venous return from the head and neck and rapid rise in CSF tension.

The pia mater which is thin and transparent is closely applied to the surface of the brain and spinal cord. The blood vessels which run on the surface penetrate this membrane and reach the inner structures. A sheath of pia is carried down along with these vessels and this constitutes the *Virchow Robin space*.

The brain receives its blood supply from the internal carotid and vertebral arteries. These two systems effectively communicate between them at the circle of Willis named after Thomas Willis (1621-1675), who was trained under William Harvey.

This arrangement ensures optimal distribution of blood to the different areas of supply and also provides for collateral circulation in the event of obstruction to any of the major arteries. More than 17% of the cardiac output goes to the brain to meet its intense metabolic demand. The blood flow is autoregulated to 45-50 ml/mt/100 g of brain tissue at a mean blood pressure range of

60-130 mm Hg. The brain utilizes mainly glucose for its metabolism. Hence impairment of cerebral blood flow and hypoglycemia lead to the rapid development of neurological dysfunction. About 20% of total oxygen consumption in the body is by the brain. The arteries that supply the brain are, in a sense end-arteries. This is true of the perforating branches which arise from the main arterial trunks to supply the deeper parts of the nervous tissue. The vascular territories of the major arterial branches show considerable overlap. Congenital variations are not infrequent. Moreover, anastomosis between the external carotid and internal carotid systems can also develop. On account of these factors, the extent of infarct and the anatomical blood supply to the brain may not always correlate. The cerebral blood flow is subject to dynamic variations depending upon the cardiac output, state of tone of cerebral vessels, presence of vasodilator substances such as carbon dioxide, level of intracranial tension, and the presence of external influences such as accelerating or gravitational forces. Venous blood from the interior of the brain is drained through the cerebral veins into the straight sinus.

The cerebrum consists of the external gray matter which contains the neurons and the internal white matter which is mainly made up of myelinated nerve fibres. This arrangement is seen in the cerebellum as well. But in the spinal cord, the white matter is external and the gray matter which is arranged as the anterior and the posterior horns is internal. Masses of nuclei such as the corpus striatum are seen as islands of gray matter deep inside the cerebrum. On either side, the cerebral hemisphere is divided into the frontal lobe, parietal lobe, temporal lobe, and occipital lobe. Functions of all parts of the cerebral cortex have been accurately mapped and these functional areas have been numbered. The nuclear masses of gray matter contained within the **cerebellum** are the nucleus dentatus, globosus, emboliformis and fastigial nucleus.

Functional Organization of the Central Nervous System

Voluntary activity is initiated in the cerebral motor cortex. It is executed through various descending nerve tracts. It is influenced by the activity of the cerebellum and extrapyramidal system.

Motor System

Voluntary movement results from coordinated contraction and relaxation of groups of muscles. The prime movers or agonist muscles contract while reciprocal antagonist muscles relax. Synergists are those muscles which stabilize to make the movement most effective. Voluntary activity is initiated by the corticospinal tracts (also called pyramidal tracts or the upper motor neurons) which

originate from pyramidal neurons of the motor cortex of the precentral area. The rate, range, rhythm, direction and amplitude of motor activity are controlled by the cerebellum which modifies the action of the agonist, antagonist and synergist groups of muscles.

The maintenance of posture is mediated largely through the extrapyramidal system and the vestibular and spinal reflexes. Information processing for programming the movement occurs in the extrapyramidal system. The influences from the pyramidal system, extrapyramidal system and cerebellum act upon the anterior horn cells of the spinal cord or the motor nuclei of the brainstem (the lower motor neurons) which have connections with the various muscles in the body.

Upper Motor Neuron (UMN)

Motor neurons in the cerebral cortex, basal ganglia and the brainstem are called the “upper motor neurons”. These upper motor neurons that influence voluntary motor activity, give rise to corticospinal tracts, reticulospinal tracts, tectospinal tracts, rubrospinal tracts, vestibulospinal tracts, and the olivospinal tracts.

In the motor cortex, which represents the opposite side of the body, parts are represented from above downwards on the lateral surface in the order of thigh, trunk, arm, forearm, hand, face, and tongue. The perineum, leg and foot are represented on the medial surface of the cerebral hemispheres. This representation of the body is called the homunculus. The extent of the area of motor representation is proportional to the functional importance of the part, so that the hand, face, and foot receive a wider representation than the other parts.

The corticospinal tracts are concerned with voluntary, discrete, skilled and rapid movements especially of the distal part of the limbs. The fibres of the tracts arise mainly from pyramidal cells in the precentral gyrus (areas 4 and 6) and to a smaller extent from the postcentral gyrus also (areas 3, 1 and 2). From the cortex the fibres pass down through the subcortical region. These fibres descend in the corona radiata and then pass through the internal capsule, the brainstem and the spinal cord. In the internal capsule they form a compact bundle and occupy a small area in the genu and anterior part of the posterior limb. Here the fibres for the head and neck are anterior and those for the lower limbs are posterior. Still further behind in the posterior limb of the internal capsule are the sensory fibres, visual fibres, and auditory fibres. From the internal capsule the motor fibres pass through the midbrain, the pons and the medulla. In the pons the UMN fibres are criss-crossed by pontine nuclei (Fig. 182.1).

At the anterior surface of the medulla 80% of the corticospinal fibres become grouped together to form the visible swellings known as the pyramids. Only these corticospinal fibres that form the pyramid in the medulla

are generally referred to as the pyramidal tract. At the lower border of the medulla they cross to the opposite side and form the crossed corticospinal tract. The supra-nuclear pathways upto the cranial nerve nuclei in the brain stem and the anterior horn cells of the spinal cord constitute the upper motor neuron (UMN).

In the brainstem corticospinal fibres cross to the opposite side to provide UMN innervation to the cranial nerve nuclei of the opposite side. In the midbrain corticospinal fibres are in close relation with the third cranial nerve nucleus, in the pons close to the 7th cranial nerve nucleus, and in the medulla close to the 12th cranial nerve nucleus. Therefore, lesions at these levels usually produce ipsilateral LMN paralysis of these cranial nerves and contralateral hemiplegia. Except for that part of the 7th cranial nerve nucleus that supplies the muscles of the lower part of the face and the part of the 12th cranial nerve supplying the genioglossus muscle, all the cranial nerve nuclei receive bilateral UMN connection.

The uncrossed fibres descend on the same side as the anterior corticospinal tract. At different levels they also cross to the opposite side to synapse with the anterior horn cells up to mid thoracic level. The corticonuclear and corticospinal fibres end by synapsing with the cranial nerve nuclei or anterior horn cells either directly or indirectly though internuncial neurons, also known as interneurons or connection neurons.

The *reticulospinal tracts* facilitate or inhibit voluntary and reflex motor activity. The *tectospinal tracts* are responsible for reflex postural movements in response to visual stimuli. The *rubrospinal tracts* facilitate the motor activity of flexor muscles and inhibit the activity of extensor muscles. The *vestibulospinal tracts* are concerned with postural activity associated with balance and equilibration. The *olivospinal tracts* also regulate motor activity.

Lesions of the corticospinal tract result in loss of voluntary motor activity. Since the UMN normally carries fibres which inhibit the stretch reflexes mediated by the LMN, lesions of the UMN result in exaggeration of these stretch reflexes. The superficial reflexes which are also known as cutaneous protective reflexes also show characteristic changes.

Signs of Upper Motor Neuron Lesions

1. **Loss of Voluntary Movements—Paralysis**
2. **Increase in Motor Tone—Spasticity**

Spasticity: This term refers to the velocity-dependent increase in resistance to passive stretch felt by the examiner as a sudden catch which will also give way suddenly leading to the clasp-knife phenomenon. When spasticity is severe it can be appreciated in all limbs in all groups of movements. In early and mild cases the

spasticity may be appreciated in the pronators and supinators of the forearm and adductors of the thigh. For eliciting spasticity the limb has to be moved passively. To elicit spasticity better, the movement has to be rapid.

3. **Exaggerated stretch reflexes—Hyper-reflexia** When the stretch reflexes are exaggerated, they are increased in amplitude and also sustained. Simple increase in amplitude may occur even without neurological disorders, e.g. anxiety. Exaggerated reflexes are abnormal if they are:
 - i. Asymmetrical
 - ii. Associated with changes in power or tone and
 - iii. Associated with changes in superficial reflexes

Inequality between corresponding reflexes on either side is of great diagnostic value. In bilateral UMN lesions above the level of the pons, the jaw jerk is also exaggerated. When the UMN lesion is well established, clonus may develop. In clinical practice patellar clonus and ankle clonus in the lower limbs and wrist clonus in the upper limbs are the ones commonly looked for.

4. **Alteration in superficial reflexes:** The abdominal and cremasteric reflexes are lost. The plantar reflex or response becomes extensor. This is referred to as Babinski's sign. Joseph Babinski, a French neurologist described the Babinski's sign in 1896. Normally on stroking the lateral aspect of the foot from the heel to the ball of the big toe with a sharp object a set of responses occurs. The big toe flexes, the lateral four toes also flex and crowd together. Minimal contraction of the tensor fascia lata, the adductors of the thigh and sartorius also occurs. This whole response is referred to as the 'flexor' plantar response. Flexion movement of the foot and toes are more powerful than extension since stronger flexion is needed for locomotion. Therefore the normal plantar response is flexor. Even in normal persons stroking the medial margin of the foot may elicit an extensor response. Therefore plantar response is not elicited on the medial side.

In UMN lesion the big toe extends (dorsiflexes), and the other toes fan out and dorsiflex when a nociceptive stimulus is applied to the lateral aspect of the foot, with stronger stimuli the ankle dorsiflexes with flexion at the hip and knee. If the UMN lesion is small, this abnormal response is elicitable only from the lateral margin of the sole of the foot. As the lesion extends, the response can be elicited by applying the stimulus over a wider area such as the medial aspect of the foot and the leg. These pathological reflexes are known by different eponyms.

Oppenheim's sign: Extensor plantar responses elicited by stroking down on the shin of the leg.

Schäfer's sign: Squeezing the tendo-Achilles to elicit the extensor plantar response.

Gordon's sign: Squeezing calf muscles elicits extensor plantar response.

Chaddock's sign: Light stroke applied to the lateral aspect of the dorsum of the foot elicits the extensor response.

It is important to elicit the plantar response carefully since it is of great value in deciding upon the presence or absence of an UMN lesion. Fibres, from the area 6 are concerned with extensor plantar response. The plantar response is normally extensor in babies till the age of one year by which time the corticospinal tract becomes myelinated. When the baby learns to walk the plantar response becomes flexor. The plantar response is bilaterally extensor in deep sleep and coma.

5. **Absence of muscle atrophy:** Unlike as in LMN lesion, UMN lesion does not lead to marked wasting of muscles. This is because the lower motor unit is intact, so that reflex activity and trophic influences are preserved. However, prolonged disuse of muscles in UMN lesions, gives rise to slight disuse atrophy.

6. **Electrical reaction of the affected muscles are not altered.**

Localization of the Level of Lesion of the UMN

Since the UMN extends from the cerebral cortex and passes through several structures of the central nervous system finally to ramify on the anterior horn cells in the spinal cord it is necessary to determine the level at which this tract is affected. Lesions at different levels give rise to distinct groups of clinical abnormalities.

Cortical lesions: These are characterized by restricted paralysis of either of the face or a limb on the contralateral side. Since the motor area of the cerebral cortex is extensive, only large lesions result in total hemiplegia. Presence of other cortical dysfunctions such as aphasia and convulsions is also suggestive of a cortical lesion. In the cortex a lesion in middle cerebral distribution produces hemiplegia where arm is weaker than leg. Aphasia occurs if the lesion is on the dominant side. In lesions in the anterior cerebral distribution leg is weaker than the arm and there is no aphasia.

Internal capsule lesions: Since all the corticospinal fibres are held together within a small area in this structure, small lesions at this level result in extensive paralysis of the opposite side leading to hemiplegia in which the face, upper and lower limbs and the trunk are paralyzed. Extension of the lesion more posteriorly results in hemianesthesia and hemianopia as well. Weakness of arms and legs is equal.

Brainstem lesions: Lesions in the midbrain, pons and medulla lead to lower motor neuron paralysis of the corresponding cranial nerves on the side of the lesion and paralysis of the limbs on the opposite side (crossed hemiplegia).

Midbrain lesions: Ipsilateral 3rd cranial nerve palsy and hemiplegia of the opposite side.

Pontine lesions: Ipsilateral 7th cranial nerve palsy and hemiplegia of the opposite side.

Medullary lesions: Ipsilateral 12th cranial nerve palsy and hemiplegia of the opposite side.

Spinal cord lesions: Since the major portion of the corticospinal tract has crossed at the lower margin of the medulla, lesions of the pyramidal tract below this level in the spinal cord produce ipsilateral UMN palsy. In many cases however the lesion usually affects the corticospinal tract in both sides. In pure corticospinal tract lesions, the upper level is determined by the loss of voluntary motor power and abnormalities in superficial and stretch reflexes.

If the lesion in the spinal cord is above the fifth cervical segment the stretch reflexes of the upper and lower limbs are exaggerated. Other signs of UMN lesion such as *Hoffman's sign* may appear. Lesions at C5 or C6 levels give rise to the phenomenon of *inversion of the supinator reflex*. This consists of absence of elbow flexion and exaggeration of finger flexion when the radial styloid is tapped.

If the lesion is below T1 spinal segment, but above second lumbar segment (L2) both the knee and ankle reflexes are exaggerated and clonus may develop.

If the lesion is between L2 and L5 segments, both the ankle jerks will be exaggerated.

Lower Motor Neuron (LMN)

The motor neurons of the cranial nerve nuclei in the brainstem and the anterior horn of the spinal cord form the lower motor neurons. The axons from these cells form cranial and peripheral nerves respectively and reach the motor end plates of corresponding muscles. The motor cranial nuclei or the anterior horn cell, its axon, and all the muscle fibres it innervates comprise a lower motor unit. Each muscle is composed of several such motor units. The lower motor neuron is an integral part of the spinal reflex arc. It is the final common path for all motor activity (both voluntary and reflex) of all muscles. The lower motor neurons are influenced by impulses from the UMN, extrapyramidal tracts, cerebellum and sensory afferents from the sensory nerve roots. Integrity of the lower motor neuron is essential for maintaining the normal nutrition and size of the muscle fibres and when the lower motor neuron is damaged the corresponding muscles undergo atrophy. LMN is the final common path for eliciting contraction of the muscles it innervates. Whereas the LMN controls contraction of individual muscles, the UMN controls movements as a whole.

Signs of Lower Motor Neuron Lesion

1. *Loss of all movements*—Voluntary and reflex.
2. *Loss of motor tone*—Flaccidity.
3. *Loss of stretch and superficial reflexes*—Hyporeflexia.
4. *Atrophy of affected muscles* appears within 2-3 weeks of the lesion.
5. *Denervated muscle fibres contract spontaneously*. This is not visible, but can be detected by electromyography. Spontaneous contraction of individual motor units causes fasciculation.
6. *Electrical activity of the muscle fibres is altered* and this can be detected by electromyography. The pattern of altered electrical activity depends on the site of damage in the lower motor neuron unit.

Lesions of anterior horn cells produce selective wasting and weakness of motor units, which will be patchy, whereas lesions of the anterior roots produce fairly uniform involvement of all muscles supplied by that root. Lesions in the peripheral nerve give rise to paralysis of the muscles supplied by that nerve. Often peripheral nerve lesions are associated with sensory disturbances.

Extrapyramidal System (EPS)

This consists of a complex neuronal network extending from the cortex through the brain stem to the spinal cord. The descending pathways emerging from this system influence the lower motor neuron in the brainstem and the spinal cord.

Components of the Extrapyramidal System

These are cortical, subcortical and spinal.

1. Areas in the cerebral cortex, which are diffuse, and nondefinable and are arising from cells other than pyramidal cells. These constitute the cortical component.
2. Basal ganglia composed of : (a) the caudate nucleus, (b) the lentiform nucleus which can be functionally divided into the globus pallidus and the putamen, (c) the substantia nigra, and (d) the nuclei of the thalamus and subthalamic nuclei. These constitute the subcortical component.
3. The tegmental nuclear system: (a) red nucleus, (b) reticular nuclei, and (c) vestibular nuclei. These constitute the spinal component.

The main descending pathways are the rubrospinal, olivospinal, vestibulospinal, and tectospinal tracts. Their fibres synapse with the lower motor neuron. The extrapyramidal system assists the pyramidal system to perform motor activity smoothly. In addition, it controls functions such as maintenance of tone and posture and associated movements on walking.

The extrapyramidal system intimately connects the cerebral cortex with the cerebellum and the lower motor

neurons on the opposite side. The neurotransmitters of the EPS are dopamine and acetylcholine. When the balance between dopamine and acetylcholine is maintained the system functions normally. This balance is disturbed in disorders of the EPS.

Signs of Extrapyrarnidal Disorders

1. *Alterations in tone*, e.g. rigidity of either cog-wheel type or lead pipe type in parkinsonism and flaccidity in chorea.
2. *Involuntary movements*, e.g. tremors, chorea, athetosis, myoclonus.
3. *Bradykinesia and paucity of spontaneous movements*, e.g. parkinsonism.
4. *Disturbances in posture*, e.g. parkinsonism and dystonia.
5. *Several other subtle abnormalities* in fine motor activities, sensory perception and cognitive functions are being recognized. These account for considerable functional disability in advanced stage of some of these disorders.

Cerebellar System

Main function of the cerebellum is to coordinate synergistic and smooth action of muscles during voluntary and automatic movements. It is also involved in the maintenance of posture, and muscle tone. Afferent impulses reach the cerebellum from the proprioceptive end organs, skin, and vestibular nuclei. Fibres from the opposite cerebral cortex and basal ganglia also reach the cerebellum. Efferent fibres from cerebellar cortex via the cerebellar nuclei reach the reticular formation in the brainstem, red nucleus, and vestibular nuclei of the opposite side from where distinct tracts descend in the spinal cord, cross to the opposite side and reach the anterior horn cells at various levels. Due to this double crossing, the cerebellum controls activities of the same side of the body. Fibres from the cerebellum also pass up to the contralateral thalamus and thence to the cerebral cortex. There is evidence that the cerebellum plays an important part in modulating memory, intelligence and behaviour.

Signs of Cerebellar Disease

Clinical abnormalities are very prominent when the lesion appears acutely. As time passes compensatory mechanisms develop, and therefore, the disability becomes milder. Clinical effects are seen on the same side as the cerebellar lesion. These are:

1. **Alteration in motor tone:** Generalized hypotonia.
2. **Disorders of posture and gait:** The patient tends to sway towards the side of lesion on walking. The head may be turned to the same side. The gait is reeling

and can be compared to that of a drunken man. Truncal ataxia results from midline vermis lesions whereas cerebellar hemispherical lesions affect ipsilateral extremities and eye and speech.

3. **Disorders of movement** occur as a result of hypotonia. Incoordination and abnormalities of rate, range, rhythm, direction and amplitude lead to ataxia which can be elicited in several ways.
 - i. **Dysmetria:** When the patient is asked to touch an object with a finger repeatedly, it can be noticed that the force and amplitude of movement are not accurately adjusted to locate the object. The finger either falls short of the object or overshoots it. Past-pointing is the phenomenon which is elicited when the patient is asked to touch an object with a finger with the eyes open. The finger overshoots the target on the side of cerebellar lesion.
 - ii. **Dyssynergia:** When movements involving several joints are attempted, the movements are broken up into their component parts and they appear jerky.
 - iii. **Intention tremor:** When the patient is asked to touch an object with a finger, coarse irregular tremor appears and increases as the finger approaches the target. This phenomenon is the result of a combination of dyssynergia and dysmetria. Similarly, the muscles which maintain posture of the trunk may be affected giving rise to truncal ataxia.
 - iv. **Dysdiadochokinesis (adiadochokinesis):** Performance of alternating movements rapidly, i.e. to stop one movement and start the opposite one in quick succession, requires proper coordination of the muscles and synergy. In cerebellar lesions rapid alternating movements become impossible, or are performed in a clumsy and jerky manner.
 - v. **Rebound phenomenon:** In a normal person when the resistance to contraction of a muscle is suddenly withdrawn, the contraction can be arrested without the limb overshooting. In cerebellar disease, the limb shoots beyond the normal range.
4. **Alteration in stretch reflexes:** As a result of hypotonia, the stretch reflexes are either diminished or pendular. The pendular knee reflex is elicited with the patient sitting and legs hanging. The legs are seen to oscillate more than three times. This phenomenon is the result of muscular hypotonia.
5. **Disturbances of speech:** Articulation and phonation become incoordinated (dysarthria). As a result, speech becomes irregular, slurred and explosive (*staccato*). The volume of sound is poorly controlled. The syllables in a word tend to be separated and this is called *scanning speech*.
6. **Nystagmus:** Jerky nystagmus develops usually in the horizontal plane as a result of defect in postural

Fig. 182.2: Dermatomes—segmental innervation
(1) Front (2) Back

fixation of conjugate gaze. In unilateral lesions the nystagmus increases in amplitude and slows down in rate when the eyes are turned towards the side of lesion.

Sensory System

The sensory representation over the body is arranged depending on the distribution of the sensory roots arising from the brainstem and spinal cord. The sensory areas subscribed by these sensory fibres are called dermatomes (Fig. 182.2).

The sensations can be broadly divided into: (1) *superficial sensations* (touch, pain and temperature); (2) *deep sensations* (deep pain, pressure, sense of position, sense of movement, joint sensation and vibration); and (3) *cortical sensations* (tactile localisation, tactile discrimination and stereognosis). At the periphery, there are receptors to appreciate different sensory modalities.

- Touch** : Free nerve endings, nerve endings in the hair follicles, Meissner’s corpuscles, Merkel’s discs.
- Pain** : Free nerve endings

- Temperature** : Free nerve endings, Krause’s corpuscles, Ruffini’s corpuscles.
- Pressure** : Pacinian corpuscles
- Proprioception** : Muscle spindles Golgi tendon organs.

The sensations of itching (pruritus) and pain are transmitted through C fibres of polymodal nociceptors, by distinct subgroups of neurons. There are no identifiable receptors for pruritus in the skin. Centrally situated opioid receptors may also modulate the sensation of itching.

Pain receptors are not strictly specific to any kind of stimuli. Even though specific stimuli such as pin prick are appreciated as pain, any stimulus beyond threshold levels is appreciated initially as pain. After the delay of a few seconds the true nature is appreciated. This phenomenon is known as ‘*Lewis’ double response.*’

Sub-threshold sensations are perceived as itch (pruritus), through a special group of C-fibres which ascend up to the thalamus where it is appreciated. These fibres may be specifically involved in multiple sclerosis.

When the receptors are stimulated, afferent impulses pass in the dendrites of the first sensory neuron into the spinal cord through the posterior root ganglion. The axons of the cells from the ganglion pass through the posterior root into the spinal cord and ascend up as the sensory tracts. Fibres subserving different sensations take different paths.

Fibres subserving proprioception, vibration, and a portion of touch ascend up on the same side as the posterior column (*column of Goll and Burdach*) in the spinal cord to reach the lower part of the medulla, where they synapse with the cells in the *gracile* and *cuneate nuclei*. Medial fibres carry sensation from the lower limbs. After synapse the second order neurons cross the midline in the medulla and pass up in the medial lemniscus to reach the main sensory nucleus of the thalamus.

Fibres subserving the remaining part of touch, pain, heat and cold synapse with the cells in the posterior horn of the spinal cord soon after their entry. The second order neurons arising from these cross to the opposite side at different levels. Pain and temperature fibres cross more or less horizontally whereas touch fibres cross more obliquely one or two segments above and pass up on the other side as the *anterior spinothalamic tract* (touch) and *lateral spinothalamic tract* (pain and temperature). In the lateral spinothalamic tract fibres from the lower limbs are placed laterally and fibres from the upper limbs are medial. Some fibres do not cross and they pass up as the ipsilateral spinothalamic tracts. In the brainstem the spinothalamic tracts pass up lateral to the medial lemniscus to reach the thalamus. Third order neurons arise from the thalamus and their fibres which maintain their functional specificity pass up through the internal capsule to be relayed to the sensory area of the cortex in the postcentral gyrus (Fig. 182.3).

8. Posterior nerve roots forming the posterior column	

In the sensory cortex the body image is arranged similar to that in the motor area from above downwards. From the postcentral gyrus fibres project to other cortical areas. In the parietal lobe the sensory information derived from superficial and deep sensations is integrated to give the impression of size, shape, texture, weight and pattern of the objects (*stereognosis*). The mental picture of the body (*body image*) is obtained by integration of the sensory information with information obtained from the special senses. This function of “body image” is mainly carried

out by the nondominant parietal lobe. The corresponding portion of the dominant hemisphere carries out the function of receptive and interpretative components of speech. This part of the parietal lobe has connection with the ipsilateral motor cortex. This arrangement helps to produce patterns of movements in the lips, tongue, fingers, and respiratory muscles which form motor symbols to represent speech—*gestural language*. It is now known that the dominant cerebral hemisphere contains the major centres for speech. The nondominant hemisphere is responsible for several other higher functions including emotions, feelings and the like.

Developing cells of the nervous system produce signals which give them identity, help to make the topographic map for migration and make the right synapses. Defects in the signalling causes mis- identity, defective migration and defective synaptogenesis.

Occasionally the organisation of neurons in the grey matter may be disorderly due to defects of migration of these cells during brain development. Such disorders are called ‘**neuronal migration disorders.**’ They may lead to several defects such as seizures, mental retardation and cognitive disturbances and tumours.

The thalamus appreciates crude (*protopathic*) sensation and pain. The fine sensations (*epicritic*) are appreciated in the cortex. Among the myriad afferent impulses reaching the CNS, many do not reach consciousness.

Some subserve spinal reflexes. These afferent fibres make contact either directly or through interneurons with the spinal motor nuclei. Other fibres which carry muscle and joint sensations end in the base of the posterior horn of the spinal cord and in the Clarke’s column. The second order of neurons. These neurons form tracts which ascend up as the anterior and posterior spinocerebellar tracts to reach the cerebellar cortex of the same side. Most of the fibres ascend on the same side but some fibres of this tract cross to the opposite side to ascend as the anterior spinocerebellar tracts.

These tracts carry proprioceptive impulses which enable the cerebellum to coordinate activity.

Some other sensory fibres which do not bring sensation to consciousness are collateral branches of the main spinothalamic pathways and of the special sensory paths which join the upper part of the reticular formation in the midbrain. In the reticular formation there is an inter-communicating system of short neurons which also receive fibres from most parts of the cerebral cortex. This system is important for maintaining consciousness.

Clinical Examination

HISTORY

Pathological lesions in the nervous system may give rise to either positive or negative symptoms. Convulsions, pain and paresthesia are examples of positive symptoms whereas loss of motor strength and loss of sensations indicate negative symptoms. Generally positive symptoms are due to irritative lesions and negative symptoms arise from destructive lesions. At times, positive symptoms may occur in destructive lesions as well, due to release of some structures from inhibition, e.g. spasticity.

In neurological diagnosis, a properly taken history is one of the most important helpful tools for the physician. Broadly, neurological disorders may be divided into the following pathological classes—congenital, developmental derangements, vascular disorders, inflammations, infections, neoplasia and space occupying lesions, degenerations and traumatic injuries. Vascular accidents such as embolism, thrombosis, and hemorrhage come on abruptly, often within minutes to hours. Inflammatory or infective lesions (e.g. meningitis, encephalitis, and brain abscess) start acutely or subacutely and evolve over a

period of days to weeks. In addition to the neurological features, they are usually accompanied by signs of infection such as fever and toxemia.

Generally, space occupying lesions have subacute onset and course progressing to the full-fledged stage over a period of weeks to months. The progress may be steady or punctuated by periodic exacerbations caused by complications such as vascular thrombosis, hemorrhage or edema in the tumour. It should be borne in mind that in conditions such as intracranial bleeding and cerebral edema, the progress of the disease may be rapid and steady.

Degenerative lesions (e.g. presenile dementia, spinocerebellar degeneration) have a very insidious onset and progressive course extending over several years.

HIGHER FUNCTIONS

These include the level of consciousness, intelligence, memory, emotional state and speech. These are all cortical functions. These are deranged in cortical lesions.

SPEECH

This is a highly evolved function of the cerebral cortex and is defined as that human faculty by which thought processes are symbolically expressed.

In neurological parlance, speech has many more facets to it than what is understood by the lay public. *Speech* and *language* are the main modes of expression and communication available to humans. In addition to spoken speech, gestures, signs, signals and graphic symbols of written language all can serve the same purpose. All these modes of expression of thoughts and ideas to others and comprehension of others' thoughts and ideas constitute language. Language is defined as symbolization of ideas (i.e.) ability to convert thoughts into comprehensible words. Language consists of five parameters. These include **speaking, writing, repeating and comprehending through visual stimuli and auditory stimuli**.

Speech is the mechanical function of one's ability to communicate in oral language and this includes articulation and phonation.

The subcortical structures concerned with language are well-delineated. They include the claustrum, lentiform and caudate nuclei, thalamus and the internal capsule, which are contained in the **Marie's quadrilateral space**.

Communication through signs, signals, gestures and vocalisations, mainly to convey one's emotions is called **emotional language**. Communication through the medium of symbols or words is called **symbolic language** (*spoken and written speech*). Infants and, to some degree, animals, communicate through emotional language. As opposed to this, the symbolic language which is unique to man is dependent on fully mature, intact cerebral functions. Synthesis of spoken and written language is a function of the brain. This function is lateralised in the left cerebral hemisphere in 99% of right handed and 75% of left handed individuals and it is the dominant hemisphere for speech and language.

Four distinct areas concerned with speech and language are identified in the brain which constitute the cortical areas for speech. Two of these are anterior to the central sulcus and the other two are posterior to it. All the four are located in the perisylvian region which is called the central zone of language. Just as the cortex anterior to the central sulcus is motor and that posterior to it is sensory in function, the two anterior speech areas are responsible for motor aspects of speech, one for *spoken speech* and the other for *writing*. The two posterior areas are concerned with the sensory aspects of speech, one for comprehension of spoken speech and the other for comprehension of visual speech, i.e., *reading*. The motor area for spoken speech is situated in the posterior part of the left inferior frontal gyrus and it is called *Broca's area*. Pierre Paul Broca, a French surgeon described the Broca's areas in 1865.

The motor centre for writing is thought to be just anterior and superior to the *Broca's area*, very close to that part of the motor cortex that controls the hand muscles *Exner's centre*. The auditory comprehension of spoken speech takes place in the posterior end of the left superior temporal gyrus (*Wernicke's area*). Karl Wernicke, a German neurologist identified the Wernicke's area and later described the conducting pathways between the Broca's and Wernicke's areas. The Broca's and Wernicke's areas are connected by arcuate fasciculus. These three structures are situated around the sylvian fissure, and hence called the peri-sylvian area. The area of the cerebral cortex surrounding this zone is called the para sylvian area. Structures in the subcortical region within an area called Marie's quadrilateral space constitute the subcortical language areas. These include the caudate nucleus, thalamus, lentiform nucleus, claustrum and the internal capsule (Figs 183.1 and 183.2).

Fig. 183.1: Marie's quadrilateral space

Fig. 183.2: Left cerebral hemisphere—cortical areas of speech

A. Broca's area	D. Transcortical motor area
B. Wernicke's area	E. Transcortical sensory area
C. Conduction area	

The centre for reading is thought to be in the medial aspect of the left occipital lobe and the splenium of the corpus callosum. All these speech areas are connected with each other and the rest of the brain by the neural pathways in the underlying white matter.

The conversion of the intended ideas into words and syllables requires synchronized delicate movements involving structures in the larynx, palate, tongue and lips which are supplied by motor cranial nerves. This neuromuscular apparatus constitutes the peripheral mechanism of *motor speech*, i.e., *articulation*. Cerebellum coordinates these movements and sounds to produce proper prosodic speech. Defects occurring in specific areas in the central pathways produce characteristic abnormalities. By analysis of the abnormality, the central defect can be inferred. Research to understand the interrelationship between speech abnormalities and the lesion in the

central mechanisms of speech is continuing and new information has emerged in the recent past. For instance the possible roles of the subcortical grey matter such as the thalamus and caudate nucleus of the left side and also the right cerebral hemisphere are beginning to unfold.

When a question is asked, it is received by the aWernicke's area and comprehended, then by interacting with various areas in the brain, the answer is formed. This is transmitted through the arcuate fasciculus to the Broca's area for execution. The unique function of the perisylvian area is to receive the information and transmit it to the Broca's area. If the perisylvian area is disconnected from the rest of the brain the only function that will be retained is repetition of the examiners words- also known as *parrot's speech*. The parasylvian zone conveys message from the rest of the brain to perisylvian speech area. The subcortical zones are mainly concerned with the motor scheme of language.

Loss of the language due to a dysfunction of the central mechanism in the brain is called **aphasia**, and a minor disturbance is called *dysphasia*. Loss of ability to read, is called **alexia**. Loss of ability to write is called **agraphia**. Dysfunction of the peripheral mechanism of speech leads to defective articulation which is called **dysarthria**.

Speech disturbance is due to defects in articulation (**dysarthria**), or disturbance of phonation (**aphonia**). Articulation is the process of production of syllables by the coordinated action of facial, lingual and palatal muscles controlled by the cerebellum.

Precise rate, range and strength of movements of these muscles are necessary for normal speech. Alteration in any of these aspects of motor speech resulting from a neurological disorder leads to dysarthria. Depending on the nature of the underlying neurological disorder, the pattern of dysarthria varies. Dysarthria may be spastic,

TABLE 183.1

Depending on the site of the lesion in the speech areas in the brain, the following types of aphasia may occur:

Aphasia type	Site of lesion
1. Broca's aphasia Syn: Expressive aphasia Nonfluent aphasia Motor aphasia Anterior aphasia	Posterior end of left inferior frontal gyrus
2. Wernicke's aphasia Syn: Receptive aphasia Fluent aphasia Sensory aphasia Posterior aphasia	Posterior end of left superior temporal gyrus
3. Global aphasia	In both the above sites (1 and 2)
4. Conduction aphasia	Between the above two sites (1 and 2)
5. Transcortical aphasia a. Motor b. Sensory c. Mixed transcortical	Anterior and/or superior to Broca's area Posterior and inferior to Wernicke's area.
6. Subcortical	

flaccid, ataxic, hypokinetic, hyperkinetic or mixed in type (Tables 183.1 to 183.4).

Dysarthria: There are three main types of dysarthria.

In cerebellar disease the speech is slow, deliberate and scanning or staccato. This is called **ataxic dysarthria**.

In bilateral corticospinal lesions occurring above the level of the brainstem the speech is spastic, e.g. pseudo-bulbar palsy-which may be vascular or degenerative. Such patients show evidence of upper motor neuron lesion of the cranial nerves supplying the muscles of the face, larynx, tongue, and respiration. Other associated features such as dysphagia are present because of spasticity of the muscles of deglutition. Lower motor neuron lesions of the muscles supplied by the brainstem nuclei give rise to

TABLE 183.2

Representation of various components of speech in anatomical areas of the cerebral cortex

Components of speech	Anatomical areas of cerebral cortex
1. Ability to read and comprehend written speech	1. Visual cortex and its association areas
2. Ability to hear and comprehend	2. Heschl's gyrus (transverse temporal gyrus) and the superior temporal gyrus
3. Ability to comprehend symbols	3. Superior temporal gyrus and parieto-occipital areas
4. Ability to identify and name objects	4. Supra-marginal and angular gyrus
5. Genesis of motor engram of speech	5. Broca's area (posterior part of inferior frontal gyrus)
6. Genesis of motor engram for writing	6. Exner's area in the middle frontal gyrus
7. Execution of the expressive part through the motor system coordinated by the pyramidal, extrapyramidal and the cerebellar connections along with the emotional component executed by the prefrontal lobe and connections.	
8. The main white fibre tracts connecting the Broca's and Wernicke's areas constitute the arcuate fasciculus.	

TABLE 183.3

Lesions in different regions of the brain affect language modalities differently	
Site of lesion	Results
1. Left temporal lobe	Disturbance of verbal comprehension, repetition and writing
2. Left frontal lobe	Articulation and fluency of verbal expression are mainly affected
3. Left parieto-occipital region	Impairment of reading (visual language function)
4. Left parietal lobe	Writing is particularly impaired

flaccid dysarthria. The speech is slurred, e.g. bulbar palsy. The muscles of the tongue and lips are mainly affected. This manifests as difficulty in pronunciation of labials (P and B) and linguals (L).

Dyskinetic dysarthria may be hypo- or hyperkinetic. Hypokinetic dysarthria is slow monotonous speech with steady decline of the level of voice. This occurs in Parkinsonism. Hyperkinetic dysarthria occurs in chorea and dystonias affecting the tongue muscles. The speech in chorea is characterized by sudden unwarranted punctuations when chorea occurs. Action dystonia of the tongue (aphthogonia) is a special action-induced movement disorder caused by lesions in the corpus striatum. The patient goes into a twisting spasm and the speech stops abruptly.

Aphonia: *Phonation* is the process by which voice is produced by the vocal cords. Inability to produce sounds while still able to make syllables and gestures is termed

aphonia. This may be organic as a result of bulbar or pseudobulbar palsy or it may be a hysterical phenomenon.

Anterior Aphasia (Broca’s aphasia)

In Broca’s aphasia there is difficulty in repeating spoken words and also difficulty in grammar, but the matter is conveyed – This is called **telegraphic speech**. The same phenomenon occurs in writing also. Reading loud is not possible, but he can read and obey; since comprehension is preserved.

In parietal lobe lesions occurring with defects in the central mechanisms of speech, sometimes an element of apraxia may alter language function giving it a dysarthric character in addition to the language defect (dysphasia).

In anterior aphasia (Broca’s) the patient is unable to express properly, but when the first syllable is prompted he catches the correct word. In severe degree of Broca’s aphasia he can not respond to prompting, but he can select the correct word when multiple choice is given.

In lesions of the left posterior temporal region, speech is made up only of asyllabic neologisms without producing any normal sense. This is called **jargon aphasia or empty speech**. There is considerable impairment of comprehension of spoken speech in posterior aphasias (Wernicke’s aphasia). *Patients with Wernicke’s aphasia cannot repeat spoken words. They cannot also read loud or read for comprehension. They cannot respond to prompting by the examiner nor can they choose the correct word from multiple choice.*

Conduction Aphasia

This occurs due to lesions of the arcuate fasciculus with the Broca’s and Wernicke’s areas remaining intact. This

TABLE 183.4

Showing the features of different types of dysarthria							
Dysarthria type	Phonation	Prosody	Nasality	Pitch	Loudness	Rate	Disease
Spastic	Strained/voice tremor	Excess or insufficient	Hyper or hypo	Low or monotonous	Harsh or monotonous	Slow	Pseudobulbar palsy
Flaccid	Impaired	Insufficient	Hyper	Low	Reduced	Slow	Bulbar palsy
Spastic and Flaccid	Strained	Excess/insufficient	Hyper	Low	Hoarse	Slow	Amyotrophic lateral sclerosis
Ataxic	Strained	Excess	Normal	Irregular	Irregular	Slow	Cerebellar disease
Extra-pyramidal	Impaired	Insufficient	Normal	Reduced monotonous	Reduced monotonous	Slow	Parkinsonism
Dyskinetic	Variable	Variable	Variable	Unpredictable	Speech arrest	Slow	Chorea
Dystonia	Do	Do	Do	Variable	Unwanted	Variable punctuation	Dystonia

Features of Perisylvian Aphasia		
Broca's aphasia	Wernicke's aphasia	Arcuate (conduction aphasia)
Repetition not possible	Not possible	Not possible
Non-fluent	Fluent	Moderately fluent
Effortful	Effortless	Moderately effortful
Emotional	No significant emotion	Moderate depression
Telegraphic speech (meaning not affected)	Neologism (no meaning)	Moderate paraphasia
No paraphasia	Paraphasia: (letters and words substituted)	Moderate affection of meaning
Grammar affected	Not affected	Occasional paraphasia
Comprehension normal	Affected	Occasional mistakes
Writing similarly affected (telegraphic)	Writing meaningless	Mild affection
Reading loud-defective	Not possible	Mild mixture of both elements
Reading for comprehension normal	Not possible	Mild disability
		Mild disability—moderate alteration of all faculties, but, with severe affection of repetition

is a unique situation where the patient has only minor difficulty in motor and sensory language function, but severe impairment of the capacity to repeat even single words spoken by the examiner.

Global aphasia is a combination of all the above three resulting in inability to comprehend, express and repeat.

Gestural language is unaffected in verbal language disorders, since it is a function of the non-dominant hemisphere.

Parasyylvian disorders include transcortical motor, transcortical sensory, and mixed transcortical aphasia. Parasyylvian disorders resemble the perisylvian aphasia except that repetition is retained. Broca's aphasia with retained repetition is **transcortical motor aphasia**. Wernicke's aphasia with retained repetition is **transcortical sensory aphasia**. Global aphasia with retained repetition is **mixed transcortical aphasia**.

Subcortical disorders include striatal, thalamic and capsular aphasia.

Subcortical Aphasia

Subcortical aphasia are characterized by loss of speech followed by rapid recovery. There is severe naming defect and a dysarthric element.

Apart from the common features, defect of each structure produces specific characteristics which help to identify the lesion precisely.

Blood Supply of the Language Areas

Middle cerebral artery supplies the perisylvian area. Its upper division supplies the Broca's area, lower division

supplies the Wernicke's area.

Parasyylvian area is the watershed area which receives its blood supply by perfusion from middle cerebral and anterior cerebral arteries. When these arteries are affected infarction occur in these areas due to hypoperfusion. Subcortical structures receive their blood supply from the carotid and basilar systems.

Special Language Disorders

These include **visual agnosia, auditory agnosia and tactile agnosia**. In these disorders the patient has difficulty for comprehension and expression through a particular sensory mode only, while the same object can be correctly comprehended and expressed when presented through another sensory mode.

Apraxia: The inability to perform learned complex motor acts in the absence of motor or sensory paralysis is known as apraxia. Apraxic subjects may be able to perform the components of such acts but are unable to complete them. Apraxic subjects cannot make use of objects, though their use will be recognized by them. For example the patient may know the use of a pencil, but when asked to write he may not be able to do so. Apraxia results from damage to left parietal cortex, parietal white matter of left or both hemispheres or the interhemispherical fibres passing through the corpus callosum.

CRANIAL NERVES

The next step is to examine the cranial nerves. This is described along with the individual cranial nerves, in Chapter 184.

OPHTHALMOSCOPY

Optic nerve head and retina can be inspected using an ophthalmoscope. Both direct and indirect ophthalmoscopy are available. In direct ophthalmoscopy the image of the retina is upright. In indirect ophthalmoscopy it is inverted.

Direct ophthalmoscopy (funduscopy): The direct ophthalmoscope gives a direct view of the fundus and other structures of the eye. Opacities in the media and lesions of optic nerve and retina are seen with great accuracy and under a magnification of 15. Lesions of retina in front of the equator are not detected with this technique. When the media are hazy fundus details may be indistinct. These two defects are remedied to a great extent in indirect ophthalmoscopy.

Method: The direct ophthalmoscope is used with a positive 12 lens. Corneal and lenticular opacities are outlined against the red reflex of the fundus. The power of the lens in the ophthalmoscope is then reduced until the retina is in focus. The power of lens in the ophthalmoscope required to focus upon the optic disc corresponds approximately to the patient's refraction.

The examiner should systematically examine the media of the eyes, optic disc, blood vessels and all portions of the retina.

Abnormalities that can be detected by ophthalmoscopy are:

1. Opacities in the media,
2. Abnormalities of optic disc,
3. Vascular abnormalities,
4. Hemorrhages,
5. Exudates,
6. Degenerative changes,
7. New growths,
8. Retinal detachment, and
9. Several others.

Appearances of Normal Fundus

Optic Disc

When the patient looks straight ahead, the optic disc comes into view as the most prominent structure. It is pink in colour and oval or circular in shape. The margins are sharp and there is a small depression in the centre — the *physiological cup*. The central retinal vein and artery are seen to course over to the retina. These divide into the superior and inferior trunks at or near the surface of the disc. Each trunk divides further into temporal and nasal branches. The vessels should be followed in all the four quadrants as far as the equator, with the patient looking in all the four directions.

The arteries are bright red and narrower than veins, which are purplish. The normal A-V ratio is 2 : 3. After examining the disc and the vessels, the macula is

examined. A mydriatic may be instilled into the eye to facilitate proper examination, since light falling on the macula leads to pupillary constriction.

Major abnormalities of the optic disc include papilledema, optic atrophy, papillitis and glaucomatous cupping. Medullated nerve fibres may appear as bright streaks fanning out from the margin of the optic disc into the retina. These are congenital variations, which are not pathological and which should not be mistaken for pathological lesions.

Blood Vessels

Arteries: Normally arterial blood column is seen through the transparent arterial wall and gives the appearance of the normal streak. Thickening of arterial wall leads to reflection of light. The streak becomes wider and appears as burnished copper—*copper wire arteries*. When the arteries are seen as white lines they are called ghost vessels.

Sheathing: When the arteries are bordered by white lines this is referred to as sheathing.

Generalized narrowing of arteries occurs in hypertension, arteriosclerosis, vasculitis from various causes, central retinal artery occlusion, toxic amblyopias, migraine and conditions that cause retinal degeneration.

Irregular narrowing appears as irregularity in size of the arteries. Constricted segments alternate with normal or dilated segments. These changes occur mainly due to endothelial proliferation of the intima.

Pulsation: Normally pulsations of arteries are not visible. Arterial pulsation at the disc is always pathological. This is seen in aortic regurgitation, aneurysms and exophthalmic goitre. Capillary pulsation can occur in aortic regurgitation and this is seen as alternating hyperemia and pallor of the disc corresponding to systole and diastole. Veins normally pulsate due to transmission of the pulsations of the brain.

Veins: Congestion of retinal veins occurs in systemic diseases such as cardiac failure, polycythemia, respiratory failure, coarctation of aorta, thyrotoxicosis, chronic myeloid leukemia, acute leukemias and hyperviscosity states. All these conditions may predispose to venous occlusion. Marked congestion, tortuosity and dilation of veins occur in papilledema.

Arteriovenous changes: Normally the veins can be seen through the transparent arteries. In sclerosis, loss of transparency of the artery obscures the vein. A thickened artery may press the vein at crossings and therefore the vein appears to be interrupted proximally and distended distally. This is called nipping. Sometimes the vein may be pushed aside at crossings. New vessels develop in long-

standing venous occlusion and diabetes. This is called neovascularisation.

Hemorrhages: Retinal hemorrhages are always pathological. When the hemorrhage is superficial it occupies the nerve fibre layer and appears as striate or flame shaped bright red patches. When deeply placed, they appear as rounded irregular patches which are darker in colour. When hemorrhage occurs between retina and the vitreous, i.e. pre-retinal or subhyaloid hemorrhage, usually the macular area shows it up as a large spherical reddish patch. It becomes hemispherical slowly due to settling down of erythrocytes.

Exudates: Soft exudates are spherical cottonwool-like patches in the retina. These are caused by microinfarcts and are seen in vasculitis and hypertension associated with renal disease. Hard exudates are irregular yellowish white patches or plaques usually seen around the macula. They are due to neuronal degeneration and lipid infiltration of the retina. They are seen in diabetes and arteriosclerosis.

Motor System

The muscle groups have to be examined with a view to elicit the following points:

- 1. Bulk,
- 2. Tone,
- 3. Strength,
- 4. Fasciculations,
- 5. Presence of involuntary movements,
- 6. Stretch reflexes and superficial reflexes
- 7. Coordination, and
- 8. Gait.

In assessing these parameters it is important to have an idea of the normal bulk and strength and tone of the different muscles in relation to the general body build and age of the individual.

Muscle strength: This is to be graded as follows:

- Grade 0 Complete paralysis with no movement.
- Grade 1 Only a flicker of contraction is present.
- Grade 2 Patient can move the limb when gravity is eliminated by suitable positioning.
- Grade 3 Limb can be moved against gravity, but not against further resistance.
- Grade 4 There is some degree of muscle contraction ranging from poor, fair or moderate strength, against mild to moderate resistance.
- Grade 5 Normal power is present. Movement against full resistance is possible.

Neurological motor disability may take several patterns.

Hemiplegia: Paralysis of the limbs of one side of the body with paralysis of the face in most cases; this results from contralateral lesions of corticospinal tract above the brainstem.

Crossed: Lower motor neuron paralysis of cranial nerves on one side hemiplegia on the opposite side; this results from lesions in the brainstem ipsilateral to cranial nerve palsy.

Paraplegia: Paralysis of both lower limbs.

Monoplegia: Paralysis of only one limb.

Quadriplegia: Paralysis of all four limbs.

Double hemiplegia: Hemiplegia occurring on both sides.

Stretch reflexes: The stretch reflexes are monosynaptic reflexes. Sudden tap on a lightly stretched muscle tendon evokes a sharp contraction. Elicitation of these reflexes gives valuable clues about the integrity of the afferent and efferent reflex pathways and excitability of the reflex centre. Several reflexes are elicited in clinical examination. The reflex pathways of stretch reflexes are located in different levels in the spinal cord and brainstem. Their elicitation helps to determine the level of neurological lesion.

From above downwards, these reflexes are:

Stretch reflexes	Centre
Jaw reflex	Trigeminal nuclei in the pons
Biceps reflex	C5, C6 spinal segments
Triceps reflex	C6, C7 spinal segments
Supinator reflex	C5, C6 spinal segments
Knee reflex	L2, 3 and 4 spinal segments
Ankle reflex	S1 and 2 spinal segments

Stretch reflexes may be absent, normal or exaggerated (very brisk). Exaggerated stretch reflexed may be accompanied by clonus.

Superficial reflexes: These are polysynaptic reflexes elicited by stimulating the skin or mucous membrane. Several superficial reflexes can be elicited by appropriate stimuli. These are also altered in upper and lower motor neuron lesions. These also help to establish the location of neurological lesion.

Superficial reflexes	Centre
Abdominal reflexes	T7 to T12 spinal segments
Cremasteric reflex	L1 and 2 spinal segments
Anal reflex	S3, 4 and 5 spinal segments
Bulbocavernous reflex	S3 and 4 spinal segments
Plantar reflex	L5, S1 and 2 spinal segments

Co-ordination: This term implies the smooth recruitment, interaction and cooperation of agonists the prime movers, antagonists which oppose them and synergists which are supportive, which result in a smooth and definite motor act. Coordination is effected by several factors such as afferent proprioceptive impulses from muscle spindles and joint receptors, cerebellar function and muscle tone. Incoordination results in imperfect performance of the motor act and leads to ataxia. Ataxia may be due to loss of proprioceptive sensations (sensory ataxia) or diseases of the cerebellum (cerebellar ataxia). In the case of sensory ataxia (e.g., tabes dorsalis), visual clues can compensate to maintain posture and movement so that with eyes open the patient is able to maintain posture, but with the eyes closed, ataxia manifests. Ataxia occurring in cerebellar disease is not influenced by visual impulses.

Gait: The term gait refers to the manner in which a person walks. Normal gait involves both central mechanisms and peripheral mechanisms to execute the act of walking. These include:

- a. Antigravity stretch
- b. Stepping
- c. Propulsion, and
- d. Equilibration.

The peripheral mechanisms include muscles, tendons and joints. Components of the gait are **stance, pace, turns stamp**.

Stance is the distance between the two feet, necessary for stable standing. Normally it is equal to the length of one's own foot.

Pace is the distance covered between two feet during stable walking.

Turns: Sudden turning from one direction to another needs fine adjustments of motor skills to maintain balance. So, subtle problems in balancing will be manifest only during sudden turning.

Stamp is the force with which the feet are brought down to the ground on walking. It is determined by the height to which the toe is raised before the foot is brought down.

Disorders of gait can be due to disorders of:

1. Antigravity stretch, e.g. apraxic gait
2. Stepping, e.g. shuffling and hopping gait
3. Propulsion, e.g. dragging gait
4. Equilibration, e.g. swaying and reeling.

Defects due to peripheral mechanisms lead to limping and waddling. Analysis of the gait gives valuable neurological information. Well-defined neurological disorders give rise to characteristic types of gait.

Spastic gait

Indicates corticospinal tract lesions such as spastic paraplegia or hemiplegia.

Stamping gait

This occurs in sensory ataxia in which the patient stamps his foot on the ground with the heel touching first. This gait is seen in posterior column lesions.

Cerebellar gait

This is described as the reeling or drunken gait.

Festinant gait

It is seen in florid Parkinsonism.

Waddling gait

It resembles the gait of a duck. This results from defects in maintaining posture due to weakness of the truncal and gluteal muscles. This is seen in proximal myopathies. A similar gait may occur in bilateral disease of the hip joints as well.

High stepping gait

The patient lifts up his feet high to avoid tripping from the toes catching the ground. This type of gait is seen in patients with foot drop. e.g. peripheral neuropathy.

Apraxic gait :

The patient appears to be glued to the ground without moving forward. He tries to move the trunk instead of the feet. This is seen in frontal lobe disease.

Shuffling gait:

In this, the pace is short so the speed is grossly reduced. This is seen in frontal lobe disease.

Sensory System

Reliable results of sensory examination are obtained only when the patient is alert and cooperative. Considerable skill is required to elicit the sensations properly without unduly tiring out the patient. When testing the sensation it is better to proceed from the abnormal to the normal area.

The primary modalities that are tested include:

1. *Tactile sensitivity*, including light touch, pressure, tactile localization and discrimination;
2. *Pain (superficial and deep)*;
3. *Temperature (heat and cold)*;
4. *Position sense and appreciation of passive movement*;
5. *Vibration*; and
6. *Stereognosis* — Recognition of size, shape, weight, texture and form of objects.

RECORDING OF NEUROLOGICAL FINDINGS

The findings elicited on clinical examination should be systematically recorded. Many neurological disorders progress or resolve within short periods. Therefore, the examination may have to be repeated at regular intervals depending on the type of the disorder. This is all the more important in conditions such as transient ischemic attacks (TIAs), head injury, and meningitis.

Investigations

LUMBAR PUNCTURE (LP)

This can be safely performed in the absence of raised intracranial tension. The LP needle is introduced between the third and fourth lumbar vertebrae. The cerebrospinal fluid (CSF) is collected in four bottles for: (1) cytology, (2) biochemical examination, (3) microbiological studies and (4) for special tests like oligoclonal bands, immunoglobulins, lactate, pyruvate and others.

Manometry during LP is performed to measure the CSF tension. Compression of the jugular vein leads to rapid rise in lumbar CSF tension and release of the compression results in its rapid fall. This phenomenon is abolished in spinal block. **Queckenstedt's test** is done to detect block in the spinal subarachnoid space as occurring in spinal tumours or arachnoiditis. In the Queckenstedt's test the jugular vein is compressed on one side and then on the other side while doing spinal manometry. In lateral sinus thrombosis pressure on the ipsilateral jugular vein fails to raise the intracranial and spinal CSF pressure. Compression on the unaffected side leads to rise in CSF tension and the spinal subarachnoid fluid pressure.

In the **Tobey Ayer test** the jugular veins on either side of the neck are compressed in succession (not together).

Normally rise in intracranial CSF pressure is transmitted to spinal subarachnoid space and the lumbar CSF pressure rises. Failure to raise the spinal subarachnoid CSF pressure by jugular compression done on both sides, is indicative of spinal subarachnoid block.

Normal CSF is colourless, clear, and watery. Xanthochromia (yellow colour) occurs following subarachnoid hemorrhage and in Froin's syndrome. Turbidity results from increase in cells. Normally the cells number below 5/cmm and all of them are lymphocytes. Rise in cells is called pleocytosis. Lymphocytic pleocytosis occurs in viral, tuberculous and syphilitic meningitis. Neutrophil pleocytosis occurs in pyogenic meningitis, e.g. meningococci, pneumococci. Mixed pleocytosis (both lymphocytes and neutrophils) occurs in leptospirosis, tuberculosis or following subarachnoid hemorrhage. In neuroleukemia immature white cells may be seen in the CSF. Malignant lesions involving the meninges or extending to the surface of the brain or ventricles may give rise to presence of malignant cells in the CSF which can be detected by appropriate staining or millipore filtration (Table 183.5).

Biochemical composition of normal CSF		
Proteins	30-40 mg/dL	Much lower than serum level
Sugar	60-80 mg/dL	≥ 50% of serum level
Chlorides	720 mg/dL	same as serum level

The CSF cytology, biochemical characteristics, and serology alter in disease (Table 183.5).

The CSF should be examined with Gram stain for pyogenic organisms, Ziehl-Neelsen stain for mycobacteria and India ink preparation for cryptococci. In meningitis

Alterations in CSF in health and CNS infections					
	Tension	Colour	Cells	Protein	Sugar
Normal	50-150 mm water	Clear	0-5 lymph/cm	30-40 mg/dL	60-80 mg/dl
Pyogenic meningitis	Raised	Turbid	>1000, mostly neutrophils	Increased considerably	Very low
Tuberculous meningitis	Raised	Cloudy (cob-web)	Up to 300-500, mostly lymphocytes	200-300 mg/dL or more	Very low
Viral meningitis	Raised	Clear	10-100, mostly lymphocytes	50-100 mg/dL	Normal
Syphilitic meningitis	Raised	Clear	Up to 20-500, mostly lymphocytes	100-200 mg/dL	Normal
General paralysis of the insane	Normal	Clear	up to 100, mostly lymphocytes	40-100 mg/dL	Normal
Tabes dorsalis	Normal	Clear	Up to 100, mostly lymphocytes	30-60 mg/dL	Normal
Encephalitis	Raised	Clear	Up to 100, mostly lymphocytes	Normal or marginally raised	Normal or raised

this is an excellent method for early etiological diagnosis. The specimen for microbiological examination should be cultured without delay to get positive cultures. In tuberculous meningitis a fine coagulum (*cob-web*) forms when the CSF is left at room temperature for 12-24 hr. This is due to coagulated fibrin and it may show acid fast organisms on staining.

The rise of proteins in the CSF may be selective and this can be used for diagnosis. Selective rise in globulin fraction can be identified by suitable tests. Previously the colloidal gold test (*Lange's test*) used to be done for this purpose. A more modern and accurate method is to do immunoelectrophoresis. Determination of the immunoglobulins in the CSF and comparing them with the blood levels give diagnostic information. For example, in multiple sclerosis, CSF shows rise in oligoclonal IgG. Early identification of infective agents is made possible by molecular biological methods such as polymerase chain reaction.

The complications of lumbar puncture include sudden herniation of the cerebellar tonsils or uncus of temporal lobe, severe headache and introduction of infection into the meninges (iatrogenic meningitis).

Lumbar puncture is very risky in the presence of raised intracranial tension. Sudden release of CSF pressure by LP leads to herniation of the cerebellar tonsils into the foramen magnum or uncus of temporal lobe through the tentorium cerebelli resulting in fatal depression of respiration and other vital functions. Therefore, lumbar puncture is contraindicated in such situations unless a neurosurgical team is ready at hand. If available, CT scanning of the head which is a noninvasive but expensive procedure should be done to assess the intracranial pathology before undertaking a risky lumbar puncture. At least in some cases such as subdural hematoma or localized fluid collection, the LP can be shelved. **If meningitis or encephalitis is clinically suspected, lumbar puncture should be done with due precautions without delay, since early institution of specific antibiotic treatment is the most important factor leading to a successful outcome.**

Sometimes when an LP cannot be performed or the lumbar subarachnoid space is obliterated, CSF can be obtained by cisternal puncture. When the CSF tension is high a safe method to obtain CSF is ventricular puncture through a burr hole in the skull.

Electrophysiological Studies

ELECTROENCEPHALOGRAPHY (EEG)

EEG is a specialized neurological investigation which involves recording of the spontaneous electrical activity of the brain from the scalp. This is a safe, non-invasive, relatively inexpensive, painless, easily repeatable procedure to know the functional status as opposed to the CT and MRI scan which reveal the morphology

of the brain. Since the EEG findings in many of the cerebral disorders are non-specific, its diagnostic value is confined to a few conditions such as epilepsies, encephalitides, metabolic, toxic, anoxic and drug induced encephalopathies, brain death, and sleep disorders. EEG was introduced into clinical medicine by Hans Burger. The modern EEG machine has 8 to 16 channels to record the brain's electrical activity simultaneously from many areas of the scalp. Electrodes, which are usually silver—silver chloride discs are applied to the scalp, by means of an adhesive material which also provides good electrical contact between the electrode and the skin after the hair and the scalp are cleaned of oil and grease. The placement of these electrodes on the scalp is standardized internationally (10-20% system), and the tracing is recorded on a moving sheet of paper for about 30-60 minutes during the awake state, while the patient comfortably lies in a quiet room. The patient need not fast for this test nor miss his medication, including the anticonvulsants. In many laboratories, hyperventilation for three minutes, photic stimulation at different rates with a flickering light (strobe) and sleep are used as provoking procedures.

The EEG tracing is studied to note the frequency, amplitude, morphology and topography of the brain electrical activity. Four types of frequency bands of EEG are encountered. They are (i) delta (less than 4 Hz activity), (ii) theta (4-8 Hz), (iii) alpha (8-13 Hz), and (iv) beta (more than 13 Hz) bands.

The EEG of a normal adult in the awake and resting state with eyes closed consists of alpha rhythm of 30-60 microvolts over the posterior regions of the head. In children, the frequency is slower in the theta or delta range, depending on the age.

The abnormalities in the EEG may be in the form of asymmetrical activity, faster or slower frequency activity, low or high amplitude activity or abnormal wave forms like sharp waves, slow waves and/or spikes. Localised or focal abnormalities, though highly significant, cannot reliably distinguish the underlying pathological lesion such as tumour, abscess, hematoma or infarct.

EEG is of greatest value in seizure disorders not only to document the inter-ictal subclinical seizure activity but also to classify the epilepsy as partial or generalized, depending on whether the seizure activity is focal or generalized. Sporadic spikes, sharp waves, spike and slow wave complexes or 3 Hz spike and wave complexes in absence attacks are some of the EEG patterns seen in epilepsy. However, it should be mentioned here that a normal EEG does not exclude epilepsy because in only 50-60% of these patients EEG will be abnormal in the interictal period.

The characteristic periodic EEG complexes in subacute sclerosing panencephalitis and Jacob-Cruetzfeldt disease, the triphasic waves in hepatic coma and the electrocerebral silence in brain death are some of the other diagnostic EEG patterns.

Evoked Potentials

Evoked potentials are specific cortical, thalamic or brainstem responses to visual, auditory or somatosensory stimuli. They have several components beginning at a constant latency after application of the stimuli. They are maximal in the cortical areas appropriate to the modality and laterality of the stimulus. Since these electrical potentials are very low in amplitude (0.5-20 microvolts), computers are required to amplify them and distinguish them from background electrical activity of the brain. Three main evoked potential tests are in current use. These are: (1) *visual*, (2) *brainstem auditory*, and (3) *somatosensory*. They are found to be of great value in the diagnosis of several disorders, which may present problems in diagnosis, e.g. visual evoked potentials are useful in identifying demyelinating disease, multiple sclerosis, compressive lesions of the visual pathway, Friedreich's ataxia, Huntington's chorea, etc. It also helps in distinguishing factitious visual loss from genuine blindness. Auditory evoked potentials help to diagnose acoustic neuroma, multiple sclerosis, and central pontine myelinolysis. Somatosensory evoked potentials help in the diagnosis of sensory peripheral neuropathy, tabes dorsalis, subacute combined degeneration, progressive myoclonic epilepsy, etc.

Magnetoencephalography

Magnetoencephalography has been employed to record molar evoked potentials in humans. The magnetic fields generated by the neuronal and other activities of the brain are evaluated using an array of magnetic probes. This investigational tool may form an adjunct to the other available methods, especially in the investigation of disorders such as epilepsy demyelination and others.

Polysomnography records EEG, eye movements, EMG of chin muscles and tibialis anterior muscles, ECG, oral

and nasal airflow, respiratory movements of the chest and abdomen, and oxygen saturation. This is indicated for study of sleep disorders, sleep apnea syndrome, seizures, and other forms of brain disease. The study is done in special sleep-laboratories. It helps to distinguish between wakefulness and sleep and also to record the stages of sleep.

ELECTROMYOGRAPHY (EMG)

EMG is an investigation in which the electrical activity of muscle is picked up with a needle electrode inserted into the muscle and is displayed on a cathode ray oscilloscope and played over a loudspeaker for simultaneous visual and auditory analysis. Usually, this is performed by the neurologist and is associated with some amount of discomfort to the patient because of multiple needle insertions into the muscles. Interpretation of EMG is done taking into consideration the following parameters (Table 183.6):

- 1. Insertional activity.
- 2. Spontaneous activity.
- 3. Activity in minimal muscle contraction.
- 4. Activity in maximal muscle contraction.

Basically, it is carried out to know whether a muscle is normal or shows evidence of myopathy or neurogenic lesion, both of which can lead to muscle weakness and wasting. A normal muscle is electrically silent when it is at complete rest. When it is minimally contracted voluntarily, the action potentials of motor units that are activated appear on the oscilloscope which have a certain configuration, amplitude and duration. With more and more vigorous voluntary contraction, the number of these action potentials increases and during maximal contraction which recruits all the motor units for contraction, these potentials merge with each other to give full recruitment pattern. When the muscle contraction ceases, again the muscle becomes electrically silent.

TABLE 183.6

EMG abnormalities in different neurological disorders

EMG parameters	Myopathy	Neuropathy	Myotonia
Insertional activity	Normal	Increased	Increased
Spontaneous activity	Normal	Increased fibrillation, fasciculation	Normal
Minimal voluntary contraction	Low amplitude short duration with polyphasic complexes	Large amplitude Long duration polyphasic complexes	Discharges wax and wane in amplitude and frequency
Maximal voluntary contraction	Full recruitment	Incomplete recruitment	Not affected
Audio	Nil characteristic	Rain on roof top sound due to fibrillation	Dive bomber sound

When a muscle becomes weak due to a primary muscle disease like myopathy, its EMG pattern differs from that of a normal muscle. When the affected muscle is at rest, there will be spontaneous electrical activity in the form of fibrillation potentials. During minimal voluntary contraction, the generated action potentials will be of lower amplitude and shorter duration as compared to a normal muscle and during maximal contraction, the recruitment potentials will be full. As against this, a muscle which is weak due to a neurogenic lesion, i.e. its neural connection to the anterior horn cells of the spinal cord is affected, it shows spontaneous electrical activity at rest in the form of fibrillation and fasciculation potentials and during minimal voluntary contraction, the action potentials will be of larger amplitude and longer duration than normal and during maximal contraction, the recruiting potentials will be less than normal.

Thus, EMG helps to differentiate muscle weakness due to a primary muscle disease from that due to a nerve or anterior horn cell disease. But it does not indicate the causes of the disease for which other supplementary investigations are required. Many a time it is possible to distinguish primary myopathy from neuropathy clinically, but occasionally it is difficult. EMG is most valuable to distinguish such cases. Characteristic EMG pattern occurs in myotonic disorders (dive-bomber sound) and EMG also helps to differentiate true myotonia from pseudomyotonia and true weakness from hysterical weakness.

Muscle enzyme levels like creatine phosphokinase (CPK) and lactic dehydrogenase (LDH) in the serum may transiently increase, following an EMG investigation because of the needle trauma to muscles. Therefore, the blood samples for estimation of these enzymes should be collected before performing the EMG.

Nerve Conduction Studies

Nerve conduction study is employed to test the integrity of a peripheral nerve. The presence or absence of denervation, the site of nerve block if any, and nature of the lesion such as demyelination or axonal lesion can be detected easily even if the patient is not cooperative. Hence this test can be employed in infants, children and in comatose patients.

Nerve conduction velocity studies (NCV) are of two types:

1. Motor nerve conduction velocity study (MNCV), and
2. Sensory nerve conduction velocity study (SNCV).

NCV studies are valuable (i) to detect demyelination in the peripheral nerves where the NCV will be significantly slowed down, and (ii) to detect axonal lesion where the NCV may be within normal limits but the evoked muscle action potential will be of abnormally low amplitude and longer duration. NCV study also helps to localize the site of pathology in the peripheral nerves. NCV and EMG are complementary investigations and

should be done together. Prognosis for muscle recovery should take into account the results of both.

In demyelinating neuropathy the NCV is grossly delayed, but EMG is normal. Axonopathy shows normal NCV with abnormal EMG. This combination (i.e) **normal NCV with low amplitude EMG indicates a poor prognosis for recovery whereas abnormal NCV with normal EMG indicates good prognosis.**

Imaging Studies

Neuroradiology: This branch of radiology has expanded tremendously and several diagnostic techniques are available.

Plain X-ray of skull in the anteroposterior, lateral and special views, (e.g., Towne's view for the internal auditory meatus) help to detect rarefaction of the skull, fractures, bony erosions, calcification, enlargement of the sella turcica, and shift of midline structures such as a calcified pineal gland. Radiology of the cervical spine helps to visualize bony lesions, vascular calcification and abnormalities of the craniovertebral junction.

X-ray of the skull is a very useful investigation to detect congenital and other acquired abnormalities of the skull such as hydrocephalus, Paget's disease of bone, punched out lesions occurring in multiple myeloma, histiocytosis and malignant secondaries, hyperplasia of bone marrow as occurring in thalassemia, endocrine abnormalities such as hyperparathyroidism, fractures of the skull vault and base of the skull and several others. With the availability of CT scans and MRI, the preference is for them for the detection of intracranial lesions, particularly of the soft tissues and blood vessels.

Special radiological studies: Myelography demonstrates the spinal subarachnoid space. Direct myelography is an invasive procedure associated with the risk of reactive myelopathy. Hence, where MRI myelography using contrasts it is the procedure of choice.

Angiography: A very elegant method is *digital subtraction angiography* by which the background shadow of the skull and other structures are eliminated so that the vascular lesion stands out in prominence. Another great advantage of digital subtraction angiography is that the contrast medium can be given by a simple intravenous injection thereby avoiding arterial puncture.

COMPUTED TOMOGRAPHY

This is a non-invasive method which has obtained universal acceptance due to its safety and usefulness. Moreover, CT scan can be repeated without much inconvenience to the patient, and therefore, the progress of lesions can be followed. The principle of the method is as follows: A beam of X-ray is passed through the tissue to be investigated. Part of the X-ray is absorbed by the

tissue depending on its optical density, and the remainder comes out. Highly sensitive detectors pick up this emergent beam. The source of X-ray is rotated through 360° and then a transectional image is produced by feeding the emergent beam into a computer. The resultant picture gives details of the bony structures, brain, ventricles, and other soft tissues. It is easy to interpret the picture. Space-occupying lesions, infarcts, aneurysms, vascular malformations, subdural collections, etc. can all be diagnosed with precision. Refinements of techniques enable the coronal or sagittal reconstruction of the image. The vertebral canal and spinal cord can also be visualized by appropriate techniques.

Indications: CT scan of the head is indicated and essential for the diagnosis and management of the following conditions. A patient with:

1. Focal neurological deficit of relatively recent onset and of undetermined cause,
2. Features of definite or suspected raised intracranial pressure,
3. Altered sensorium or mental status of undetermined cause,
4. Focal seizures of recent onset,
5. Late onset seizures,
6. Subarachnoid hemorrhage,
7. Head trauma, and
8. Suspected intracranial mass lesion.

CT scan is also the procedure of choice in patients in whom MRI is contraindicated due to the presence of implanted cardiac pacemakers, mechanical heart valves or magnetizable intracranial aneurysmal metal clips.

Although a normal CT is sometimes reassuring to the patient as well as to the clinician, the practice of ordering CT scan indiscriminately should be discouraged. Under no circumstances, CT should be considered as a substitute to clinical examination except in dire emergencies.

Limitations: While CT imaging of the supratentorial structures in the brain is quite good, its use in the evaluation of the posterior fossa structures such as brainstem and the cerebellum is limited because of the beam hardening artifacts of adjacent bones. For the same reason, CT for the evaluation of spinal cord disease is less than satisfactory. The other limitations of CT are its inability to reveal very small lesions, isodense lesions (lesion density same as that of normal brain) and cerebral infarcts in the first 24 to 48 hours of their occurrence. Hence, a normal CT does not ensure that all possible structural pathologies have been excluded. In such situations MRI may reveal abnormalities. In a few cases of meningitis encephalitis and brain abscess CT may be normal in the early stages. In these situations MRI is more rewarding.

Modern machines such as the third generation CT scanners are much faster and technically more perfect than the older generation machines. Several procedures such as aspiration of brain abscess and hematoma and stereotaxic procedures can be undertaken with CT guidance. CT exposes the patient to ionizing X- rays

CT has advantage over MRI in conditions like sub-arachnoid and other intracranial bleeds, calcified lesions and bony lesions. However distinction between grey matter and white matter is poor. Very small lesions (< 1 cm) and lesions in tissues surrounded by bone (e.g. pituitary) can be missed by C T. In intracerebral vascular accidents infarction may be missed in the first 24 hours.

CT is indicated before LP in the following conditions:

1. Unknown unconscious patient
2. Raised intracranial tension
3. Intracranial bleed suspected, and
4. Acute posterior fossa lesions.

MAGNETIC RESONANCE IMAGING (MRI)

Magnetic resonance imaging offers better visualization of the anatomy of the brain and the spinal cord because of its high resolution. This is also a safe, rapid and non-invasive procedure like CT. MRI distinguishes white matter and grey matter of the brain better. For MRI scan, the patient is placed in a powerful magnetic field which makes the atoms of the tissues to align themselves in the orientation of the external magnetic field. A brief radio-frequency pulse is introduced into the magnetic field which excites the atoms (protons) and changes their alignment. When the pulse excitation ends, the protons return to their previous orientation in the magnetic field and radiofrequency energy is emitted from the tissues. By computer analysis of this emitted energy, a series of images of the tissue is created, in horizontal, coronal and sagittal planes. Differences in proton characteristics of tissues are imaged with T1 or T2 weighted sequences. T1 is the time required after excitation for longitudinal magnetization to return close to its pre-excitation state. T2 is the time required after excitation for transverse magnetization to return close to its pre-magnetization level. While T1 weighted images provide higher resolution and low contrast, the T2 weighted images are of lower resolution but of higher contrast. Intravenous administration of contrast agents such as gadolinium diethylene triamine penta-acetic acid improves the contrast if there is disruption in the blood brain barrier. The advantages of MRI over CT scan are:

1. It has better spatial and contrast resolution than CT,
2. It is free of exposure to radiation, and
3. It is free of bone artifacts.

Because of its higher resolution, it is also useful to detect smaller lesions in the cerebral hemispheres such

as lacunar infarcts, demyelinating plaques in multiple sclerosis, small granulomas such as tuberculomas and cysticercosis cysts, which may escape detection on CT. At present, because of its higher cost, it may be reserved for investigation of lesions in the posterior fossa and spinal cord, such as syringomyelia and other structural lesions.

Further developments in MRI imaging include MRI angiography which produces images of blood flow in brain without the need to inject contrast agent and MRI spectroscopy which helps in the chemical analysis of the tissues in the living brain.

Advances in ultrafast and echoplanar imaging has made MRI as fast as CT. Functional MRI is a method of imaging the functional state of brain, and assess cerebral blood flow and other metabolic parameters. For MRI scan, the patient has to be kept in a highly confined space which makes some patients claustrophobic. Open MRI machines which do not cause claustrophobia are available at present. MRI is contraindicated in patients with implanted cardiac pacemakers, mechanical heart valves, magnetizable intracranial aneurysm clips or any other implanted metallic prosthetic device.

Positron Emission Tomography (PET)

Whereas CT and MRI techniques provide information regarding the structural details of the brain and the spinal cord, PET provides information about their function also.

It is performed by administering intravenously or by inhalation, a positron-emitting radionuclide of very short half-life. This necessitates the availability of a cyclotron near the scanning site in order to provide the radio-isotopes. Because of this requirement, at present, its cost is very prohibitive and this investigation is available in only a few advanced centres in the world, mainly as a research tool rather than an investigative technique in clinical medicine. Processes such as cerebral blood volume can be studied noninvasively both in health and disease. The concentrations and locations of various neurotransmitters and their receptors can also be determined with PET. SPECT and PET are also useful in identifying regional cerebral blood flow, regional glucose metabolism and other cerebral metabolic activities. Their use in psychiatric and metabolic disorders has helped to identify the functional and metabolic basis of some of them, like schizophrenia.

Single Photon Emission Computed Tomography (SPECT)

Like PET, SPECT also provides information about the function of the brain. It also involves administration of gamma ray emitting radionuclides. However, these radionuclides are of longer half-life and hence do not need a costly cyclotron nearby. Therefore, SPECT can be described as a poor man's PET. It is now available only in some centres for clinical use, especially to study

cerebral blood flow, cerebral blood volume and cerebral neurotransmitter receptors.

Isotopic studies: Imaging and flow studies are available for the diagnosis of brain tumours, cerebrovascular disease, subdural hematomas and brain abscess. The commonly used radionuclide is ^{99m}Tc technetium pertechnetate.

Echoencephalography

This non-invasive ultrasound investigation, which was popular before the advent of CT scanner is still useful to detect the shift of the midline structures caused by supratentorial space occupying lesions, and to detect the size of the ventricles. Currently, an advanced real time ultrasound scanner capable of high resolution is available to diagnose intracranial hemorrhage in infants.

Transcranial Doppler Study

This is a noninvasive method employed to study the flow pattern in extracranial vascular tree and medium sized intracranial vessels. It also gives information on the nature of vessel wall stenosis, atheroma and luminal aperture.

During cardiac interventions and other surgical procedures on major vessels which are likely to release atheromatous emboli into the circulation and lead to residual cognitive defects, doppler study can be employed to monitor the procedural risk of embolism.

Histopathological Studies

Brain Biopsy

Brain biopsy as a diagnostic method, though available for many years, is sparingly undertaken at present due to availability of advanced neuroradiological and neurophysiological techniques.

In the majority of cases, this procedure is undertaken by neurosurgeons. With the availability of stereotaxic frames, stereotaxic brain biopsy of very localized and small lesions can be performed with precision and safety.

The indications for brain biopsy are:

1. Focal intracranial lesions, and
2. Chronic, progressive cerebral disorders of diffuse character accompanied by mental retardation or dementia, in whom all other possible diagnostic methods have already been done, but have failed to provide sufficient diagnostic information.

Brain biopsy should be undertaken only when laboratory facilities and staff experienced in the interpretation of the biopsy material are available.

Muscle and nerve biopsy: These biopsy procedures should be carried out by experienced persons because any damage to the tissue during biopsy will seriously hamper the correct interpretation by the pathologist.

Muscle biopsy is of value in the diagnosis of congenital myopathies, storage diseases of the muscle, vasculitis and polymyositis. It is also helpful in differentiating long-standing muscle weakness and wasting due to a primary muscle disease from neurogenic atrophy, when clinical and electrophysiological features are equivocal.

Nerve biopsy is useful to differentiate axonal from demyelinating neuropathies. Hereditary hypertrophic neuropathies, infective neuropathies like leprosy and infiltrative neuropathies such as sarcoidosis and amyloidosis and vasculitis, can also be identified by nerve biopsy.

Cranial Nerves

S.R. Chandra, P.K. Mohan

Chapter Summary

Olfactory Nerve 1200
 Optic Nerve 1201
 Oculomotor Nerve 1203
 Trochlear Nerve 1203
 Abducent Nerve 1203
 Trigeminal Nerve 1207
 Facial Nerve 1208
 Acoustic Nerve 1211
 Glossopharyngeal and Vagus Nerves 1213
 Accessory Nerve 1214
 Hypoglossal Nerve 1214

Olfactory Nerve

Syn: Cranial nerve I

The olfactory nerves which subserve the sense of smell have their cells of origin in the mucous membrane of the upper and posterior part of the nasal cavity. They are bipolar sensory cells, the distal portions of which consist of ciliated processes which penetrate the mucous membrane in the upper portion of the nasal cavity. The central processes of these nerves, approximately twenty on each side, pass through the cribriform plate of the ethmoid bone and synapse in the olfactory bulbs with specialised cells called mitral cells, the dendrites of which form brush-like terminals or olfactory glomeruli.

The axons of the mitral cells enter the olfactory tract, which course along the olfactory groove of the frontal bones to reach cerebrum. Posteriorly the olfactory tract divides into medial and lateral olfactory striae. The medial striae pass to the opposite side through the anterior commissure. Fibres in the lateral striae give off collaterals to the anterior perforated substance and terminate in the medial and cortical nuclei of the amygdaloid complex and prepyriform area. The latter represents the primary olfactory cortex.

Testing: Before evaluating olfactory sensations one must ascertain that the nasal passages are not blocked. Local lesions such as allergic rhinitis, polyps, and sinusitis which impair olfaction have to be excluded. The test substance should be nonirritant and volatile. Freshly ground coffee powder, asafoetida, eucalyptus oil or lemon oil are some of the common test substances used. Substances like chloroform which may stimulate gustatory end-organs or the peripheral endings of the trigeminal nerves in the nasal mucosa instead of stimulating the olfactory nerves, should be avoided. Each nostril should be tested separately with the other nostril kept occluded. The patient should be asked to inhale and identify the test substance. The perception of odour is more important than its identification.

Disorders of Olfaction

- Quantitative:** Loss (*anosmia*), reduction (*hyposmia*) or increased acuity (*hyperosmia*).
- Qualitative:** Distortion of smell (*dysosmia* or *parosmia*).
- Illusions and hallucinations of smell.**

Anosmia due to lesions in olfactory cortex occurs only if the disease is bilateral. Head injury, olfactory groove meningioma, frontal lobe tumours and aneurysms of anterior cerebral or anterior communicating artery are some of the causes of unilateral anosmia. Hyperosmia is usually a feature of neurotic patients, but can also occur in organic conditions such as cystic fibrosis and aura phase of migraine and epilepsy – It may occur during pregnancy in normal subjects. Dysosmia or parosmia may occur with local abnormalities in the nose. Olfactory hallucinations and delusions usually suggest psychiatric disorders. However, they may be associated with complex partial epilepsy (uncinate seizures) where there is brief olfactory experience

accompanied by alteration of consciousness and other epileptic phenomena.

Optic Nerve

Syn: Cranial nerve II

The optic nerve is not a peripheral nerve in the strict sense since it represents the fibre pathway that unites the retina with the brain. The receptors through which the visual impulses are perceived are the rods and cones which synapse with the inner nuclear or bipolar layer of the retina, the cells of which in turn synapse with those of the ganglion cell layer. The axons of the ganglion cells constitute the optic nerves. The *rods* react to dim light, peripheral vision and night vision. They are absent over the macula, where only the cones are present in abundance. The *cones* are concerned with vision in bright light and colour vision. The optic disc is devoid of *rods* and *cones* and hence in the visual field it projects as an area known as the *physiological blind spot*.

The optic nerve extends from the retina to the optic chiasma through the optic foramina, where the fibres from both the nasal sides cross. Fibres from the lateral (temporal) half of the retina are situated in the temporal

half of the nerve and they pass through the chiasma without crossing. Posterior to the chiasma the fibres constitute the *optic tract* which consists of the ipsilateral temporal fibres and contralateral nasal fibres. The optic tract fibres end in the lateral geniculate body by synapsing with neurons there. The axons of neurons from the lateral geniculate body pass posteriorly as the optic radiations which terminate on the striate or visual cortex (area 17) of the occipital cortex. The parastriate (area 18) and peristriate (area 19) areas in the occipital cortex function in a more complex way for visual perception and colour vision. The fibres subserving light reflex pass to the pretectal nucleus and the superior colliculus of the midbrain from the lateral geniculate body (Fig. 184.1).

Testing: Clinical examination of the optic nerve includes tests for visual acuity, visual fields and colour vision. Funduscopy should always be done as a routine. The visual acuity is ideally tested using a Snellen's chart. However, at the bedside one could examine grossly any defect in the near and distant vision (1) using flash light (2) finger counting and (3) Rosenthal chart. Visual fields are ideally tested by using a perimeter for peripheral fields and the Bjerrum's

Fig. 184.1: Visual pathways and visual field defects produced by lesions at different levels

Right lower quadrantanopia 6. Right homonymous hemianopia with sparing of macula

screen for the central field. At the bedside it can be tested by the confrontation method. Here the field under investigation is compared with the examiner's visual field which is used as a standard. The examiner stands with one eye closed about one metre in front of the patient. The right eye of the patient is compared with the left eye of the examiner and vice versa. The patient is made to close one eye and instructed to fix the eye to be tested on the examiner's nose. Each eye is tested individually. Either a pin with a white or coloured head or even the examiner's finger is used as a test object. The test object, held midway between the patient and the examiner, is brought into the field of vision through various meridians of the visual field. The patient is asked to respond when he first notices the object. In this way the temporal, nasal, upper and lower visual fields can be compared with those of the examiner and field defects could be identified. During the same sitting visual inattention or extinction can be tested by simultaneously presenting objects in the upper or lower temporal quadrants of vision on both sides.

Colour vision is tested either by asking the patient to identify primary colours (red, green and blue) or by matching the colours of different objects in case he cannot name the colours—using Ishihara's chart and Holmgren's wools.

Disorders of vision: Amaurosis refers to blindness from any cause. Amblyopia refers to impairment or loss of vision which is not due to an error of refraction or to other diseases of the eye itself.

Visual impairment can be secondary to a disease process anywhere along the visual pathway from the cornea to visual cortex. Disorders affecting the media of the eye are included under ophthalmological disorders. Diseases of the retina may cause visual impairment owing to involvement of the peripheral neurons, the rods or cones. Conditions like retinitis, chorioretinitis, vascular diseases, retinal detachment and hemorrhages cause patchy or even complete loss of vision depending on the extent of lesion.

The optic nerve may be affected by demyelinating disorders, infections, neoplasms, toxins, trauma or vascular insufficiency. Such disorders begin as a central scotoma or a partial field defect and proceed to complete visual loss in that eye.

A lesion in the optic chiasma produces a characteristic field defect depending on whether the lesion begins at the centre of the chiasma or from the outer aspect. The former produces bitemporal hemianopia. The latter produces binasal hemianopia, usually due to extrinsic compression by a tumour.

Lesions in the optic tract produce contralateral hemianopia, with absent pupillary light reflex. However, if the

pupillary light reflex is preserved then the lesion is either at the lateral geniculate body or in the optic radiation. Involvement of the lower fibres of the optic radiation coursing in the temporal lobe causes contralateral superior quadrantic hemianopia, and affection of the upper fibres in the parietal lobe causes contralateral inferior quadrantic hemianopia. Lesions of one occipital lobe cause contralateral hemianopia. Involvement of the upper lip of the calcarine fissure causes inferior quadrantic hemianopia, and that of the lower lip causes superior quadrantic hemianopia. Lesions involving the optic radiation and the occipital cortex do not affect the pupillary light reflex. Incomplete lesions of the optic tract and radiation usually spare central (macular) vision. A lesion of the tip of one occipital lobe produces a central homonymous hemianopic scotoma since half the macular fibres from both eyes terminate there. Lesions of both occipital poles as in bilateral posterior cerebral artery embolization cause bilateral central scotoma, and bilateral lesions of the entire calcarine cortex cause cortical blindness.

Optic neuritis: This can be unilateral or bilateral, associated with marked loss of vision. It may be due to demyelination or toxic damage to the optic nerve. The condition is usually associated with pain behind the eyeball. When the underlying cause is removed or treated, the vision gradually recovers, but some cases may lead to inflammation of the optic disc (papillitis) and optic atrophy.

Causes: Toxic agents such as methyl alcohol, nicotine, lead, quinine, ethambutol or demyelinating diseases such as multiple sclerosis and neuromyelitis optica (a combination of optic neuritis and transverse myelitis).

Papilledema: This is swelling of the optic disc as seen through the ophthalmoscope. The margins of the disc are indistinct. The physiological cup is filled. The medial margin of the disc shows more marked changes. The veins are congested.

Papilledema leads to concentric diminution of the field of vision and enlargement of the blind spot. Compared to optic neuritis, visual loss due to papilledema is much less severe.

Causes: Increased intracranial pressure due to any cause, malignant hypertension, diseases of the retinal arteries such as giant cell arteritis, retinal vein thrombosis, cavernous sinus thrombosis, hematological disorders like acute leukemia and polycythemia vera, emphysema and pre-eclamptic toxemia.

Optic atrophy: The ophthalmoscopic appearance of optic atrophy consists of pallor of the optic disc, with a punched out appearance, prominence of the lamina

cribrosa and narrowing of the retinal arteries. Based on funduscopic appearance optic atrophy can be differentiated into primary and secondary. In primary optic atrophy the disc margins are clear and punched out and the lamina cribrosa is visible through the disc. Secondary optic atrophy follows papilledema. In this form, the disc margins as well as the lamina cribrosa are less distinct and venous congestion persists. The term “*consecutive optic atrophy*” is used when the optic atrophy results from retinal diseases. Optic atrophy may be unilateral or bilateral leading to progressive loss of vision.

Causes: All causes of optic neuritis may lead to optic atrophy as well. Other rarer causes include pressure on the optic nerve or optic chiasma, occlusion of the central retinal artery and injury to the optic nerve. Primary optic atrophy occurs in association with hereditary cerebellar ataxias and Leber’s optic atrophy.

Motor Nerves of the Eyes

These are the oculomotor, trochlear, and abducent nerves. Since they function together in the regulation of eye movements, they are examined together.

Oculomotor Nerve

Syn: Cranial nerve III

The oculomotor nuclei in the midbrain consist of several paired groups of nerve cells, adjacent to the midline, ventral to the aqueduct of Sylvius at the level of the superior colliculi. A centrally located group of nerve cells, the Edinger-Westphal nucleus, innervates the pupillary constrictor and ciliary muscles. It is situated more dorsally, and constitutes the parasympathetic portion of the oculomotor nerve. The nerve cells that mediate the action of the ocular muscles show a definite dorso-ventral topographic representation in the oculomotor nucleus. The nerve fibres from these neurons course anteriorly through the mesencephalon, medial to the red nucleus, the substantia nigra and the cerebral peduncle. The nerve emerges from the anterior aspect of the midbrain just above the pons, between the superior cerebellar and the posterior cerebral arteries. It penetrates the dura mater lateral and anterior to the posterior clinoid process and enters the lateral wall of cavernous sinus. From there it enters the orbit through the superior orbital fissure and supplies the levator palpebrae superioris, the inferior oblique, and the superior, medial and inferior recti muscles. The preganglionic para-sympathetic fibres from the Edinger-Westphal nucleus pass up to the ciliary ganglion in the orbit from where the postganglionic fibres supply the pupillary constrictors and the ciliary muscles which function in accommodation.

Trochlear Nerve

Syn: Cranial nerve IV

This is the shortest of all cranial nerves. Its nucleus is situated just anterior to the aqueduct in the midbrain immediately above pons. The axons of these neurons pass posteriorly around the aqueduct and decussate with those from the opposite side in the superior medullary velum on the dorsal surface of the midbrain. The nerve penetrates the dura mater posterolateral to the posterior clinoid process to enter the cavernous sinus where it is lateral and inferior to the 3rd cranial nerve. Through the superior orbital fissure, it enters the orbit to supply the superior oblique muscle.

Abducent Nerve

Syn: Abducens nerve, cranial nerve VI

This nerve arises from the lower part of the pons in the floor of the fourth ventricle. The nerve emerges from the brainstem at the pontomedullary junction. It has the longest intracranial course among all the cranial nerves and lies between the pons and the clivus. It pierces the dura mater at the dorsum sellae, between the posterior clinoid and apex of the petrous bone to enter the cavernous sinus, inferomedial to the 3rd cranial nerve. It enters the orbit through the superior orbital fissure to supply the external (lateral) rectus muscle.

The medial longitudinal fasciculus: This fibre tract unites the nuclei of 3rd, 4th, 5th, 6th, 7th, 8th, 11th, and the 12th cranial nerves and the motor nuclei of upper cervical nerves. Owing to this interconnection, both the eyes move in a coordinated manner simultaneously and isolated movements in one eye independent of the other do not occur usually. Visual, auditory, sensory, vestibular, and other stimuli produce conjugate deviation of the eyes and head.

Sympathetic innervation: The sympathetic fibres which control oculopupillary action arise from the eighth cervical and first thoracic spinal segments. The preganglionic fibres go to the inferior, middle, and superior sympathetic ganglia in the neck. The postganglionic fibres follow the course of the internal carotid artery and travel along the ophthalmic division of the fifth cranial nerve into the orbit. Through the long ciliary nerves they supply the pupillary dilators, the tarsal muscles, and the orbital muscle of Muller.

Cortical control: The posterior portion of the second and third frontal convolutions constitute the volitional cortical control of conjugate ocular movements. A pontine centre for lateral gaze has also been described in the vicinity of the abducens nerve—the *parapontine gaze centre*.

The light reflex: When light is focussed on one eye, there is constriction of both the homolateral (*direct light reflex*) and the contralateral pupil (*indirect or consensual light reflex*).

The accommodation reflex (near vision reflex): The phenomena which occur sequentially in this reflex are convergence of the eyes, pupillary constriction and increase in thickness of the lens due to relaxation of ciliary muscles. This is elicited by asking the patient to shift his gaze to some near object after he has relaxed his accommodation by gazing into the distance. The response to be noted is pupillary constriction and convergence of the eyes.

The afferent pathway for the light reflex passes along the optic nerve and chiasma to the superior colliculus and the pretectal region of the midbrain. From there the efferent fibres pass forward in two paths: (1) close to the aqueduct to enter the **Edinger-Westphal nucleus** of 3rd cranial nerve on the same side, and (2) through the posterior commissure to the opposite Edinger-Westphal nucleus. From the Edinger-Westphal nucleus fibres pass to the ciliary ganglion and through the short ciliary nerves, reach the constrictor pupillae muscles.

Pupillary dilatation is also under reflex control. Pinching the nape of the neck or other painful stimuli cause reflex dilatation of the pupils; the **cilio-spinal reflex**. Impulses arise from the posterior hypothalamus with activation of sympathetic fibres which pass down the brainstem and reach the orbit along the cervical sympathetic ganglia. The pupillary dilatation is facilitated by simultaneous inhibition of the Edinger-Westphal nuclei.

The cilio-spinal reflex is abolished in lesions of cervical sympathetic nerves, lesions of the cervical and upper thoracic segments of the spinal cord, medulla oblongata and T1 spinal roots.

Abnormal pupillary reflexes: Apart from sluggishness or loss of light and accommodation reflexes due to ocular or neurological diseases, qualitative abnormalities of pupillary reflexes may be seen. These include **Argyll Robertson pupil, Holmes-Adie pupil and the Marcus Gunn pupil**.

Argyll Robertson pupil: When the pupillary light reflex is abolished and the accommodation reflex is preserved it is called Argyll Robertson pupil. The pupils are constricted and irregular in the well-developed case. They react slowly, and do not react to mydriatics. Though the condition is usually bilateral, rarely it may be unilateral or asymmetric. The lesion is in the pretectal region of the midbrain affecting the light reflex fibres but not those for accommodation reflex. Classically seen in neurosyphilis (tabes dorsalis, and general paralysis of the insane), very rarely it may occur

in other midbrain lesions such as viral encephalitis, intracranial tumours, Wernicke's encephalopathy and demyelination. Argyll Robertson's pupils do not impair visual function.

Holmes-Adie pupil (Syn: Tonic pupillary reaction): In this the pupillary light reflex appears to be absent, or it may be present but delayed. Once the pupil constricts, the constriction may persist even after the source of light is removed. Once constricted, the pupils dilate only slowly in darkness as well as for distant vision. The pupils may therefore appear small or large on first examination and vary in size from time to time. The condition may be bilateral or unilateral and this results in inequality of the size of pupils (*anisocoria*). Absence of tendon reflexes especially ankle reflex, is noticed. The abnormal pupillary reaction may be due to partial parasympathetic denervation of the pupillary muscles. Adie's pupil has to be distinguished from Argyll Robertson pupil since the former is of only minor clinical significance, whereas the latter is not so. Adie pupil constricts in response to instillation of 2% methacholine drops into the eyes but the Argyll Robertson pupil does not, and this test distinguishes them.

Marcus Gunn pupil: This phenomenon is seen in partial afferent failure as occurring in optic neuritis or injury. Normally, when a bright light is swung from one eye to the other, both pupils constrict promptly as a result of direct and consensual light reflex. In partial lesions of the optic nerve such as optic neuritis or injury, the ipsilateral pupil which is partly constricted due to consensual light reflex, dilates when light falls on to it, since the abnormal optic nerve cannot transmit afferent impulses sufficient enough to produce full pupillary constriction.

Hippus: It is rhythmic alternating constriction and dilatation of the pupils. It may not be always abnormal but it is seen more often in retrobulbar neuritis and encephalitis.

Horner's syndrome: This is seen in paralysis of sympathetic innervation of the pupil. The affected pupil is smaller than its fellow (miosis), but it reacts normally to light and accommodation reflex. There is partial ptosis as a result of paralysis of the tarsal muscles of the eyelids (*Muller's muscles*). On the affected side a mild degree of *enophthalmos* (sunken eye) may also be noticeable.

The palpebral fissures: The patient is asked to look at a distance with the eyes in neutral position. Note the size of the palpebral fissure. Paralysis of the levator palpebrae superioris causes drooping of the upper eyelid (ptosis). Paralysis of upper tarsal muscles causes pseudoptosis, in which there is partial ptosis but the patient can voluntarily raise the eyelid. Partial ptosis is often compensated by the patient by the overaction

Fig. 184.2: 3rd nerve palsy—note ptosis right secondaries from abdominal tumour

Fig. 184.3: Action of external ocular muscles

Fig. 184.4: Ophthalmoplegia due to orbital cellulitis—right; note ptosis

of the frontalis muscle of the forehead on that side. A narrow palpebral fissure indicates paralysis either of third cranial nerve or cervical sympathetic chain, whereas a wide palpebral fissure indicates seventh cranial nerve paralysis or cervical sympathetic overactivity.

The ocular movements: These are tested by having the patient move his eyeballs in the six cardinal directions—laterally, medially, upward and laterally, upward and medially, downward and laterally, and downward and medially. The lateral rectus moves the eye outwards and the medial rectus inwards. When the eye is turned outwards, the elevator is superior rectus and the depressor is inferior rectus. When the eye is turned inwards, the elevator and depressor are the inferior and superior oblique muscles respectively. In third cranial nerve palsy, there is ptosis, with inability to move the eyeball upward, downward and medially. On lifting the lid passively, the eye is found deviated outwards and slightly downward due to unopposed action of lateral rectus and superior oblique muscles. In addition, the pupil is dilated and non-reacting (*iridoplegia*). There is also paralysis of accommodation reflex (*cycloplegia*) due to parasympathetic involvement. In paralysis of the fourth cranial nerve, the eye is rotated outwards with weakness on downward movement, most marked when the eye is turned inwards. The patient often complains of special difficulty in reading or going down stairs and the head is tilted towards the opposite shoulder. In sixth cranial nerve lesion the eyeball is deviated inwards due to the unopposed action of the medial rectus (Figs 184.2 to 184.4).

Diplopia: When the visual axes of both the eyes are not in alignment the patient experiences double vision (*diplopia*). Study of the relative position of the images from the two eyes helps to determine the paretic muscle. The image arising from the normal eye is bright (*true image*) and that from the paralyzed eye is faint (*false image*). Patient is asked to follow visually the examiner's finger which is moved in all directions. He is then asked to indicate whether he sees double images and also the position of the finger where there is maximum separation of the two images. He is also asked to indicate when the double vision disappears. Diplopia is maximum when the eye is moved in the direction of action of the paretic muscle. Thus, in a right lateral rectus palsy, there is maximum separation of the images on looking to the right, while the diplopia disappears on looking to the left. By placing a red glass in front of one eye the source of the false image could be identified.

Disorders of ocular movements: Nuclear and infranuclear lesions of oculomotor nerves cause isolated paralysis of one or more extraocular muscles. Involvement of extraocular muscles sparing the pupillary sphincters is called **external ophthalmoplegia**. In total external ophthalmoplegia all the ocular muscles are paralyzed. Weakness of ocular muscles due to a nuclear lesion is identified by the associated brainstem signs like involvement of other cranial nerve nuclei and the long tracts. In midbrain

lesions paralysis of the third cranial nerve occurs along with contralateral hemiplegia (**Weber's syndrome**). The nuclei of the sixth and seventh cranial nerves are involved in pontine lesions with contralateral hemiplegia (**Millard-Gubler syndrome**). Infranuclear ocular palsy may or may not be solitary. The common causes include tumours at the base of the brain, injuries to the base of the skull, aneurysms of circle of Willis, infarction of the nerve as in diabetes and basal meningitis, especially due to tuberculosis and neuroleukemia. Less common causes include ophthalmoplegic migraine, herpes zoster, subdural hematoma, temporal arteritis and sarcoidosis. Myasthenia gravis has to be excluded in all cases of acute ocular palsy. Third, fourth and sixth cranial nerves may be affected together by lesions in the cavernous sinus and superior orbital fissure where these nerves along with ophthalmic division of fifth cranial nerve run in close proximity. Lesions in the cavernous sinus include thrombosis of the cavernous sinus, carotico-cavernous fistula and aneurysm of internal carotid artery. In the superior orbital fissure these nerves may be compressed by inflammatory masses, tumours, fractures or metastatic deposits (**Superior orbital fissure syndrome**). Rise in intracranial tension causes traction on the cranial nerves leading to cranial nerve palsies. Most commonly affected is the abducent nerve, but others may also be affected. The cranial palsy disappears when the cause is promptly corrected. Such cranial nerve palsies constitute false localizing signs. In about 20-30% of cases of ocular palsies the exact cause cannot be determined and usually such a palsy disappears in a few weeks (idiopathic ophthalmoplegia). In third cranial nerve lesions due to external compression by aneurysms, tumour or temporal lobe herniation, pupillary dilatation is an early sign since, the pupillary fibres are peripheral in the nerve trunk. In contrast, in cases of infarction of this nerve, that may occur in diabetes, the pupil is spared since infarction involves more of the central portion of the nerve.

Supranuclear and internuclear lesions: Cerebral lesions involving the frontal eye fields may be irritative as in seizures or paralytic as in an infarct or tumour. Irritative lesions produce conjugate deviation of both eyes to the opposite side. In paralytic lesions, there is paresis of conjugate deviation to the opposite side and hence the eyes will be pointing to the side of lesion. However, this is a transitory phenomenon. In contrast to this, in lesions of the brainstem involving the parapontine gaze centre, the eyes can move only to opposite side (i.e.) away from the side of lesion.

A lesion of the medial longitudinal fasciculus that interrupts the impulses from the centre for lateral gaze in

the lower pons to the third cranial nerve nucleus in the midbrain causes a dissociation of conjugate eye movements. This manifests as failure of adduction in the ipsilateral eye and nystagmus in the contralateral eye. This is called **internuclear ophthalmoplegia**. Usually presence of internuclear ophthalmoplegia indicates an intrinsic brainstem lesion like multiple sclerosis, glioma or infarct of the brainstem.

Nystagmus: This refers to involuntary rhythmic movements of the eyes. This may be jerky or pendular. Jerky nystagmus is characterized by alternate quick and slow movements. In pendular nystagmus, the oscillations are almost equal in speed in both directions.

While testing for nystagmus, the eyes should be examined first in the central position, then during upward, downward, and lateral movements. A complete description of nystagmus should include the type, direction, rate, amplitude, duration, intensity, and relationship of the response to movements of the eyes, head and body. Sometimes only a few irregular jerks without any sustained rhythmic movements may be observed. These are **nystagmoid movements** and they may not indicate any pathology. Also, while testing, extreme lateral gaze beyond the field of binocular vision should be avoided. Jerky nystagmus may be horizontal, vertical or rotary. The direction of nystagmus is named according to the direction of the fast component. In cerebellar lesions, the nystagmus (fast component) is in the direction of the gaze, irrespective of the side of lesion. In vestibular lesions, the nystagmus is only transient and may have a rotary component. In peripheral vestibular lesions of the labyrinth the nystagmus is horizontal and rotary with the slow component always towards the affected side.

In central vestibular lesions affecting the central connections, nystagmus can be purely up-beat or down-beat or rotary, if the nuclei are selectively affected. If the lesion is complete, the nystagmus resembles that of the peripheral lesions without any specific difference.

Downbeat nystagmus which is a subtype of vertical nystagmus is a characteristic feature in cervico-medullary junction lesions such as tonsillar herniation in Arnold-Chiari malformation.

Pendular nystagmus: This term refers to the type of nystagmus in which the eyes oscillate from side to side or other directions at the same speed and extent. This is the result of failure to develop postural mechanisms of the eyeballs, as occurring in congenital blindness or blindness developing in childhood. Pendular nystagmus may be an acquired phenomenon in subjects working for long periods under dark environment such as deep mines (miner's nystagmus).

Opsoclonus

This term refers to irregular, jerky conjugate movements of the eyes occurring in lesions of the brainstem such as multiple sclerosis, viral encephalitis and tumours, hyperosmolar nonketotic coma, as a paraneoplastic phenomenon and in poisonings. It consists of ocular saccades (brief rapid movements of eyeballs) occurring reflexly or voluntarily. These rapid eye movements are under control of several populations of neurones in the paramedian reticular formation. One group of neurones (*burst neurones*) are responsible for the production of saccades while another group (*pause neurones*) terminate them. Opsoclonus is the result of imbalance between these neuronal groups.

Trigeminal Nerve

Syn: Cranial nerve V

This is the largest cranial nerve and serves both sensory and motor functions. The cell bodies of the sensory part of the nerve lie in the *gasserian ganglion*. The sensory root arising proximally from this ganglion enters the pons and divides into ascending and descending branches. The ascending branch is concerned with touch and deep sensation, and ends in the mesencephalic nucleus. The descending branch forms spinal tract of the trigeminal nerve which is concerned with pain and temperature. This tract extends caudally down into the upper cervical cord. From the nucleus of the tract, second order fibres cross to the opposite side to the thalamus.

From the gasserian ganglion, peripherally three branches arise. The first (*ophthalmic*) passes through the superior orbital fissure, the second (*maxillary*) passes through the foramen rotundum, and the third (*mandibular*) through the foramen ovale. The motor part of the trigeminal nerve has its origin in the mid-pons, the fibres passing beneath the ganglia, to become incorporated into the mandibular nerve.

Trigeminal nerve has four nuclei—the main sensory nucleus, the spinal nucleus, the mesencephalic nucleus and the motor nucleus. The main sensory nucleus is situated in the posterior part of the pons and is continuous below with the spinal nucleus. The spinal nucleus extends from the pons down through the whole length of the medulla oblongata and into the spinal cord as far as the second cervical segment. The mesencephalic nucleus is situated in the lateral part of the gray matter around the cerebral aqueduct in the midbrain and extends inferiorly into the pons as far as the main sensory nucleus. The motor nucleus is situated in the pons, medial to the main sensory nucleus.

The motor nucleus of the trigeminal nerve supplies the muscles of mastication (temporalis, masseter, the medial and lateral pterygoid muscles, the tensor tympani, tensor veli palatini, mylohyoid and anterior belly of the

digastric) through its mandibular division. The motor nucleus receives corticonuclear fibres from both cerebral hemispheres, fibres from the reticular formation, the red nucleus, the tectum, medial longitudinal fasciculus and from the mesencephalic nucleus.

The ophthalmic division supplies the ipsilateral eye, eyelids, forehead, and the scalp up to the line joining the two ears. The maxillary division supplies ipsilateral upper jaw, paranasal sinuses, side of nose, palate and neighbouring structures. The mandibular division supplies ipsilateral lower jaw except the angle of the mandible, up to the upper part of the neck.

Some secondary trigeminal fibres, both crossed and uncrossed, establish reflex connections between the muscles of mastication, skin of the face and mucous membranes of the tongue, mouth and nasal cavities.

Testing

Motor: The patient is asked to clench the jaw, while the examiner palpates for the contraction of the masseter and temporal muscles on both sides. Next he is asked to open the mouth, and move the lower jaw from side to side. In paralysis of the trigeminal nerve the jaw will deviate to the paralyzed side due to the unopposed action of the lateral pterygoid muscle on the normal side. While moving the lower jaw from side to side weakness of the paralyzed lateral pterygoid can be appreciated as inability to push the jaw to the opposite side.

Corneal sensation is subserved by the ophthalmic division of the trigeminal nerve. The cornea has only free nerve endings. The corneal reflex is tested by touching the cornea lightly with a wisp of moist cotton wool. The patient should gaze in the opposite direction, and the cotton wool should be brought from the side to avoid the blink reflex. The response is closure of the ipsilateral eye (*direct cornea! reflex*) and the contralateral eye (*indirect corneal reflex*). The efferent is through the seventh cranial nerve.

Marcus Gunn phenomenon: The upper eyelid elevates and eyes open when the mouth is opened or mandible moved from side to side. It is caused by abnormal connections between the nerve supply of the pterygoids and levator palpebrae superioris.

If the eyes close on opening the mouth, it is called *inverse Marcus-Gunn phenomenon*. This is caused by aberrant facial reinnervation on recovery from facial nerve lesions.

Trigeminal Neuralgia Syn: *Tic douloureux*

This is the most common disorder of the trigeminal nerve. It occurs usually in middle and late ages and consists of sudden severe, brief paroxysms of excruciating stabbing or electric shock like pain in the distribution of the man-

dibular and maxillary divisions and rarely in the ophthalmic division. The attack seldom lasts more than a minute, but it is so severe that the patient winces. The attacks recur frequently for several weeks at a time and they are usually precipitated by stimuli applied to certain areas of the face, lips or tongue, or by movement of these parts in chewing, speech or yawning (*the trigger zones*). Usually there is no demonstrable cause—idiopathic. Sometimes trigeminal neuralgia may be a symptom of involvement of the trigeminal nerve in multiple sclerosis, dyscollagenoses, pressure effects from basilar artery aneurysm, tumour in the cerebellopontine angle, or congenital vascular anomaly.

A small proportion of patients have persistent trigeminal artery which is a branchial arch artery. Normally this artery gets obliterated in postnatal life. If it persists and becomes arteriosclerotic, it may press on the trigeminal nerve at its point of exit from the brain stem and cause neuralgia. Such cases can be relieved by resection of this artery and release of the nerve.

Chronic dental infection and metallic dental fillings may predispose to trigeminal neuralgia. Bilateral trigeminal neuralgia may occur in multiple sclerosis, hereditary sensori-motor neuropathy of Dejerene and Sotta and also stilbamidine toxicity. The symptomatic variety should be suspected in the presence of sensory and/or motor deficit which is not a feature of idiopathic trigeminal neuralgia.

Trigeminal neuralgia usually manifests in persons, who have no other neurological disorder, and therefore, the condition may be initially mistaken for other painful conditions such as migraine, dental pain or temporomandibular arthritis. In many cases there may be a psychological overlay such as anxiety or depression. The recurrent severely painful episodes occurring without warning instil fear to carry out even daily duties such as washing the face, brushing the teeth, shaving or eating. Even suicidal tendencies may develop. Untreated, the condition persists for weeks to years, with the same or increasing severity.

Diagnosis should be suspected when a person complains of excruciating facial pain occurring repeatedly with absence of any physical signs in between the attacks. To a large extent, diagnosis is clinical. Cranial CT scan help to rule out other conditions which involve the trigeminal nerve. In some cases there may be abnormalities at the trigeminal nerve root entry zone in the form of compression by an aberrant arterial loop. Cerebral or MRI angiography is required to demonstrate the aberrant arterial loop crossing the trigeminal root entry zone.

Management: Initial treatment is medical. The condition responds satisfactorily in many cases to drug therapy. Gabapentin in a dose of 100-300 mg bid or tid is the drug

of choice on account of its effectiveness and safety but it is considerably more expensive compared to carbamazepine (Rs. 17 vs 313 for 10 equipotent tablets). Carbamazepine in a total dose of 600-800 mg/day is consistently effective in the majority of cases at least initially. Toxic effects include hepatic damage, aplastic anemia, and syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and Stevens-Johnson's syndrome. Phenytoin sodium and baclofen can be given as alternative or adjuvant drugs to carbamazepine. Pregabalin given in doses of 75 mg b.d. is also useful.

If this fails, relief of pain can be obtained by injection of either alcohol or phenol at the foramen ovale or rotundum or in the vicinity of the gasserian ganglion. Percutaneous coagulation of the involved division of the nerve utilising radiofrequency waves has been very useful in intractable cases. The advantage of this procedure is that it selectively destroys the pain fibres without affecting other sensations over the face.

The major problem following surgery is severe dysaesthesia over the face, which may be very disturbing. This complication is less with selective radio frequency procedure. Modern treatment is to release the aberrant arterial loop compressing the nerve root by microvascular technique.

Facial Nerve

Syn: Cranial nerve VII

The *facial nerve* is a mixed nerve. It has 3 nuclei—the main motor nucleus, parasympathetic nucleus and sensory nucleus. The main motor nucleus is situated deep in the pons and receives UMN innervation from the cerebral cortex. That part of the nucleus which supplies the muscles of the lower part of the face receives corticonuclear fibres only from the contralateral cerebral hemisphere, whereas that part of the nucleus which supplies the muscles of the upper part of the face receives corticonuclear fibres from both cerebral hemispheres. This accounts for the fact that in unilateral upper motor neuron (UMN) type of facial palsy only the lower part of the face is affected on the opposite side. The superior salivary and lacrymal nuclei, which are parasympathetic, lie posterolateral to the motor nucleus. The sensory nucleus is the upper part of the nucleus to the tractus solitarius and lies close to the motor nucleus. Sensation of taste from the anterior 2/3 of the tongue travels through the chorda tympani to the sensory nucleus. The fibres from the facial nucleus wind round the abducent nucleus in the pons and emerge from the brainstem at the junction between the pons and the medulla. In lesions of the pons, these two nuclei are often affected together.

After its emergence from the brainstem the facial nerve travels through the middle cranial fossa and enters the petrous temporal bone through the internal auditory meatus. The nerve then passes through the facial canal in the temporal bone. Within this canal it gives off a branch to stapedius muscle and distal to that branch the chorda tympani leaves the facial nerve to join the lingual nerve. In the petrous temporal bone, the nerve makes a sharp bend (genu) where the geniculate ganglion is situated. In the facial canal it lies in close relationship to the medial wall of the middle ear. This relationship makes the nerve vulnerable to damage in lesions of the middle ear. The nerve leaves the temporal bone through the stylomastoid foramen and traverses through the parotid gland to divide into terminal branches that supply all the muscles of facial expression, auricular muscles, posterior belly of the digastric and stylohyoid muscle.

The sensory nucleus receives taste fibres from the anterior 2/3 of the tongue, the floor of the mouth and the soft palate. Facial nerve carries general sensations from the external auditory canal, tympanic membrane, lateral surface of pinna, a small area behind the ear and skin over the mastoid process. It also carries proprioceptive sensations from the muscles it supplies, and deep pain and pressure from the face. However, it does not carry any superficial sensation from the face.

The superior salivary nucleus supplies the submandibular and sublingual salivary glands and the lacrimal nucleus supplies the lacrimal gland.

Testing: Ask the patient to frown, wrinkle his forehead, raise his eyebrows, close his eyes tightly against resistance, retract the angle of his mouth, show his teeth, blow his cheeks and whistle. If there is difficulty in any of the above functions it could be compared with the healthy side. Also look for any asymmetry of palpebral fissure and the nasolabial fold in the resting position. The palpebral fissure will be wider on the paralyzed side. The nasolabial fold will be flatter and the angle of the mouth will be at a lower level than the normal side (Fig. 184.5).

The term **Bell's phenomenon** is given to denote the rolling up of the eyeball when the patient attempts to close the eye. This is due to the physiologic synkinesis between the orbicularis oculi and the superior rectus muscles. This is a normal phenomenon in both eyes. In Bell's palsy the rolling up on the affected side will be exaggerated. In UMN facial palsy there is no exaggeration of rolling up of the eyeball (Fig. 184.6).

The sensation of the anterior aspect of the external auditory canal is tested with cotton wool. Taste from the anterior two-thirds of the tongue is tested using sugar for sweetness, sodium chloride for salty taste, 1% acetic acid for sour taste and quinine for bitter taste. The tongue should be held protruding throughout the test and the patient should not be allowed to speak. The words—sweet, salt, sour and bitter are written on a paper, and the subject is asked to indicate the taste he perceives. For the posterior third of the tongue, the same materials

Fig. 184.5: Herpes zoster ophthalmicus left with facial palsy. Note the vesicles and deviation of angle of mouth to the right

Fig. 184.6: Bilateral facial palsy. Note inability to close the eyes and Bell's phenomenon

can be used for testing. As an alternative stimulus, galvanic current can be used. *Ageusiometer* is used since it is difficult to test the posterior third of the tongue by the conventional method. Loss of taste is called **ageusia**. Diminution of taste perception is called **hypogeusia**. Altered appreciation of taste is **parageusia**.

Facial Paralysis

Syn: Facial palsy

Paralysis of the facial nerve may be of the *upper motor neurone type (UMN)* or *lower motor neurone type (LMN)*. In the former the corticonuclear tract supplying the facial nerve nucleus is affected and the lesion is above the level of the pons. In LMN paralysis the lesion is at the facial nerve nucleus or in the course of the nerve.

Supranuclear Facial Palsy

Syn: *UMN facial palsy*

In this only the lower half of the face is affected, contralateral to the side of lesion.

Supranuclear palsy is of two types—volitional and emotional. In volitional palsy, the involvement is most marked on voluntary contraction. On automatic involuntary movements such as crying or smiling, there is preservation of function. Here the lesion is in the motor cortex or in the corticobulbar fibres as they go through the internal capsule, cerebral peduncle and pons to reach the facial nucleus. In emotional or *mimetic facial paresis*, there is no asymmetry of the facial muscles on voluntary movements. The patient can close his eye, retract his mouth or blow his cheeks without difficulty. However, the paresis becomes apparent during smiling or crying. Here the lesion is either in the frontal lobes anterior to the precentral cortex or deep seated in the thalamus or basal ganglia.

Nuclear or Infranuclear Facial Palsy

Syn: *LMN facial palsy*

As the lower motor neuron (facial nucleus) is the final common pathway, lesions at this site produce weakness of the entire half of the face on the ipsilateral side. The exact site of lesion is determined by the associated signs. In pontine lesions as in a tumour or vascular occlusion, the facial palsy is associated with ipsilateral sixth cranial nerve paralysis. In cerebellopontine angle lesion, such as acoustic neuroma facial palsy is associated with ipsilateral eighth and fifth nerve palsies, cerebellar signs, and contralateral pyramidal signs.

Within the facial canal the nerve can be affected in many ways. Inflammatory conditions such as herpes zoster can affect the geniculate ganglion to produce **Ramsay-Hunt syndrome**. Other infections like mumps, scarlet fever and malaria, metabolic conditions like diabetes, alcoholism and nutritional deficiency, metastatic neoplasms and neuroleukemia can affect the facial nerve within the facial canal. Owing to the proximity of the nerve to the middle ear facial paresis can be a complication of otitis media, suppuration of temporal bone or mastoiditis. Immediately outside the stylomastoid foramen, the nerve could be involved by tumours of the parotid gland, injuries and obstetrical trauma due to forceps delivery in the newborns. Involvement of the terminal branches of the nerve is a feature of leprosy. Involvement of the upper part of the face, sparing the lower part is not an uncommon manifestation of leprosy. Bilateral facial palsy is usually due to Guillain-Barré syndrome or sarcoidosis. Facial palsy can occur during the course of tick-borne relapsing fever and Lyme borreliosis.

This condition is named after Sir Charles Bell, a Scottish physiologist and surgeon (1774-1842). This is the most common cause of unilateral LMN facial palsy. It usually develops suddenly and spontaneously, often starting with a mild pain in the ear. Sometimes a history of exposure to cold or wind, or a mild systemic infection is obtained. The lesion may be either compression of the nerve by edema or periostitis at the facial canal, ischemia of the nerve or a viral infection. *Herpes simplex virus* type 1 (HSV-1) is found to be a common cause for Bell's palsy, as revealed by raised antibody levels. The onset is abrupt with the occurrence of weakness of pursing movements of the lips, inability to hold water in the mouth, deviation of the angle of the mouth to the normal side, incomplete closure of the eyes and watering from the eyes. While washing the mouth the water escapes through the paralysed side. Food materials collect in the vestibule on mastication. Severity of paralysis varies. As time passes the condition becomes stable and recovery starts within days to weeks. In the majority of patients sensory symptoms may be minimal or absent, but some complain of a numb feeling and heaviness of the affected side. In the majority of patients the facial palsy completely improves. In a few cases the paralysis may be irreversible. In those that recover, signs of recovery start within a week and recovery may be complete in a month. Complications include corneal ulceration and exposure keratitis, facial contracture and aberrant innervations on recovery.

Chronic facial palsy may lead to contracture of the ipsilateral paralysed muscles giving a picture which may be mistaken for paralysis of the contralateral (normal) side while at rest. On testing, the weakness of the paralysed muscles will become apparent. The affected side may develop hemifacial spasm due to faulty conduction of nerve impulses through the partially damaged nerve fibres.

Management: Facial palsy is a frightening event and so the patient has to be reassured about the condition and the generally benign nature of the malady. It is important to distinguish LMN facial palsy from the UMN types since the latter may be a part of more serious neurological disease such as stroke.

Aims of Treatment

1. To prevent damage to the eye due to exposure keratitis,
2. To avoid further damage to the paralyzed muscles resulting from unopposed action of the normal side, and
3. To hasten recovery.

Exposure keratitis can be avoided by wearing dark glasses. Distortion of the angle of the mouth can be prevented by appropriate splints. Prednisolone in a dose of 40-60 mg/day orally may be given for 5-7 days, by which time the response is well-manifest. Further

maintenance dose depends on the response. Since herpes virus is a common cause for Bell's palsy, a c y c l o v i r 800 mg five times a day for 7-10 days may be started early. However recent reports confirm the superiority of steroids over acyclovir. The drugs have to be continued for 7 days. Early institution of specific therapy, ideally within six hours to 48 hours is most beneficial.

Physiotherapy consists of massage over the face and electrical stimulation of the facial nerve at the stylomastoid foramen. Electrophysiological assessment with EMG and NCV done after one week will help to devise decompressive therapy and also to assess prognosis for recovery. Evidence for axonopathy with early denervation potentials indicates poor chances for recovery. If there is conduction block indicating entrapment, decompression at the stylomastoid foramen will be beneficial.

If at the end of six months deformity and paralysis persist, facial muscle reconstructive surgery should be considered.

In those cases which do not recover, plastic surgery procedures to reduce deformity and facial nerve anastomosis to glossopharyngeal nerve have been successfully employed.

Ramsay-Hunt syndrome: This consists of severe facial palsy associated with vesicles in the pharynx, external auditory canal, and sometimes over the mastoid. The 8th cranial nerve may also be involved in many. The lesion is due to herpes zoster affecting the geniculate ganglion.

Acoustic Nerve

Syn: Cranial nerve VIII, auditory nerve

The acoustic nerve has two components—the *cochlear nerve* or the nerve of hearing, and the *vestibular nerve* which subserves equilibration.

Cochlear system: The end-organs of the cochlear nerve are the hair cells in the organ of Corti, within the cochlea of the inner ear. The central fibres from the cell bodies, pass as the cochlear nerve. It traverses the internal auditory meatus, where it is inferolateral to the facial nerve and crosses the subarachnoid space at the cerebellopontine angle and enters the upper part of the medulla to terminate in the dorsal and ventral cochlear nuclei. Secondary acoustic fibres project via the trapezoid body and lateral lemniscus to the primary auditory receptive areas in the transverse temporal gyri of Heschl through the auditory radiations.

Vestibular system: The vestibular system consisting of the semicircular canals has the function of orienting the subject in space (all the 3 planes), and also maintaining the relative position between the head and the body. Changes in position set up electrical discharges in the neuroepithelium of the ampullae of the semicircular canals and the maculae of the utricle and saccule. Bipolar cells of the Scarpa's ganglion transmit these impulses to the vestibular nuclei of the

same and opposite sides in the upper part of the medulla. Vestibular nuclei are connected to the cerebellum through the inferior cerebellar peduncle, to the spinal centres through the vestibulospinal tracts and to the motor nuclei of the eye muscles, through the medial longitudinal fasciculus.

Disturbances of vestibular function lead to vertigo, inability to maintain posture, nystagmus and systemic disturbances such as nausea, vomiting, visual hallucination, feeling of rotation of the surroundings, sweating, tachycardia, and hypotension. Vertigo, an illusion of movement, is the cardinal symptom of vestibular dysfunction. Rotational vertigo may indicate dysfunction of the semicircular canals or their central connections. A feeling of tilting or linear displacement may occur in disorders affecting otolith organs or their projections. In vertigo there is a distinct sense of rotation. The objects may seem to revolve around the patient (*objective vertigo*) or the person may experience the sensation of spinning in the surroundings (*subjective vertigo*).

Testing of cochlear system: Hearing is evaluated by noting the patient's ability to perceive the sound made when the examiner rubs his thumb and index finger or better still by a ticking watch held in front of the external auditory meatus. The distance from the ear is noted, and the examiner compares the patient's acuity of hearing with his own. Better information can be obtained by using a tuning fork.

Rinne test: Here the patient's air conduction is compared with the bone conduction. The base of a vibrating tuning fork (512 Hz) is placed firmly against the mastoid and the patient is asked to indicate when the sound is no longer heard. It is then placed in front of the external auditory meatus and the time during which it is heard is noted. Normally, air conduction is better than bone conduction—*Rinne positive*. In conductive deafness due to middle ear disease bone conduction is better than air conduction (*Rinne negative*). In sensorineural deafness, both bone and air conduction are diminished, but they retain the normal relationship and the Rinne is positive.

Weber test: Here the base of the vibrating tuning fork is placed over the forehead and the patient is asked to point to the ear he hears better. Normally, it is heard equally well in both ears. In conductive deafness the sound is better heard by the involved ear, while in sensorineural deafness it is better heard by the uninvolved ear.

Disorders of acoustic function: Sensorineural deafness can be secondary to diseases of the cochlea, auditory nerve or brainstem. The cochlea may be congenitally aplastic, or it could be damaged by maternal rubella. Mumps or meningitis may cause nerve deafness from childhood. Herpes simplex virus 1 (HSV-1) DNA has been detected in the vestibular ganglia by

PCR in about 60%. Both vestibular and cochlear neuritis may be caused by HSV-1. Drugs like streptomycin, gentamicin, quinine, and salicylates could damage the cochlear hair cells and produce deafness. The auditory nerve could be involved by tumours of the cerebellopontine angle, or by basal meningitis. Deafness could also result by demyelinating lesions in the brainstem. Middle ear deafness is usually secondary to wax, chronic otitis media, otosclerosis, and fracture of temporal bone. Other rarer causes include glomus jugulare tumours, cholesteatomas and nasopharyngeal carcinomas.

Tests for vestibular system: Vestibular dysfunction usually presents with vertigo, especially if the lesion is acute.

Objective testing includes the elicitation of the vertigo in specific positions of the head and observation of the nystagmus. The caloric tests help to identify the lesions in the different parts of the membranous labyrinth and their connections. Other tests include the rotation test done in a Barany's chair, cupulometry and electronystagmography. These require special equipment.

Caloric tests: Each ear is syringed with warm water (44°C) and cold water (30°C) with the patient resting supine and head flexed to 30° till a jerky nystagmus sets in. The slow phase is due to local stimulation and the fast phase is mediated through cortical connections. Irrigation with cold water produces nystagmus with fast component to the opposite side, nausea, vomiting, tendency to fall to the same side and past-pointing to the opposite side. The nystagmus persists for 90-140 sec. Syringing with warm water produces nystagmus with the fast component to the same side. The time for onset of nystagmus and its duration are recorded. When there is perforation of the tympanic membrane water should not be used for the test, instead jets of air at different temperatures can be used.

Significance of caloric tests: The caloric tests depend upon the integrity of the vestibular apparatus, its connections and the higher cortical influences. This test is used in assessing the integrity of these structures. In addition, since the fast phase of the nystagmus is mediated through the cortical connections, in conditions with deepening coma, loss of the fast phase indicates progressive loss of cortical function.

Tinnitus: This is a sensation of noise caused by abnormal excitation of the acoustic pathway in the absence of any external stimuli. Tinnitus may take several forms such as tuning, roaring, whistling, buzzing, and the like. It is felt most during sleep when the environment is silent. It may interfere with normal hearing.

Common causes include lesions of the nose and middle ear such as eustachian catarrh, otitis media or occlusion of the external auditory meatus by wax. Several drugs like salicylates, quinine, and streptomycin may produce tinnitus. Neurological disorders like acoustic neuroma, meningitis, and vascular lesions of the lateral aspects of the pons may lead to tinnitus. High pitched tinnitus is produced by lesions of the cochlear nucleus or auditory nerve apparatus. Low pitched tinnitus occurs in middle ear disease. Pulsatile tinnitus is characteristic of vascular anomalies of the brain stem. Tinnitus associated with pain in the affected ear should suggest the possibility of Meniere's disease. Tinnitus may also occur as an aura of temporal lobe epilepsy.

Acute vestibular neuronitis could occur at any age and it is characterized clinically by either paroxysmal or usually a single attack of vertigo without tinnitus or deafness.

Ménière's Disease

Ménière's disease is a disorder of labyrinthine function characterised by recurrent attacks of vertigo associated with tinnitus and deafness. Prosper Ménière, a French physician described the disease. His name was given to the syndrome consisting of vertigo, tinnitus and deafness in 1870, ten years after his death. The diagnostic criteria include:

1. At least two episodes of vertigo of 20 minutes or longer duration
2. Hearing loss confirmed by audiometry at least on one occasion and
3. Tinnitus or aural fullness during the attacks.

It begins in the fifth decade. These attacks last for minutes to an hour. Nystagmus is present during the acute attack with a slow phase towards the affected ear. The attacks usually occur in clusters with progressive hearing loss. The pathologic change consists of dilatation of the endolymphatic system with destruction of the cochlear hair cells.

Treatment consists of salt restriction to 2.5 g salt / day and drugs.

These include:

1. Acetazolamide 500-750 mg daily is divided doses which will reduce endolymphatic hydrops,
2. Labyrinthine sedatives such as prochlorperazine or cyclizine. Paradoxically histamine analogues such as betahistine 8 mg given in repeated doses may also help.
3. Anxiolytics such as alprazolam 0.25 mg/tds help to allay fear and insecurity.

Surgical measure used to be done to interrupt labyrinthine afferent impulses. These are not commonly done now. External appliances which counteract the

tinnitus by neutralizing the frequencies from the labyrinth are helpful. These have to be made specifically for individual patients.

Labyrinthine adaptive exercises help to reduce the attacks.

Glossopharyngeal and Vagus Nerves

Syn: Cranial nerves IX and X

These two cranial nerves are intimately connected and hence they are described together.

Glossopharyngeal Nerve

This has sensory and motor components. The motor fibres arise from the *nucleus ambiguus* situated in the lateral part of the medulla. Along with the vagus and accessory nerves, this nerve leaves the skull through the jugular foramen and supplies the stylopharyngeus muscle whose function is to elevate the pharynx. Autonomic efferent fibres of the glossopharyngeal nerve arise from the inferior salivatory nucleus. The preganglionic fibres pass to the otic ganglion through the lesser superficial petrosal nerve, and postganglionic fibres pass through the auriculo-temporal branch of the fifth cranial nerve to reach the parotid gland. The nuclei of the sensory fibres of the glossopharyngeal nerve are situated in the petrous ganglion which lies within the petrous bone below the jugular foramen and also the superior ganglion, which is small. The sensory fibres supply the faucial tonsils, posterior wall of the pharynx, part of the soft palate and taste sensations from the posterior third of the tongue.

The Vagus

This is the longest among all the cranial nerves and serves both motor and sensory functions. The motor fibres arise from the nucleus ambiguus and supply all the muscles of the pharynx, soft palate and larynx, with the exception of tensor veli palati and stylopharyngeus. The parasympathetic fibres arise from the dorsal efferent nucleus and leave the medulla as preganglionic fibres of the craniosacral portion of the autonomic nervous system. These fibres terminate on ganglia close to the viscera which they supply by postganglionic fibres. They are parasympathetic in function. Thus vagal stimulation produces bradycardia, bronchial constriction, secretion of gastric and pancreatic juice and increased peristalsis. The sensory portion of the vagus has its nuclei in the *jugular ganglion* and *ganglion nodosum*. The vagus carries sensations from the posterior aspect of the external

auditory meatus and adjacent pinna and pain sensation from the dura mater lining the posterior cranial fossa.

Testing: It is better to test the 9th and 10th cranial nerve functions together as they are usually affected together leading to symptoms like dysphagia, dysarthria, nasal regurgitation of fluids, and hoarseness of voice.

The motor part is tested by examining the position of the median raphe in the midline above the uvula when the patient is made to open his mouth. In unilateral vagal paralysis the ipsilateral palatal arch will be flattened and lowered. On phonation, the median raphe deviates to the normal side.

The **gag reflex** or the pharyngeal reflex is elicited by applying a stimulus, such as a tongue blade or cotton swab stick to the posterior pharyngeal wall or tonsillar region. If the reflex is present, there will be elevation and contraction of the pharyngeal musculature accompanied by retraction of the tongue. The afferent arch of this reflex is subserved by the glossopharyngeal nerve while the efferent is through the vagus nerve. This reflex is lost in the lesions of either of these cranial nerves. General sensations over the posterior pharyngeal wall, soft plate and faucial tonsils, and taste over the posterior third of the tongue should also be tested. These are impaired in glossopharyngeal paralysis. Isolated involvement of either nerve is rare and usually they are involved together. Eleventh and twelfth cranial nerves may also be affected.

Testing laryngeal muscles: These are tested by asking the patient to speak. Loss of phonation (producing vocal sounds) is called aphonia. Common neurological cause for aphonia is uni- or bilateral vagal paralysis. In unilateral or bilateral adductor paralysis of vocal cords the tussive phase of cough will be abolished and this is described as bovine cough. Movements of the vocal cords can be visualized by direct or indirect laryngoscopy. Bilateral paralysis of the abductors of the vocal cords leads to laryngeal obstruction and this is fatal, unless emergency measures to restore the airway are undertaken. Persons with vocal cord paralysis cannot hold their breaths and they run the risk of drowning if they get into water.

Glossopharyngeal neuralgia is a rare condition which presents with lancinating pain or other types of severe pain felt episodically at the back of the throat. The pharyngeal phase of swallowing triggers the attack. This may prevent the patient from taking foods. Most of the cases are idiopathic. Rarely glossopharyngeal neuralgia may be the symptom of primary demyelinating lesions affecting the brain stem such as multiple sclerosis. At times vagal phenomena such as bradycardia may also occur. These are referred to as vago-glossopharyngeal neuralgia. As in the case of trigeminal neuralgia,

physical examination is usually normal. This condition also responds to carbamazepine and phenytoin. More effective drug is gabapentin in a total daily dose of 300-1200 mg given in divided doses.

The nuclei of IX and X cranial nerves may be involved together either unilaterally or bilaterally in diseases affecting the brainstem such as motor neuron disease, lateral medullary infarction, bulbar poliomyelitis and tumours. Posterior fossa tumours, basal meningitis and demyelinating diseases may involve these nerves outside the brainstem.

Accessory Nerve

Syn: Cranial nerve XI

This is purely a motor nerve. This has two roots—*cranial* and *spinal*. The spinal root arises from the anterior horn cells of the upper five cervical segments, and it enters the skull through the foramen magnum. These fibres are joined by the cranial root which arises from the caudal part of the *nucleus ambiguus* and together they leave the skull through the jugular foramen along with the vagus nerve. In the jugular foramen the cranial root fibres join the vagus nerve fibres to be distributed to the pharynx and larynx. This part of the nerve cannot be tested separately. The spinal part supplies the sternomastoid and upper part of the trapezius muscles. At the nuclear level the representation is the contralateral trapezius and ipsilateral sternomastoid muscles. On the other hand the accessory nerve innervates both the ipsilateral muscles. This phenomenon can be made use of to distinguish between intrinsic and extrinsic lesions of the brainstem (i.e.) whether the lesion affects the nucleus or the nerve.

Testing: This is limited to evaluation of the motor power of the sternomastoid and the trapezius. The sternomastoid is evaluated by inspection and palpation as the patient turns his head to one side against resistance. The paralysed muscle is flat and it does not prominently stand out on turning the head to the opposite side. Strength of the muscle can be tested by asking patient to turn his head to the opposite side while applying resistance at the chin.

The trapezius is tested by asking the patient to shrug the shoulders against resistance.

Hypoglossal Nerve

Syn: Cranial nerve XII

This is also a purely motor nerve which supplies the muscles of the tongue. It arises by a series of rootlets from the medulla between the pyramid and the inferior

part of the olive and emerges out of the skull through the hypoglossal foramen before supplying the tongue.

Testing: Ask the patient to open the mouth without protruding the tongue. In unilateral LMN paralysis, the tongue curves slightly to the healthy side. On protruding the tongue, it deviates to the paralyzed side. This phenomenon helps to distinguish an UMN paralysis from LMN paralysis. In UMN paralysis the tongue always deviates to the side opposite to the lesion irrespective of whether it is inside or outside the mouth. Strength of sideways movements of the tongue can be tested by asking the patient to push with his tongue the examiner's finger kept outside the cheek. Unilateral paralysis leads to loss of strength while pushing to the opposite side. Examine for fasciculations and wasting with the tongue lying in the floor of the mouth. Presence of these suggests LMN lesion. Wasting of the tongue leads to longitudinal furrows on it. In upper motor neuron lesions, the tongue is small and spastic.

Lower Cranial Nerve Palsies

LMN paralysis of the IX, X, XI and XII cranial nerves which arise from the medulla (bulb) occurring in various combinations, constitutes **bulbar palsy**. UMN lesion affecting these cranial nerves leads to supranuclear bulbar palsy, also known as **pseudobulbar palsy**. Clinically these two conditions have to be differentiated from each other. Dysphagia, dysphonia, dysarthria and nasal regurgitation of fluids occur in bulbar as well as pseudobulbar palsies. Emotional lability in the form of unprovoked and uncontrollable laughter or crying is an added feature in pseudobulbar palsy. Examination reveals marked wasting and fasciculations of the tongue and sternomastoid muscles in bulbar palsy, but not in pseudobulbar palsy. However in acute bulbar palsy as in diphtheria, poliomyelitis or Guillain-Barré syndrome, there is no time for these muscles to undergo atrophy. The jaw reflex is usually absent in cases of bulbar palsy while it is brisk and exaggerated in pseudobulbar palsy.

LMN Lesions of the Lower Cranial Nerves

i. Brainstem Lesions

Vascular occlusions, tumours, motor neuron disease, poliomyelitis, demyelinating diseases including multiple sclerosis and syringobulbia.

ii. Lesions Outside the Brainstem

Fractures of the base of the skull, primary or secondary neoplasms affecting the base of the skull, basal meningitis, tonsillar herniation, coning of the brainstem,

paralytic diphtheria, rabies, Guillain-Barré syndrome and others.

iii. Lesions Outside the Cranial Cavity

Left recurrent laryngeal nerve may be involved in upper thoracic lesions such as mediastinal tumours, or other causes of thoracic outlet syndrome.

UMN Lesions of the Lower Cranial Nerves

These are due to bilateral lesions of the cerebral cortex or corticospinal tracts above the level of the medulla. Common causes include bilateral cerebrovascular accidents, motor neuron diseases, metastatic tumours and degenerative and demyelinating diseases.

Distinction between bulbar and pseudobulbar palsy		
Clinical features	Bulbar palsy	Pseudobulbar palsy
Emotional lability	Nil	Present
Wasting of tongue and sternomastoid	+	Nil
Fasciculation of tongue and sternomastoid	++	Nil
Jaw reflex	Absent	Exaggerated
Type of lesion	LMN	UMN

185

Coma and Brain Death

S.R. Chandra, P.K. Mohan

Chapter Summary

General Considerations 1215

Glasgow Coma Scale 1215

Examination of a Comatose Patient 1216

Clinical Features 1216

Investigations 1217

Brain Death 1218

Management of Comatose Patient 1219

General Considerations

Consciousness has two clinical aspects, namely, wakefulness and awareness. Disorders of the reticular system leads to coma in which the patient remains with eyes closed, he lacks both wakefulness and awareness, and is unresponsive to external stimuli. The essence of the vegetative state is wakefulness without awareness. Consciousness is a stage of normal awareness of the self and surroundings and the ability to respond to various types of stimuli, both endogenous and exogenous. During sleep the subject can be roused by appropriate stimuli to full consciousness. Coma is a state of unarousable unresponsiveness which implies defects in arousal, awareness of surroundings and ability to respond. In coma

generally the eyes are closed and the sleep-wake cycles are absent.

Coma is defined as deep unconsciousness from which the patient cannot be aroused even by painful stimuli. When a patient gradually sinks into coma, the following stages may be recognizable:

Confusional state: The patient is conscious, but may be disoriented in time, space and person. He shows misperception of the environment.

Stupor: In this state of disturbed consciousness, only vigorous external stimuli produce arousal. The spells of consciousness tend to be brief and the patient slips back into stupor soon.

Coma: The patient is unarousable by all external stimuli. In this stage all the protective reflexes (sneeze, cough, withdrawal to nociceptive stimuli, etc.) are absent.

Glasgow Coma Scale (EMV Scoring)

An objective method of evaluating the depth of coma is the Glasgow coma scale. Recording the progress of the patient by this method is extremely useful for initial assessment and follow-up in cases of coma due to head trauma and cardiorespiratory arrest.

Glasgow Coma Scale

Test		Scoring
1. Eye opening (E)	Spontaneous	4
	To sound	3
	To pain	2
	Nil	1
2. Motor movements (M)	Obeys command	6
	Localises pain	5
	Normal flexion withdrawal	4
	Abnormal flexion (decorticate rigidity)	3
	Extension (decerebrate rigidity)	2
	No response	1
3. Verbal response (V)	Well-oriented	5
	Disoriented and converses	4
	Confusedly	3
	Inappropriate words	2
	Incomprehensible sound	1

A conscious individual will have a score of 15.

The scores progressively diminish as the coma becomes deeper. The fallacy of Glasgow coma scale is that even a dead person will have a score of 3. This has not in any way reduced the importance of the Glasgow coma scale.

TABLE 185.1

Causes of coma

Neurological causes

1. Ischemia to the brain and brainstem. e.g. stroke, Stokes-Adams attacks, low cardiac output states, and cardiac arrest.
2. Infections, e.g. meningitis, encephalitis.
3. Rise in intracranial tension due to various causes.
4. Physical agents, e.g. craniocerebral injuries, hyperpyrexia, hypothermia.
5. Degenerative disease, e.g. Tay-Sachs disease, Creutzfeldt-Jakob's disease.
6. Demyelination — Postvaccinal, infective, and allergic causes.
7. Seizure disorders like status epilepticus.

Systemic diseases

1. *Metabolic causes*—Diabetic coma, uremia, hypoglycemia, acidosis, alkalosis, hyperosmolar states, respiratory failure, hepatic failure and endocrine disorders such as hypothyroidism, Addison's disease and hypopituitarism.
2. *Poisoning*—Alcohol, narcotics, and other poisons, cobra and krait bites.
3. *Infections*—Several infections affecting the brain or meninges directly as in meningitis and encephalitis lead to coma. Others give rise to toxic encephalopathy, e.g., septicemias, septic shock, salmonellosis.

Psychiatric disorders

Though these are not comatose states, their presentation may very closely resemble that of coma from which they have to be distinguished e.g., catatonic stupor and hysterical coma.

In the case of nontraumatic coma, extending for at least 5-6 hours, the common causes are:

1. Sedative drugs with or without alcohol 40%
2. Cerebral hypoxic and ischemic damage caused by cardiac arrest and anesthetic accidents 25%
3. Stroke and subarachnoid hemorrhage 20%
4. Infections and metabolic derangements 15%

Mechanism of coma: Coma may develop due to several mechanisms.

General mechanisms leading to coma are: (i) reduction in blood supply to the brain, (2) lesions affecting the reticular formation, (3) electrical disturbances as in seizure disorders, and (4) disturbance in metabolism leading to dysfunction of cellular processes in the neurons.

Common causes of coma are given in Table 185.1.

Examination of a Comatose Patient

CLINICAL FEATURES

The history given by immediate attendants and the circumstances of the illness give valuable clue to the diagnosis.

General examination should elicit the following features.

1. Evidence for trauma.
2. Bleeding from the nose or ears suggesting fracture of the base of the skull.
3. Pallor and shock indicating recent blood loss.
4. Smell of alcohol and evidence of poisoning.
5. Signs of repeated venepunctures seen in intravenous drug abusers.
6. Type of respiration—Acidotic breathing, Cheyne-Stokes respiration or respiratory depression.
7. Presence of systemic diseases such as diabetes, renal failure, hepatic failure, hypertension, cardiovascular lesions which may act as sources of emboli, etc.
8. Convulsions, e.g. epilepsy.
9. Signs of systemic or intracranial infection.
10. Pupils: Inequality of the pupils suggests transtentorial herniation. The dilated nonreacting pupil is the result of oculomotor paralysis, which may be due to an involvement of the nerve or its nuclei in the midbrain.

Any patient in deep irreversible coma due to neurological or systemic disease may have fixed dilated pupils as a terminal or preterminal phenomenon.

Bilateral pin-point pupils, non-reactive to light are seen in pontine and thalamic hemorrhage. Pin-point pupils may be seen as well in narcotic poisoning (e.g., morphine).

After ascertaining the general condition of the patient, and depth of coma, systematic neurological examination should be carried out.

Oculocephalic Reflex (reflex eye movements)

This is tested by turning the head of the patient firmly to either side by 70° and then passively flexing and extending the neck. The eyes move opposite to the movement of the head. These “dolls-eye movements” depend on the intactness of the third, fourth and sixth cranial nerves and their nuclei, the labyrinth, otoliths and their central connections in the brainstem including the vestibular nuclei and the medial longitudinal fasciculi.

Preservation of the “doll’s-eye movement” helps to exclude disease of the brainstem. Unilateral absence of doll’s eye movement suggests ipsilateral pontine lesion. The doll’s eye movements are totally abolished in extensive structural damage to the brainstem and deep metabolic coma. However, this test should not be performed when injury to the cervical spine is suspected.

Conjugate Deviation of the Eyes

This should be looked for. Lateral conjugate deviation occurs in cerebral or pontine lesions. Conjugate deviation is towards the side of the lesion in destructive disorders and to the contralateral side in irritative disorders in cortical lesions. The converse is true of pontine lesions. In tectal and thalamic lesions the eyeballs are depressed. In brainstem lesions spontaneous vertical nystagmus and skew deviation may occur. The eyeballs are deviated to the opposite side in cerebellar hemorrhage.

The caloric tests: These tests give information of the integrity of the vestibular apparatus, its connections in the brainstem and the connections with higher cortical centres. In deepening coma, when cortical function becomes progressively depressed, the fast phase of the nystagmus tends to disappear. Abnormal caloric tests indicate irreversible damage to the brainstem.

Posture

Decerebrate posture/rigidity: A patient in coma caused by structural lesions in the brain such as tumour, hemorrhage, infarct and others may assume this posture unilaterally or bilaterally either spontaneously or in response to painful stimuli. This is characterized by tonic extension and internal rotation of the upper extremity and tonic extension and plantar flexion of the lower extremity associated with jaw clenching and head retraction.

It is important to recognize this grave sign because it indicates dysfunction of upper brainstem between the superior colliculus of the midbrain and vestibular nuclei in the pons. In metabolic and drug induced coma, this posture does not develop. Decerebrate posture is caused by uninhibited vestibulospinal discharges.

Decorticate posture/rigidity: This posture is characterized by tonic flexion of the forearms at the elbow, adduction and flexion of the arm at the shoulder and flexion of the fingers, with tonic extension of the lower extremity, either on one or both sides. This is seen in lesions above the brainstem, affecting the cortex or the corticospinal tracts. Like decerebrate posture, this also occurs in coma and in chronic stages of hemiplegia. It indicates uninhibited rubrospinal discharges.

Funduscopy

This procedure should be performed in all cases to exclude papilledema and retinal abnormalities. It is mandatory to exclude raised intracranial tension before lumbar puncture is attempted.

DIAGNOSIS OF COMA

In neurological disorders, localizing signs pointing to damage to parts of the nervous system may be present such as hemiplegia, cranial nerve palsies or focal seizures. Meningitis and subarachnoid hemorrhage are associated with signs of meningeal irritation such as neck rigidity, Kernig’s sign and Brudzinski’s signs. In metabolic coma localizing signs may be absent. In poisoning, other effects of the poison may also be evident.

Investigations

1. Routine investigations to exclude systemic disorders include complete urinalysis, estimation of blood sugar, urea, electrolytes, blood gases and pH.
2. In suspected poisoning the gastric contents, blood, urine and other materials should be sent for chemical examination for the poison.
3. Cerebrospinal fluid should be examined when meningitis, encephalitis, subarachnoid hemorrhage, or meningeal leukemia are suspected.
4. Further tests are decided by the clinical examination and progress of the case. EEG, CT scanning, MRI and radio-isotopic scanning may be indicated in some cases.

Differential Diagnosis of Coma

- A. Coma with focal or lateralizing neurological signs, e.g. cerebral tumour, cerebral hemorrhage, infarction, abscess.
- B. Coma without focal neurological signs, but with signs of meningeal irritation, e.g. meningitis, encephalitis, subarachnoid hemorrhage.
- C. Coma without focal or lateralizing neurological signs or meningism, e.g. anoxic-ischemic lesions, metabolic disorders, intoxications, systemic infections, seizures, physical agents such as heat or cold.

Differential diagnosis of coma includes brain death, vegetative state, minimally conscious state, locked-in syndrome, catatonic stupor and hysterical behaviour (Table 185.2).

TABLE 185.2

The main differentiating features of the major conditions						
	Awareness	Wakefulness	Brainstem respiratory cycles	Motor reflexes	EEG	Evoked potential
Coma	–	–	±	±	Abnormal	Abnormal
Brain death	–	–	–	–	Silence	Absent
Vegetative state	–	Present, intact sleep wakefulness rhythm	+	±	Abnormal	Abnormal
Minimally conscious state	Intact but poor response	+	+	±	Non-specific	Abnormal
Locked in syndrome	Intact but communication poor	+	+	Quadruplegia, pseudobulbar normal palsy	Normal	Abnormal

key: + normal; – absent; ± variable

Locked-in Syndrome

The locked in syndrome is not a disorder of consciousness. This is a condition in which voluntary control of almost all body movements is abolished without abolition of arousal or awareness. Locked in syndrome is a state of profound paralysis with intact consciousness and cognition which may be mistaken for coma. In many cases it is due to a disorder of the pons caused by infarction or hemorrhage which de-afferents all supranuclear motor circuits except those of vertical eye movements.

Brain Death

The term “brain death” is used to denote irreversible loss of all brain functions. Most common cause is cardiac arrest persisting for over 3 mintues. Other causes include traumatic damage to the brainstem, extensive infarction and others.

Brain death has become an important issue since removal of organs for transplantation is done from comatose patients who are not likely to recover. Patients who are on supportive measures including artificial ventilation may pass into a stage where the cerebral and brainstem functions are irreversibly lost, still the patient may continue to have circulation on account of the supportive measures. Withdrawal of these supports will lead to physical death. The decision to withdraw these supports is a medicolegal one. Therefore, brain death has to be recognised clinically and supported by EEG wherever it is possible (Table 185.3).

TABLE 185.3

Criteria for brain death and vegetative states
1. Non-receptivity and non-responsivity to external stimuli, unawareness of self and surroundings
2. Absence of spontaneous movement and breathing and social intractions
3. Abnormality of brainstem reflexes such as pupillary reflexes, corneal reflex, caloric tests and cough and gag reflexes
4. Preservation of sleep-wakefulness rhythm
5. Preservation of autonomic and hypothalamic functions which enables them to survive with the provision of medical and nursing care.
6. Incontinence of micturition and defecation
7. Preservation of cranial nerve relfexes
8. Isoelectric EEG – i.e., flat EEG.

Deep coma without any movement or reflexes for over 24 hours, absence of brainstem reflexes such as oculoccephalic reflexes, light reflex, caloric tests and spontaneous respiration; and a flat EEG record indicate irreversible brain damage — i.e., brain death. These criteria are not valid if the coma is the result of overdose of poisons or hypothermia.

Persistent Vegetative State (PVS)

This denotes a state of wakefulness without awareness. Normal functioning of the cerebral cortex and midline structures of the upper pons, midbrain and thalamus are crucial to the maintenance of wakefulness. When these are disrupted the normal higher functions are lost. PVS results from any injury or other destructive process which grossly damages the cerebral hemispheres or the upper brainstem

structures. Common causes include ischemic damage to the brain stem and other parts, trauma and end stages of degenerative neurological disorders such as Alzheimer's disease and parkinsonism. PVS is a state of mere physical life without any intellectual activity or social interaction. The body maintains life without appreciating any sensation and devoid of all higher functions. Some of the autonomic reflexes and vital functions are preserved. Some spontaneous limb movements may occur. All signs of conscious perception and deliberate action are abolished.

Prognosis for recovery is better in children, traumatic lesions and in PVS of shorter duration.

These criteria should persist when repeated 24 hours later. For legal purposes three physicians, none of them forming part of any organ transplant team should independently certify brain death, before removing organs for transplantation.

MANAGEMENT OF COMATOSE PATIENT

General management: Comatose patients are very susceptible to develop several complications as a result of loss of protective reflexes and these have to be prevented.

Maintenance of the airway is of utmost importance. The neck has to be kept extended to prevent "falling-back" of the tongue. If necessary a patent airway should be introduced. Secretions have to be removed by postural drainage and suction. In cases with respiratory depression assisted ventilation has to be instituted early. Tracheostomy may be required in some cases.

Maintenance of Nutrition, Fluid and Electrolyte Balance

Adequate nutrition (at least 2000 cal/day and 2L of fluid) in the form of milk, sugar, eggs, cereals, salt and water are given through a nasogastric tube. Oral feeding carries the risk of aspiration into the respiratory tract, and therefore, this should be avoided. Parenteral nutrition is started through the intravenous route to supplement nasogastric feeding. The intravenous needle should be maintained aseptically. In prolonged illness, the

position of the needle should be changed every 36-48 hours to avoid thrombophlebitis.

Care of the Skin

Bedsore develop due to continuous pressure on localised areas. This risk is avoided by turning the patient in bed every 2-4 h and keeping the skin clean and dry. Adequate intake of proteins helps to minimize the risk of bedsore. When coma is likely to be prolonged, special beds which are capable of turning the patients, and which help to avoid pressure over localized areas may be used with advantage.

Care of Bladder and Bowel

The unconscious patient voids his bladder and bowel automatically and this creates many problems in nursing. Institution of a closed drainage system for the bladder helps to avoid soiling of the clothes and prevents infection. Bowels are moved by small enemas or suppositories at regular intervals.

Positioning of the Limbs and Physiotherapy

The limbs should be maintained in optimal position to avoid fixed deformities. Regular passive movements of the limbs help to prevent venous thrombosis and subsequent pulmonary embolism.

Specific Therapy

This depends upon the cause of the coma. Anticonvulsant medication is indicated if seizures occur. Intercurrent infection (respiratory, urinary or cutaneous) has to be treated with antibiotics.

Note: With the wide spread use of organs for transplantation and the international network for donor recipient matching and transplation procedures the importance of brain dead persons as donors has increased considerably. Since the chance for recovery is almost nil, supportive care which sustains life is withdrawn after strictly following legal procedures including the consent of relatives, independent certification of brain death and other formalities.

Chapter Summary

General Considerations 1220
 Migraine 1221
 Chronic Daily Headache 1222
 Cluster Headache 1223

General Considerations

Headache is one of the most common, and yet the most difficult clinical problem encountered by the physician. Though the term 'headache' can mean pain anywhere in the head, it is usually confined to pain arising in the region of the cranial vault. Most often headache is a symptomatic expression of some minor ailment, mental tension or fatigue, and in the vast majority of cases the cause is non-neurological. Occasionally, it is of sinister significance, indicative of serious intracranial disease.

Pain in the head may arise from different structures, which include:

1. The cranial vault consisting of skin, subcutaneous tissue, muscles, arteries, and periosteum of skull;
2. Intracranial venous sinuses and their tributaries;
3. Intracranial arteries before they penetrate brain parenchyma;
4. Meninges at the base of the brain;
5. Trigeminal, glossopharyngeal, vagal, and the first three cervical nerves; and
6. Structures of eye, ear, and nasal cavity.

Classification

Headache may be broadly classified into:

1. Referred headache.
2. Neuralgic headache.
3. Headache due to meningeal irritation.
4. Vascular headache.
5. Headache due to traction on intracranial structures, and
6. Psychogenic headache.

Headache is one of the most common nonspecific symptom occurring in several systemic illnesses such as

infections, fever, digestive disturbances, fatigue and others. It is also a very common adverse side effect of several drugs.

Referred headache: This includes pain arising from the eyes, ears, nose, air sinuses, teeth, cervical spine, and other structures which may be referred as headache. Iridocyclitis and glaucoma produce headache which is referred to the frontal region. Nasal and paranasal sinus diseases may cause pain over the frontal or malar region. Cervical spondylosis may cause severe occipital headache. In some people a cold stimulus in the soft palate may produce referred headache which is spoken of as an "ice-cream headache."

Neuralgic headache: Trigeminal neuralgia is a typical example of cranial neuralgia. The pain is episodic and lancinating in character. This occurs within the distribution of the fifth cranial nerve. In post-herpetic neuralgia pain is continuous and burning in character. In glossopharyngeal neuralgia a pain of stabbing character is felt in the pharynx and deep in the ear. Loss of teeth or ill-fitting dentures cause malalignment of the bite and secondary to this, changes occur in the temporomandibular joint resulting in temporomandibular neuralgia. Here the pain varies from dull ache to intense agonizing stabbing pain. The pain may radiate from the region of the affected joint to temporal and frontal areas and to the cheek or neck.

Meningeal irritation: Headache is almost always a symptom of meningitis and encephalitis. This results from meningeal inflammation which lowers the threshold of pain-sensitive structures at the base of the brain and hence minimal mechanical stimuli produce headache. This headache may be generalized or sometimes more severe in the occipital region. It is aggravated even by minimal movements of the head. The diagnosis is suggested by the associated fever, photophobia and neck stiffness.

Head ache of subarachnoid hemorrhage is often abrupt in onset, sometimes precipitated by exertion and felt at particular regions depending on the vessel involved. The patient is afebrile. Many become unconscious. At times incontinence may develop. It is important to recognize the

extremely severe headache of subarachnoid hemorrhage which demands immediate, referral to a centre where neurosurgical intervention can be undertaken.

Tension headaches which may be either episodic or chronic are the most common headaches and include muscle contraction headache, stress headache and psychogenic headache. The sensation is often described as the pressure exerted by a tight hat. The pain is mild to moderate, bilateral and does not worsen with normal physical activity. This group can be further subdivided into two: (1) those with abnormalities of the pericranial muscles, detected by palpation or demonstrating overactivity by electromyographic studies, and (2) those without such abnormalities. Muscle contraction headaches may also be secondary to localized disease of the head, temporomandibular joint dysfunction, cervical spondylosis, eye muscle disorders and sinus diseases. Treatment of such headaches consists of attention to any removable underlying cause, use of sedatives, altering the lifestyle and relaxing techniques such as biofeedback, meditation and leisure activities.

Vascular headache: This type of headache is the result of dilatation of intracranial or extracranial vessels. The pain is throbbing in nature and it tends to aggravate with head movement.

Migraine

The most common form of vascular headache is migraine (megrim means hemicranial). Migraine is characterized by episodic, throbbing hemicranial headache, beginning in childhood, adolescence or early adult life with a tendency to decrease in intensity and frequency as age advances. It is estimated that 5% of the population suffers from migraine. Women are slightly more affected. In many cases a positive family history is elicitable.

Mechanism of migraine: Though the exact mechanism is unknown, it is the consensus that an attack of migraine consists of a neurovascular disorder of the intracranial as well as the extracranial vessels. Sequential studies of cerebral blood flow show an initial reduction which may be localized or generalized followed by increase in blood flow (35-50%) later. The basic cause of this circulatory disturbance is not known. It is found that the blood levels of histamine, serotonin, and norepinephrine increase during the attacks. There is also increase in platelet aggregability. This may account for strokes which sometimes complicate migraine. The headache has been attributed to excessive pulsation of extracranial arteries, and possibly intracranial ones also.

Migraine with aura or classic migraine: Here the episode begins with prominent neurologic symptoms (*auras*) such

as visual disturbances like dazzling zig-zag lines, spreading scotoma, homonymous hemianopia, field defects or rarely total blindness, sensory disturbances affecting one-half of the body, disturbances of speech or hemiparesis. These neurologic symptoms last for 15-30 minutes and usually merge into a hemicranial or generalized throbbing headache with nausea and vomiting, all of which may last even for 1 to 2 days. In the majority of cases the duration is much shorter. Many complain of photophobia and phonophobia during the attacks.

Migraine without aura or common migraine: Here there is no preceding neurological symptoms, but there is unheralded onset of headache, nausea and vomiting following the same sequence.

Diagnosis of both classic and common types of migraine is made mainly from history. Long duration of illness, onset during childhood, positive family history and relief with ergot derivatives are in favour of migraine. Migraine has to be differentiated from other organic disorders such as raised intracranial tension, subarachnoid hemorrhage and arteriovenous malformations.

Course and prognosis: In the majority of patients migraine tends to be chronic with periods of exacerbation and remission. With increasing age the attacks tend to come down. Complications may occur rarely in some cases. These include cerebrovascular accidents, ocular and other cranial nerve palsies.

TREATMENT OF MIGRAINE

The physician should give full explanation of the nature and phenomena of migraine to the patient and this often relieves the patient's anxiety and helps to restore his morale. All known precipitating factors such as emotional tension, exposure to cold, foods such as cheese, and chocolates should be avoided. Hypoglycemia is a common precipitating factor and this should be avoided by proper timing of meals.

Many cases are made symptom-free by simple analgesics such as *aspirin in a dose of 900 mg or paracetamol 0.5-1 g given at suitable intervals. NSAIDs such as ibuprofen, naproxen and mefenamic acid are good alternatives.* If nausea and vomiting are troublesome metoclopramide 10 mg or domperidone 30 mg may be helpful. These drugs often help to abort an attack if given early. The specific drug which helps to abort an attack if taken at the earliest symptom is **ergotamine** which is a nonselective 5-hydroxy tryptamine agonist, in a dose of 1 mg. Available preparations include sublingual tablets of 1 mg, chewable tablets, subcutaneous injection (0.25 mg) or aerosols. If the drug is taken after the headache has set in, higher doses and repeated medication may be needed. In any case the weekly dose should not exceed 12 mg. Ergotamine preparations are contraindicated during pregnancy and in patients with ischemic heart disease, hypertension and peripheral occlusive vascular disease.

Adverse side effects include nausea, muscle cramps and peripheral vasoconstriction. Other drugs which can terminate an attack are metoclopramide 10 mg IV and prochlorperazine 10 mg IV.

Selective Serotonin Receptor Modifying Drugs in Migraine

The serotonin receptors 5HT₁, 5HT₂ and 5HT₃ are relevant to migraine. 5HT₁ inhibitory receptors produce vasoconstriction. 5HT₂ receptors are excitatory. Drugs such as cyproheptadine, propranolol and methysergide are 5HT₂ antagonists.

5HT₁ receptors are subclassified into 5HT_{1A}, 1B, 1D and 1F. Most of the triptan drugs which act in acute migraine act as agonists on 5HT_{1B} or 5HT_{1D}. **Sumatriptan** was the first drug of this class introduced to stop acute migraine attacks.

It is effective in the treatment of acute attacks of migraine, complicated migraine and cluster headache. The dose is 50-100 mg to be taken soon after the onset of migraine. For the same attack a second dose should not be given. If migraine attacks recur, doses upto 300 mg can be given in 24 hours.

A parenteral preparation of sumatriptan is available for subcutaneous injection in a dose of 6 mg as soon as possible after the onset. Peak plasma levels are reached in 20 minutes. For the same attack of migraine the drug should not be repeated. A second dose can be given for subsequent attacks upto a total dose of 12 mg in 24 hours.

Side effects include tingling, feeling of tightness of the different parts of the body, flushing, transient rise in blood pressure, hypotension, brady- or tachycardia and seizures.

Newer analogues are available for treatment of acute attacks of migraine. These include **zolmitriptan, naratriptan, rizatriptan, almotriptan and others**. Side effects, especially cardiac side effects are less for the newer analogues. Rizatriptan is available in India-It is given in a dose of 5-10 mg at the onset of the attack.

Drug prophylaxis: This is employed to prevent migraine attacks and allay their severity. The commonly used drugs include:

Propranolol 10-40 mg/day bid or tid

Cyproheptadine 4 mg HS

Calcium channel blockers: Nimodipine 30 mg bid, verapamil 40-60 mg bid. Flunarazine 5-10 mg HS.

These drugs have to be continued at first for six months after which the case has to be reviewed for continuation of therapy. In asthmatic subjects, propranolol may have to be replaced by more selective beta adrenergic blockers.

General measures such as regulated life, physical exercise, avoidance of smoking and leisure activities are important to prevent relapse.

CHRONIC DAILY HEADACHE

This term denotes the presence of headache for more than 15 days in a month for longer than three months. The term *transformed migraine* is used to denote the condition where classic migraine is altered, to assume the character of chronic daily headache, often due to overuse of drugs. The term *medication overuse headache* is given to conditions where headache is present at least for 15 days a month, associated with worsening of the headache during medication overuse, and reversion to previous episodic pattern (< 15 days per month) within 2 months after withdrawal of the medication.

Transformed migraine is an iatrogenic condition in which head pain occurs daily or almost daily (> 15 days per month), each attack lasting for 4 hours or more and worsening over the previous three months. At some point of time features of episodic migraine, meeting the International Headache Society (IHS) criteria, may be elicitable. The reason for this transformation is not clear. The IHS criteria for migraine without aura include the following:

1. At least five attacks that last for 4-72 hours—untreated or successfully treated.
2. Headache must have at least two of the characteristics given below;
Unilateral location, pulsating quality, and moderate or severe pain intensity, avoidance of usual physical activities such as walking or climbing stairs.
3. These attacks, themselves should be accompanied by at least one of the features such as nausea, vomiting, phonophobia not accountable by other conditions. Most patients with transformed migraine and medication overuse headache are women and they have a history of episodic migraine from adolescence or early adulthood.

The transformation from *migraine* to *transformed migraine* occurs over a period of months or years and the clinical picture is a mixture of tension type headache and migraine.

The over use of acute-headache medications such as aspirin, acetaminophen, caffeine, ergot, opioids or triptans by patients with frequent headache gives rise to **medication—overuse headache** which occurs almost daily (at least > 15 days a month) and maintained by the same medications used to relieve pain. Withdrawal of medication relieves the headache dramatically. Once the drugs are withdrawn, the headache reverts to the original pre-treatment pattern within months.

Management of Transformed Migraine and Medication Overuse Headache

1. Withdrawal of the offending medications,
2. Lifestyle changes including regular exercise, leisure activities,
3. Yoga and meditation,
4. Reintroduction of drugs should be based on trial and observations. In addition to regulated use of the common analgesics, drugs like amitriptyline 10 mg HS, corticosteroids (prednisolone 20-40 mg/day for 5 days) and nonsteroidal anti-inflammatory drugs have been used with benefit. Physical measures such as injections of botulinum toxin into specific points over the forehead and neck 25-75 units once in 4-6 weeks allays the frequency and severity of the headache in many cases.

Cluster Headache

Syn: histamine headache,
Horton's syndrome

This is a migrainous variant. The name 'cluster headache' refers to its occurrence in bouts. Men are more affected than women in the ratio of 4 : 1. The headache starts within 3 hours of falling asleep, it is non-throbbing, unilateral, and orbital in location. Along with pain there may be lacrimation, nasal obstruction, rhinorrhea, and sometimes miosis, ptosis, and flushing, and edema of cheek—all lasting approximately for an hour or two. It tends to occur every night for weeks or months followed by complete freedom for years. Such clusters of headache may recur over the years. Periods of headache are brought on by stress, prolonged strain, overwork and emotional disturbances. Alcohol, nitroglycerine or tyramine-containing foods may precipitate the headache. The Hypothalamus is probably at fault. Diagnosis is clinical.

Treatment of cluster headache: This may respond to antihistamine drugs. In resistant cases, drugs used in migraine may be necessary. Acute attacks respond to oxygen inhalation at the rate of 7 L/minute. Sumatriptan is given in doses of 6 mg by SC injection. It controls 75% of attacks. Ergot preparations given oral or by aerosol inhalation (1-2 mg) are effective. Nasal instillation of 1% lidocaine solution on the side of headache helps to arrest the attack.

Prevention of recurrence: Verapamil in doses of 240-320 mg or lithium in doses of 600-1500 mg a day is effective. In intractable cases surgical treatment on the gasserian ganglion of the trigeminal nerve and deep brain stimulation have been employed.

CHRONIC PAROXYSMAL HEMICRANIA

This term refers to brief spells of headache recurring frequently and following a chronic unremitting course,

unless modified by drugs. It differs from cluster headaches in the brevity of attacks. Response to indomethacin is dramatic.

OTHER VASCULAR HEADACHES

Headache following an alcoholic bout (*"hangover" headache*) is thought to be due to vascular mechanisms. Vascular dilatation and headache may be a feature of hypercapnia in patients with respiratory failure. Severe arterial hypertension may cause headache. In the elderly, localized temporal headache may be due to cranial arteritis (temporal arteritis).

Headache due to Traction on Intracranial Structures

An intracranial lesion such as a growing tumour or subdural hematoma may press upon pain sensitive structures situated intracranially and produce headache. This may occur even if there is no generalised rise in intracranial pressure.

Rise in intracranial pressure almost invariably produces headache which is often diffuse and aggravated by maneuvers which increase intracranial pressure further, such as straining at stools, stooping forward or coughing. Headache of raised intracranial pressure tends to be troublesome on waking up in the morning and when the patient is lying flat. When he assumes the erect posture, there is a slight fall in pressure and this relieves the headache to some extent in early cases. Headache is an important symptom in benign intracranial hypertension.

Post-lumbar puncture headache: Following lumbar puncture, if there is excessive leak of CSF through the puncture site the CSF pressure falls and this leads to traction on intracranial structures. This produces post-lumbar puncture headache. Other mechanisms also operate to perpetuate this symptom.

This can be avoided by doing LP with a small-bore needle, withdrawing only small quantities of CSF (< 2 mL) and administering drugs like caffeine (50-100 mg) and theophylline 100 mg orally. Creation of an epidural blood patch may be necessary if the headache is persistent.

Psychogenic headache and other cranial pains occurring in psychiatric diseases:

Headache is a common symptom in psychiatric disorders. Such headache involves the whole head or may be confined to the front or vertex. Though the sensation is usually described as pain, further scrutiny reveals it as a sort of pressure or tightness felt by the patients. Tension headache tends to occur following emotional excitement or other stresses. Constant tension developing in the muscles of the forehead and upper part of the face leads to this symptom. This type of headache may persist continuously for days or weeks. Common analgesics like salicylates and

paracetamol are ineffective. Patients with tension headache reveal prominent symptoms of depression, anxiety, and hypochondriasis. Majority of patients with anxiety neurosis, hysteria, obsessive compulsive neurosis and schizophrenia with prominent anxiety, exhibit this type of headache. Miscellaneous headaches not associated with structural lesions are characterized by severe stabbing pains lasting for very brief periods (probably only seconds) commonly felt in the distribution of the first division of the trigeminal nerve. They respond to reassurance. Indomethacin is very effective in some cases.

Coital headache occurs at the time of sexual intercourse and may cause severe anxiety. This is a benign condition in the vast majority of cases, but if it is of recent onset, subarachnoid hemorrhage has to be excluded by suitable investigations before reassuring the patient. Exercise induced headache also comes under the same category.

Diagnosis

Majority of headaches encountered in clinical practice are nonrecurrent and occur as manifestations of systemic illnesses. Recurrent headaches present a common diagnostic problem since one has to differentiate conditions like migraine and tension headache from more serious causes like intracranial structural lesions. Presence of accompanying signs like neurological deficits simplifies the problem, but usually history is the only

clinical guide for diagnosis and further management. Some general points help to assess the severity of the disorder.

Headache described as throbbing or burning is more significant than tension headaches. Localised headaches are often indicative of serious underlying disease than diffuse pain. Headache situated over the occipital or frontal region is more important than that situated over the vertex. Headaches which disturb sleep usually arise from organic lesions. Headache of recent onset is more sinister than that of long standing. Presence of phenomena like double vision or epilepsy indicates the presence of an intracranial lesion. **Late onset headache and recent change in pattern in chronic headaches are indications for brain imaging studies.**

Management

The investigation and treatment depend upon the clinical setting. Detailed history serves to sort out the cause in the majority of cases. Investigative procedures such as X-ray chest, EEG and computerized tomography of the brain are done before embarking upon more advanced procedures like MRI and angiography. In those cases in whom no serious underlying lesion is detected, reassurance and periodic follow-up is all that is required. It is important to avoid unnecessary medication and life-long invalidism.

Nutritional Disorders of the Nervous System

Jalesh N. Panicker, P.K. Mohan, K.V. Krishna Das

17

Chapter Summary

- Vitamin B₁₂ Deficiency 1225
- Thiamine Deficiency 1225
- Wernicke-Korsakoff Syndrome 1226
- Other Nutritional Deficiencies 1226

Vitamins and minerals are required in optimal quantities for proper maturation and functioning of central and peripheral nervous system. Though more than 40 nutrients

are recognized today, neurological disorders usually manifest only from deficiency of B vitamins (thiamine, pyridoxine, nicotinic acid, B₁₂ and folic acid) and vitamin E. Deficiency of thiamine and vitamin B₁₂ are the commonest nutritional disorders in India which present with neurological dysfunction. Vitamin deficiency can affect various parts of the nervous system and hence the presentation may be varied (Table 187.1). Less commonly, vitamin excess may also impair neurological functions and manifest as neurological disorders (Table 187.2).

TABLE 187.1

Neurological syndromes associated with nutrient deficiency	
Dementia/encephalopathy	Vitamin B ₁₂ , nicotinic acid, thiamine, folate
Seizures	Pyridoxine, biotin
Extrapyramidal syndrome	Nicotinic acid
Cerebellar ataxia	Vitamin E, vitamin B ₁₂ ,
Myelopathy	Vitamin B ₁₂ , folate, vitamin E
Optic neuropathy	Vitamin B ₁₂ , folate, vitamin E
Polyneuropathy	Thiamine, vitamin B ₁₂ , folate, pyridoxine, vitamin E, nicotinic acid
Myopathy	Vitamin B ₁₂ , folate, vitamin E

TABLE 187.2

Neurological syndromes associated with vitamin excess	
Vitamin A	Idiopathic intracranial hypertension
Pyridoxine	Peripheral neuropathy

VITAMIN B₁₂ DEFICIENCY

Vitamin B₁₂ deficiency is a common cause for nutritional disorder of the nervous system. It is estimated that 10 - 25% of people over 80 years of age have vitamin B₁₂ deficiency. There are several causes of B₁₂ deficiency. A strict vegetarian diet excluding even dairy products may predispose to vitamin B₁₂ deficiency because animal-based foods such as red meat, dairy products, fish, poultry and eggs are the only rich source of dietary B₁₂. However, vegetarians rarely develop clinically evident vitamin B₁₂ deficiency as the daily requirement is only 0.5 µg and small amounts may be obtained from legumes and buttermilk and curd. Impaired absorption from the gut and utilization may predispose to deficiency. Causes include malabsorption syndromes and prolonged use of H₂ receptor antagonists or proton pump inhibitors, autoimmune diseases such as pernicious anemia, pancreatic disease, ileal resection, Crohn's disease, HIV infection, chronic gastritis and gastric or small intestine surgery.

Only 15% of patients with megaloblastic anemia develop neurological dysfunction. Neurological dysfunction arises due to impaired DNA synthesis and myelin formation.

Pathological findings include demyelination and axonal degeneration in the posterior and lateral columns of the cervical and thoracic cord, called as *subacute combined degeneration of the spinal cord*. Similar findings may be found in the peripheral nerves. It commonly presents as myeloneuropathy with tingling paraesthesias and reduced pain and touch sensation in a

stocking-glove distribution along with loss of vibration and joint/position sense, rombergism, sensory ataxia, pyramidal weakness in lower limbs and lower limb areflexia. Patients may also manifest with cognitive/psychiatric symptoms and visual impairment due to optic atrophy and centrocecal scotoma. In India, vitamin B₁₂ deficiency most commonly presents as peripheral neuropathy.

Diagnosis is essentially clinical and patients may have other markers of B₁₂ deficiency such as anemia, glossitis and hyperpigmentation over the knuckles. Diagnosis is supported by direct and indirect laboratory evidence of B₁₂ deficiency such as presence of macrocytic anemia, hypersegmented neutrophils in the peripheral smear and megaloblasts in bone marrow. Low serum B₁₂ levels below 100 pg/mL, increased excretion of methyl malonic acid in urine and elevated levels of serum homocysteine levels confirm the diagnosis. Magnetic resonance imaging may show lesions in the posterior and lateral columns of spinal cord and deep white matter of brain. MRI is required only to exclude other causes of myeloneuropathy in a doubtful case.

Treatment

As the most common cause for deficiency is malabsorption and impaired utilization the role of oral supplementation is limited. Parenteral vitamin B₁₂ gives gratifying results and treatment should begin with intramuscular injections of 1000 µg of cobalamin for 7 days, followed by weekly injections for a month. Patients may require to be continued on monthly injections, depending on the etiology. Cases of pure nutritional deficiency should have supplementation of cobalamin 1-2 µg in the diet. Correction of the dietary and gastrointestinal disease should receive attention.

THIAMINE DEFICIENCY

Thiamine deficiency occurs in the setting of poor nutritional status either due to poor intake, malabsorption or increased requirement. In India it occurs most commonly in nutritionally deprived chronic alcoholics and in individuals consuming polished rice. However it can be precipitated in individuals with borderline nutritional status in the setting of raised metabolic requirements for thiamine such as pregnancy, strenuous exercise, systemic infection and malignancy. In fact, acute presentation of Wernicke encephalopathy may occur when large doses of carbohydrates, especially parenteral glucose therapy, are administered without concurrent thiamine administration. The spectrum of thiamine deficiency involves the cardiovascular system (wet beriberi) and the nervous system (*dry beriberi* and *Wernicke-Korsakoff syndrome*). Consumption of a low thiamine, low carbohydrate diet

with relative physical inactivity favours the development of dry beriberi. Diagnosis of thiamine deficiency is essentially clinical and may be supported by reduced blood transketolase activity and elevated pyruvate levels.

Beriberi

Polyneuropathy due to thiamine deficiency is called dry beriberi. Classical wet and dry forms of beriberi refer to the presence or absence of edema. It manifests as a stocking-glove (length dependent) symmetric sensorimotor polyneuropathy affecting predominantly the lower limbs. Clinical features include tingling paraesthesias, pain and muscle cramps and tenderness, distal muscle weakness and loss of deep tendon reflexes. Rarely, optic neuropathy and laryngeal palsy have been described. Associated pedal edema occurs due to cardiac involvement. Signs of cardiac failure may be prominent. Unless promptly detected and treated death may occur due to cardiac failure.

Wernicke-Korsakoff Syndrome

The spectrum of central nervous system involvement due to thiamine deficiency ranges from acute Wernicke's encephalopathy to chronic Korsakoff's psychosis. The two conditions represent different stages of the same disease process. Pathological changes consist of hemorrhagic lesions in the peri-aqueductal grey matter and mamillary bodies. MRI may show lesions in the mamillary body, medial thalamus and peri-aqueductal grey matter. Wernicke's encephalopathy consists of acute or subacute onset of the clinical triad of *confusion*, *ophthalmoplegia* and *truncal ataxia*. Oculomotor abnormalities consist of nystagmus, lateral rectus palsy and conjugate gaze palsy. In addition, hypothermia and postural hypotension may occur. Treatment consists of parenteral thiamine 50-100 mg given IM or IV in 5% glucose solution slowly. Effects are dramatic and ocular signs may resolve within hours. Apathy and lethargy improve over days and gait disturbance resolves slowly. If the condition is not detected in time and promptly treated, it may be fatal. In some patients, as global confusion state recedes, selective impairment of learning and memory become prominent, characteristic of Korsakoff's psychosis.

The amnesic syndrome of Korsakoff's psychosis is characterized by impairment of memory out of proportion to other cognitive domains. Patients have anterograde and retrograde amnesia, with preservation of immediate and remote memory, disorientation to time and place and confabulation to fill up the gaps in the memory. The syndrome may improve with thiamine, but, only partially.

Abstinence from alcohol, avoidance of smoking and nutritional improvement serve to prevent relapse.

Other Nutritional Deficiencies

1. **Pyridoxine (vit. B₆).** Its deficiency produces polyneuropathy. It is commonly seen as a complication of therapy with isonicotinic acid hydrazide (INH) in marginally nourished individuals.
2. **Burning feet syndrome Syn. Gopalan's syndrome**
This syndrome is named after C Gopalan the eminent nutrition scientist from India. Patients experience burning pain in the feet, especially during night, interrupting sleep. Examination may reveal pallor, cyanosis, excessive sweating and areas of capillary dilation over both feet.

A third of these patients may show loss of sensation over these areas. More often, hyperalgesia may occur. Deficiencies of vitamin B factors and proteins and possibly toxic factors in old polished rice are considered as potential etiologic factors. Most of the patients respond dramatically to injections of pantothenic acid suggesting that this deficiency plays a major role in the pathogenesis of this syndrome.

3. **Strachan syndrome** was first described amongst sugarcane workers in Jamaica and consists of painful peripheral neuropathy, ataxia, optic neuropathy and stomatitis. Patients may also develop sensorineural deafness, spasticity, dizziness and confusion. It is most commonly seen in the setting of poor nutrition associated with famines or incarceration as prisoners of war. More recently, an outbreak resembling Strachan's syndrome occurred in Cuba following loss of food and fuel imports. The exact cause is not known, though postulates put forward include vitamin B deficiency and cyanide toxicity. Most patients respond to supplementation of B-complex vitamins.
4. **Protein energy malnutrition:** The human brain shows developmental spurt from 13th week of gestation and growth continues for about 3 to 4 years after birth. The major events during this critical period include proliferation of neurons and glial cells and myelination of nerves. These processes are mainly dependent upon proper nutrition of the mother and infant among other factors. Severe malnutrition (protein and energy) occurring during fetal life and in the early part of infancy may leave behind damage which may not be correctable with subsequent therapy. Children manifest with apathy, irritability, delayed acquisition of mental and fine motor skills, clumsiness, generalized muscle wasting, hypotonia and hyporeflexia. Neuropsychological changes are more profound in Kwashiorkor. Twenty five per cent of children with protein energy malnutrition may show

subtle cerebral atrophy. During the first few weeks of starting protein re-feeding, some children with Kwashiorkor may develop encephalopathy ranging from mild drowsiness to rigidity, myoclonus, coarse tremors and rarely coma, known as **nutritional recovery syndrome**. As the problem of infant malnutrition is closely linked with socioeconomic and geographic factors, it is of utmost public health importance to ensure proper nutrition during pregnancy and infancy

Nutritional Amblyopia

Visual disturbances may develop due to deficiency of multiple nutrients, including vitamin B factors. This sets in insidiously with dimness of vision, photophobia, and retrobulbar discomfort on moving the eyes. Visual acuity is reduced. Central or paracentral scotomas develop, but the peripheral fields of vision may remain intact.

Infections of the Central Nervous System

Jalesh N. Panicker, P.K. Mohan,
K.V. Krishna Das

Chapter Summary

Bacterial Meningitis	1227
Neurosyphilis	1228
Meningovascular Disease	1228
Parenchymal Disease	1230
Brain Abscess	1231
Tuberculosis (TB) of the CNS	1233
Viral Encephalitis	1234
Japanese Encephalitis (JE)	1235
Slow Virus Infections	1235
Subacute Sclerosing Panencephalitis (SSPE)	1235
Progressive Multifocal Leukoencephalopathy (PML)	1235
Slow Infection by Prions	1236
Creutzfeldt-Jakob Disease (CJD)	1236
New Variant CJD (vCJD)	1236
Kuru	1237

Nervous system is commonly affected by infections. The nervous system may be the primary target of infection, e.g. Herpes simplex encephalitis, rabies or purulent meningitis. On the other hand, it may be affected secondary to systemic infections, in which case the neurological lesions develop as part of the systemic manifestation of disease, e.g. encephalopathy complicating enteric fever.

The clinical presentations of various infections are distinct and identification of the pattern of clinical presentation helps in diagnosis and management (Table 188.1). Meningitis affects the leptomeninges and presents with the classical triad of fever, headache, vomiting. Depending on duration of symptoms, meningitis may be acute or chronic. Encephalopathy, characterized by altered level of sensorium and seizures, is characteristic of encephalitis where there is direct involvement of brain parenchyma. Infections causing focal structural brain parenchymal damage present with focal neurological deficits such as hemiplegia or aphasia. Infections affecting the spinal cord present with myelopathy. Rarely, CNS infections can present with chronic behavioral disturbances and dementia when the parenchyma and/or the vasculature is affected.

Bacterial Meningitis

Bacterial meningitis is the condition characterized by inflammatory response to bacterial infection of the leptomeninges. Likelihood of infection with a specific pathogen depends upon the age, immune status and any focus of sepsis in the patient. *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Neisseria meningitidis* account for 80% of cases of acute purulent meningitis. In pre-term and neonate babies group B streptococcus is most common. Next in frequency are coliform bacilli especially those possessing K₁ antigen. Other organisms include Klebsiella, Enterobacter, Salmonella, Listeria and others. Tuberculosis, cryptococcosis other fungal infections account for the majority of chronic meningitis.

TABLE 188.1

Classification of infections of the CNS based on clinical presentation

ACUTE MENINGITIS
Bacteriae <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> , <i>Haemophilus influenzae</i> , <i>Staphylococcus aureus</i> , <i>Listeria monocytogenes</i> , gram-negative bacilli, <i>Leptospira interrogans</i> , <i>Mycoplasma pneumoniae</i>
Viruses Coxsackie virus, echovirus, mumps, arbovirus, herpes, HIV
CHRONIC MENINGITIS
Bacteria Partially treated bacterial meningitis, <i>Mycobacterium tuberculosis</i> , <i>Treponema pallidum</i>
Fungus <i>Cryptococcus neoformans</i> , aspergillus, candida
Parasite Cysticercosis, toxoplasma, amebae
FOCAL NEUROLOGICAL DEFICIT
Abscess Brain abscess, subdural empyema, epidural abscess
Granulomas Tuberculoma, cysticercosis, fungal infections
Toxoplasma
Echinococcosis
Complication of meningitis: Arteritis, infarction
Focal encephalitis
ACUTE ENCEPHALOPATHY
Herpes simplex Arboviruses: Japanese B, West Nile, Kyasanur forest disease Enteroviruses, Varicella zoster Mumps Rabies Dengue
MYELOPATHY
Viruses Varicella zoster, Herpes simplex, rabies, cytomegalovirus, Japanese B
Bacteria Pyogenic abscess
Granuloma Tuberculoma, cysticercosis
Dementia Subacute sclerosing panencephalitis (SSPE) Prion diseases - kuru, Creutzfeldt-Jakob disease, variant BSE Neurosyphilis HIV associated dementia

The details of the organism, pathogenesis and clinical features are described in Section 6 Chapter 37.

Lumbar puncture is the investigation of choice and CSF pressure will be elevated (200-500 mm H₂O), protein content will be elevated (100-500 mg/dl or more), glucose will be reduced (< 40% of the serum glucose) and CSF will show marked pleocytosis (100-10000 leukocytes with 60% or more being neutrophil leukocytes). CSF Gram staining is positive in 60% and the organisms can be isolated in cultures in approximately 75%, if the CSF is collected and sent for culture ideally prior administration of antibiotics reduces the yield of CSF Gram staining and culture by 5-40%. Latex agglutination tests can detect antigens of the various pathogens.

Diagnostic workup includes evaluation for the source of bacterial infection such as otitis media, pneumonia, or any extracranial communications of CSF as in CSF rhinorrhea and otorrhea secondary to bone defects. Differential diagnoses include viral and tuberculous meningitis and febrile encephalopathies due to systemic infections. Antibiotic use is guided by the clinical setting (Table 188.2).

Dexamethasone should be started early along with the appropriate antibiotics.

Neurosyphilis

(See also Chapter 47).
Involvement of the nervous system in syphilis used to be common before 1950s, but now it is distinctly uncommon to see fresh cases. Neurological involvement occurs in 4% of untreated cases of syphilis. Men are affected 4-5 times more commonly than women. Along with the AIDS pandemic, syphilis has assumed greater importance since it predisposes to AIDS infection and the two diseases influence each other to causes greater severity. Neurological lesions are caused by direct invasion of the tissues by *Treponema pallidum*. Meningovascular involvement is more common in India, constituting 60-70% of cases (Table 188.3).

MENINGOVASCULAR DISEASE

Cerebral Involvement

Leptomeningitis is the common lesion, affecting the pia and arachnoid mater. It develops 2-7 years after primary infection, most often between the ages 18-40 years. Meningitis is most often seen at the base of the brain and over the cerebral hemispheres. Basal meningitis may involve the lower cranial nerves, leading to multiple cranial nerve palsies, and occlude the fourth ventricle outlet foramina, leading to obstructive hydrocephalus. Vascular lesion is endarteritis obliterans, characterized by vascular intimal thickening and infiltration of the arterial

TABLE 188.2

Antibiotic recommendations for specific pathogens

Clinical setting	Empirical therapy	Organism	Specific therapy
Age < 3 months	Ampicillin + gentamicin or Ampicillin + 3rd generation cephalosporin*	Group B <i>Streptococcus</i> <i>Enterobacteriaceae</i> <i>L. monocytogenes</i>	Ampicillin + gentamicin 3rd generation cephalosporin + aminoglycosides Ampicillin + gentamicin
3 months - 18 years	3rd generation cephalosporin	<i>N. meningitidis</i> <i>S. pneumoniae</i> <i>H. influenzae</i>	Benzyl penicillin Benzyl penicillin or 3rd generation cephalosporin 3rd generation cephalosporin or ampicillin + chloramphenicol
18 years – 50 years	3rd generation cephalosporin	<i>S. pneumoniae</i>	Benzyl penicillin or 3rd generation cephalosporin Alternatives –vancomycin + 3rd generation cephalosporin Rifampicin may be added to vancomycin
> 50 years	Ampicillin+ 3rd generation cephalosporin	<i>S. pneumoniae</i> <i>L. monocytogenes</i> Gram-negative bacilli	As above
Head trauma / neurosurgical procedure	Vancomycin + ceftazidime	<i>Staph. aureus</i> <i>Staph. epidermidis</i> Gram-negative bacilli including pseudomonas <i>S. pneumoniae</i>	Vancomycin + oxacillin Ceftazidime + aminoglycoside As above
Immunocom- promised state	Ampicillin+ ceftazidime	<i>L. monocytogenes</i> Gram-negative bacilli <i>S. pneumoniae</i> <i>Staph. aureus</i>	As above
Setting of sinusitis, otitis	Vancomycin + ceftazidime + metronidazole	<i>S. pneumoniae</i> <i>H. influenzae</i> Gram-negative bacilli Anaerobes	As above

*3rd generation cephalosporins includes ceftriaxone and cefotaxime

TABLE 188.3

Involvement of the nervous system in syphilis

- I. Secondary syphilis—meningitis
- II. Asymptomatic stage
- III. Tertiary syphilis
 - a. **Meningovascular disease**
Cerebral involvement: Basal meningitis, pachymeningitis, vascular thrombosis, optic atrophy, gumma
Spinal cord involvement: Meningomyelitis, Erb's spastic paraplegia, cervical pachymeningitis, syphilitic amyotrophy, radiculitis, gumma
 - b. **Parenchymal disease**
Cerebral involvement: General paralysis of the insane (GPI)
Spinal involvement: Tabes dorsalis
Optic nerve involvement: Optic atrophy
- IV. Congenital syphilis—Meningovascular disease, optic atrophy, deafness, general paralysis of the insane, tabes dorsalis

Granulomatous changes are also seen in the vessel wall. Less commonly, the dura mater over the cerebral hemispheres may be involved by the granulomatous process, leading to its thickening, called as *cerebral pachymeningitis*.

Syphilitic basal meningitis leads to subacute or chronic meningitis characterized by headache, cranial nerve palsies, raised intracranial tension and signs of meningeal irritation. CSF shows elevated proteins and lymphocytic pleocytosis. CSF sugar and chloride levels are normal. CSF serology for syphilis is positive.

Cranial pachymeningitis causes headache, seizures and focal neurological deficits such as aphasia or hemiparesis.

Syphilitic endarteritis used to be one of the common causes for occlusive stroke in the young. Patients present as cerebral thrombosis with hemiplegia. Lower motor neuron facial palsy and even trigeminal neuralgia may occur. The prognosis for recovery is good if the condition is diagnosed and treated early.

wall by lymphocytes and plasma cells. Thrombosis supervenes and this occludes the arterial lumen.

Spinal Involvement

Meningomyelitis: This gives rise to the picture of acute transverse myelitis or varying degrees of cord compression with root pains. In Erb's syphilitic paraplegia, spastic paraplegia develops with bladder dysfunction; sensory symptoms are rare.

Hypertrophic cervical pachymeningitis: Compression of the cervical roots leads to root pain, weakness and wasting of the upper limb and shoulder girdle muscles or quadriparesis.

Such a picture is also referred to as *syphilitic amyotrophy*.

The cauda equina may also be involved leading to root pain, areflexia, weakness and wasting affecting the thighs and legs.

PARENCHYMAL DISEASE

Cerebral Involvement

General Paralysis of the Insane (GPI)
Syn Dementia paralytica

GPI develops 15-20 years after the primary infection. Men above 40 years are more affected. The frontal and temporal lobes of the brain show cortical atrophy with gliosis. The meninges show thickening and lymphocytic infiltration. Ventricles show dilation and ependymitis. In about 50% of cases the organism (*T. pallidum*) can be demonstrated in brain biopsy.

Clinical features are characteristic. Higher mental faculties deteriorate gradually, leading to reduction in intellectual capacity, loss of memory and personality changes. Patients lack judgment and insight. Euphoria, loss of inhibition, as revealed by abnormal social behaviour, depression or mania may develop. Less commonly, grandiose delusions may be the prominent features. Around 50% of cases show *Argyll Robertson pupil* characterized by small irregular pupils with loss of light reflex, but preservation of the accommodation reflex. Optic atrophy occurs in 5-10% of cases and seizures develop in 50%. Limbs, lips and tongue may be tremulous and the to and fro movements of the tongue are described as "*trombone tremor*" since it bears similarity to the movements of the musical instrument trombone.

Vascular episodes occur from time-to-time. These manifest as focal neurological deficits such as hemiparesis, dysphasia or hemianopia. These recover spontaneously. The course of the disease is one of gradual progression with fluctuations, finally proceeding to incapacitation.

SPINAL INVOLVEMENT

Tabes Dorsalis

This form of parenchymal neurosyphilis is less common than GPI. It develops 25-30 years after the primary infection. Males are affected five times more frequently than females. Primary damage is in the dorsal root ganglia and is characterized by inflammation. Later, the posterior roots and posterior columns of spinal cord undergo atrophy.

Initial symptoms are pain and paresthesia of the limbs. As the condition progresses, sensory ataxia sets in. Clinical features include loss of joint and position sense and vibration perception. Gait is stamping in quality. Lower limb areflexia is common and the ankle reflex is abolished before knee reflex. Limbs are hypotonic. Romberg's sign is positive. Argyll Robertson pupil may be present. Optic atrophy occurs in a few cases. There is loss of deep pain sensation. This is elicited by squeezing the tendo-Achilles which normally causes pain, but in tabes dorsalis it does not elicit pain (*Abadie's sign*). Testicular sensation is also lost. Some patients reveal loss of touch and delay in the appreciation of pin-prick over the central parts of the face, ulnar border of the hands, distal parts of the legs, perianal region and over the chest.

Autonomic disturbances are characteristic. Bladder sensation is lost early and atonic distension of the urinary bladder and urinary incontinence may develop. Impotence occurs early. Partial ptosis develops due to sympathetic dysfunction and paralysis of Muller's muscle of eyelid. Many patients overcome the disability caused by partial ptosis by tilting the head backwards and wrinkling the forehead. This appearance is described as **tabetic facies**. Due to loss of trophic influences, the major joints develop painless swelling and undergo degenerative changes, called **Charcot's joints**. Painless trophic ulcers develop on the feet and other areas of pressure.

The course of the disease is often disturbed by the occurrence of **lightning pains**, which are unique for tabes dorsalis. These are lancinating pains occurring in transverse directions in the limbs, chest and face. Lightning pains differ from neuralgic pains in that the former do not follow the direction of nerve roots. Visceral crises develop frequently. Gastric crisis is characterized by severe epigastric pain and vomiting. Rectal crises give rise to tenesmus. Stridor develops as a result of laryngeal crisis.

OPTIC ATROPHY

Optic nerve involvement may result from meningo-vascular or parenchymal involvement. Former leads to arachnoiditis, optic neuritis or retrobulbar neuritis. Changes occur early during the tertiary stage of syphilis. At this stage, specific treatment may help to reverse the

condition. Optic atrophy due to parenchymal involvement occurs during the late stages.

CONGENITAL NEUROSYPHILIS

Stigmata of congenital infection with *T. pallidum* may be present at birth and include hydrocephalus, mental retardation, seizures, chorioretinitis, optic atrophy and sensorineural deafness. These may be associated with other evidence of congenital syphilis. Neurological involvement developing later in congenital syphilis may take the form of meningovascular lesions, optic atrophy, tabes dorsalis or GPI. Parenchymal lesions occur at a younger age (juvenile GPI, juvenile tabes dorsalis).

GUMMA OF THE CENTRAL NERVOUS SYSTEM

Gumma occur in tertiary syphilis. Pathologically the gumma consists of collagen deposition forming an amorphous matrix with lymphocytes and plasma cells at the periphery and multinucleated giant cells in the center. Later the lesions undergo fibrosis *T. pallidum* is not demonstrable in these lesions. Gumma may be seen in the cranium, dura, leptomeninges, cerebrum and spinal cord where they behave as space occupying lesions. Response to treatment is poor.

Syphilitic Deafness

Deafness may result from several mechanisms in the different stages of syphilis. It may result from affection of the cochlea, acoustic nerve, basal meninges or damage to the middle ear.

DIAGNOSIS

Neurosyphilis should be considered in the differential diagnosis of many neurological disorders. GPI should be differentiated from cerebrovascular disease, primary dementias, intracranial space occupying lesions and progressive degenerative disorders. Tabes dorsalis should be considered in the differential diagnosis of diabetic, toxic and nutritional neuropathies, hereditary ataxias and syringomyelia. Presence of **Argyll Robertson pupil** is a strong point to support the diagnosis of neurosyphilis.

Laboratory diagnosis: Blood serology is positive in 60-70% of cases. CSF analysis shows lymphocytic pleocytosis and elevated protein content. Neurosyphilis is confirmed by a positive CSF VDRL along with a positive serum FTA ABS or *T. pallidum* immobilization test. Clinical features should also be supportive. CSF abnormalities are positive especially in the early stages of meningovascular disease. Previous therapy with penicillin may mask the CSF changes.

PROGNOSIS

Meningovascular disease has the best outcome. Early cases of GPI may also show improvement. However,

results are poor in established cases of tabes dorsalis and optic atrophy.

TREATMENT

This is described in Chapter 47 As benzyl penicillin penetrates into the CSF, it is the drug of choice for neurosyphilis. Repeated courses of penicillin may be required and this has to be decided depending upon blood and CSF serology. Tabetic pains may respond to analgesics and carbamazepine. Visceral crises are treated by sedation and supportive measures.

Follow-up lumbar punctures are required to assess response to therapy.

Brain Abscess

Focal suppuration followed by loculation of pus within the brain parenchyma is called brain abscess. Despite advances in neurodiagnostic techniques, neurologic practice and antimicrobial therapy, diagnosis and management of brain abscess remains a challenge to the physician and surgeon even today.

Pathogenesis

The healthy brain resists the development of an infective focus within its substance even if bacteria gain entry into it. For suppuration to happen within the brain parenchyma, there should be:

1. An area of pre-existing brain damage.
2. Entry of infective organisms into that region.

Several conditions lead to such brain damage. These include:

1. Cortical thrombophlebitis resulting from the spread of infection from contiguous suppurative lesions such as otitis media, sinusitis or cranial osteomyelitis.
2. Septic or even sterile emboli.
3. Hypoxic or ischemic brain damage.

Infection supervening on such damaged neural tissue leads to abscess formation. Typically, the evolution of brain abscess passes through four stages:

1. The first stage is focal cerebritis of the white matter and edema around it.
2. In the second stage the focal cerebritis enlarges with central necrosis and early formation of a peripheral capsule.
3. The third stage is one of further developments of the capsule.
4. The fourth stage is one of capsular maturation. Depending on the virulence of the causative organism and immune status of the host, it may take three weeks or even longer for the brain abscess to mature.

Predisposing Conditions

1. Extension of infection from suppurative foci such as otitis media and mastoiditis (otogenic brain abscess) or sinusitis (rhinogenic brain abscess).

- 2. Spread of infection from a distant focus in the body such as lung abscess, empyema, infective endocarditis, dental sepsis, pelvic sepsis and congenital cyanotic heart disease (hematogenous brain abscess).
- 3. Introduction of infection from outside as in the case of head trauma (post-traumatic brain abscess) or during a surgical procedure in and around the head (iatrogenic brain abscess).

However, in a quarter of patients no predisposing factor may be evident (cryptogenic brain abscess).

There is generally a relationship between the primary site of infection, location of abscess in the brain and the causative organism:

Type of brain abscess	Location in brain	Causative organism
Otogenic	Temporal lobe Cerebellar hemisphere	<i>Streptococcus</i> <i>Bacteroides</i> Enterobacteriaceae <i>Staph. aureus</i>
Rhinogenic	Frontal lobe Temporal lobe	Same as above
Hematogenous	Gray and white matter junction	<i>Staphylococcus</i> <i>Str. viridans</i> Anaerobes <i>H. influenzae</i> Other gram-negative bacteria in case of cyanotic congenital heart disease
Post-traumatic Post-surgical	Near site of entry	<i>Staph. aureus</i> Enterobacteriaceae

In immunocompromised individuals, opportunistic infections due to low virulence bacteria may cause abscess formation. Apart from pyogenic bacteria, nocardia, toxoplasma and mycobacteria may rarely be the etiological agents. In over 75% of cases, only one pathogen may be present whereas in about 25% the microbial flora may be mixed.

Clinical Features

Typically, patient with brain abscess has a combination of:

- 1. Signs of infection.
- 2. Focal neurological signs which depend on the site and size of the abscess.
- 3. Raised intracranial pressure.

However, this classic picture is seen in only about 50% of patients. Absence of fever and acute phase reactants should not exclude brain abscess from the differential diagnosis of patients presenting with an intracranial space occupying lesion. Seizures, which may be focal or secondarily generalized, occur in majority of patients. Brain abscess may frequently present as a

Fig. 188.1: Contrast enhanced CT scan brain showing left cerebellar abscess—arrow

neurological emergency because of complications such as brain herniation.

INVESTIGATIONS

Whenever brain abscess is suspected, investigations are prioritized to confirm the diagnosis, identify the organism and detect any possible source for infection. Diagnosis can be established in almost all cases by CT scan, which should be done at the earliest and repeated if needed for follow-up. Mature brain abscess has a ring like appearance in contrast enhanced CT, due to capsule formation (Fig. 188.1). However in the earlier stages of infection, only a non-enhancing, hypodense area may be seen with surrounding brain edema. MRI is more sensitive than CT in identifying early stages of cerebritis. Attempts to isolate the infecting organism and establish its drug sensitivity should be undertaken depending on the individual case.

The organism can be identified and drug sensitivity ascertained by culturing specimens obtained from the primary focus of infection, blood or direct aspiration of pus from the abscess through a burr hole under CT scan guidance.

Lumbar puncture should not be routinely carried out when brain abscess is suspected or confirmed on CT or MRI because of the risk of brain herniation leading to deterioration of the neurological status or death. Moreover, CSF may not show diagnostic changes unless brain abscess is associated with ventriculitis or meningitis.

Complications

Rupture of the brain abscess into the cerebral ventricles may lead to ventriculitis and meningitis. Brain herniation due to raised intracranial pressure may occur leading to cardiovascular and respiratory compromise. Seizures may occur during the course of the disease or may develop much later as a result of scar formation. Brain abscess is fatal unless treated promptly. With early diagnosis and prompt treatment, full recovery is the rule in most cases.

Management

Specific Therapy

Early institution of antibiotics is the most important factor that predicts good outcome. Antibiotics are the mainstay of management , especially if abscesses are multiple and deep. The choice of antibiotics is initially empirical. A combination of penicillin 24 million units per day and chloramphenicol 0.5 g I.V. 6 h or penicillin/ 3rd generation cephalosporin and metronidazole 0.5 g I.V. 6 h has broad spectrum coverage and is sufficient as empirical therapy. Modifications should be made based upon the culture and sensitivity report. Antibiotic therapy should be continued for at least six weeks or even longer. Clinical improvement should be correlated with microbiological tests and repeat CT scans.

Anticerebral Edema Measures

Infusion of 200 ml of 20% mannitol rapidly over a period of 15 minutes helps to bring down the intracranial tension temporarily. Dexamethasone given in a dose of 4-8 mg I.V. 6h intravenously after instituting antibiotic therapy effectively lowers intracranial tension and cerebral edema.

Antiepileptic Drugs

Phenytoin and phenobarbitone are the usual medications and should be given after a loading dose. The drugs have to be given parenterally in the acute stage and later may be given orally. Prophylactic use of anti-epileptic drugs is however controversial.

Surgery

Surgical procedures include:

- 1. Aspiration of the pus with antibiotic instillation locally.
- 2. Excision of the abscess.

Decision regarding surgical intervention depends on the individual case. Indications for surgery can be diagnostic or therapeutic. Surgical procedures are prefer-

red in cases of post-traumatic, gas containing, multilobulated or fungal abscesses or if neurological status is deteriorating. Medical management is preferred:

- 1. In patients with multiple deep abscesses,
- 2. Location at important areas of the brain such as motor cortex or language areas,
- 3. Size less than 3cm and abscesses that shrink after antibiotics,
- 4. During the stage of early cerebritis, and
- 5. In cases of simultaneous meningitis or ependymitis.

In the case of rhinogenic or otogenic abscesses, the primary source should also receive proper attention in order to hasten recovery and prevent recurrence.

Prevention

Prompt treatment of infections such as mastoiditis, otitis media, sinusitis, dental sepsis and lung abscess helps to prevent the development of brain abscess. In subjects with congenital cyanotic heart disease, incidence and mortality due to brain abscess is high. Neurological manifestations in such patients may also be atypical. A high index of suspicion is required for early diagnosis in such patients.

Tuberculosis (TB) of the CNS

Tuberculosis (TB) of the CNS constitutes 10-15% of all cases of extrapulmonary TB. A general account of TB is given in Section: 6 Chapter: 49. Manifestation of tuberculosis in the nervous system includes:

- 1. Tuberculous meningitis.
- 2. Tuberculous arachnoiditis: optochiasmatic, basal, spinal.
- 3. Tuberculoma: Cerebral, spinal.
- 4. Tuberculous abscess.
- 5. Tuberculous encephalopathy.

Tuberculous meningitis (TBM) accounts for 70-80% of all the cases of CNS tuberculosis and is the commonest cause for chronic meningitis in India. It presents as subacute onset fever, headache and vomiting with signs of meningeal irritation of 2-6 weeks duration.

Table 188.4 gives the potential complications due to tuberculous meningitis.

TABLE 188.4
Complications of tuberculous meningitis
Raised intracranial tension
Cranial nerve palsies: 6th, 3rd or other cranial nerves
Hydrocephalus: Communicating and noncommunicating
Arteritis
Tuberculoma/tuberculous abscess
Spinal block
Syndrome of inappropriate antidiuretic hormone (SIADH)

Fig. 188.2: Contrast enhanced MRI scan of a patient with TBM showing enhancement in the basal cisterns, suggestive of exudates

Diagnosis

The clinical diagnosis of TBM should be confirmed by CSF examination. X-ray chest may show evidence of concomitant pulmonary tuberculosis in 25-50% of adults and 50-90% of children. CT or MRI scan can demonstrate direct or indirect evidence for tuberculous meningitis such as contrast enhancement in the cisterns due to exudates. Figure 188.2 hydrocephalus, arteritis and tuberculomas.

CSF analysis is essential for diagnosis. Demonstrating acid-fast bacilli by microscopy and/or isolation by culture from CSF is the gold standard in the diagnosis of TBM. However, as TBM is a paucibacillary state, demonstration of *Mycobacterium tuberculosis* is often a challenge and hence several techniques have been developed to facilitate the diagnosis of TBM. Table 188.5 gives the CSF changes

TABLE 188.5

CSF findings in TBM

<i>Appearance:</i> Hazy or xanthochromic, presence of cob web formation
<i>Routine analysis:</i> Elevated protein, reduced sugar and lymphocytic pleocytosis
<i>Microbiological techniques:</i> Demonstration of acid-fast bacilli in CSF smears, isolation in solid media such as Lowenstein–Jensen medium
<i>Molecular technique:</i> Polymerase chain reaction (PCR) technique
<i>Immunological techniques:</i> Detection of mycobacterial antibodies, antigens, immune complexes
<i>Radiometric technique:</i> BACTEC technique
<i>Biochemical techniques:</i> Adenosine deaminase, detection of tuberculostearic acid by HPLC

and possible investigations in a suspected case of TBM.

Treatment involves using 3-4 first line antituberculosis medications for 9-18 months. Drug penetration into the CSF is maximal for INH, pyrazinamide, streptomycin and ethambutol. Corticosteroids play an important role by reducing inflammation, edema and fibrous tissue formation.

Viral Encephalitis

Encephalitis is most commonly due to viral etiology. Present epidemiological studies suggest that in India, herpes simplex and Japanese encephalitis are commonest, though other viruses such as rabies, mumps, West Nile, enterovirus, Kyasanur forest disease and Chandipura viruses are also responsible.

Herpes Simplex Encephalitis

HSV-1 encephalitis is the commonest cause for sporadic fatal encephalitis. HSV-1 is acquired by respiratory droplets or salivary contact. However in majority of cases, encephalitis is a consequence of reactivation and centripetal spread of latent virus in the trigeminal ganglion. Patients present with fever and headache along with behavioral changes, memory impairment, aphasia and focal neurological deficits. Subsequently, recurrent tonic clonic and complex partial seizures and altered sensorium dominate the picture. Diagnosis is established by CSF study that demonstrates lymphocytic pleocytosis, red blood cells, elevated protein content, normal or reduced glucose and detection of HSV DNA by PCR (sensitivity 95%, specificity 100% in first 2 weeks) or antibodies to HSV-1. EEG shows focal slowing or periodic lateralised epileptiform discharges (PLEDs). MRI

Fig. 188.3: MRI scan showing lesions in left temporal lobe in a patient with herpes simplex encephalitis—arrow

shows changes in mesial temporal lobe, insula and cingulate gyrus (Fig. 188.3).

Herpes simplex virus is the only viral encephalitis amenable to treatment and early treatment with acyclovir 10 mg/kg intravenously every 8 hours for 14 days reduces mortality from 70% to 20%. Vidarabine can also be given especially in cases of relapse (See Chapter 53).

Japanese Encephalitis (JE)

JE is the leading cause for epidemic encephalitis. Children are generally affected. Incubation period is 1-6 days after mosquito bite. Patients present with fever, headache, altered sensorium and recurrent seizures. Parkinsonism, dystonia or dyskinesias may develop during the illness or as sequelae. CSF shows lymphocytic pleocytosis, elevated protein content and IgM antibodies against JE virus. No specific therapy is available. MRI may show bilateral thalamic and basal ganglia changes. Eradication of vector and initiation of vaccination programmes can control the spread of JE. Ref: Section:6 for further details (See also Chapter 60).

Slow Virus Infections

Slow infections are persistent infections of the central nervous system where the infecting agent is capable of remaining dormant for long periods of time producing inflammatory or degenerative damage over several years. These are characterized by:

- a. Long period of latency lasting for several months to even years.
- b. Protracted course, usually ending in severe illness or death, and
- c. Limitation of the infection to a single host species and anatomical lesions in only a single organ system.

The following two groups are distinguishable according to the infecting agent:

1. **Slow infections by conventional viruses:** This group is caused by conventional viruses and is characterized by progressive encephalopathy following covert or overt infection by these viruses. These include subacute sclerosing panencephalitis (SSPE) caused by modified measles virus, progressive rubella panencephalitis (PRP) caused by rubella virus and progressive multifocal leukoencephalopathy caused by JC virus.
2. **Slow virus infections by unconventional viruses:** The second group, is caused by unconventional infective agents called prions, many of which may exhibit only a protein moiety of virus without the nucleic acid part.

TABLE 188.6	
Modified Jabbour's clinical staging of SSPE	
Stage 1	Cognitive deterioration, behavioural changes
Stage 2	Stereotyped, repetitive slow myoclonic jerks, choreathetosis, ataxia, seizures
Stage 3	Decerebration, decortication, autonomic instability
Stage 4	Bedridden, mute

SUBACUTE SCLEROSING PAN-ENCEPHALITIS (SSPE)

SSPE is a slowly progressive inflammatory disease caused by the modified measles virus. SSPE develops as sequelae to early measles infection, usually within the first two years of life, though the history of measles infection may be obtained in only one-half to two-thirds of SSPE patients. Occurrence of measles below one year of age is associated with higher risk of developing SSPE. Usual incubation period is 6-8 years following on overt clinical measles infection. Most frequent age group affected is 5-15 years. Clinical features are grouped into four stages (Table 188.6).

Patients may develop papilledema, optic atrophy and choreoretinitis. Progression of illness is subacute in 80% of patients and is fatal within 1-3 years. In 10%, the disease is fulminant and fatal within 3 months while in another 10%, it slowly evolves over 4-8 years. Diagnosis is essentially clinical and EEG shows typical periodic complexes characterized by repetitive discharges of high amplitude slow waves followed by spells of relatively flat patterns. CSF shows elevated protein concentration with normal sugar and cells. Raised anti-measles antibody titers by ELISA of 1:4 or greater in CSF is considered diagnostic. Treatment is generally unsatisfactory though isoprinosine and interferon have been tried. Implementation of universal measles vaccination will minimize the incidence of SSPE (See also Chapter 53).

PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY (PML)

PML is a subacute multifocal demyelinating disease caused by an opportunistic virus, J.C. virus or rarely SV40. Incidence is rising because of the HIV/AIDS pandemic. It may occur in association with any disorder that impairs cellular immunity such as lymphoproliferative disorders, sarcoidosis, prolonged immunosuppression and inherited immunodeficiency states. It is characterized by cortical blindness, cerebellar ataxia, motor weakness, confusion, amnesia, speech abnormalities and later dementia. Headache and seizures are rare. MRI establishes the diagnosis and shows multifocal confluent asymmetric

lesions of the parieto-occipital cerebellar and brainstem white matter without mass effect or contrast enhancement. The virus typically affects the oligodendroglial cells and pathologically there are multifocal areas of demyelination in the subcortical white matter. Routine CSF studies are normal but JC virus DNA may be detected using PCR technique. In patients of HIV/AIDS, lesions of PML improve with commencement of HAART. Cytarabine and Interferon- α have been tried.

SLOW INFECTION BY PRIONS

Transmissible spongiform encephalopathies refer to subacute, fatal, transmissible neurodegenerative disorders characterized by spongiform encephalopathy due to accumulation of abnormal proteins in the CNS. Stanley Prusiner (Nobel Prize laureate for medicine, 1997) proposed that the infective agent consisted only of a protein moiety without DNA or RNA and named it “prion” or proteinaceous infectious particle. Prion protein is a normally found protease sensitive cellular protein of unknown function encoded by the PRNP gene on chromosome 20. In prion disease, the normal cellular protein (PrP^C) is converted to an abnormal protease resistant isoform (PrP^{SC}) by a change in physical conformation. PrP^{SC} has a tendency to aggregate, leading to neuronal death. Four cardinal features of prions are:

- 1. At present prions are the only known infectious agents devoid of nucleic acid. All other known pathogens contain genomes containing either RNA or DNA which direct the synthesis of their progeny.
- 2. Prion disease may manifest as infections, genetic or sporadic disorders. This wide spectrum of pathogenesis is not possessed by other pathogens.
- 3. Prion diseases result from the accumulation of PrP^{SC} which has a substantially different conformation than PrP^C.
- 4. PrP^{SC} can have different conformations and depending upon this, the pathogenesis varies.

It is not known how a particular conformation of PrP^{SC} is produced, nor the factors which determine the localization in the CNS where PrP^{SC} gets deposited.

Prions are resistant to alcohol, formalin, ionizing radiations, proteases and nucleases which inactivate ordinary viruses. Prions are inactivated by methods which disrupt proteins such as autoclaving, exposure to detergents or extremes of pH changes.

Prions are resistant to the usual antiviral drugs. They do not evoke antibody response. The lesions caused by them are not inflammatory in nature.

For example, Kuru, Creutzfeldt-Jakob disease and others.

Though commonly presenting as a sporadic disease, prion diseases may manifest as a familial disease due to

TABLE 188.7

Prion diseases in humans
Creutzfeldt-Jakob Disease (CJD)
Kuru
Fatal familial insomnia (rare)
Gerstmann-Straussler-Scheinker disease (rare)

TABLE 188.8

Modes of transmission of CJD

Familial (10%): PRNP gene mutations
Iatrogenic: Neurosurgical procedures, dura mater grafts, cadaveric pituitary hormone extracts, corneal transplant
New variant CJD

various genetic mutations. Pathology is characterized by neuronal loss, gliosis and striking vacuolation or spongy state of affected areas (hence termed spongiform encephalopathy) with sparse inflammatory response. Table 188.7 gives the spectrum of human prion diseases.

Creutzfeldt-Jakob Disease (CJD)

Commonest of human prion diseases, it is a rare cause for dementia. Modes of transmission are enlisted in Table 188.8.

CJD presents with deficits in concentration, memory, problem solving abilities, inappropriate behaviour and visual hallucinations. Ultimately, patient progresses to global dementia. Initial neurological deficits include cerebellar ataxia and cortical blindness and with time, patients develop classical myoclonic jerks, extrapyramidal deficits, choreoathetosis and distal wasting and areflexia. Rarely, cerebellar ataxia (Brownell-Oppenheimer variant) or cortical blindness (Heidenhain variant) may precede cognitive and behavioral changes and may be the most prominent features. Diagnosis is facilitated by EEG, which shows periodic generalized sharp wave complexes and triphasic waves. CSF is usually normal, though protein concentration may be elevated. Immunoassay that detects a class of 14-3-3 proteinase inhibitor proteins released from damaged neurons into the CSF has sensitivity and specificity exceeding 90% and is available only at reference laboratories. MRI may show cerebral atrophy and symmetric lesions in bilateral basal ganglia. No specific treatment is known. Average time for survival is 4-6 months.

New Variant CJD (vCJD)

Recently, a CJD like illness has been reported in young individuals (mean age 28 years) characterized by psychiatric or sensory symptoms from Britain and other European countries. The illness progresses slowly and EEG changes are nonspecific. It has been associated with consumption of beef from cattle afflicted with bovine spongiform encephalopathy (mad cow disease). The source of infection of cattle in the UK is believed to be animal feeds produced from imported bones and animal carcasses from several countries. It is likely that the animal products would have been contaminated by human tissues as well. The diagnosis may be established by tonsillar biopsy. MRI shows thalamic lesions especially in the pulvinar. The epidemic has been controlled by removing infected cattle in large numbers and avoiding the consumption of beef from possibly infected

sources. Since the incubation period of vCJD may go up to several years it is likely that more cases may show up in future also.

Kuru

This disease was first described in the local tribal women and children of the island of Papua New Guinea. It is thought to be transmitted by ritualistic cannibalism practiced there and is clinically characterized by dysarthria, tremors, cerebellar ataxia, behavioural changes and dementia which ends fatally within 3 to 9 months. Pathologically, there is marked hypertrophy and proliferation of astroglial cells and status spongiosus (vacuolation of neurons) particularly affecting the cerebellum. There is no inflammatory reaction and no demonstrable antibody response.

Dementias and Metabolic Encephalopathy

A.S. Girija, P.K. Mohan

Chapter Summary

- General Considerations 1237
- Alzheimer's Disease 1238
- Frontotemporal Dementia 1239
- Multi-infarct Dementia 1239
- Metabolic Encephalopathy 1239

General Considerations

Dementia is an acquired loss of cognitive (intellectual) functions due to an abnormal brain condition that leads to functional decline significantly interfering with work or usual normal activities. Three or more of the spheres of mental activity—namely, memory, language, visuo-spatial perception, praxis, calculation, semantic knowledge, executive function, personality and emotional expression are impaired. Failing memory and loss of other cognitive functions can result from multiple causes. In some the cognitive decline is progressive while in the others it is non-progressive. Dementia may be reversible or irreversible depending on its cause. Dementia may be the most prominent manifestation of many neurological diseases and it is rare to be the sole manifestation. Sometimes, depressed individuals appear to have cognitive impairment and slowed motor activity, but they

do not have true dementia. The term *pseudodementia* is used to denote such a condition. Patients with pseudodementia may not have symptoms of overt depression, but they have a flat affect and they tend to give up easily or fail to perform a task when their mental functions are being examined. They may exhibit changing patterns of mental deficits when subjected to repeated tests. This helps to differentiate pseudodementia from true dementia.

Delirium or acute confusional state has to be differentiated from dementia. Delirium can be distinguished from dementia by the following features:

1. Sudden onset
2. Altered consciousness
3. Disproportionately impaired attention and concentration
4. Fluctuations in cognitive function with lucid intervals
5. Psychomotor and autonomic overactivity, and
6. Hallucinations.

The Folstein's Mini Mental Status Examination (MMSE) is commonly used to screen for dementia and to grade the severity of dementia.

Causes of Dementia

1. Diseases where dementia is the only abnormality
 - a. Alzheimer's disease

- b. Pick's disease.
2. Diseases where dementia is associated with other neurological signs
 - a. Huntington's chorea
 - b. Leukodystrophy
 - c. Lipid storage diseases
 - d. Progressive myoclonic encephalopathy
 - e. Creutzfeldt-Jakob disease
 - f. Multiple cerebral infarctions (multi-infarct dementia) including cerebral vasculitis
 - g. Brain tumours
 - h. Subdural hematoma
 - i. Normal pressure hydrocephalus
 - j. Parkinsonism.
3. Diseases where dementia is a part of other systemic disorders
 - a. Hypothyroidism
 - b. Cushing's syndrome
 - c. Vitamin deficiencies (B_{12} , B_1 and B_6), Wernicke-Korsakoff's syndrome, pellagra and pernicious anemia
 - d. Neurosyphilis, neurotuberculosis, neurocysticercosis
 - e. Wilson's disease
 - f. AIDS
 - g. Chronic metabolic conditions—Chronic liver failure, renal failure, hyponatremia, hypercalcemia
 - h. Toxins—Lead, organic mercury and others.

A generalized reduction in the size of the brain occurs in old age and this may lead to mild senile dementia, which is known as *mild cognitive impairment*. In contrast, development of severe cortical atrophy in elderly age group (> 60 years) with progressive dementia is termed. Alzheimer's disease. Localized atrophy of the cerebral cortex with dementia, which may occur in the presenile age group (< 60 years) is known as frontotemporal dementia. Previously it was known as Pick's disease. Nearly 50% of dementias in the elderly is constituted by *Alzheimer's disease* and Frontotemporal dementia.

Alzheimer's Disease

This is one of the more common causes of dementia in adults. This usually occurs in the elderly. The onset of mental symptoms is so insidious that neither the family nor the patient can date its beginning. Day-to-day activities are forgotten and appointments not kept. The speech becomes discontinuous due to failure to recall the needed word. Simple calculations cannot be done. Visual-spatial disorientation soon sets in. The patient gets lost even along familiar routes. He forgets the use of common objects and tools. Later, social behaviour becomes changed. Stable marriages may be disrupted by sexual indiscretion. Difficulty in walking, with features of parkinsonism and

cerebellar ataxia appear. The legs may finally curl into paraplegia in flexion. Death occurs within a period of five or more years from the start.

Pathology

At autopsy the brain is atrophied. The atrophy is most prominent in the frontal and temporal lobes. Microscopically there are deposits of amorphous material scattered throughout the cerebral cortex, best seen by silver staining methods (senile plaques). Presence of fibre like strands of silver staining material in the form of loops and coils within the nerve cell cytoplasm (Alzheimer neurofibrillary tangles) and granulovacuolar degeneration of the neurons are the other remarkable pathological features. Extracellular amyloid fibrils consisting of 4-KD peptide, designated as beta amyloid protein (A4 protein) accumulate in cerebral and meningeal microvasculature. Other proteins involved in the plaques are presenilin 1 and 2, alpha-1 antichymotrypsin, apolipoprotein E(ApoE), alpha 2 macroglobulin and ubiquitin. Hyperphosphorylated tau protein and ubiquitin are found in the neurofibrillary tangles.

A subgroup of Alzheimer's disease has a genetic basis. Three to five percent of Alzheimer's dementia cases show autosomal dominant inheritance. Familial Alzheimer's disease shows abnormality in chromosome 21 and the gene for beta amyloid protein is situated on this chromosome. The gene for ApoE is situated on chromosome 19. ApoE can be used as a marker for Alzheimer's disease since it is absent in other dementias. Abnormalities in chromosomes 1 and 14 are also incriminated in familial, early onset Alzheimer's disease. The genes for presenilin 1 and 2 are located on these chromosomes respectively. The exact pathogenesis of the disease is not clear. It is possible that deficiency of choline acetyl transferase could be an important factor.

Role of viral and vascular causes have been suggested but not confirmed. Another mechanism recently implicated in the pathogenesis of Alzheimer's disease is dysregulation of apoptosis either by genetically determined processes or by subsequent mutation. This may result in premature degeneration of neurons with consequent dementia.

Investigations

These are aimed at identifying remediable causes. These include estimation of blood glucose, electrolytes, tests for hepatic and renal failure, thyroid function tests, serum levels of vit B_{12} , folate, homocysteine, antinuclear antibodies (ANAs), hexosaminidase levels and cortisol. HIV infection and neurosyphilis have to be excluded. Imaging studies such as MRI and PET and Doppler studies

to assess the extra- and intracranial circulation are indicated in cases of doubt.

Management

Tacrine was the earliest drug introduced for the treatment of Alzheimer's disease. It is an active noncompetitive inhibitor of acetylcholine esterase. Positive benefit occurs in 40% of cases. The drug is expensive and toxic. Main adverse effect is hepatotoxicity.

The less toxic anticholinesterase drug donepezil is effective, when given orally in doses of 5 mg daily for six weeks and followed up with 5 mg bid thereafter. This drug does not produce hepatotoxicity.

Other drugs include rivastigmine which can be given in all stages of the disease. It is an inhibitor of choline esterase action. It gives good symptomatic control of Alzheimer's disease. Galamine hydrobromide (galantamine) which acts on acetyl choline and nicotine receptors is beneficial in early cases.

Memantine-N-methyl D-aspartate (NMDA) receptor blocking agent is of use, in later stages, when given along with rivastigmine. NMDA is an excitotoxin.

Several other drugs such as dihydroergotamine mesylate, nicergoline and piraridil have been tried with varying results.

On account of the apparent increase in incidence of dementia in the aging population there is worldwide interest in the study of this disease and its management. Non-governmental organisations such as Alzheimer's societies are active in many parts of the world, including many towns in India.

Frontotemporal Dementia

Syn. Pick's lobar atrophy

Here the atrophy is limited to the frontal and temporal lobes with involvement of both grey and white matter. In contrast to Alzheimer's disease where the atrophy is diffuse and mild, here there is severe and localised brain atrophy. Clinically it is difficult to distinguish from Alzheimer's disease. However, focal disturbances appear to be more prominent in the former. The course of the illness is usually 2-5 years before the fatal outcome and there is no treatment except nursing care. Rarely the disease may show an autosomal dominant pattern. The proteins involved include ubiquitin and tau.

OTHER DEMENTING DISEASES

While Alzheimer's disease and fronto temporal dementia represent degenerative disorders where treatment is still unsatisfactory, there are other situations where reversible dementia occurs as a symptom of known diseases. These include hypothyroidism, brain tumour, subdural

hematoma, cryptococcosis, neurosyphilis, pellagra, other nutritional deficiencies, and normal pressure hydrocephalus. Specific neurological investigations like skull X-ray, EEG, CSF examination, CT scan and MRI can help to determine the particular disease.

MULTI-INFARCT DEMENTIA

This refers to impairment of intellectual functions due to multiple cerebral infarcts. In such cases, history of one or more strokes can usually be elicited. Multiple lacunae produce a picture of pseudobulbar palsy, slurred speech, dysphagia, and emotional lability. *Binswanger's disease* is a form of progressive arteriosclerosis with multiple lacunar infarcts that tend to be localized in the cerebral white matter and associated with dementia.

METABOLIC ENCEPHALOPATHY

Altered sensorium unassociated with any focal neurological deficit and a normal CSF is usually secondary to a metabolic disturbance.

General features of metabolic encephalopathy include:

1. Progressive deterioration of level of consciousness
2. Myoclonus
3. Flapping tremours in some types, eg. hepatic encephalopathy; and
4. Absence of any localizing signs.

Hypoxic Encephalopathy

This usually results from conditions producing asphyxia such as drowning, strangulation, aspiration into the respiratory tract, carbon monoxide poisoning, respiratory paralysis secondary to Guillain-Barré syndrome or poliomyelitis and shock states following myocardial infarction or cardiac arrest.

Mild degree of hypoxia causes inattentiveness, errors in judgement and confusion which are transitory. Prolonged and severe hypoxia lasting for more than 3 to 5 minutes produces serious and permanent injury to the brain resulting in coma. In such conditions presence of pupillary reflexes, intact Doll's head-eye movement and other brainstem reflexes generally indicate a favourable prognosis.

Doll's head-eye movement (oculocephalic reflex) is elicited by turning the head to either side, when the eyes are seen to deviate to the opposite direction. This sign is absent in conscious individuals. It becomes positive in the initial stages of coma, but it is lost as the coma deepens. However, when brainstem reflexes are absent with absence of spontaneous respiration, loss of Doll's eye movement suggests brain death. Absence of electrical activity in the EEG (flat EEG) supports the diagnosis. In less severe hypoxic damage,

the patient may recover from coma with some permanent neurological sequelae like dementia, extrapyramidal disturbances, choreoathetosis, ataxia and myoclonus.

The diagnosis of hypoxic brain damage depends on the clinical setting for hypoxia and arterial oxygen tension below 50 mmHg. The emergency treatment includes provision of a clear airway, cardiopulmonary resuscitation and oxygenation. Intravenous dexamethasone helps to reduce brain edema.

Hypoglycemic Encephalopathy

Abnormal lowering of blood sugar leads to confusion, stupor, convulsions or coma depending on the degree of hypoglycemia. Generally, when the blood sugar is 30 mg/dl confusional state sets in and when it is 10 mg/dl the patient becomes comatose.

Causes

1. Accidental overdose of insulin or a long-acting oral antidiabetic drug.
2. Insulin secreting tumours of the pancreas.
3. Alcoholic bouts.
4. Extensive malignant disease like fibrosarcoma.
5. Cerebral malaria, quinine therapy.

The effects of hypoglycemia manifest more slowly than those of hypoxia. Transient episodic behavior disturbances such as topographic memory loss or motor phenomena such as weakness or paralysis of limbs recurring at the same time can occur in diabetes treated with oral hypoglycemic drugs. These may be mistaken for transient ischemic attacks (TIAs)

As the condition progresses the medullary phase sets in. This is characterised by deep coma, shallow breathing and dilated pupils. Administration of glucose before the onset of the medullary phase results in complete reversal of the neurological lesions. However, once the medullary phase sets in, recovery may be delayed for months or may even be incomplete.

Hyperglycemic Encephalopathy

This may be either due to hyperglycemia with ketoacidosis or due to hyperosmolar non-ketotic state. In both conditions the patient becomes confused, stuporous, and comatose.

Convulsions may develop in some with non-ketotic hyperglycemia, resembling *epilepsia partialis continua*.

Hepatic Coma

Hepatic failure can lead to coma. Ammonia and toxic metabolic products which are formed in the bowel are carried in the portal circulation. They bypass the liver, not being further metabolized by the failing liver cells, and reach the cerebral circulation. This gives rise to neurological dysfunction (see Chapter: 85)

The onset of coma may be precipitated by high protein intake, hematemesis or electrolyte imbalance. It starts with mental confusion, increased psychomotor activity and progressive deterioration of the sensorium to end-up in deep coma. During the initial stage, the patient exhibits flapping tremors (*asterexis*) and this can be brought out when the hands are outstretched. Other signs of hepatic failure may be evident. The EEG reveals characteristic triphasic waves. Treatment consists of management of the hepatic failure. L-dopa has been found to improve the level of alertness in some cases. With improvement in hepatic function, the neurological syndrome also improves.

Uremic Encephalopathy

Both acute and chronic renal failure can result in confusion and stupor. This is usually due to rising blood levels of toxic nitrogenous products. Muscular twitchings, irregular muscular jerks and occasionally, convulsions predominate the clinical picture. The diagnosis can be established by the biochemical tests which reveal renal failure. The nature of the renal disease determines the prognosis. In chronic irreversible renal disease the condition does not improve without dialysis or renal transplantation. If convulsions occur, anticonvulsants should be given in small doses.

Management of Epilepsy	1249
Status Epilepticus	1252
Surgical Management of Epilepsy	1254

General Considerations

An epileptic seizure is electrophysiologically characterized by abnormal transient and excessive electrical discharge of cerebral neurons and clinically characterized by paroxysmal episodes of loss or excess of motor, sensory, autonomic or psychic functions with or without alteration in consciousness. The abnormal electrical discharges (epileptic or seizure discharges) may involve only a small part of the brain or a much wider area in both cerebral hemispheres. The clinical manifestations of epilepsy correspond to the activation of the brain area(s) affected by the electrical discharges. This explains the wide diversity of clinical forms that a seizure might take. The term epilepsy denotes the peripheral events resulting from the abnormal electrical discharges from the brain, recurring on two or more occasions.

In other words seizure is a symptom and epilepsy is a syndrome. Though epilepsy begins first with a seizure, not all first seizures lead to epilepsy. Seizures may often occur in acute systemic conditions such as metabolic disturbances (hypoglycemia), drug toxicity (chloroquine) and drug withdrawal (diazepam) but usually they do not constitute epilepsy.

Prevalence

One in 20 persons in the general population would have had seizures at some point in their lives. One in 200 among the general population have epilepsy at any one period of time. A house to house study done on 25000 persons in Central Travancore gave the prevalence rate as 5/1,000 of persons (Radhakrishnan et al, Epilepsia 1999, 40;179-185). The International League Against Epilepsy gives the incidence as 50-100/100,000 population. Epilepsy is one among the common neurological abnormalities seen in general practice. Although eminently treatable in the majority of cases, in a minority it leads to poor long-term outcome with loss of employment and productivity, adverse psychosocial effects and poor quality of life. The family physician whom an epileptic patient first contacts has to suspect the diagnosis, initiate the appropriate treatment and arrange for further specialist advice.

ETIOLOGY OF EPILEPSY

In about 70% of cases of epilepsy, no cause can be determined even after extensive investigations (primary or idiopathic epilepsy). In the remaining group the etiology varies and is multifactorial depending upon the age of onset and the type of epilepsy. The causes include a large variety of genetically determined, congenital and acquired conditions. Among the acquired causes CNS infections (encephalitis, meningitis and brain abscess), cerebrovascular diseases (cerebral arteriovenous malformation, cerebral hemorrhage and infarction), perinatal hypoxic ischaemic cerebral damage, head trauma and brain tumours predominate. Drug induced seizures are common.

Most of the centrally acting drugs cause generalised convulsions following parenteral administration at high doses. Likewise, withdrawal of drugs like phenobarbitone, benzodiazepines and also alcohol may precipitate generalised convulsions. The onset of epilepsy due to hereditary, metabolic or genetic disorders like hypocalcemia and aminoaciduria is in childhood. Sturge-Weber syndrome and tuberous sclerosis usually lead to epilepsy in early life. Seizures in the first few days after birth are most commonly due to birth anoxia or neonatal intracerebral hemorrhage. Seizures in the first few weeks of life are due to CNS infections, hypocalcemia or other metabolic disturbances. Onset of seizures after the second week of life usually indicates developmental abnormalities of the brain. Epilepsy due to birth trauma manifests in childhood but occasionally the first attack may occur in adult life. Cerebral tumours, head trauma, neurotuberculomas, neurocysticercosis, cerebrovascular disease (overt or salient) and presenile dementia are the common causes of late onset epilepsy.

Simple partial seizures starting in adult life should suggest a newly developed focal structural lesion in the brain (e.g. tumour, tuberculoma or cysticercosis). Complex partial seizures are most frequently due to unilateral temporal lobe damage such as mesial temporal sclerosis or hamartomas. Typical absence seizures and generalised tonic-clonic seizures without aura are almost exclusively manifestations of primary generalised epilepsy. Atypical absence and atonic, tonic or clonic seizures usually occur in children with mental retardation and brain damage due to a variety of causes. Myoclonic seizures can be a manifestation of primary generalised epilepsy as well as several other symptomatic epilepsies.

PATHOGENESIS

The cortical neurons become abnormally excitable due to differentiation. The cytoplasm and cell membrane of such cells have increased permeability rendering them susceptible to activation by hyperthermia, hypoxia, hypoglycemia, and hyponatremia. Deficiency of the inhibitory neurotransmitter gamma-amino butyric acid (GABA) and disturbance of local regulation of extracellular K^+ , Na^+ , Ca^{2+} or Mg^{2+} are probably responsible for the membrane instability which leads to abnormal electrical discharge. Transition from normal to epileptiform behaviour of the brain is caused by greater spread and neuronal recruitment secondary to a combination of enhanced connectivity, enhanced excitatory transmission, failure of inhibitory mechanisms and changes in intrinsic neuronal properties. Generalized epilepsies are due to electrical activity occurring throughout the cerebral cortex, because of lowering of seizure threshold. Often this is genetically determined. If unchecked, this electrical discharge spreads to the ipsilateral and contralateral hemisphere across intra and

interhemispheric pathways and also to the subcortical structures like basal ganglia and brain stem reticular nuclei, from where the excitatory activity is fed back to the rest of the cortex.

MOLECULAR GENETICS OF EPILEPSY

Epilepsies have both a simple and complex inheritance pattern. Most idiopathic epilepsy syndromes have a complex inheritance. In these cases, more than one gene with or without the influence of acquired factors leads to a particular epilepsy syndrome. A number of syndromes with simple inheritance are also known. To site examples, benign familial neonatal convulsions is linked to 20q, the abnormal gene being KCNQ2. That for autosomal dominant nocturnal frontal lobe epilepsy is linked to 20q, the abnormal gene being CHRNA4. Juvenile myoclonic epilepsy is linked to 6p and 15q. The readers can refer to monographs on epilepsy for details.

Classification of Epilepsies

The classification of epilepsy has undergone several changes from time to time and it is likely that further changes may follow. To standardize the classification, the International League Against Epilepsy has suggested the following two classifications:

1. **Classification of epileptic seizures:** This is largely based on the seizure type and to a lesser extent on EEG findings. In this classification, seizures are divided into two main categories depending upon the location of the initial epileptic discharge in the brain, i.e. localized to a small area (partial seizures) or larger areas in both hemispheres (generalised seizures).
2. **Classifications of epilepsies and epileptic syndromes:** This is based on clinical manifestations, age of onset, genetic predisposition, associated neurological and other abnormalities, response to specific anti-epileptic drugs and overall prognosis.

Classification of Epileptic Seizures

Partial Seizures

- A. Simple partial seizures
 1. with motor manifestations
 2. with somatosensory or special sensory manifestations
 3. with autonomic manifestations
 4. with psychic manifestations.
- B. Complex partial seizures
 1. with simple partial features at onset followed by impairment of consciousness
 2. with impairment of consciousness at onset.
- C. Partial seizures evolving to secondarily generalised seizures
 1. simple partial seizure – generalised seizure

2. complex partial seizure – generalised seizure
3. simple partial seizure – complex partial seizure – generalised seizure.

Generalised Seizures

- A. Absence seizures
- B. Myoclonic seizures
- C. Clonic seizures
- D. Tonic seizures
- E. Tonic-clonic seizures
- F. Atonic seizures

Unclassified Seizures

CLASSIFICATION OF EPILEPSIES AND EPILEPTIC SYNDROMES

1. Localization related (focal, local, partial) epilepsies and syndromes

- 1.1 Idiopathic with age related onset
 - Benign childhood epilepsy with centrottemporal spikes
 - Childhood epilepsy with occipital paroxysms
 - Primary reading epilepsy.
- 1.2 Symptomatic
 - Chronic progressive epilepsia partialis continua of childhood
 - Syndromes characterized by seizures with specific mode of precipitation
 - Temporal lobe epilepsies
 - Frontal lobe epilepsies
 - Parietal lobe epilepsies
 - Occipital lobe epilepsies
- 1.3 Cryptogenic.

2. Generalised epilepsies and syndromes

- 2.1 Idiopathic with age related onset
 - Benign neonatal familial convulsions
 - Benign myoclonic epilepsy of infancy
 - Childhood absence epilepsy (pyknolepsy)
 - Juvenile absence epilepsy
 - Juvenile myoclonic epilepsy (impulsive petit mal)
 - Epilepsy with grand mal seizures on awakening
 - Other generalised idiopathic epilepsies not defined above
 - Epilepsies with seizures precipitated by specific modes of activation.
- 2.2 Cryptogenic
 - West syndrome (infantile spasms, Salam seizures)
 - Lennox-Gastaut syndrome
 - Epilepsy with myoclonic/astatic seizures
 - Epilepsy with myoclonic absences.
- 2.3 Symptomatic
 - 2.3.1 Nonspecific etiology

Early myoclonic encephalopathy
 Early infantile epileptic encephalopathy with suppression burst
 Other symptomatic generalised epilepsies.

2.3.2 Specific syndromes
 Epilepsies, which form part of the clinical profile of certain neurological disorders.

3. Epilepsies and syndromes, undetermined whether focal or generalised

- 3.1 With both generalised and focal seizures
 - Neonatal seizures
 - Severe myoclonic epilepsy of infancy
 - Epilepsy with continuous spike and wave during slow wave sleep
 - Acquired epileptic aphasia
 - Other undetermined epilepsies not included above.

4. Special syndromes

- 4.1 Situation related seizures
 - Febrile convulsions
 - Isolated seizures or status epilepticus
 - Seizures occurring only when there is an acute metabolic or toxic event caused by factors such as alcohol, drugs, eclampsia and nonketotic hyperglycemia.

PARTIAL SEIZURES

Partial seizures or focal seizures are due to a small epileptic focus in the brain. They are divided into two main categories.

- a. simple partial seizure in which the seizure starts as a focal discharge and remains focal throughout without alteration of consciousness and
- b. complex partial seizure when a seizure starts as a focal discharge, but consciousness is also altered or lost.

Simple Partial Seizures

These seizures may have motor, sensory, autonomic or psychic manifestations.

Simple focal or partial motor seizures are due to a discharging epileptic focus in the opposite frontal lobe (motor cortex). These consist of clonic movements of the hand, foot or angle of mouth or turning of the head or eyes. These movements may constitute the entire motor component of the seizure or may be followed by generalised clonic movements and loss of consciousness. The term jacksonian motor seizures (Jacksonian epilepsy) is applied to the type where clonic contractions start in the fingers of one hand, one side of the face or the foot and slowly spread (march) to the other muscles on the same side of the body. This may or may not be followed

by involvement of the opposite side and loss of consciousness. The presence of the characteristic march distinguishes Jacksonian seizures from partial motor seizures. However, both have the same localizing significance.

Complex Partial Seizures (Psychomotor Epilepsy)

These are defined as focal or partial seizures in which consciousness is impaired or lost. They are frequently due to epileptic discharges in the temporal or frontal lobes. Less commonly they may arise from discharges in other parts of the brain. This forms the single most common type of seizure in adults. The seizure usually consists of complex hallucination of perceptual illusions, indicating its origin from the temporal lobe. The hallucinations are usually auditory and visual but sometimes they may be olfactory or gustatory. The subjects may show increased familiarity (*déjà vu*) or unfamiliarity (*jamais vu*) with the surroundings. In some cases these subjective experiences may constitute the entire seizure. Often this is followed by a period of unresponsiveness, during which the patient exhibits certain automatic behaviour like smacking of the lips or chewing movements (automatism). The patient may walk about or repeat a habitual act. However, when asked a question the unresponsiveness becomes evident. Sometimes unprovoked aggression or laughter may be the striking feature. The automatism usually lasts for a few minutes, but may sometimes be prolonged. The patient is totally amnesic for the whole period of automatism. The EEG recorded during sleep or hyperventilation may demonstrate the temporal lobe focus. Rarely, other areas of brain like the orbital surface of the frontal lobe or limbic system may be seat of epileptic discharge.

Partial Seizures Evolving to Secondarily Generalised Seizures

In many cases the generalised seizures are not generalised from their onset. They start as partial seizures, either simple or complex and then soon spread to become generalised, usually as tonic-clonic convulsions. These are called partial seizures becoming secondarily generalised. In such cases the initial manifestations of partial seizures are called “aura” or warning symptoms.

invariably impaired or lost at the onset of the attack. Generalised seizures are divided into several clinical types and some patients may suffer from more than one seizure type. Atypical seizure patterns may also occur, especially if the patient is on treatment.

Tonic Clonic Seizures

These are also called grand mal epilepsy.

The seizure attack occurs in different stages sequentially. The stages may be subdivided into the prodromal phase, tonic phase, clonic phase and the postictal phase. The prodromal phase may start several hours before the ictus (fit). It consists of several subjective phenomena like depressed or apathetic mood, irritability, vague abdominal cramps or other funny sensations, which are easily recognised by the patient. In many instances there is no aura and the patient gets the attack without any forewarning. Presence of aura suggests the nature of the seizure as of focal onset (i.e.) partial seizure.

The tonic phase consists of rolling up of the eyes associated with stiffening of the limbs followed by clenching of the jaws, often resulting in injury to the tongue. The attack may be heralded by an epileptic cry as the entire musculature goes into spasm forcing air through the closed vocal cords. The patient becomes cyanosed due to spasm of respiratory muscles. This phase lasts for about 10 to 30 seconds.

The tonic phase is followed by clonic phase characterised by alternate flexion-extension movements of all the four limbs (convulsions), strenuous breathing, sweating, frothing of the mouth and excess salivation. Urine and feces may be voided. The clonic phase usually lasts for 1-2 minutes. This is followed by a deep comatose state, which lasts for about 5 minutes. The pupils slowly begin to react and the patient then resumes speech, but still remains confused. If left undisturbed, he goes into sleep for several hours and often wakes up with severe headache and at times, vomiting. This is the post-ictal phase and the patient does not remember anything that had happened.

Electroencephalogram (EEG) taken during the attack or sometimes even during the intervals shows generalised seizure discharges. The EEG is often normal in the interictal period.

Absence Seizures (Petit Mal)

These are seen mostly in children. These are distinguished by brevity and absence of motor phenomena. The child does not fall. The attacks come on without any warning and consciousness is impaired only for a brief period often < 10 seconds. The child abruptly stops all ongoing motor activity and speech. There is a vacant stare. External

Primary Generalised Seizures

These are seizures in which there is no evidence of an epileptic focus, either clinically or on EEG, as opposed to secondary generalised seizures. The epileptic discharge involves both cerebral hemispheres simultaneously from the onset of the seizures. Hence, consciousness is almost

stimuli fail to evoke any response from the patient at that period. These attacks usually last for 2-10 sec after which the patient resumes the pre-seizure activity. At times there may be clonic movements of the eyelids or occasionally automatisms like smacking of lips or chewing movements. The attacks can be precipitated by hyperventilation. The attacks occur several times during the day, but they become less frequent or may even disappear in adolescence. Sometimes these may be replaced by tonic-clonic seizures.

The EEG abnormality in petit mal epilepsy is diagnostic. It shows classic “three per second” spike and wave generalised discharges.

Juvenile Myoclonic Epilepsy (Myoclonic Jerks)

This term refers to brisk, brief contractions of one or several muscle groups or a single muscle. The movements are jerky, generally abrupt and uncontrollable and render the patient momentarily helpless. The attacks may occur as a single jerk or may recur every few seconds. Recovery from the attacks is immediate and the subject does not lose consciousness.

Juvenile myoclonic epilepsy (JME) starts in early adolescence. Myoclonic jerks occur with or without generalized tonic-clonic seizures. Attacks occur early in the morning on waking up. A small proportion of childhood absence seizures may evolve into JME. Often the myoclonus may be missed or misinterpreted as seizure activity. It is important to make a proper diagnosis since anti-epilepsy drugs such as phenytoin and carbamazepine may worsen the myoclonus.

Myoclonic jerks are not always ‘epileptic in origin, and may occur in many other non-epileptic neurological conditions. The abnormal electrical discharges may arise from the cerebral cortex, brainstem or spinal cord. Myoclonus may be associated with other forms of epilepsy like absences or generalised tonic-clonic seizures. Myoclonus is seen in a variety of conditions. All types of metabolic encephalopathies like hepatic failure, renal failure, electrolyte disturbances and others may lead to myoclonus. It is an important feature of progressive myoclonic encephalopathy. At times it is precipitated by light, sound and touch stimuli.

Atonic Seizures

These are less common generalised seizures characterised by sudden loss of postural tone and consciousness without any other motor phenomena. This may lead to sudden “drop” of the individual to the floor without any warning. Atonic seizures have to be distinguished from cataplexy in which the drop attacks are not accompanied by loss of consciousness and syncope.

Common Epileptic Syndromes

INFANTILE SPASMS

Syn: Salaam spasm (hypsarrhythmia):

This condition is seen in infants below 1 year of age. This is characterized by brief sudden jerky flexion or less commonly extension movements of both arms, neck and torso. Usually these jerks or spasms occur in clusters, precipitated by sudden noise or tactile stimulus and may occur several times in a day. Usually there is evidence of other neurological disorders, secondary cerebral anoxia or birth injury. As the infant grows, the frequency of the spasms comes down but other forms of seizures may supervene. The characteristic EEG pattern is called hypsarrhythmia.

LENNOX-GASTAUT SYNDROME

This is an epileptic syndrome with onset between 1 and 6 years of age. It is characterised by mental retardation, and intractable seizures with mixture of tonic, atonic, tonic-clonic and atypical absence seizures. EEG shows diffuse slow and spike wave disturbances. The syndrome may occur without any definite cause or may be associated with a variety of neurodevelopmental or metabolic abnormalities in which case the prognosis is poor.

BENIGN ROLANDIC EPILEPSY

This is a common form of partial epilepsy in childhood with onset between 3 and 11 years. It is characterised by attacks of hemifacial twitches sometimes with involuntary vocalizations which may progress to a generalised or unilateral convulsion. These seizures usually or exclusively occur in sleep. The family history suggestive of autosomal dominant inheritance may be available. The EEG abnormality is highly characteristic showing frequent spike discharge in the rolandic area, especially during non-REM sleep. The prognosis is excellent as it is not associated with any other neurological, psychiatric or behavioural disorder and the seizures respond well to anticonvulsant drugs. In some they may remit spontaneously around puberty.

Febrile Convulsions

A febrile convulsion may be defined as a brief generalised convulsion occurring during fever in a child in the age group of 6 months to 5 years without pre-existing or concurrent neurological abnormalities or intracranial infection. About 70% of febrile convulsions occur in the age of 6 to 18 months. The convulsions usually last for a few seconds but may extend upto 15 min. At least 5% of children have one febrile fit before the age of 5 years and nearly 25-50% of them have recurrent attacks, but the risk

progressively diminishes with age. A strong family history of febrile fits is evident in many cases. The fits usually occur when the rectal temperature rises above 39°C.

Generally, the body temperature normalises after the fit. About 4 to 20% cases may develop convulsions even without noticeable fever. Though the risk of developing chronic epilepsy in such children is only about 2%, it is however higher than in the general population. The risk of developing epilepsy in later life is higher in the following groups:

1. When the first febrile convulsion is complicated, i.e. prolonged (> 30 minutes) or localised or is followed by multiple seizures in 24 hours.
2. Presence of neurological abnormalities before or after the onset of convulsion.

In general, the intellectual performance of children who had febrile convulsions does not differ from normals but prolonged or recurrent frequent febrile convulsions lead to brain damage and medial temporal sclerosis, which in later life, causes epilepsy.

Management: An acute attack can be controlled by diazepam in a dose of 0.08-0.3 mg/kg body weight given intravenously. Rectal administration is equally effective. Intramuscular administration should be avoided since absorption is erratic.

The temperature should be brought down by the administration of paracetamol in a dose of 30 mg/kg body weight and tepid sponging.

Further convulsions can be prevented by the administration of phenobarbitone in a dose of 15 mg/kg given intramuscularly or 30 mg orally repeated 6 hourly. In children below the age of 18 months, since fever and convulsions may be a presenting feature of meningitis, lumbar puncture is indicated, so also in children showing prolonged or lateralized seizures. Prophylactic administration of oral diazepam 0.25mg/kg/day or clobazam 5-10mg oral is useful in preventing fits. Clobazam is contraindicated in children below 3 years of age.

Prolonged prophylaxis is indicated for children who show:

1. Complicated and prolonged convulsions or focal seizures.
2. Frequent recurrence.
3. Abnormal birth history or neurodevelopmental abnormalities.
4. Onset before 6 months or after 4 years of age.
5. Presence of inter-ictal EEG abnormality.

Sodium valproate given in doses of 20 mg/kg/day oral is a good and safe prophylactic for prolonged use.

Progressive Myoclonic Epilepsies (PME)

These are rare, distinctive epileptic disorders with myoclonic seizures, tonic-clonic seizures and progressive

neurologic dysfunction, particularly ataxia and dementia. Myoclonic seizures are described as sudden, brief, lightning like jerks that may be generalised or limited to one or more muscle groups. They are not associated with loss of consciousness and are frequently precipitated by stimuli such as movement, bright light or stress. Physiological myoclonus may occur in many normal persons during sleep or in other disease states. This has to be distinguished from PME. A heterogeneous group of disorders may give rise to PME.

- a. **Biochemical disorders:** Unverricht-Lundborg disease, Lafora body disease, neuronal ceroid lipofuscinosis, sialidosis, mitochondrial encephalomyopathy, non-infantile neuronopathic Gaucher's disease, and others.
- b. **Clinically defined groups:** May give rise to seizures West's syndrome, Ramsay-Hunt syndrome (dyssynergia cerebellaris myoclonica), and others.

Diagnosis of these groups of disorders depends on the clinical patterns, characteristic fundal changes and biopsy studies of the skin, skeletal muscle, liver, rectal mucosa or brain. Study of these diseases is the realm of the specialist. Management consists of accurate diagnosis, genetic counselling and control of myoclonus by sodium valproate or clonazepam.

REFLEX EPILEPSY

Epilepsy precipitated by external stimuli has been designated as reflex epilepsy. The common stimuli which precipitate reflex epilepsy in susceptible people are hot water bath of the head, photic stimulation such as flickering light and TV watching, exposure to sunlight, reading, hearing music, startle and eating. Avoidance of precipitating factors and prophylactic anticonvulsants serve to prevent the attacks.

Epilepsy and Pregnancy

One-fourth to one-third of pregnant women with epilepsy get aggravation of seizure tendency during pregnancy. Status epilepticus may complicate 1-2% of epileptics who are in labor. Since drug levels of antiepileptic drugs are lower in many pregnant women, it is better to monitor free drug levels every month during pregnancy. Risks of AED during pregnancy include the following;

First trimester of pregnancy—congenital malformation in child—12.3%.

Status epilepticus: generalized convulsions during labour:

- Risk of hypoxia and acidosis for mother and fetus is high.
- Increased rate of neonatal hypoxia, low APGAR scores in the baby.

Pregnant women with epilepsy have higher risks of hyperemesis gravidarum, pre-eclampsia, abruptio placentae and premature labour. Serum AED levels rise after delivery and therefore monitoring is required.

Complication in the Offspring

These include fetal congenital malformations and developmental delay. Teratogenicity has been established for valproate, carbamazepine, phenytoin and phenobarbitone. Minor congenital malformations occur in 6-20% and major abnormalities occur in 4-6% of infants exposed to these drugs in utero, compared to 3% in babies of epileptic mothers not exposed to drugs.

Major malformations are particularly seen in babies exposed to phenytoin and phenobarbitone. These include cleft lip, cleft palate and congenital heart disease. Neural tube defects increase from a general rate of 0.2% to 1-2% in pregnancies exposed to valproate and carbamazepine. Administration of 5 mg folate daily early in pregnancy may reduce this risk. Perinatal death rates of the baby may rise from 1-3.9% in controls to 1.3-7.8% in the case of epileptic mothers. Low birth weight (7-10%) and prematurity (4-11%) may occur. Risk of epilepsy is higher in children of parents with epilepsy, especially so if the mother is epileptic. Mental retardation is more frequent in children of epileptic parents—8% if only mother is affected, 4% if only father is affected and 25% if both are affected.

Management of Women with Epilepsy

1. Pre-conception counselling.
2. Lamotrigine may be less teratogenic and hence it should be preferred.
3. Monitoring of serum alfa-fetoprotein (AFP) in the mother for neural tube defects.
4. USG examination with vaginal probe for demonstration of neural tube defects – Ultrasonography at 18 weeks should be able to detect most of the abnormalities. Serum level of anti-epileptic drugs (AED) may be monitored.
5. AEDs may impair the metabolism of vitamin K and lead to bleeding tendencies Oral supplementation of vitamin K 20 mg/day through out pregnancy reduces this risk. The baby should be given vitamin K 1-2 mg IM at birth.
6. Delivery: Elective lower segment cesarean delivery is done in those with risk of status epilepticus. If seizures occur lorazepam is the drug of choice. Pethidine should be avoided since it can exacerbate seizures.
7. Concurrent administration of oral contraceptives leads to lowering of serum levels of anti-epileptic drug and precipitate seizures.

Menopause: Usually the seizure tendency subsides, but hormone replacement therapy increases seizure tendency.

Diagnosis

Diagnosis of epilepsy is essentially clinical. History is most important in making the diagnosis. Careful interrogation of witnesses of an attack is essential to

determine the nature of the diagnosis. Epilepsy should be differentiated from simple faint and syncopal attacks. The epileptic attack can occur during day or night regardless of the position of the patient. Syncopal attacks usually do not occur in the recumbent posture. Also the occurrence of pallor at the onset, gradual loss of consciousness and prompt return of consciousness on adopting recumbent posture are diagnostic of syncope. In epilepsy loss of consciousness is abrupt and consciousness returns only slowly. Occurrence of post-ictal headache and vomiting should suggest the possibility of epilepsy. So also, occurrence of seizure during deep sleep is a strong point in favour of epilepsy. Occurrence of injuries such as biting the tongue or due to falls should suggest seizure disorder since these are practically absent in hysterical convulsions.

Hysterical attacks should be differentiated by the lack of aura, absence of injuries and incontinence, presence of peculiar grimacing or squirming movements and the retention of consciousness during a motor seizure, which involves both sides of the body. Moreover hysterical convulsions are bizarre and they continue for long periods, as long as the patient is being observed.

Diagnosis of the type of epilepsy depends upon the description of the attack and clinical examination. The epileptic focus and pattern of epilepsy are determined by investigations.

The electroencephalogram (EEG) is the most useful investigation to establish the diagnosis of epilepsy. The EEG gives positive records in 60-90% of cases, if the records are repeated during or after an attack and after 24 hours of sleep deprivation. Refinements in EEG procedure include the use of special electrodes such as sphenoidal, nasoethmoidal, nasopharyngeal and in selected cases, intracerebral electrodes. Photoc stimulation, sleep and hyperventilation are measures used to elicit abnormalities in the EEG (Figs 190.1A and B).

However, normal EEG does not exclude the diagnosis of epilepsy. Conversely, a small number of normal persons may show paroxysmal EEG abnormalities. Thus EEG can be used only as an additional evidence to the clinical diagnosis of epilepsy. So, also its role in predicting remission or selection of antiepileptic drugs is also limited. But in confirmed epileptics with EEG abnormalities, the decision to stop drug therapy can be based on the persistence of the abnormality.

In epilepsy occurring for the first time after 20 years of age, partial epilepsy, presence of focal neurological deficit and in those where the disease is resistant to conventional treatment, further investigations to exclude anatomical abnormalities and space occupying lesions in the brain are indicated. These include CT and MRI scans of brain.

PROGNOSIS

Over 60% of patients attain remission, which is defined as freedom from seizures for 2-5 years after stopping their

Figs 190.1A and B: Normal EEG and EEG in seizure

antiepileptic treatment. About a third do not achieve this state.

Chances for achieving remission are greater within the first few years after diagnosis and treatment. In those in whom remission does not occur within 1-2 years of starting therapy the chances of remission are low and these patients may require life- long anticonvulsant therapy. As a practical guide to long-term management, epileptics can be categorised into four groups.

- 17
1. Mild cases which may even be self-limiting or remit after short course of treatment—30%.
 2. Easily controlled with drugs and go into remission early—30%
 3. Chronic epilepsy which responds partially to drugs but relapses on withdrawal of the drugs—20%
 4. Response to drugs is unsatisfactory and remission is unusual (intractable)—20%

Factor which predict recurrence of seizures after the first attack

If risk factors are present, recurrence is more likely. In those with more than 2 risk factors the chance of recurrence is about 100%.

Risk Factors

1. Prior neurological insult
2. Partial seizure
3. abnormal EEG
4. Todd's paralysis, family history of epilepsy, seizure occurring during sleep and absence of precipitating factors.

Various rating systems are available to quantitate intractable seizures but as practical guide those that have one or more seizures per month despite regular, adequate and appropriate treatment may be considered as intractable seizures.

Epilepsy and its treatment can have deleterious cognitive and behavioral consequences. Affected individuals have a higher prevalence of neuropsychological dysfunction compared to the non-epileptic population. **Convulsive status is consistently associated with neuronal necrosis in vulnerable parts of the brain, especially the hippocampus, amygdala, cerebellar cortex, thalami and cerebral cortex.**

Sudden death in epilepsy is due to trauma, aspiration, continued status leading to hyperthermia, aspiration

pneumonia and cardiac asystole. Symptomatic epilepsy reduces life expectancy by 18 years.

MANAGEMENT OF EPILEPSY

This consists of (i) treatment of the acute convulsions, and (ii) prophylactic management of convulsive and non-convulsive seizures.

The latter consists of :

1. Removal of precipitating or causative factors.
2. Antiepileptic medication.
3. Social rehabilitation.

Management of an Acute Convulsion

Convulsion is a medical emergency especially if prolonged, which should be arrested without delay. The patient is put on a soft bed to avoid injuries, tight clothing is loosened and the airway is protected so as to avoid asphyxiation and aspiration. Dentures and foreign bodies in the mouth should be removed and a suitable mouth gag is applied in the position of the molar teeth, to keep the mouth open and prevent injury to the tongue. The patient should be kept with head low, so as to avoid aspiration of vomitus into the respiratory tract.

Most convulsions are self-limited and need no immediate treatment. However, prolonged or recurring convulsion should be controlled by slow intravenous injection of 5-10 mg or more of diazepam. An alternate anticonvulsant drug is lorazepam 4 mg IV given slowly over 5-10 minutes. Other drug that must be given parenterally is phenytoin sodium 100-200 mg IV. This helps to prevent recurrence as well.

The physician may encounter the patient with convulsions in the most embarrassing situations, and therefore, the first injection of anticonvulsant medication may have to be given IV in order to terminate the convulsion forthwith, fully realising the risk involved. Adverse drug effects include anaphylaxis, respiratory depression, hypotension and allergic manifestations.

Once the convulsions are controlled, further management has to be carefully planned.

Failure to arrest the convulsions leads to asphyxia, severe exhaustion, hyperpyrexia, electrolyte imbalance, further cerebral damage and death.

All cases of convulsions should be investigated for the presence of primary or secondary neurological conditions giving rise to symptomatic seizure. Conditions like meningitis, encephalitis, neurosyphilis, neurocysticercosis, fluid and electrolyte imbalance, hypocalcemia, abnormal glucose levels and intracranial space occupying lesions have to be excluded.

Prophylactic Management

Antiepileptic Drugs

Treatment of epilepsy is primarily medical and the mainstay is the use of anti-epileptic drugs (AEDs). Though AEDs are not curative in epilepsy, they help to control seizures and give symptomatic relief. In many instances prolonged administration results in abolition of the epileptic tendency. The response varies in the different types of seizures and hence it is necessary to administer the appropriate AED in optimum dosage. *The present consensus is to start with a single drug and add others later on, only when absolutely necessary. The first line AEDs are the time tested drugs such as phenytoin, phenobarbitone, primidone, carbamazepine, ethosuximide, sodium valproate, and clonazepam.* At present oxcarbazepine, topiramate and lamotrigine are also increasingly used as first line drugs (Table 190.1).

If the response to a single drug is not adequate, another drug should be added. In some the combination produces better effect. A stable drug regimen should not, however, be frequently changed. Sudden withdrawal of AED should be avoided since this is the most common cause for precipitation of status epilepticus.

Indications for starting antiepileptic therapy: When more than one unprovoked seizure has occurred in the preceding one to two years or when the risk of recurrent convulsion is high as in head injury or intracranial infections. AEDs should be started. Since the medication has to be prolonged and the drugs are potentially toxic and expensive, patients with single attack without demonstrable focal abnormalities either clinically or on investigations such as EEG, CT or MRI, the patient should be observed and therapy started only if seizures recur.

Guidelines for AED Therapy

1. Start with a single drug and adjust its dosage to achieve maximal clinical benefit without side effects.
2. If seizures occur even after achieving tolerable dose of the single drug a second drug should be introduced and the first one slowly withdrawn.
3. Different combinations of two drugs may be tried, each trial lasting for a maximum of six months, till the ideal combination is arrived at. There is no role for combining more than two drugs.
4. ***Therapy should continue till at least a 3-year seizure-free period*** is completed after which the drugs can be gradually withdrawn. Nearly 50% of the patients may not require any further treatment. The rest may relapse and this usually occurs within five years. Children who develop primary epilepsy in early life and who show prompt response to AED have greater chance for permanent remission.

TABLE 190.1

Details of the commonly used anticonvulsant-drugs				
Name of the drugs	Children dose	Adult dose	Toxic effects	Serum half-life in hours
Phenobarbitone (Luminal)	3-5 mg/kg	60-200 mg	Sedation, cognitive decline, ataxia	96 ± 12
Phenytoin (Dilantin)	4-7 mg/kg	300-400 mg	Gingival hypertrophy, ataxia, chorea, dyskinesia lymphadenopathy peripheral (Fig. 190.2) neuropathy, anemia hirsutism	24 ± 12
Carbamazepine (Tegretol)	20-30 mg/kg	600-1200 mg	Diplopia, giddiness, Stevens-Johnson syndrome hyponatremia, weight gain	12 ± 3
Oxcarbazepine	20-30 mg/kg	600-2400 mg	Oxcarbazepine is less toxic, toxicity similar	12 ± 3
Ethosuximide (zarontin)	20-30 mg/kg	750-1500 mg	Hepatotoxicity, blood dyscrasias, nephrotoxicity	30 ± 6
Valproic acid (sodium-valproate)	30-60 mg/kg	1000-3000 mg	Transient hair loss, tremors, obesity, thrombocytopenia	8 ± 2
Clonazepam	0.01-0.3 mg/kg	1.5-20 mg	Ataxia, sedation, lethargy	18-50

Fig. 190.2: Dilantin induced pseudolymphoma

5. Twenty-five percent of cases may develop chronic epilepsy and require life-long medication. Risk of chronicity is high in patients with neurological and psychological abnormalities and social handicaps. Partial seizures are more refractory to medical treatment in upto 20% of cases. These may require surgery. When confronted with intractable seizures, newer drugs should be considered. Before doing so it is wise to verify the following:
1. Is the diagnosis correct.
 2. Is the epilepsy secondary to other disease processes.
 3. Are the appropriate drugs taken regularly and in full doses.
 4. Are there any adverse psychosocial factors.

Newer Antiepileptic Drugs

Several newer antiepileptic drugs are on the anvil. Many of these are now freely available in India. At present, these newer drugs are recommended as add-on drugs along with conventional drugs, to treat intractable cases, although some of them are found effective as initial monotherapy.

Vigabatrin: Gamma vinyl GABA (GVG): This drug irreversibly inhibits GABA aminotransferase.

Dose: 50-100 mg/kg/day.

Indications: Complex partial seizures with secondary generalisation, infantile spasms. Adverse effects are mild. These include defects in the visual fields, sedation and behavioural disturbances.

Zonisamide: This is a benzisoxazole derivative.

Dose: 6-10 mg/kg/day. The initial dose is 100 mg/day.

Indications: Partial seizures with secondary generalisation, primary generalised tonic-clonic, atonic and myoclonic seizures. Adverse effects include feverishness, ataxia, leucopenia and urinary calculi.

Oxcarbazepine: This is chemically related to carbamazepine. Its action is similar to carbamazepine but this drug is better tolerated. Ataxia is the main adverse effect.

Dose: 1200-2400 mg/day.

Gabapentin(Neurontin): This is a GABA-related amino acid with broad spectrum anti-epileptic activity.

Dose: The initial daily dose is 300 mg increased to 600 to 1300 mg over a few days. Even doses as high as 3600 mg/day are safe. This drug is well tolerated and the full dose can be attained within 3-4 days. It can be safely

TABLE 190.2

Details of newer AEDS				
Drug	Indications	Daily dose mg	Benefits	Toxicity
Oxcarbamazepine	Partial and partial complex seizures	600-2400	Drug interactions	Ataxia, hyponatremia
Vigabatrin	do + secondary generalized	1000-2000	Broad spectrum	Psychosis, visual field defect weight gain, depression
Gabapentin	-do-	1800-3600	No drug interactions, rapid titration	Somnolence, fatigue, ataxia
Lamotrigine	-do-	100-500	Broad spectrum, wide experience, once or twice daily dosing	Skin rash, ataxia, tremor, gastrointestinal disturbances
Topiramate	-do-	100-500	Broad spectrum, wide experience, twice daily dosing	Ataxia, confusion, loss of weight, renal stones, word finding difficulty
Clobazam	Complex partial, secondary and primary generalized seizures	20-50	Less side effects and few drug interactions	Sedation, irritability, weight gain
Felbamate	-do- + Lennox-Gastaut syndrome	2400-3600	—	Aplastic anemia, hepatic failure
Tiagabine	Partial and secondary generalized	32-56	Only a few drug interactions	Gastrointestinal disturbances, confusion
Zonisamide	-do-	100-600	Broad spectrum, few drug interactions, once-daily dosing	Somnolence, renal calculi, ataxia
Leviteracetum	Broad spectrum, mainly partial epilepsies	1000-3000	Broad spectrum, few drug interactions, once-daily dosing	Somnolence, fatigue, ataxia, behavioral abnormalities

combined with any other antiepileptic drug. Gabapentin is an add-on drug for resistant partial and secondarily generalised seizures. Main adverse effects are somnolence, ataxia, fatigue, nystagmus, GI upset and weight gain.

Lamotrigine: This drug inhibits the release of the excitatory amino acid glutamate. The effective dose is 200-300 mg/day. The drug is started at 50 mg/day and gradually increased till the full dose is reached over 3-6 weeks. Further increase in dosage should be done only very cautiously, when combined with sodium valproate, it should be used in smaller doses. Lamotrigine is indicated in intractable partial seizures with secondary generalization, infantile status and Lennox-Gastaut syndrome. Adverse effects include dystonia, ataxia, severe hepatotoxicity, and skin rash.

Clobazam: Its antiepileptic activity is related to its binding to one or more specific GABA receptors increasing GABA mediated inhibition. It is effective in complex partial seizures and primary or secondarily generalised seizures. The adult daily dose is 20-50 mg. Sedation, irritability and weight gain are the main side effects.

Tiagabine: (30-60 mg), and

Topiramate (100-500 mg) are the other newer drugs found to be useful in partial seizures with secondary generalisation and primary generalised seizures.

Leviteracetum is an add-on drug for refractory partial seizures and for the generalised seizure in adults in a dose of 500 mg bd. It has the least drug interactions. It is useful in the presence of hepatic and renal insufficiency.

Felbamate: This drug raises the seizure threshold. Adult dose may vary from 1800-4800 mg/day. Daily dose for children is 15-45 mg/kg given in 3-4 doses.

Felbamate is used as add – on therapy for partial seizures with generalization resistant to other drugs and for Lennox-Gastaut syndrome.

When used as an add-on drug, the dosage of the original drug should be reduced progressively and withdrawn, when the full dose of felbamate is reached.

Side effects include insomnia, weight loss, nausea, anorexia and aplastic anemia. Due to serious toxic effects this drug is not licenced in many countries (Table 190.2).

TABLE 190.4

Type of epilepsy and choice of AED	
Types of epilepsy	Drugs of choice
1. Generalised tonic-clonic seizures with partial onset	Phenytoin sodium Carbamazepine Phenobarbitone Sodium valproate
2. Simple partial seizures	Carbamazepine Phenytoin sodium Primidone Phenobarbitone Sodium valproate
3. Complex partial seizures	Carbamazepine Sodium valproate Primidone Phenytoin sodium Phenobarbitone
4. Absence seizures with 3/sec spike and waves on EEG	Sodium valproate Ethosuximide Clonazepam
5. Myoclonic seizures	Sodium valproate Nitrazepam Clonazepam Ethosuximide
6. Infantile spasms	ACTH/ Corticosteroids Nitrazepam Clonazepam
7. Neonatal seizures, Febrile seizures	Phenobarbitone Sodium valproate
8. Status epilepticus	Diazepam Phenytoin sodium Phenobarbitone Lorazepam

A serious problem on long-term AED therapy is the occurrence of drug interactions when other drugs are given concurrently. These may lead to rise or fall in blood levels of the AED, resulting in occurrence of toxic effects of the drug or the development of seizures (Tables 190.3 and 190.4).

Status Epilepticus

When recurrent seizures occur at a frequency which does not allow consciousness to be regained in the interval between seizures, it is called *status epilepticus*. Severe and permanent brain damage may result from status epilepticus persisting for more than an hour. Since prolonged or frequent seizures also lead to permanent damage to the brain (hippocampus, Purkinje cells of cerebellum and extrapyramidal system) it is the current consensus to consider any seizure (both clinical or electrical) lasting for more than 30 minutes, or more than one seizure within 30 minutes even if consciousness is not lost, as status epilepticus, for purposes of management. Status epilepticus may be convulsive or nonconvulsive. Convulsive status which may be partial or generalised may be tonic, clonic, or myoclonic types and secondary generalised forms. Nonconvulsive status (absence status) or complex partial status may vary from simple slowing of ideas to marked stupor from which the patient can be woken up only by painful stimuli. Nonconvulsive status can be diagnosed only by EEG recordings. Such patients are also prone to develop damage to the brain.

Lactic acidosis, hypoglycemia, autonomic dysfunction, hyperthermia and shock may follow if the status epilepticus continues for a long period. Longer the duration of the convulsive status epilepticus, the more difficult it is to control and higher is the incidence of morbidity and mortality. The mortality in uncontrolled convulsive status epilepticus may range from 5-50%.

Hypoglycemia and hypocalcemia which give rise to convulsions should be excluded by appropriate tests.

Management

Time is a critical factor in the management of status epilepticus. There are many therapeutic regimes but none of them is totally satisfactorily. Benzodiazepines such as **diazepam**, **lorazepam**, **midazolam** and **clonazepam** are all potent fast-acting antiepileptic drugs, preferred for terminating the attack immediately. Initially, when the patient is first seen, 10 mg diazepam (0.3-0.5 mg/kg bw) should be given slowly intravenously over a period of 2-5 minutes. Its action lasts for 20-30 minutes. Lorazepam in doses of 0.1 mg/kg at 2 mg/minute is preferable to IV Diazepam as it has longer duration of action (> 4 hrs) and lesser respiratory depression.

Acetazolamide which is a carbonic anhydrase inhibitor can be used as a second line drug along with other antiepileptic drugs to potentiate their action. Acetazolamide also reduces intracranial tension. Dose is 0.25-1 g in divided doses daily.

Simultaneously a loading dose of phenytoin, i.e. 0.5-1g (18 mg/kg) is given intravenously over 20 minutes at a rate of 50 mg/min in those who are not already on this drug. This dose serves to achieve optimum therapeutic blood level and maintains the antiseizure effect, for a longer period. The anticonvulsant action of **intravenous phenytoin** is manifest within 10-20 minutes. Phenytoin is not absorbed properly after IM injection, and therefore this route should not be relied upon. Large doses of IV phenytoin may lead to hypotension and cardiac arrhythmias, and therefore the patient should be closely monitored clinically and with ECG. In the absence of such a facility phenytoin should be given as IV bolus in doses of 200 mg. Phenytoin levels can be maintained by giving it as an IV drip containing 100 mg in 500 mL of normal saline or distilled water, run at the rate of 40 mL per hour, the infusion lasting for 12 hours. **Phenytoin is incompatible with glucose containing solutions and hence it should not be mixed with them.** If status epilepticus still persists, phenytoin is to be repeated at a dose of 5 mg/kg IV till a maximal total dose of 30 mg/kg is reached. Fosphenytoin is a water soluble prodrug of phenytoin which is similar in action and dosage, but with less of local irritant property. 150 mg fosphenytoin is equivalent to 100 mg phenytoin.

Phenobarbitone given intravenously in doses upto 0.8-1 g in 24 hours (20 mg/kg at 100 mg/min) is an effective anticonvulsant and this should be added if seizures are not controlled by diazepam and phenytoin. In intractable cases thiopental anesthesia is induced with IV injection of 0.3-0.6 g of the drug and this is very effective. Assisted ventilation is mandatory when phenobarb or thiopentone is given, especially after diazepam administration. Once the patient is seizure free, and is able to take oral medication, phenytoin or other antiepileptic drugs are introduced by the oral route.

Guidelines for the Management of Intractable Status Epilepticus

Time Interval Action

0-9 minutes	Assess cardiorespiratory function. Obtain history and perform neurologic and general physical examination. Draw venous blood sample for antiepileptic drug level (if the patient is already on them), glucose, blood urea and electrolyte tests. Establish an IV line with isotonic saline. Administer 25 g of glucose (50 mL of 50%) and 100 mg thiamine IV. Insert oral airway and administer oxygen if needed.
10-30 minutes	If convulsions recur after the IV line is established, administer diazepam (5 mg/min) or lorazepam (2 mg/min) until

seizures stop or the maximum diazepam dose of 20-30 mg or lorazepam dose of 1 mg/kg bw is administered. If convulsions have stopped, start phenytoin at the rate of 50 mg per minute IV to a total bolus dose of upto 18 mg/kg bw (100 mg) at a time and repeated 8 hourly.

31-70 minutes If seizures persist, intubate and ventilate the patient. Start phenobarbitone I.V. at the rate of 100 mg/min to a total dose of 20 mg/kg bw. At the end of 1 hour if seizures persist, continue phenobarbitone at the rate of 5 mg /kg loading dose and thereafter 1-3 mg/kg/hour so as to abolish the electrical seizure activity but without producing hypotension.

If the convulsions persist despite medications, the anesthetist's help is summoned. Patient is given ventilatory support and anesthesia is induced using medazolam or propofol. This controls the convulsions in almost all cases.

On many occasions status epilepticus may be encountered outside hospital settings. Management of such cases becomes more difficult due to problems of intravenous medication in a convulsing patient and the possibility of fatal toxicity of high doses of drugs. In such situations drugs such as **midazolam** in a dose of 0.07-0.08 mg / kg bw, given IM, may be effective. The seizure stops within 10 minutes.

Another safe, but less effective method is to administer any available parenteral preparation of **diazepam rectally** in a dose of 0.5 mg / kg bw to a maximum of 20 mg at a time. The seizure stops within 15 minutes.

IV sodium valproate in doses of 30 mg/kg in 100 mL saline given over 15 minutes has been found to be superior to phenytoin in status—epilepticus (Misra UK et al. Neurology 2006;67:340-42).

General supportive measures include

1. Maintenance of the airway and prevention of aspiration
2. Prevention of injuries
3. Proper oxygenation
4. Attention to fluid and electrolyte balance, and
5. Maintenance of nutrition.

Failure to control status epilepticus is due to one of the following causes:

1. Delay in starting treatment
2. Inadequate dosage of anticonvulsants
3. Improper route of administration of drugs
4. Inadequate supportive care, and
5. Gross involvement of the brain by disease processes such as encephalitis.

Ketogenic Diet

Induction of mild ketosis by instituting ketogenic diets has been found to reduce the frequency of seizure in children. Diet which contains 80% of energy by fat induces ketosis. This diet is not of much use in adults.

Surgical Management of Epilepsy

Cases not responding to medical treatment should be considered for surgery, especially if they have demonstrably abnormal focal brain lesions. When morphologically abnormal lesions are not demonstrable, the epileptogenic focus has to be demarcated by investigations such as intraoperative electrocorticography.

Removal of such an epileptogenic focus often improves neurological function as well. The surgical procedures include cortical excision, hemispherectomy and stereotaxic surgery. Several other procedures have also been developed. A common indication for surgical ablation is temporal lobe epilepsy. The surgical procedure is anterior temporal lobectomy.

Vagal stimulation is an accepted treatment modality for intractable epilepsy. It is advocated for patients above 12 years. This implanted programmable pacemaker like device is set to stimulate the left vagus nerve. Adverse effects include transient hoarseness of voice. In 30 percent of cases the seizure frequency is reduced by 50 percent or more.

Parkinson's Disease 1258

Atypical Parkinsonian Disorders 1262

Secondary Parkinsonism 1262

Neurological Features of Wilson's Disease 1263

Huntington's Disease 1263

Tardive Dyskinesias 1264

Essential Tremor 1264

disease (e.g. tremor in patients with essential tremor, chorea in Sydenham's chorea), or part of the neurological manifestations of the disease, e.g. chorea occurring along with dementia and psychiatric problems in Huntington's disease and finally, delineating the probable etiology of the involuntary movements.

Classically, abnormal involuntary movements are classified into

- 1. **Hyperkinesia**, when there is excess movements and
- 2. **Hypokinesia**, when there is a relative paucity of movements that cannot be accounted for, by weakness or spasticity. The term dyskinesia denotes any involuntary movement but often, hyperkinesia.

Based on the clinical patterns, hyperkinetic movements are subcategorized into *chorea*, *ballism*, *dystonia*, *myoclonus*, *tremor* and *tics*. Identification of involuntary movements can be particularly difficult when a combination of movements coexist in the same individual.

Analysis of involuntary movements are based on the following characteristics: Distribution, velocity, amplitude, rhythmicity, suppressibility, relation to posture, activity and sleep, type of precipitating and relieving

Abnormal Involuntary Movements

GENERAL CONSIDERATIONS

Approach to a patient with involuntary movements involves identifying the type of involuntary movement, determining whether it is the sole manifestation of the

factors, diurnal variation if any and associated sensory and emotional components.

- 1. **Distribution:** Classic tardive dyskinesias in the orofacial region.
- 2. **Velocity:** Very fast in myoclonus, slow in dystonia, intermediate speed in chorea and tremor.
- 3. **Relation to posture:** Tremor at rest in rest tremor of Parkinson's disease, tremor in certain postures in essential tremor.
- 4. **Rhythm:** Regular, e.g. tremor and irregular, e.g. chorea, ballism.
- 5. **Relation to action:** Action tremor, action dystonia, action myoclonus.
- 6. **Relation to sleep:** Palatal tremor can persist in sleep. Most involuntary movements disappear in sleep.
- 7. **Suppressibility:** For example voluntary suppression of tics, sensory tricks such as touching a body part can suppress some forms of dystonia.
- 8. **Aggravating factors:** Stress and anxiety worsen almost all movement disorders.

HYPERKINESIAS

Chorea and Ballism: They resemble each other and often coexist. Chorea consists of rapid, jerky, irregular, movements that may be simple or complex and are usually distal and of low amplitude. The movements have a flowing character and migrate from one part of the body to the other. The movements are purposeless but patients may incorporate them into their voluntary movements as if to make them less conspicuous (quasi-purposive). At times, the movements can be very discreet and resemble fidgetiness, particularly in children.

Walking is interrupted by sudden stops and starts (dancing gait). The patient is unable to maintain smooth muscle contraction. The grip tightens and loosens alternately (milking sign). When the mouth is held open, the tongue is protruded and withdrawn alternately (Jack-in-pot sign). The tendon jerks are often pendular or sustained as a result of added muscular contractions (hung-up knee jerk). Main causes of chorea are Sydenham's chorea, chorea gravidarum, senile chorea, thyrotoxicosis, SLE, encephalitis and drugs like L. dopa and phenytoin.

Very large amplitude chorea with a violent flinging character and arising proximally in the limbs is termed **ballism**. Both chorea and ballism may be bilateral or unilateral; *hemichorea*, *hemiballism*. Hemichorea arises most often from dysfunction of the contralateral caudate nucleus, and ballism from vascular injury to the contralateral subthalamic region.

SYDENHAM'S CHOREA

Syn: Rheumatic chorea, **St. vitus dance**

This is one of the acute rheumatic manifestations. Pathological changes consist of edema and congestion of

different regions of the brain. Microscopy shows marked changes in the corpus striatum, subthalamic nuclei, substantia nigra, and cerebral cortex. The acute changes consist of vasodilatation and perivascular degeneration. Neuronal loss and perivascular glial proliferation have been described (See Chapter 37).

Adolescent girls are affected more often. The onset is abrupt with generalized chorea and emotional lability. Volitional activity and emotional excitement worsen the abnormal movements. Most of the cases recover fully even without treatment. Haloperidol and diazepam give symptomatic relief of the abnormal movements.

Causes of Chorea	
Hereditary-AD	Huntington's disease, benign hereditary chorea
Hereditary-AR	Wilson's disease, ataxia telengiectasia,
Hereditary-maternal inheritance	Mitochondrial encephalopathies
Immune mediated	Rheumatic chorea, SLE, chorea gravidarum
Vascular	Infarcts
Metabolic	Hypo or hypernatremia, hypocalcemia, hypo or hyperglycemia
	hyperthyroidism, hypoparathyroidism
Toxic agents	Carbon monoxide, mercury
Inflammatory drugs	Encephalitis, ADEM
	Neuroleptics, metoclopramide, L-dopa, phenytoin, steroids, oral contraceptives and several others
Key AD- autosomal dominant AR- autosomal recessive ADEM- acute disseminated encephalomyelitis	

TREMOR

Tremor consists of rhythmic involuntary oscillations of a body part produced by alternating or synchronous contractions of reciprocally innervated muscles. Tremor may be present solely at rest, on assuming a posture, during action or on reaching a target. Tremor may be fine or coarse. Tremor may be physiological when it is caused by subtetanic contractions of muscle fibres and is usually fine and detectable only with amplification systems. When this tremor becomes noticeable when the arms are held out against gravity or during action, it is called enhanced physiological tremor. Anxiety and fear are common situations which *enhance physiological tremor*. Thyrotoxicosis, hypoglycemia, alcohol withdrawal, drugs such as salbutamol and ephedrine, sodium valproate, lithium, amphetamines and caffeine can cause enhanced physiological tremor. These conditions should be excluded before diagnosing pathological tremor.

Essential tremor (ET): Tremor is the sole neurological sign. Tremor in ET is most often seen in the hands. It can also occur in the head, lips, chin, voice and rarely in the

legs. ET becomes manifest when the hands assume certain postures and may change with varying postures.

Parkinsonian tremor: Tremor at rest (RT) when the limb is in repose, is typical of Parkinson's disease and uncommon in other parkinsonian disorders. RT is coarse and slow with a frequency of 4-5 Hz, is often intermittent and begins in one of the hands. It is precipitated by anxiety and emotional excitement. It disappears during action or on assuming a posture and in sleep. Postural and action tremor can also occur in PD.

Intention tremor: Tremor of the limbs that exacerbate on reaching a target is called intention tremor (IT). It is coarse and the oscillations of the limb occur at right angles to the direction of movement of the limb. It indicates involvement of the cerebellum or its connections.

Wing-beating tremor: This tremor is typical of Wilson's disease and results in large amplitude of the outstretched limbs and is more proximal in its distribution. It results in the limbs being thrown up and down like flapping wings, particularly when the arms are kept abducted at the shoulder and flexed at the elbow with palms facing down.

Psychogenic tremor. The onset of tremor is usually abrupt and in the majority the maximum intensity is at onset and does not worsen with time. The tremors can occur at rest and persist during posture and action. With distraction, the tremor usually lessens in amplitude or changes frequency or may disappear. Even though other forms of organic tremor can be intermittent, complete cessation with distraction is not seen in organic tremors and it may even worsen during distracting actions demanding mental concentration. The arms are most commonly affected, followed by the head and then the legs.

DYSTONIA

The term dystonia was coined by Oppenheim in 1911 to describe a disorder causing variable muscle tone and recurrent muscle spasm. Dystonia is an abnormal involuntary movement characterized by sustained muscle contractions, frequently causing twisting and repetitive movements or abnormal postures. Dystonic movements are usually slow, but quick components may also coexist causing confusion with myoclonic jerks. They are arrhythmic and tend to aggravate with stress, fatigue and emotional upset but are relieved by sleep and rest. An interesting feature of dystonia is the patient's ability to suppress the movement by a sensory trick that is usually tactile or proprioceptive, e.g. dystonia of the neck may be suppressed by the patient by touching the chin or side of the face.

According to the site of involvement, dystonia is classified into (i) focal, e.g. dystonia of the neck (*spasmodic torticollis*) or eye lids (*blepharospasm*) or limb, (ii) segmental, when 2 or more contiguous parts are affected, e.g. *Meig's syndrome* which is a combination of blepharospasm with oromandibular dystonia, (iii) *multifocal*, when 2 or more noncontiguous parts are affected, (iv) *hemidystonia*, affecting hemibody and (v) *generalized* (leg with involvement of other parts). Dystonia is also classified based on etiology into primary or secondary dystonia. Many of the primary dystonias are due to known genetic defects and pathology is not clear. Secondary dystonias have a known cause, e.g. hemidystonia is often due to a pathology involving the opposite basal ganglia or its connections, e.g. infarct in the opposite putamen.

Secondary dystonias: These include:

1. Heredo-degenerative dystonias with known neuropathological features.
2. Drug-induced dystonia.
3. Dystonia caused by acquired structural lesions.

Athetosis

This term was used to denote a syndrome in which there is inability to maintain a single muscle or muscle groups in a fixed posture. The limbs, face, tongue or the whole body undergo a slow sinuous writhing involuntary movement which continuously goes on. The distal parts are affected more often. Athetosis may be unilateral at times. Choreoathetosis occurring at an early age is a sequel of hypoxic damage to the brain or kernicterus. Temporary athetosis may occur in hepatic encephalopathy or as a toxic reaction to phenothiazines and antipsychotic drugs. The term athetosis is seldom used now since the abnormalities merge under the common term dystonia.

Treatment

1. **Drugs:** Some dystonias are dopa-responsive. A trial of carbidopa-levodopa 25/100 mg tds is beneficial in 50% of cases. High dose anti-cholinergic drug treatment with trihexyphenidyl 6-80 mg/day or benzotropine 4-8 mg/day is partially effective in 40-50% of primary and secondary dystonias. Several other drugs including antiepileptic drugs have been tried.

Botulism toxin serotypes A and B inhibit the release of acetylcholine at the neuromuscular junctions, when injected into dystonic muscles. It reduces muscle spasm and dystonia in 70-90% of cases for varying periods.

2. **Surgery:** Selective peripheral denervation gives variable results. Deep brain stimulation of the globus

pallidus is being introduced for the treatment of medically refractory dystonia.

3. Physiotherapy

Muscle stretching and strengthening may be used to avoid contractures. Mechanical assisting devices reduce disability.

For additional on line information on dystonia the reader is referred to [www. dystonia-foundation. org](http://www.dystonia-foundation.org) and at [www. wemove. org](http://www.wemove.org).

MYOCLONUS

Myoclonus is a brief shock- like muscle jerk caused by neuronal discharges. A sudden interruption in ongoing muscular contractions can produce a postural lapse, called negative myoclonus, e.g. asterexis. Myoclonus can be spontaneous or triggered by an external stimulus (reflex myoclonus) or by voluntary muscle activation (action myoclonus). Myoclonus can be rhythmic or irregular. According to its distribution, myoclonus is classified as focal, segmental, multifocal or generalized. Based on its neurophysiological origin, myoclonus may be cortical, subcortical (brainstem) or spinal.

Classification of myoclonus

Clinical Presentation

- Spontaneous
- Reflex
- Action

Topography

- Focal
- Segmental
- Multifocal
- Generalized

Neurophysiological Origin

- Cortical
- Subcortical
- Spinal

Etiology

- Physiological
- Essential
- Symptomatic

Myoclonus can be associated with other involuntary movements in the same patient, e.g. myoclonus and dystonia in patients with hereditary essential myoclonus, chorea and myoclonus in patients with Huntington's disease. Myoclonus may be a major clinical manifestation of idiopathic epilepsy, e.g. juvenile myoclonic epilepsy. Myoclonus may be secondary to CNS dysfunction, e.g., post hypoxic myoclonus (**Lance-Adams syndrome**), myoclonus due to metabolic disturbances, drug-induced myoclonus, etc.

Sometimes myoclonus may occur in normal persons during sleep, without any evidence of disease.

Fig. 191.1: Facial hemispasm

Tics

Tics are recurrent, nonrhythmic, stereotyped movements (motor tics) or sounds (vocal tics). Motor tics can be simple such as eye blink, shoulder shrug, head jerk or complex movements such as jumping, kicking, touching etc. Vocal tics can be inarticulate sounds like throat clearing, sniffing or grunting and complex when they are words with meaning. These complex vocal tics could be repeating words of others (*echolalia*), repeating one's own words (*palilalia*), or obscene words (*coprolalia*). An irresistible urge precedes the tic. Tics can be suppressed temporarily but with a build-up of inner tension which is relieved only by execution of the tic (Fig. 191.1).

Extrapyramidal Disorders

Parkinsonism is the prototype of hypokinetic movement disorders and refers to a syndrome comprising of bradykinesia (slowness of movements), rigidity, tremor and postural instability. *Parkinson's disease* (PD) is the most common form of parkinsonism and the symptoms of parkinsonism constitute the predominant manifestation of PD. There is no biological marker for PD and the diagnosis is based entirely on the history and neurological examination. A few other conditions have in addition to parkinsonism, other distinctive neurological signs and are called *atypical parkinsonism*, e.g. progressive supranuclear palsy (PSP), multiple system atrophy (MSA), corticobasal degeneration (CBD) and dementia with Lewy bodies (DLB). In a third category of diseases called *secondary parkinsonism*, the causative factor is known, e.g. parkinsonism due to exposure to dopamine receptor blocking drugs like neuroleptics, dopamine depletors like

tetrabenazine and reserpine, infections, strokes, hydrocephalus and others. In one series, 20% of patients diagnosed as PD during life had some form of atypical parkinsonism at autopsy.

Parkinson's Disease

James Parkinson in 1817 wrote the original description of the disease in his monograph “An essay on Shaking Palsy” and the condition he described now bears his name. Interestingly, descriptions of similar symptoms can be found for the condition called “*Kampavatha*” in ‘*Charaka Samhitha*’ written in the Vedic times (1500 to 1000BC).

Epidemiology

PD is found world-wide and is one of the most common extrapyramidal disorders seen in clinical practice. PD occurs at a frequency of 1% in people older than 60 years and 0.3% of the general population, according to western statistics. Epidemiological studies have shown a relatively lesser incidence and crude prevalence of PD in countries like Africa, India and China when compared to Western populations except among the Parsis of India who have a high incidence of the disease. However, these observations are controversial because of the inadequate design of most studies. PD affects men and women with a slightly higher incidence among men. The mean age of onset of the disease is in the early 60s though it can occur at younger ages in 5-10% of cases. PD with age of onset less than 40-50 years is called “*young-onset PD*” and when less than 20 years, is called “*juvenile-onset PD*”.

Etiology and Pathology

The etiology of sporadic forms of PD is not known. Besides older age and positive family history, case – control studies seeking an association between environmental exposure and PD have suggested an increased risk associated with farming, rural residence, herbicide/pesticide exposure, employment in industries manufacturing chemicals, and mining and steel. There is

an inverse association between cigarette smoking and coffee drinking with PD and the exact mechanisms of these effects are unknown.

Pathologically, the disease is characterized by loss of pigmented neurons, most prominently but not solely, in the substantia pars compacta of the midbrain and in the locus coeruleus and the presence of ubiquitin-positive and alpha synuclein-positive inclusions called *Lewy bodies* in the degenerating neurons.

Genetics of Parkinson's Disease

About 10 to 15% of patients with PD have a first degree relative with the disease. In recent years, six genes (alpha synuclein, parkin, UCH-L1, DJ1, PINK1, LRRK2) and several more loci have confirmed the existence of genetic forms of PD, both autosomal recessive and dominant. Some of the defective genes cause disease by protein aggregation within cells and their discovery has enhanced the understanding of the potential mechanisms of neurodegeneration in both genetic and sporadic forms of PD.

CLINICAL FEATURES

- 1. **Hypokinesia or bradykinesia:** These terms refer to the poverty of automatic and voluntary movements due to defective motor planning. Voluntary movements are slow to initiate, reduced, and they lack precision. The associated movements on walking such as swinging of the arms and movements of the body are considerably reduced. Even though voluntary activity is difficult and slow, reflex activity remains normal for considerable periods. Though the voluntary movements are slow, the motor power is usually normal.
- 2. **Rigidity:** Increase in tone manifesting as rigidity of the limbs and trunk is characteristic of parkinsonism. This rigidity is present throughout the range of movement (‘lead pipe’ rigidity), unlike the spasticity of upper motor neuron lesion where the increase in tone is felt maximally at the commencement of the movement. When rigidity is associated with tremor,

Genetic forms of PD				
Name	Gene product	Mode	Difference from sporadic PD	Pathology
PARK 1	Alpha synuclein	AD	Early onset, less tremor	Lewy body +
PARK 2	Parkin	AR	Juvenile, dystonia, LIDS, slow	Lewy body –
PARK 3	Unknown	AD	Dementia, rapid progression	Lewy body +
PARK 4	Alpha synuclein	AD	Dementia, rapid progression	Lewy body +
PARK 5	UCH-L1	AD	Typical PD	Unknown
PARK 6	PINK-1	AR	Early onset, slow progression	Unknown
PARK 7	DJ-1	AR	Early onset, slow progression	Unknown
PARK 8	LRRK 2	AD	Typical PD	Lewy body –
PARK 9	Unknown	AR	Spasticity, gaze palsy, dementia	Unknown
PARK10	Unknown	Non	Typical PD	Unknown

it results in 'cogwheel' type of rigidity. Rigidity of the facial muscles gives rise to a 'mask-like facies' with no expression and also infrequent blinking.

3. **Tremor:** The characteristic tremor occurs at rest. Initially tremor is seen in the hands, but later this extends to the lower limbs. The thumb moves transversely across the tip of the flexed fingers rhythmically and this is aptly described as the 'pill rolling tremor'. Later the tremor becomes more extensive and in addition to the limbs, the face, lips and tongue also become tremulous.
4. **Alteration in posture:** The patient assumes an attitude of generalized flexion, which makes him stoop forward. He walks with short steps and as he walks he gains speed and tends to run forwards. This phenomenon is termed 'festination'. The terms 'propulsion' and 'retropulsion' are used to denote the phenomenon seen when the standing patient is gently pushed forwards or backwards. The patient continues to move forwards or backwards without control. Due to the rigidity in movement the patient finds it difficult to turn around while walking. He tends to trip and fall more often and postural adjustments become difficult. Speech becomes slow and monotonous. There is lack of initiative and the patient tends to restrict his activity progressively. The deep reflexes and sensations are generally unaffected.

Higher faculties such as intelligence and memory are usually preserved.

Resistant symptoms: In addition to the obvious classic symptoms, several others occur which are disabling and prove resistant to treatment. These include:

- a. Imbalance and postural instability,
- b. Paroxysmal akinesia,
- c. Vague body pains,
- d. Dystonias,
- e. Autonomic disturbances leading to difficulty in micturition, constipation, sexual problems, seborrhea, and excessive salivation,
- f. Speech difficulty, and
- g. Psychological abnormalities such as depression, melancholia and paranoid fears.

The clinical diagnosis of PD is made from history, clinical examination and response of symptoms and signs to the drug levodopa, which is the precursor of dopamine.

Presence of bradykinesia along with any of the 3 other cardinal signs of PD, i.e. rest tremor, rigidity and postural instability suggests PD. Bradykinesia or slowness of movement is the most disabling early symptom of PD. Patients often have micrographia, hypophonia and reduced armswing before the typical signs appear. It results in slowness of walking, difficulty in rising, doing fine motor tasks and other activities of daily living. Limb bradykinesia, rigidity and rest tremor of PD are typically

asymmetric at onset and the asymmetry often persists even after the disease becomes generalized. The rest tremor of PD is seen in the hands early, has a frequency of 3-5 Hz (resembles pill rolling) and is the first symptom in 70% cases of PD.

Muscle sounds in Parkinson's disease: A sound with a frequency of 40 Hz can be heard with a stethoscope over the muscles of the hand and forearm during tonic condition or movement in normal subjects. In parkinsonism this is replaced by slow activity sounds at 10 Hz. The sounds correlate with the piper-rhythm seen in EMG records of muscle activity.

The exclusion criteria to diagnose PD are causes of secondary parkinsonism,

These include

1. presence of signs that suggest atypical parkinsonism such as supranuclear gaze palsy (except mild upgaze restriction seen in old age),
 2. cerebellar signs,
 3. early and severe autonomic dysfunction such as orthostatic hypotension (unrelated to dopaminergic drugs), early urinary incontinence, early falls,
 4. cortical sensory loss, prominent pyramidal signs,
 5. early dementia, myoclonus,
 6. MRI evidence of subcortical white matter disease, focal atrophy, structural lesions or hydrocephalus.
- MRI is not required to make a diagnosis of PD but is necessary if there are atypical signs or symptoms.

The non-motor symptoms of Parkinson's disease include depression, anxiety, dementia late in the disease, psychosis, insomnia, rapid eye movement, sleep-disorder, autonomic dysfunction, urological, constipation and sexual disturbances, sensory symptoms, dysphagia and gastric dysfunction.

Natural History and Prognosis

Untreated, the progress of the disease is steady and relentless. The tremor is less disabling than rigidity and hypokinesia, since the tremor reduces or stops during voluntary activity. Rigidity and hypokinesia restrict motor activities considerably so that the patient is unable to get-up from bed and carry-out the activities of daily life. PD shortens life. Death is due to inanition, respiratory and other infections, falls and trauma. With treatment, the quality of life improves.

TREATMENT OF PD

At present there is no cure for PD. The concept of neuroprotection in PD is attractive and refers to therapeutic strategies that might modify the course of the disease by interfering with the underlying disease mechanisms. The first agent to be tested as a neuro-protective agent in PD was *selegiline*, which is an

irreversible inhibitor of the enzyme monoamine oxidase-B (MAO-B), which produces oxidative deamination of dopamine. A large multicentre trial (DATATOP study) which tested the neuroprotective roles of selegiline and vitamin E (antioxidant) showed that selegiline delayed the need for levodopa treatment. However, the latter effect could be attributed to the symptomatic benefits of selegiline on parkinsonism and hence its neuroprotective role remains unproven. *Coenzyme Q10 (COQ)* is an electron acceptor for complexes I and II in the mitochondrial electron transport chain and is also an antioxidant. Pilot studies have shown less disability in patients taking COQ. Larger studies are underway to test coenzyme Q 10 and the antibiotic minocycline for neuroprotective functions. There is preliminary data from functional imaging of the dopaminergic system suggesting that dopamine agonists may slow the progression of PD when compared with levodopa. However, the interpretations of these data have been debated and the issue of the neuroprotective role of dopamine agonists also remains unresolved. Even though the neurotrophic factor, *glial cell line derived neurotrophic factor (GDNF)*, was found effective when directly delivered to the putamen in PD in a small open labeled study of five patients, the observation remains to be replicated in large double blind studies. Based on the available information, there is no compound which can be considered to be unequivocally effective as a neuroprotective agent in the treatment of PD.

Symptomatic treatment of PD: In the general management, it is important to encourage the patient to continue in his job and daily activities, since restriction of activity leads to rapid deterioration.

The medical treatment of PD is challenging at every phase of the disease. The goal of therapy is to maximize the control of motor symptoms and minimize the complications of treatment which are also due to progression of the disease. Treatment is begun when patients experience functional or social disability because of their symptoms. The age of the patient, the most problematic symptom, severity of disability, presence of cognitive impairment, co-morbid medical conditions and cost of drugs influence the choice of drugs for early treatment. *The treatment options for early PD includes dopamine agonists (DA), anticholinergics, amantadine, MAO inhibitors (selegiline, rasagiline) and levodopa which should always be combined with peripheral decarboxylase inhibitor carbidopa or benserazide to prevent the peripheral metabolism of levodopa.*

Patients with young-onset PD develop motor response variations to levodopa treatment and levodopa-induced involuntary movements (chorea, ballism, dystonia) within 3-5 years of exposure to levodopa. For this reason, levodopa treatment is delayed in them till disease severity

or disability demands its use. Until then, early cases are best treated with dopamine agonists (DA). Dopamine agonists belong to two categories (i) ergot –derived (*bromocriptine, pergolide* and *cabergoline*) and (ii) the non-ergot- derived compounds (*ropinirole, pramipexole, apomorphine*). The long-term use of ergot-derived agonists is associated with the risk of retroperitoneal, pulmonary and cardiac-valve fibrosis. Therefore, non-ergot compounds are preferred. Apomorphine can be given subcutaneously or as an intravenous infusion, but is usually used in patients with advanced disease. Pergolide and apomorphine are not yet available in India. Many patients with early PD can be maintained on dopamine agonist monotherapy for the initial 2 years of the disease and L.dopa therapy can be instituted when dopamine agonist therapy becomes ineffective to control the symptoms. Motor response fluctuations and drug-induced dyskinesias are rarely seen during DA monotherapy. The common side effects of DA are nausea, hypotension, pedal edema, vivid dreams, nightmares, hallucinations and delusions, day time somnolence and sudden sleep attacks. Psychotoxic side effects of DA agonists are more in the elderly population (Table 191.1).

Young patients with prominent tremor may benefit from anticholinergic drugs like trihexyphenidyl and bztropine, even though these drugs are not superior to levodopa in controlling tremor.

Amantadine is a tricyclic amine and has multiple actions in the CNS. It has mild antiparkinsonian benefits similar to anticholinergic drugs. Patients may develop tolerance to its effects within a year of its use. In developing countries, *trihexyphenidyl* (up to 6mg daily) and *amantadine* (100mg 2-3 times /day) are often given to young patients who cannot afford dopamine agonist treatment.

Selegiline (MAO inhibitor) can also be tried in doses of 5 to 10 mg per day in early PD in the young. Its benefits are modest. Rasagiline, another MAO-B inhibitor and Zydus selegiline, a novel formulation of selegiline are under evaluation for use in early and late PD.

Levodopa (L. dopa)

Of all the available antiparkinsonian drugs, levodopa is most effective for relieving the signs and symptoms of PD. Tremor can be resistant to all drugs including levodopa. Treatment is begun in small doses of levodopa-carbidopa combination which contains 50-100 mg of levodopa and 5-10 mg once or twice a day for a week and increased gradually to a TID schedule. The lowest effective dose needed for improvement in activities of daily living should be maintained at all times. The average dose requirement is around 400 to 600 mg. Levodopa-carbidopa is also available as a sustained release formulation but it is still required in TID to QID doses. Monotherapy with the

TABLE 191.1

Details of the commonly used anti -Parkinsonism drugs			
Class of drug	Adverse events	Dosing	Dosage
Dopamine agonists <i>Bromocryptine</i>	Nausea, hallucinations, somnolence, orthostatic hypotension	TID	2.5 mg HS to start with later 2.5 mg to 5 mg bd or tid up to 40 mg/day
Anticholinergics <i>trihexyphenidyl</i>	Dry mouth, constipation, urinary retention, memory impairment, confusion, hallucinations	TID	Trihexyphenidyl 2 mg tid
Amantadine	Mental confusion, disorientation, leg edema	BID-TID	100 mg tid
Selegiline	Nausea, headache, insomnia, hallucinations	BID (no evening dosing)	5 mg bid with breakfast and lunch
Levodopa	Nausea, dizziness, somnolence hallucinations, on- off episodes	TID-QID	100-200 mg tid
COMT inhibitors (tolcapone, entocapone)	Somnolence, insomnia, hallucinations	Combine with each levodopa dose	

sustained released formulation has not been found to prevent the development of motor response fluctuations or levodopa-induced dyskinesias.

If the disease severity warrants levodopa treatment, it may be used as monotherapy in the minimum required doses to young-onset PD cases for whom quick and substantial relief of symptoms is needed. DA can be added later to this regimen if more dopaminergic treatment is required.

In view of the enhanced side effect profile of these non-levodopa classes of drugs in the elderly, treatment is begun initially with levodopa in older patients. Levodopa is contraindicated during pregnancy, lactation, severe psychosis, narrow angle glaucoma, children below 18 years and in the presence of allergy to the drug.

Complications of Levodopa Treatment

Long- term treatment with levodopa is associated with motor fluctuations. The exact mechanism of this phenomenon is not known but is related to the severity of the underlying disease as well as treatment related factors such as duration of treatment and dose of levodopa. It is believed to be caused by the short half life of levodopa (90-120mts). “Wearing off” is a type of motor fluctuation characterized by the perception of loss of mobility or dexterity, usually taking place over minutes up to an hour and usually has a close temporal relation to the timing of antiparkinsonian medications. “On –Off” fluctuations are unpredictable and cause sudden shifts between periods of good mobility (On) and immobility (Off) that are not related to the timing of antiparkinsonian medications. An increase in the interval between dose of medication and the patients experience of an “On” response (“delayed On”) and the absence of a response to an individual dose (“dose failure” or “no on”) may relate to delayed gastric emptying.

Treatment of fluctuations focuses on trying to improve gastric absorption, increasing the dosing frequency and prolonging the effect of individual doses by switching to sustained release formulation or addition of a new class of drugs called Catechol-O-methyl-transferse inhibitors (COMTI) e.g. *entacapone* or *tolcapone*, with each dose of L-dopa to prevent its metabolism by COMT. Combination of levodopa, carbidopa and entacapone are available. Tolcapone has been withdrawn from the US market because of reports of fatal hepatotoxicity with its use. Addition of DA can also reduce the duration of time spent by the patients in “off” state.

Levodopa-induced involuntary movements (levodopa-induced dyskinesias-LIDs) can take several patterns. Pulsatile stimulation of dopaminergic receptors by intermittent oral doses of levodopa is thought to be the underlying mechanism of development of LIDs. They are most common at peak dose and can be chorea, ballism or dystonia. Dyskinesias may appear only at the beginning or end of the effect of levodopa and are called diphasic dyskinesias. Patients can develop painful dystonia at the end of the levodopa dose cycle. Peak dose LIDs can be controlled by reducing the dose of levodopa but that can lead to worsening of the control of parkinsonism. Surgical treatment is recommended for patients with disabling motor fluctuations and dyskinesias that cannot be controlled by medical management.

Surgery for Advanced Parkinson’s Disease

In the pre-levodopa era, thalamotomy (chemical or electrical destruction of thalamic nucleus) was practiced for the control of tremor and pallidotomy (lesioning of globus pallidus) for parkinsonism, with variable results. Surgical treatment has been revived from the early 1990s to manage the problems of medically intractable motor

fluctuations. Currently newer imaging modalities such as MRI, intraoperative microelectrode recording for locating the target nucleus and macrostimulation with intra-operative neurological assessments for testing the safety and efficacy of the procedure in the target, are employed to make these procedures safer and more rewarding.

The two major targets for surgery are the globus pallidus interna (GPi) and the subthalamic nucleus (STN) which are the two nuclei in the basal ganglia motor circuit that become pathologically overactive as a consequence of dopamine deficiency. The currently used technique of pallidotomy involves a radiofrequency lesioning of the GPi. It relieves all contralateral parkinsonian signs for 2-3 years but more long-lasting and substantial benefit is seen in tremor and LIDs. Bilateral simultaneous pallidotomy carries the risk of cognitive side effects.

Deep brain stimulation (DBS) is the technique which involves implantation of electrodes into the GPi or STN and stimulating these nuclei at high frequency to reduce their neural activity, using an implantable pulse generator which is also programable. The stimulation is reversible and does not involve brain injury as in ablative procedures. Bilateral DBS provides substantial relief to all the motor symptoms of PD and long- term results of the procedure are awaited. Even though DBS has replaced pallidotomy in the West, the cost of the former procedure limits its wide spread use in developing countries. In India pallidotomy continues to be practiced in many centres.

Atypical Parkinsonian Disorders

The “atypical parkinsonian disorders” (previously known as “Parkinson-plus syndromes”) are characterized by a rapidly evolving parkinsonism that has a poor or transient

response to dopaminergic therapy and is often associated with one or more atypical features for PD. Some of these features include early presence of postural instability, early autonomic failure, vertical supranuclear gaze palsy, pyramidal or cerebellar signs, early dementia, loss of cortical sensations and apraxia. In clinical practice and research, it is important to differentiate atypical parkinsonism from PD as the former is associated with reduced life span, and diminished response to dopaminergic treatment. It is associated with more severe complications early in the disease. Such patients also need to be excluded from surgical treatment programmes.

The sporadic forms of atypical parkinsonism are progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), multiple system atrophy (MSA) and dementia with Lewy bodies (DLB). The familial atypical parkinsonian disorders include frontotemporal dementia with parkinsonism linked to chromosome17 (FTDP-17), spinocerebellar ataxia, rigid form of Huntington’s disease, Wilson’s disease, and pantothenate kinase associated neurodegeneration (PKAN, previously called Hallervoden-Spatz syndrome).

Secondary Parkinsonism

Causes: Parkinsonism may develop as a complication of several conditions—

- 1. Drugs—Neuroleptics, calcium channel blockers, some anti-emetics.
- 2. Heavy metals—Manganese, mercury.
- 3. Normal pressure hydrocephalus (NPH).
- 4. Infections—HIV, Creutzfeldt-Jakob disease.
- 5. Vascular injury—Infarcts in basal ganglia and subcortical white matter.
- 6. Hypoxia.

Differential diagnosis of atypical parkinsonian disorders				
	PSP	MSA	CBD	DLB
Progression	Rapid	Rapid	Rapid	Rapid
Postural instability/falls	Early	Early	Late	Early
Parkinsonism	Symmetrical axial more than limbs	Symmetric	Asymmetric	Symmetric
Vertical gaze palsy	++	-	Late	Rare
Dystonia	Neck, limbs	Neck	Asymmetric in limbs	Late
Myoclonus	Absent	++	++	++
Pyramidal signs	++	++	Asymmetric	Late
L-dopa response	+/-	1/3 may respond	No response	Variable response
Dementia	Early	Mild	Lateralized cortical dysfunction	Early, severe
PSP- progressive supranuclear palsy MSD- multiple system atrophy CBD- corticobasal degeneration DLB- dementia with lewy bodies				

7. Endocrine disorders—Hypoparathyroidism.
8. Toxins—Methyl phenyl tetra hydropyridine (MPTP) which is used for drug abuse.

Neurological Features of Wilson's Disease (WD)

See also Chapters 32 and 93.

In 1912, Kinnier Wilson described the clinical and pathological features of this condition in his doctoral thesis under the name of progressive hepatolenticular degeneration. Though case reports of similar cases were published by others before him, the disease bears his name for his accurate descriptions of its detailed characteristics which helped to define it as a distinct clinical syndrome. Wilson's disease was identified as a hereditary process in 1921 by Hall. In 1985 Frydman and colleagues suggested that WD gene (Wc1) was located on chromosome 13. In 1993 WD was discovered to be caused by a defect in the gene that encodes a copper transporting P-type adenosine triphosphatase (ATPase) that is expressed in the liver and kidney. WD is a disease of copper toxicity. The problem is not one of excessive absorption of copper but a consequence of faulty transportation and elimination of copper. Ceruloplasmin is a globulin that binds and transports copper molecules. Although ceruloplasmin is characteristically reduced in WD it is not merely a disease of ceruloplasmin deficiency. In fact 5-15% of cases with WD may have normal or only slightly reduced ceruloplasmin.

Clinical Features

Untreated WD will eventually develop symptoms and signs of neurological dysfunction and in 40% of patients, it may be the initial manifestation. The average age at which neurological symptoms manifest is later than the average age of onset of hepatic manifestations (18 years versus 11 years), although neurological symptoms can occur in childhood and in adults even beyond 50 years.

The most common neurological presenting symptom in WD is tremor which may be rest, postural or intention tremor, fine or coarse, proximal or distal in the limbs and is invariably asymmetric. The proximal coarse tremor of the upper limbs in WD has been called "wing beating" tremor. Dysarthria, drooling of saliva and a fixed grimace-like smile (risus sardonius) are common in WD. In addition to facial and pharyngeal dystonia which cause the latter symptoms, dystonia can frequently affect the limbs and trunk in WD. Wilson's disease can also have features of parkinsonism. Some cases of WD can give rise to a cerebellar syndrome with scanning or staccato speech, intention tremor and impaired coordination. This is called pseudosclerotic type of WD because of the superficial

resemblance to multiple sclerosis. Seizures can occur rarely. Pyramidal signs and lower motor neuron signs (wasting, areflexia) are not seen in WD.

A high index of suspicion is required to diagnose WD. It is important to examine for **Kayser Fleischer (KF) ring** which is formed by the deposition of copper in the Descemet's membrane of the cornea in children, adolescents and adults with dystonia, tremor, parkinsonism, psychiatric disturbances and cerebellar syndrome. The ring appears first at the periphery of the cornea in the upper pole, followed by lower pole and then spreads around and centrally. The colour of the ring can vary from golden brown to green and may be difficult to visualize in patients with brown or black eyes. It is therefore essential to get a slit lamp examination by an experienced ophthalmologist to see the KF ring. The diagnosis is confirmed by the demonstration of KF ring, 24-hour urinary copper which is high, serum ceruloplasmin which is low and estimation of hepatic copper by liver biopsy. MRI brain is more sensitive than CT scan to look for brain involvement in WD. The basal ganglia, brain stem and thalami are characteristically involved in WD and the MR changes appear as hyperintense (white) signals in these areas in T2-weighted MRI scans. Molecular genetic testing of WD is not yet commercially available. The treatment of WD consists of 4 approaches: Limiting dietary copper, drugs that chelate copper such as pencillamine, trientine (triethylene tetramine dihydrochloride), drugs that reduce intestinal copper absorption, e.g. zinc sulphate or zinc acetate and ammonium tetrathiomolybdate, and finally liver transplantation. For dosage details see section 10 Chapter 93.

Huntington's Disease

Huntington's disease (HD) is an autosomal dominant neurodegenerative disease caused by mutation in the gene that encodes for the protein Huntington (IT15) which is expressed in normal neural and non-neural tissues. The genetic defect in chromosome 4 consists of an excessive number of trinucleotide CAG repeats that code for the polyglutamine stretch in the Huntingtin protein. HD occurs worldwide but the highest concentration is in Venezuela.

HD is characterized by choreiform movements, intellectual decline and behavioral disturbances and it runs a relentless course. The majority of patients develop the symptoms in the late 30s while 5-10% of cases occur before the age of 20 years (juvenile HD). Rigidity, dystonia and slowness of movements (bradykinesia) are the predominant features of juvenile HD (in whom paternal inheritance is more common) than in the typical adult-onset form. They also have longer CAG repeat lengths in their abnormal gene. Cognitive and psychiatric

features of HD are the most important indicators of functional decline. Around 30 to 50% of patients develop depression and the risk of suicide is high. Psychosis is seen in 10% of cases.

CT and MRI brain show atrophy of the caudate nuclei and volumetric MRI may show atrophy of putamen as well. The disease is confirmed by genetic testing. Pre-symptomatic testing of unaffected family members has ethical, psychological and social implications and should be done only after professional counselling in experienced centres. Treatment of HD is only symptomatic for chorea and behavioral problems. There is ongoing research on neuroprotective strategies in HD.

Tardive Dyskinesias

The term tardive dyskinesias (TD) applies only to the abnormal movements that result from chronic treatment with agents that block central dopamine receptors for at least 3 months in persons with no other identifiable cause for the movement disorder. Most often these are antipsychotic neuroleptic agents (NL). Antidepressants with dopamine receptor blockade (e.g. amoxapine), anti-nausea medications like metoclopramide and rarely calcium channel blockers (e.g. cinnarizine) can also cause TD. A variety of abnormal movements occur in TD. The most common movements are choreic or stereotypies which are regular repetitive movements in the same anatomic distribution. Any body area may be affected, but mouth is more often affected causing lip smacking, tongue protrusion or grimacing (classical TD). Dystonic movements (tardive dystonia) can occur in TD alone or in combination with chorea or stereotypies. Tardive akathisia is an unpleasant sensation of internal restlessness which is partially relieved by volitional movements, usually of the lower extremities. Tics, myoclonus and tremor can occur as part of TD.

TD has no universally effective therapy and therefore prevention is most important. Neuroleptics should be used

conservatively and only when necessary. The new class of atypical neuroleptics (e.g. clozapine, olanzapine and quetiapine) are less frequently associated with TD and should be preferred over the typical neuroleptics.

Essential Tremor

Essential Tremor (ET) is most likely the most common movement disorder in the population. The prevalence has been estimated to be around 1074 per 100,000 population in a western population and 1.59 in the Parsi community in India. The prevalence increases with advancing age and is more in men than women. Positive family history for ET varies from 17 to 70% and such cases are inherited in an AD manner. The genetic locus has been identified in some families but the abnormal gene has not been located.

ET can begin at any age and the course is variable. Tremor is the sole manifestation of ET and most frequently occurs in the hands. Minor abnormalities in tone or gait may be seen occasionally. Tremor is of the postural type best seen in the outstretched hands and sometimes manifesting only in specific postures. Voluntary goal directed action aggravates the tremors. Rest tremors may occur rarely. The frequency of the tremor may range from 4 to 12 cycles per second. The tremors may start unilaterally but later it involves both hands. The hand writing becomes tremulous and angular but there is no micrographia as in Parkinson's disease. Tremor of ET can affect the head, tongue and voice in isolation or combination with limb tremor. Alcohol may produce marked amelioration of ET. It is important to exclude anxiety, thyrotoxicosis and exposure to tremorogenic drugs before diagnosing ET. ET is often mistaken for PD because of the coarse tremor and the age related slowness in some individuals. Treatment involves the use of beta blockers such as propranolol and primidone. Severe disabling ET that does not respond to medical treatment can be ameliorated considerably by surgeries such as thalamotomy or deep brain stimulation in the ventral intermediate nucleus of thalamus.

Miscellaneous Extrapyrarnidal Syndromes

P.K. Mohan, K.V. Krishna Das

Chapter Summary

Kernicterus 1265
 Drug Induced Extrapyrarnidal Syndromes 1265
 Stiff Man Syndrome 1265
 ISSAC Syndrome 1266
 Writer's Cramp 1266
 Restless Legs Syndrome 1266
 Periodic Limb Movements Syndrome 1267

Kernicterus

This is a sequel to severe neonatal jaundice occurring in Rh incompatibility or ABO hemolytic disease. The unconjugated bilirubin crosses the blood brain barrier and depresses oxidative metabolism of brain cells, especially the basal ganglia. Initial symptoms include convulsions, opisthotonus, rigidity, and coma. Late sequelae are athetoid movements, spasticity, nerve deafness, and mental deficiency, which manifest by the age of 6-7 months. The pathological changes include loss of neurons and gliosis in the subthalamic nuclei, thalamus, globus pallidus, and the nuclei of the oculomotor and cochlear nerves. Once established, the condition tends to be permanent. Early detection of neonatal jaundice and treatment by exchange transfusion are important prophylactic measures to avoid neurological damage.

Drug Induced Extrapyrarnidal Syndromes

Several drugs give rise to extrapyramidal dysfunction as troublesome side effects. Important among them are neuroleptics, such as phenothiazines, butyrophenones, thioxanthenes, reserpine, metoclopramide and the like. In many instances, development of these syndromes limit further use of the drug. The clinical presentations may be:

1. **Acute akathisia:** Akathisia means inability to sit down quietly for a while associated with a feeling of restlessness and anxiety.

Fig. 192.1: Oculogyric crisis

2. **Acute dystonic reactions:** Adoption of grotesque postures.
3. **Oculogyric crisis:** Eyes are suddenly deviated to fixed postures lasting for minutes to hours (Fig. 192.1).
4. **Secondary Parkinsonism.**
5. **Tardive dyskinesia:** (tardive means late onset): This is a chorea like disorder in which facial grimaces are more prominent.
6. **Tardive dystonia:** It is a persistent dystonia often affecting the neck and upper limbs and stiff postures.
7. **Tardive akathisia:** In addition to the motor phenomena, they have subjective (psychological) symptoms which include feeling of tension, inability to remain still and urge to move.

Treatment consists of withdrawing the offending drug and parenteral administration of diazepam 5-7.5 mg, antihistamines like diphenhydramine 15 mg, or an anticholinergic like benztropine 2 mg.

Stiff Man Syndrome

Stiff man syndrome (Syn. Stiff-person syndrome, Meersch-Woltman syndrome, Anti-GAD antibody syndrome).

Patients with this rare disorder present with severe, symmetric stiffness of the axial and limb muscles that may wax and wane in intensity but progress steadily over several years. The stiffness is superimposed by muscle spasms which are triggered by volitional or passive movements, emotional stress, tactile stimulation or sudden noise. Typically, these symptoms disappear during sleep. The age of onset is usually between 30 and 50 years and women are more commonly affected than men.

The pathophysiology appears to be due to faulty modulation of spinal cord reflexes, mediated by GABA-ergic neurons in the spinal cord, which produce GABA at their synaptic nerve terminals. Glutamic acid decarboxylase, (GAD) is an enzyme required for the production of GABA at the motor nerve terminals. Autoantibodies against GAD are found in the serum of many patients with stiff man syndrome. This suggests that the disorder is of an autoimmune etiology. This is further supported by the presence of other autoantibodies, coexistence of other autoimmune diseases such as insulin dependent diabetes mellitus, thyroid disease and positive family history of autoimmune diseases.

EMG shows continuous normal motor unit potentials simultaneously in the agonist and antagonist muscles, even when they are apparently at rest. This motor activity disappears only with general anesthesia, spinal anesthesia, peripheral nerve blocks and therapy with diazepam, which is still the most effective drug to relieve muscle stiffness. Steroids, intravenous immunoglobulin and plasmapheresis are helpful in some patients.

ISSAC Syndrome

It is a syndrome of continuous muscle activity, pseudo-myotonia and neuromyotonia. Issac syndrome is a condition which is also characterised by progressive muscle stiffness, constant rippling movements of the muscles under the skin (myokymia), autonomic disturbances in the form of hyperhidrosis and tachycardia and grip or action myotonia, is referred to as *Issac syndrome*. Unlike in stiff man syndrome, the continuous muscle activity in Issac's syndrome persists even during sleep.

Phenytoin, carbamazepine and valproate, but not diazepam help to relieve muscle stiffness in Issac's syndrome. Antibodies against the potassium channels in the motor nerve terminals are thought to be responsible for the condition.

Writer's Cramp

Writer's cramp, the best known occupational (action-induced or task specific) dystonia is a form of action dystonia triggered only when the person attempts to write. It occurs usually between the ages of 30 and 50 years.

The symptoms usually begin as soon as the pen is picked up or only after writing a few words. The common symptoms are excessive gripping of the pen, flexion of the wrist, extension of one or more fingers, elevation of the elbow while writing and increase in muscle tone. Although cramps or aching of the hand is not invariable, many patients complain of discomfort in the fingers, wrists or forearms.

If the symptoms appear only during the act of writing the condition is referred to as *simple writer's cramp*. If dystonic symptoms appear also with other tasks such as eating with a spoon, shaving, using scissors or screw drivers, it is called *dystonic writer's cramp*. In either type, the course is variable. In the majority of patients, the severity will remain unchanged while some people may experience spontaneous improvement. The diagnosis of writer's cramp is essentially clinical. EMG can be employed to delineate the extent of the overactive muscles while writing.

Treatment of writer's cramp is unsatisfactory and it requires patience on the part of both the physician and the patient. Change of hand posture while writing, use of larger sized pens or pencils, and learning to write with the opposite hand are some of the strategies found to be useful. Anticholinergic drugs and botulinum toxin injections into selected muscles are helpful in treating severe dystonic spasms. Physical and occupational therapy, reassurance and relaxation techniques are beneficial.

Restless Legs Syndrome

The restless legs syndrome is characterized by unpleasant or uncomfortable feeling (aching, burning or crawling sensation) in the lower limbs and sometimes also in the arms and the trunk when the patient is supine. It is aggravated by nightfall and rest and is temporarily relieved by standing, walking or moving the legs, only to recur within a few seconds. The symptoms last from a few minutes to several hours and can disturb sleep. The neurological examination is normal. The cause is unknown. Genetic factors have been suspected. The course is protracted, although gradual improvement is sometimes observed. Restless legs syndrome is different from nocturnal leg and hand cramps, in which the affected person awakes from sleep with calf pain and muscle spasms.

Medication with L.dopa, bromocriptine, pergolide, benzodiazepines such as clonazepam, nitrazepam and diazepam, opioids such as propoxyphene and codeine administered at bed time are all reported to be beneficial in relieving symptoms. Recently, drugs like gabapentin, clonidine, baclofen, propranolol carbamazepine and pramipexole in a dose of 1.5 mg/day are also used.

Periodic Limb Movements Syndrome

Many individuals with restless leg syndrome also experience periodic limb movements (nocturnal myoclonus) only during sleep. These movements typically involve unilateral or bilateral flexion of the big toes, rapid ankle flexion and partial flexion of the knees and hips. Occasionally the arms may be affected. These movements last for less than five seconds but recur regularly every 20-40 seconds throughout the night during sleep.

However, most patients are unaware that these movements occur in their sleep but they usually complain of insomnia or excessive day time sleepiness, fatigue or asthenia. Periodic limb movement disorder is difficult to treat. The same drugs used for the treatment of restless legs syndrome may be tried with variable results.

Restlessness and movements of the upper limbs may be associated with local discomfort such as itching, burning and others. Pramipexole in a dose of 1.5 mg/day daily may be successful.

Cerebrovascular Diseases

S.R. Chandra, P.K. Mohan

Chapter Summary

General Considerations	1267
Neurovascular Syndromes Caused by Arterial Occlusion	1269
Transient Ischemic Attacks	1270
Completed Stroke	1271
Lacunar Infarcts	1271
Neurological Deficits Caused by Cerebral Infarction	1272
Cerebral Thrombosis	1272
Cerebral Embolism	1274
Subarachnoid Hemorrhage	1276
Arteriovenous Malformation	1279
Intracranial Venous Thrombosis	1279

General Considerations

Disorders of the central nervous system secondary to pathological, processes involving the blood vessels are very common after the fifth decade of life. Sudden neurological deficit due to ischemia or bleeding involving one or more cerebral blood vessels is called stroke. Vascular disorders are characterized generally by their abrupt onset. Strokes are broadly divided into 'ischemic' and 'hemorrhagic' types. Ischemic strokes include transient ischemic attacks, thrombotic stroke and embolic stroke. Hemorrhagic stroke may be caused by intracerebral and subarachnoid hemorrhage. When the supply of oxygen and glucose to the brain is interfered with due to vascular

occlusion, ischemic necrosis and infarction develop. Obstruction of an artery may be either by a thrombus or an embolus- cerebral thrombosis or cerebral embolism. Sometimes gross impairment of the cerebral circulation may result from hypotension produced by cardiac failure or shock and this may also lead to cerebral ischemia when the mean arterial blood pressure falls below 60 mm Hg. The cerebral blood flow depends upon the gradient between the mean arterial blood pressure and intracranial pressure.

Strokes are common in India. Though it is predominantly a disease beyond the age of 50 years strokes in the young occurring below the age of 40 years are not uncommon. Before the advent of CT scan, it was thought that 75% of strokes are ischemic and the rest hemorrhagic. Now it is realized that several pathological processes can lead to stroke and their etiology differs in the different age groups.

Complete Stroke

Incidence of stroke types:

Thrombosis	:	40%
Embolism	:	30%
Lacunes	:	20%
Hemorrhage	:	10%

Causes of Stroke in Persons above the Age of 50 Years

Atherosclerosis of the cerebral arteries: This accounts for the majority of cases. Lesions may be in the

intracranial portions of the arteries, particularly the striate branches of the middle cerebral artery and perforating branches of the basilar artery, or in the cervical portions of the internal carotid and vertebral arteries. Atherosclerosis may be complicated by thrombosis, embolization of subintimal plaques or hemorrhage. Platelet aggregates and atheromatous emboli arising from the carotid bifurcation are common causes of transient ischemic attacks (TIA) and further cerebral infarction. Cardiac sources of emboli in ischemic heart disease, atrial fibrillation and cardiomyopathies account for a good number of ischemic strokes in elderly subjects.

An epidemiological study conducted by the Indian Council of Medical Research (ICMR) in 1986 revealed that the main risk factors for stroke are hypertension, tobacco smoking and low hemoglobin levels. The combination of hypertension and tobacco smoking increases the risk of stroke twenty times. Increase in the systolic and diastolic blood pressures correlate with the risk. Carotid and vertebral artery atherosclerosis is associated with hypercholesterolemia. In many of them atherosclerosis of the coronary and peripheral arteries also occurs. Other known risk factors are diabetes mellitus, dyslipidemias, obesity, polycythemia and use of oral contraceptive drugs.

Causes of Stroke in the Young (Under 40 years)

Nonspecific aortic arteritis which is common in India accounts for many cases. Endarteritis occurring in syphilis, meningitis, brain abscess and other infective conditions may be complicated by arterial thrombosis and cerebral infarction. Embolism complicating several cardiovascular diseases is a common cause, the chief among them being rheumatic mitral stenosis with atrial fibrillation. Postpartum cerebral venous thrombosis and hematological disorders such as sickle cell disease and thrombophilia are also common causes for stroke in the young. Hyperhomocysteinemia is an accepted cause for stroke in all age groups. Hyperhomocysteinemia may be acquired as in deficiency of folate and vitamins B₁₂ and B₆ or may be an inborn error of metabolism. The intima becomes coarse and predisposes to thrombosis.

Pathogenesis

The brain tissue is most vulnerable to ischemia and the sequence of events leading to neuronal death sets in and proceeds rapidly following vascular occlusion. Normal blood flow is 50 mL/100 g of brain tissue per minute. At this rate of blood flow hemodynamic changes in any of the feeding arteries is compensated by autoregulatory mechanisms so that the cerebral blood flow is not compromised.

Fall of blood flow to 30 mL/mt: Autoregulation fails. Patients become stuporose and focal neurological deficits may occur.

Fall of blood flow to 20 mL/mt: Electrical changes occur. Normal EEG rhythm changes to slow wave activity. Focal neurological deficits worsen.

Fall of blood flow to 10 mL or less/mt: Irreversible brain damage.

Within ten seconds of arterial occlusion or circulatory arrest the patient becomes unconscious.

Neuronal ischemia may be due to disease or hemodynamic changes in the major arteries (macrocirculation) or the arteriolar circulation (microcirculation). 80% of ischemic strokes occur in the anterior circulation and 20% in the posterior circulation.

The electrical activity ceases within twenty seconds. Maximum affection occurs at the epicenter of the infarcted territory. Towards the periphery where some amount of oxygen may be available from neighbouring tissues or collateral circulation the ischemic damage may be less severe and these tissues may not be irreversibly damaged. It is now recognized that this “**ischemic penumbra**” may recover if therapeutic measures are instituted early to limit the extent and severity of brain damage.

The net effect of arterial occlusion on the cerebral tissue depends upon the available amount of collateral blood flow to the affected zone. The circle of Willis normally provides adequate blood flow in the event of occlusion of any artery proximal to it such as the occlusion of the internal carotid artery. There may be a retrograde anastomotic flow from the external carotid artery through the ophthalmic artery. In addition to the patency of the collateral vessels, the speed of occlusion also influences the collateral supply. Gradual narrowing of a vessel allows time for collateral channels to open up. Presence of hypotension or hypoxia at a critical moment may render the anastomotic channels ineffective.

With the progress of neuronal death, the ischemic area becomes edematous. This may lead to rise in intracranial tension (ICT) which will further impair the blood supply to the affected region. Other complications such as uncal herniation can occur.

Rise of ICT is even more pronounced with hemorrhagic strokes. In these, vasospasm may supervene and lead to extensive damage to nervous tissue. Hemorrhagic strokes are caused by extravasation of blood into the brain tissue due to rupture of arteries, veins or vascular anomalies such as arteriovenous malformation and aneurysms. In addition, any type of infarction of the brain may lead to softening of the infarcted tissue and secondary bleeding from unsupported blood vessels. The blood that extravasates ploughs its way through nervous tissue leading to its destruction. It may also rupture onto the

surface of the brain or into the cerebral ventricles leading to secondary subarachnoid hemorrhage.

The course of development of neurological events often gives clue to the type of stroke. In cerebral embolism, the deficit starts dramatically, reaching its peak within minutes, and thereafter recovery starts. Cerebral thrombosis also has an abrupt onset but it evolves slowly over a period of several minutes, hours, or days in a series of steps rather than in a smooth course. Cerebral thrombosis generally occurs when the blood pressure and cerebral blood flow are low as in sleep. The patient may notice the disability on waking up. In cerebral hemorrhage, the deficit usually manifests from the moment of onset of hemorrhage and steadily progresses over a period of minutes or hours. Cerebral hemorrhage occurs more commonly during the height of physical activity or emotional outburst. Though it was thought that cerebral hemorrhage inexorably proceeds to end fatally, it is now known with the advent of CT that in several cases the progress may be arrested and the lesion may even regress. However, the clinical presentation of cerebral infarction and hemorrhage may overlap, and diagnosis based on clinical features alone is bound to be inaccurate in many cases.

Neurovascular Syndromes Caused by Arterial Occlusion

CLINICAL FEATURES

Occlusion of arterial supply to the brain gives rise to diagnostic clinical features. Though as a general rule the infarcted area corresponds to the vascular supply, this may not be the case in many instances. Clinical localization, therefore, has its own limitation (Table 193.1).

Internal carotid artery (ICA): The ICA supplies the eye as well as the anterior two-third of the cerebral hemi-

sphere, via the anterior and middle cerebral arteries. The clinical features of ICA include:

- a. Contralateral paralysis of the limbs and face (hemiplegia),
- b. Contralateral hemisensory loss (hemianesthesia)
- c. Aphasia (if the lesion is in the dominant hemisphere),
- d. Visuospatial disturbance (if the lesion is in the non-dominant hemisphere), and
- e. Ipsilateral monocular blindness (due to occlusion of the ophthalmic artery).

Ipsilateral blindness occurring with contralateral hemiplegia is called **carotid hemiplegia**. The common carotid and ICA in the neck are accessible for direct examination. Palpation of the carotid pulse is a valuable method to identify occlusion of these arteries. Though the occluded common carotid artery can be palpated in the neck, palpation through the tonsillar fossa is a more reliable method to assess pulsation of the ICA. Severe atherosclerotic narrowing of the carotid artery gives rise to a bruit detectable by auscultation. The site of the bruit indicates the site of stenosis. A bruit heard over the angle of the jaw indicates stenosis of the carotid siphon . If it is heard lower in the neck, it is in the common carotid artery. In a severe stenosis bruit may not be heard over the affected side, but on the normal side a bruit may be heard due to compensatory increase in blood flow. Therefore, full reliance cannot be given to the bruit alone in determining the side of occlusion. Availability of doppler studies has facilitated the study of blood flow in these arteries.

Middle cerebral artery (MCA): The MCA which is the largest branch of the ICA supplies the entire lateral surface of the cerebral hemisphere excluding the motor area for the leg. It may be occluded in its stem or in its deep penetrating or superficial cortical branches. Occlusions of the MCA are mostly embolic, especially those of the cortical branches. The clinical picture in MCA stem

TABLE 193.1			
Distinctive clinical features in stroke			
	Thrombosis	Embolism	Hemorrhage
Age group	Elderly	Young or old	Younger
Time of onset	Sleep	Activity	Activity
Waking the patient during sleep	No	No	Yes
Headache	Present due to vasodilation of extracranial vessels	Not much	Sudden bursting headache
Seizures	Occurs late, when gliosis develops	Solitary seizures at onset	Recurrent seizures
Disturbance of consciousness	Minor	Minor or nil	Often severe
Recovery	Slow, mortality less, morbidity more	Good recovery	Mortality more, but in survivors morbidity is less

occlusion is similar to ICA occlusion except for the absence of monocular blindness. However, most of the emboli entering the MCA tend to drift into the cortical branches and very rarely to the deep penetrating vessels. Smaller emboli tend to occlude smaller branches so that the clinical picture tends to be less complete. Thus patients may present with weakness limited only to the face and arm (*facio-brachial paralysis*). The right or left hemispheric lesion is accompanied usually by contralateral homonymous hemianopia.

Anterior cerebral artery (ACA): This supplies mainly the medial surface of the anterior three-fourth of the cerebral hemisphere, anterior four-fifth of the corpus callosum and the anterior limb of the internal capsule. There is no serious disturbance in occlusion of the ACA proximal to the anterior communicating artery since adequate collateral flow develops from the opposite ACA. However, if the occlusion is distal to the anterior communicating artery, it results in weakness of the contralateral lower limb and slight weakness of the upper limb. The face is spared. Sometimes both the anterior cerebrals arise from a common stem. In such instances, occlusion produces paraplegia, incontinence of urine and abulia in which there is slowness of reaction and reduction of all activity.

Posterior cerebral artery (PCA): The anterior branches of the PCA supply the sensory nuclei of the thalamus through the thalamogeniculate branches, central midbrain through the paramedian branches and parts of the basal ganglia through the thalamoperforate branches. Occlusion of these branches results in characteristic syndromes. Infarction of the thalamus causes severe sensory loss and mild hemiparesis contralaterally. After sometime sensations begin to return and patient complains of pain and *hyperpathia* on the affected side. The term *hyperpathia* indicates an increased threshold to pain, but once pain is produced it is severe (*thalamic syndrome of Dejerine and Roussy*).

Infarction of the midbrain results in ipsilateral third nerve palsy and contralateral hemiparesis (**Weber's syndrome**). Sometimes ataxia on the side of hemiparesis occurs (*ataxic hemiparesis*). This indicates involvement of the cerebellar connections. Hemiballismus, hemichoreoathetosis or tremors result from occlusion of the thalamoperforate branches.

The cortical branches supply the calcarine cortex as well as the inferomedial portion of the temporal lobe. Bilateral occipital infarction causes total blindness of the cortical type. Here the pupillary reflexes are preserved and the fundus is normal. Many a time the patient is unaware of his blindness. This type of blindness has to be distinguished from hysterical blindness. Infarction involving the inferomedial portions of the temporal lobe

causes impairment of memory, especially for recent events (**Korsakoff's amnesic state**).

Vertebral artery: The two vertebral arteries supply the medulla. It is not uncommon for one of the arteries to be congenitally hypoplastic. In such instances occlusion of the dominant vertebral artery may produce significant bilateral disturbances. Sometimes in occlusion of the subclavian artery proximal to the origin of the vertebral, exercise of the ipsilateral upper limb results in syphoning of blood from the vertebral to the distal part of the subclavian. This retrograde flow of blood from the vertebral artery renders the brainstem ischemic and symptoms of vertebro-basilar insufficiency develop (**subclavian steal syndrome**).

In occlusion of posterior-inferior cerebellar artery supplying the lateral aspect of the medulla a characteristic syndrome called the **lateral medullary syndrome (Wallenberg's syndrome)** develops. This is perhaps the most common mode of presentation of vertebral artery occlusion. The resultant neurological features consist of sensory impairment over the face, Horner's syndrome and ataxia on the ipsilateral side, and impaired pain and temperature sensations on the contralateral side. In addition, vertigo, nausea, vomiting, dysphagia, hoarseness of voice, and hiccups also occur in many cases. In the pure form of this syndrome there is no weakness or pyramidal tract dysfunction.

In the medial medullary syndrome there is paralysis of the ipsilateral half of the tongue with contralateral hemiparesis. The face is spared. In addition, there is impaired proprioceptive sensations contralaterally. In total unilateral vertebral occlusion a combination of both medial and lateral medullary syndromes may be present.

Basilar artery: The basilar artery supplies essentially the pons, the middle and superior cerebellar peduncles and through the cerebellar arteries the cerebellar hemispheres. Basilar artery stem occlusion is usually due to thrombosis. Emboli usually lodge at the basilar bifurcation or in one of the posterior cerebral arteries. Total occlusion of the basilar artery is fatal, but rare. More frequently its branches are occluded. Often the deficit includes bilateral long tract signs with variable abnormalities of the cranial nerves and cerebellum. The patient is usually comatose (Table 193.2).

Transient Ischemic Attacks (TIA)

These are focal neurological deficits due to vascular cause developing suddenly and disappearing completely within 24 hours, without any residual abnormality. The common presentations are uni or binocular visual loss, paralysis of one or more limbs, aphasia, disturbances of cognition and /or numbness and sensory disturbances lasting for a

TABLE 193.2

Pattern of clinical features in various vascular syndromes				
Middle cerebral artery (MCA)	Anterior cerebral artery (ACA)	Common carotid artery (CCA)	Internal capsule (IC)	Vertebro-basilar artery (VBA)
Upper limbs weaker than lower	Lower limbs weaker than upper	Ipsilateral eye and contralateral hemiparesis resembling MCA, ACA or both	Equal weakness of upper and lower limbs	Bilateral affection
Aphasia if lesion is on the dominant side	Nil	±	Nil	Nil
Hemianopia often present	Absent	Present	Present	Present if PCA is affected
Hemianesthesia present	Cortical sensory loss in lower limbs	Hemianesthesia +	Present	Crossed anesthesia
Rarely cerebellar signs +	Absent	Absent	Rarely present	Cerebellar signs common
Recovery poor in patients with Wernicke's aphasia and hemianopia	Recovery poor due to frontal lobe infarct. Apathy and lack of drive	Variable	Variable	Recovery variable

few to several minutes. If the disability persists beyond 24 hours and upto 72 hours, it is called *Reversible Ischemic Neurological Deficit*- (RIND). If the disability persists beyond 72 hours but still recovers completely it is called *Prolonged Ischemic Neurological Deficit* (PIND). In more than 90% of cases the symptoms last for < 10 minutes. Recurrent TIA s should suggest critical narrowing of the feeding artery by atherosclerosis or other pathological processes and recent thrombo-embolic overlay. Since TIA s may be followed by total occlusion of the arterial supply, they are medical emergencies demanding assessment of the vascular status and immediate therapy.

The common sources of emboli are the following

- 1. Atheromatous plaques and platelet emboli from the aorta and the carotid or vertebro-basilar arteries.
- 2. Atrial appendage in atrial fibrillation.
- 3. Mural infarcts in myocardial infarction.
- 4. Cardiac valves and others.

Recurrent TIA s in the same territory suggest lowered arterial blood flow, often due to recurrent emboli. Presence of cervical spondylosis predisposes to the development of TIAs. At the stage of TIA s it is possible to prevent major strokes which may follow.

Differential diagnosis of TIAs include aural vertigo, arterial dissection, subdural hematoma, thrombophilia, seizure disorders, postural hypotension, hypoglycemia and cerebral venous thrombosis.

Management: Start antiplatelet drugs such as aspirin in a doses of 150 mg/daily oral and clopidogrel 75 mg qid on first day oral without delay, later reduce it to once daily. Anticoagulation with conventional heparin or preferably

with low molecular weight heparin should be started, and followed up with warfarin to keep the prothrombin time at INR 2.5.

Investigations for the underlying causes should be instituted simultaneously. These include Doppler studies of the carotid and vertebral systems, digital subtraction angiography of the major arteries in the neck and intracranial cavity, C T and /or MRI imaging of the brain, MRI angiography and investigations to detect cardiac and aortic lesions.

COMPLETED STROKE

Generally, occlusion of major artery is preceded by one or more transient ischemic attacks. Sometimes abrupt focal neurologic deficit occurs without preceding TIAs. The term completed stroke denotes the condition where there is no further progression of the neurological deficit over the previous 48 hours. The paralysis tends to be complete. If the neurologic deficit progresses over several hours or days, it is called “stroke-in-evolution”. In the initial 48 hours there is gradual deterioration of neurological status due to extension of the infarct and the development of cerebral edema. The patient may become comatose during this period and the condition may end fatally.

LACUNAR INFARCTS

This term is applied to infarcts smaller than 2 cm in diameter caused by occlusion of the deep penetrating arterial branches. Lacunes > 1.5 cm in diameter are called giant lacunes.

Fig. 193.1: Hemiplegia left—boy, hemiplegia right—woman see the characteristic posture

Lacunar infarcts are seen commonly in the internal capsule, basal ganglia and pons, usually in hypertensive individuals. Clinical features may be absent and if at all they occur, they are mild. The lacunar syndromes are characterized by a combination of motor, sensory and speech deficits depending upon the location of the lesions. Ataxic hemiparesis is a common presentation. The other clinical presentations include pure motor hemiparesis, pure hemianesthesia, dysarthria and 'clumsy hand syndrome'. Pure motor paralysis shows prompt recovery within a week.

Neurological Deficits Caused by Cerebral Infarction

CEREBRAL THROMBOSIS

Involvement of Cerebral Cortex and Subcortical Areas

This leads to hemiplegia, hemisensory loss of cortical type and hemianopia on the contralateral side, aphasia, abnormality of higher functions such as unconsciousness, and altered behavior. In many cases pattern may be stroke in evolution (Fig. 193.1).

Internal capsule: This is probably the most common site for infarction and the lesion gives rise to dense hemiplegia with upper motor neuron type of facial palsy on the opposite side of the lesion. Depending on the posterior extension of the lesion, sensory and visual phenomena may be evident.

Some capsular infarctions may extend to involve the lenticular nucleus and thalamus. This results in hemichoreoathetosis or hemitremor of the paralysed side. This is called striatal hemiplegia.

Brainstem: Lesions in the brainstem give rise to crossed hemiplegia. Midbrain lesions give rise to ipsilateral LMN palsy of the oculomotor nerve and contralateral hemiplegia — **Weber's syndrome**. Pontine lesions give rise to ipsilateral LMN facial palsy and contralateral hemiplegia. Medullary lesions give rise to ipsilateral LMN palsy of the tongue (XII nerve) and contralateral hemiplegia.

The course of the stroke is often unpredictable. Deterioration of the condition is usually due either to extension of the thrombus along the vessel, progressive stenosis of the artery, or acute brain edema. Intercurrent infections of the respiratory or urinary tract are constant dangers, which lead to rapid deterioration if they set in. On the other hand, patients with lacunar infarcts with pure motor hemiparesis start improving within hours and recover completely in a week. Delay in recovery suggests a poor prognosis.

Poor prognostic factors include:

1. Persistent gaze palsy
2. Persistent hypotonia
3. Sensory aphasia
4. Hemianopia and
5. Symptoms on one side with signs on the other side.

The paralysed limbs are flaccid in the acute stage and this flaccidity persists for the first few days or weeks. Gradually spasticity develops and the tendon jerks become brisk. The upper limb assumes a flexed adducted posture while the lower limb remains extended.

Investigations: Diagnosis of cerebral thrombosis should be suspected when a focal neurological deficit develops abruptly. Investigations help to confirm the nature of underlying pathology and extent of the disease. CT scan of brain is the investigation of choice in stroke. It may be useful even upto 48 hours after the onset of cerebral vascular occlusion. It confirms the nature of underlying brain pathology and also indicates the location and extent of brain damage. The infarcted area is seen as a low density lesion (black). CT scan may be normal in about 3-5% of cases if it is done too soon after the onset of cerebral vascular occlusion. However, early CT scan helps to exclude cerebral hemorrhage. Further improvements on CT scan include contrast enhanced CT scan, perfusion scan and CT angiography after IV administration of iodinated contrast.

In a few cases, in order to exclude meningitis and subarachnoid hemorrhage LP and CSF analysis have to be undertaken, preferably after a CT examination to exclude any serious contraindication for LP. Occasionally, LP may reveal subarachnoid hemorrhage even when the CT scan is normal.

Fig. 193.2: Internal carotid artery stenosis, arteriogram
(1) Note the narrowing—arrow (2) after correction

The electroencephalogram which may show low voltage records of a lower frequency over the infarcted area is neither diagnostic nor specific.

MRI gives the details better about the ischemic zone. Radionuclide scans and positron emission tomography (PET) reveal the infarct even before it is recognized by CT.

Intravenous digital subtraction angiography is a non-invasive investigation which demonstrates the occlusion clearly. When the carotid lumen is reduced to 25% or less, the distal flow is compromised. Information on carotid blood flow can also be obtained noninvasively by periorbital directional doppler ultrasonography, phonoangiography, or a combination of multi-gated pulsed doppler ultrasonography and high resolution B-mode scanning (*duplex system*) (Fig. 193.2).

Investigations for risk factors of stroke should be carried out.

Management of Thrombotic Stroke

The undisputed therapeutic principles in the management of brain ischemia are: (i) restoration of normal systemic blood pressure, (ii) adequate oxygenation, (iii) avoidance of hypercapnia, and (iv) abolition of seizures, if present. In the acute stage the aim is to ensure adequate cerebral perfusion and to avoid all factors that interfere with cerebral blood flow. The patient is nursed in the recumbent posture, carefully avoiding the upright posture. Coexistent disorders like anemia or polycythemia should be corrected. In chronic hypertensive patients, higher than normal blood pressure may be needed to maintain cerebral perfusion. Cerebral blood flow may come down if the blood pressure is lowered below 150 mm Hg systolic. Therefore, careful watch is necessary while administering antihypertensive therapy. Blood pressure should not be lowered in the acute phase unless it is above 200/120 mm Hg. Exceptions include, concomitant aortic dissection, acute myocardial infarction, severe heart failure or hypertensive encephalopathy. Rapid reduction of BP is indicated urgently in hypertensive encephalopathy. It is controversial in cerebral hemorrhage. In other forms of stroke it is better to wait for 48-72 hours after the onset,

for instituting antihypertensive therapy to reduce blood pressure. When drug therapy is required, useful agents include sodium nitroprusside, labetalol and calcium channel blockers. Further rise in blood pressure can be prevented by oral doses of atenolol or nifedipine.

Mannitol 200 mL of 20% solution given in a dose of upto 1.5 g of mannitol/kg bw given intravenously rapidly within 20 minutes helps to reduce cerebral edema. Barbiturates in high doses lower cerebral metabolic activity and help to mitigate the ischemic damage independent of their antiepileptic action.

Hypothermia reduces cerebral metabolism and oxygen demand. In ideal situations this can be tried. Seizures increase the metabolic demands of brain tissue. Hence, antiepileptic drugs are employed if seizures occur.

The use of anticoagulants: They have a role in patients with recurrent TIAs or 'stroke in evolution' in arresting further thrombosis. When cardiac embolism is evident, these drugs are clearly indicated. It is important to exclude intracranial hemorrhage by CT scan before starting anticoagulants. Mild to moderate hypertension is not an absolute contraindication.

Anticoagulants are used with advantage in the following conditions:

1. Thromboembolic stroke
2. Venous sinus thrombosis
3. Progressive thrombosis
4. Thrombophilias and
5. TIAs
6. Possibility of peripheral venous thrombosis.

The anticoagulants are maintained at dosage levels needed to keep INR 2-3.

The usual regime is to start heparin 5000 units 4 h intravenously for 1-2 weeks. Low molecular weight heparin is a safe alternative but more expensive. Heparin therapy is followed up with oral anticoagulants of the coumarin group for 8-16 weeks. Since anticoagulation is always associated with the risk of hemorrhagic lesions in the brain, this form of therapy should be undertaken only in specialized centres, preferably in "**acute stroke care units**". They have no role in completed stroke.

Thrombolytic therapy is recommended as a modality of treatment in acute ischemic stroke. However selection of cases has to be meticulous and individualized. Thrombolytic therapy employs recombinant tissue plasminogen activator (rtPA) given IV. The time of administration is crucial in bringing out good outcome. In carotid territory strokes it has to be given IV within 3 hours of onset. In the vertebro-basilar territory rtPA is useful if given up to 12 hours from the onset or even later if intra-arterial injection is given. Dose is 0.9 mg/kg body weight up to a maximum of 90 mg. Ten percent of the drug is to be given as a bolus and the rest as IV infusion over 60 minutes. Intra-arterial administration is associated with

slightly higher risk of bleeding. CT evaluation is mandatory. CT evidences of massive infarction such as subdural effacement, mass effect, edema are all contraindications.

Other contraindications include:

1. Rapidly progressing neurological deficit
2. Seizures at the onset of stroke
3. Presence of systolic BP > 180 mm Hg and diastolic BP > 110 mm Hg
4. Prior occurrence of intracranial bleeding
5. Occurrence of previous stroke or head injury within 3 months
6. Major surgical procedure within the preceding two weeks.

Relative contraindications include

- a. Concurrent anticoagulant therapy
- b. Age above 80 years
- c. Blood glucose levels < 50 mg/dL or > 400 mg/dL
- d. Platelet counts < 100,000/cmm
- e. Rapidly improving stroke and
- f. Those who wake-up from sleep due to stroke.

If employed under ideal conditions rtPA produces better outcome in the immediate post-stroke period and also quality of life at the end of 2-3 months. rtPA leads to bleeding complications intracranially and also outside the cranium. The drug is very expensive cost—Rs. 35000 for one injection of 50 mg and it has to be used only in tertiary care centers, by personnel experienced in its use. Measures to improve the efficacy of rtPA such as use of ultrasound energy to facilitate thrombolysis are under trial. Direct administration of rtPA into the artery gives better results. In view of the adverse side effects and high cost other, thrombolytic drugs are being developed.

Physiotherapy is to be started early to facilitate movement and rehabilitation. Early ambulation is advocated, since this helps to avoid the development of contracture, periarthritis, and bedsores.

Surgical treatment: Whenever recurrent TIAs are associated with demonstrable significant (>75%) stenosis due to atheroma or ulcerating plaques in the internal carotid artery or the arch of aorta, surgical intervention is indicated. Thromboendarterectomy or bypass graft of the carotid, innominate or subclavian arteries has been employed to revascularise the part. Present evidence suggests that prophylactic endarterectomy reduces the risk of subsequent strokes. Results of Medical Research council (MRC UK) Asymptomatic Carotid Surgery Trial (ACST) 2002 showed that in asymptomatic patients younger than 70 years who have 70% or more reduction of carotid artery diameter, immediate carotid endarterectomy reduced the risk of stroke at 5 years follow-up, by 50% (12% vs 6%). Perioperative mortality risk is 3%. Stenting of the carotid artery in the neck or intracranially

is also done. The long-term results seem to be encouraging (Fig. 193.2).

Prevention: Since ischemic stroke is largely a preventable disease, the present stress is on prevention. Attention to the risk factors for atherosclerosis and correction of lesions giving rise to embolic episodes form the mainstay for primary prevention.

Proper control of hypertension is the most effective prophylactic intervention in the prevention of ischemic as well as hemorrhagic strokes.

Aspirin in a dose of 150 mg should be started as early as possible after the diagnosis of ischemic stroke as a treatment and for prophylaxis against recurrence. Clopidogrel, given orally in a dose of 75 mg od is also an effective antiplatelet drug. This can be given as the sole antiplatelet drug or can be combined with aspirin for better results.

Dyslipidemia is corrected by life style modifications and the use of statins.

Cerebral Embolism

Cardiogenic embolism to brain: 15-20% of cerebral emboli are cardiovascular in origin.

Major risk factors include atrial fibrillation, prosthetic heart valves, mitral stenosis, recurrent myocardial infarction, left ventricular thrombus, atrial myxoma, infective endocarditis, non-ischemic dilated cardiomyopathy and marantic endocarditis. In India where rheumatic heart disease is still prevalent it is a frequent cause for the occurrence of stroke in the young. Atrial fibrillation, irrespective of the cause increases the risk of embolic stroke. Risk of embolism in patients above the age of 60 years with atrial fibrillation is 5-8% annually. In the presence of structural abnormalities such as valvular defects or infarcted myocardium the risk is increased several folds. In ischemic heart disease embolism occurs commonly in the week following acute infarction. In patients with persistent ventricular thrombi the risk is 10% in the initial 6-12 months.

Minor risk factors are mitral valve prolapse, severe mitral annulus calcification, patent foramen ovale, atrial septal defect and calcific aortic stenosis.

Probable sources with minimal risk include carotid artery stenosis narrowing the lumen to 50% or less, left ventricular aneurysms, sick-sinus syndrome and peripartum cerebral venous or arterial thrombi.

Paradoxical embolism may occur in atrial septal defect, ventricular septal defect and pulmonary arteriovenous fistulae. Patent foramen of ovale is a possible source for cerebral embolism.

Risk for mechanical prosthetic valves is 2-4% yearly. Rates are higher for valves in the mitral position than in the aortic.

Emboli commonly consist of platelet thrombi, atheromatous plaques, cardiac vegetations and calcareous particles, but rarely fat, air and tumour tissue may be seen. The clinical setting in which embolism occurs often provides the clue to the nature of the embolus. When an embolus lodges in an artery, it leads to distal thrombosis along the ramifying vessels or it may fragment and get impacted in smaller vessels. Infarcts caused by emboli are often hemorrhagic since the blood flowing into damaged vessels escapes into ischemic or necrotic brain tissue. The middle cerebral artery territory is most frequently involved in embolism. The most common cause is chronic atrial fibrillation occurring in either rheumatic or atherosclerotic heart disease. The other causes include mural thrombi from myocardial infarction, vegetations on prosthetic valves, bacterial endocarditis and rarely mitral valve prolapse. Iatrogenic causes include complications during arteriography or surgery of the neck and thorax.

The clinical picture depends on the artery involved. Usually the embolus lodges in one of the branches rather than the mainstem of an artery. Thus it is more common to produce a focal deficit like monoplegia or motor aphasia rather than a complete hemiplegia. Often the deficit is transitory since the embolus passes distally into smaller vessels. Occurrence of distal thrombosis leads to extension of the infarct.

Investigations: Cerebral ischemia is confirmed by a CT scan. Detection of the source for embolus strengthens the diagnosis of embolism.

Management: Prevention of cerebral embolism is more important than its treatment. Restoring atrial fibrillation to normal sinus rhythm and long-term anticoagulant therapy in patients with myocardial infarction and cardiac valve prosthesis prevent embolic complications. However, once the embolism results in infarction, it is necessary to exclude a hemorrhagic infarct before anticoagulant therapy is started. Low dose heparin therapy started early and followed up with oral warfarin anticoagulation, the prothrombin time being kept at INR 2.5–3.5 reduces the risk of recurrent stroke by 75%.

In cardioembolic stroke secondary hemorrhage into the infarct may develop, and therefore, anticoagulation therapy should be deferred for at least 48 hours after the stroke. Large infarct, i.e. infarct with 2/3 or more involvement of the occluded arterial territory is a contraindication for starting heparin, since there is a high risk of hemorrhagic transformation. In such cases anticoagulant therapy may be deferred for upto 2 weeks.

In cerebral embolism complicating bacterial endocarditis, it is advisable to withhold anticoagulants because of the danger of intracranial bleeding. Effective antibiotic therapy reduces the risk.

Intracranial Hemorrhage

Hemorrhage in the intracranial cavity may be extracerebral, intracerebral, or intraventricular. Extracerebral hemorrhage may be extradural, subdural or subarachnoid in location. Hypertension is the most common cause of non-traumatic intracranial hemorrhage, followed by ruptured aneurysms, and vascular malformations. Hemorrhage may result from bleeding disorders or inflammatory disease of the cerebral arteries but it is less common.

INTRACEREBRAL HEMORRHAGE

Syn: Spontaneous nontraumatic-intracerebral hematoma

Intracerebral bleeding is most common in the sixth and seventh decades of life. Analysis of 100 consecutive cases at the Medical College Hospital, Trivandrum, revealed that hypertension, arteriovenous malformation, eclampsia, brain tumours, arteritis and anticoagulant medication accounted for a total of 50% of the cases. In the others no causal factor was demonstrable. Among the known causes, hypertension was the most frequent. Rarely the blood pressure may be in the normal range when first examined after the stroke.

Other causes include amyloid angiopathy in patients above 70 years, A-V malformation, angiomas, tumours, dural venous sinus thrombosis, coagulopathies and bleeding into ischemic area. The extravasated blood accumulates to form a circular or oval mass and behaves like a space occupying lesion displacing the midline structures to the opposite side. *The common sites of hypertensive hemorrhage* in the order of frequency are: (i) putamen and internal capsule, (ii) cerebral white matter, (iii) thalamus, (iv) cerebellum, and (v) pons. Majority of intracerebral bleeds develop due to rupture of minute aneurysms (**Charcot-Bouchard aneurysms**) seen in hypertensives.

CLINICAL FEATURES

The onset is usually abrupt with rapid evolution of symptoms. Hemorrhage generally occurs while the patient is up and active. Recurrence of bleeding is rare. The clinical signs depend on the location and size of the hematoma. Headache is a common symptom preceding the attack.

In hemorrhage into the putamen, internal capsule and lobar white matter, there is contralateral hemiplegia becoming complete within 5-30 minutes. The level of consciousness worsens and the patient lapses into coma. Upper brainstem signs appear in large lesions.

In thalamic hemorrhage hemisensory loss equals or even outstrips the motor deficit. The characteristic ocular abnormality is the skew deviation of the eye with the

opposite eye deviated downward and medially. In pontine hemorrhage the patient is deeply comatose with pin-point, but reacting pupils.

In cerebellar hemorrhage the patient complains of occipital headache and repeated vomiting, followed by vertigo and ataxia. There is ipsilateral sixth and seventh nerve palsy with paralysis of conjugate lateral gaze to the side of hemorrhage.

Once deep stupor or coma has supervened, patients rarely survive. Sometimes the hemorrhage extends into the ventricles or it produces secondary brainstem compression leading to coma. Death occurs in about 60-70% of cases. In those with smaller hemorrhages the hematoma resolves and in such patients the prognosis is better than that of infarction.

Investigations: With the advent of the CT scan, localization of the site of hemorrhage has become very easy and accurate, and this is the investigation of choice. The area of hemorrhage on CT scan appears as hyperdense (white) lesion and the surrounding brain edema as hypodense (black) lesion.

MRI, CT angiography and conventional X-ray angiography are used when the cause of intracranial hemorrhage is uncertain, particularly if the patient is young or not hypertensive and the hematoma is not in the usual site for hypertensive hemorrhage.

MANAGEMENT

The immediate management of an unconscious patient with intracranial hemorrhage consists of assistance to ventilation, fluid restriction, and measures to reduce intracranial tension such as intravenous administration of 20% mannitol or 200 mL given IV as a rapid infusion within 10 minutes, and repeated fourth hourly.

Blood may compress brain tissue in the acute stage. Surgical evacuation of the hematoma is indicated in patients who are not comatose, (i) if the hemorrhage lies near the cortex, and (ii) in cerebellar hematoma and intraventricular hematoma. In deeply comatose patients surgery carries high risk. In those showing improvement with medical management, it may not be considered necessary. In addition to the general measures instituted in comatose patients, proper control of hypertension is also important. The mean BP should be kept above 70 mm Hg by appropriate therapy. Recombinant factor VII a has been used IV to arrest progression of hematoma.

Summary of Treatment Options in Acute Strokes

1. Improve and stabilize cerebral perfusion—Avoid hypotension, cardiac failure and cardiac arrhythmias.
2. Control of cerebral edema — Rapid IV infusion of 20% mannitol initially and followed up with oral

glycerine 15 mL 6 h help to prevent the rise of intracranial tension.

3. Hemorrhheological methods to improve microcirculation.
Controlled hemodilution,
4. Antiplatelet drugs to prevent platelet aggregation and thrombosis—These are more useful for prevention of recurrence.
5. Anticoagulants — indicated in cardio-embolic stroke, stroke in evolution and recurrent TIAs.
6. Thrombolysis — in carefully selected patients within 3 hours of onset.
7. Tissue protectors—these are employed to protect the jeopardized neural tissue from further damage. Metabolism of brain cells can be reduced by inducing barbiturate coma. Partially affected neurons may undergo reperfusion injury especially as a result of free-radical accumulation. Free-radical scavengers like vitamin E have been tried with a view to reduce this damage.
8. Surgical measures such as removal of the extravasated blood are indicated when these can be undertaken with safety. When the hematoma is localized within the brain and gives rise to pressure effects surgical evacuation is life-saving.

Preventive Strategies to Avoid Recurrence of Ischemic Stroke

Correction of dystepidemia and stopping of tobacco smoking should be instituted forthwith.

Aspirin in a dose of 75-150 mg daily is recommended in thromboembolic strokes. Clopidogrel is an alternate drug which is to be considered in those who are intolerant to aspirin. Its cost is higher. Combination of aspirin and clopidogrel gives synergistic effects.

Warfarin or other anticoagulants may be employed in those who have potential for recurrent cardiogenic embolism.

The period for which prophylactic therapy has to be continued is not standardized. This decision should be made in each case depending on its merits.

Subarachnoid Hemorrhage

Bleeding into the subarachnoid space constitutes subarachnoid hemorrhage (SAH). The ICMR collaborative study (1988) revealed that subarachnoid hemorrhage is not uncommon in India. Males are affected more (M : F = 1 : 0.73). Maximum prevalence was in the fifth and sixth decades. 46.7% were due to berry aneurysms, and 9.4% due to arteriovenous malformations (AVM).

Other less common causes of subarachnoid hemorrhage include malignant tumours, trauma, bleeding disorders like thrombocytopenic purpura and hemophilia excessive anticoagulation, and hemorrhagic meningitis. In

these cases the clinical evidence of the underlying disorder will be evident.

Aneurysms develop at sites of developmental defects in the media and elastica of the cerebral arteries. Often they are multiloculated and sometimes, multiple. These are called berry aneurysms. They are usually located at bifurcations and branchings of the vessels. Approximately 90% of the aneurysms are located on the anterior part of the circle of Willis.

The common sites include the anterior communicating artery, origin of the posterior communicating artery (PCA), major bifurcations of the middle cerebral artery (MCA), and the bifurcation of the internal carotid artery (ICA) into MCA and ACA (anterior cerebral artery). Other sites include ICA in the cavernous sinus and bifurcation of the basilar artery.

Aneurysms are not present at birth. They develop after the period of adolescence and some of them continue to grow. Those above 3 mm in diameter tend to rupture. If they grow bigger (10 mm or more) they give rise to pressure symptoms and their tendency to rupture also increases.

Genetically determined conditions may be associated with increased occurrence of intracranial aneurysms.

These include:

1. Autosomal dominant polycystic disease of the kidney
2. Ehlers-Danlos syndrome type IV
3. Neurofibromatosis type I
4. Marfan's syndrome.

As compared to sporadic aneurysms, the familial cases tend to rupture earlier even when they are smaller. Such patients also develop fresh aneurysms on follow-up.

In addition to congenital defects, arterial wall may be weakened by emboli developing in infective endocarditis (mycotic aneurysms). Many of these aneurysms may not rupture at all. When they do so, the rate and amount of bleeding is highly variable.

PATHOPHYSIOLOGY

When an artery ruptures into the subarachnoid space there is rapid rise of intracranial pressure (ICP) which may reach arterial pressure levels. This impairs normal cerebral blood flow and leads to coma. If the bleeding stops spontaneously the ICP falls and coma passes off. If the ICP remains high for considerable periods, brain death follows and patient does not recover from coma. Intracerebral hemorrhage and herniation of brain due to ICP worsen the problem further. Blood collecting at the base of the brain obstructs the foramina of fourth ventricle leading to obstructive hydrocephalus. The portion of the arteries bathed in subarachnoid blood go into vasospasm leading to infarction of the brain. This results in delayed ischemic neurological deficit. Blood which has entered the CSF undergoes defibrination and hemoglobin

undergoes further changes with release of bilirubin which makes the CSF xanthochromic (yellow colour).

Other clinical presentations result from mass effect due to the size of the aneurysm and features of cerebral ischemia.

CLINICAL FEATURES

Before Rupture

Most of the aneurysms are asymptomatic until they rupture. They may, however, become symptomatic by causing pressure on the adjacent structures. A large aneurysm of the ICA may produce compression of the optic chiasma, third, fourth and sixth cranial nerves, and ophthalmic division of the fifth cranial nerve. Posterior communicating artery aneurysms may press upon the ipsilateral oculomotor nerve.

After Rupture

Rupture of an aneurysm results in subarachnoid hemorrhage. The patient usually presents with excruciating headache of sudden onset followed by loss of consciousness. Sometimes consciousness is lost without any premonitory symptoms. Rarely the leak is small and only mild headache may develop without further progression. The sensorium may improve within a few hours but usually confusion lasts for ten days or more. In many cases focal neurological signs may not be present. When present, these signs help to localize the aneurysm. Signs of meningeal irritation like neck rigidity, Kernig's sign, and Brudzinski signs are usually present. Examination of the fundus frequently reveals pre-retinal or subhyaloid hemorrhages. In those with raised intracranial tension papilledema may develop. Reversible electrocardiographic abnormalities such as T wave inversion, ST depression, prolongation of QT interval and others may be seen in about 80% of cases.

INVESTIGATIONS

Imaging Studies

Subarachnoid hemorrhage should be suspected when an otherwise healthy individual suddenly develops severe headache associated with features of meningeal irritation without fever or other signs of infection. CT scan is the investigation of first choice wherever available. In the early phase of the bleed, CT is the most sensitive diagnostic test. The blood from the CSF is rapidly cleared and so the sensitivity of CT scanning falls to 80% at 3 days, 50% at 2 weeks and 30% at 3 weeks. MRI is less sensitive than CT in the early stages, but later in the course of the disease it becomes more diagnostic. MRI reveals parenchymal pathology such as arteriovenous malformations, cavernomas or vasculitis, which can all lead to SAH.

Lumbar Puncture

In those cases that come late even if the CT scan is negative, if the clinical suspicion is high, a diagnostic LP may be necessary to confirm the diagnosis. However LP is a risky procedure which should be undertaken only when facilities for management of brainstem herniation are ready at hand. The CSF shows uniform blood staining and on centrifuging the supernatant is xanthochromic if the hemorrhage is of at least 6 hours duration. Occurrence of xanthochromia is a highly suggestive point favoring SAH. On standing, the blood does not clot, and the erythrocytes settle at the bottom. This has to be distinguished from blood staining of the CSF caused by accidental injury to veins during the LP (traumatic hemorrhage). In this condition the CSF clears-up as it flows out, the initial samples being more bloodstained than the later ones. On standing the blood clots and on centrifugation the supernatant is not xanthochromic. After a bout of subarachnoid hemorrhage the xanthochromia persists for at least three weeks.

Cerebral Angiography

If CT or LP shows positive evidence of SAH and if there is no other obvious cause, four-vessel angiography is indicated to exclude aneurysm. The most frequently used investigations to delineate intracranial aneurysm are **digital subtraction angiography**, MRI angiography and helical (also called spiral) CT angiography. DSA or conventional angiography of the cerebral vessels is the gold standard, but are associated with the risks of TIA in 4%, permanent ischemic damage in 1% and death in 0.1%. Three dimensional DSA angiography is available in a few centers. By this technique full details of the intracranial aneurysms can be obtained. Angiography will reveal site, size and number of patent aneurysms, arteriovenous malformations, midline shifts and other abnormalities. In some cases initial angiography may be negative due to vasospasm. If the clinical suspicion is strong a second

angiography undertaken 2-6 weeks later may reveal the underlying cause in such cases (Fig. 193.3).

Course

Approximately 10-15% die before seeking medical attention. 40% of hospitalized patients die within a month. More than a third of the survivors develop major neurological deficits.

Initial mortality is 20-25% in spontaneous subarachnoid hemorrhage. Aneurysms tend to re-bleed after initial hemostasis at the rate of 4% on the first day and thereafter 1-2% daily for the first two weeks during which time the risk is highest. Thereafter the risk comes down. Recurrent bleeds tend to be more severe and are accompanied by higher mortality.

The Hunt and Hess Grading System of SAH

- Grade 1 Asymptomatic or minimal headache and neck rigidity.
- Grade 2 Moderately severe headache, nuchal rigidity, no neurological deficit other than cranial nerve palsy.
- Grade 3 Drowsiness, confusion, mild focal deficit.
- Grade 4 Stupor, moderate to severe hemiparesis, possibly, early decerebrate rigidity and disturbance of vital functions.
- Grade 5 Deep coma, decerebrate rigidity, moribund appearance.

Management

Definitive treatment of the aneurysm is surgical. Once subarachnoid hemorrhage is diagnosed and aneurysms are identified by angiography, the next step is to decide the time of surgery. In deeply comatose patients, surgery carries a high risk. Hence it is better to operate when the patient's general condition has improved. General management in such instances consists of absolute bed rest,

Fig. 193.3: Carotid angiography. A and B show berry aneurysm—arrows

continuous sedation, and control of hypertension and seizures if present.

Nimodipine given orally in a dose of 60 mg every four hours helps to relieve cerebral vasospasm and improve the circulation. Nimodipine can also be given IV in a dose of 3 mg/hour.

Another approach which is also experimental is to increase blood volume by giving IV infusions and improve perfusion pressure using dopamine infusions.

Early surgery is more beneficial. Suitability for surgery is best assessed by a modified Glasgow Coma Scale, recommended by the World Federation of Neurological Societies (WFNS).

World Federation of Neurologic Societies Grading system of SAH		
Grade	Glasgow coma scale	Motor deficit
Grade 1	15	No
Grade 2	13-14	No
Grade 3	13-14	Yes
Grade 4	7-12	No or Yes
Grade 5	3-6	No or Yes

The tendency at present is to clip the aneurysm using operating microscope within 96 hours of hemorrhage in patients in grades 1 and 2. In patients with intracranial hematoma early evacuation is life-saving. Operation between the 4th and 10th day of ictus carries heavy risk of ischemic neurological deficit.

Careful monitoring to avoid undue fall in blood pressure is essential. Liquid paraffin 10 mL may be given twice daily to keep feces soft and avoid straining. Once the general condition is stabilized, surgical ligation or clipping of the aneurysm is advised to prevent recurrence of bleeding. Other surgical procedures include occluding the aneurysm by introducing coils into the aneurysmal sac and inducing thrombosis by embolization; or strengthening the sac by fascial or muscle covering.

Prophylaxis

Close relatives of patients who had subarachnoid hemorrhage due to aneurysms and those who have genetic predisposition have been subjected to screening test with a view to detect aneurysms before they rupture. Marginal benefit has been reported.

Arteriovenous Malformation (AVM)

These developmental anomalies consist of abnormal communications between the arterial and venous systems resulting in a cluster of dilated vessels. There are no capillary vessels between the two systems.

They vary in size from a few millimeters to huge masses lying in the cortex or white matter, usually in the

posterior half of the cerebral hemispheres. They usually become symptomatic in the second or third decade. They present initially as subarachnoid or intracerebral hemorrhage, focal epilepsy, vascular headache, hemiparesis or any focal neurological deficit. The combination of epilepsy with subarachnoid hemorrhage should suggest this possibility. The annual risk of hemorrhage is 1.3-4%. History of previous bleed and hypertension increase the risk.

X-ray skull may reveal abnormal linear (rail track) or crescentic calcification. CT scan and MRI will confirm the diagnosis. Arteriography delineates the abnormal vessels.

Indications for radical treatment include seizures resistant to drugs, progressive neurological deficit and intractable headache. Microsurgical resection is the gold standard of treatment. Other modalities include endovascular embolisation and radio-surgery.

Secondary Subarachnoid Hemorrhage

This occurs when blood from cerebral hemorrhage enters the general subarachnoid space by rupturing the cerebral cortex or rupturing into the ventricles.

Intracranial Venous Thrombosis

Etiology

In India this is one of the common causes of stroke in the young. It may be secondary to bacterial thrombophlebitis or simple cerebral phlebothrombosis secondary to congenital or acquired thrombophilic states. Bacterial thrombophlebitis complicates infections on the face, neck, scalp, and particularly the central part of the face. Other causes of thrombophilia include postpartum and postoperative states, polycythemia, sickle cell disease, severe dehydration in children and the aged, vasculitis, deficiencies of protein C, protein S, antithrombin-III, Factor V Leyden, mutation of the prothrombin gene and myeloproliferative conditions. They predispose to venous thrombosis in different sites. Use of oral contraceptives aggravates this tendency. A stroke occurring in the background of such a clinical setting is suggestive of cerebral venous thrombosis. Sometimes, even in the absence of intracranial infection, occlusion of the superior sagittal sinus or lateral sinus develops with rise of intracranial tension.

CLINICAL FEATURES

Intracranial thrombophlebitis is usually secondary to infections in the middle ear, paranasal sinuses, mastoids or skin over the face. In such instances, high grade fever and toxemia are present. The lateral sinuses, cavernous sinuses and superior longitudinal sinus are commonly involved.

Fig. 193.4: Cerebral venous thrombosis

In lateral sinus thrombosis, the infection spreads to involve the jugular bulb to give rise to the **jugular foramen syndrome** with paralysis of IX, X and XI cranial nerves. In such patients compression of the ipsilateral jugular vein fails to produce rise of CSF pressure during lumbar puncture and the Queckenstedt's test. The CSF pressure rises if the patent jugular vein on the opposite side is compressed. Venous thrombosis evolves more slowly compared to arterial occlusions and it has a greater tendency to produce seizures and hemorrhagic infarcts, compared to the latter.

Cavernous sinus thrombosis is usually secondary to infections of the ethmoid or maxillary sinuses or the skin around the eyes and nose. The clinical features include high grade fever, chemosis of the conjunctiva, proptosis,

and edema of the ipsilateral eyelid. Later the fundus shows papilledema with retinal hemorrhages. Unilateral or bilateral paralysis of the third, fourth, sixth, and ophthalmic division of the fifth cranial nerves develop. Within a few days the infection spreads to the other cavernous sinus through the interconnecting vessels (Fig. 193.4). Sooner or later meningeal infection supervenes and meningitis develops.

In superior longitudinal sinus occlusion, symptoms start with unilateral convulsions and hemiplegia. Subsequently the occlusion spreads to involve the superficial cortical veins.

Treatment: Treatment consists of attention to the primary cause and anticoagulant therapy. When infection is suspected the mainstay of treatment consists of high doses of appropriate antibiotics and measures to prevent or reduce cerebral edema and convulsions. Once the infection is controlled, the focus of infection in the offending ear or paranasal sinus should be tackled surgically to prevent recurrence. At present intravenous injection of thrombolytic agents have been used to dissolve the clot and restore patency.

Anticoagulants: Role of anticoagulants in infective thrombosis is controversial. Anticoagulants are indicated in the absence of any hemorrhagic lesion. Except in the presence of infection anticoagulant therapy has to be started with low molecular weight heparin and maintained with oral anticoagulants at INR 2-3, for periods upto one year or longer, depending on the condition.

Intracranial Space Occupying Lesions

Ananda Kumar, P.K. Mohan

Chapter Summary

General Considerations	1280
Intracranial Hematomas	1281
Intracranial Tumours	1283
Hydrocephalus	1286
Increased Intracranial Tension	1287
Idiopathic Intracranial Hypertension	1288

General Considerations

The term 'intracranial space occupying lesion' (ICSOL) includes lesions which expand in volume to displace normal neural structures and lead to increase in intracranial tension.

Intracranial space occupying lesions encompass tumours, parasitic cysts, abscesses, granulomas,

lymphoma, large infarcts and hematomas in the brain. All these conditions are fairly common in India. Around 5-6% of neurological disorders in India are constituted by space occupying lesions.

These lesions give rise to the following three groups of symptoms in general.

- 1. **Neurological phenomena caused by irritation or destruction** of brain tissue, e.g. focal seizures (Jacksonian epilepsy) and paralysis.
- 2. **Features of raised intracranial tension (ICT):** The rate of increase of tension and its level depend upon the nature of the lesion and its location. For example, rapidly growing tumours and multiple secondaries give rise to rapid rise in ICT whereas slow growing tumours and cysts may be accommodated within the cranium for considerable periods without symptoms. Moreover, in general, posterior fossa lesions lead to more rapid rise in tension than supratentorial lesions.
- 3. **False localizing signs:** (a) These are neurological phenomena arising from secondary effects of the lesions. As a result of herniation of brain tissue under the falx cerebri or downward herniation through the tentorium cerebelli and foramen magnum, pressure effects on other parts of the brain develop. (b) *Countre-coupe effect:* This is pressure effect caused on the side opposite to the side of lesion when a space occupying lesion expands. The midline

structures such as brainstem may be pushed against the opposite free margin of the tentorium cerebelli to give rise to focal neurological deficit ipsilateral to the space occupying lesion.

In addition to these general features different lesions may produce symptoms specific to their nature. For example, brain abscess may be associated with fever and other signs of infection. Secondary subarachnoid hemorrhage may be associated with signs of meningeal irritation. Table 194.1 gives the common ICSOLs.

Clinical Features

- 1. *Persistent headache* not due to any other detectable cause and unresponsive to simple medication should suggest the possibility of ICSOL. The headache may be felt in the midline over the head or at times it may be referred over the site of lesion, e.g. meningioma. It may be continuous and progressive, paroxysmal (as in migraine), or aggravated by coughing, stooping forward or changing postures.
- 2. *Vomiting and visual loss:* In many cases projectile vomiting is a usual symptom. The term projectile vomiting refers to vomiting unassociated with nausea. Projectile vomiting may be mistaken for gastrointestinal or psychiatric disturbances. Visual disturbances due to papilledema develops with time.
- 3. Recent onset of behavioral changes.
- 4. *Late onset seizures:* Any type of seizure occurring for the first time after the age of 15 years should suggest the possibility of ICSOL and this demands full investigation.
- 5. Onset of neurological deficits.

TABLE 194.1

Common intracranial space occupying lesions

- 1. *Congenital:* Dermoid, epidermoid, hamartoma, and teratoma.
- 2. *Traumatic:* Subdural and extradural hematomas.
- 3. *Inflammatory:* Abscesses (acute and chronic), tuberculomas, syphilitic gumma, fungal granulomas.
- 4. *Parasitic causes:* Cysticercosis, hydatid cyst, amebic abscess, *Schistosoma japonicum*.
- 5. *Neoplasms:*
 - a. *Tumours arising from neural structures*
Gliomas—astrocytoma, ependymoma, oligodendroglioma, mixed glioma, medulloblastoma, medulloepithelioma, sarcoma, pinealoma.
 - b. *Tumours arising from appendages*
Meningioma, neurilemmoma (Schwannoma, e.g. acoustic neuroma), chordoma, osteoma.
 - c. *Pituitary tumours*
Adenomas of the pituitary which are intracellular, and craniopharyngiomas which arise from remnants of the *Rathke's pouch*— which are suprasellar.
- 6. *Vascular lesions:*
Angioma, hemangioblastoma, hemangiopericytoma, and papilloma of the choroid plexus.
- 7. *Secondary neoplasms:*
The brain is a common site of secondaries from carcinoma of the lung, kidney, breast and alimentary tract. In addition, acute leukemias and lymphomas cause infiltration and tumour formation in the central nervous system leading to rise in ICT.

Intracranial Hematomas

Hematomas are common complications following injury to the skull. Blood may collect in the extradural space or subdural space.

EXTRADURAL HEMATOMA

This is collection of blood between the dura and the skull. The blood may be derived from injury to the middle meningeal vein, middle meningeal artery, diploic vein, dural venous sinuses or small vessels lying between the dura and the skull. The commonest site is the temporal fossa. Other sites include the frontal, subfrontal and occipital regions, vertex and posterior fossa.

Pathogenesis: The initial collection of blood in the extradural space results in stripping of the dura from bone. Further oozing from the damaged vessels increases this space and the hematoma enlarges. Clinically significant hematomas exceed 25 mL in volume. The extent and location of the hematomas are determined by the ease of

stripping of the dura; the site of injury and its severity, and the presence of fissured or depressed fractures of the skull.

Clinical features: Extradural hematomas are seen in 1-2% of patients suffering from head injuries. It is uncommon in children below 3 years of age and in old age. In the latter, adherence of the dura to the skull prevents its easy stripping.

Immediately following trauma there may be a period of loss of consciousness, after which there is a period of apparent normalcy with clear consciousness (*lucid interval*). This is again followed by deterioration of the mental state. If the bleeding is rapid, this lucid interval may be absent.

Classical features include rise in intracranial tension leading to progressive deterioration of the level of consciousness, pupillary abnormalities and contralateral hemiparesis.

Pupillary changes: The pupil on the side of lesion constricts initially, then it dilates. As the ICT rises, the opposite pupil also dilates. This sequence of events is referred to as **Hutchinson's pupillary reaction**.

In children massive bleeding into the cranium may lead to pallor.

Diagnosis: Intracranial bleeding should be suspected when there is change in the level of consciousness, rise in ICT. Pupillary abnormalities and focal neurological deficits following major or even minor head injuries. Presence of fracture of the skull strengthens this suspicion. The most reliable methods to demonstrate the hematoma are CT scan and MRI. Cerebral angiography may be required in some cases to demonstrate the cause of hematoma, especially in atypical locations (Fig. 194.1).

Course and prognosis: Progressive collection of blood leads to rise in ICT and death. Early diagnosis and treatment are rewarded by full recovery. Therefore, the investigations should not be delayed when intracranial hematomas are suspected. Though early treatment ensures full recovery, seizures may develop as a sequel in some cases.

Treatment: Medical treatment consists of measures to lower intracranial tension and anticonvulsant medication. Definitive therapy consists of surgical evacuation of the hematoma through burr holes.

SUBDURAL HEMATOMA

This is collection of blood between the dura and the arachnoid. This may follow injuries which may be apparently trivial or even unnoticed. The development of the hematoma may be acute (within 3 days), subacute (within two weeks) or chronic (within months). Chronic subdural hematomas are more common in alcoholics, epileptics, patients receiving anticoagulation therapy and in dehydrated children. Sudden reduction of ICT following shunt surgery for hydrocephalus or even lumbar puncture may give rise to subdural hematoma.

Common cause of subdural hematoma is bleeding from superficial veins or venous sinuses but it may also develop as a complication of cerebral hemorrhage or cortical tumours. The usual sites are the frontal, anterior temporal, and parietal region. The lesion is bilateral in 10% cases. The hematoma may consist of fluid or clotted blood or blood mixed with CSF (*subdural hygroma*).

Pathology: The hematoma consists of fluid blood covered on the inner and outer aspects by layers of fibrin. The blood is defibrinated on account of the constant pulsation

Fig. 194.1: C T scan showing (A) extradural and (B) subdural hematomas. Note the hematoma compressing the brain tissue and leading to pressure effects (i.e.) distortion of the ventricles and shift of mid line structures

of the brain. The high protein content of the fluid makes it hyperosmotic. It absorbs fluid from the surroundings and enlarges, thereby increasing the ICT. Subdural hematoma may be the only lesion in many patients. In others it may coexist with extradural hematoma or intracerebral hemorrhage. Acute and subacute subdural hematomas are often associated with cerebral contusion, laceration or edema.

Clinical features: The symptoms, in general, are similar to those of extradural hematoma but less dramatic and often atypical.

Chronic subdural hematoma differs in symptomatology from the acute and subacute varieties. It presents as dementia, altered behaviour, psychiatric manifestations, or focal neurological deficits. The level of consciousness fluctuates. History of trauma may be doubtful or may be absent in many cases. In the middle aged and elderly, headache, contralateral hemiplegia and papilledema are the prominent features. Children present with vomiting, restlessness, irritability, refusal to feed, anemia, seizures, and failure to thrive.

Diagnosis: In the acute and subacute form diagnosis may be easy. Around 60% of cases of fracture of the skull show accompanying subdural hematoma.

A high degree of clinical suspicion is necessary for the diagnosis of chronic subdural hematoma in the elderly and children, especially so if history of trauma is not forthcoming. CT scanning shows up the hematoma clearly in almost all cases and this is the investigation of choice (Fig. 194.1). The hematoma appears as a clear avascular zone between the compressed brain below and the skull above on cerebral angiography.

Course and prognosis: Acute subdural hematoma which is often associated with underlying injury to the brain is associated with a mortality of 40-60%. Subacute and chronic subdural hematomas act as progressive space occupying lesions and end fatally, if left untreated. If treated in time, recovery is complete and prognosis is excellent.

Treatment: Surgical evacuation should be undertaken without delay, after locating the hematoma. Medical therapy consists of measures to lower intracranial tension and anticonvulsants.

Intracranial Tumours

These may be primary or secondary. Primary tumours arise from the brain parenchyma, the cerebral blood vessels, the cranial nerves, the meninges, the pituitary gland and the skull. They may be benign or malignant. Secondary tumours are due to hematogenous metastases from malignant tumours at distant sites. Intracranial metastasis

may be lodged in the brain parenchyma, skull vault or the meninges. The common primary tumours that give rise to intracranial metastases are carcinoma of the lungs, breasts, thyroid and the abdominal and pelvic viscera. Most of the intracranial metastatic lesions are solid. Some may be cystic or hemorrhagic. Neoplastic cells from the abdominal and pelvic viscera can also reach the intracranial structures directly through the vertebral venous plexus (*Batson's system of veins*).

PRIMARY INTRACRANIAL NEOPLASMS

Among the primary tumours gliomas which arise from glial cells are the commonest. They are more common in men. Astrocyte, being the most common glial cell, astrocytomas is the most common among glial tumours. The other glial tumours are oligodendrogliomas, ependymomas and medulloblastomas in the order of frequency. Depending on their histology, these tumours are classified into four grades (I to IV) grade I being the least and grade IV the most malignant neoplasm.

Next to gliomas meningiomas are common. These are slow growing benign tumours arising from dural covering of the brain. They are usually located in the parasagittal regions. Unlike gliomas, the meningiomas are more common in women.

Depending on the age of the patient and the intracranial location of the tumour, the nature of the lesion can be inferred accurately in many cases.

Age	Supratentorial brain tumours	Infratentorial brain tumours
Infancy and adolescence	Glioma	Cerebellar astrocytoma
	Craniopharyngioma	adolescence
	Choroid plexus papilloma	Medulloblastoma
	Pinealoma	Brainstem glioma
Middle age	Optic nerve glioma	Ependymoma of fourth ventricle
	Glioblastoma	Metastases
	Meningioma	Acoustic neuroma
	Astrocytoma	Meningioma
	Metastases	
Elderly age	Pituitary adenoma	
	Metastases	Metastases
	Glioblastoma	Acoustic neuroma
	Meningioma	Meningioma

GENERAL CLINICAL FEATURES

Clinical presentation of a patient with intracranial tumour depends upon:

- i. The site, size and rate of growth of the tumour,
- ii. The rate of rise in intracranial pressure, and
- iii. The mass effect on the neighbouring structures.

Rapidly growing tumours in the posterior cranial fossa may present as an acute emergency while slow growing tumours such as meningiomas and oligodendrogliomas in the supratentorial region may remain silent for long periods. As a rule, the symptoms produced by an intracranial tumour are generally progressive over a period of weeks to months but occasionally they may appear more rapidly or abruptly. Cerebral edema around the tumour, hemorrhage into the tumour or displacement of brain structures are the usual causes for rapid worsening of symptoms in some cases. ***The constellation of headache, vomiting and papilledema are the classic clinical features of an established intracranial tumour.*** However, these findings are inconstant in many cases and may be even late to appear in the course of the illness, but when they do occur, especially in association with progressive neurological deficits such as dysphasia, diplopia, blurring of vision, sphincter incontinence or altered state of consciousness they invariably indicate the presence of a brain tumour or any other intracranial space occupying lesion.

The classic description of tumour headache is that it usually starts as mild episodic dull ache at night or on rising-up from sleep in the morning. It becomes worse by coughing or straining and gets better as the day progresses or the patient assumes erect posture. Over a period of time the headache becomes continuous and intense. In one-third of the cases, the headache may occur as an early symptom. However, it should be remembered that cases with headache due to tumour account for only a small proportion of the total number of headaches seen in clinical practice. Neither the location, nor the intensity of the headache correlates directly with the level of intracranial pressure (ICP). Even when the ICP is within the normal range, headache may result from traction or pressure on the dura mater, major cerebral blood vessels or pain sensitive cranial nerves.

Vomiting occurs in one-third of the cases with intracranial tumour. It is more common and early in onset, when the tumour is located in the posterior cranial fossa. Like headache, vomiting also usually occurs soon after getting up from sleep.

Papilledema is a common and sinister finding in intracranial tumours, as it reflects the raised intracranial pressure. It is often bilateral but it can be unilateral or asymmetric at times. Blurring of vision and constriction of the visual fields are early symptoms. Objective testing of vision reveals concentric constriction of the visual fields and enlargement of the blind spot.

Focal or generalised seizures occur in 25-30% of the cases with brain tumours. They are more common with supratentorial tumours.

The neurological deficits caused by brain tumours depend upon:

1. The location of the tumour.
2. The level of the intracranial pressure, and
3. The presence or absence of complications such as brain herniation.

When the tumour is located in the frontal lobe or is associated with significant hydrocephalus, it may manifest as dementia, altered behavior, mood or personality in the early stage. Sometimes, the patients may present with hallucinations, delusions or confusional state. Sometimes, false localising neurological signs may develop due to herniation of brain structures. The medial part of the temporal lobe (uncus) ipsilateral to a supratentorial tumour may be displaced downwards and medially through the tentorial notch. This is called ***transtentorial uncal herniation.***

This leads to the following sequence of neurological phenomena:

1. Compression of the third cranial nerve on the side of the tumour results in pupillary dilatation and ptosis which are the earliest clinical signs of uncal herniation.
2. Compression of the posterior cerebral artery ipsilateral to the tumour gives rise to ischemia of the occipital cortex and hemianopia on the contralateral side.
3. Compression of the cerebral peduncle on the side opposite to the tumour (countre-coup effect) leads to hemiparesis on the side of the tumour.
4. Compression of the midbrain on the side of the tumour leads to contralateral hemiplegia. When this occurs along with the compression of the cerebral peduncle on the opposite side, bilateral upper motor neuron signs develop.

Downward displacement of the brain may also occur due to raised ICP in the supratentorial compartment (brainstem herniation). This stretches the bulbar cranial nerves leading to their dysfunction.

In many cases, even without brain herniation, unilateral or less commonly bilateral VI cranial nerve palsy may occur as a false localising sign.

Special Clinical Features

Gliomas: These constitute half of all the neural tumours. Depending on the histological features, they are pathologically divided into grades I to IV depending on the malignant nature of the neoplasm. Grade I is the least malignant whereas Grade IV is the worst. Grade IV gliomas are known as glioblastoma multiforme and they form 80-90% of all gliomas. In 20-30% of cases the tumours are multicentric and bilateral. The common locations for gliomas are the cerebral hemispheres, brainstem, cerebellum, and spinal cord.

Astrocytomas: These are slow-growing tumours, seen more commonly in the cerebrum, cerebellum, thalamus,

pons, and optic chiasma. Cavitation and/or calcification may develop in many cases. Malignant change may supervene later.

Oligodendrogliomas: These are rare, slow growing tumours, usually seen in the cerebrum, often with calcification.

Ependymomas: These grow inside the fourth ventricle and less commonly in other sites. They are more frequent in children.

Meningiomas (endotheliomas): These benign tumours arise from the dural covering of the brain particularly seen in sites having arachnoid granulations. The sites of predilection are para-sagittal regions, olfactory groove, tuberculum sellae, sylvian fissure, sphenoidal wing, occipital region, and the spinal cord. Older age groups are affected more. More than 90% of meningiomas are associated with abnormalities of chromosome 22.

The tumours are firm, lobulated, highly vascular and adherent to the dura. They compress subjacent brain tissue and lie embedded in it without actual invasion. Commonly the tumours may be calcified. The overlying bone may show erosion or more commonly hyperostosis. Arterial bruit may be heard over highly vascular meningiomas. Surgical removal of meningiomas gives very satisfactory results.

Medulloblastoma: This term is a misnomer which has been handed down by common usage, because medulloblasts are not identifiable in these lesions. These are rapidly growing primitive neuroectodermal tumours affecting the vermis of the cerebellum and giving rise to widespread metastases in ventricles, spinal cord, and meninges. The course and progress are rapid so that clinically these tumours may resemble inflammatory lesions. Children are affected more.

Schwannoma syn: Neurofibroma, neurinoma, neurilemmoma: These are benign, slow growing tumours arising from nerve sheaths with maximum frequency in the fourth and fifth decade. The commonly affected nerve is auditory nerve (**acoustic neurinoma**) and less commonly the trigeminal. The extramedullary part of the VIII nerve is affected and the tumour is located in the cerebellopontine angle (C-P angle) in the posterior cranial fossa. Bilateral acoustic neuromas are seen to be strongly associated with neurofibromatosis type 2.

Acoustic neurinomas produce a characteristic progression of symptoms which depend on the anatomical configuration of this region. The onset is with tinnitus, vertigo, or deafness. Later on there is rise in intracranial tension. As the lesion extends, there is progressive compression of the VII, V, IX and X cranial nerves sequentially. Compression of the brainstem may cause contralateral hemiplegia and hemianesthesia. As the

compression progresses, counter-coup pressure on the side opposite to the brainstem gives rise to the development of hemiplegia and sensory disturbances on the same side as well. The tumour is highly vascular. The internal auditory meatus is often eroded and this can be demonstrated by X-ray of the base of the skull (**Towne's view**). Isolated 10th nerve palsy, raised intracranial tension and even post papilledematous optic atrophy can be the presenting feature of acoustic neurinoma. This occurs as it is a slow growing tumour and compensatory mechanisms mask the localizing features and even the symptoms of raised ICT. CT or MRI scan visualises the lesion. Treatment is surgical removal.

Other tumours in the C-P angle region include meningiomas, trigeminal schwannomas, cholesteatomas, arachnoid cysts and aneurysms.

Tumours in the Region of the Pituitary Fossa

Tumours arising from the pituitary start within the sella turcica. These may be chromophobe or chromophil adenomas. They produce enlargement of the sella turcica and as they grow big, the diaphragm sellae is eroded and the tumour may press on the under aspect of the optic chiasma. In addition to pressure effects determined by their location, endocrine manifestations are also seen. Overproduction of hormones by the tumour gives rise to features such as acromegaly, gigantism, and hyperprolactinemia, depending on the type of neoplasm. Many a time pressure of the tumour on the surrounding normal tissue may lead to pituitary hypofunction.

Craniopharyngioma: Suprasellar tumours and cysts arise commonly from the remnants of the pituitary stalk. These are called *Rathke's pouch tumours*. These are midline tumours occurring at variable distances above the diaphragm sellae. In addition to local pressure effects, they lead to bitemporal hemianopia and later on total blindness and optic atrophy as a result of pressure on the optic chiasma from above. Pressure on the region of the hypothalamus gives rise to somnolence, hyperphagia, obesity, and diabetes insipidus.

Stunted growth with papilledema in a child, should make one suspect craniopharyngioma. It can present in the fifth decade with features of dementia and visual loss.

Suprasellar tumours are generally very slow-growing. Many show calcification in skull radiographs. CT and/or MRI will delineate the lesion.

Pineal Tumours: See section 11, Chapter 97

Patency of the normal foramina of the fourth ventricle allows free communication between the ventricular and subarachnoid CSF spaces. These foramina may be congenitally blocked as in *Dandy-Walker syndrome*. It may occur as acquired phenomenon in basal meningitis or tumours.

Tumours that invade the base of the skull from below: *Nasopharyngeal carcinoma* infiltrates several cranial nerves arising from the medulla and pons.

Glomus jugutare tumours arise from glomus tissue embedded in the external coat of the jugular vein. These tumours may grow into the jugular foramen leading to pressure effects on the VIII, XII, IX, X and VII cranial nerves. Glomus tumours give rise to intense pain. Erosion of the jugular foramen can be demonstrated by CT scan.

Secondary deposits: Carcinomas of the lungs and breast are prone to produce cerebral metastases. Other primaries include carcinomas of the kidney and alimentary tract. Acute lymphatic leukemia and to a lesser extent acute myeloid leukemia may produce lesions in the central nervous system. Lymphomas also may produce neurological manifestations by infiltration. See section: 15 Chapter 159.

MANAGEMENT OF INTRACRANIAL TUMOURS

Early diagnosis is very essential. A high index of clinical suspicion is absolutely essential to plan the appropriate investigation. Proper history and clinical examination including funduscopy should enable the physician to arrive at a provisional diagnosis, not only of the possibility of a brain tumour, but also its site and nature.

Investigations

CT or MRI scan of the brain provides the diagnosis promptly and noninvasively in almost all cases of brain tumour and hence these are the investigations of choice whenever available. MRI is superior to CT in detecting small or isodense tumours, tumours located in the posterior cranial fossa or tumour close to the skull vault or skull base. MRI also picks up multiple metastatic lesions that may be missed by CT.

A thorough search for the primary should be made when intracranial metastases are suspected. A radiograph of the chest should always be obtained in order to exclude carcinoma of the lung which is a common source of intracranial metastases.

Conventional cerebral angiography is seldom done to diagnose a brain tumour. However, in some cases if it is required to elucidate the vascular pattern of the tumour and its relation to the major blood vessels CT angiography or MRI angiography are done. These are relatively non-invasive procedures which will give valuable clues. This helps in the surgical procedure when needed and also helps to exclude the possibility of a giant intracranial aneurysm presenting as a tumour.

Lumbar puncture is contraindicated when an intracranial tumour or other space occupying lesion is clinically suspected or confirmed on CT or MRI scan because of the risk of fatal brain herniation.

Apart from electron microscopy and immunocytochemistry other techniques have evolved as regards the diagnosis of intracranial neoplasms. These include specific markers for glial cells, neurons and epithelial cells. There are also methods to identify gene structure and gene localization by molecular probes.

Differential Diagnosis

Whenever a brain tumour is suspected, other intracranial space occupying lesions such as subdural hematomas, brain abscess, tuberculoma, cysticercosis, fungal granulomas, large demyelinating plaques, large cerebral infarcts and cerebral hematomas should be considered in the differential diagnosis. Sometimes, conditions like hydrocephalus and benign intracranial hypertension (BIH) may masquerade as tumours.

TREATMENT, COURSE AND PROGNOSIS

The course and prognosis of a brain tumour depend upon its site, size, degree of malignancy, rate of growth, invasiveness and the response to treatment. Less than 20% of the patients with glioblastoma survive 1 year after the onset of symptoms. Survival can be prolonged by a few months by radiotherapy. Chemotherapy increases survival to a limited extent. Less malignant tumours such as astrocytomas are more amenable to surgery and radiation therapy. Their survival is 5-6 years. Tumours confined to the cerebellum have better survival rates.

Meningiomas, and acoustic neuromas can be removed by surgery completely. However if the surgical resection is incomplete recurrence is likely.

Symptomatic medical therapy aims at reducing intracranial tension with IV steroids (dexamethasone), mannitol and frusemide. Antiepileptic drugs should be given to control seizures.

The present day management of brain tumour is not uniformly ideal. Recent advances in refined microsurgical techniques, radiation therapy and chemotherapy have made the therapeutic regimen more acceptable and effective. In recent years conventional surgery is being replaced by destruction of the tumour using gamma knife, wherever it is available. The principle is to destroy the lesion by radiation, applied to the target precisely by computed focussing. Use of the gamma knife is limited since it can be employed only for few tumours satisfying specific criteria.

Gene therapy, gene transfer therapy and immunotherapy with monoclonal antibody are promises for the future.

Hydrocephalus

Syn: Hydroencephalus

Dilatation of the ventricular system of the brain due to accumulation of CSF is called hydrocephalus. This may

Fig. 194.2: CT scan showing hydrocephalus
Note: The dilated ventricles and thinned cortex

be congenital or acquired. If the communication between the ventricular system and the subarachnoid space remains patent, it is called **communicating hydrocephalus**. If this communication is blocked, it is termed **obstructive hydrocephalus**. In some cases the hydrocephalus may be normotensive, i.e. the pressure in the ventricular system may be normal, in others it may be raised. Tissue loss resulting in compensatory ventricular enlargement without obstruction is called *hydrocephalus ex vacuo* (Fig. 194.2).

In congenital hydrocephalus and those developing in early infancy the fontanelle and skull sutures separate and the head is enlarged. The eyeballs are depressed and optic atrophy may develop. The brain and skull are thinned out. Percussion over the skull may give a cracked-pot note.

NORMAL PRESSURE HYDROCEPHALUS (NPH)

Normal pressure hydrocephalus (NPH) denotes a chronic, communicating adult onset hydrocephalus. Typical presentation is with a triad of mental impairment, gait disturbance and incontinence. Although called NPH, long term monitoring shows intermittent elevation of pressure. In selected patients shunt surgery may help to alleviate symptoms.

Causes of Hydrocephalus Developing in Infancy

1. Bleeding into the brain during delivery and subsequent adhesions.
2. Congenital absence of arachnoid granulations.
3. Stenosis of the aqueduct.
4. Improper development of the mantle layer of the brain. In the early stages of embryonal development the ventricular system is relatively larger. As the mantle layer develops and the brain grows this relative

TABLE 194.2

Surgical procedures and their principles	
Type of surgery	CSF diverted into
Ventriculo-peritoneal shunt	the peritoneum
Ventriculo-atrial shunt	the right atrium
Ventriculo-sinus shunt	the sagittal sinus
Theco-peritoneal shunt	draining the spinal subarachnoid space into the peritoneum.

disparity disappears. In conditions where the mantle layer does not develop normally, hydrocephalus persists.

5. Arnold-Chiari malformation.
6. Obstruction to the foramina of Magendie and Lushka.

Course and prognosis: If the obstruction is not relieved, the condition progresses. Mental deficiency, optic atrophy, and convulsions may develop in many.

Treatment: Surgical procedures are available to divert CSF from the ventricles and relieve tension using suitable valves, in case of obstructive hydrocephalus. Endoscopic third ventriculostomy is another surgical method employed (Table 194.2).

Causes of Hydrocephalus in Adults

- Subarachnoid hemorrhage
 - Basal meningitis
 - Neoplasms obstructing the aqueduct.
- The basal foramina may be obstructed in meningitis and subarachnoid hemorrhage. The skull is not enlarged if hydrocephalus occurs after closure of the fontanelle. Rise of intracranial tension leads to radiological features such as resorption of the clinoid processes and thinning of the skull vault giving rise to a ‘*silver beaten*’ appearance.

INCREASED INTRACRANIAL TENSION

Persistent increase in tension of CSF above 180 mm CSF (or water) in the recumbent posture constitutes *raised intracranial tension* (ICT). The normal contents of the cranium are the nervous tissue, circulating blood and CSF. Rise in intracranial tension may result from increase in the contents of the cranium, e.g. clots, tumours, abscesses or edema of the brain or due to obstruction to the flow of CSF or impaired CSF absorption by the arachnoid granulations. Some degree of compensation is possible to normalize the intracranial tension in health and disease. These mechanisms include (1) displacement of CSF from the cranium, and (2) drainage of blood by the emissary veins. When rise of intracranial tension proceeds, these compensatory mechanisms fail.

Common Causes of Raised ICT

1. Space occupying lesions: Tumours, abscesses, granulomas, cysts, subdural hematomas.
2. Inflammation: Meningitis, encephalitis, cerebral edema.
3. Vascular accidents: Cerebral and subarachnoid hemorrhage, thromboembolic episodes giving rise to cerebral infarctions, cerebral venous thrombosis.
4. Obstruction to flow of CSF: Hydrocephalus.
5. Miscellaneous causes: Systemic hypertension, especially malignant hypertension; chronic respiratory failure, water intoxication, high altitude cerebral edema.

Pathogenesis: Rise in intracranial tension leads to disturbances of hypothalamic vasomotor regulatory mechanisms. These lead to the development of bradycardia and systolic hypertension (*Cushing's vasomotor phenomena*). Further rise in tension results in displacement of the brain.

If the rise in tension is caused by a unilateral lesion in the cerebral hemisphere, the ipsilateral hemisphere is pushed to the opposite side under the falx cerebri—*subfalcine herniation*. The medial part of the temporal lobe is pushed down through the tentorial hiatus—*transtentorial herniation*. This gives rise to paralysis of the third nerve. Pressure on the ipsilateral cerebral peduncle gives rise to contralateral hemiparesis. *Countercoup pressure* on the opposite cerebral peduncle by the free margin of the tentorium cerebelli gives rise to hemiparesis of the ipsilateral side as well. As the tension increases further, both the pupils dilate, both the cerebral peduncles are compressed with loss of consciousness and the picture is one of decerebrate rigidity. Opisthotonic seizures may develop. When the intracranial tension reaches that of arterial blood pressure, cerebral blood flow is considerably diminished. Medullary centres are depressed. The cerebellar tonsils herniate down the foramen magnum (tonsillar herniation) compressing the medulla and this leads to respiratory paralysis and death. Lesions in the posterior-cranial fossa give rise to ICT earlier than supratentorial lesions.

CLINICAL FEATURES

Headache: The earliest symptom is headache, which is dull initially and it tends to worsen in the mornings. Later it becomes persistent and assumes a bursting character. Sharp rise in intracranial tension caused by coughing, straining at stools or stooping forwards gives rise to aggravation of the headache. Later the headache may become so constant that the patient may not even complain of it unless specifically asked for.

Vomiting: Stimulation of midline structures in the medulla (vomiting centre) gives rise to effortless and projectile vomiting. In projectile vomiting nausea is usually absent.

Visual symptoms: As the ICT rises, vision deteriorates. Initially, there will be transient episodes of visual blurring. Later visual symptoms, defects in the visual fields, diplopia, and total blindness may follow. Funduscopy shows papilledema and later on, optic atrophy. Papilledema occurs when CSF pressure is > 200 mm CSF.

Mental changes: These include apathy, abnormal behavior and lack of attention to personal details. With further rise in ICT the patient may become comatose.

Seizures: These may be the presenting symptom in many. These may be generalized motor or partial seizures with or without secondary generalization.

Focal neurological deficits: These occur if the ICT is due to a focal ICSOL.

Hypothalamic disturbances: Endocrine disturbances develop in long-standing cases where the rise in ICT is gradual and prolonged. These may result in disturbance of the hypothalamus, pituitary or both. Symptoms include amenorrhea, precocious puberty, obesity, gigantism, somnolence, and hyperphagia.

In children constipation is frequent and this results from the fear to defecate since the act of defecation causes rapid worsening of the headache.

Investigations: Apart from general investigations to exclude systemic disorders, specific investigations include radiological studies, electroencephalography, CT scanning, MRI, isotope studies, and CSF examination. It is to be remembered that lumbar puncture is a risky procedure in the presence of raised ICT and this should not be performed without neurosurgical assistance. When LP is contraindicated, CSF can be obtained for tests by ventricular puncture.

MANAGEMENT

General Measures

Anti-edema agents: Administration of 20% mannitol solution 200 mL as an intravenous drip within 30 min helps to draw fluid from the brain and transfer it to the vascular compartment. This leads to a temporary fall in ICT. Other hyperosmotic solutions such as 3% saline and glycerol act by the same principle but they are less efficient. Dexamethasone in a dose of 4-12 mg given intravenously every 6 h also serves to lower ICT.

Specific management: Treatment of the cause relieves the raised ICT also. Surgical measures may be required in some cases.

IDIOPATHIC INTRACRANIAL HYPERTENSION (IIH)

This is a condition (previously known as benign intracranial hypertension – BIH) in which there is rise in

intracranial pressure, often above 200-250 mm of water, in the absence of any space occupying lesion. It is more common in young obese women. Majority of the cases are idiopathic and no specific etiology is detectable. Secondary IIH may result from the use of steroids or withdrawal of steroid therapy, hypoparathyroidism, cortical venous sinus thrombosis, hypervitaminosis A and use of drugs such as outdated tetracycline, phenytoin therapy oral contraceptive pills and others. Pathologically there is obstruction to the arachnoid granulations and this prevents absorption of CSF into the venous sinuses.

Clinically, patients with IIH present with headache, vomiting and visual disturbances. Except for gross papilledema with retinal hemorrhage as on funduscopy and occasionally VI cranial nerve palsy, there is no other neurological deficit.

Diagnosis

Although as a general rule LP is contraindicated when there is papilledema, in IIH, it is relatively safe and should be performed after excluding intracranial space occupying

lesion. LP helps to exclude meningitis and also to record the high CSF pressure, often >250 mm of water. Otherwise it is normal in cytology and biochemistry.

CT scan or MRI scan shows slit like lateral ventricles and normal brain parenchyma. MRI brain scan and MR venogram are the gold standard investigations to diagnose IIH. The former helps to exclude space occupying lesions, particularly cysticercosis which is prevalent in many states of India and which can present as isolated raised ICT. MR venogram helps to exclude cortical venous thrombosis which can also present as isolated raised ICT. Simple CT study often fails to identify these conditions.

Treatment: Some cases are self-limiting and the condition may regress. They may be left alone and observed. In the others repeated LP may have to be done to drain out CSF.

CSF production can be inhibited by acetazolamide 250-500 mg tid or prednisolone 1 mg/kg body weight. These drugs may give partial benefit when tried sequentially. In cases of impending visual loss, optic nerve sheath fenestration has to be undertaken.

Multiple Sclerosis and Other Demyelinating Lesions

Anand Kumar, P.K. Mohan

Chapter Summary

- General Considerations 1289
- Multiple Sclerosis 1290
- Acute Disseminated Encephalomyelitis 1293
- Schilder's Diffuse Cerebral Sclerosis 1294

General Considerations

Myelin is a membrane that ensheathes the axons to improve their ability to conduct electrical action potentials. Oligodendrocytes make myelin and wrap it around axons. The myelin sheath of an axon is not continuous. There are gaps at variable intervals called

nodes of Ranvier, where membrane ionic channels are concentrated. These can generate powerful axon potentials. Loss of myelin leading to exposure of the axons is called demyelination. Demyelination prevents depolarisation due to insufficient flow of ions through the ionic channels. This in turn leads to non-conduction of an action potential across the damaged nerve segment, rendering the nerve functionless.

The term 'demyelinating diseases' refers to a group of acquired disorders where the myelin sheath is destroyed with relative sparing of the other elements of nervous tissue like axis cylinders, nerve cells and supporting tissues. This should not be confused with disorders where myelin is not formed adequately at birth, which are referred to as dysmyelination, e.g. leukodystrophy.

Classification of Diseases of Myelin

Autoimmune

Acute disseminated encephalomyelitis (ADEM).

- Post-infectious: Following viral, bacterial, mycoplasma and rickettsial infections
- Post-vaccinal, e.g. following rabies, smallpox vaccination.

Acute hemorrhagic leukoencephalopathy

Multiple sclerosis

- Chronic relapsing encephalomyelopathic form
- Acute multiple sclerosis
- Diffuse cerebral sclerosis (Schilder's disease, concentric sclerosis of Baló)

Infections

Progressive multifocal leukoencephalopathy

Toxic/ metabolic

Carbon monoxide

Vitamin B₁₂ deficiency

Mercury intoxication (Minamata disease)

Alcohol/ tobacco amblyopia

Central pontine myelinolysis, a complication of rapid correction of hyponatremia

Marchiafava- Bignami syndrome

Hypoxia

Radiation.

Vascular

Binswanger's disease

Reversible posterior leukoencephalopathy

Hereditary disorders of myelin metabolism (Dysmyelination)

Adrenoleukodystrophy due to defect in metabolism of long chain fatty acids. Metachromatic leukodystrophy due to deficiency of arylsulphatase enzyme. Krabbe's globoid leukodystrophy.

Alexander's disease

Canavan's disease

Phenylketonuria.

Multiple Sclerosis

Multiple sclerosis (MS) is the most common demyelinating disease in the west, however, it is less common in India and other Asian countries. In India, MS constitutes 0.05% of all diseases seen in neurology services in the southern and 1.5% in the northern parts of the country. The disease is characterized by neurological deficits due to involvement of optic nerves, cerebrum, cerebellum, brainstem and the spinal cord, to varying extents. It usually affects women between 20-35 years and men between 35-45 years. It is rare before the age of 14 years and after the age of 60 years. Women are more often affected than men

(F:M=2:1). Sometimes it appears to be familial, the first degree relatives having 10 to 20 times increased risk of developing MS.

Etiology: The exact cause of this disease is not clear. However, several epidemiological factors have been clearly established. The disease has a prevalence of less than 1 in 100,000 in equatorial areas, 6 to 14 in 100,000 in southern USA, and 30 to 80 in 100,000 in Canada. The increasing risk of developing multiple sclerosis with increasing latitude has been confirmed by many studies. Also persons who migrate from a high risk to a low risk zone carry with them at least a part of the risk of their country of origin. Those who migrate before the age of 15 carry the risk of developing multiple sclerosis similar to the country of settlement, while the risk in those who migrate after the age of 15 is similar to that of their country of origin. The importance of environmental factors in the genesis of multiple sclerosis is clear. There is no definite inheritance pattern for the disease. HLA-A3,-B7, and DW2 appear to have a possible relationship.

Immunopathogenesis of Multiple Sclerosis

The presence of T and B lymphocytes, macrophages and activated microglia in MS lesions is proof to the fact that immune mechanisms play a role in the genesis of MS plaques. What triggers the immune cascade in MS is still unclear.

Immunopathogenesis in MS is evidenced by the following factors:

1. Presence of immune reactive cells
2. Inflammatory cytokines in serum, CSF and brain
3. Immunomodulators are effective therapeutically
4. MS is initiated by immune cells in animal models.

An antigen presenting cell [APC] engages the antigen in the groove present on the major histocompatibility antigen [MHC]. Antigen presenting cells are usually dendritic cells, macrophages or microglia. T cells with receptors programmed for the antigen proliferate and differentiate into effector subsets of T cells named as Th1 and Th2. These cells produce cytokines. Th 1 and Th 2 cells produce proinflammatory and anti-inflammatory cytokines respectively. T cells with receptors specific for myelin proteins are present in healthy individuals. They are kept suppressed in normal individuals. The mechanisms responsible for the same are decreased activity of suppressor regulator cells and the presence of molecular mimicry. Many pathogens and foreign antigens can activate the myelin reactive T cells. This explains the exacerbations in MS due to multiple triggers. Currently there is evidence to implicate role of B cells in the pathogenesis of MS as well.

Myelin reactive T cells gain entry into the central nervous system by crossing the blood-brain barrier. For

this to happen, adhesion molecules on T cells and endothelial cells are upregulated. After crossing the endothelial barrier the cells reach the outer basement membrane. Matrix metalloproteases (MMP) alter the basement membrane for easy passage of T cells. Later on, chemokines also help in the migration of T cells.

Multi-level loss of tolerance in MS can be due to:

1. Activation of quiescent myelin reactive T cells
2. Influx of T cells into CNS
3. Priming CNS for inflammatory response.

Pathology: The gross appearance of the brain and the spinal cord is normal. The cut surface of the brain shows numerous scattered lesions which are slightly depressed and stand out from the surrounding white matter by virtue of their pinkish grey colour due to loss of myelin. The lesions vary from less than 1 mm to several centimeters in size and are located in the periventricular areas of the brain in relation to the veins.

Histopathological hallmarks are the breach in the integrity of blood-brain barrier; up-regulation of adhesion molecules on the endothelium of brain and spinal cord and further pathological processes. Leukocytes enter the normal immunologically privileged CNS. If lymphocytes programmed to react with myelin antigen enter the tissues, acute inflammatory demyelinating lesions ensue. These lesions primarily involve white matter where the primary targets are the myelin sheath and the myelinating cell which is the oligodendrocyte. However, gray-matter lesions are also known to occur where the primary target is still the myelin antigen.

During an attack of MS, inflammation occurs in areas of white matter of CNS in random patches called 'plaques'. This process is followed by destruction of the myelin sheath which insulates the nerve fibers in the brain and spinal cord. The central problem seems to be the autoimmune destruction of myelin in the CNS.

CLINICAL PRESENTATIONS

MS is a heterogeneous disease both etiologically and clinically. However, based on its clinical course, MS is classified into the following subtypes:

1. **Relapsing:** Remitting type (R-R type): Most common (85%)
2. **Progressive type:** Deterioration continues for at least 1 year
 - a. **Primary progressive (PPMS):** In this type, the neurological deficit is progressive from the onset without acute exacerbation, plateau or remissions.
 - b. **Progressive-relapsing (PRMS):** Consists of patients with primary progressive disease who later in their course develop acute relapses with or without full recovery.

- c. **Secondary progressive (SPMS):** Illness starts as a relapsing-remitting MS, but later assumes a progressive course.

There are distinct ethnic differences in the clinical presentation of MS. Mainly, they are categorized as:

- i. Western type MS
- ii. Asian type MS

Western type MS shows lesions disseminated widely throughout the CNS including the cerebrum, cerebellum and brainstem whereas lesions in Asian type are mainly confined to the optic nerves and spinal cord-opticospinal MS. The opticospinal MS differs from western type MS in the following aspects:

- i. A higher frequency of female patients
- ii. Older age of onset
- iii. More frequent exacerbations
- iv. Fewer number of lesions in the cerebrum on MRI
- v. Higher cell counts and total proteins in the CSF
- vi. Low frequency of oligoclonal bands (OB) or increased IgG index in the CSF, i.e.: (OB negative MS) and
- vii. A benign course.

This large difference in the clinical presentation among ethnic groups is probably due to differences in the HLA class II molecules. The CNS antigens presented to T cells in these two ethnic types may also be different, thereby producing marked differences in the distribution of CNS lesions.

Following the initial acute attack of MS, about one-third of cases recover completely, one-third improve, though not completely, and the remaining cases show no improvement. The most dramatic symptom is visual loss caused by optic neuritis. Loss of vision may be total or partial, acute or subacute and usually unocular, rarely binocular. Some cases present with weakness or numbness in one or more limbs. Other modes of presentation are unsteadiness of gait, brain stem symptoms—diplopia, vertigo, vomiting and bladder disturbances. Dementia, aphasia, seizures, and extrapyramidal movements are rare. Once established, the disease is characterized by remissions and relapses at multiple sites at varying intervals. Due to the presence of heavily myelinated fibres, posterior column deficits and pyramidal involvement are common in MS. Polysynaptic reflexes such as the superficial reflexes may be affected early. Optic atrophy, spastic paraparesis, cerebellar signs like intention tremor or ataxia, and internuclear ophthalmoplegia due to involvement of the medial longitudinal fasciculus are some of the distinctive findings. Bilateral trigeminal neuralgia is characteristic of MS. Rarely a combination of cerebral, brainstem and spinal manifestations evolve over a few weeks rendering the patient stuporous or comatose. In such cases death may occur within a few weeks.

Diagnosis: Clinically definite MS is diagnosed when there are at least two attacks separated in time by at least one month with clinical evidence of at least two separate lesions in the central nervous system or two attacks with clinical evidence of one and investigational evidence of another separate lesion. The clinical attacks should indicate objective involvement of white matter in the CNS. If the attacks are two or more in the relapsing-relapsing type, they should occur in two or more separate anatomical sites.

In the progressive type the duration of illness should be more than one year. In both types there should be no other evident reason to account for the neurological deficit.

There is no pathognomonic laboratory test for MS. CSF may show lymphocyte pleocytosis, up to 20 cells/cmm during the acute attack. Slight rise in total protein (up to 100 mg/dL) may occur. Sugar level is normal. The IgG component in CSF is increased above 13% of the total CSF protein, the total protein being normal or only moderately raised. Electrophoresis of CSF IgG in multiple sclerosis reveals a restricted number of bands called the “oligoclonal bands”. Higher levels of IgG and greater number of *oligoclonal bands* are seen in severe and chronic cases. During the acute phase, high levels of myelin basic protein and myelin debris can be found in the CSF.

In early stage, methods to establish the presence of other asymptomatic lesions are of great help in diagnosis. This is done by recording the evoked potentials by visual, auditory, and somatosensory stimuli. Thus identification of abnormal visual evoked response in a case of paraplegia might help in the diagnosis of multiple sclerosis, even though clinical examination of the visual pathway is normal.

MRI imaging clearly brings out the plaques of demyelination and the lesion can be demonstrated non-invasively (Fig. 195.1).

It is important to exclude other conditions before the diagnosis of MS is established. In India, it still remains a diagnosis by exclusion.

Prognosis: Depends on the type of disease and its progression. Single and localized attacks may remain with partial recovery for varying periods of time but relapses are the rule. Each attack leaves behind residual disability to varying extent. In progressive types severe disability may result, crippling the patient.

TREATMENT OF MULTIPLE SCLEROSIS

There are three main categories in the treatment of MS

- Treatment of exacerbations
- Disease modifying therapy
- Symptomatic treatment.

Fig. 195.1: MRI showing periventricular lesions in MS
Note: The demyelinated plaques

Treatment of Exacerbations

In 1970, Ross and colleagues used ACTH in MS and found a beneficial effect as compared to placebo. Currently most centers use intravenous methyl prednisolone in dose of 1 g per day for a three or five day course often followed by a rapid tapering course of oral steroids. There are also studies claiming equal efficacy for high dose oral steroids. The use of adhesion molecule blockers, has not yielded much benefit.

Plasmapheresis: At least one study has demonstrated significant functional improvement in patients treated with plasmapheresis who had failed to respond to corticosteroids.

Disease Modifying Therapies

There are five approved agents, belonging to three different classes of drugs, presently available as disease modifying therapies for MS. These agents are effective in relapsing remitting MS and in clinically isolated syndromes that do not satisfy the criteria for MS.

Interferon β 1b: Interferon β 1b (IFN β 1b) given in dose of 8 mIU every other day has been shown to reduce the relapse rate in MS by 30%. The proportion of patients remaining exacerbation free and median time to first exacerbation were favourably affected by IFN β 1b. MRI data from patients on IFN β 1b showed a dramatic effect with a reduction in the rate of new lesions and the number

of patients free of new lesions. MRI lesion burden calculated from T2 weighted images was also less in the treated group. The most common side effects of IFN β 1b are flu like syndrome and elevation of liver enzymes. As regards the role of interferon beta in secondary progressive MS two major studies have given conflicting results.

Interferon beta -1a (IFN β 1a) Studies on IFN β 1a have shown beneficial effect in slowing progression of disease, preventing relapses and in delaying second attack in clinically isolated syndromes. MRI data also showed improvement. One study has shown slowing of progression in secondary progressive MS. However, the study used a new outcome measure. The dose used is 30 mcg IM every week and the side effect profile is similar to IFN β 1b.

Glatiramer Acetate Two placebo controlled studies have shown favourable results with glatiramer as regards relapse rate and progression of MS. Glatiramer achieved a reduction in MRI disease burden in another study.

One problem with the use of disease modifying agents is the emergence of neutralizing antibodies (NAB). Relapses are more frequent in patient, with NAB. They occur more in low dose treated group, and many patients lose them over time.

Mitoxantrone is a cytotoxic anthracenedione which has been approved for use in worsening forms of relapsing MS. These include relapsing remitting, progressive relapsing and secondary progressive MS. The dose used is 12 mg/m² IV every three months and the major toxicity is cardiac.

Repetitive courses of steroids: A recent study used pulses of IV methyl prednisolone in relapsing remitting MS, every four months for three years and every six months for two years. There was less disability and evidence of reduction of neuronal loss in the treated group.

Intravenous immunoglobulin (IVIG): The data on the use of IVIG in MS is not convincing, but definitely encouraging. There is no consensus on the dose or frequency of administration of IVIG.

Selective therapy: Natalizumab, a recombinant monoclonal antibody against α_4 integrins is employed for treatment of relapsing MS. It is effective as a short term and medium term (2-3 years) therapy. It reduces relapses and also reduces the lesions seen on MRI. There was a fear of progressive multifocal leucoencephalopathy (PML) developing as a complication of the drug, but this risk is low.

The dose is 300 mg by IV infusion, once in four weeks for more than 2 years.

Fingolimod is a new oral immunomodulating agent being evaluated for the treatment of relapsing MS. Initial results

on its efficacy in reducing clinical disease activity and MRI abnormalities are encouraging. The dose used was 1.5 mg and 5 mg for patients with one lesion or three lesions, respectively, given oral daily for six months (Ludwig Kappos et al Oral Fingolimod (FTY720) for Relapsing Multiple Sclerosis N Engl J Med 2006, 355: 1124-1140).

Bone Marrow/ Stem cell transplantation: Only anecdotal reports are available on the use of this mode of therapy for MS. This is likely to be put to use in the future.

Symptomatic Management

- Amantadine—for fatigue
- Baclofen, dantrolene and diazepam—to allay spasticity
- Clonazepam and high dose INH—to allay intention tremors
- Oxybutinin and propantheline—to reduce urinary frequency and urgency.

VARIANTS OF MS

Devic's Disease (Neuromyelitis optica)

It is a combination of symptoms and signs resulting from spinal cord and optic nerve involvement. Brain is spared, both clinically and on neuroimaging. MRI of spinal cord shows striking lesions of demyelination.

The CSF shows neutrophil pleocytosis and elevated protein.

Balo's Concentric Sclerosis

It occurs more commonly in Philippines and China where the demyelinating attack effects young adults and lasts for a few months. Concentric bands of intact myelin and demyelination zones are present in the CNS.

Marburg's Disease

It is an acute fulminant, progressive disease with extensive destruction of myelin and axon cylinders.

Monophasic Demyelinating Syndromes

These may take the form of optic neuritis, transverse myelitis, acute inflammatory brainstem syndromes or acute disseminated encephalomyelitis (ADEM).

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis (ADEM) is an autoimmune, monophasic, demyelinating disease generally associated with preceding viral infection. The disease has an immunological basis and is thought to be secondary to molecular mimicry and formation of T-cell

and B-cell response to endogenous proteins in the myelin layer. Although most cases begin within a few days of a preceding infection or vaccination, at times there is no history of antecedent event. It may be difficult to differentiate ADEM from the first attack of multiple sclerosis, and the two may have a similar underlying pathophysiology. ADEM is a monophasic illness as opposed to multiple sclerosis, which is polyphasic or progressiv. Recently multiphasic ADEM (MDEM) has also been reported.

Infectious agents thought to precede the development of ADEM include the following:

1. **Measles** which is most common, 1/1000 measles cases, with autoreactive T-cells and antibodies to myelin basic protein.
2. **Other viruses** such as rubella, corona virus, mycoplasma, influenza, parainfluenza, CMV, EBV, HHV-6, Varicella, and nonspecific upper respiratory pathogens.
3. **Vaccinations:** ADEM also follows vaccination to several diseases such as smallpox, rabies, mumps, rubella and influenza.

These various triggers may initiate immune responses within the CNS, or uncover myelin proteins not previously detected by the immune system, resulting in a vigorous inflammatory response.

The clinical course is highly variable, ranging from a slow progression over weeks to a fulminant course over hours to days. A clinical hallmark of the condition is its monophasic course, differentiating it from multiple sclerosis.

Neurological signs and symptoms are variable and nonspecific, but evidence of upper motor neuron dysfunction invariably occurs. Headache, meningism, and altered mental status with confusion progressing to lethargy and coma are common. Cranial nerve involvement, particularly optic neuritis, is common. Motor involvement ranges from focal spastic weakness to quadriplegia. Sensory findings and cerebellar dysfunction are also common.

Laboratory evaluation typically shows a CSF pleocytosis with up to 150-200 WBCs, generally with a lymphocytic predominance. Sometimes polymorphonuclear cells predominate in the CSF (a finding that initially suggests meningitis rather than ADEM). The protein level is usually elevated, but generally not higher than 180 mg/dL.

MRI images show multiple white matter lesions on T2 and flair sequences with gadolinium enhancement on T1. These findings are typical, but not diagnostic, of inflammatory demyelinating lesions as seen in multiple

Fig. 195.2: Showing white matter and basal ganglia lesions in ADEM

sclerosis. They are frequently more confluent and larger in size than typical MS plaques. Lesions may occur in basal ganglia and thalamus which are not seen in MS. Cortical lesions may occur. Frequently, the posterior fossa and spinal cord are involved, with uniform enhancement of lesions (suggesting active disease) unlike MS in which there are often multiple lesions of different ages (Fig. 195.2).

CSF examination: There is no elevation of CSF IgG unlike in MS.

Prognosis: In milder cases, 90% of patients recover completely. In more severe cases, mortality may be as high as 5-20%; and 50% of patients so affected are left with permanent neurological disability.

Treatment is with high dose corticosteroids such as IV methyl prednisolone 1g daily for 3 to 5 days. Plasma exchange and IV IG have also been employed with benefit.

Schilder's Diffuse Cerebral Sclerosis

This is a rare familial disease encountered in children and young adults. Pathologically it is characterized by sharply outlined, asymmetrical foci of myelin destruction involving one or both cerebral hemispheres. It is clinically characterized by a progressive course of dementia, seizures, homonymous hemianopia, cortical blindness, varying degrees of hemiplegia, quadriplegia, and pseudobulbar palsy. In majority of cases death occurs within a few months or years.

Chapter Summary

General Considerations	1295
Motor Neuron Disease	1296
Variant Forms	1296
Progressive Muscular Atrophy	1297
Primary Lateral Sclerosis	1297
Progressive Bulbar Palsy	1297
Progressive Pseudobulbar Palsy	1297
Spinal Muscular Atrophies	1297
Differential Diagnosis	1298
Treatment	1298

General Considerations

Motor neuron disease (MND): This term refers to disorders in which the primary pathology is degeneration of motor neurons. They include a wide variety of clinical conditions.

Etiology: The exact nature of the disease is not known, though it is generally considered to be a degenerative disease. Several etiological factors have been postulated from time to time. These include chronic toxicity due to aluminium and manganese, slow virus infection, low intake of calcium and magnesium and auto immunity. Another hypothesis is that glutamate, which is a primary excitatory neurotransmitter in the central nervous system, accumulates to toxic levels at synapses and causes the neurons to die, probably through a calcium dependent mechanism and free radical production.

Pathology: The motor neurons in the cerebral cortex, brainstem and spinal cord show atrophy and their axons show degenerative changes. Muscles show groups of atrophic fibers amidst groups of normal fibers.

The clinical pattern may follow the classical description in most of the cases, but some may show atypical features. Variant forms of the disease have been described from different geographical regions, including Madras (Chennai).

Classification of Motor Neuron Disorders

- A. *Non-familial or sporadic forms*
 - I. *Of unknown etiology—Motor Neuron Disease (MND)*
 - With UMN and LMN involvement
 - (a) In the spinal cord—amyotrophic lateral sclerosis
 - (b) In the brain—progressive bulbar and pseudo-bulbar palsy
 - With predominantly UMN involvement
 - (a) in the spinal cord—primary lateral sclerosis
 - (b) in the brain—progressive pseudobulbar palsy
 - With predominantly LMN involvement
 - (a) in the spinal cord—progressive muscular atrophy
 - (b) in the brain—progressive bulbar palsy
 - II. *Of known etiology*
 - Infections—polio, tetanus, herpes zoster, HIV
 - Toxins—lead, aluminum, manganese
 - Immunological—plasma cell dyscrasias
 - Metabolic—hypoglycemia, hyperthyroidism, hyperparathyroidism
- B. *Familial/Hereditary/Genetically transmitted forms*
 - I. *Of unknown mechanism*
 - Spinal muscular atrophy (SMA)
 - Infantile onset—Werdnig-Hoffmann disease
 - Childhood onset
 - Adolescent onset—Kugelberg-Welander disease
 - Familial amyotrophic lateral sclerosis
 - Progressive juvenile bulbar palsy
 - Hereditary spastic paraplegia
 - II. *Of known metabolic basis*
 - Hexosaminidase A and B deficiency
 - Superoxide dismutase deficiency
 - Hyperlipidemia
 - Hyperglycemia
- C. *Atypical variants:*
 - Madras motor neuron disease
 - Mill's variant- hemiplegia variant
 - Monomelic atrophy
 - Hirayama type -both upper limbs
 - Gourie Devi's – upper limb
 - Chopra's – lower limb
 - MND with dementia
 - MND with Parkinsonism

Motor Neuron Disease (MND)

Syn: Maladis de Charcot (named after Charcot who first described the condition in 1869) lou Gehrig's disease.

The term 'Motor neuron disease' refers to progressive involvement of upper and/or lower motor neurons usually with little or no clinical involvement of sensory or other non-motor tracts. Five types of MND can be identified on the basis of their clinical, pathological and prognostic characteristics. These are referred to as classic or sporadic forms. MND occurs all over the world, the incidence being 1/100,000. In the islands of Guam and some other regions, the incidence exceeds 50-100/100,000. This is probably due to exposure to an yet unidentified toxin. In some countries the term ALS and MND are used synonymously.

AMYOTROPHIC LATERAL SCLEROSIS (ALS)

This is the most common type of MND. The disease sets in insidiously by the age of 50-55 years, males suffer twice as commonly as females. Average age of onset is 45 years in India, a decade younger than in the West. It is not uncommon to find several members of a family affected. The classic form starts with wasting of the small muscles of the hand, deltoid and shoulder girdle muscles and then progresses to involve the other muscles of the limb. In the majority of cases the affection is bilateral, though asymmetrical. Rarely the manifestations may remain unilateral for considerable periods of time. Still minor manifestations such as fasciculations can be observed over more extensive areas. Bulbar muscles are affected later. Finally all muscles of the body may be involved. The wasted muscles show fasciculations readily, whereas they are less prominent in the apparently unaffected muscles. *Fasciculations* can be made more prominent by exerting the muscle, exposure to cold air or subcutaneous injection of 0.5 mg neostigmine. Atrophy of small muscles of the hand gives rise to claw hand in which there is extension of the metacarpophalangeal joints and flexion of the interphalangeal joints. In the feet, atrophy of the intrinsic muscles gives rise to pes cavus (exaggeration of the arch of the foot), when the feet are in the resting position. As the condition proceeds, trunk muscles and other major muscles of the limbs may also be affected giving rise to considerable wasting and paralysis. Some muscles show evidence of UMN lesion in the form of spasticity and exaggeration of deep tendon reflexes, and also evidence of LMN lesion in the form of fasciculations and atrophy. Affection of the bulbar muscles gives rise to LMN lesion of the tongue, leading to its atrophy, and UMN lesion of the soft palate and pharynx giving rise to exaggeration of gag reflex and dysphagia. The jaw jerk is exaggerated. The plantar responses are bilaterally extensor indicating UMN lesion.

Sensations and mental functions are unaffected. Oculomotor nuclei are spared for some unknown reason. Autonomic functions such as micturition and defecation remain intact, for considerable periods. Speech is affected early. Spastic dysarthria develops with time. In the advanced case, the picture is of extreme wasting. Death is due to respiratory infection, aspiration pneumonia, nutritional inadequacy or cardiovascular causes.

Course and prognosis: The course is one of relentless progression to produce severe disability and death in 4-5 years. Known prognostic factors include age, site of initial involvement, extent and severity of wasting, severity of bulbar muscle dysfunction and respiratory functions.

VARIANT FORMS

1. Madras pattern of MND: Weakness and wasting may be uni- or bilateral, proximal or distal, and asymmetrical. Bulbar muscles may be involved in 60% of cases. Unilateral or bilateral sensorineural deafness, younger age of onset with ALS-like features and a benign course are characteristic of this condition. Indian workers have incriminated defects of glucose utilization by spinal motor neurons to have a causative role (Valmikinathan).

Although this condition was initially described in patients from Madras in South India, similar cases are now encountered in many parts of India.

2. Monomelic amyotrophy: This is a non-familial, insidiously progressive condition, usually affecting adolescents and adults. It is characterised by weakness, wasting and fasciculations restricted only to one extremity—either upper or lower. In some cases, the involvement may be only focal or segmental in one extremity—focal or segmental MND. UMN signs are usually absent. The course is benign. Although clinically one limb is affected, electromyographically subclinical involvement of lower motor neurons in other limb muscles may be evident.

3. Juvenile MND: The typical features of classical ALS may sometimes occur even in young adults.

4. Western Pacific form: It is clinically similar to classic form of ALS, but neuropathologically distinct with neurofibrillary changes and granulovacuolar bodies.

5. Familial form of ALS: About 5 to 10% of ALS cases occur in families suggesting a dominant inheritance pattern. Younger age of onset and a 1:1 sex ratio differentiate this form from classical ALS. A defect in a gene on chromosome 21 has been identified.

6. Amyotrophic lateral sclerosis-parkinsonism—dementia complex, described from Guam islands.

PROGRESSIVE MUSCULAR ATROPHY

In this condition there is selective LMN degeneration leading to weakness and wasting in one upper extremity (75%) or one lower extremity (25%) and this becomes generalized over a period of 3-5 years. Fasciculations are visible but less common. Despite the marked wasting, reflexes are preserved normally or they may even be brisk, but there will be no other signs of UMN involvement.

PRIMARY LATERAL SCLEROSIS

It is an uncommon form of MND in which only signs of UMN lesion in the limbs are present. These signs may persist for many years before the development of bulbar or LMN signs. Disease progression varies between patients. Fifty percent die within 3 years of onset of symptoms. Majority of deaths is due to respiratory failure.

PROGRESSIVE BULBAR PALSY

This is the most serious form of MND since it terminates life within a period of 1 year. There is LMN paralysis of cranial muscles as evidenced by wasting of the muscles of the tongue, muscles of mastication and face. Fasciculations are most marked in the tongue. Progressive involvement of the palatal, pharyngeal, and laryngeal muscles leads to difficulty in speech and deglutition. Patient develops dysarthria and inability to swallow and cough. Emaciation develops rapidly. The jaw reflex is normal or absent. There is no emotional lability.

PROGRESSIVE PSEUDOBULBAR PALSY (SPASTIC BULBAR PALSY)

In this form of palsy the affection of the bulbar muscles is of the UMN type. There is weakness of the bulbar muscles. The palatal muscles, tongue and pharyngeal muscles are spastic. Palatal movements are slow, but the gag reflex is brisk. Speech becomes slurred due to spastic dysarthria. Jaw jerk is exaggerated. Emotional lability is common. Other signs of amyotrophic lateral sclerosis may be associated with progressive bulbar palsy and pseudobulbar palsy.

SPINAL MUSCULAR ATROPHIES (SMA)

These are pure anterior horn cell degenerations with a definite genetic pattern of inheritance, and hence can be considered as hereditary motor neuronopathies. They are subdivided into various types depending on the pattern of muscle involvement, age of onset and mode of genetic transmission.

- i. Werdnig-Hoffmann disease—when the onset is in infancy
- ii. Childhood onset SMA

Spinal Muscular Atrophies Clinical Features			
Distribution	Age of onset	Mode of inheritance	Remarks
Generalised	Infancy	AR	Werdnig-Hoffmann's disease, rapidly progressive Death before the fourth year
Proximal	Childhood	AR	
	Adolescence	AR, AD	Kugelberg-Welander's disease
Distal	Childhood to adult life	AD, AR?	Rare
Scapulo-peroneal	20-60 years	AD, AR ?	Rare
Facioscapulo-humeral		X-linked (?)	
		AD	Rare
Note: AD—autosomal dominant AR—autosomal recessive			

- iii. Kugelberg-Welander disease—when the onset is in adolescence.

Werdnig-Hoffmann disease: This form of progressive muscular atrophy is seen in infancy. It runs a more rapid course.

Kugelberg-Welander disease: This is one of the forms of spinal muscular atrophy characterized by affection of the proximal muscles of all four limbs, starting at adolescence. This has a benign chronic course.

Other forms of spinal muscular atrophy: These occur at any age after infancy. They manifest as asymmetrical uni- or bilateral weakness and wasting of muscles with predominantly LMN features. The affection may be proximal or distal and the former may be mistaken for muscular dystrophy. The diaphragm may be affected early in the disease.

Diagnosis: Motor neuron disease has to be suspected under the following circumstances:

1. Insidious onset of selective motor system involvement characterized by affection of the lower and upper motor neurons.
2. Weakness and atrophy of muscles and fasciculations.
3. Electromyographic abnormalities manifesting as:
 - a. fibrillation and fasciculations at rest,
 - b. reduction in the number of motor unit potentials, and
 - c. giant potentials with increased duration and amplitude.

The motor and sensory nerve conduction velocities are normal. Serum muscle enzymes (CK) and CSF studies are normal.

Differential Diagnosis

Carcinomatous neuromyopathy may resemble MND. In diabetic amyotrophy wasting of the proximal muscles of the lower limbs may develop. This is correctable with proper control of diabetes. In syphilitic amyotrophy there is wasting of the muscles of the hands with upper motor neuron lesion of the lower limbs. Compression of the cervical cord occurring in tumours and cervical spondylosis may present as wasting of hands and spastic paralysis of the lower limbs. In cervical spondylotic myelopathy C₅₋₆ segments are more affected and hence the proximal muscles are more wasted than the hands as in motor neuron disease. Sensory manifestations are usually present in these conditions.

Motor neuropathy with multifocal nerve conduction block is an autoimmune peripheral neuropathy affecting young males, especially the upper limbs. Nerve conduction velocity is affected in motor nerves. GM-1 antibodies develop against the myelin components. GM-1 antibodies may be present in serum. This condition promptly responds to I.V. immunoglobulin. This has to be differentiated from the spinal forms and variant forms of MND.

Myopathies and chronic polymyositis may present with muscle wasting and atrophy. In these fasciculations are absent. Muscle biopsy is diagnostic. Electromyography

helps to distinguish myopathy from MND. Muscle enzymes like CK are elevated in myopathies.

Treatment

At present none of the known modalities arrest the progress of the disease. Palliative measures include physiotherapy, use of orthotic devices to help functioning of the limbs and treatment of intercurrent illness and ventilatory support.

Drugs that modulate the glutaminergic system have been proposed for therapy of MND. Riluzole (2-amino-6-trifluoromethoxy benzathiole) has given encouraging results in arresting the progression temporarily, especially in the bulbar forms of MND. The drug crosses the blood brain barrier. It is an inhibitor of glutamate release and it exerts its beneficial effect by reducing the neurotoxicity of glutamate. The dose is 100 mg a day. It is available as 50 and 100 mg tablets.

It postpones the onset of ventilatory failure and ventilator-dependence by a few months. The drug is available with Sun pharma.

Cyclophosphamide given in doses of 1.5 g/m² body surface in divided doses IV has been shown to relieve bulbar symptoms temporarily, by Indian workers. The effect wanes off after varying periods.

Diseases of the Cerebellum

Anand Kumar, P.K. Mohan

Chapter Summary

- General Considerations 1298
- Heredofamilial Ataxias 1299
- Friedreich's Ataxia 1299
- Other Forms of Heredofamilial Ataxias 1300
- Ataxia Telangiectasia 1302
- Hereditary Spastic Paraplegia 1302
- Cerebellar Tumours 1302
- Inflammatory Lesions of the Cerebellum 1302

- Vascular Lesions of the Cerebellum 1302
- Other Causes of Cerebellar Dysfunction 1302

General Considerations

The cerebellum lies below the tentorium cerebelli in the posterior cranial fossa. It consists of two cerebellar hemispheres on either side, connected by the vermis in the middle. The cerebellar hemispheres consist of three lobes.

TABLE 197.1

Autosomal dominant ataxia – Harding’s classification		
Type	Clinical phenotype	Common genotypes
ADCA I	Cerebella ataxia plus other symptoms: extrapyramidal symptoms, neuropathy	SCA 1, 2, 3, 4, 12, 17, 21, 23 and 25
ADCA II	Cerebellar ataxis plus retinal degeneration	SCA 7
ADCA III	Cerebellar ataxia-pure	SCA 5, 6, 8, 10, 11, 14, 15, 16 and 22
ADCA: Autosomal dominant cerebellar ataxia; SCA: Spinocerebellar ataxia		

The cerebellum consists of the outer grey matter, inner white matter and four deep nuclear masses—fastigial, globosus, emboliformis and dentate nuclei. The cerebellar cortex consists of the outermost molecular layer, middle Purkinje cell layer and inner granular layer.

The three lobes are:

- 1. Anterior lobe—functionally related to the gross movements of heads and neck
- 2. Middle lobe—related to fine voluntary movements
- 3. Floculonodular lobe related to equilibration.

The vermis controls the midline structures of the body and trunk, whereas the lateral hemispheres control the limbs of the same side.

The cerebellum is connected to the brainstem by three peduncles (superior, middle and inferior) through which afferent and efferent fibers connect to various parts of the brain and spinal cord.

Blood supply is derived from three pairs of arteries—superior cerebellar and anterior inferior cerebellar arteries from the basilar artery and posterior inferior cerebellar arteries from the vertebral arteries.

Functions of the Cerebellum

- 1. Coordination of voluntary and reflex movements
- 2. Modulation of muscle tone and
- 3. Maintenance of body posture.

The clinical features of cerebellar disease and testing for cerebellar function are described in Chapters 182 and 183. Acute lesions of the cerebellar system produce sudden, severe and disabling symptoms. Chronic lesions lead to insidious deterioration of function.

HEREDOFAMILIAL ATAXIAS

These include a wide spectrum of degenerative diseases which are progressive, familial and manifesting in early life, with their main brunt on the cerebellar pathways. Variable degrees of involvement of the spinal cord, brainstem and cranial nerves also occur. The exact etiology is not known but recent evidence points to defects in mitochondrial energy systems and pyruvate metabolism as probably important factors. Hereditary ataxias are of many types, the most common being Fiedreich’s ataxia.

HEREDITARY ATAXIAS

Hereditary ataxias are broadly defined by mode of inheritance - autosomal dominant, autosomal recessive, or X-linked. With better understanding of the molecular basis and pathogenesis of these diseases, other classification schemes have been suggested. These classifications are based on disorders of trinucleotide repeat expansions or toxic “gain of function” due to abnormal proteins and accumulation of polyglutamine inclusions, channelopathies, mitochondrial dysfunction, defective DNA repair and metabolic disorders. Autosomal dominant cerebellar ataxias (ADCA) were initially classified according to phenotype and accompanying signs by Harding, as given in Table 197.1. Genetic advances have led to modification of these criteria as specific genes and mutations responsible for cerebellar ataxias have been discovered.

SPINOCEREBELLAR ATAXIA (SCA)

SCA is characterized by cerebellar ataxia manifesting with gait ataxia, dysarthria, slow saccades, nystagmus, corticospinal tract signs, neuropathy and later on with ophthalmoplegia and bulbar dysfunction (dysphagia, tongue fasciculations). Extrapyramidal signs may be seen but cognitive deficits are not typically present. Age of onset varies from adolescence to late adulthood with the average age of onset around third to fourth decades. SCA1 is due to an expansion of an unstable trinucleotide CAG repeat on chromosome 6p23.

So far about 25 types of autosomal dominant ataxias have been described and the list is likely to extend further.

Friedreich’s Ataxia

This is an autosomal recessive disorder. Prevalence in European population is 1/50,000. The locus of genetic defect is on chromosome 9. The gene which encodes a protein ‘frataxin’ undergoes mutation.

Frataxin is a mitochondrial protein taking part in energy metabolism. Defect in frataxin leads to abnormal accumulation of iron in the mitochondria followed by cell death. There is neuronal loss in the motor and sensory systems.

Pathology: There is degeneration of the spinocerebellar tracts, posterior columns, Clarke's columns, and the pyramidal tracts. Cardiac involvement occurs in many, taking the form of interstitial myocarditis and conduction defects.

CLINICAL FEATURES

The onset is in the first or second decade of life. Cardinal features of Friedreich's ataxia include ataxia of all four limbs, cerebellar dysarthria, areflexia in the lower limbs, sensory loss and pyramidal signs. Earliest manifestations are ankle areflexia and gait ataxia due to loss of posterior column sensations and cerebellar disturbances. Later, other signs of cerebellar disease and posterior column dysfunction are evident. Ankle jerks are lost earlier than the knee jerks. Loss of vibration and proprioceptive sensations are more evident in the lower limbs. Skeletal deformities such as kyphoscoliosis and pes cavus (increased convexity of the arch of the foot) are common. Optic atrophy and muscle wasting may develop in some cases. Diabetes develops in 10% of cases. Features of cardiomyopathy may develop in those with cardiac involvement.

DIAGNOSIS

It is entirely clinical. Insidious onset of ataxia with signs of cerebellar and posterior column dysfunction, absence of ankle jerks, and presence of Babinski's sign in the first two decades of life should suggest this diagnosis. Associated congenital defects such as kyphoscoliosis and pes cavus are further suggestive. Presence of the disease or other stigmata in family members strengthen the diagnosis. Relatives of the patient may show abnormalities such as pes cavus, kyphoscoliosis, loss of ankle jerks, nystagmus or upper motor neuron signs.

Differential Diagnosis

Several neurological disorders may resemble Friedreich's ataxia superficially. These include multiple sclerosis, other forms of ataxias, craniovertebral junction anomalies, intracranial tumours, tabes dorsalis, and diabetic neuropathy.

Course and Prognosis

The disease progresses steadily over several years, but rate of progression may vary widely between cases. In many cases considerable disability in gait, speech, and daily activities develops, though lifespan is not shortened. Interstitial myocardial fibrosis and cardiac conduction defects may occur in some cases and this may account for premature death in such cases.

Treatment

Specific therapy is not available. Physiotherapy to improve coordination is beneficial. Occupational therapy to

rehabilitate these patients is to be instituted early. High doses of choline have been claimed to allay progress of the disease.

Other Forms of Heredofamilial Ataxias

These rare forms include:

1. **Roussy-Levy syndrome:** It is characterized by sensory ataxia, wasting of extremities, areflexia and pes cavus, without nystagmus.
2. **Sanger-Brown's ataxia:** It manifests as ophthalmoplegia, optic atrophy, and spasticity with nystagmus and pes cavus.
3. **Marie's cerebellar ataxia:** Occurs in the 3rd and 4th decades of life, with cerebellar ataxia and optic atrophy without posterior column deficits.
4. **Primary cerebellar degeneration:** This is clinically characterized by nystagmus, dysarthria and ataxia. The cerebellar cortex and olivocerebellar fibers of the inferior peduncle show atrophy.
5. **Olivopontocerebellar atrophy (OPCA):** It is a large heterogeneous group characterized by degeneration of pontine arcuate and olivary nuclei and middle cerebellar peduncles together with loss of white matter and Purkinje cells in the cerebellar hemispheres. The clinical presentation varies considerably. This occurs sporadically and is seen after the age of 45 years. There is atrophy of the superior and middle cerebellar peduncles, Purkinje cells, olive and pontine nuclei. The disease presents with ataxia of the trunk and extremities, titubation, unsteadiness, and dysarthria. Some patients develop urinary incontinence, parkinsonism and cognitive decline.

Familial, essentially autosomal dominant cerebellar ataxia associated with slow saccadic eye movements. It has been described by N.H. Wadia from (Bombay) as a distinct subgroup of hereditary ataxias. There are up to 21 varieties of familial autosomal dominant spinocerebellar degenerative disorders leading to ataxia.

CEREBELLAR ATAXIAS RESPONSIVE TO SPECIFIC THERAPY

Most of these have a metabolic abnormality caused by congenital or acquired defects of enzymes which take part in the metabolism of amino acids.

These disorders usually present in early life but can also manifest in later life. The presentation can be acute or recurrent, static or progressive.

Acute Recurrent Ataxia

Familial episodic ataxia is an autosomal dominant disorder of uncertain etiology.

Clinical features include paroxysmal ataxia, nausea and vertigo. There are two types; type 2 is more common.

Attacks begin in late childhood or adolescence and are precipitated by stress, exertion and fatigue. Duration is from hours to days. The episodes may be superimposed on mild form of chronic progressive truncal ataxia. The disease predominantly affects the vestibulo-cerebellum. Diagnosis is made by the episodic nature of attacks, positive family history and MRI evidence of cerebellar vermis atrophy. Therapy is with acetazolamide which reduces the frequency and severity of episodic ataxia. Type 1 is earlier in onset with briefer attacks and absence of signs between attacks. Myokymia of the hands and face can occur.

Maple Syrup Urine Disease (MSUD)

MSUD is an autosomal recessive disorder due to deficiency of branched chain ketoacid dehydrogenase. The intermittent form of MSUD can present with episodic ataxia and encephalopathy. Infection and excess dietary protein precipitate attacks and diagnosis is established by finding increased levels of branched chain amino and ketoacids in plasma and urine. Dietary restriction of branched chain amino acids and use of thiamine are the modes of treatment.

Hartnup Disease

Hartnup disease is an autosomal recessive disorder resulting from defective transfer of neutral amino acids. Affected individuals present with episodic ataxia, personality change and pellagra like skin rashes. There is increased excretion of neutral amino acids and indole products in the urine. Treatment is by giving high protein diet and nicotinamide.

Multiple Carboxylase Deficiency

Multiple carboxylase deficiency is an autosomal recessive disorder due to deficiency of biotinidase [biotin recycling enzyme] or biotin containing carboxylase. The disorder often presents in the first six months of life with seizures, alopecia and decreased hearing. Milder forms may present in later life. Diagnosis is by finding reduced levels of biotin in serum and urine and lactic acidemia. Treatment is oral biotin 10 mg per day.

Urea Cycle Disorders

Urea cycle disorders present in infancy with ataxia, seizures, vomiting and varying levels of altered sensorium. They are autosomal recessive disorders with the exception of ornithine transcarbamylase deficiency which is X-linked. Altered function of several enzymes involved in the urea cycle can present with increased levels of ammonia and abnormality in levels of specific amino

acids. Insulin-glucose regime, sodium benzoate and sodium phenylacetate are used to bring down ammonia. Severe cases may require dialysis.

CHRONIC PROGRESSIVE ATAXIA

Abetalipoproteinemia

Abetalipoproteinemia is an autosomal recessive disorder presenting with steatorrhea in infancy followed a few years later by ataxia, peripheral neuropathy and retinitis pigmentosa. There is absence of apolipoprotein B resulting in fat malabsorption and deficiency of Vitamins A,E and K. Investigations reveal acanthocytes in peripheral smear, low serum cholesterol and triglycerides and absence of apolipoprotein in serum. Treatment is by giving vitamins A,E and K. Diet should be low in long chain fatty acids.

Ataxia due to Vitamin E Deficiency

This is an autosomal recessive disorder presenting in the second decade of life with progressive ataxia, areflexia and proprioceptive loss. Diagnosis is made by finding low serum levels of Vitamin E and treatment is vitamin E supplementation.

Refsum's disease is an autosomal recessive disorder due to deficiency of the enzyme *phytanic acid alpha hydroxylase*. Ataxia, Polyneuropathy, retinitis pigmentosa and deafness are the common clinical manifestations. Phytanic acid levels are increased in blood and urine. Treatment is by giving diet low in phytanic acid. During acute exacerbations, plasmapheresis may be required.

Cerebrotendinous Xanthomatosis

This is an autosomal recessive disorder due to deficiency of chenodeoxycholic acid which is necessary for the synthesis of bile acids. Presentation is in adolescence or early childhood with ataxia, spasticity, neuropathy and dementia. Diagnosis is suggested by the typical association of tendinous xanthomas and cataract. Serum cholesterol level is increased and treatment is by giving chenodeoxycholic acid.

Wilson's disease an abnormality of copper metabolism, may be present with cerebellar ataxia (see Chapter 32).

von Hippel-Lindau Syndrome

von Hippel-Lindau syndrome is an autosomal dominant disorder presenting with hemangioblastoma of the cerebellum and angioma of the retina. Other associations include renal cell carcinoma, renal and pancreatic cysts, pheochromocytomas and polycythemia.

Ataxia Telangiectasia

Syn: Madame-Louis-Bar syndrome

This is an autosomal recessive condition occurring in children and manifesting by the age of 10 years. The features are cerebellar ataxia, wasting of legs and areflexia. The bulbar conjunctiva shows telangiectasia. There is deficiency of immunoglobulins and this leads to repeated sino-pulmonary infection. The condition is associated with poor prognosis.

Hereditary Spastic Paraplegia

In this form, the predominant lesion is degeneration of the pyramidal tracts with minor involvement of the spinocerebellar tracts and posterior columns. It is inherited as autosomal dominant disorder and the disease manifests clinically between 3 and 15 years of age. In the fully evolved form the picture is one of spastic paraplegia with lesser affection of the upper limbs, dysarthria, and pseudobulbar palsy.

Cerebellar Tumours

The cerebellum may be the seat of tumours such as medulloblastoma, cystic astrocytoma, and oligodendroglioma, which are common in children. Medulloblastoma affects the midline structures of the cerebellum more often. Astrocytoma affects the lateral hemispheres more. Hemangioblastoma and metastatic deposits usually occur in adults.

Inflammatory Lesions of the Cerebellum

Cerebellum may be involved in viral and bacterial meningo-encephalitis, chickenpox and postvaccinal encephalitis. Cerebellar abscess may occur as a complication of otitis media. Tuberculomas are not uncommon in the cerebellum, especially in children (See Chapter 49).

Vascular Lesions of the Cerebellum

Cerebellum is the seat of hemorrhage in 5-10% of all hemorrhagic strokes occurring in hypertension. The patient presents with headache, neck rigidity, nystagmus, vomiting and ataxia. If the bleeding increases or edema develops, other features such as ocular palsy, loss of sensation in the trigeminal territory, facial palsy, and coma may set in. Surgical evacuation of the clot is life-saving. If left untreated, 50% die within a week. Occlusive lesions of the vertebrobasilar system lead to cerebellar infarction.

OTHER CAUSES OF CEREBELLAR DYSFUNCTION

Alcoholism: Acute alcoholic bout may lead to ataxia, nystagmus, and dysarthria. Cerebellar degeneration as a complication of chronic alcoholism results in ataxia of gait and stance, often without nystagmus and dysarthria.

Multiple sclerosis: The cerebellum and its connections are affected in multiple sclerosis.

Subacute cerebellar cortical degeneration: This may occur as a nonmetastatic complication of malignancy, especially bronchogenic carcinoma. The cerebellar lesion manifests as ataxia, dysarthria, rarely nystagmus, depression of tendon reflexes, and Babinski's sign.

Metabolic disturbances: Cerebellar ataxia may occur in hypoglycemia, hypothyroidism, hypoxia and hyperthermia. In the early stages this is reversible.

Drugs: Drugs like phenytoin may lead to reversible cerebellar disturbances such as dysarthria, ataxia, and nystagmus. In advanced cases the Purkinje cells may show degeneration and the condition becomes irreversible.

Nutritional deficiencies: Thiamine and niacin deficiency (pellagra) produce cerebellar deficit similar to chronic alcoholism.

Developmental anomalies: Arnold-Chiari malformation, basilar invagination, Dandy-Walker cyst and cerebellar aplasia cause cerebellar dysfunction along with other deficits.

Diseases of the Spinal Cord, Nerve Roots and Plexus

General Considerations

The spinal cord extends from the foramen magnum to the lower border of first lumbar vertebra. Pia and arachnoid mater extend to the 2nd sacral vertebra and dura further below to merge with the periosteum of coccyx. The pia mater, which extends down as a connective tissue filament, is called *filum terminale*. The length of the spinal cord is 45 cm (male) and 40 cm (female) and consists of 31 segments: eight cervical, twelve dorsal, five lumbar,

five sacral and one coccygeal. From each spinal segment, the anterior and posterior roots arise which join to form the spinal nerve. The spinal roots exit the spinal canal through neural foramina formed by adjacent vertebrae. The spinal cord is shorter than the spinal canal, and therefore, vertebral bodies and the spinal cord segments do not correspond with each other. The first seven cervical roots exit above their corresponding cervical vertebral bodies and the eighth cervical root exits below the seventh cervical vertebra. The other spinal roots exit below their corresponding vertebral bodies. The lumbar and sacral roots are long because they descend from their respective cord segment to their exit points in the spinal canal. These descending roots form a bundle termed as *cauda equina* (horse's tail). The spinal segment corresponding to each vertebra is determined as follows:

For cervical vertebrae add 1, e.g. spinal cord segment corresponding to C5 vertebra is C6.

For thoracic (dorsal) vertebrae, 1- 6 add 2

For thoracic vertebrae 7-9, add 3

10th thoracic vertebral arch overlies L1 and L2 segments

11th thoracic arch overlies L3 and L4 segments

12th thoracic arch overlies L5 segment

1st lumbar arch overlies sacral and coccygeal segments.

Group of muscles and area of skin supplied by a spinal cord segment is called *myotome* and *dermatome*, respectively. Knowledge of the segmental innervation of muscles and skin is essential to determine the level of affection of spinal cord disease.

The spinal cord is supplied by one anterior and 2-4 posterior spinal arteries. The anterior spinal artery is formed by the confluence of two branches arising from the vertebral arteries and it descends in the anterior median fissure throughout the length of the spinal cord. The two posterior spinal arteries arise from the corresponding vertebral or posterior inferior cerebellar arteries and descend along the entire length of the cord. Anterior spinal artery supplies the anterior 2/3 of the spinal cord including anterior horn, central canal and anterolateral columns,

whereas the posterior spinal arteries supply the posterior 1/3 including posterior horn and posterior columns. The spinal arteries send descending branches to supply the cauda equina. The anterior spinal artery is reinforced by 4-8 radiculomedullary arteries derived from the vertebral, intercostal and lumbar arteries. The feeder vessels of the lower cervical and lower thoracolumbar regions are most important. **The artery of Adamkiewicz** (arteria radicularis magna) is a major radicular artery that arises from the aorta and enters the cord between T10 and L3 segments and supplies the lower thoracic and lumbar spinal cord. As the feeder vessels in the thoracic region are small in caliber and sparsely distributed, the thoracic cord (especially T4 to T8 regions) is vulnerable to ischemia during global hypoperfusion and hence this region represents a watershed zone in the spinal cord. The direction of blood flow along the spinal arteries varies and can depend on various factors such as changes in posture and intra abdominal and intrathoracic pressure. Veins draining the cord are situated dorsally and ventrally as six longitudinal channels. They drain rostrally into the vertebral veins.

The motor neurons supplying different groups of muscles are arranged in the anterior horn of the spinal cord in a definite manner:

Muscle groups	Position of neuron in the anterior horn
Distal muscles of the extremities	Lateral
Proximal muscles of the extremities	Medial
Extensors and abductors	Anterior
Flexors and adductors	Posterior

The sensory and motor tracts passing through the spinal cord are shown in Table 198.1 and Figure 198.1 The pathway for bladder and bowel control is located in the lateral column.

TABLE 198.1		
Tracts of the spinal cord		
Tract	Location in spinal cord	Function
Fasciculus gracilis Fasciculus cuneatus	Dorsal column	Proprioception, vibration sense, touch
Pyramidal	Lateral column – deep and anteromedial	Voluntary muscle contraction
Lateral spinothalamic	Venterolateral column	Pain and temperature
Anterior spinothalamic	Anterior column	Touch
Spinocerebellar	Lateral column - superficial	Muscle position, tone

Fig. 198.1: Spinal cord section—diagrammatic representation

Functional Representation	Anatomy of tracts
10. and 13. Voluntary movement	1. Fasciculus gracilis
11. Pain, temperature and touch	2. Fasciculus cuneatus
12. Equilibration	3. Lateral (crossed) pyramidal tract
14. Position sense, vibration sense, touch	4. Posterior spinocerebellar tract
	5. Anterior spinocerebellar tract
	6. Lateral spinothalamic tract
	7. Extrapyramidal tracts
	8. Anterior spinothalamic tract
	9. Anterior (uncrossed) pyramidal tract

Fibers in the spinal cord tracts are arranged in a specific pattern, called as laminations. In the dorsal columns, sacral fibers are medially placed while thoracic and cervical fibers are arranged more laterally. In the lateral spinothalamic and pyramidal tracts, the arrangement of fibers is reverse, sacral fibers being more lateral and cervical fibers medial.

Clinical Features of Spinal Cord Disease

Motor phenomena: Interruption of the descending corticospinal (pyramidal) tract gives rise to UMN type of paralysis below that level, characterized by distal weakness and spasticity. At the level of lesion, LMN type of paralysis may occur, manifesting as wasting and fasciculation of muscles supplied by that spinal cord segment. Weakness of upper and lower limbs is called quadriplegia (tetraplegia) and weakness of lower limbs alone is paraplegia. Pattern of muscle weakness may vary depending on the degree of spinal cord compression. Classically, patients may present with **paraplegia in extension** if the pyramidal tract is solely damaged and **paraplegia in flexion** if both the pyramidal and extra-

pyramidal tracts are damaged. As the spinal cord lesion progresses, the lower limbs assume a position of flexion and persistent shortening and contracture of muscles. With involvement of both pyramidal and extrapyramidal tracts, the paralyzed limbs may develop frequent spasms (*flexor spasms*) that may occur either spontaneously or in response to external stimuli. With cord lesions at T₁₀ level, upper abdominal muscles are normal while lower abdominal muscles are weak and maneuvers that require contraction of the abdominal muscles results in pulling up of the umbilicus, resulting in **Beevor's sign**.

Sensory phenomena: Interruption of ascending sensory tracts may lead to various patterns of sensory deficits. Involvement at a particular spinal cord level results in bilateral impairment of sensations with a distinct level that separates it from the region of normal sensation above. Interruption of spinothalamic tracts results in loss of pain and temperature sensations. Lesion of the dorsal column results in loss of proprioception and vibration sense. Compression of posterior spinal roots gives rise to root pains (*radicular pain*) and loss of sensations in the corresponding dermatome. **Radicular pain** is characterized by unilateral, sharp dermatomal pain exacerbated by cough, sneeze or Valsalva maneuver and results from root irritation. **Vertebral pain** arises from the vertebrae and is characterized by aching pain localized to the point of the spine involved by the lesion and is often accompanied by point tenderness. **Funicular pain** (tract pain) is a deep ill-defined painful dysaesthesia usually occurring away from the affected spinal cord level and is caused by involvement of spinal tracts. Lesions of the dorsal column may result in tingling or vibratory paraesthesias. Patients may complain that the skin is "too tight" or an extremity is "wrapped in bandages". Lesions of the spinothalamic tracts may result in pain that is poorly characterized or localized.

Neck flexion at times may give rise to an electric shock like sensation down the spine due to stretching and irritation of nerve fibers in the dorsal column of the cervical cord. This is referred to as **Lhermitte's sign**. It occurs in cervical spondylotic myelopathy and demyelinating diseases affecting the cervical cord.

Reflex changes: Deep tendon reflexes are exaggerated below the level of lesion in localized spinal cord lesions. If the substance of the cord is destroyed over long segments, the tendon reflexes mediated by these segments are also lost. Following acute lesions which interrupt the motor pathways completely, there is a period of flaccidity and areflexia. This period of **spinal shock** may last from a few hours to days after which, tone and reflexes return. Spasticity then develops, initially in the extensor group of muscles of the lower limbs and flexor group of muscles of the upper limbs. The *mass reflex* consists of widespread

reflex contraction of the muscles of the lower limbs and trunk, sweating, and evacuation of the bladder, rectum and seminal vesicles in response to noxious stimuli.

Autonomic Disturbances

Sweating is lost below the level of complete transection of the cord. Rarely, excessive sweating may occur.

Blood pressure fluctuations may also occur in myelopathies. Lesions above T5 spinal segment leads to impaired vasomotor control, resulting in orthostatic hypotension. Such patients may also have episodic autonomic dysreflexia characterized by excessive sweating, cutaneous flushing, hypertension, pounding headache and reflex bradycardia following any noxious stimulus.

Bladder disturbances are common in spinal cord disease. Parasympathetic and sympathetic fibers mediate the voiding and storage functions of urinary bladder while somatic fibers are responsible for voluntary control. Bladder receives parasympathetic fibers from intermediolateral zone of S2, S3 and S4 spinal segments that travel via pelvic nerves and innervate the detrusor muscle, bladder neck and internal sphincter. Sympathetic fibers arise from L1 and L2 spinal segments and reach the bladder via hypogastric nerves. They predominantly innervate the bladder neck and internal sphincter. External sphincter is under voluntary control and is supplied by somatic efferent fibers arising from S2, S3 and S4 spinal segments (Onuf's nucleus) that travel via the pudendal nerve. Sensory impulses from the bladder pressure receptors are carried by somatic (pudendal nerve) and autonomic (pelvic and hypogastric nerves) fibers. Micturition is mediated by a supraspinal reflex with pontine micturition centre and its initiation and termination are under voluntary control. Voiding of urine occurs by relaxation of the sphincters and contraction of detrusor muscle, mediated by the parasympathetic system. Once micturition is complete, detrusor muscle relaxes and sphincters contract due to parasympathetic inhibition and sympathetic system facilitation. Subsequently, the bladder begins to store urine. Voluntary control of initiation and termination of micturition is mediated by the paracentral motor region of frontal cortex via descending fibers in the lateral columns of spinal cord. Bladder sensations are carried via the spinothalamic tracts. Lesions of the spinal cord above the sacral segments results in an upper motor neuron type of neurogenic bladder characterized by increased contractions of the detrusor muscle (detrusor hyperreflexia) and lack of coordination between contraction of the detrusor and sphincter muscles (detrusor sphincter dyssynergia). This results in the symptoms of urgency, urge incontinence, frequency of micturition and

hesitancy. However, initially in the acute phase, the patient may present with retention of urine and reduced detrusor muscle activity due to the stage of spinal shock. Lesions of the sacral segments results in the symptoms of hesitancy of micturition, chronic retention, continuous dribbling of urine due to overflow incontinence, inability to initiate micturition and reduced bladder sensations.

Sexual dysfunction is also common in myelopathies and may result in impotence (failure to obtain erection sufficient enough to perform the sexual act). Penile erection, mediated by parasympathetic pathways, is often affected in lesions of spinal cord. Psychogenic erection is mediated by impulses passing from spinal segments T12 to L3. Reflex erection resulting from penile stimulation, is mediated by S2, S3 and S4 spinal segments. In lesions above T12 segment, psychogenic erection is lost while reflex erection persists, whereas both are lost in lesions affecting the sacral segments. Occasionally, patients may manifest with priapism, characterized by sustained erection without psychological sexual stimuli. In females, disturbances of sexual function manifest commonly as loss of the sexual drive and dyspareunia, often difficult to assess objectively.

Disturbances of defecation are less severe and often transient in myelopathies. Common complaints include constipation and loss of rectal sensation. Fecal incontinence is rare and may occur in lesions of the conus medullaris. It is associated with patulous rectal sphincter as appreciated during digital examination and loss of anal reflex.

Diseases of the Spinal Cord

Several disease processes affect the spinal cord and cause varying degrees and patterns of neurological dysfunction. These are referred to as *myelopathies*. Myelopathies can be approached syndromically based on the constellation of symptoms and signs. The common spinal cord syndromes include:

Complete transverse section: Syndrome of complete transverse section at a particular level of the spinal cord results in symmetric UMN paralysis, sensory loss and autonomic disturbance below the level. This syndrome is classically seen in transverse myelitis, but can occur in post-traumatic spinal cord injury and acute spinal cord compression.

Unilateral transverse section: Syn: *Brown-Sequard syndrome*. This syndrome of hemisection of spinal cord results in ipsilateral UMN paralysis and loss of sensation for vibration and proprioception and contralateral loss of appreciation of pain and temperature. Otherwise known

as the *Brown-Sequard syndrome*, it most commonly occurs following spinal cord trauma or compression due to tumour.

Central cord syndrome: Intramedullary lesions damage the decussating fibers of the spinothalamic tract that carry sensations of pain and temperature at that level, resulting in dissociated sensory loss. This is characterized by loss of pain and temperature sensations and preserved appreciation of joint and proprioception sensations. Because of the arrangement of fibers in the spinothalamic tract, sacral sensations are usually preserved resulting in a *suspended pattern* of sensory loss. Common causes include syringomyelia, intramedullary tumours and post-traumatic hematomyelia or contusion.

Anterior spinal artery syndrome: Occlusion of the anterior spinal artery results in a characteristic constellation of signs due to infarction of spinal cord parenchyma supplied by it. It is characterized by involvement of anterior horn cells and anterolateral tracts leading to motor paralysis, loss of bowel, bladder and sexual functions and sensory disturbances characterized by loss of appreciation of pain and temperature sensations and preservation of joint and proprioception sensations. This can occur following vascular and thoraco-abdominal surgeries.

Anterior horn and pyramidal tract syndrome: Disturbance of anterior horn and pyramidal tract function with preservation of sensory and autonomic nervous system function can occur in motor neuron disease (MND).

Combined Posterior and Lateral Column Disease: Syndrome of loss of joint and proprioception sense with UMN pattern of weakness leads to spastic ataxic gait and is seen in vitamin B₁₂ deficiency (subacute combined degeneration). Friedreich's ataxia, neurosyphilis and HIV myelopathy may show signs of loss of pyramidal tract, posterior columns, lateral columns and spinocerebellar tract functions.

For practical purpose of evaluation and management, myelopathies can be broadly categorized into compressive or non-compressive, based on whether or not myelopathy is caused by a lesion that is compressing the spinal cord. General clinical features that are usually seen in compressive myelopathy include:

- Asymmetric onset
- Steadily progressive symptoms
- Asymmetric symptoms and signs
- Presence of flexor spasms
- Well-defined sensory, reflex or motor level
- Bladder dysfunction.

The lesion compressing the spinal cord may be either extramedullary, arising outside the spinal cord, e.g.

TABLE 198.2
Causes for myelopathy
• Tumour • Infections-tuberculosis, syphilis • Trauma • Degenerative disc diseases • Congenital anomalies • Diseases of vertebral column, e.g. tuberculosis, epidural malignant lesions, primary and secondary; pachymeningitis, arachnoiditis

meningioma, or may be intramedullary, arising from within, e.g. ependymoma. Differentiation between the two may be difficult clinically, though presence of certain symptoms and signs may be helpful. Table 198.2 and Figure 198.2 give a simple approach to the patient presenting with myelopathy. The common causes of myelopathy are enlisted in Table 198.2.

MYELOPATHY

Myelopathy may be caused by compressive or non-compressive lesions.

COMPRESSIVE MYELOPATHIES

The spinal cord may be the seat of compression in several pathological entities on account of its location within a narrow, restricted bony canal —the spinal canal. *Source of the spinal cord compression may be extramedullary in 80% and intramedullary in 20%.* The common causes are enlisted in Table 198.3.

TABLE 198.3
Causes for compressive myelopathy
Intramedullary Primary tumours (astrocytoma, ependymoma) Metastasis Syringomyelia, hematomyelia Infections: spinal cord abscess, tuberculoma, cysticercosis
Extramedullary and intradural Primary tumours: neurofibroma, meningioma Vascular: AV malformation Metastases: leukemia, lymphoma, myeloma Infections: syphilitic pachymeningitis, arachnoiditis, e.g. tuberculous
Extramedullary and extradural Infections: epidural abscess, tuberculosis of the vertebrae (Pott's disease) Metastases: breast, lung, GI tract, prostate, thyroid, myeloma Congenital anomalies: craniovertebral junction anomalies Epidural hematoma Trauma: vertebra fracture Spondylosis cervical and lumbar/intervertebral disc prolapse Fluorosis

Two-third of extramedullary tumours are situated on the dorso-lateral aspect of the cord, and one-third ventrally. Damage to the spinal cord may result from direct pressure of the tumour, and/or pressure on the arteries leading to infarction or edema caused by venous obstruction. In slow spinal compression, the corticospinal

Fig. 198.2: Clinical approach to a patient with myelopathy

TABLE 198.4

Clinical guidelines to differentiate intramedullary from extramedullary compressive lesions

Symptom/ sign	Intramedullary lesion	Extramedullary lesion
Radicular pain (girdle pain)	Unusual	Common, may occur early
Vertebral pain	Unusual	Common
Funicular (tract) pain	Common	Less common
Upper motor neuron signs	Yes, late	Yes, early
Lower motor neuron signs	Prominent and diffuse	Unusual; if present, segmental distribution
Progression of pain/temperature sensation loss	Descending (sacral sparing)	Ascending
Dissociation of sensory loss	Present	Absent
Bladder disturbances	Early	Late

tracts are more susceptible to compression and ischemia and only later are the posterior column and spinothalamic tracts affected (Table 198.3).

CLINICAL FEATURES

Onset of symptoms may be acute, subacute or insidious and clinical features depend upon the site and cause of compression Table 198.4 SCA—spine-cerebellar ataxia.

In extramedullary compression, the initial symptom is pain felt over the spine or in the distribution of the spinal root. Coughing, sneezing or movements of the spine may aggravate this pain in the case of extradural lesions. As the compression proceeds, paresthesias and numbness develop over the limbs as a result of compression of the spinothalamic tracts and posterior column. Motor symptoms consist of heaviness, stiffness and weakness of the lower limbs if the lesion is below T1 level. Upper limbs will also be involved if site of compression is cervical spinal cord. **Classically, the march of paralysis in cervical cord extramedullary compression is initially ipsilateral upper limb, then ipsilateral lower limb, opposite lower limb, and finally opposite upper limb (Elseberg rule).** This sequence is due to initial compression of the ipsilateral corticospinal tract and as it progresses, subsequent compression of the contralateral corticospinal tract by *contre-coup* pressure. Involvement of bladder occurs late, as the fibers subserving bladder function are placed deep in the spinal cord.

Intramedullary compression causes disturbance of bladder function early. Sensory loss generally takes the form of dissociated anesthesia. Dissociated sensory loss may develop either as a result of pressure on the crossing sensory fibers in the anterior commissure or compression on the lateral spinothalamic tracts. In the former case, sensory loss is confined to the segment affected. Since the lateral spinothalamic tract is compressed from within, cervical lesions cause loss of sensation in the upper limb first and then only lower limb. Thus sacral sensations are spared till late in the disease, called **sacral sparing**. Root pains are uncommon.

Lesions at the level of foramen magnum and upper cervical cord lead to a constellation of symptoms and signs. These include suboccipital pain (C2 distribution), loss of pain and temperature sensation of face, lower cranial nerve palsies (9,10,11,12), cerebellar signs, diaphragmatic weakness, downbeat nystagmus, papilledema and cruciate hemiplegia (contralateral upper limb and ipsilateral lower limb weakness).

LESIONS OF THE CONUS MEDULLARIS AND CAUDA EQUINA

Lesions of the cauda equina and conus medullaris cause similar symptoms and it is often not possible to differentiate between the two. When the cauda equina is affected, symptoms and signs are attributed to root involvement. Common conditions include neoplasms, prolapsed intervertebral discs and spinal arachnoiditis. Lumbar canal stenosis may lead to the additional symptom of intermittent neurogenic claudication. Lesions of the **conus medullaris** (S3,4,5,coccygeal spinal segments) are characterized by early loss of sphincter functions. Common conditions include neoplasms such as ependymoma and demyelination. Lesions of the **epiconus** affect the L4, 5, S1 and S2 spinal segments. Table 198.5 enlists the points useful to differentiate between conus medullaris and cauda equina lesions

DIAGNOSIS (SEE FIG. 198.2)

Diagnosis of compressive myelopathy involves the following steps:

1. Determining the level of compression
2. Determining whether compression is extra- or intramedullary
3. Ascertaining the pathological nature of the lesion.

X-rays of the spine may reveal vertebral or disc pathology. Enlargement of the intervertebral foramina suggests the presence of neurofibroma. CT scan can demonstrate the spinal canal and identify the cause of compression. MRI is superior to CT to reveal spinal cord lesions and whenever available is the investigation of choice.

TABLE 198.5

Clinical features useful to differentiate conus medullaris and cauda equina lesions

Clinical feature	Conus medullaris	Cauda equina
Onset	Sudden, bilateral	Usually gradual, unilateral
Motor weakness	Symmetric, minimal	Asymmetric, may be severe, fasciculations common
Sensory loss	Saddle anaesthesia, symmetric	Asymmetric
Spontaneous pain	Unusual, not severe	Prominent, severe, asymmetric
Neurogenic claudication	Absent	May be present
Dissociated sensory loss	Present	Absent
Sphincter incontinence	Early and marked	Late, less severe
Erectile dysfunction	Early	Late, less severe
Loss of anal and bulbocavernosus reflexes	Early	Late
Ankle jerk	Preserved	May be lost

Role of lumbar puncture is limited, and presence of elevated protein levels suggest significant cord compression. L.P. is contraindicated in cord compression due to tumours since it may worsen the paralysis due to leakage of CSF and inspissation of the tumour at the site. In cases of obstruction of the spinal canal **Froin's syndrome** characterized by xanthochromia and elevated CSF protein, may develop.

Differential diagnosis: When the signs and symptoms of myelopathy are associated with spinal pain, tenderness and deformity or nerve root pains, it strongly suggests a remediable surgical etiology. Figure 198.2 is useful to localize the source of compression. Sometimes, clinical distinction between extra- and intramedullary lesions may be difficult.

Spinal cord compression has to be distinguished from other intrinsic disorders such as syringomyelia, motor neuron disease and multiple sclerosis.

MANAGEMENT OF SPINAL CORD COMPRESSION

Whenever spinal cord compression is confirmed by MRI, CT scan or myelography, neurosurgical intervention should be sought without delay. Surgical treatment should be undertaken early to avoid permanent damage to the cord by direct compression or vascular occlusion. Early treatment restores function but if compression is allowed to persist for long periods, secondary changes develop in the cord. Late surgery is often unrewarding and the functional results are poor. Conditions such as tuberculosis of the vertebrae may resolve to a great extent with medical therapy. Acute cord compression leading to sudden onset paraplegia is a neurosurgical emergency. Appropriate and prompt decompressive surgery reverses

the neurological damage. The prognosis for recovery depends upon the severity and the duration of the neurological deficit prior to surgery. Therefore, it is important to make an early diagnosis.

MYELOPATHY IN TUBERCULOSIS

Tuberculosis can present as myelopathy in several ways. Spinal tuberculosis commonly affects the dorsal spine and can lead to *Pott's paraplegia* due to spinal cord compression. X-ray shows anterior wedging of adjacent vertebrae with loss of intervening disc space, which can be confirmed by CT or MR imaging. Table 198.6 enlists the causes for myelopathy in tuberculosis.

TABLE 198.6

Myelopathy due to tuberculosis

Due to extramedullary lesions	Due to intramedullary lesions
Cold abscess, granulation tissue	Myelitis
Sequestered bone and disc fragment	Tuberculoma
Pathological subluxation of vertebra	Thrombosis of anterior spinal artery (rare)

Spinal Epidural Abscess

It commonly presents as subacute progressive compressive myelopathy associated with fever. However, it may occasionally present as acute paraplegia. Epidural abscess develops as a result of septic emboli reaching the epidural space during systemic infection. Root pains may develop. Fever is highly variable and some patients may have mild fever while others may have hectic fever and appear toxic. *Staphylococcus aureus* is the causative organism in 50%

of cases. Diagnosis is established by MRI and confirmed by evacuation of pus and culture/sensitivity. At times, the condition will be diagnosed when pus is aspirated during a lumbar puncture for other indications.

INJURY TO SPINAL CORD

Spinal cord damage is a common complication of injuries to the vertebral column. When the spinal cord is injured by forces occurring during violence without fracture, dislocation of the spine or structural cord damage, it is termed *concussion*. *Contusion* is the term used to denote bruising of the cord without rupture of the pia arachnoid. More severe injury results in *laceration* of the cord in which the pia is ruptured and often the cord may even be completely transected. Clinical features depend upon the site and type of injury. Injury to the cervical cord above C4 is fatal due to associated paralysis of the diaphragm and intercostal muscles.

Management: On the first suspicion of spinal cord injury, further movements of the spine should be prevented by proper splinting. Transportation to a neurosurgical center should be done without delay. Surgical decompression is undertaken if conservative measures such as immobilization of the spine and traction are unsuccessful.

Spinal cord lesions are not uncommon in dysbarism (caisson disease). This should be borne in mind when injury is associated with activities under water (see Chapter 14).

HEMATOMYELIA

Bleeding into the substance of the spinal cord is termed *hematomyelia*. Though bleeding into the cord may follow injuries, the term *hematomyelia* is reserved for those conditions where there is no obvious precipitating factor.

Etiology

- 1. Transmitted violence
- 2. Intramedullary telangiectasia or angioma
- 3. Spontaneous hemorrhage into the cavity of syringomyelia
- 4. Hemorrhagic disorders, especially purpura.

Common site is the cervical cord enlargement. The bleeding is primarily into the central grey matter and the long tracts are compressed by the hematoma.

Clinical features: The onset may be sudden or gradual and progressive. The condition is clinically characterized by the syndrome of partial or complete transection of the cord, depending on the extent of the hematoma. Usually, patients gradually improve as the hematoma resolves. Rarely the condition may be fatal if the hematoma extends to the cervical cord leading to diaphragmatic paralysis.

Treatment: This consists of complete rest and immobilization of the neck in a collar or suitably made splints. The underlying cause should receive appropriate treatment.

Syringomyelia

This is a chronic disorder pathologically characterized by progressive cavitation (*syrix*) and gliosis of the central portions of the spinal cord. Usually the syringomyelic cavity is longitudinal and extends over a few segments and rarely the entire length of the cord. Transversely, it tends to extend irregularly into the anterior horns and lateral columns. Dorsal columns are late to be involved. The contours of the cavity are irregular and its walls are formed by gliosis. When the lesion extends into the medulla, it is called *syringobulbia*. The condition may be primary (congenital) or secondary (acquired) (Table 198.7). In about 50% of cases of primary syringomyelia, there are associated bony and soft tissue abnormalities at the craniovertebral junction.

Pathogenesis: No theory adequately explains the pathophysiology of syringomyelia. Disruption of CSF circulation at the level of foramen magnum is seen in many cases of syrix. Pressure waves develop at the foramen magnum due to periodic downward displacement of the cerebellar tonsils during systole and results in compression and elongation of the syrix. Following trauma and infection such as tuberculous arachnoiditis, scarring results and leads to altered CSF dynamics and tethering of the cord.

Pathology: The site of predilection of primary or congenital syringomyelia is the lower cervical region, but the cavity may extend for several segments down into the thoracic region or up into the medulla. Lumbosacral cord may be affected either by extension of the cavity or by independent cavities. Usually the cavity starts as enlargement of the central canal of the spinal cord, which extends forward and laterally to involve the anterior commissure, anterior horns, and lateral columns. The anterior horn cells and the segmental fibers carrying pain

TABLE 198.7	
Causes for syringomyelia	
• Foramen magnum obstruction – Arnold Chiari malformation, basilar invagination • Spinal cord tumour: astrocytoma, ependymoma, hemangioblastoma • Myelomalacia and loss of spinal cord parenchyma • Intracranial communicating hydrocephalus • Post-traumatic • Post-infectious, post-inflammatory • Idiopathic	

and temperature, which cross in the anterior commissure, are affected early. The corticospinal and lateral spinothalamic tracts are involved subsequently. The posterior columns get involved only late in the disease or not at all.

CLINICAL FEATURES

The age of onset is usually between 25-40 years in the primary form. Initial symptoms in cervicothoracic syringomyelia consists of loss of pain and thermal sensation in the cervicothoracic segments (especially C8, T1) associated with weakness, wasting and even fasciculations of the small muscles of the hands. Loss of pain and temperature sensation with preservation of touch (*dissociated anesthesia*) in an irregular distribution is the hallmark of syringomyelia. The patient may not appreciate burns and injuries. Depending upon the level of interruption of the crossing fibers and the lateral spinothalamic tracts, the distribution of dissociated sensory loss varies. In high cervical lesions, the spinal tract of the trigeminal nerve is affected and this also gives rise to dissociated anesthesia over the face. Trophic changes develop as a result of loss of pain sensation. These include painless perforating ulcers and neuropathic joint (*Charcot's joints*). Destructive changes in joints induced by denervation was described by Jean Martin Charcot (French physician) in 1868. The affected joints undergo degenerative changes due to hypermobility and laxity of the capsule and ligaments, and the articular surfaces may disintegrate. Commonly, elbow and shoulder joints are also affected. Radiological changes of destruction are demonstrable in these joints. Patients may complain of vague pains and paraesthesias over the affected parts. In some, sensory symptoms may be the most troublesome presenting symptom.

Horner's syndrome occurs due to involvement of the sympathetic fibers in the cervical cord or medulla. Function of bladder and rectum are generally not affected. When the cavity extends into the brainstem, patients develop multiple cranial nerve palsies.

Course and prognosis: The condition is slowly progressive and causes significant disability over several years. Some cases are self-limiting. In a few, rapid worsening may be due to bleeding into the syrinx.

Diagnosis: The combination of lower motor neuron paralysis, dissociated sensory loss at the level of the lesion and upper motor neuron features below the level of lesion should raise the possibility of syringomyelia. Intramedullary tumours, vascular lesions and hematomyelia have to be excluded. Syringomyelia and craniovertebral anomalies may coexist in some cases. MRI is the investigation of choice. In all cases therefore, it is necessary to

investigate the craniovertebral region with X-ray, and CT scan or MRI.

Treatment: Treatment depends upon the cause. Syrinx due to Arnold Chiari malformation is managed by foramen magnum decompression. Syrinx associated with hydrocephalus is managed with ventricular shunt. Tumour removal is the treatment of choice for tumour related syrinx. Syrinx related to trauma and infection is managed by adhesiolysis and duroplasty. Second line treatment for syringomyelia includes syringostomy, which drains the syrinx cavity into the spinal subarachnoid space.

Non-compressive Myelopathies

However in some cases of myelopathy, despite extensive investigations, the cause may still remain obscure (myelopathy of undetermined etiology) (Table 198.8).

TABLE 198.8

Causes for non-compressive myelopathy

- Inflammatory
 - Infections: enterovirus, herpes zoster, herpes simplex, mumps, HIV, HTLV-1 (tropical spastic paraplegia), tuberculosis, syphilis, mycoplasma
 - Non-infectious: transverse myelitis, multiple sclerosis, neuromyelitis optica, vasculitis, SLE, Sjögren's disease, antiphospholipid antibody syndrome, Eale's disease
- Nutritional
 - Vitamin B₁₂ deficiency, Vitamin E deficiency, Pellagra
- Vascular
 - Spinal artery occlusion, arteriovenous (A-V) malformation
- Heredofamilial/degenerative
 - Hereditary spastic paraparesis, spinocerebellar ataxia, motor neuron disease, adreno-myelo-neuropathy
- Toxins
 - Lathyrism, triorthocresyl phosphate, subacute myelo-optic neuropathy (SMON)
- Physical
 - Lightning, electricity, radiation
- Paraneoplastic
 - Lymphoma, carcinoma breast, ovary

Transverse Myelitis

Inflammatory disease affecting the grey and white matter of the cord is called myelitis. Involvement of the anterior horn is called *poliomyelitis*. Selective involvement of the white matter is called *leucomyelitis*. When the disease is localised over several segments of the cord, it is called transverse myelitis. The cord lesion may occur alone or as part of a more extensive disease such as meningitis or encephalitis (encephalomyelitis).

TABLE 198.9

Causes for transverse myelitis

- a. Demyelinating illnesses**
Postinfectious/postvaccinial myelitis: allergic response to infection or vaccination, e.g. antirabies vaccine, smallpox vaccine
Multiple sclerosis
Neuromyelitis optica
- b. Direct infections**
Virus: enterovirus, herpes zoster, rabies
Bacteria: syphilis, pyogenic infection, tuberculosis
- c. Vasculitis**
SLE, Sjögren's disease, antiphospholipid antibody syndrome

Table 198.9 enlists the cause for transverse myelitis. However in nearly 40% of cases no specific cause may be detectable even after investigations.

Pathology

The affected segment of the cord becomes hyperemic and edematous. Histologically there is perivascular inflammation, edema, vascular thrombosis, and in the chronic stage, neuroglial proliferation.

CLINICAL FEATURES

Transverse myelitis usually affects thoracic segments of the spinal cord. Initial symptoms may be nonspecific such as fever, malaise, backache and root pains. Spinal cord involvement results in a syndrome of complete or partial transection of the cord. Patient presents with sudden weakness and sensory loss involving the lower limbs extending up to the trunk and upper limbs, depending upon the upper level of involvement. Neurological deficits are often asymmetric. Bladder and bowel disturbances occur early. Within 24-48 hours, paralysis and sensory loss are fully manifest and a clear upper level of sensory and reflex loss is definable which indicates the level of the lesion. The initial phase is one of spinal shock in which there is flaccidity and areflexia. The spinal shock period extends for a few days to weeks and is followed by hyperreflexia and spasticity.

CSF shows moderate lymphocytic pleocytosis and rise in proteins (up to 400 mg/dL). CSF sugar remains normal. MRI is the investigation of choice and confirms the diagnosis and facilitates identification of etiology. MRI shows hyperintense lesions in the spinal cord, representing myelitis and demyelination.

Course and prognosis: Improvement occurs with time and complete or near complete recovery occurs in most cases.

Differential diagnosis: Transverse myelitis should be considered when the syndrome of complete cord

Fig. 198.4: MRI cervical spine showing demyelinating lesions in a patient with transverse myelitis. Note: (1) General swelling of the cord and (2) Hyper intense (whitish) lesions

transection develops within hours or a few days. Acute cord compression can present similarly. This may be seen in conditions such as epidural abscess, tuberculosis, metastasis, bleeding or edema into spinal cord tumour, bleeding from a vascular malformation or occlusion of the anterior spinal artery. MRI is useful to distinguish these conditions (Fig. 198.4). Occasionally, Guillain-Barré syndrome may mimic acute myelopathy.

Occasionally, postinfectious/postvaccinial demyelination may affect other regions of the nervous system as well and patient may have encephalopathy, ataxia or brainstem signs in addition. This condition is called as **acute disseminated encephalomyelitis (ADEM)**.

Management: Investigations (blood and CSF) should be done to exclude conditions such as multiple sclerosis, vasculitis or any infections such as herpes zoster, HIV, HTLV -1, tuberculosis, syphilis, etc. If a specific cause is identified, appropriate treatment can be initiated. When no specific cause is detectable or when immune mediated disease is suspected, trial of high dose corticosteroids such as intravenous methyl prednisolone may be given. Plasma exchange and intravenous immunoglobulin have also been used in refractory cases. General management of paraplegia consists of attention to nutrition, frequent change of position and skin care to avoid bedsores, proper positioning of the limbs to avoid contractures, physiotherapy to prevent venous thrombosis and to improve muscle tone and drainage of urine using an indwelling catheter. Constipation is treated using laxatives or small enemas. Flexor spasms can be controlled by avoiding stimuli to the lower limbs and administering medications such as diazepam 5 mg b.d or baclofen. As the patient improves, active physiotherapy and occupational therapy are instituted.

Anterior Spinal Artery Occlusion

The anterior spinal artery supplies the anterior 2/3 of the cord. The artery may be occluded by thrombosis or embolism leading to ischemia and infarction in the vascular territory. Arterial occlusion may be due to vascular disease of aorta, generalized atherosclerosis, vasculitis, cardiac arrest and global hypoperfusion, diseases of the vertebral artery such as dissection, aortoarteritis or descending aorta aneurysm repair. Embolism may occur as a complication of infective endocarditis or ischemic heart disease. Clinical features depend on the level of arterial occlusion. Recovery may start within a few days of onset and improvement may occur with time.

Subacute Combined Degeneration of the Spinal Cord

Subacute combined degeneration of the spinal cord represents the commonest cause for metabolic myelopathy. This condition results from vitamin B₁₂ deficiency. Further account is given in chapters 151 and 187.

Neuromyelitis Optica (Devic's disease)

This is a syndrome of acute severe transverse myelitis with bilateral simultaneous or sequential optic neuritis occurring in close temporal succession and resulting in paraplegia and blindness. There is no evidence of clinical disease outside the optic nerve or spinal cord. Aetiopathogenesis and natural history are controversial. Recently anti-aquaporin-4 antibodies have been implicated.

HIV Related Myelopathy

Subacute or chronic myelopathy occurs late in HIV infection. It affects predominantly the posterior and lateral columns and clinical presentation has a striking resemblance to subacute combined degeneration of spinal cord secondary to vitamin B₁₂ deficiency. Usually upper limbs are spared. As per the pathological changes, vacuolar myelopathy is also used to describe this condition. It may coexist with other manifestations of neuroAIDS such as dementia and distal painful sensory neuropathy. CSF shows mild lymphocytic pleocytosis and MRI may reveal spinal cord atrophy. Diagnosis is established after ruling out opportunistic infections and malignancy that may also cause myelopathy in AIDS.

Eale's Disease

This is an idiopathic inflammatory venous disorder manifesting as retinal perivascular phlebitis and subsequent vitreous hemorrhage. Neurological manifestations are rare and subacute or acute myelopathy is described. There may be an association with tuberculosis.

Tropical Spastic Paraplegia

This condition, commonly seen in tropical areas and in Japan, is characterized by chronic progressive spastic paraplegia associated with mild impairment of proprioception and vibration in 50% of patients. Visual impairment occurs in 15%. The condition is caused by infection by a retrovirus, HTLV-1, and hence it is also called HTLV-1 associated myelopathy. Diagnosis is established by the demonstration of anti-HTLV-1 antibodies in CSF.

Lathyrism

It is a form of spastic paraparesis produced by excessive intake of the chickling pea or grass pea (khesari dal, toor dal), lathyrus sativus. It is found in north and central India. Beta oxalyl amino alanine (BOAA) is the toxin implicated. Being drought resistant, lathyrus sativus becomes the chief constituent of diet during famines. It commonly manifests as a chronic spastic paraparesis. The degree of disability has been staged according to the amount of support with walking stick that is required for ambulation: no stick stage, one stick stage and two stick stage. Objective sensory loss does not occur (See Chapter 24).

Hereditary Spastic Paraplegia

Otherwise known as *Strumpell-Lorraine* syndrome or familial spastic paraplegia (FSP), HSP comprises a heterogeneous group of inherited disorders in which the chief clinical feature is progressive spasticity of lower limbs. Inheritance can be autosomal dominant, autosomal recessive or X-linked. Onset may be below the age of 35 years, or later. Clinical features are dominated by spasticity and UMN pattern of weakness, predominantly in the lower limbs. Sensory loss and micturition disturbances are variable. Complicated HSP is the term applied when there are additional systemic or neurological deficits such as optic atrophy, retinopathy, amyotrophy, dementia, deafness or ataxia.

Diseases Affecting the Spinal Roots

Nerve roots are susceptible to local compressive lesions as well as many of the disorders affecting peripheral nerves. Otherwise known as radiculopathies, their clinical features include radicular pains, paresthesias, dermatomal distribution of sensory loss, myotomal loss of muscle power and diminished segmental deep tendon reflexes. Involvement of multiple roots is called polyradiculopathy. Common causes for radiculopathy are enlisted in Table 198.10

Radiculopathies are evaluated according to the clinical presentation. Investigations include nerve conduction study, CSF study and MRI.

TABLE 198.10
Common causes of radiculopathy
1. Degenerative disc disease
2. Traumatic root avulsion
3. Inflammation: Guillain-Barré syndrome, CIDP, vasculitis
4. Neoplasms/paraneoplastic syndrome
5. Infections: Herpes zoster, tuberculosis, cytomegalovirus
6. Diabetes mellitus
CIPD: Chronic inflammatory demyelinating polyradiculopathy

Neurogenic Claudication
(Pseudoclaudication)

This is a syndrome in which pain is felt in the regions supplied by the lumbosacral segments of the spinal cord. The symptoms typically consist of exercise (walking)-induced pain in the gluteal, thigh or leg regions and weakness in the legs. Symptoms and signs promptly recover with cessation of exercise in the early stages but later on deficits persist even at rest. Symptoms may be confused with vascular claudication and Table 198.11 lists points to differentiate between the two. Neurogenic claudication is caused by lesions that narrow the spinal canal and compress the nerve roots of the cauda equina. This most commonly arises due to **lumbar canal stenosis**, which may be congenital or acquired. Congenital causes include achondroplasia and acquired causes include spondylosis, fractures or degenerative spondylo-lithesis. Symptoms are attributed to the compressive effects on the nerves of the cauda equina, impaired arterial supply and venous stasis and hypertension. During exertion there is a 50-100% rise in nerve tissue metabolism when action potentials begin to fire. Exercise in the setting of compromised nerve roots causes pain due to accumulation of metabolites such as lactic acid. After stopping exercise, reduction in metabolic demand is associated with improvement of pain and neurological symptoms and signs.

Treatment: If narrowing of the spinal canal can be demonstrated by MRI, CT imaging or myelography, surgical decompression is undertaken. The results are often gratifying.

Disorders of Nerve Plexuses (Plexopathy)

Disorders of the brachial plexus and lumbosacral plexus manifest with characteristic clinical syndromes. Lesions of the upper trunk of brachial plexus manifest with LMN weakness and sensory loss in a C5 C6 distribution. Lesions of lower trunk produce deficits in a C8 and T1 distribution.

Common causes for plexopathies are enlisted in Tables 198.12 and 198.13. Investigations include nerve conduction study and MRI.

TABLE 198.11		
Differentiating neurogenic from vascular claudication		
Clinical manifestation	Neurogenic	Vascular
Distribution of exertional pain	Thigh and buttocks	Calf
Symptoms when using bicycle	No effect	Reproduces symptoms
Symptoms when walking incline	Worse coming down	Worse climbing up
Symptoms when standing	Reproduces symptoms	No effect
Weakness after exertion	Present often	Nil
Sensory deficits after exertion	Occasionally	Nil
Diminished reflexes after exertion	Occasionally	Nil
Back hyper-extension	Reproduces symptoms	Nil
Pain relief	Stopping activity, sitting, leaning forward	Stopping activity
Time required for relief	Variable (5-15 min)	Prompt (15-20 sec)
Preventive measures	Leaning forward using a support while walking	Walking slower
Peripheral pulses	Preserved	Usually absent

TABLE 199.1

Classification of craniovertebral anomalies

- I. *Skeletal anomalies*
 - a. Basilar invagination—primary or secondary
 - b. Platybasia
 - c. Occipitalisation of atlas
 - d. Atlantoaxial dislocation—congenital or acquired.
 - e. Klippel-Feil anomaly
- II. *Neuraxial anomalies*
 - a. Arnold-Chiari malformation
 - b. Dandy-Walker syndrome, i.e. failure of the foramina of Magendie and Luschka to open, associated with cerebellar hypoplasia
 - c. Occipitocervical meningocele
 - d. Cysts in the posterior fossa
- III. *Combined neural and skeletal anomalies*

Craniovertebral Anomalies

Definition: Craniovertebral anomalies are developmental defects involving the bony and/or neural structures at the occipitocervical transition zone. These defects manifest clinically in a variable manner as craniospinal deformities and/or neurological deficits. Secondary changes such as repeated trauma, pressure effects, and vascular occlusion aggravate the neurological disability and lead to its progression. Several major and minor abnormalities have been described. Common features which should draw attention to the presence of craniovertebral anomalies are short neck (total body height/neck length ratio > 13.86), low hairline (posterior hairline below C4 spine level) and facial asymmetry. Neck movements may also be abnormal.

Classification: The more important anomalies have been classified in Table 199.1.

Basilar Invagination (Basilar impression)

In this condition, there is invagination of whole or part of the margins of the foramen magnum into the posterior cranial fossa. Although most often it is a developmental anomaly, it may also be acquired because of softening of the bones as in osteomalacia, Paget's disease of the bone, osteogenesis imperfecta, achondroplasia and gargoylism.

Clinical features: Primary basilar invagination may present at any age and may be symptomatic or asymptomatic. In symptomatic cases, occipital headache, and hyperalgesia in the distribution of the second cervical nerve roots are common features. Episodic vertigo, diplopia and drop attacks reflect circulatory disturbances in the vertebrobasilar territory. **Drop attacks** are sudden episodes of loss of tone in the limbs leading to falls. Motor weakness with pain and paresthesiae in the limbs may progress gradually or in a stepwise manner. Dysphagia, dysarthria, dysphonia, and ataxia are the other well recognized symptoms. Nystagmus, ataxia, and intention tremors occur due to cerebellar involvement. Paralysis of the lower cranial nerves occurs due to compression along their course. Among the pressure effects on the cervicomedullary region of the cord, pyramidal tract involvement is the commonest. This manifests as spastic quadriparesis or rarely hemi- or monoparesis. Weakness and wasting of the small muscles of the hands may develop in some and this has been attributed to ischemic myelopathy. Posterior column disturbances are maximum in the distal aspects of the limbs. Dissociated sensory disturbances may occur in some cases which may suggest coexisting *syringomyelia* or *secondary hydromyelia*. This

Fig. 199.1: McGregor's line—Line from posterosuperior margin of hard palate to the lowermost point of the occipital bone in the midline. Tip of odontoid does not project more than 3 mm above this line in normal individuals

association is seen in about 30% of cases. Sphincteric disturbances are uncommon but they may develop late in the disease.

Diagnosis: The clinical diagnosis is confirmed by radiological studies of the craniovertebral region and MRI.

Lateral View of Skull and Cervical Spine in the Skiagram

McGregor's line: This imaginary line joins the posterior tip of the hard palate and the most caudal point (inferior tip) on the occipital squama. Normally, the tip of the odontoid is below or up to 3 mm above this line. In basilar impression the tip of the odontoid lies at a higher level than normal (Fig. 199.1).

Fig. 199.2: Bull's—angle formed between: 1. Line drawn along the plane of the hard palate, and 2. Along the plane of the atlas. If this angle (indicated by arrows) exceeds 13°, the position of the odontoid is abnormal

Fig. 199.3: Inter-mastoid (MM) and digastric (D.D) lines. The intermastoid line (MM) joins the tips of the mastoid processes. The digastric line joins the two digastric grooves lying medial to the bases of the mastoid processes. Tip of odontoid should always be below these lines

Bull's angle: The line drawn extending the hard palate backwards and the line drawn through the plane of the atlas subtend an angle less than 13°. Increase in this angle is suggestive of basilar invagination (Fig. 199.2).

Antero-posterior view of skull and craniovertebral junction: The tip of the odontoid lies at or below a line joining the tip of both mastoid processes in normal individuals. If it lies above this line it suggests basilar impression (Fig. 199.3).

Platybasia

It is defined as flattening of the base of the skull. As a result, there is an increase in the angle subtended by lines (1) joining the nasion to the tuberculum sellae, and (2) from the tuberculum sellae to the anterior lip of the foramen magnum. (In normals this angle ranges between 115° and 140°). Values above 148° are abnormal. This angle can be measured in a true lateral X-ray of skull. This condition per se is asymptomatic. It may be associated with other craniovertebral anomalies.

Occipitalisation of Atlas

This refers to the bony fusion of whole or part of the atlas to the occipital bone. This may occur as an isolated lesion or as part of multiple anomalies. It is often accompanied by congenital atlantoaxial dislocation.

Atlantoaxial Dislocation

The transverse ligament of the atlas holds the dens (odontoid) of the axis against the anterior arch of the atlas and prevents posterior subluxation in normal subjects. The apical and the two alar ligaments fix the tip of the dens to the occiput. They limit the degrees of rotation and lateral flexion. Abnormal mobility of the atlas on the axis

may be due to congenital or acquired causes. Congenital anomalies include non-fusion of the odontoid with the axis, agenesis of part of the odontoid, or agenesis of the transverse ligament of the atlas. Acquired causes may be traumatic, or may follow vertebral tuberculosis, rheumatoid arthritis and ankylosing spondylitis. Atlantoaxial dislocation has been classified radiologically depending on the presence or absence of occipitalization of the atlas and state of the odontoid process.

Types of Atlantoaxial Dislocation (Wadia)

Type IA— Odontoid normal with occipitalisation of atlas

Type IB— Odontoid normal without occipitalisation of atlas

Type II— Odontoid detached from body of axis or agenesis of part or whole of odontoid.

Due to subluxation, the odontoid presses on the cervico-medullary region of the spinal cord in certain positions of the head. This gives rise to pressure effects, secondary vascular changes and progressive degenerative changes in the lower part of the medulla and upper part of the spinal cord. Neurological symptoms may be abrupt such as drop-attacks and quadriplegia, or slowly progressive due to degenerative changes in this region.

CLINICAL FEATURES

Symptoms may begin abruptly or gradually, but once symptoms start, they show stepwise progression. Trivial trauma may precipitate the symptoms in many patients. Suboccipital pain, painful restriction of neck movements and clicking sounds on movements of the neck are the local symptoms.

Spastic quadriplegia, paresthesia and sensory disturbances in the extremities, and wasting and fasciculations of the small muscles of hands constitute the other manifestations. Lower cranial nerve palsies and cerebellar disturbances are less common than in basilar impression. Horner's syndrome may be present.

DIAGNOSIS

Once atlantoaxial dislocation is suspected, violent movements of the head over the neck, with a view to elicit the "click", should not be attempted. Diagnosis is confirmed by radiology. Lateral view pictures are taken with the neck in full flexion and extension to visualize the atlantoaxial joint. In atlantoaxial dislocation the distance between the posterior surface of the anterior arch of atlas and the anterior surface of the dens is increased (normal distance is less than 3 mm in adults). In addition, the morphology of the odontoid can also be studied. An open mouth view in an anteroposterior projection gives a good picture of the odontoid process. MRI gives a clear picture of the whole abnormality.

Klippel-Feil Syndrome

Syn: Block vertebra

Fusion of two or several of the cervical vertebral bodies or their spines occurs in Klippel-Feil syndrome. This may be associated with congenital hemivertebrae, kyphoscoliosis, limitation of neck movements, short-neck, low hairline and facial asymmetry. *Mirror movements* of the upper limbs may be seen in this condition i.e. any movement initiated by one hand is involuntarily initiated by the other. The exact pathogenesis of this remains unclear, though anomalous decussation of the cortico-spinal tracts is a possible explanation in some cases. Various other congenital abnormalities involving the nervous, musculoskeletal, cardiopulmonary, gastrointestinal, and excretory systems may be associated with Klippel-Feil syndrome.

Arnold-Chiari Malformation

This is characterized by herniation of the cerebellar tonsils with or without the medulla and fourth ventricle into the cervical spinal canal. In some patients this is associated with cervical meningocele and syringomyelia. This is one of the causes of hydrocephalus in infancy. Other features are cerebellar and lower cranial nerve involvement which may develop in older patients. Contrast myelography done with the patient in the supine position demonstrates obstruction to the flow of dye and kinking of the cord in the cervical region due to the herniated cerebellar tonsil. CT scan studies give details about the neurological and vertebral abnormalities. MRI gives a more vivid picture of the total abnormality (Fig. 199.4).

Principles of Management of Craniovertebral Anomalies

Mild and asymptomatic cases may be left alone with advice to avoid violent neck movements, weight-bearing

Fig. 199.4: MRI showing Arnold-Chiari malformation. Note the herniation of the cerebellar tonsils through the foramen magnum.

on the head and to continue physiotherapy of the neck to strengthen the neck muscles. Conservative measures like graded cervical traction and cervical collar may be used in atlantoaxial dislocation. Surgical decompression and fixation is required only when the above measures fail. Surgical treatment has to be undertaken in symptomatic patients. The surgical procedures include methods to reduce the compressive effects on the neural structures and measures to limit abnormal mobility. Surgical treatment of Arnold-Chiari malformation is accompanied by good clinical improvement.

Cervical Spondylosis

Degenerative changes develop in the vertebral column with advancing age. The nucleus pulposus of the intervertebral discs undergoes degeneration with reduction in their fluid content, and this results in their collapse and narrowing of the intervertebral spaces. The annulus fibrosus also shows degenerative changes and they protrude backwards behind the vertebral bodies to form ridges. Osteophytes develop from the vertebral bodies and laminae resulting in compression of the nerve roots in the intervertebral foramina.

The cord may be compressed by osteophytic bars formed in the midline behind the vertebral bodies or the roots may be compressed by osteophytes growing into the intervertebral foramina. Degenerative changes are seen most markedly and symptoms are more frequent in the cervical and lumbar regions of the vertebral column. In addition to the higher mobility of the spine in these regions which accounts for greater predilection to degenerative changes, it is also likely that subjects who develop cervical spondylotic myelopathy have congenitally narrower spinal canal.

In addition to the bony changes, soft tissue changes also develop. The ligamenta flava loses its elasticity and tends to buckle forwards when the cervical spine is extended. This leads to compression of the posterior aspect of the cord. In the intervertebral foramina, fibrosis of the dural sheaths contributes to further pressure on the spinal nerves and their roots. Pressure on the spinal arteries and the vertebral arteries occurs during their course in the bony structures of cervical vertebrae. This leads to secondary vascular changes which cause vascular occlusion and ischemic damage to the cord and lower brainstem. The clinical presentation may vary widely from that of a myelopathy, radiculopathy or both. The site of cord dysfunction may be at the actual level of compression, or even distant from that, on account of vascular occlusion.

Neurological Complications: Clinical Features

Cervical radiculopathy: This condition develops when the intervertebral foramina are grossly narrowed. In the cervical region, maximal degenerative changes are seen between the fifth, sixth and seventh cervical vertebrae and these nerve roots are most frequently affected.

Cervical spondylosis is a common condition seen in day-to-day practice. Though the older age groups are more affected by osteoarthritis, many patients even in the fourth and fifth decades of life may suffer from this disease and this fact should be borne in mind in all cases presenting with painful symptoms in the neck and around the pectoral girdle. Initial symptoms consist of paresthesia and pain in the distribution of fifth to the eighth cervical dermatomes, pain being felt most frequently over the shoulder, arm, scapular region, forearm, and hands. Movements of the neck, travel, and adoption of certain postures aggravate the pain, which may be intermittent or even constant. In the majority of patients objective sensory loss to pin-prick may be demonstrable. Motor phenomena consist of weakness and wasting of the deltoid, triceps, biceps or forearm muscles. Wasting of small muscles of the hand is rare in pure cervical spondylosis. Involvement of the C5 segment gives rise to *inversion of the supinator jerks*. Fasciculations may be seen over the affected muscles. Tendon reflexes of the affected roots are diminished. The lesion may be unilateral or asymmetrically bilateral.

Compressive myelopathy: This develops as a result of compression of the spinal cord by the osteophytic bars in front and ligamentum flavum behind. Most frequent site of compression is the C5-C6 region. Ischemia further enhances the damage.

The clinical picture is one of insidious onset of spastic paraparesis with motor and sensory symptoms. Pressure on the posterior columns is more common than the spinothalamic tract and this gives rise to sensory ataxia. Bladder and bowel dysfunction is less common.

Vertebrobasilar ischemia: The vertebral artery which ascends through the foramina in the transverse processes of the cervical vertebrae and passes over the atlas to enter the foramen magnum is kinked, compressed and stretched, when the vertebral column loses height and spondylotic changes occur. In addition, atherosclerotic changes develop early. These changes result in vertebrobasilar ischemia.

Diagnosis: Cervical spondylosis has to be suspected in all cases presenting with cervical cord or root symptoms in persons above the age of 40 years. Differential diagnosis includes other causes of cord compression, syphilitic pachymeningitis, arachnoiditis, syringomyelia,

Fig. 199.5: X-ray cervical spine / cervical spondylosis

and motor neuron disease. In some cases of cervical spondylosis, flexion or extension of the cervical spine causes “electric shock-like sensation” over the segments affected. This is called **Lhermitte’s sign**. This may occur in other causes of cervical cord compression as well.

The clinical diagnosis should be confirmed by radiological studies of the spine. X-ray taken in the lateral view with the neck in straight, flexed, and extended positions and oblique views reveal the abnormalities well. Radiological changes include narrowing and irregularity of the intervertebral spaces, osteophytes, and encroachment of the intervertebral foramina. In young subjects bony outgrowths may not be evident, but alteration in the alignment of cervical vertebrae, especially loss of the cervical curvature caused by spasm of neck muscles should be taken as a suggestive sign (Fig. 199.5). Myelography reveals the narrowing of the spinal canal and compression of the cord. A-P diameter of the spinal cord in the cervical region is 9-10 mm. If the spinal canal is less than 10 mm in the lateral view X-ray cord compression is likely. MRI clearly brings out the total picture of vertebral changes and compression of the neural structures. Somatosensory evoked potentials help to evaluate physiological and anatomical malfunction of the posterior column of spinal cord.

It has to be borne in mind that radiological changes in the cervical spine are seen in a high proportion of elderly subjects without neurological damage and the mere presence of such changes is not adequate to establish the diagnosis of cord compression as due to vertebral disease. Cervical spondylosis may coexist with other disorders involving the spinal cord such as motor neuron disease, tumours and syringomyelia.

Treatment: In the early stages of spondylotic radiculopathy proper positioning of the neck, physiotherapy and use of a cervical collar to restrict neck movements help to relieve root pains. Exercises designed to strengthen the shoulder girdle muscles, especially elevators of the scapula help to relieve traction on the nerve roots and prevent recurrence of symptoms. Persons who have had symptoms should be advised to wear cervical collar during long journeys, so as to prevent recurrence of the symptoms. Graded cervical traction may help to relieve pressure on the nerve roots. Nonsteroidal anti-inflammatory drugs are of some benefit. If definite bony ridges are demonstrable causing root or cord compression surgery is indicated to relieve pressure and to prevent further neurological deterioration. Presence of motor phenomena such as paresis, or muscle wasting is an indication for early surgery. Before surgery all cases should be fully investigated to exclude other causes of myelopathy which may also present with similar clinical picture.

Treatment has to be based on individual considerations. There is no general agreement on any standard therapy.

Lumbar Disc Lesions

The lumbar intervertebral discs are particularly vulnerable to injury and degenerative damage, irrespective of age. Males engaged in heavy manual work and weight-lifting are particularly affected. Sudden jerky movements, unaccustomed lifting of heavy weights and heavy falls on the gluteal region or back may lead to sudden rupture of the annulus fibrosus even in otherwise normal persons. The nucleus pulposus herniates through ruptured annulus fibrosus to impinge upon the nerve roots. The L4-5 or L5-SI discs are more often affected. The onset is generally abrupt with severe radicular pain in the lumbosacral dermatomes in the sciatic distribution (*sciatica*). The pain is aggravated by flexion of the spine, coughing, sneezing or jolting movements. Motor weakness of spinal root distribution will occur if the anterior roots are impinged upon.

Flexion of the spine is more restricted than extension. Objective neurological findings of root compression may be evident. In acute cases the normal lumbar lordosis is obliterated. Local tenderness may be elicited over the affected region and the paraspinal muscles may exhibit spasm. Straight *leg raising test* is positive—*Lasegue’s sign*. This sign is elicited by passively lifting up the lower limb held straight by the examiner when the patient is in supine position. In normal subjects the limb can be brought to near-vertical position without discomfort. In lumbosacral root irritation due to disc prolapse this movement is restricted by severe pain.

Diagnosis: Low back pain, especially aggravated by coughing or sneezing, should suggest the possibility of lumbar disc prolapse. X-ray spine may reveal narrowing of the inter-vertebral spaces. CT scan, MRI and myelography bring out the actual pathology distinctly.

Course and prognosis: This is variable. In mild cases the condition may improve with rest and conservative measures. Progressive neurological disability may develop in some cases. In many, sudden onset of sciatica may be very disabling.

Management: Conservative measures include uninterrupted rest in bed with slight extension of the back on a hard non-sagging bed for periods of two to three weeks, traction on the legs, exercises to strengthen the paraspinal muscles and to prevent wasting of the affected muscles and use of spinal braces to limit spinal movement. Analgesics and muscle relaxants like diazepam help in the acute stage or intractable pain.

Presence of progressive neurological damage or intractable pain is an indication for surgical treatment which consists of laminectomy and removal of the prolapsed disc.

Modern surgical techniques employ keyhole procedures to remove the damaged disc without conventional laminectomy.

Lumbar Canal Stenosis

The term *spinal canal stenosis* covers any type of narrowing of the spinal canal, but it usually affects the lumbar spinal canal. Most often it is congenital, but the patient becomes symptomatic later in life due to the development of other pathological changes that result in the compression of neurovascular tissues. The compression may be due to any of the following causes:

1. Prolapse of the intervertebral disc,
2. Hypertrophic changes of the ligaments within the narrowed spinal canal,
3. Angulation of vertebrae due to loss of disc height,
4. Spondylolisthesis,

5. Paget's disease of bone,
6. Neural arch degeneration (spondylolysis),
7. Bony and ligamentous compression at the exit foramina.

In addition to mechanical compression, the arterial supply of the cord may also be compressed. Multiple factors may operate in the same case. Males are generally affected more than females, except in case of spondylolisthesis. L5 and S1 roots, which run a long oblique course within the spinal canal before changing direction to emerge through the exit foramina, are most affected.

Clinical features: Symptoms fall into three categories. These are:

1. lumbago (backache) in almost all cases,
2. lumbosacral radicular symptoms in a third, and
3. neurogenic claudication in another third of cases. Cases with neurogenic claudication get pain when bending backwards or on walking. Such patients assume a stooping posture to avoid pain. Both postural and exertional claudication result in transient root pain, paresthesia, weakness or numbness. Dermatomal sensory loss, muscle weakness and other motor deficits may be present. All these symptoms temporarily subside following rest. Straight leg raising test is positive in a third of the cases, especially if tested after exertion.

Diagnosis: Clinical diagnosis should be supported by radiography. The narrowed lumbar canal may be demonstrable in lateral and A-P view skiagrams. MRI demonstrates the narrowing precisely. Electromyographic demonstration of segmental muscle denervation in the legs gives diagnostic localization and this procedure is done routinely before surgical decompression.

Treatment is preferably surgical decompression by a partial undercutting facetectomy with decompression of the nerve root canal by removal of the hypertrophied bony fragments, ligamentum flavum and degenerated disc. The results are excellent in majority of cases.

Diseases of the Peripheral Nervous System

Anand Kumar, P.K. Mohan

Chapter Summary

General Considerations 1321
 Guillain-Barré Syndrome 1323
 Chronic Inflammatory Demyelinating
 Polyradiculoneuropathy 1324
 Hereditary Motor-sensory Neuropathies 1325
 Neuropathy in Systemic Diseases 1326
 Diabetic Neuropathy 1326
 Entrapment Neuropathies 1326
 Neuralgic Amyotrophy 1327
 Neurofibromatosis 1327
 Critical-illness Neuropathy 1328

General Considerations

Functionally, the peripheral nervous system consists of the anterior horn cells, anterior nerve roots, posterior root ganglion cells, posterior roots, the part of the nerve fascicles within the spinal cord and the peripheral nerves up to the myoneural junctions. But for practical purposes the extent of the peripheral nervous system (PNS) is limited to the part of the nervous system outside the pia-arachnoid. The cranio-sacral and thoracolumbar outflows contribute the parasympathetic and sympathetic fibers to the peripheral nerves.

The peripheral nerves consist of axons invested by the Schwann cells. There are two types of fibers—the myelinated and the unmyelinated. The myelinated nerve fiber has a single axon surrounded by Schwann cells which spiral round the axon and provide the myelin sheath. There are gaps in the myelin sheath where the axon is exposed. These are called the *nodes of Ranvier*. The myelinated nerve fibers conduct impulses at a faster rate than the unmyelinated nerve fibers. They are also prone to acquire diseases which affect myelin. These include: (1) the demyelinating diseases where there is destruction of myelin sheath, and (2) the dysmyelinating diseases where there is deposition of abnormal myelin, e.g. leukodystrophies.

In the case of unmyelinated nerve fibers the Schwann cells do not provide the myelin sheath and several axons are accommodated by the same Schwann cell. According to the fiber diameter, the nerve fibers may be grouped into *small diameter fibers* and *large diameter fibers*. Large diameter fibers carry sensations like touch, vibration and joint sense. Pain and temperature are carried by the small diameter fibers. Several diseases affect the small or large diameter fibers selectively, e.g. leprosy and amyloidosis affect the small diameter fibers. The response of the nerve fiber to different forms of pathological injury is limited. The neural reaction may take the form of axonal degeneration where there is destruction of axons, segmental demyelination where there is patchy loss of myelin, or both. In polyneuropathies the disease process affects the nerve cell body, which loses its ability to maintain the integrity of the axon. It undergoes degeneration, starting from the most distal part and spreading proximally. The lower limbs are affected earlier than the upper limbs, since the axons supplying the lower limbs are longer.

Apart from the myelin and axons, the peripheral nerve has investing layers of connective tissue which form the endo-, epi-, and perineurium. The peripheral nerves have a rich anastomosis of blood vessels around them. When disease processes affect these elements, they may lead to interstitial neuropathy and ischemic neuropathy respectively. Moreover, since the anterior and posterior roots are bathed in the cerebrospinal fluid (CSF), abnormalities of the CSF may result in dysfunction of the PNS as well.

A nerve can be damaged by injury to the myelin, the axon, the cell body or the vasa nervorum. There are three basic mechanisms underlying nerve injuries.

1. Degeneration in which both the axon and myelin are affected, e.g: transection of a nerve
2. Segmental demyelination in which only the myelin is affected leaving the axon relatively intact, and
3. Axon degeneration in which damage to the cell body leads to death of the distal part of the neuron.

In segmental demyelination, because the axon is intact, there is no denervation and hence there is no muscle

atrophy whereas in axonal degeneration there is muscle atrophy. Recovery from nerve damage is slow and incomplete in axonal neuropathies.

CLINICAL SYMPTOMATOLOGY

Clinical features are due to affection of the sensory, motor autonomic fibers alone or in combination.

Sensory Phenomena

These may be positive, i.e. irritative in nature; or negative, i.e. due to loss of function.

Hyperpathia: These are excessively painful or unpleasant sensations from noxious stimulation of skin.

Causalgia: This is a severe, dysaesthetic pain, associated with autonomic disturbances probably due to erratic transmission (cross talk) in damaged nerves.

Neuralgia: This refers to paroxysmal pain in the distribution of a nerve e.g. trigeminal neuralgia, sciatica.

Positive phenomena

1. **Spontaneous pain:** This occurs due to irritation of the small fibers which carry pain or due to loss of large fibers which usually inhibit the pain sensation carried by the small fibers.
2. **Paresthesia** in the form of pins and needles.
3. **Contact dysesthesia**—where contact with the affected part elicits a disturbing sensation.
4. **Hyperalgesia:** Increased appreciation of pain resulting from decrease in the sensory threshold for pain.
5. **Burning feet:** This is a frequent symptom but its mechanism is not clear. It may occur in neuropathies, accompanying alcoholism, diabetes and beriberi.
6. **Lancinating pains:** These are sharp and paroxysmal pains occurring usually in the transverse plane in the lower limbs in patients suffering from tabes dorsalis and diabetes.

Negative phenomena

Numbness is an important negative symptom which indicates that at least 50% of the nerve fibers are destroyed. Patients may have a feeling as though they are walking on cotton wool. They may have unsteadiness of gait, particularly in the dark due to loss of joint and position sense. Nonhealing painless ulcers and neuropathic joints develop due to loss of pain and temperature sensation and loss of protective reflexes. When the protective influence of pain is lost, the joints undergo minor and major trauma due to overuse and injuries. Degenerative and destructive changes of joint structures develop, leading to disorganization of the joint (*Charcot's joints*). Such joints may occur in severe peripheral neuropathy and also in tabes dorsalis and syringomyelia.

The pattern of sensory loss differs depending upon the site of affection. In posterior radiculopathies, the

sensory loss is segmental. When a single peripheral nerve is affected the sensory and motor abnormalities occur in the distribution of that nerve (**mononeuritis**). Affection of several nerve trunks in an asymmetrical fashion is termed **mononeuritis multiplex**, e.g., leprosy. In classic polyneuropathies, there is symmetrical distal sensory loss in the extremities, described as *glove and stocking* anesthesia. All the nerve fibers in the distal part of the limbs are affected irrespective of the peripheral nerve to which they belong.

Motor Phenomena

These also may be negative or positive. Weakness is a negative phenomenon. Fasciculations, cramps, spasms and neuromyotonia are positive symptoms. Compared to diseases affecting the anterior horn cells, fasciculations are much less marked in peripheral nerve damage.

The tendon reflexes are lost early in peripheral neuropathies which affect the large fibers. The reflexes may be spared in neuropathies which affect the small fibers alone, e.g. leprosy.

Autonomic Phenomena

This manifests as loss of sweating, postural hypotension, and trophic disturbances. Pupillary changes, bladder and bowel dysfunction and impotence point to central lesions, these do not occur in pure peripheral neuropathy.

CLINICAL APPROACH TO A PATIENT WITH PERIPHERAL NERVE DISEASE

The clinical features of peripheral nerve disease depend upon a number of factors. These factors are important not only in the production of various clinical features in different neuropathies but also in the clinical diagnosis. The clinical features which are most helpful in the clinical diagnosis are given below.

1. Onset and rate of progression:

Acute: Less than 1 week, e.g: Guillain-Barré syndrome, porphyria, toxins.

Subacute: Less than 1 month, e.g: Acquired demyelinating polyneuropathies, toxins, metastatic lesions.

Chronic: More than 1 month, e.g: Toxic neuropathies, metabolic neuropathies, chronic inflammatory demyelinating polyneuropathies, hereditary neuropathies, diabetic neuropathy, paraproteinemic neuropathy. They may continue to exist over several years.

Relapsing: Multiple episodes occur, e.g: relapsing forms of neuropathy, repeated exposure to toxins.

2. Clinical pattern:

Mononeuropathy: Involvement of one nerve, e.g: nerve entrapments and nerve injuries.

Mononeuritis multiplex: Asymmetrical simultaneous or sequential affection of more than one nerve e.g: systemic vasculitis, cryoglobulinemia.

Polyneuropathy: Symmetric involvement of multiple nerves, e.g. diabetic polyneuropathy.

Radiculopathy: Involvement of isolated spinal nerve root.

Polyradiculopathy: Involvement of several isolated spinal nerve roots.

3. Clinical deficit

Sensorimotor: Many of the common neuropathies show involvement of sensory and motor functions.

Motor predominant: Lead, porphyria, Guillain-Barré syndrome, diphtheritic neuropathy, dapsone induced neuropathy.

Autonomic predominant: Diabetes, demyelinating neuropathies.

4. Initial distribution in the limbs

Distal: Common pattern of most of the neuropathies.

Proximal: Rare.

5. Type of sensory impairment

- a. Selective loss of pain and temperature—small fiber neuropathy.
- b. Impaired proprioceptron: Large fiber neuropathy.
- c. All sensory modalities: Involvement of all fibers.

Peripheral nerves may be palpably hypertrophic in conditions such as leprosy, amyloidosis, acromegaly, neurofibromatosis, and Refsum’s disease.

Table 200.1 lists the common causes.

TABLE 200.1	
Causes of peripheral neuropathy	
Hereditary	Hereditary sensory-motor neuropathies
Metabolic	Diabetes mellitus, hepatic failure, renal failure porphyria
Endocrine	Hypothyroidism
Toxic	Alcohol, organophosphates, arsenic, lead, gold, thallium, lithium
Drugs	Vincristine, INH
Immune mediated	Guillain-Barré syndrome
Chronic idiopathic demyelinating polyneuropathy (CIDP)	
Infections	Leprosy, diphtheria
Vasculitis	Polyarteritis nodosa, other forms of vasculitis in sarcoidosis, Wegener’s granulomatosis, Behcet’s syndrome
Nutritional	Vitamin deficiencies, e.g. Vit B ₁₂ , B ₁ , B ₆
Miscellaneous	Lymphomas, paraneoplastic syndromes, critical illness neuropathy

Guillain-Barré Syndrome (GBS)

Syn: Acute idiopathic polyneuropathy, Acute inflammatory polyneuropathy, postinfective polyneuropathy

Guillain-Barré syndrome is a symmetrical, predominantly motor polyneuropathy or polyradiculopathy, frequently involving facial and bulbar muscles, with areflexia. The weakness develops abruptly and reaches its peak within four weeks of the onset and the illness follows a monophasic course with more or less complete recovery in majority of patients. There is no specific cause for this illness, but commonly it is preceded by a viral infection of the respiratory or less commonly, the gastrointestinal tract. Particular temporal association with herpes viruses, cytomegalovirus, Epstein-Barr virus, mycoplasma and *Campylobacter jejuni* infections are present in some cases (14-18%). Vaccinations for rabies, typhoid and tetanus may be followed by this syndrome. All age groups and both sexes are affected. Male to female ratio is 1.25. Most of the cases are sporadic but small epidemics have been reported. Infection leads to activation of antigen specific T and B cells. Antibody reaction and cell mediated immune processes lead to toxic damage to Schwann cells resulting in demyelination and axonal degeneration. Anterior nerve roots are most commonly affected.

Pathogenesis: In cases where there is preceding infection, immunological reactions involving T-cells directed against peptides from myelin proteins, antibodies and complement take place and lead to the neural lesion. Experimental studies have shown that components of the bacterial wall of *C. jejuni* contains ganglioside-like structures which trigger neuropathy, resembling acute motor axonal neuropathy in rabbits. The lesions in GBS include at least four subtypes of acute peripheral neuropathy.

These include:

- 1. Acute inflammatory demyelinating polyradiculoneuropathy (AIDP).
- 2. Acute motor axonal neuropathy (AMAN).
- 3. Acute motor and sensory axonal neuropathy (AMSAN)
- 4. Miller Fischer syndrome

The distribution of ganglioside may explain the distribution of lesions and symptoms in GBS.

Clinical Features

Sudden onset of paresthesia and pain in the back and the extremities without fever is the most common initial presentation. These sensory symptoms are soon followed by symmetrical, predominantly proximal muscle weakness in the lower limbs which rapidly ascends to involve the upper limbs and some times facial and bulbar muscles as well. Rarely the weakness is distal or appears first in upper limbs. The paralysis may remain mild and stable or it may

rapidly progress to total quadriplegia and respiratory paralysis within a few days. The cranial nerves that are commonly involved are facial (40%), bulbar (30%) and ocular (10%). The tendon reflexes are usually absent or reduced even in the early stage of the illness. There is associated hypotonia. Sensory impairment is mild with impairment of all modalities of sensation, especially in a glove and stocking distribution. Sphincters are involved only rarely. Dysautonomic features may be present in the form of brady- or tachycardia and rapid fluctuations in blood pressure.

The disability may progress steadily to reach its peak within three weeks, by which time 60% of patients are unable to walk. Respiratory function is impaired in about 50% of patients of which about 15-20% will require assisted ventilation. Almost 80% make good recovery. Some (10-20%) may be left with residual paralysis.

Diagnosis

Onset of rapid or subacute symmetrical polyradiculoneuropathy should suggest the possibility of Guillain-Barré syndrome. Differential diagnosis at this stage includes toxic polyneuritis, poliomyelitis, transverse myelitis, demyelinating diseases, acute myopathies associated with polymyositis, hypokalemic paralysis, botulism and myasthenia. Neurotoxic snake bite particularly *krait* may give rise to diagnostic problem, especially if the bite occurs during sleep. Pure sensory syndrome, a definite sensory level over the trunk, severe and persistent sphincteric disturbances and more than 50 cells/cmm in the CSF make the diagnosis of GB syndrome unlikely.

Investigations: Blood counts and blood chemistry are non-contributory. Cerebrospinal fluid characteristically shows albuminocytological dissociation if examined about a week after the onset of the disease. This abnormality may persist for a few weeks. The term *albuminocytological dissociation* refers to the rise in proteins without a corresponding rise in cell count. EMG and nerve conduction studies help to distinguish the condition from myopathies and poliomyelitis.

Prognosis: In about 10% of cases with rapid onset and progress, respiratory failure may threaten life. Mortality is around 5%. Vast majority of patients start improving after a week or so of onset and recovery is complete within 6 weeks and in about 25% of cases resolution is slow. In a smaller number, severe paralysis may persist and the patient may become crippled for life. Presence of axonal degeneration and occurrence of the disease at the extremes of age are associated with bad prognosis. About 3% of cases will have a relapse or second episode.

Management

Early recognition and treatment of respiratory failure is of utmost importance. As respiratory paralysis may occur very rapidly, close observation with monitoring of vital capacity is essential. Assisted ventilation through endotracheal intubation or tracheostomy should be given when respiratory paralysis sets in. Although steroids are still used by some physicians, neither oral prednisolone nor intravenous methyl prednisolone has proved to be of definite benefit in clinical trials.

Plasmapheresis is indicated in all patients who have severe disability such as inability to walk. Plasma exchange at the rate of 50 mL/kg body weight during each session, up to a total of five sessions over 7-14 days is sufficient in the majority.

Intravenous immunoglobulin (I.V.I.G.) in a dose 0.4 g/kg body weight daily for 5 days has emerged as an effective alternative to plasmapheresis, with good functional recovery.

Since patients may be paralysed for prolonged periods, careful nursing care with regular turning in bed, attention to pressure areas, proper care of the eyes when there is facial palsy, care of the oral cavity, and attention to bowel and bladder are of great importance. Lung and urinary tract infections should be treated promptly. As deep vein thrombosis and pulmonary emboli are recognised complications, prophylaxis with heparin in a dose of 5000 units twice daily as sub-cutaneous injections is advisable.

Autonomic disturbances are complications demanding emergency intervention. Continuous ECG and BP monitoring in an intensive care unit is essential in such cases. On recovery, physiotherapy and rehabilitation should be started.

Variants of GB Syndrome

- i. Miller-Fischer syndrome: This is characterised by the triad of acute ophthalmoplegia, ataxia and areflexia without significant weakness or sensory symptoms or signs. This presentation is more frequently associated with *Campylobacter jejuni* infection. This condition has a benign course and complete recovery is the rule.
- ii. Acute sensory ataxia with areflexia.
- iii. Acute autonomic neuropathy.
- iv. Acute polyneuritis cranialis.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy [CIDP]

The presentation of CIDP is with signs of motor and sensory polyneuropathy that evolves subacutely over more than eight weeks or chronically over many months. There is weakness in proximal and distal muscles and

involvement is usually symmetrical, accompanied by sensory deficits and paresthesias. Pain is a rare symptom. CIDP can begin at any age and the course is either progressive, step wise progressive or relapsing. Patients can become considerably disabled. Spontaneous remissions are rare and CIDP can occur in the presymptomatic phase of HIV infection.

Work up for CIDP includes: detailed electrophysiological examination of all four limbs, lumbar puncture to look for CSF protein elevation and pleocytosis (in HIV related CIDP), serum and urine protein electrophoresis to rule out monoclonal gammopathy and skeletal survey to exclude myeloma. A nerve biopsy and teased fiber analysis will be confirmative. If required, a genomic DNA testing can be done for exclusion of hereditary demyelinating neuropathy.

There are two main forms of therapy for CIDP. As there is clinical and laboratory support for autoimmune etiology, immunosuppressive drugs and plasma exchange form the mainstay of treatment. High dose steroid is required in initial dose of 60-80 mg per day for 6 to 8 weeks with subsequent tapering by 10 mg per month and then switching to alternate day regime. Plasma exchange is equally efficacious for selected cases of CIDP. More recently, high dose intravenous immunoglobulins [IVIG] have been introduced for immunomodulation in CIDP. The dose is 0.4 gm per Kg body weight to be given for five consecutive days. IVIG and plasma exchange are safe but expensive. Prednisolone although cheap, takes time to act and long-term complications are to be anticipated. Current practice is to recommend IVIG or plasma exchange as primary treatment.

Vasculitic Neuropathy

Many forms of vasculitis cause widespread destruction of epineural arterioles with resultant ischemic damage to peripheral nerves. Peripheral neuropathy can be an early manifestation of vasculitis and diagnosis can be established by nerve biopsy. The three major categories of diseases that cause vasculitic neuropathy are:

1. Systemic lupus erythematosus and rheumatoid arthritis.
2. Systemic necrotizing vasculitis, e.g. Polyarteritis nodosa.
3. Non-systemic vasculitic neuropathy.

Clinically the most common presentation is as mononeuritis multiplex caused by segmental nerve trunk infarction. Radiculopathies, distal sensorimotor neuropathy and cutaneous neuropathy are other manifestations of vasculitic neuropathy. Cranial neuropathies are common in Wegener's granulomatosis and sarcoidosis. Painful paresthesias can be severe and disturbing and difficult to treat. Specific treatment is directed at the vasculitis itself.

Hereditary Motor Sensory Neuropathies

Hereditary motor sensory neuropathies (HMSN) are complex clinically and genetically heterogeneous group of disorders that cause slowly progressive degeneration of peripheral nerves. Recent advances in the understanding of the molecular basis of hereditary neuropathies have resulted in a new genetic classification of HMSN. This is important for genetic counselling and planning future research for effective therapy. Type I and II are known as **Charcot-Marie-Tooth disease** 1 and 2 [CMT1 and CMT2]. CMT1 is the more common demyelinating form with loss of muscle stretch reflexes, hypertrophy of nerves and a markedly slow conduction velocity in the nerves. Genetic studies have revealed subtypes under each group depending on the chromosome affected. Thus there are four subtypes of type 1 CMT. CMT 2 is the less common neuronal form where there is no nerve hypertrophy or delayed conduction. Muscle stretch reflexes are usually preserved. There are six subtypes of autosomal dominant type 2 CMT.

The disease is transmitted as an autosomal dominant or recessive trait and sex linked forms. The two forms are distinguishable based on electrophysiological studies. These are;

Type 1: Nerve conduction velocity is slowed and tendon reflexes are absent. This type is probably a defect of the Schwann cells. It follows an autosomal dominant inheritance pattern.

Type 2: Nerve conduction velocity is normal and tendon reflexes are also normal. The defect is in the axon.

Neuropathy of Dejerine and Sottas is an autosomal recessive demyelinating sensory neuropathy in which the onset is much earlier and the disease progresses to make the patient bed ridden by the age of 20-30 years. The nerves are thickened. Sensory impairment is more marked. It may be associated with other neurological abnormalities such as optic atrophy, deafness, retinitis pigmentosa and spastic paralysis.

Clinical Features

The symptoms of CMT1 appear in the first decade or early second decade. Toe walking, gait abnormalities, loss of balance and foot deformities are common presentations. Weakness of peroneal and anterior tibial muscles results in foot drop with high stepping gait. Pes cavus deformity and hammer toes are relatively late manifestations. Atrophy of legs give the classical *inverted champagne bottle* appearance. Vibratory sense is the usual sensory modality affected. Diagnosis is made based on the family pedigree, neurological examination, electrophysiological studies and DNA analysis. As of now there is no effective

treatment. Steroid responsive forms of CMT1 and hereditary neuropathy with liability to pressure palsy have been described.

Neuropathy in Systemic Diseases

DIABETIC NEUROPATHY

This manifests as four main types.

- 1. Distal symmetrical neuropathy—sensory, motor, autonomic or mixed—most common.
- 2. Proximal neuropathy—(a) symmetrical proximal sensori-motor neuropathy, and (b) asymmetrical proximal neuropathy.
- 3. Mononeuritis and mononeuritis multiplex: (a) cranial nerves, and (b) peripheral limb and trunk nerves.
- 4. Entrapment neuropathies.

Several of these neuropathic manifestations and autonomic neuropathy may co-exist in the same patient. The major pathological finding is axonal degeneration. Proper control of diabetes with all-time euglycemia helps to reduce the frequency and severity of neuropathies.

See also section: 10 chapter 90.

Other systemic diseases like hypothyroidism, chronic liver failure, porphyria, uremia, connective tissue disorders, malignancy and paraproteinemias may be associated with peripheral nerve involvement (Table 200.2).

Several disorders of the peripheral nervous system termed ‘**paraproteinemic neuropathies**’ are closely

connected with the presence of excessive amounts of abnormal immunoglobulins in blood which can be detected by immunoelectrophoresis or the more sensitive immunofixation test. The neuropathies may precede or occur concurrently along with benign monoclonal gammopathies or conditions like multiple myeloma, Waldenstrom’s macroglobulinemia, osteosclerotic myeloma, primary amyloidosis, Castleman’s disease, other lymphatic diseases and chronic leukemias. The polyneuropathy of cryoglobulinemia is due to vasculitis in numerous nerve fascicles. The final picture is the sum total of incomplete multiple mononeuropathies. Sensorimotor neuropathy also develops. Treatment of the primary condition halts the progress of the neuropathy also.

Toxic and Drug Induced Neuropathies

Exposure to several toxins like alcohol, lead, arsenic, triortho-cresyl phosphate and organophosphorus compounds and drugs like dilantin sodium, INH, nitrofurantoin, methotrexate and vincristine can lead to polyneuropathies.

Entrapment Neuropathies

These result from compression of the nerve trunks by normal anatomical structures at certain sites. The common entrapment neuropathies are **carpal tunnel syndrome** caused by compression of median nerve under the flexor retinaculum at the wrist and **meralgia paresthetica** caused

TABLE 200.2

Salient features of the common types of peripheral neuropathy

Disease	Type of onset	Distribution	Pattern	Fiber affected	Pathology
Diabetes melitus	Acute or chronic	Proximal or distal	Polyneuropathy or mononeuropathy	Small and large	AD and SD
Porphyria	Acute	Proximal/diffuse	Polyneuropathy	-do-	AD
Vitamin B ₁₂ deficiency	Chronic	Distal	Polyneuropathy	-do-	AD
Lead poisoning	Subacute	Distal	Mononeuropathy	-do-	AD
Arsenic poisoning	Subacute	Distal	Polyneuropathy	-do-	AD
Leprosy	Subacute or chronic	Mononeuritic or distal symmetrical	Mono- or poly-neuropathy	Small	AD and SD
Diphtheria	Acute	Distal, proximal or diffuse	Poly- or mononeuropathy	Small and large	SD
Connective tissue disorders and vasculitis	Chronic or acute	Distal	Poly- or mono-neuropathy	-do-	SD
Guillain-Barré syndrome	Acute	Proximal or diffuse	Polyneuropathy	-do-	SD
Paraneoplastic	Chronic	Distal	Poly- or mononeuropathy	-do-	AD
Hereditary sensori-motor neuropathy	Chronic	Distal	Polyneuropathy	-do-	AD

Note: - AD – Axonal degeneration; SD – Segmental demyelination.

by compression of lateral cutaneous nerve of thigh between the anterior superior iliac spine and inguinal ligament.

Carpal tunnel syndrome (CTS) presents as pain and paresthesia in the lateral three fingers, worsened at night. The pain may spread proximally. Shaking the hand in the air gives relief (flick test). Sensations over the median nerve distribution are dulled. This may be accompanied by weakness of the thenar muscles. In about half the cases the condition is primary. In the others some underlying cause is evident.

Carpal tunnel syndrome may occur in acromegaly, myxedema, multiple myeloma, rheumatoid arthritis, and in pregnancy.

Flexion of the wrist for 60 seconds causes pain—**Phalen's sign**. **Tinel's sign** is the occurrence of sharp shooting pain along the distribution of the median nerve when the flexor retinaculum is tapped gently.

Electrophysiological studies facilitate the diagnosis but the results may be inconclusive.

Treatment: When the condition is curable with medical treatment as in pregnancy or myxedema, splinting of the hand, use of diuretics and local instillation of hydrocortisone acetate may give temporary relief. Decompression of the nerve by surgical splitting of the flexor retinaculum gives permanent relief.

Meralgia paresthetica presents as pain and paresthesia in the lateral aspect of the thigh. There are no motor signs in this disorder. This responds to surgical decompression. Other nerves likely to be compressed in other sites are the radial, suprascapular, femoral, obturator, posterior tibial, plantar and intercostal nerves.

Neuralgic Amyotrophy

Syn: *Brachial neuralgia*

This disorder is thought to be caused by demyelination occurring secondary to several causes such as infection, immunization and surgery. The patients complain of sudden severe pain in the shoulder region. This is followed by weakness and wasting of muscles around the shoulder joint. Most commonly muscles supplied by the axillary nerve (circumflex nerve) or long thoracic nerve (nerve to serratus anterior) are affected. Objective sensory signs are minimal. Recovery occurs within six months to one year.

NEUROFIBROMATOSIS

This entity consists of two distinct subgroups designated as **von Recklinghausen's neurofibromatosis** (VRN or Type 1), and **bilateral acoustic neurofibromatosis** (BANF or Type 2). The former used to be called peripheral neuro-

Fig. 200.1: Café au lait lesions in VRN type-I

fibromatosis and the latter central. Both entities are genetically and clinically distinct.

Peripheral Neurofibromatosis

Syn: von Recklinghausen's (VRN Type I)

Peripheral neurofibromatosis has a prevalence of one in 3000 adults. It is inherited as an autosomal dominant condition with 100% penetrance. The abnormal gene is located on chromosome 17. About 50% of cases arise as new mutations without family history. Clinical picture is varied. This includes dermatological features such as *café au lait patches* which grow with age, *Lisch nodules* (brown hamartomas seen in iris) and *dermal neurofibromas* which appear during puberty and continue to grow throughout life. *Plexiform neurofibromas* may produce local hypertrophy and physical disfigurement. Rare associations include congenital defects in the posterior orbital wall, proptosis due to orbital neurofibroma, pseudo-arthroses of tibia and ulna and vertebral lesions giving rise to kyphoscoliosis. Neurofibromas in the spinal roots or in the intracranial structures, gliomas and meningiomas may occur but the risk is much less than in the central type (Fig. 200.1).

Acoustic neuromas are extremely rare, but optic nerve or chiasmal gliomas may occur. Plexiform neurofibromas may develop malignancy, but not dermal neurofibromas. Two rare associations include pheochromocytoma and renal artery stenosis.

Central Neurofibromatosis

Syn: Type II or Bilateral acoustic neurofibromatosis (BANF)

This is much rarer than Type 1 (1 in 100,000), transmitted by a different autosomal dominant gene located on chromosome 22 with a 95% penetrance so that 50% of offsprings develop the disease. There is a very high prevalence of bilateral acoustic neuromas (Schwannomas). The

TABLE 200.3

Diagnostic criteria in neurofibromatosis

Type I	Type II
Two or more of the following must be present	At least one criterion must be present for diagnosis
1. Cafe-au-lait macules with the greatest diameter 5 mm in prepubertal and 15 mm in postpubertal patients, atleast six in number.	1. Bilateral eighth nerve tumours seen by imaging techniques.
2. Two or more neuro-fibromas of any type or one plexiform neuroma	2. Parent, sibling or child with neurofibromatosis-2 showing neurological tumours or juvenile posterior lenticular opacity.
3. Presence of optic glioma	
4. Two or more Lisch nodules	
5. Bony lesion in sphenoid or long bones	
6. Parent, sibling or child with neurofibromatosis	

early symptoms manifest in the second or third decades with eighth nerve dysfunction. Rarely the condition may be unilateral.

Other CNS tumours such as Schwannomas in other sites, gliomas and meningiomas may occur simultaneously. Management consists of surgical removal of the tumours and genetic counselling. Patients with BANF and their close relatives should avoid underwater swimming.

Diagnostic criteria are given in Table 200.3.

Critical-illness Neuropathy

It is a type of sensory-motor neuropathy that develops in about 50% of patients who stay in critical care units for more than 2 weeks, for a variety of critical illnesses. They also have past or current infections and multiple organ failure. Difficulty to wean the patient off the ventilator raises the suspicion of this type of neuropathy. Prognosis is good in those who survive the original illness.

General Considerations

Autonomic Nervous System (ANS)

Definition: This is the part of the nervous system which functions autonomically with very little role for voluntary control. Autonomic neuropathies are common. They may occur more often along with other forms of neuropathy

such as diabetic neuropathy and systemic amyloidosis or autonomic neuropathy may be the predominant or only manifestation as in acute pan-dysautonomia.

Anatomically, the ANS can be divided into cortical, peripheral and enteric components.

Centers in the brain include orbito-frontal cortex, cingulum, amygdala, insula, claustrum which converges on the hypothalamus, bulbar reticular formation, and nucleus tractus solitarius.

The highest control of the autonomic nervous system (ANS) is from the hypothalamus and this is influenced by the orbitofrontal cortex and limbic system. The autonomic nervous system innervates smooth muscles of viscera and secretory glands. It consists of the sympathetic and parasympathetic nerves.

The afferents to the ANS include:

- 1. All the sensory pathways,
- 2. Carotid and aortic sinus baroreceptors via the IX and X cranial nerves and
- 3. Cardiopulmonary baroreceptors, skin, muscles, and the viscera.

Sympathetic system: The peripheral sympathetic system is formed by fibers leaving the spinal cord from C8 to L3 segments. Fibers emerging from the C8 and T1 segments pass up through the inferior and middle cervical ganglia and synapse in the superior cervical ganglion. Postganglionic fibers from these ganglia pass along with the branches of the internal and external carotid arteries to supply cranial structures.

The thoracolumbar outflow consists of fibers which arise from neurons in the intermediolateral column of the cord from T1 to L3 segments. The preganglionic fibers (myelinated) pass out along with the ventral roots and reach the paraspinal sympathetic ganglia chain in the white rami communicantes. Unmyelinated postganglionic fibers (grey rami) leave these ganglia to reach the various organs along with the spinal nerves.

The paraspinal sympathetic chains consist of three cervical, eleven thoracic, four lumbar and four sacral ganglia which are all paired, and a single unpaired coccygeal ganglion. The upper limb is supplied through the stellate ganglion by fibers arising from the upper thoracic segments. Cardiac fibers arise from the upper thoracic segments. The greater splanchnic nerve derived from T5 to T10 ganglia reaches the celiac plexus. Lesser splanchnic nerve (T9 to T10) reaches the aortorenal plexus. These supply the digestive tract and other abdominal organs.

Parasympathetic system: The centers are situated in special visceral nuclei in the brainstem and in the lateral horns of S2-S4 segments of the spinal cord. Fibers from these nuclei leave along the cranial nerves (III, VII , IX and X) or the sacral nerves and synapse in the ganglia situated near the viscera which receive their supply. The sacral fibers supply the urinary bladder, colon, and other viscera.

Functions: The sympathetic and parasympathetic systems have complementary roles. The former is more active during wakefulness and activity whereas the latter is more active during sleep. *Sympathetic nervous system consists of adrenergic nerve fibers, with the exception of fibers to sweat glands which alone are cholinergic.* The important actions mediated by adrenergic nerves are pupillary dilatation, cardiac acceleration, splenic contraction, vasoconstriction in the skin and viscera, coronary vasodilatation, inhibition of intestinal motility, bronchodilatation, sweating, ejaculation of semen, contraction of sphincters, and hepatic gluconeogenesis and glycolysis.

Parasympathetic fibers are cholinergic. Their main actions include pupillary constriction, slowing of the heart rate, vasodilatation in the skin and viscera, secretory activity of glands, bronchoconstriction, increasing peristalsis and secretion of the gastrointestinal tract, contraction of urinary bladder, penile erection, and increased secretion of insulin.

Visceral pain is carried by the ANS, the stimuli being distension of viscera, hypermotility, and inflammation. This is poorly localized and diffuse. Often it is felt as referred pain over cutaneous areas supplied by the spinal nerves arising from the same spinal segment, e.g. hepatic pain is referred to the right shoulder and cardiac pain is referred to the inner aspect of the left arm.

The two systems show differences

Parasympathetic system	Sympathetic system
1. Pre-ganglionic and post ganglionic fibers are cholinergic	Postganglionic fibers are adrenergic except for sweat glands.
2. Ganglia close to target	Away from the target
3. Specific function	Different effects

The enteric system, also called the *minibrain* consists of the Auerbach's and Meissner's plexuses and the Henle's plexus. They sense parameters such as wall tension, osmolality of the luminal contents, pH and others, and activate the neural network for performing programmed digestive behaviour by providing information, generating output signals via the motor nerves to muscles, secretory apparatus and vasculature of the gut.

Preganglionic fibers are small lightly myelinated B' fibers and postganglionic fibers are unmyelinated C' fibers. Since these fibers are small, generally abnormalities of nerve conduction may not be evident on clinical testing.

Autonomic nerves subserve almost all organs and take part in all involuntary and reflex activities taking place in the body. The terms autonomic neuropathy (ANP) denotes the autonomic disturbances arising out of diseases of the peripheral autonomic nervous system

AUTONOMIC NEUROPATHY

Most of the ANPs have features of both sympathetic and parasympathetic dysfunction, manifesting in varying degrees. The onset and course are generally insidious and chronic in conditions such as diabetes and leprosy. It may be acute and even fulminant in conditions such as acute intermittent porphyria, Guillain-Barre syndrome, acute pan-dysautonomia, botulism and diphtheria. The course also varies. In diabetes mellitus ANP progresses to cause severe disability. In the acute forms it may recover completely, or to varying extent (Table 201.1).

Clinical Features and Diagnosis

Clinical suspicion of the presence of autonomic neuropathy (ANP) is essential to make a diagnosis (Table 201.2).

TABLE 201.1

Causes of autonomic neuropathy	
A. Secondary to other diseases	
1. Systemic disease	– Diabetes mellitus, uremia, hepatic failure, acquired amyloidosis, porphyrias.
2. Infections	– Leprosy, diphtheria, botulism, Chagas disease, HIV.
3. Drug induced	– Vincristine, cisplatin, taxols, amiodarone, perhexiline.
4. Toxic	– Alcohol, heavy metals, organic solvents.
5. Immune-mediated	– Guillain-Barre syndrome, paraneoplastic syndromes (Eaton-Lambert syndrome), connective tissue disorders, inflammatory bowel diseases, chronic inflammatory demyelinating polyneuropathy, acute pan-dysautonomia.
6. Nutritional	– Vit B ₁₂ deficiency.
B. Primary autonomic neuropathies	
1. Primary affections of autonomic nervous system	– Progressive autonomic failure (<i>Bradbury and Eggleston syndrome</i>). – Progressive autonomic failure with multiple system atrophy (<i>Shy-Drager syndrome</i>). – Progressive autonomic failure with Parkinson's disease.
7. Hereditary	– Hereditary sensory and autonomic neuropathy (HSAN). Fabry's disease, Tangier's disease, Allgrove's syndrome, multiple endocrine neoplasia (MEN).
8. Idiopathic	– Idiopathic distal small fiber neuropathy, chronic idiopathic anhydrosis.

TABLE 201.2

Shows the manifestations specifically attributable to autonomic neuropathy	
1. Cardiovascular system	– Orthostatic hypotension, syncope, labile hypertension, brady-tachy arrhythmias
2. Gastro intestinal	– Constipation, fecal incontinence, bloating of abdomen, gastroparesis, episodic diarrhea, dysphagia, abdominal pain and vomiting.
3. Urogenital	– Impotence, ejaculatory failure, retrograde ejaculation, vaginal dryness. Urinary retention and/or incontinence, urgency, precipitancy, nocturia, enuresis, incomplete evacuation of urine.
4. Secretomotor disturbances	– Anhidrosis, hypohydrosis, hyperhidrosis mainly of hands feet and face, gustatory sweating, xerostomia, ptyalism, dryness of the eyes, bronchorrhea.
5. Skin	– Feeling of coldness, flushing and warmth, pallor, acrocyanosis, mottling, loss of hair, thickening and discolouration of nails.
6. Bones and joints	– Charcot's joints, rarefaction and destruction of bone, analgesia or pain in joints.
Thermo regulation	– Hypothermia, hyperpyrexia.
Eyes	– Horner's syndrome, Argyll Robertson pupils. Adie's pupil, mydriasis.

Features Suggestive of Autonomic Neuropathy (ANP)

<i>Skin and mucous membranes</i>	– Dry skin, nail changes, loss of hair, trophic changes, vasomotor disturbances, dryness of mucous membranes or excess secretions.
<i>Pupils</i>	– Horner's syndrome, Adie's pupil, Argyll Robertson pupil.
<i>Cardiovascular</i>	– Orthostatic hypotension, abolition of sinus arrhythmia, absence of heart rate and blood pressure changes to Valsalva maneuvers and exercise.
<i>Urogenital</i>	– Impotence, other forms of sexual dysfunction, disorders of micturition.

TABLE 201.3

Tests employed to detect ANP
A. <i>Tests for parasympathetic functions</i> Recording of sinus arrhythmia and blood pressure (BP) 1. Heart rate response to Valsalva maneuver.
B. <i>Tests for sympathetic adrenergic and cholinergic functions</i> 2. Heart rate and BP responses to standing. 3. BP response to Valsalva maneuver. 4. Cold pressor test – BP rises. 5. Isometric exercise test-BP rises. BP response to drugs such as noradrenaline, angiotensin II, atropine and neostigmine
C. <i>Tests for sympathetic cholinergic functions</i> 6. Thermoregulatory sweat test. 7. Quantitative sudomotor axon test. 8. Sympathetic skin response. 9. Sweat imprint methods.
D. <i>Test for lacrimal secretion (parasympathetic)</i> 10. Schirmer's test. 11. Test for cutaneous flare response. Subcutaneous histamine injection or scratch test 12. Tests for pupillary responses. Instillation of drugs such as homatropine, cocaine, pilocarpine –response depends on the type of drug instilled.

Several Tests are Available for Detecting ANP

See Table 201.3.

Importance of Autonomic Neuropathy

Several diseases lead to ANP. Occurrence of ANP increases the risk of fatal complications e.g. diabetic autonomic neuropathy. They impair the quality of life e.g.

TABLE 201.4

Principles of symptomatic management of autonomic neuropathy	
Condition	Therapy
Orthostatic hypotension	Oral fluids, salt intake, mineralocorticoid fludrocortisone 0.1 to 0.3 mg/day or alpha receptor agonist like midodrine 2.5-10 mg tabs daily
Bowel disorders	Adjustment of diet, prokinetics
Erectile failure	Sildenafil 25-100 mg oral
Urinary dysfunction	Timed voiding, cholinergic drugs self catheterisation
Labile hypertension	Beta blockers
Tachyarrhythmias	
Hyperhidrosis	Trihexyphenidyl, glycopyrrolate

sexual dysfunction, urinary and fecal incontinence, orthostatic hypotension and others.

Syndromes of Primary Autonomic Failure

- 1. Primary orthostatic hypotension- fall in blood pressure severe enough to cause syncope on assuming the erect posture is indicative of sympathetic dysfunction.
- 2. Shy-Drager syndrome—This has features of chronic autonomic failure along with parkinsonism, cerebellar and pyramidal features.

Management of Autonomic Neuropathy

All primary underlying conditions should be treated. Chances of recovery of autonomic functions are variable. Proper control of the primary disease may prevent deterioration.

In symptomatic cases, management aims at treating the symptoms (Table 201.4).

Chapter Summary

Myasthenia Gravis 1332

Neonatal Myasthenia 1334

Congenital Myasthenic Syndromes 1334

Myasthenic Reactions 1334

The term myasthenia denotes muscle weakness. In practice the weakness aggravates with repeated action.

Myasthenia occurs due to defective impulse transmission at the neuromuscular junction. The most common among the neuromuscular disorders is myasthenia gravis.

Myasthenia Gravis

Myasthenia gravis (MG) is a disease characterised by weakness and easy fatigability of skeletal muscles with predilection for cranial and limb muscles. The disease improves after administration of cholinergic drugs.

Etiopathogenesis: The defect in myasthenia gravis is at the neuromuscular junction where acetylcholine is the principal neurotransmitter. In normal muscle, acetylcholine released in the synaptic cleft binds to acetylcholine receptors located on the muscle membrane and depolarize them. In myasthenia gravis, the primary abnormality is the autoimmune mechanism leading to blocking and destruction of acetylcholine receptors. Antibodies against acetylcholine receptors do not allow acetylcholine to bind with the receptors, thus blocking the chemical transmission. There is also gross reduction in the number of acetylcholine receptors. Patients may have only 1/3 the number of acetylcholine receptors compared to normals. IgG antibodies are demonstrable in the serum. Family members of MG are 1000 times more susceptible to develop MG than the general population.

It is possible that the thymus gland may act as the source of antigen directing the humoral and cellular immune response. Moreover, the normal homeostasis of the immune system by the T-cell suppressor system is also

altered. Around 85% of myasthenic patients have thymic hyperplasia and 15% have thymoma, especially those in whom the onset is below 40 years.

Myasthenic syndromes can develop in several other conditions as a result of formation of humoral factors which block the action of the receptors, e.g. bronchogenic carcinoma.

Classification of Myasthenia gravis (MG)—(Osserman)**A. Adult MG:**

- Group 1. Ocular myasthenia (20%)
- Group 2. Generalized myasthenia (60%)
 - a. Mild-generalised
 - b. Generalised with bulbar involvement
 - c. Severe-generalised
- Group 3. Acute fulminant myasthenia with early involvement of respiratory muscles (10%).
- Group 4. Late severe myasthenia developing after at least 2 years of group 1 or 2 symptoms (10%).

CLINICAL FEATURES

Myasthenia may start at any age but the peak incidence is around 20-30 years and females are more often affected. 5-7% of cases are familial. In 10% of cases spontaneous remissions occur. Genetic susceptibility is associated with certain HLA types. Muscle weakness may or may not be present at rest but occurs or increases after sustained or repetitive exercise. The hallmark of myasthenia is easy fatigability of skeletal muscles, worsened on exercise and this disability is relieved after short rest. The weakness has diurnal variation, being less in the morning and worse in the afternoon or evening. Diplopia, ptosis, ophthalmoplegia, dysphagia, and dysphonia commonly occur due to involvement of muscles supplied by the cranial nerves. The disease then involves the proximal muscles of the lower and upper limbs. There are no sensory symptoms or signs. Deep tendon reflexes are normal. Muscle weakness is not accompanied by wasting or fasciculations.

In many cases the onset is insidious and severity is mild to moderate. The common presentations are diplopia,

weakness of voice, inability to chew food or progressive fatigue on doing repetitive activities, particularly towards the latter part of the day. Less commonly the onset may be subacute or in a few cases it may even be acute. Infections, emotions, insomnia and menstruation may aggravate myasthenia leading to myasthenic crisis. Many drugs such as quinidine, quinine, aminoglycosides, polymyxin, procainamide, penicillamine, oral contraceptives, opiate analgesics, propranolol, calcium channel blockers, diazepam, muscle relaxants, anti-epileptic drugs, chloroquine and colistin also worsen myasthenic symptoms.

Diagnosis

Diagnosis of myasthenia is clinical. It can be confirmed by investigations.

Pharmacological Tests

- Tensilon test—Tensilon (edrophonium chloride) given intravenously in a dose of 2 mg initially as a test dose followed by 8 mg slowly, improves myasthenic weakness dramatically within 60 seconds. Atropine should be available at hand to terminate unpleasant side effects. Complications include syncope and respiratory distress.
- Recovery of muscle strength within 15-30 minutes on injecting neostigmine in a dose of 0.04 mg/kg body weight S.C is also diagnostic.
- Acetylcholine receptor antibodies can be detected in serum by radioimmunoassay tests. Presence of the antibody confirms the diagnosis but its level in the serum and clinical severity do not correlate. These antibodies are present in 80% of cases of generalized and severe forms of MG. In ocular MG and MG in remission this frequency is much lower. Antibodies to striated muscle in the serum are also present in some cases. Anti-muscle antibody positive MG constitutes 8-10% of seronegative MG in children.
- Repetitive nerve stimulation and EMG*: In myasthenia, on repetitive stimulation of the peripheral motor nerves in the limbs at a rate of 3 stimuli per second, the amplitude of the evoked motor action potentials progressively diminishes (>10%). This is called decremental response. On single fiber—EMG examination there will be increased jitter.
- X-ray, CT scan or MRI of the chest help to demonstrate enlargement of the thymus, pulmonary lesions and other abnormalities.

Differential diagnosis: Myasthenia has to be differentiated from hysterical conversion reaction, motor neuron disease, myositis and myopathies. Precipitation or aggravation of symptoms by emotion may suggest a diagnosis of hysterical conversion reaction. The bulbar type of motor neuron disease and polymyositis seldom

involve the external ocular muscles. The absence of fatigability and presence of fasciculations in motor neuron disease and occurrence of muscle tenderness in polymyositis help to differentiate these diseases from myasthenia.

In myopathy involving the cranial muscles, especially ocular myopathy, the weakness is confined to the affected muscles and there is no worsening with repeated activity.

Complications

Myasthenic crisis and cholinergic crisis are two acute complications which may develop. These are characterized by sudden occurrence of severe degree of paralysis affecting several muscles in the body including respiratory paralysis. The former is due to aggravation of myasthenia due to precipitating causes. The latter is caused by over use of anticholinesterase drugs.

Clinically both may appear similar, except for the history of drug administration and presence of fasciculations in the latter. Unless emergency measures are instituted to tide over the paralytic episode, the condition may prove fatal. A simple test to distinguish the two types is the I.V administration of 2 mg edrophonium (available as Tensilon) which rapidly relieves myasthenic crisis, but not cholinergic crisis.

Irrespective of the cause, all such patients need intensive care management with ventilatory support. Myasthenic crisis is usually precipitated by intercurrent infections.

Cholinergic crisis is caused by excessive dose of anticholinesterase drugs.

Course and Prognosis

Many cases are only mild to moderate in severity and the patients learn to manage themselves with optimal drug therapy. The severity may show fluctuations from time to time. In about 10% of cases spontaneous remission may occur during the first few years. Purely ocular myasthenia runs a mild course. Prognosis is worse for acute fulminant and late onset cases. Cases associated with thyrotoxicosis show a see-saw relationship with the severity of the latter. Occurrence of crisis is a fatal complication if not managed promptly. Patients suffering from myasthenia may develop other autoimmune diseases.

TREATMENT

- Onset of MG before the age of 60 years:** Thymectomy is the preferred modality of treatment, even in those who do not have thymoma. In some cases pretreatment with plasmapheresis or anticholinesterase drugs may be required to reduce severity of the symptoms before surgery. After thymectomy if the result is not satisfactory, high doses of prednisolone or other immunosuppressant drugs may be necessary. Some patients require anticholinesterase drugs.

B. **Onset of MG after the age of 60:** Anticholinesterase drugs along with prednisolone or immunosuppressant drugs are preferred. Plasmapheresis or intravenous human immunoglobulin (I.V.I.G.) should be considered for severe exacerbations of the symptoms and during myasthenic crises until the drugs take effect. Thymectomy should be reserved for those who do not respond to medications.

C. In patients with thymoma, thymectomy should be performed, irrespective of the age at which the diagnosis is made.

The commonly used anticholinesterase drugs are:

1. **Neostigmine** (15 mg tablet) 60-200 mg/day in divided doses.
2. **Pyridostigmine** (60 mg tablet) 1 tablet given every 4 hours.

The dose and frequency of administration of these drugs have to be tailored to the patient's requirement.

Corticosteroids are indicated:

- i. in those cases where there is insufficient response to anticholinesterase drugs,
- ii. when ocular symptoms are predominant and
- iii. in older males. Oral prednisolone is the preferred steroid which is given in a high dose—100 mg daily to start with and then on alternate days. Once remission of symptoms occurs, it is slowly tapered off over 6-12 months. Initial worsening of the myasthenic symptoms may occur with steroids in some cases.

Immunosuppressant drugs may be required for those cases of MG that are resistant to thymectomy and steroids. These include azathioprine, cyclophosphamide and cyclosporine in the usual dosage. Mycophenolate mofetil, in doses of 2 g/daily orally is a good immunosuppressant which acts as an adjunctive therapy in MG. It helps to reduce the dose of corticosteroids.

Treatment of myasthenic crisis: Injection of edrophonium chloride in a dose of 2 mg relieves myasthenic crisis within one minute. If the weakness aggravates, cholinergic crisis should be diagnosed. In such a case all drugs should be withdrawn and the patient's respiration should be maintained by artificial ventilation till the condition passes off.

In cases of myasthenic crisis further doses of anticholinesterase drugs should be given with care. If there is no relief two options are available. (1) **emergency plasmapheresis** and (2) **I.V human immunoglobulin** in a dose of 0.4 g/kg/body weight daily for 3-5 days. Both have been tried extensively in different centers and found to be quite effective. The former requires expensive equipment and donor plasma, the latter is more expensive (Rs 80,000 to 1, 00,000 per course).

Treatment of the underlying cause should be instituted simultaneously.

Myasthenia Gravis in Pregnancy

Usually when pregnancy occurs the myasthenia abates. Neostigmine is quite safe during pregnancy. Cytotoxic drugs should be avoided.

The newborn may show transient myasthenia lasting for a few hours to days due to passive transfer of maternal antibodies. Oral administration of pyridostigmine corrects the condition.

Neonatal Myasthenia

Transient neonatal MG may be present in 15% of babies born to mothers with MG due to trans-placental transfer of antibodies. Usually the condition clears in a few days. These babies need specific management during the myasthenic phase.

Congenital Myasthenic Syndromes

Neonates and infants manifest with myasthenic symptoms which persist into adult life. Anti-acetylcholine receptor (AChR) antibodies are not demonstrable. Mothers do not have MG. Several congenital myasthenic syndromes have been described. These are hereditary disorders of neuromuscular transmission. Most of them except a few (e.g. slow channel syndrome) are autosomal recessive: They are characterized by ophthalmoplegia, muscle weakness and fatigue. They may have delayed milestones in infancy, and respiratory distress which may extend into childhood. Repetitive nerve stimulation shows decremental response, especially at slow rates of stimulation. The defect may be presynaptic, synaptic or postsynaptic. Genetic studies are available to identify the defect.

Treatment: Some patients benefit with anticholinesterases such as neostigmine. Drugs like quinine and fluoxetine are beneficial in slow- channel syndrome. Thymectomy has no role in this condition.

Myasthenic Reactions

Syn: Secondary myasthenia

A clinical picture closely resembling myasthenia gravis may develop as a paraneoplastic phenomenon, particularly in oat cell carcinoma of the lung (**Eaton-Lambert syndrome**). This is caused by immunological reaction at the neuromuscular junctions by antibodies developing against the membrane proteins of the tumour cells which may resemble antigen present in normal nervous tissue and receptors at the neuromuscular junction. Immunological injury leads to damage to calcium channels and results in failure of release of acetylcholine at motor and autonomic nerve terminals. Other manifestations of carcinomatous neuromyopathy may also be evident in many cases. Though it superficially resembles myasthenia gravis, it differs in that the ocular muscles are not affected. So, also muscle wasting and loss of tendon reflexes may be seen. Unlike in MG, the muscle weakness in these

patients improves with exercise (**reverse myasthenia**). The electromyographic pattern also shows marked difference. Removal of the primary tumour leads to symptomatic remission. Guanidine in a dose of 35 mg/kg given orally is beneficial. Another drug found to be useful in this condition is 3,4 diamino pyridine.

Myasthenic reaction may develop in thyrotoxicosis, snake bites, (especially cobra and krait) and use of drugs

like aminoglycosides, penicillamine and others. AchR antibodies may be present in penicillamine induced myasthenia.

Recognition of this complication in snake bites and anticholinesterase therapy along with ventilatory support are life saving. In neoplastic conditions, treatment of the neoplasm relieves the myasthenia too. Drug induced myasthenia subsides on withdrawal of the drug.

GENERAL CONSIDERATIONS

Study of the diseases of muscles (clinical myology) has advanced considerably in the last few decades as a result of improvement in investigations like biochemical tests, electrophysiology, histological studies, electron microscopy, histochemistry and genetic studies.

Skeletal muscle is composed of several muscle fibers that run along its longitudinal axis. Each muscle fiber represents a separate anatomic and physiologic unit. The cytoplasmic membrane is called sarcolemma and the

cytoplasm is called sarcoplasm. Sarcoplasm contains myofibrils which in turn are composed of contractile myofilaments—actin and myosin. Connective tissue invests the muscle fibers, fasciculi and the entire muscles and this is known as endomysium, epimysium, and perimysium respectively. The integrity of the muscle depends upon its adequate blood supply and intact nerve connections. Muscle disorders may be caused by affection of one or more of these components, i.e. enzyme systems in the sarcoplasm, abnormalities in connective tissue coverings, ischemia or loss of trophic influences. By special staining techniques, two types of muscle fibers are recognized. Type I fibers are richer in oxidative enzymes and they are abundant in muscles which are intended for sustained contraction for long periods, e.g. muscles which maintain posture. Type II fibers are high in phosphorylase enzyme activity. They are present more in muscles which are intended for fast action, e.g. hand muscles. Both fiber types are present in all the muscles in differing proportions.

Type I fibers are also known as *slow twitch* or *red fibers* and *Type II* fibers are known as *fast twitch* or *white fibers*.

The muscle fiber, like any other cell, has a resting action potential (RAP). An action potential is triggered off when the sodium permeability of the sarcolemma increases. Potassium moves out of the cell and sodium moves in. The intracellular sodium releases calcium, which activates the ATPase enzyme in the presence of

magnesium (Mg^{++}). The release of energy-rich bonds in turn produces a sliding movement of the actin-myosin filaments, resulting in mechanical contraction. The whole process is called excitation-contraction coupling. Changes in ionic concentration of Na^+ , K^+ , Ca^{++} , Mg^{++} and others can influence activity of the muscle fiber.

Damage to the sarcolemma gives rise to leak of sarcolemmal enzymes into the general circulation. Transaminases, lactic dehydrogenase (LDH), aldolase and creatine kinase (CK) appear in large amounts in blood in muscle diseases. Since other tissues like the heart, liver, brain and others also contain similar enzymes, rise in the level of these enzymes in blood may result from damage to other tissues as well. But in each case the specific isoenzyme can be identified by appropriate methods. This helps to identify the affected tissue more specifically.

Creatine is found in large amounts in muscle and it is required for the formation of energy-rich phosphate bonds. Creatinine is the metabolic product of creatine. Normal sarcolemma is highly impermeable to creatine, but not to creatinine. In disease states permeability to creatine increases, resulting in rise in serum creatine levels and appearance of creatine in urine (creatinuria).

The muscle plasma membrane is a trilaminar structure which houses thousands of proteins forming various channels, pores, receptors and anchoring proteins, all performing specific functions. The various structural components of muscles are genetically determined and each has a distinct function to perform. Classification of inherited muscle diseases is based on the abnormal component. Terms such as dystrophinopathies, sarcoglycanopathies and lamininopathies are being used to denote the underlying pathology of muscle disorders.

SYMPTOMATOLOGY OF MUSCLE DISEASES

Muscle disorders often present with weakness and wasting of proximal muscles. Some diseases of muscles may show hypertrophy, pseudohypertrophy (apparent increase in bulk due to overgrowth of fat and connective tissue) or contractures. Unlike in neuropathy, tendon reflexes are usually preserved until late in the disease and sensations are normal although sensory symptoms like aches, cramps and painful muscle spasms may occur in some patients. Fasciculations are not present, though there are exceptions.

Myotonia is the failure of relaxation after contraction and this is a feature of some muscle disorders. *Action myotonia* is failure to relax after voluntary action such as shaking hands with the examiner. *Percussion myotonia* is the persistence of contraction after tapping the muscle, best demonstrated in the muscles of the tongue or hand.

Myoedema is a localized bulge of the muscle on tapping, found in hypothyroidism and cachexia.

Bilateral weakness of the gluteus medius and minimus muscles produces **waddling gait**. Proximal muscle weakness in the lower limbs gives rise to difficulty in getting up from the squatting posture, and the patient gets up with the assistance from his hands over the thighs. This is known as **Gower's sign**. Weakness of the iliopsoas and paraspinal muscles gives rise to exaggeration of lumbar lordosis and protuberance of the abdomen. Winging of scapulae occurs due to weakness of the serratus anterior, lower part of trapezius and rhomboids. Muscles supplied by the cranial nerves may be affected in some forms of myopathies (e.g. ocular myopathies). Muscle tenderness may be present in myositis.

Some patients may not use the term weakness for their symptoms but instead describe them as difficulty in combing hair, rising out of chair or climbing up a stair case. The distribution of these symptoms or weakness offers a clue to the diagnosis. Proximal limb weakness without significant wasting is the presenting symptom in polymyositis, mitochondrial myopathies, glycogen or lipid storage myopathy and Lambert-Eaton myasthenic syndrome. Proximal limb weakness with significant wasting is seen in facioscapulo-humeral, limb girdle, Duchenne and Becker types of muscular dystrophies and juvenile spinal muscular atrophy.

Distal limb weakness presents with difficulty in performing fine coordinated movements or weakness of hand grip, going over a step or going down stairs. Myotonic dystrophy, scapulo-peroneal muscular dystrophy, distal myopathy, distal spinal muscular atrophy and amyotrophic lateral sclerosis are the conditions with predominantly distal weakness. Ptosis and ophthalmoplegia occurs in myasthenia gravis, hyperthyroid ophthalmopathy, oculopharyngeal muscular dystrophy and mitochondrial myopathies. Generalised wasting without focal weakness is seen in cachexia and malnutrition. Focal weakness and wasting of hand muscles without pain is an early manifestation of motor neuron disease or syringomyelia. Accompanying pain in the hand and forearm suggests cervical radiculopathy or peripheral nerve entrapment. Frank enlargement of calf muscles is seen in Duchenne and Becker types of muscular dystrophy, myopathy due to congenital hypothyroidism and cysticercosis. Generalised muscular hypertrophy occurs in myotonia congenita.

Classification

Diseases of the muscle that cause acute, subacute or chronic weakness, wasting, myalgia, muscle cramps and stiffness, asthenia and easy fatigue or myoglobinuria are called myopathies. Several schemes of classification of myopathies have been followed by different authors. Earlier classifications were based on the pattern of muscle

TABLE 203.1

Classification of myopathies

A. Genetically determined myopathies	
1. Muscular dystrophy (MD)	
a. X-linked	
i. Severe form	: Duchenne type (DMD)
ii. Mild form	: Becker type (BMD)
b. Autosomal recessive	: Limb-girdle type
c. Autosomal dominant	: Facioscapulohumeral type. Syn: Landouzy-Dejerine type,
d. Localized types	: Distal MD Ocular MD Oculopharyngeal MD
2. Congenital myopathies, e.g. congenital muscular dystrophy, nemaline myopathy, central core disease, myotubular myopathy	
3. Myotonic disorders, e.g. dystrophia myotonica, myotonia congenita (Thomsen's disease)	
4. Glycogen storage disorders	
5. Mitochondrial myopathies	
6. Myopathies associated with disordered lipid metabolism	
7. Familial periodic paralysis	
B. Inflammatory myopathies: Polymyositis, dermatomyositis	
C. Myopathies due to endocrine and metabolic disorders	
a. Thyrotoxicosis	
b. Myxedema	
c. Cushing's disease	
d. Addison's disease	
e. Hyperparathyroidism	
f. Primary aldosteronism	
g. Acromegaly	
h. Osteomalacia	
i. Nutritional myopathy	
j. Drugs: Steroids, clofibrate, chloroquine, phenformin, d-penicillamine, zidovudine.	
D. Myopathy in malignant diseases — Carcinomatous myopathy	
A detailed description of all these disorders is beyond the scope of this chapter. Hence brief descriptions of the more common disorders are attempted here. The student may refer monographs on muscle diseases for further details.	

groups involved and the mode of inheritance, e.g. limb-girdle dystrophy and facioscapulohumeral myopathy. Later, myopathies where electrical abnormalities were demonstrable by electromyography (EMG) were added, e.g. congenital myopathies. Classification of metabolic myopathies takes into consideration the enzymic defects occurring in muscle metabolism. A simplified system of classification is given below for purpose of clarity. Several terms have been employed to indicate muscle disorders. These are muscular dystrophy, myopathy and myositis (Table 203.1).

“Myopathy” is a broad general term that includes all diseases of the muscles. Muscular dystrophies are myopathies that are characterised by a specific pattern of inheritance. Myositis is a type of myopathy where inflammation is the predominant feature.

The muscular dystrophies are inherited myogenic disorders characterized by progressive muscle wasting and weakness, of variable distribution and severity. These are genetically determined and each type shows a unique pathology. In them the structural proteins are defective and classification of the muscular dystrophies is based on the abnormality of the structural proteins.

CLINICAL APPROACH TO THE PATIENT WITH MUSCLE DISEASE

A muscle disorder is first suspected when a patient presents with muscle wasting and weakness, predominantly proximal in distribution or in one of the characteristic patterns. The important differential diagnosis includes spinal muscular atrophy and motor neuropathies. Absence of deep tendon reflexes, presence of fasciculations and insidious course of the disorder help to distinguish spinal muscular atrophy from muscular dystrophy. Peripheral neuropathies commonly affect the distal muscles, contrary to muscular dystrophy which affects the proximal muscles more. Pure motor neuropathy is extremely rare and in many cases of neuropathy sensory abnormalities are demonstrable. Investigations like muscle enzymes, EMG, and nerve biopsy help to make a definite diagnosis in most cases and these should be done in all cases for confirmation. These investigations should be done for the family members also to detect subclinical cases and carriers in cases of suspected genetically transmitted myopathies. Muscle histochemistry and electron microscopy may help in the diagnosis of early cases even when routine muscle histology on light microscopy is not confirmatory.

Muscle enzymes estimation should be done before EMG examination as the needle pricks spuriously elevate these enzymes. For muscle biopsy, a muscle which is not submitted to EMG examination should be selected to avoid needle injury artefacts on histology.

Duchenne Muscular Dystrophy (DMD)
Syn: Pseudohypertrophic muscular dystrophy

The disease manifests only in males whereas females act as carriers. It is transmitted as an X-linked recessive trait. The Duchenne Muscular Dystrophy (DMD) locus is in Xp21 region. At present specific DNA probes are available to identify this locus. Duchenne and Becker type dystrophies are due to defects in the same gene locus and its product “dystrophin” is probably required for

maintaining the stability of muscle membrane. Mutations of dystrophin gene, usually deletion or gene inversions; lead to total or near-total loss of dystrophin protein from skeletal muscle causing early and progressive loss of muscle function. Dystrophin is part of a multifunctional transmembrane protein complex; the dystrophin-glycoprotein complex. This acts as a scaffold for adhesion and signalling of cytoskeletal proteins. Disruption of this complex leads to death of muscle cells from apoptosis and necrosis. Milder defects lead to Becker's muscle dystrophy. Since the genetic defects in Duchenne's muscular dystrophy and Becker's muscular dystrophy are the same, these disorders together are called *dystrophinopathies*.

CLINICAL FEATURES

Whereas DMD is rapidly progressive and incapacitating before reaching adolescence, the progress in Becker type is slow and the patient can be ambulant even up to the age of 60 years. The frequency of DMD is one in 3000-5000 male children. Onset of the disease is usually before the fourth year. Symmetrical involvement of pelvic girdle muscles occurs. The initial complaint is that the child falls frequently while walking. *Gower's sign* is demonstrable at this stage. This is followed by weakness of the muscles of the shoulder girdle. Pseudohypertrophy of the calf muscles is an important clinical finding at this stage. Involvement of the muscles is selective at first, later it becomes generalized. Weakness of muscles progresses and within 10 years of onset of the disease, the child is disabled considerably. About 20% of affected boys have IQ below 40%. About 5-10% of female carriers may have some degree of muscle weakness and enlargement of the calf muscles.

Cardiac involvement occurs invariably, and manifests as persistent tachycardia or sudden death due to cardiac failure. Characteristic ECG changes may occur. These include tall R-waves in right precordial leads and deep Q-waves in the limb leads and left precordial leads. Skeletal changes take the form of severe scoliosis, exaggerated lumbar lordosis, and increased tendency for fractures.

DIAGNOSIS

This is confirmed by markedly elevated serum CK level, myopathic pattern on EMG and characteristic muscle biopsy. Since genetic studies are now available for diagnosis, muscle biopsy is required only rarely. The EMG shows brief duration small amplitude motor unit potentials with complete interference pattern. These investigations are marginally abnormal in carriers and this helps in carrier detection. There is no effective treatment at present. It is possible to diagnose affection of the fetus prenatally. Genetic counselling and prenatal diagnosis should be undertaken in affected families.

Differential diagnosis includes other causes of myopathies, myositis, Hoffman's syndrome in myxedema and rarely S₁ radiculopathy.

Though generally damage to spinal nerve roots or peripheral nerve causes muscle atrophy, at times S₁ spinal root radiculopathy may give rise to unilateral calf swelling. Histology of the muscle shows hypertrophy, pseudo hypertrophy or focal myositis. Evidence of myositis such as elevation of serum creatine kinase (CK) may be evident. The condition generally resolves spontaneously. Rarely decompression of S₁ spinal root may be needed.

Course and Prognosis

The course is one of steady progression to involve all muscles in the body and death occurs in 10-12 years as a result of malnutrition, respiratory infection or respiratory failure.

Management

Supportive care maintenance of nutrition, proper schooling as long as it is possible, avoidance and prompt treatment of respiratory infections, proper physiotherapy and use of appropriate appliances for daily life help to maintain mobility and preserve the morale.

Early recognition and prevention: The growth and development of affected boys are slow, they start walking only around 18 months and their speech is slow. Serum creatine kinase is elevated. Early diagnosis helps in proper genetic counselling.

Clinical manifestations such as muscle weakness and dilated cardiomyopathy can be detected by investigations in 20% of carriers of DMD and BMD. 40% may show left ventricular dilatation.

Limb-Girdle Muscular Dystrophy

This is transmitted as an autosomal recessive trait and it occurs in both sexes. The disease manifests in the second and third decades of life as primary involvement of the pelvic or shoulder girdle muscles. Hypertrophy of muscles may be seen in some cases. Most patients are severely disabled by middle life. In the upper limbs, the muscles usually affected are serratus anterior, trapezius, rhomboids, latissimus dorsi and sternal head of pectoralis major. Deltoids are spared until late in the disease. Cardiac involvement is rare.

Different types of limb girdle muscular dystrophy occur; depending on their genetic abnormality. They differ in

1. the pattern of inheritance
2. clinical pattern— age and distribution of lesions
3. the chromosomal defect and
4. type of muscle protein affected.

Facioscapulohumeral Muscular Dystrophy

This disease is usually transmitted as an autosomal dominant trait. The onset of the disease may be at any age from childhood to adult life. The facial and shoulder girdle muscles are involved first. Muscular hypertrophy, contractures and skeletal deformities are rare. Life expectancy is normal as the disease runs an insidious course.

Congenital Myopathies

Different types of congenital myopathies have been recognized with the advent of muscle histochemistry and EMG. These diseases are transmitted as autosomal dominant or recessive traits. Proximal muscles are usually involved. Congenital myopathy leads to severe hypotonia in the infant. The disease is slowly progressive and muscle enzymes are seldom elevated.

Emery-Dreifuss muscular dystrophy: This is a X-linked recessive disease. Autosomal dominant and recessive forms are also seen. There is absence of emerin in muscles. The defect is in the STA gene in chromosome q 28 which encodes emerin. The clinical triad includes:

1. Early occurrence of contractures
2. Slowly progressive muscle wasting and weakness with a humero-peroneal distribution and
3. Cardiomyopathy with conduction defects.

Ocular Myopathy

This is due to affection of the external ocular muscles. It starts with bilateral ptosis and progressive ophthalmoplegia which becomes almost complete over a period of several years. Diplopia is only rarely complained of. Some cases may be associated with dysphagia resulting from involvement of pharyngeal muscles.

Myotonic Disorders

Myotonia is defined as the continued active contraction of a skeletal muscle which persists even after the cessation of voluntary effort or stimulation. Myotonia is an abnormality of the muscle fiber itself and it persists even after interrupting the nerve. Myotonic disorders may be genetically determined or acquired.

1. Genetically Determined Myotonias

- a. Autosomal dominant—Myotonia congenita (*Thomsen's disease*)
- b. Autosomal recessive—Myotonia congenita (*Becker type*)
- c. Myotonic dystrophy (*Stemert's disease*)
- d. Paramyotonia congenita (*von Eulenberg disease*)

- e. Chondrodystrophic myotonia (*Alberfeld Hinter-Buchner Schneider disease*)

2. Acquired myotonias

- a. Drug induced
- b. Toxins e.g.: Weed killers containing monocarboxy aromatic acids.

Myotonia is now recognized to be a channelopathy.

Channelopathies are disorders caused by inherited mutations in ion channels. Several diseases occur in this group. Most channelopathies affect either muscle or the nervous system. Despite phenotypic heterogeneity, a striking feature is the association with paroxysmal dysfunction. Periodic paralysis and non-dystrophic myotonias are also classified as channelopathies.

Ion channels are transmembrane glycoprotein pores that control cell excitability by regulating ion flow into and out of cells. The channels are composed of distinct proteins called channel subunits. Different genes encode each subunit. Two mutations within the same gene can result in different physiological defects. The concept that different mutations in the same gene can cause different phenotypes is termed *phenotypic heterogeneity*. For example, mutations in the same muscle sodium channel gene can result in hyperkalemic periodic paralysis, hypokalemic periodic paralysis or paramyotonia congenita. Genetic heterogeneity is manifested where different mutations in the skeletal muscle sodium channel cause the hyperkalemic periodic paralysis phenotype. Hypokalemic periodic paralysis can also occur due to α -type calcium channel mutations.

Dystrophia Myotonica (Myotonic Dystrophy)

This is an autosomal dominant disorder mediated by a mutant gene located on chromosome 19. It is an example of triplet repeat disease, the repeated triplet being CTG.

It is characterized by myotonia and dystrophic changes in muscles demonstrable histologically. Both sexes are affected. Usual age at onset is 20-30 years. Main brunt of disease falls on facial muscles, temporalis, masseter, sternomastoid, shoulder girdle muscles, quadriceps and distal muscles of the limb. Both action myotonia and percussion myotonia are demonstrable. The muscles show wasting. The facial appearance is distinctive. Ptosis, frontal baldness, and wasting of the facial muscles and sternomastoid give a characteristic appearance.

Systemic manifestations include posterior subcapsular cataract, cardiomyopathy, gonadal failure, bone changes, respiratory failure and endocrinopathies. Intellectual impairment may develop. Males develop impotence and females suffer from amenorrhea. Usually the disease lasts for 15-20 years, death occurring due to cardiac or respiratory causes.

The EMG shows diagnostic abnormalities consisting of electrical after-discharge after cessation of voluntary effort. Phonographic recording of these discharges give the characteristic pattern described as *dive bomber* phenomenon and this is diagnostic of myotonia. Histopathological investigations may reveal widespread nervous system abnormalities especially affecting the peripheral large diameter motor and sensory fibers and small diameter sensory fibers.

Management: Myotonia responds to procainamide, mexilitine or phenytoin given orally in the usual doses. Avoidance of cold environment, overexertion and stressful situations help to prevent exacerbation. Quinine sulphate in a dose of 600 mg twice or thrice a day is beneficial in some cases. Myotonia may be relieved by drugs, but not the muscle weakness.

Patients with mild degrees of myotonia are able to manage themselves by adjusting their life styles.

MYOTONIA CONGENITA

Syn: *Thomsen's disease*

This disorder is transmitted as an autosomal dominant disorder and is usually present at birth. There is severe action myotonia. Myotonia congenita is due to mutation in the chloride channel. The muscles are all hypertrophied. Mexilitine and procainamide are helpful in myotonia congenita and paramyotonia.

Chondrodystrophic Myotonia

This is associated with myotonia, skeletal deformities, and short stature.

Polymyositis

This is a non-suppurative inflammatory disorder of the skeletal muscles of presumed autoimmune etiology. When the pathological process affects only the muscles it is called polymyositis (PM) and when it is associated with characteristic skin rash it is known as dermatomyositis (DM). Various connective tissue disorders may be associated with polymyositis in 1/3 of cases and malignancy in 1/10 of cases. Based on the presence or absence

of skin lesions and other associated conditions, the disease has been classified as follows.

- Group I: Primary, idiopathic polymyositis
- Group II: Primary, idiopathic dermatomyositis
- Group III: Poly- or dermatomyositis with neoplasia
- Group IV: Childhood dermato- or polymyositis with vasculitis
- Group V: Poly or dermatomyositis with collagen vascular disease

Inflammatory myopathy may also be seen in sarcoidosis, AIDS and other infections due to toxoplasma, spirochetes, viruses and trichinella.

Staphylococcal and streptococcal infections of the muscles lead to suppurative inflammation which is referred to as pyomyositis. Sometimes instead of diffuse involvement of the muscles, there may be rapidly developing painful focal inflammatory nodules in the muscles. This condition is called focal nodular myositis. *Inclusion body myositis* (IBM) is another condition which mimics polymyositis, but differs from that with onset at age above 50 years, distal muscle involvement and a longer course of illness that does not usually respond to either steroids or cytotoxic drugs.

CLINICAL FEATURES

The peak incidence of PM is between 20-60 years. Females are more frequently affected. The disease presents with subacute symmetrical weakness, and pain and tenderness of the muscles of the proximal parts of the limbs and trunk and neck muscles. The pharyngeal and laryngeal muscles are frequently involved. Ocular muscles are not affected. Muscle tenderness may be elicited in about 50% of cases (Table 203.2).

The course is gradual and slow, extending from weeks to months and this contrasts with muscular dystrophies which extend over years. Rarely the course may be acute.

Diagnosis

The muscle enzyme CK is markedly elevated more than 10 times. The EMG findings are abnormal. Diagnosis is established by demonstrating inflammatory changes in histological specimen of muscle biopsy. The course and progress depend on the type of myositis. Muscle

TABLE 203.2

Clinical features of the different types of myositis			
	DM	PM	IBM
Age	All	Second decade	Above 50 yrs
Sex	Females more	Females more	Males more
Distribution of muscle weakness	Proximal	Proximal	Distal
	Symmetrical	Symmetrical	Symmetrical
DM—Dermatomyositis; PM—Polmyositis; IBM—Inclusion body myositis			

TABLE 203.3

Summary of the features of common myopathies					
Muscle disorder	Age of onset	Pattern of involvement	Muscle enzymes	EMG	Prognosis
1. Duchenne muscular dystrophy (DMD)	Before 4 years	Proximal muscles	Markedly elevated	Myopathic	Gross disability in 10 years
2. Congenital myopathy	Infancy	Proximal muscles	Normal or marginally elevated	Myopathic	Insidious course
3. Limb-girdle dystrophy	2nd or 3rd decade	Proximal muscles	Mild to moderate elevation	Myopathic by middle age	Severe disability
4. Facioscapulohumeral dystrophy	Childhood to adult life	Facial and shoulder girdle muscles	Mild to moderate	Myopathic	Normal life expectancy
5. Dystrophia myotonica	20-30 years	Facial muscles, temporalis, masseter, quadriceps and distal limb muscles	Mild elevation	Myotonic pattern "dive-bomber phenomenon"	Severely disabled in 15-20 years
6. Polymyositis	20-60 years	Proximal limb muscles, trunk muscles, neck pharyngeal and laryngeal muscles	Markedly elevated	Myopathic, spontaneous activity in the form of fibrillations	Responds to corticosteroids and immuno-suppressants

histochemistry and electronmicroscopy may help in the diagnosis of early cases even when routine muscle histology on light microscopy is not confirmatory (Table 203.3).

Treatment: Prednisolone in high doses at 1-2 mg/kg body weight/day gives the best results, which takes 1-4 weeks to set in.

Where there is good improvement the dose of prednisolone may be gradually tapered off at a rate of 5 mg every 4 weeks. In the majority of patients maintenance dose of prednisolone, either daily or on alternate days is required for several years. Cytotoxic drugs such as azathioprine, cyclophosphamide, methotrexate or cyclosporine are indicated under the following conditions.

1. Steroids fail to bring improvement in 1-3 months
2. Severe disease
3. Relapses occur while on steroid treatment.

In resistant cases, plasmapheresis or high dose intravenous immunoglobulin therapy may be useful. Bed rest during the acute phase and remedial physiotherapy subsequently, help to hasten recovery.

Prognosis: Inclusion body myositis is resistant to treatment. The others respond favourably and attain functional recovery.

METABOLIC MYOPATHIES

These result from abnormalities in muscle metabolism caused by deficiency or abnormalities of the enzymes concerned with metabolic process. The immediate source of energy for muscle contraction is the hydrolysis of ATP to ADP. Availability of fuel and the rate at which energy

can be produced are the limiting factors for exercise. Muscles utilize carbohydrates in the form of muscle glycogen and lipids in the form of free fatty acid as fuel. Glycogen can be metabolized both aerobically and anaerobically, whereas lipids can be metabolized only aerobically.

Metabolic myopathies result from abnormalities of enzymes concerned with metabolism of carbohydrates or lipids. The clinical picture is different for each type. Deficiency of the enzyme carnitine palmitoyl transferase leads to abnormalities of lipid metabolism. Deficiency of phosphofructokinase leads to abnormality of glycogen metabolism. This occurs in **McArdle's syndrome**.

Several toxic myopathies may result from exposure to toxins. **Eosinophilia-myalgia syndrome** is characterized by peripheral blood eosinophilia and scleroderma like features. Possible etiological factor is toxic chemicals contaminating tryptophan which is consumed as a health food.

Mitochondrial Disorders

The mitochondrial disorders represent a group of diseases in which defects in the oxidative metabolism are found due to inborn defects in the mitochondria. Although these defects affect all cells in the body, organs with a high demand for energy such as brain, muscle and heart are most affected clinically.

Mitochondria are responsible for the utilization of oxygen and conversion of fatty acids, carbohydrates and proteins into energy, by producing adenosine triphosphate (ATP). Mitochondria have their own DNA (mtDNA). They

are also influenced by DNA in the nucleus (n-DNA). Defects in either type of DNA can seriously affect the vital functions of mitochondria. When mutations occur which affect mitochondria the vital supply of ATP is disrupted and the systems or organs begin to fail.

Understanding of mitochondrial disorders was scanty until recently, but with advances in molecular genetics, mitochondrial disorders are increasingly being recognized. Frequency of mitochondrial dysfunction is one in 4000 of the population. Mitochondrial disorders have a wide variety of symptoms. Different persons having exactly the same defect in their mtDNA may differ in their clinical manifestations. Some mitochondrial disorders are not manifest until adulthood and some never cause symptoms. Some are so severe that the victim dies in infancy itself.

Individuals with mitochondrial disorders may present with a wide spectrum of clinical manifestations. These include the following neurological features:

- i. Poor growth and development
- ii. Loss of motor control
- iii. Muscle weakness
- iv. Visual or hearing impairment
- v. Mental retardation
- vi. Seizures

In addition, affection of other organ systems such as cardiac disease, gastrointestinal diseases, respiratory disorders, diabetes mellitus, liver diseases, renal dysfunction and susceptibility to infection may manifest.

Three types of inheritance can occur:

- i. Maternal inheritance due to defects such as point mutations, deletions or duplication in the mtDNA, derived from the mother.
- ii. Autosomal (dominant or recessive) inheritance due to defects in the n-DNA contributed by both parents.
- iii. X-linked inheritance due to defect in the X chromosome.

Mitochondrial Myopathies

The historical term 'mitochondrial myopathy' is too restrictive since in most patients muscle is not the only tissue affected. Hence it has now been replaced by the more general term—*mitochondrial encephalomyopathy*, which includes the occurrence of widespread CNS and systemic involvement.

The symptoms of mitochondrial encephalomyopathies include muscle weakness or exercise intolerance, dementia, movement disorders, stroke like episodes, deafness, blindness, seizures and ataxia. The disorders range in severity from progressive weakness to premature death. The age of onset ranges from birth to adulthood and the majority of cases occur by the age of 20 years. Some of the more common mitochondrial disorders include:

- i. **Kearns-Sayre syndrome:** Progressive external ophthalmoplegia, pigmentary retinopathy, heart block, cerebellar syndrome and increase in CSF protein (> 100 mg/dL)
- ii. **Myoclonic epilepsy** with ragged red fibers (MERRF)
- iii. **Mitochondrial encephalopathy**, lactic acidosis and stroke-like episodes (MELAS)
- iv. **Leber's optic atrophy**
- v. **Progressive external ophthalmoplegia** (PEO).

Muscle biopsy tissue, when stained with Gomori trichrome stain reveals characteristic muscle fibers with structurally abnormal mitochondria, known as ragged red fibers (RRF) because of the staining appearance.

There is no specific treatment for any of the mitochondrial encephalomyopathies. Occupational therapy and physiotherapy serve to keep the muscles functional for longer periods. Vitamin therapies such as riboflavin, coenzyme Q, vitamins C and K and carnitine may improve muscle function in some patients. Prognosis varies greatly depending upon the type of the disorder and other individual factors.

Chapter Summary

Structure of the Skin 1344
Clinical Examination 1346
Principles of Therapy 1347

Structure of the Skin

The skin is a major organ in the body with a surface area of 1.8 square m in an adult, constituting up to 16% of the total body weight. Skin is composed of three layers, the epidermis, dermis and subcutaneous tissue.

Epidermis

The epidermis which originates from ectoderm, is a stratified squamous epithelium about 0.1 mm thick. The thickness varies in different parts of the body. Its main function is to act as a protective barrier. Epidermis is mainly composed of keratinocytes, which produce a protein called keratin. It is devoid of blood vessels and lymphatics. It gets its nutrition from the underlying dermis. Histologically, the epidermis consists of four layers, the stratum basale, stratum spinosum, stratum granulosum and the stratum corneum.

Stratum basale (basal cell layer) is composed of columnar cells. This layer rests on a basement membrane, which attaches it to the dermis. These cells are attached to the basement membrane by attachment plaques called hemidesmosomes. 30% of basal cells divide. One of the daughter cells moves into the suprabasal layer and differentiates and synthesizes keratin. Stem cells reside amongst the basal cells and divide in response to injury.

Melanocytes, seen as clear cells in between the basal keratinocytes, constitute about 5-10% of the basal cells. They arise from the neural crest. Melanocytes synthesize melanin and transfer it to neighbouring keratinocytes via the dendritic processes. Melanin granules are uniformly distributed in the stratum corneum and they reduce the ultraviolet radiation penetrating the skin. In the deeper layers of the epidermis, the melanin granules form a

protective cap over the outer part of the nucleus of the keratinocyte.

Stratum spinosum (prickle cell layer) is composed of 5-8 layers of polygonal cells called keratinocytes. These keratinocytes are interconnected by desmosomes which are seen as prickles on light microscopy. These desmosomes are specialized attachment plaques that contain desmoplakins, desmogleins and desmocollins. Auto-antibodies to these proteins are responsible for the various autoimmune blistering disorders. Tonofilaments are small fibres running from the cytoplasm to the desmosomes. Bundles of tonofilaments are called tonofibrils. In the superficial spinous layer, **lamellar granules** or **Odland bodies** which are derived from the golgi apparatus appear. They contain phospholipids, cholesterol and glucosylceramides, which are discharged into the intercellular space of the granular cell layer. These are the precursors for the lipids in the superficial layers which are very important for the barrier function of the skin.

Langerhan's cells are found mostly in this layer. These dendritic cells, derived from the bone marrow are the outermost sentinels of the cellular immune system. These cells are characterized by unique cytoplasmic organelles known as **Birbeck granules**, on electron microscopy.

Stratum granulosum (granular layer) is composed of 2-3 layers of flattened cells containing coarse basophilic keratohyaline granules which merge with the tonofibrils. These keratohyaline granules contain proteins like involucrin, loricrin and profillagrin. In the outer layers, these granules break up and their contents are dispersed throughout the cytoplasm, leading to keratinization. This tough peripheral protein coating is called the horny envelope.

Stratum corneum (horny layer) is composed of sheets of overlapping, flattened, non- nucleated, cornified, dead cells. The barrier function of the skin is due to the special properties of the horny layer. The cytoplasm is packed with keratin filaments embedded in a matrix with a peripheral tough protein coat inside the cell. These proteins bind to the lipids in the intercellular space by transglutaminases.

This envelope gives the corneocytes its toughness to withstand all the chemical and mechanical insults.

Keratinization

The epidermal keratinocytes undergo characteristic changes as they ascend and transform from undifferentiated columnar basal cells to fully differentiated horizontally aligned corneal cells. As the basal keratinocytes mature toward cornified cells, they lose their nuclei and cytoplasmic organelles and become filled with tonofilaments. This process is called *cornification* or *keratinization*.

Dermo-epidermal Junction

It is a highly specialized attachment between the epidermis and the papillary dermis. The various structures of the dermo-epidermal junction such as tonofilaments, hemidesmosomes, trilaminar plasma membrane, lamina lucida, anchoring filaments, basement membrane, anchoring fibrils, type III collagen and microfibrils provide attachment and support between the dermis and epidermis and also regulate the permeability across the junction.

Dermis

The dermis is a tough supportive connective tissue matrix found immediately below the epidermis. Its thickness varies from 0.6 mm on the eyelids to about 3 mm on the palms and soles. It is made up of connective tissue fibers like collagen (70%) and elastin in a ground substance of glycosaminoglycans.

The thin upper layer of the dermis is called papillary dermis which interdigitates with the epidermal rete ridges. The deeper thick layer is called reticular dermis with coarse bundles of collagen. The dermis also contains fibroblasts (which synthesize collagen, elastin, and the ground substance) dendritic cells, mast cells, macrophages and lymphocytes. The dermis shows epidermal downgrowths of hair follicles, the sebaceous glands and sweat glands. It also contains an extensive network of blood vessels and nerves. The caliber of the dermal blood vessels can be controlled by arteriovenous anastomoses that act as shunts. The blood vessels are under neural and hormonal control as in other parts of the body. This mechanism ensures a proper supply of blood to the cutaneous appendages like hair bulbs, sweat glands and sebaceous glands and also plays a major role in temperature regulation.

The cutaneous nerves in the dermis are both autonomic and sensory. The arterioles are supplied by adrenergic sympathetic nerves that mediate vasoconstriction. The adrenergic sympathetic fibers also supply arrectores pilorum muscles. The myoepithelial cells of the

apocrine and eccrine sweat glands are cholinergic sympathetic. The skin is devoid of any demonstrable vasodilator nerves. Free sensory nerve endings are seen in the dermis, also extending to the epidermis. There are specialized receptors called Pacinian corpuscles to detect pressure and vibration and Meissner's corpuscles in the skin of hands and feet, which detect touch. The free nerve endings that transmit pain also subserve the sensation of pruritus, the intensity of the stimulus being low.

Glands of the Skin

Sebaceous glands: These are of epidermal origin seen in close proximity of the hair follicles at the upper part of the dermis. They are most numerous on the scalp, face, front of the chest and back and they are absent on the palms and soles. Their secretion- sebum is formed by disintegration of the lining cells and this is not under neural control. The sebum is discharged to the surface through the hair follicle. The major components of sebum are triglycerides, wax esters, squalene, cholesterol esters and cholesterol. Sebum that is present on the skin surface inhibits microbial proliferation. The sebaceous glands hypertrophy during puberty under hormonal influences.

Apocrine glands: They are large coiled tubular glands opening into the hair follicles and their function is not clearly known. They are seen in the axillae, around the nipples, perineum and genital regions. Specialized apocrine glands are seen in the eyelids, and in the ear canal. Apocrine glands are surrounded by contractile myoepithelial cells that help to expel their contents. These myoepithelial cells derive their innervation from adrenergic twigs that respond to emotional stimuli.

Eccrine glands: Eccrine sweat glands are small coiled glands in the dermis whose ducts empty directly on to the cutaneous surface. Eccrine sweat produced in the gland by merocrine secretion (only the contents of the secretory vesicles are discharged, unlike in a holocrine secretion, the cells disintegrate to liberate their secretion) is colorless and odorless. They are more numerous over the forehead, axillae, palms, and soles though they are widely distributed throughout the body.

Heat and emotional stress are the main stimuli for sweat secretion. The temperature control center in the hypothalamus is able to detect minute changes in temperature and when excited, stimulates the number and the activity of sweat glands via sympathetic non-myelinated class C nerve fibers. Excessive body heat is dissipated by evaporation of sweat. Aldosterone prevents the loss of electrolytes in sweat by inducing re-absorption of sodium in the sweat ducts. Sweat moistens the skin of palms and soles and provides grip. Substances like griseofulvin, lead, mercury, ethanol and ketoconazole are excreted by eccrine glands. In healthy persons sweat contains all the

electrolytes found in the plasma or interstitial fluid but to a lesser extent.

Hair

Hairs are found over the entire surface of the skin with the exception of the glabrous skin of the palms, soles, glans penis and vulval introitus. The density of the follicles is greatest on the face. Embryologically, hair is developed from the primordial epithelial germ cells formed from the ectoderm. Hair follicle is formed by an invagination of the epidermis into the dermis.

In longitudinal sections a mature hair follicle consists of an infundibulum, isthmus, stem and bulb. The germinative cells are in the hair bulb, interspersed with melanocytes. The bulb encloses the follicular papilla which organizes and maintains the function of the hair follicle. Cut section of the hair shaft shows an outer cortex and an inner medulla.

The growth of hair is cyclical and different phases of follicle are, growing phase (anagen) which lasts for 3-10 years, involuting phase (catagen) which lasts for 2-3 weeks and the resting phase (telogen) which lasts for 3-4 months. The stem and the bulb shrink to form a thin column of epithelial cells in the catagen phase. When a new cycle of anagen phase begins, these residual undifferentiated epithelial cells proliferate and generate a new follicular matrix. At least 85% of hair follicles are in anagen phase at any one time.

There are three types of hair:

1. **Lanugo hairs** are fine and long and are formed in the fetus at 20 weeks of gestation. They are normally shed before birth, but may be seen in premature babies.
2. **Vellus hairs** are short, fine light coloured hairs that cover most body surfaces.
3. **Terminal hairs** are long, thick and dark and are found on the scalp, pubic and axillary regions, beard area, upper trunk and limbs. They originate as vellus hair and change into terminal hair at puberty under the influence of androgens.

Nails

The nail is a phylogenetic remnant of the mammalian claw and consists of hardened and densely packed keratin. It protects the finger tip, facilitates grasping and tactile sensitivity in the finger pulp. The nail matrix contains dividing cells which mature, keratinize and form the nail plate. The pink colour of the nail is due to the dermal capillaries and the white lunula is the visible distal part of the matrix. The nail plate rests on the nail bed. The nail plate grows at a rate of 0.1 mm/day for finger nail and the toe nails at a rate of 0.03 mm/day.

Functions of the skin: The skin has many vital functions.

1. The skin acts as a mechanical barrier to protect the deeper structures from external injury and invasion by microbes.

2. The eccrine sweat glands and the blood vessels of the skin play a major role in temperature regulation.
3. The skin regulates the loss of body fluids by altering the rate of perspiration.
4. Melanin pigment protects the skin from the harmful effects of ultraviolet rays.
5. Skin acts as a major sensory organ receiving all superficial sensations.
6. Vitamin D synthesis occurs in the skin on exposure to sunlight. Twenty minutes of exposure can supply the day's need of vitamin D.
7. Dendritic cells in the skin play a major role in immune surveillance.
8. Sebum has antimicrobial properties.
9. Several drugs and chemicals are absorbed through the skin when applied in suitable vehicles. This property has been made use of in therapeutics.

Clinical Examination

Skin disorders are widespread in India contributing to 20-25% of the total attendance in any general hospital. The skin closely reflects the disorders occurring in the internal organ systems and several cutaneous disorders have systemic manifestations. Therefore, clinical examination of the skin is not complete without a full systemic examination. Examination should be done under conditions of proper lighting, preferably natural light.

Descriptive Terms

The initial lesions that herald the onset of any dermatological disorder are called primary lesions. Secondary lesions are those that develop during the course of the disease.

Primary Lesions

Macule: is an alteration of color of the skin up to 1 cm in diameter and is flush with the surrounding normal skin. A macule more than 1 cm is called a *patch*.

Papule: is a solid elevated lesion up to 1 cm in diameter. A papule more than 1 cm is called a *plaque*.

Vesicle: is a clear fluid filled lesion up to 1 cm. A vesicle more than 1 cm is called a *bulla*.

Pustule: is a small vesicle containing pus. An *abscess* is a deeper and localized collection of pus in a cavity more than 1 cm in diameter.

Nodule: This is a solid elevated mass, more than 1 cm in diameter and depth, better palpated, than seen.

Wheal: is an evanescent edematous skin lesion. It may be erythematous, skin colored or pale.

Purpura: is a hemorrhagic macule or papule that does not blanch on pressure. Larger lesions are called *ecchymoses* and pinpoint lesions are called *petechiae*.

Burrow: is a tunnel produced by the movement of a parasite within the tissue. It is seen as a straight or zigzag line that may be grayish.

Comedones: are dark plugs seen inside the opening of a hair follicle.

Telangiectasia: is the visible dilatation of the small cutaneous blood vessels.

Secondary Lesions

Scales: Visible dry exfoliation of the horny layer.

Crust: Dried up discharges such as serum, pus or blood.

Erosion: An area of denuded skin due to a complete or partial loss of the epidermis.

Ulcer: Discontinuity in the skin due to a loss of epidermis as well as part or whole of the dermis.

Excoriation: Superficial denudation of the skin due to scratching.

Atrophy: Thinning of the skin (epidermis, dermis or subcutaneous fat). With epidermal atrophy, the skin becomes shiny, translucent and wrinkled. Atrophy of the deeper tissues leads to depression in the skin.

Fissure: A slit or linear tear in the epidermis.

Scar: The replacement of normal structures by fibrous tissue when a tissue heals at the site of injury.

Lichenification: Visible and palpable thickening of the epidermis with accentuated skin markings.

Induration: Thickening of the dermis that makes the skin feel more thick and firm.

Principles of Therapy

Locally applied drugs as well as systemic drugs are employed for the treatment of dermatological diseases. The fact that locally applied drugs exert their action in addition to systemic drugs is an added advantage. Many disorders respond to local therapy, some require a combination of local and systemic therapy, while a third group requires only systemic therapy. In a limited number of cases surgical as well as electrosurgical measures may also be necessary.

Local therapy: The advantages of local therapy are: (i) achievement of a high concentration of the drug at the site of lesion, which is not generally obtainable by systemic therapy, (ii) freedom from serious adverse side effects, and (iii) even drugs which cannot be administered systemically can be given locally. Though drugs applied over the skin are not absorbed significantly, systemic toxicity becomes a problem with many drugs, especially if applied over extensive raw areas for prolonged periods.

Modes of local therapy: *Compresses, soaks and baths:* These help in mechanically removing the exudates, poorly formed crusts, tissue debris, remnants of previously applied medicines, etc. The absorption of a drug from the local site is facilitated if it is administered after applying compresses, soaks or baths. Compresses and soaks are given for localized lesions, whereas baths are given for more extensive and generalized disorders.

Potassium permanganate, sodium chloride, liquor picis carbonis, ichthyl or sodium bicarbonate is added to the compresses, soaks and baths to enhance their therapeutic value.

Vehicle or base: For local applications, the active ingredients are dissolved or suspended in a vehicle called the base, the main function of which is to keep the ingredients in contact with the lesion. The base is selected according to the type and location of the lesion and also the solubility and compatibility of the active ingredients with the base. Commonly used vehicles are water, glycerine, alcohol, cream, petrolatum, and talcum.

Astringents: These are agents which when applied on raw areas of the skin, react with tissue proteins to form a protective covering on the surface. They help to reduce the pain. Liquor aluminium acetate, liquor plumbi subacetate and silver nitrate are commonly used astringents.

Soothing agents: These are applied to relieve pain, burning, and pruritus, generally associated with inflammation of the skin. Alleviation of these symptoms is achieved by the evaporation of the water component of the medication which produces a cooling effect and vasoconstriction. All aqueous preparations can act as soothing agents, e.g. calamine lotion and cream.

Emollients: These form a thin greasy layer over the surface of the skin and prevent evaporation of water from the stratum corneum. Vaseline, oils, cream, and glycerine are the commonly used emollients.

Antipruritic agents: Itching is the most common and troublesome complaint in dermatological disorders. No doubt, specific therapy is the ideal way to abolish this symptom, but when this is not possible or immediate relief is to be provided, symptomatic therapy is indicated. Chloretone (butyl chloral) which is an analogue of chloral hydrate is a safe antipruritic agent in a concentration of 3-5%. Menthol, camphor, and phenol in acceptable concentrations are also effective.

Keratolytic agents: These are employed for promoting desquamation of scales or removal of thickened stratum corneum. They are useful in the treatment of disorders like palmoplantar keratoderma, ichthyosiform dermatoses, psoriasis, and dermatitis associated with lichenification. Salicylic acid, urea and resorcin are commonly used keratolytic agents.

Anti-inflammatory agents: These agents reduce the severity of inflammation and minimize tissue damage when employed with other specific therapy. Though mild inflammatory processes can be controlled with soothing agents, severe inflammatory responses demand the use of drugs like corticosteroids, gentian violet and ichthyol. The commonly used corticosteroid preparations include betamethasone valerate (0.12%), flucinolone acetonide (0.025%), fluticasone propionate 0.05% hydrocortisone 1%, clobetasol propionate 0.05% and others.

Antibacterial agents: Topical antibacterial agents play an important role in the treatment and prophylaxis of microbial infections of the skin, especially infections of the epidermis and dermis. The commonly used topical antibacterial agents are neomycin, polymyxin, framycetin, gentamicin, silver sulfadiazine, fusidic acid and mupirocin.

Hexachlorophene, povidine iodine, benzalkonium chloride and chlorhexidine have been used as antiseptics, particularly in the context of disinfection of skin prior to surgical procedures. Topical antibacterial agents are used prophylactically in trauma, cuts, wounds and burns.

Sun screens: These are used to protect the skin from sunlight. These may act as reflectors or absorbers of light. Reflectors help to prevent the rays from entering the skin whereas chemical absorbers absorb sunlight. Agents like para-aminobenzoic acid, benzophenones, avobenzones, tannic acid, titanium dioxide, and zinc oxide are usually employed as sun screens.

Occlusive dressings: These are employed when a drug is to be applied in close contact with the skin and it is to be kept in position to favour absorption and prolonged action. Moreover, the moisture released by the skin helps to soften the lesions and favour resolution, e.g. psoriasis.

Infections of the Skin and Appendages

Usha Vaidhyathan

Chapter Summary

- Normal Microbial Flora 1348
- Bacterial Infections 1349
- Viral Infections 1350
- Fungal Infections 1352

Normal Microbial Flora

A healthy normal skin is colonized by a variety of non-pathogenic microorganisms. This constitutes the normal flora of the skin. It is classified into resident flora and transient flora. Resident flora includes bacteriae that grow on skin and are relatively stable in number and composition. Some organisms linger briefly on the skin in small numbers before disappearing, unable to multiply and thrive in the relatively inhospitable environment. These are labelled as temporary residents or transients. Most of the organisms reside on the surface of the stratum corneum in the crevices between squames in the

loose outermost layers. The hair follicles are inhabited by anaerobes like *propionibacterium* species. Streptococci are usually absent, but may be found as transient residents on perioral skin, from the mouth. Coagulase positive *S. aureus* should not be considered as a resident on healthy skin although it is frequently found in the anterior nares and perineum and on damaged skin in eczema or psoriasis. Of the coagulase negative staphylococcus species, *S. epidermidis* and *S. hominis* are the most important. Other resident flora are *micrococcus* (intertriginous areas and scalp), *corynebacterium* species (axilla), *propionibacterium* species (face, scalp, axilla), gram negative organisms (axilla, toe webs, nose) and fungi like *pityrosporum* (scalp) and *candida* species (intertriginous areas). The resident flora prevents colonization by pathogenic organisms and also other commensal flora.

An intact stratum corneum is the most important defense against invasion by pathogenic bacteriae. Skin infection results when the skin defenses are compromised

due to physical factors such as excessive hydration, occlusion and systemic factors like immunosuppression.

BACTERIAL INFECTIONS

Pyoderma

Pyoderma is an infection of the skin caused by pyogenic organisms. *Staphylococcus aureus* and group A beta hemolytic *streptococcus* are the most common. Less commonly *Pseudomonas*, *E. coli* and other organisms can also invade the skin. Pyoderma may be primary or secondary.

Primary pyoderma occurs in previously normal skin. It is caused by a single group of organisms and has a characteristic morphology.

Secondary pyoderma occurs in skin previously damaged by other diseases such as scabies, fungal infection, eczema and others.

Primary Pyoderma

Impetigo: Impetigo is a superficial infection of the epidermis due to *Staphylococcus aureus* and occasionally Group A beta hemolytic streptococci. There are two types—non-bullous (impetigo contagiosa) and bullous impetigo.

Impetigo contagiosa commonly affects the face of small children, but any site can be involved. It begins as transient superficial small vesicles or pustules on an erythematous base that soon rupture and form erosions and crusting (golden yellow crusts) (Fig. 205.1). If the lesions persist, central clearing can occur and may become confluent. Complications include cellulitis and post-streptococcal glomerulonephritis.

Bullous impetigo is common in neonates and infants, but can occur at any age. 80% are caused by *Staphylococcus aureus*, phage group 2, type 71 and 55. Vesicles and bullae containing yellow fluid arise on normal appearing skin

without surrounding erythema and persist for a few days. Lesions rupture and varnish like yellow crusts are formed. Lesions can occur anywhere and commonly involves intertriginous areas.

Ecthyma: Commonly it affects the distal extremities. The infection extends up to the dermis. It presents as a purulent tender indurated ulcer with adherent crust and surrounding erythema. Healing occurs with scarring.

Folliculitis: Folliculitis is the infection of the hair follicle mostly due to *Staph. aureus* and appears as pustules with a hair or follicular orifice at the center. Chronic folliculitis of the legs is a common problem in India. Mostly it affects the shin of young males. The pustules are chronic, recalcitrant and cause atrophy on healing. A deep folliculitis involving the whole depth of the hair follicle, affecting the beard (*sycosis barbae*) and nape of the neck (*sycosis nuchae*) is also described.

Furuncle: Infection of the hair follicle and perifollicular region is called furuncle or boil. It is an extremely painful follicular nodule that may suppurate and become an abscess. Common sites are neck, face, scalp, axilla, perineum, buttocks and thighs.

Carbuncle is a deep infection extending up to the subcutaneous tissue, involving a group of contiguous follicles, with multiple discharging points on the surface. The common sites are the back of the neck, shoulders, hips and thighs. It is frequently associated with diabetes mellitus and immunocompromised states.

Erysipelas: is an acute streptococcal infection of the dermis. Streptococci can enter only through a damaged skin. It presents as an erythematous, edematous, elevated, indurated and well-demarcated lesion, commonly on the face and the legs. There may be vesiculation at the periphery in acute cases.

Cellulitis is an acute, sub-acute or chronic streptococcal infection affecting the deeper subcutaneous tissue. The margins are indistinct, and not elevated unlike as in erysipelas. Common sites are the legs but any area can be involved.

Treatment: Majority of the cases need systemic antibiotics. Cloxacillin 500 mg qid or first generation cephalosporins like cephalexin 500 mg qid are preferred. Supportive therapy includes improvement of local hygiene, elimination of any predisposing factors, saline compresses for crusted lesions and topical antibiotics.

Fig. 205.1: Impetigo on the leg

Points to remember

- Intact stratum corneum is the most important defense against invasion by pathogenic bacteriae.
- Staphylococcal infections include impetigo, ecthyma and folliculitis.

- Streptococcal infections are erysipelas and cellulitis.
- Staphylococci and streptococci cause secondary infection of eczema or leg ulceration.
- Cloxacillin and first generation cephalosporins are preferable.

Viral Infections

Verrucae (syn: warts)

Warts are common benign epithelial hyperplasia due to infection with human papilloma viruses (HPV). Papilloma viruses are double stranded DNA viruses of the PAPOVA class with host and tissue specificity. They infect squamous epithelia of the skin and mucous membrane causing cell proliferation. The virus infects the basal layer of the epithelium, but viral replication takes place in fully differentiated cells of upper stratum spinosum and stratum granulosum. After initial infection, HPV may persist in a latent form and may be reactivated later leading to recurrence of lesion. More than 150 types of HPV have been identified and some types have a role in the oncogenesis of cutaneous malignancies. The virus infects by direct inoculation and spreads by skin-to-skin contact. Common clinical patterns are:

Common warts: These present as dome shaped papules with verrucous surface commonly on the hands (Fig. 205.2) and feet, but can affect any site. Some warts are *filiform* with fine digit like projections (Fig. 205.3).

Verruca plana: These are smooth flat topped papules, often multiple, commonly seen on the face and dorsa of the hands and these resolve spontaneously. Koebner's phenomenon is seen frequently (i.e.) new warts forming over sites of trauma.

Plantar warts: are seen on the pressure points of the soles of the feet. They are painful. When pared, reveals dark punctate spots due to thrombosed capillaries. Multiple warts can coalesce to form a *mosaic wart*.

Genital warts: are sexually transmitted, but sometimes the transmission may be non-venereal. Genital warts have a high infectivity. In one study, around two-thirds of sexual

Fig. 205.3: Filiform wart on the thigh

contacts of patients with genital warts developed lesions within 9 months. They affect the penis in males, perianal area in homosexuals and the vulva, perineum and vagina in females. The warts may be small or may be large cauliflower like *condylomata acuminata*. Rectal and cervical warts have to be identified and followed up because of the risk of malignant change. Sexual partners should be examined.

Management: In children, 30-50% of common warts resolve spontaneously within 6 months. The common modalities of treatment for different types of warts are as follows.

Hand and foot warts: Salicylic acid and lactic acid in a liquid formulation is applied daily till resolution. Other modalities of treatment include cryotherapy (liquid nitrogen at -196°C) sprayed on to the lesions and intralesional bleomycin for resistant warts. Periungual and subungual warts are difficult to treat and relapses are common.

Genital warts: Podophyllin (25%) applied under supervision weekly till resolution or podophyllotoxin (0.5%) self application, twice daily for 3 days/week for 4 weeks yields good results.

Filiform and large perineal warts: Curettage and electro-desiccation are effective.

Laser surgery is a very specialized treatment at present for any type of wart.

Points to remember

- Hand and foot warts are common and often resolve spontaneously. Duofilm application and cryotherapy are effective treatments.
- Plane warts on the face are treated by electro-surgery
- Plantar warts are painful and when pared reveals dark punctate spots.
- Genital warts are transmitted sexually. Treated by podophyllin or cryotherapy.

Note: Liquid formulation containing salicylic and lactic acids is marketed as duofilm by Stiefel Ltd.

Fig. 205.2: Verrucae on the index finger

Fig. 205.4: Molluscum contagiosum on the left knee. Note the central umbilication on the papule

Molluscum Contagiosum

Molluscum contagiosum is a self limiting epidermal viral infection caused by Molluscum contagiosum virus, a DNA pox virus. It mainly affects children or young adults. Spread is by contact, fomites or sexual route.

It presents as discrete, multiple, grouped, umbilicated, pearly, dome shaped papules with a central punctum and if squeezed, releases a cheesy material (Fig. 205.4). Lesions are commonest on the face, neck and trunk.

Diagnosis can be confirmed by incising one of the papules, smearing the contents between two slides and staining with gram's stain. *Molluscum bodies* or *Henderson Patterson bodies*, which are cytoplasmic masses of virions, appear as ovoid, homogenous inclusion bodies. The host cell is pushed to the periphery giving a signet ring appearance to the cell.

In healthy individuals, molluscum lesions persist for 6 months to 2 years and then undergo spontaneous regression. Such lesions undergoing spontaneous regression have an inflammatory erythematous halo. In HIV infected individuals, lesions persist and proliferate even after aggressive therapy. Lesions resolve with highly active anti retroviral therapy (HAART). Painful aggressive therapy is not indicated. Lesions spread by autoinoculation and cause cosmetic disfigurement. Treatment includes curettage, phenol cautery, cryotherapy, duo film (avoided on the face lesions) and electrodesiccation.

HERPES SIMPLEX

(See also Section: 6)

Herpes simplex is a primary or recurrent mucocutaneous disease caused by Herpes simplex virus (HSV), a DNA virus that infects only humans. There are two serotypes, HSV 1 and HSV 2. HSV 1 is the primary agent in orofacial herpes and HSV 2 is involved in genital infections. Overlap does occur. After the primary mucocutaneous infection, the virus enters the sensory

ganglia and remains dormant until reactivation. Precipitating factors for recurrence include ultra violet radiation, menstruation, fever, common cold, and altered immune states.

Clinical features: *Primary infections* are preceded by a prodrome of local tenderness for a day or two. *Gingivostomatitis* is the most frequent manifestation and presents as vesicles, erosion and maceration over the entire buccal mucosa. There is marked erythema and edema of the gums. There is often severe pain and tender lymphadenopathy making it difficult to eat or drink. *Recurrent lesions (cold sores)* are usually preceded by a burning or tingling sensation for several hours. Multiple grouped vesicles on a normal or erythematous skin appear at the site of premonitory symptoms. The lesions heal within 7-10 days. The most common sites are the lips, perioral area, cheeks and nose, though it can occur anywhere. Intraoral lesions are extremely rare in recurrence, except in immunocompromised hosts.

Inoculation herpes occurs when secretions containing the virus come in contact with abraded skin anywhere on the body. In wrestlers and rugby and football players, transmission occurs during contact sports. This is known as *herpes gladiatorum*. Painful vesicles, erythema and edema associated with lymphadenopathy on the fingers and hands, called *herpetic whitlow* is commonly an occupational hazard in health care professionals especially dental personnel. This is uncommon after the universal precautions are followed.

Cutaneous HSV infection in immunodeficiency causes significant morbidity. Lesions may persist for months. Dissemination can lead to esophagitis, hepatitis and pneumonia. Pre-existing skin conditions such as atopic dermatitis predispose patients to develop widespread cutaneous disease called *eczema herpeticum* or *Kaposi's varicelliform eruption*. The infection spreads via the damaged skin surface and so complications from viremia are rare. It is associated with fever and lymphadenopathy. The eruption lasts for 2-6 weeks.

Neonatal HSV infection occurs when the mother has an acute primary genital herpes infection. If untreated, neonates have a risk of visceral and CNS involvement and a mortality rate of over 50%.

Genital herpes in a pregnant woman at the time of delivery is an indication for caesarean section, as neonatal infection can be fatal. Genital herpes is covered under the section sexually transmitted diseases.

Treatment

General measures: The area should be kept dry and clean. Secondary infection, if present should be treated.

Specific therapy: Acyclovir in a dose of 200 mg 5 times daily or 400 mg thrice daily for 10 days in primary

infections and for 5 days in recurrent infections is the preferred drug. To prevent frequent attacks, prophylactic treatment with 400 mg twice daily for many months or even years may be required. Except for transient renal dysfunction following rapid IV infusion, side effects are uncommon. Valacyclovir has greater bioavailability than acyclovir. Recommended doses are 1 g bid for 10 days for primary infection, 500 mg bid for 5 days for recurrent infection and 500 mg once daily for suppressive therapy. Famciclovir 250 mg tid for 5-7 days is an effective alternative.

Points to remember

- Type 1 HSV infection has usually orofacial lesions- childhood onset.
- Type 2 HSV infection occurs in genitalia- adult onset.
- Characterized by recurrent grouped vesicles that leave superficial erosions at the same site
- Acyclovir is effective.

HERPES ZOSTER

This is caused by varicella zoster virus which belongs to the Human Herpes Virus (HHV) group. Varicella zoster virus causes two distinct clinical entities, varicella (chicken pox) and herpes zoster (shingles). This is discussed in detail in chapters 53 and 184.

Herpes zoster begins with segmental pain and the rash appears 3-5 days later as grouped papules progressing to vesicles, pustules and crusts. The lesions appear first posteriorly and progresses to the anterior and peripheral distribution of the nerve involved. Mucous membrane within the dermatosis is also affected. Thoracic nerves are most commonly involved. The areas of distribution of the trigeminal and facial nerve are also commonly involved.

Differential diagnosis includes zosteriform herpes simplex, localized bacterial infection and phyto contact dermatitis. Pre-eruption neuralgia may be mistaken for other painful conditions. Once the eruption occurs, the diagnosis becomes evident. The most common complication of zoster is post herpetic neuralgia, defined as pain persisting after the cutaneous lesions have resolved. This is common in the elderly.

Treatment

General measures: Cool compresses and application of a drying agent like calamine lotion is soothing. Analgesics and systemic antibiotics (if secondary infection occurs) are required.

Specific measures: In elderly and immunosuppressed oral acyclovir 800 mg 5 times daily or valacyclovir 1 g bid or famciclovir 250-500 mg tid for 7-10 days is advised. Treatment should be started within 2-3 days of the onset of eruption.

Points to remember

- Reactivation of the virus in the posterior root ganglion leads to grouped vesicles in a dermatomal pattern.
- Thoracic and trigeminal areas are commonly involved.
- Post-herpetic neuralgia is common in elderly.
- Dissemination suggests underlying immunosuppression
- Oral acyclovir is the mainline of treatment.

Orf: This is primarily a disease of sheep. This virus can infect human beings by contamination. It manifests as painful purplish nodules on the exposed parts of the body like hands, arms, legs and face. It heals spontaneously in 4-6 weeks.

Milker's nodule: is caused by pseudo-cowpox or para pox virus which normally infect cattle (papular lesions occur on the oral cavity and on teats of cows) and only accidentally cause infection in humans. The manifestation is similar to Orf.

Cowpox: This is a zoonotic infection accidentally transferred to humans from cattle. Cowpox is caused by vaccinia virus (*cowpox virus*). In humans, lesions start as painful papules which evolve into vesicles and then to umbilicated pustules surrounded by erythema, finally developing in to an eschar or ulcer. Fever and local lymphadenopathy are common. Multiple lesions occur on the face or hands, which resolve in 3-4 weeks.

Fungal Infections

Dermatophytoses are caused by a group of filamentous fungi known as dermatophytes or ringworm fungi. There are three genera of dermatophytes. Trichophyton (T), Microsporum (M) and Epidermophyton (E). The dermatophytes are termed geophilic, zoophilic or anthropophilic depending upon whether their normal habitat is the soil, animal or man respectively.

Dermatophytosis is commonly classified depending upon the site of infection as tinea capitis (head), corporis (body), cruris (crural region), pedis (feet), manuum (hands), faciale (face), barbae (beard region) and tinea unguium (nails).

Tinea Capitis

Tinea capitis is the dermatophyte infection of the scalp hair and scalp skin. It is common in Asia, Africa and southern and eastern Europe. It is primarily a disease of the prepubertal children between 6-10 years of age and is more common in males. It spreads by direct contact from infected humans or animals such as dogs, cattle, horses, rodents and others. *M.audouinii*, *T. tonsurans* and *T. violaceum* are commonly associated with tinea capitis. There are four distinct clinical types.

Fig. 205.5: Inflammatory tinea capitis.
Note the inflammation and crusting

Fig. 205.6: Erythematous annular plaques of tinea corporis on the upper chest

1. *Grey patch type*: presents as circular scaly patches of alopecia. Hairs are broken off 2-3 mm above the scalp surface. The infected hairs show green fluorescence under Wood's light.
2. *Inflammatory type (kerion)*: presents as a painful inflammatory mass or a boggy swelling with crusting, oozing of pus and matting of adjacent hairs (Fig. 205.5). Hairs that remain are easily detachable. This is often caused by zoophilic species like *T. verrucosum* or *T. mentagrophytes*.
3. *Black dot type*: There are irregular scaly patches of alopecia with a black dot appearance due to the breaking of affected hairs at the scalp surface.
4. *Favus*: is uncommon. Yellowish crusts (scutula) around follicular openings with a foetid odor are characteristic.

Treatment

The recommended treatment in children is oral griseofulvin in a dose of 10-15 mg/kg/day for 6-8 weeks. Treatment is to be continued till hair re-grows. Alternative treatments include 1) Terbinafine in a dose of 62.5 mg/day for children < 20 kg, 125 mg/day for those of 20-40 kg and for those >40 kg, 250 mg/day is recommended for 4 weeks. 2) Itraconazole in a dose of 3-5 mg/kg for 4-6 weeks is also effective. Topical azole creams can be adjunctive to oral therapy, but not by themselves curative.

Prevention

1. Avoid sharing of combs and brushes.
2. Asymptomatic carriers should be traced and treated.
3. Family contacts should be screened.
4. Source of infection like pets should be identified and treated.

Fig. 205.7: Tinea faciale on the forehead

Tinea Corporis

Tinea corporis is the dermatophyte infection of the trunk, legs and arms. It presents as annular polycyclic lesions with erythematous raised vesicular and scaly border and a central clearing (Fig. 205.6). The frequent misuse of combination creams with steroids modifies this picture (Tinea incognito). Lesions on the face are called tinea faciale (Fig. 205.7).

Tinea barbae

Tinea barbae is the involvement of the beard hair. Clinical features are perifollicular pustules, papules, erythema, crusting and easy pluckability of hair.

Tinea cruris

Tinea cruris is the involvement of crural regions like axillae and groins and inframammary, abdominal and inter-gluteal folds which are warm and moist. Lesions are usually bilateral but asymmetrical. Prevention is by keeping the area dry and avoiding occlusive and synthetic

under garments. Other sites of infection should be identified and treated.

Tinea pedis

Tinea pedis presents as scaling, fissuring or maceration of the interdigital spaces of the feet, commonly the lateral two web spaces or as dry hyperkeratotic scaling of the soles and rarely as vesicular type involving the instep of soles. This is commonly acquired from communal bathing places and showers.

Prevention: Maintaining the feet dry, use of antifungal powders, cotton socks and avoidance of occlusive foot wear prevents recurrence.

Tinea unguium

Tinea unguium is the dermatophyte infection of the nails commonly due to *T. rubrum* and *T. mentagrophytes*. The nails become discoloured, thickened and friable. There is onycholysis (separation of nail plate from nail beds). Nail involvement usually starts from the distal end. *Onychomycosis* is a general term that includes infection of nails due to dermatophytes, non-dermatophytes and yeasts. Onychomycosis accounts for more than 50% of nail diseases.

Laboratory Diagnosis of Superficial Fungal Infections

Direct microscopic examination of fungal scrapings provides immediate confirmation of fungal infection. Scrape the active edge of a lesion with a scalpel and collect the scales on a glass slide. Add a drop of 10% potassium hydroxide and cover with a cover slip and heat gently, but not to boiling. Examine under low power of microscope (x10 magnification) after the slide cools. Dermatophytes appear as long septate and branched hyphal filaments without constriction at the branching points. Fungal species can be identified by culture in Sabouraud's medium.

Treatment

Dermatophyte infection of the skin usually responds to topical (1) Azoles like clotrimazole 1%, ketoconazole 2%, miconazole 2%, oxiconazole 1% or terconazole cream. (2) Allyl amines like terbinafine 1% and butenafine 1%. (3) Tolnaftate 1% or (4) Ciclopirox olamine 0.77%. Topical creams should be used at least 3 cm beyond the advancing margin of the lesion, twice daily for 2-4 weeks. Treatment should be continued for at least one week after the lesions have cleared.

Oral treatment is indicated for extensive lesions and for failure of response to topical therapy. Tinea capitis, tinea pedis and manuum requires oral treatment. The drug

of choice is terbinafine 250 mg/day for 2 weeks, and for scalp infection 4-6 weeks, for nail infection 3-4 months. Itraconazole 200 mg/day for 2 weeks and griseofulvin 250 mg bid for 4-6 weeks are also effective.

Points to remember

- Dermatophytes infect the body, groins, feet, hands, nails and scalp.
- Commonest pathogen is *Trichophyton rubrum*.
- Presents clinically as annular polycyclic lesions with raised scaly border and central clearing.
- Scalp infection is common in children.
- Topical imidazoles, tolnaftate and terbinafine are effective in mild infections.
- Oral terbinafine/griseofulvin are required for severe infections.

CANDIDIASIS

Superficial candidiasis is caused mostly by *Candida albicans*, though occasionally other species of *Candida* may be responsible. This organism is found as a commensal on the skin, oral cavity, and the gastrointestinal tract. Under favorable conditions of growth such as excessive moisture and maceration, immune deficiency, diabetes mellitus or treatment with tetracyclines or immunosuppressive drugs, this fungus multiplies and becomes invasive to cause disease. In its natural habitat the organism is found in the spore or yeast form but when it invades the skin or the mucous membrane, it grows to form pseudomycelium and the filaments can be demonstrated microscopically in skin scrapings. The source of infection is usually from the individual's own endogenous reservoir. In some cases person to person transmission can occur.

Candida affects the skin, mucous membranes of the mouth and genitalia, base of the nails, and the nail plates.

Oropharyngeal candidiasis can be classified into pseudomembranous (thrush), erythematous (atrophic), and hyperplastic.

Thrush is an acute infection and can be recurrent in immunocompromised patients. It is also seen in neonates and among terminally ill patients. It is characterized by white plaques often painless, on the surfaces of the buccal mucosa, tongue, hard and soft palate and tonsils (Fig. 205.8). The white pseudo membrane can be dislodged to reveal an eroded erythematous base. Involvement of the throat causes severe dysphagia. It is the most common form of candidiasis in patients with AIDS. In HIV infected individuals, the lesions are persistent and often spread to all parts of the mouth.

Erythematous (atrophic) type is often associated with broad spectrum antibiotic treatment, chronic corticosteroid use and HIV infection. It manifests as a flat red lesion, usually on the palate or dorsum of the tongue. The dorsum

Fig. 205.8: Oral thrush. White plaques on the hard palate

of the tongue is depapillated, shiny and smooth with restriction of tongue movement. The mouth is often tender.

Hyperplastic type (*candida leukoplakia*): This condition is important because 15-20% can undergo malignant transformation. It presents as dense opaque plaques, usually asymptomatic, on the inner side of the cheeks, or less commonly on the tongue. It is often associated with smoking or local trauma. The lesions cannot be rubbed from surface in contrast to the pseudomembranous type.

Chronic atrophic candidiasis (denture stomatitis) occurs in up to 60% of denture wearers. The characteristic presenting signs are chronic mucosal erythema and edema of the portion of the hard palate that comes in contact with the denture. It is often associated with angular cheilitis.

Angular cheilitis is most common in patients with moist, deep folds at the corners of the mouth. It has been reported in up to 20% of HIV infected persons. It presents as soreness, erythema and fissuring at the corners of the mouth.

Vulvovaginal candidiasis: The condition is often abrupt in onset, with intense pruritus and burning of the vulva and vagina with or without vaginal discharge. Vulval erythema and fissuring can spread to labia majora (Fig. 205.9). Perineal intertrigo with vesicopustular lesions may be present. The discharge is often thick and curdy, but may be thin or even purulent. Dyspareunia and dysuria are common.

Balanoposthitis: In men, genital candidiasis presents as soreness, edema, fissuring, papules and diffuse erythema of the glans penis and prepuce. Patients should be investigated for diabetes mellitus.

Cutaneous candidiasis: The lesions tend to occur in the folds of the skin, such as the groins and the inter gluteal folds, where the environment is warm and moist due to maceration and occlusion. Inter digital spaces can be

Fig. 205.9: Vulvovaginal candidiasis-whitish sodden appearance with erythema and fissuring

Fig. 205.10: Diaper dermatitis

involved. Predisposing factors include over weight and diabetes mellitus.

It presents as erythematous lesions with papules or vesicopustules and an irregular margin. The main lesion is surrounded by numerous small pustules called satellite lesions. Severe itching and burning sensation are common. Lesions on the interdigital spaces are seen as white fissures with surrounding erythema and maceration. It is common in individuals whose occupations necessitate frequent immersion of hands in water. This is often associated with paronychia of the same hand.

Diaper dermatitis in infants and chronically ill patients, is primarily an irritant dermatitis with super added candidal infection (Fig. 205.10).

Nail infection: Candidal infection accounts for 5-10% of all cases of onychomycosis. It is more common in women than men and in finger nails than in toe nails. Chronic paronychia usually begins in the proximal nail fold. Periungual skin is erythematous edematous and painful with absence of cuticle. Nails become discoloured. Bacterial super infection is common.

Diagnosis is confirmed by the microscopic demonstration in 10% potassium hydroxide mount, of oval thin-walled yeasts that bud on a narrow base and filaments which are either true hyphae or pseudohyphae.

Treatment

Oral candidiasis is treated with nystatin oral suspension 100 000 units/mL at 4-6 hours interval or clotrimazole mouth paints. The medication should be retained in the mouth for as long as possible. In HIV infected persons and other immunocompromised individuals, systemic drugs are preferred. Oral fluconazole 200 mg first dose, followed by 100 mg/day for 7-14 days is more effective than itraconazole or ketoconazole 200-400 mg/day for 14 days.

Vaginal candidiasis: Imidazole compounds like clotrimazole, miconazole or terconazole cream topically and intra vaginal clotrimazole pessaries daily for 6 nights are effective in vaginal candidiasis. Oral Fluconazole 150 mg as a single dose or Itraconazole 200 mg bid for one day is as effective as topical therapy. In recurrent candidiasis, ensure that the patient avoids the potential precipitating factors. Local treatment with clotrimazole (500 mg as a single dose) at 2-4 weeks interval, suppresses the symptoms. Oral Fluconazole 150 mg/week for 3-6 months is also effective. Penile and cutaneous candidiasis responds to topical imidazole creams like clotrimazole or ketoconazole, applied twice daily for 2-3 weeks.

Candidal paronychia responds to antifungal cream or lotion applied twice daily for 6 months. Nail damage should be managed with oral drugs. Itraconazole 200-400 mg/day for 6 weeks or pulse therapy (3 pulses of 400 mg/day for 1 week per month) is the treatment of choice. Terbinafine is less effective in candidal infections. Amorolfine nail lacquer applied once or twice weekly for 3-6 months is also useful.

Points to remember

- *Candida albicans* produces opportunistic infections of the body folds, oral and genital mucosa and nail folds.
- Commonly manifests as oral thrush which are painless white plaques. Common in HIV infection.
- Predisposing factors are humidity, obesity, diabetes and immunosuppression
- Topical imidazoles and oral fluconazole are effective.

PITYRIASIS VERSICOLOR

Pityriasis versicolor (syn; tinea versicolor) is a common, mild but often recurrent infection of the stratum corneum due to lipophilic yeasts of the genus *Malassezia*. These organisms can cause serious systemic infection in immuno-compromised and debilitated individuals. *Malassezia* species form part of the normal microbial flora of the human skin where it exists in the yeast form. Most

Fig. 205.11: Pityriasis versicolor on the upper limb. Note the classical wrinkled appearance

infections are endogenous in origin, but human to human transmission is possible. Pityriasis versicolor, pityrosporum folliculitis and seborrheic dermatitis are associated with *Malassezia* species. It is most prevalent in hot, humid tropical climates, where 30-40% of the adult population may be affected.

Clinical features: It presents as hypopigmented (Fig. 205.11) or fine brown scaly patches, particularly on the face, trunk, neck and upper arms. The lesions become confluent and have a polycyclic border. Different shades of lesions can be present in the same patient and so named as 'versicolor'. It is usually asymptomatic but some patients may have itching, especially on sweating. Pityrosporum folliculitis is characterized by multiple hypopigmented follicular macules, seen commonly on the trunk and arms.

Diagnosis: Scrapings for direct microscopic examination in 10% potassium hydroxide, shows a mixture of spherical thick walled yeast cells and a coarse mycelium fragmented to short filaments, having a classical 'spaghetti and meat balls' appearance. Their isolation in culture does not contribute to diagnosis because they form a part of normal cutaneous flora. The hyphae are diagnostic and demonstrated only in its pathogenic phase.

Differential diagnosis: Pityriasis versicolor is at times difficult to differentiate from Pityriasis alba. The borders are ill-defined, lesions are mostly on the face and the initial lesions may be erythematous in pityriasis alba. In pityriasis versicolor, the borders are usually distinct, the surface is wrinkled and scaly and the lesions may involve the chest and back.

Treatment: Selenium sulphide shampoo or ketoconazole shampoo applied to the affected areas for 10-15 minutes before bath for 1-2 weeks is effective. Topical imidazole creams such as clotrimazole, oxiconazole, miconazole and ketoconazole applied twice daily for 2-3 weeks are

effective. Topical terbinafine and butenafine are also useful. Oral terbinafine and griseofulvin are not effective in tinea versicolor. Oral therapy is reserved for patients with extensive lesions or recalcitrant infection unresponsive to topical therapy. Itraconazole and ketoconazole in

doses of 200 mg/day for one week and fluconazole 400 mg, two doses, 2 weeks apart are effective. It is very important to explain to the patient that the hypopigmentation may take a long time to clear and it is not necessary to continue the treatment till hypopigmentation clears.

Skin Infestations

Usha Vaidhyathan

Chapter Summary

Scabies 1357

Pediculosis 1358

Scabies

Scabies is an intensely pruritic disease of the skin caused by the ectoparasitic mite *Sarcoptes scabiei var hominis*. Transmission to a new host is by contact and through infested clothes and linen.

Pathogenesis: Infection of a new host is initiated by the pregnant female mite that burrows into the superficial layers of the skin to lay eggs. The pruritic lesions develop about four weeks after the initial infection.

Clinical features: The patient presents with pruritus that is worse at night, but in warm humid conditions it may occur throughout the day. Itching in the early states is confined to the sites of lesion, but it becomes generalized later on. The pathognomonic lesion is the burrow which is a curvilinear track made by the mite. Papules, pustules, vesicles and excoriations are seen in the webs of the fingers (Fig. 206.1), flexor aspects of the wrist, extensor aspects of the elbow, anterior axillary fold, nipple and areola in the female, umbilicus and periumbilical regions, genitalia, upper thighs, knees, and ankles. The lower part of the gluteal region is affected, but rest of the back is spared. In general the scalp, face, palms, and soles are spared. In children these areas can also be affected.

The lesions soon get secondarily infected with nephritogenic strains of group A streptococci and *Staph*

aureus and infection converts them into pustules. In some cases the lesions are crusted and scaly. This type is called **crusted scabies** or **Norwegian scabies**. In this type, in addition to classical areas of involvement, the scalp, face, ear lobes, and back may also be affected. Large number of organisms are present in these cases and it usually occurs in people with poor nutrition or immunosuppression.

When scabies affects infants and children, it tends to involve the scalp, palms, and soles as well. Vesiculation, secondary pyoderma, and eczematization are common. Whenever an infant presents with a suggestive lesion, examination of the mother is mandatory. The diagnosis of infantile scabies may be strengthened by the presence of lesions in the mother as well.

Persistent itchy nodular lesions (nodular scabies) on male genitalia, especially scrotum (Fig. 206.2) can be very troublesome.

Fig. 206.1: Classic scabies on the interdigital space

Fig. 206.2: Nodular scabies on the scrotum

Complications: Complications occur frequently. These include pyoderma, eczematization, and development of acute glomerulonephritis. One-third of the cases of acute glomerulonephritis in India, Africa, and many other tropical countries are attributable to infected scabies.

Diagnosis: is based on the classical clinical features like characteristic distribution, nocturnal aggravation of itching and a positive family history of similar disease. Diagnosis is confirmed by the demonstration of mite or its products, larva, egg or fecal matter (scybala). Scrapings are obtained from the burrows, and examined under low power of the microscope under a drop of mineral oil.

Treatment

General measures: It is mandatory to treat all family members and close contacts simultaneously. All clothes and bed linen are disinfected by laundering or hot ironing. Secondary infection should be treated with antibiotics before the initiation of topical antiscabietic treatment. Erythromycin 500 mg qid for 5 days or cephalixin 500 mg qid for 5 days or amoxicillin plus cloxacillin 250 mg each tid for 5 days are effective.

Specific treatment: Permethrin 5% cream is the drug of choice. Gamma benzene hexachloride 1% (GBHC) is also effective. Permethrin and GBHC are to be applied overnight over the entire body below the neck. In infants and pregnant women permethrin is safe. Benzyl benzoate 25% applied all over the body after a scrub bath, three applications 12 hour apart is an effective and freely available alternative. Ivermectin, a macrocyclic lactone, is a safe oral drug available for the treatment of scabies. 200 µg/kg body weight as a single dose on empty stomach is recommended in crusted scabies and in immuno-compromised hosts in addition to topical therapy. A second dose 7-10 days later gives better results. It is also effective in classical scabies. It is available as 3 mg and 6 mg tablets.

Points to remember

- Scabies is spread by direct contact.
- Intensely itchy papules in the classical sites- interdigital spaces of fingers, genitalia.
- Severe crusted lesions occur in immunosuppression.
- common predisposing factor for glomerulonephritis in India.
- Mites and its products can be demonstrated by microscopy on scraping the burrows.
- Overnight application of permethrin is the treatment of choice .

Pediculosis

Pediculosis or louse infestation is a worldwide problem. Poor living conditions and poor personal hygiene contribute to infestation. There are two species of blood sucking lice - *Pediculus humanus capitis* and *corporis* (head and body louse respectively) and *Phthirus pubis* (crab louse).

Pediculosis Capitis (Head Louse Infestation)

Adult head lice are 1-3 mm long, flattened dorso ventrally, have three pairs of legs that end in powerful claws. The female louse lives for about one month and lays up to 300 eggs (nits) during her life time. Eggs hatch in 6-10 days. Empty egg cases remain on hair shaft. Head louse is not a vector of infectious disease. The louse is transmitted through direct contact or through fomites. It commonly affects young girls with long hair. Itching is the main symptom. As the lice feed, they inject their digestive juices and fecal material into the skin and this causes severe pruritus. Secondary infection and occipital lymphadenopathy are common. Crawling lice or nits that are firmly attached to the hair can be seen with naked eyes.

Treatment: Permethrin 1% is applied for 10-15 minutes and then washed off. 1% GBHC applied for 5 minutes and malathion 0.5% applied for 8-12 hours are also effective pediculicides. Most of the pediculicides are not effective ovicides. A second application 7-10 days later is more effective. After treatment, the hair is wet combed with a fine toothed comb to remove nits.

Pediculosis Corporis

Body lice are present on the clothes of a person and causes severe itching, excoriations, and crusting when they come in contact with the body for a blood meal. Body louse transmits many infectious agents while feeding and spread diseases like epidemic typhus, louse borne relapsing fever and trench fever. Treatment includes maintaining good personal hygiene, application of insecticides to clothing and permethrin or GBHC to body hair.

Pediculosis Pubis

Crab louse spreads commonly by sexual contact. It is mainly seen attached to the pubic hair, but may spread to axillary hair, eyebrows and eyelashes. Patients will have severe itching and blue grey macules (*maculae cerulae*) on the lower abdomen and thighs. Secondary infection and regional lymphadenopathy are common. Oral Ivermectin 200 µg /kg body weight, 2 doses, 7-10 days apart is effective for all types of pediculosis.

Points to remember

- Head lice infestation is transmitted by direct contact especially between school children.
- Secondary infection is common.
- Body lice transmits diseases like epidemic typhus, trench fever and relapsing fever.
- Body lice are present on the clothes of the infected persons.
- Crab lice spread by sexual contact and are seen attached to the pubic hair.
- Topical permethrin 1% and oral ivermectin are effective.

207

Acne and Rosacea

Usha Vaidhyathan

Chapter Summary

Acne Vulgaris 1359

Rosacea 1360

ACNE VULGARIS

Acne vulgaris, a chronic inflammation of the pilosebaceous units, is an extremely common disorder, with peak prevalence during adolescence. Acne begins early in females, but is more severe in males. Acne usually persists until early 20's, although in a few patients, it may even continue into the fifth decade.

Aetiopathogenesis: Acne is multifactorial in origin. Major pathogenic factors include:

1. Defective keratinization of the follicular infundibulum, above the opening of the sebaceous duct initiates acne. Keratinocytes multiply and show enhanced cohesiveness thereby obstructing follicular channels. Cellular debris and sebum collect behind and forms a solid mass known as 'comedo'.
2. There is increased sebum production, which is primarily controlled by androgenic hormones. In some patients, elevated androgen levels have been documented. In others with normal androgen levels, the affected skin has increased sensitivity to androgenic stimulation.
3. Inflammation due to the proliferation of *Propionibacterium acnes* within the follicles.

Clinical features: The pathognomonic lesion is the comedo. Comedones are small papules that are either open with a dilated follicular ostium with black plugs of keratin (black head) or closed (white head). The comedones develop into inflammatory papules or pustules (Fig. 207.1) and sometimes nodules or cysts. Face is the commonest site of involvement, but back, shoulders and upper chest may also be involved. Lesions may leave behind post-inflammatory hyperpigmentation and scars. Severely inflamed lesions heal with small but deeper scars known as *ice-pick scars*.

Fig. 207.1: Acne vulgaris showing inflammatory papules and pustules

Variants of Acne

1. **Acne excoriée:** It is seen in depressed or obsessional young women who often squeeze the lesion. Picking and scratching the lesions lead to exacerbation of lesions.
2. **Infantile acne:** It is seen on the face of some infants, mostly males and disappears spontaneously.
3. Drugs like systemic/topical steroids and androgens induce acne.
4. **Acne conglobata:** It presents as severe acne with abscesses, burrowing sinuses and scarring.
5. **Occupational acne:** Exposure to cutting oils and lubricating oils cause acne due to occlusion at the site of contact. Oily cosmetics can also cause acne.

Management

General measures: Gentle washing of the face with soap and water without vigorous scrubbing is recommended. Cosmetics should be non-comedogenic. Diet has no effect on acne.

Specific therapy: In the early stages with comedones and papules, a topical retinoid such as tretinoin 0.025% to 0.1%, adapalene 0.1% or tazarotene 2.5% at night and benzoyl peroxide 5% in the morning would suffice. Topical retinoids cause dryness, scaling, redness and an initial flare of acne. Benzoyl peroxide (BPO) may produce a mild burning sensation for a short period of time. Topical retinoid and BPO should never be mixed. It may take a few weeks for the response to begin. The patients should be adequately warned, about these problems. Otherwise, the patient may discontinue treatment due to irritation and lack of response. Avoidance of sun exposure and use of sun block lotions diminish the side effects.

In the pustular stage, a topical antibiotic like clindamycin or erythromycin should be added. If no response, systemic antibiotics like tetracycline, doxycycline and minocycline for 2-3 months are very effective. Erythromycin is also useful. Long term treatment for at least 3 months is required. In severe recalcitrant cases, oral retinoids (isotretinoin) and hormonal therapy may be needed.

Management of Complications

Pigmentation and scarring can have profound psychological effects. Post acne pigmentation can be reduced to some extent by chemical peeling, e.g. 70% glycolic acid peels. Multiple sittings are needed.

Superficial scars improve with multiple sittings of microdermabrasion (Figs 207.2 and 207.3). Erythema and edema may develop immediately after dermabrasion. Aluminium oxide crystals are used to abrade the skin superficially. Many other cosmetic procedures like intralesional injection of triamcinolone into the cysts,

Fig. 207.2: Post-acne scars

Fig. 207.3: Superficial scars improved after 6 sittings of microdermabrasion

subcision, punch elevation and grafting and laser surgery are also useful.

Points to remember

- Peak prevalence in adolescence
- Abnormal keratinization of the follicular epithelium, increased sebum production and proliferation of *Propionibacterium acnes* are the main causes.
- Characterized by comedones, erythematous papules, pustules, cysts and scars on the face, chest and back
- Topical benzoyl peroxide, tretinoin, clindamycin and oral tetracycline, minocycline or erythromycin are used to control the lesions.
- Severe cases need oral antiandrogens or isotretinoin.

ROSACEA

Rosacea is a chronic inflammatory facial dermatosis characterized by erythema and pustules. The cause is unknown. Rosacea commonly affects middle aged females. The earliest symptoms are the intermittent episodes of flushing that resolve with increasingly permanent erythema and telangiectasia. Papules, pustules and occasionally lymphedema involve the cheeks, nose,

forehead and chin. Sunlight and topical steroids exacerbate the condition.

Rosacea is different from acne by the absence of comedones, occurrence in middle age group, presence of flushing and telangiectasia. Other differential diagnoses include seborrheic dermatitis, lupus erythematosus and photo sensitive dermatoses.

Complications include rhinophyma (hyperplasia of the sebaceous gland and connective tissue of the nose and ocular rosacea (blepharitis, conjunctivitis).

Treatment is with oral tetracycline 500 mg qid, or doxycycline/minocycline 100 mg once daily for 2-3 months. Topical metronidazole is helpful. Sun protection with sunscreens help to allay the condition.

208

Papulosquamous Disorders

Usha Vaidhyathan

Chapter Summary

Psoriasis 1361
Lichen Planus 1365
Pityriasis Rosea 1366
Reiter's Syndrome 1367
Exfoliative Dermatitis (Erythroderma) 1367

Psoriasis

Psoriasis is a chronic recurrent, papulosquamous disorder of the skin. It affects 2% of the world population. The sex incidence is equal. The disease can start at any age but the peak onset is in the second or third decades.

Etiopathogenesis*Genetics*

Psoriasis is a multifactorial genetic disease that requires both polygenic and environmental factors for its clinical expression. About 35% of patients have a family history. There are strong correlations with the HLA antigens Cw 6 and B 57.

Immunopathogenesis

Psoriasis has a T- cell mediated immunopathogenesis. There is an interaction between environmental, genetic and immunologic factors. Antigens may be environmental antigens, super antigens or auto antigens. These antigens

are taken up by the antigen presenting cells (APC) in the skin. These APC's migrate from the skin to the lymph nodes, where they encounter naïve T cells. These T cells become activated through a series of interactions with APC's. Once activated, T cells migrate back to the skin where they secrete pro-inflammatory cytokines such as interleukin 2 (IL 2) and interferon (IFN γ). This induces further production of cytokines including tumour necrosis factor (TNF α). These cytokines induce epidermal and vascular changes that lead to psoriatic plaques. TNF- α is involved in many important cellular functions such as proliferation, activation, migration and apoptosis. The actions of TNF- α initiate and maintain the inflammatory process.

Pathophysiology

Psoriasis is characterized by erythematous scaly plaques. The characteristic pathophysiological events that occur in lesional skin are:

1. Epidermal proliferation: There is an increase in the number of proliferating keratinocytes in the basal layer of the epidermis and there is loss of differentiation. This causes the thick silvery scale. The growth rate of psoriatic epidermis is up to 10 times that of normal epidermis.
2. Expansion of the dermal vasculature: The blood vessels in the upper dermis become dilated and hyper permeable and increased in number. This accounts for the erythema of the lesions.
3. Accumulation of inflammatory cells like neutrophils and T lymphocytes in the dermis and epidermis.

The lymphocytes play a key role in the disease process and epidermal changes are secondary and a consequence of the release of mediators from infiltrating lymphocytes.

Points to remember

- Affects 2% of the population.
- Peak onset in the second or third decades.
- Polygenic inheritance. 35% have a family history of psoriasis.
- Epidermal cell proliferation rate is increased.
- Mainly T-cell mediated immunopathogenesis.

Precipitating Factors

1. Physical trauma to the skin can precipitate psoriasis in the damaged skin. This is known as Koebner phenomenon. Rubbing and scratching stimulate the proliferative process.
2. Infection: Streptococcal infection precipitates guttate psoriasis.
3. Drugs: Beta blockers, lithium, antimalarials and withdrawal of systemic steroids aggravate psoriasis.
4. Exposure to sunlight can aggravate psoriasis in about 10% of patients, although in the majority, it has a beneficial effect.
5. Psychological stress can exacerbate psoriasis.

Pathology

The characteristic histologic picture of a fully developed skin lesion shows

1. Regular elongation of rete ridges with thickening in their lower portion.
2. Papillae are edematous with dilated capillaries.
3. Supra papillary thinning of stratum malpighii with the occasional spongiform pustule.
4. Absence of stratum granulosum.
5. Parakeratosis (nucleated stratum corneum cells).
6. Collection of neutrophils (*Munro micro abscess*) in the parakeratotic mounds.

Systemic involvement includes inflammation of joint structures leading to psoriatic arthropathy.

Clinical Features

Psoriasis widely varies in severity, appearance and behaviour. Presentation patterns of psoriasis are:

1. Psoriasis vulgaris
2. Guttate psoriasis
3. Flexural psoriasis
4. Localized forms
5. Pustular psoriasis
6. Erythrodermic psoriasis.

Psoriasis Vulgaris

Psoriasis vulgaris ('vulgaris' means common) is the

Fig. 208.1: Psoriasis vulgaris

Fig. 208.2: Multiple psoriatic lesions coalesced together

erythematous papules and plaques with silvery white scales (Fig. 208.1). On removal of the loosely attached scales, minute bleeding points are seen (*Auspitz' sign*). Papules and plaques coalesce to form polycyclic (Fig. 208.2) or serpiginous patterns. Sites of predilection of lesions are elbows, knees, scalp hair margin and sacrum. Lesions are bilateral and often symmetrical. Differential diagnosis includes seborrheic dermatitis, hypertrophic lichen planus, psoriasiform drug eruption (beta blockers, gold and methyl dopa), tinea corporis, secondary syphilis, lichen simplex chronicus and mycosis fungoides.

Guttate Psoriasis: (latin- gutta, 'drop')

Guttate psoriasis is an acute symmetrical eruption of a shower of small papular lesions usually on the trunk (Fig. 208.3). Adolescents or young adults are commonly affected. It often follows a streptococcal sore throat. It should be differentiated from pityriasis rosea, which has a classical morphology of oval papules with peripheral scaling and central wrinkling. The prognosis is good with spontaneous resolution but may evolve into chronic plaque psoriasis.

Fig. 208.3: Guttate psoriasis-drop like lesions

Flexural Psoriasis

Flexural psoriasis affects the axillae, groins, submammary areas and natal cleft. Due to the moist and warm environment in these regions, psoriatic plaques are usually not scaly, but erythematous and fissured. It is commonly seen in the elderly. The sharp demarcation permits distinction from intertrigo, candidiasis, contact dermatitis, seborrheic dermatitis and tinea cruris.

Localized Forms

Palmo-plantar psoriasis: Palms and soles may be the only areas involved. There is hyperkeratosis and scaling which is not easily removed. There may be painful fissures and bleeding (Fig. 208.4).

Scalp psoriasis: is characterized by sharply marginated pruritic plaques especially at the occiput with thick adherent scales. Lesions may be discrete or the entire scalp

Fig. 208.4: Plantar psoriasis

is involved. There is no hair loss. Scalp may be the only site involved or may be a part of generalized psoriasis. Scalp psoriasis has to be differentiated from seborrheic dermatitis. Seborrheic dermatitis is diffuse in distribution, whereas psoriatic lesions are patchy and have well defined edges. Silvery scales, if present are typical of psoriasis.

Psoriasis of the nails: Psoriasis affects the matrix or nail bed in up to 50% of cases. Thumb pitting is the commonest change, followed by onycholysis (separation of nail plate from the nail bed). Discoloration of the nail bed resembling an oil drop (**oil drop sign**) is seen adjacent to onycholysis. Subungual hyperkeratosis affects mainly the toe nails. Nail changes are frequently associated with psoriatic arthropathy. Treatment is often difficult, but the condition responds to oral methotrexate.

Pustular psoriasis: Pustular psoriasis is characterized by sterile pustules, not papules, arising on a normal or inflamed skin. It is classified into two types.

1. Localized pustular psoriasis
 - a. chronic palmo- plantar
 - b. acrodermatitis continua.
 2. Generalized pustular psoriasis (GPP)
 - a. acute GPP of von Zumbusch
 - b. GPP of pregnancy.
1. a. Chronic palmo-plantar pustular psoriasis is most common in females in the fifth or sixth decades. It presents as symmetrical well defined erythematous plaques studded with pustules. The lesions cause a burning sensation, and itching is variable. The thenar eminence of the palm, the instep, heel and borders of the feet are the common sites involved. Digital lesions are uncommon. It has a prolonged course and is refractory to treatment.
 - b. Acrodermatitis continua of Hallopeau is a chronic sterile, pustular form of psoriasis affecting the tips of fingers or toes, which tends to extend proximally. There is erythema, scaling and pustules. When the pustules dry up, they leave behind glazed, red and painful digits. The nails become dystrophic. It is common in children. It often evolves into GPP in elderly patients.
 2. a. Acute GPP of von Zumbusch (Fig. 208.5) is a serious life threatening form of psoriasis. It may develop from a pre-existing typical psoriasis, often after provocation by steroid withdrawal or other factors. It can begin later in life as an atypical acral or flexural psoriasis and rapidly progress to GPP. The eruption may begin with a sensation of burning with a dry tender skin and an abrupt onset of high fever and severe malaise. Generalized sheets of erythema and pustulation occur in crops and dries up into exfoliation. The configuration of lesions can be annular, circinate, plaques of erythema with pustular collarettes, isolated

Fig. 208.5: Generalized pustular psoriasis- pustules on an erythematous base on the chest and right arm

pustules, lakes of pus or erythroderma. Nails are dystrophic. Buccal mucosa and tongue may be involved (geographic tongue). Complications include hypoalbuminemia, hypocalcemia, renal and liver damage and deep vein thrombosis.

- b. GPP of pregnancy (*impetigo herpetiformis*) is very rare and it usually begins in the third trimester of pregnancy. Clinical features are similar to Von Zumbusch type of GPP. Constitutional symptoms are severe and may be fatal. Severe and long standing disease may cause placental insufficiency leading to still birth, neonatal death or fetal abnormalities. Fulminating disease is best treated with prednisolone. Methotrexate, retinoids or PUVA may be needed after delivery to wean off the steroid.

Erythrodermic Psoriasis

It is characterized by generalized (> 90% body surface area involved) erythema, scaling, and itching. It is a medical emergency requiring hospitalization (Refer erythroderma).

Psoriatic Arthropathy

Psoriatic arthropathy is a common sero-negative poly-arthritis. If not properly managed, the arthropathy progresses, leading to considerable morbidity. It is seen in about 5% of psoriatic patients. Four types are described. (1) Distal arthritis involving the distal interphalangeal joints (2) Rheumatoid like arthritis. (3) Ankylosing spondylitis or sacroilitis and (4) Mutilating arthritis (arthritis mutilans).

Course and Prognosis

The course is prolonged, but unpredictable. It may remain as discrete plaques or may become generalized. Relapse is the rule. Guttate psoriasis has a better prognosis.

Points to remember

- Extremes of presentation from a few lesions to erythroderma or generalized pustular psoriasis.
- Chronic plaques with silvery scales over the elbows, knees and scalp are the commonest lesions. Remissions and relapses are common.
- Nails show pitting, onycholysis and oil drop sign. Associated with psoriatic arthropathy.
- Pustular psoriasis is characterized by sterile pustules. It may affect the palms and soles or may be a generalized disease.

Management

Psoriatic lesions can be cleared considerably but recurrence is the rule. The need for long-term treatment and the non infectious nature of psoriasis should be explained. Treatment depends upon the type and extent of the disease, age, social factors and general health of the patient.

Topical therapy: Topical corticosteroids and bland emollients are the mainstay of treatment in localized psoriasis. The preparations include betamethasone dipropionate, flucinolone acetonide and clobetasol propionate for lesions on the limbs and trunk and fluticasone, mometasone or clobetasone for lesions on the face and flexures.

In chronic plaque psoriasis, coal tar preparations are useful singly or in combination with keratolytics such as salicylic acid. Salicylic acid and tar shampoos used daily and lotions containing betamethasone and salicylic acid are very effective in scalp psoriasis. Dithranol as a short contact therapy applied for 30 minutes daily and washed off is very effective. Topical calcipotriol (50 µg/g) and calcitriol (3 µg/g) are safe and effective vitamin D3 analogues. Topical tacrolimus 0.1% and tazarotene 0.05% and 0.1% are alternative treatments for psoriasis. Tazarotene is a topical retinoid that modulates abnormal

keratinization and proliferation. Start with 0.05% cream and increase the strength as tolerated. Apply at night. A topical steroid application in the morning decreases the irritation due to tazarotene.

Topical psoralen soaks and exposure to sunlight is very effective in chronic plaque psoriasis. Hands and feet are immersed in a solution of 8-methoxy psoralen (10 mg/L) of warm water for 15 minutes and then exposed to UVA phototherapy units. If these equipments are not available, exposure to direct sunlight for not more than 5 minutes would suffice.

Systemic therapy is indicated when psoriasis is life threatening as in GPP or erythroderma, extensive and not responding to topical treatment. The common drugs used are:

1. Methotrexate, a folate antagonist is a well established treatment for severe psoriasis. It is given orally once a week as a single dose (7.5-15 mg) or in 3 divided doses per week, 12 hours apart in succession. Blood counts, liver and renal function tests should be normal before starting methotrexate and should also be monitored during treatment. Improvement is seen within 2-4 weeks. The major side effects include hepatotoxicity, upper gastrointestinal symptoms, leucopenia, thrombocytopenia, megaloblastic anemia, oligospermia in men and teratogenesis.
2. Photochemo therapy (PUVA): 8-methoxy psoralen is given orally 2 hours prior to ultra violet exposure from PUVA chambers or natural sunlight (PUVA – SOL). Psoralen cross-links with cellular DNA inhibiting cell division. PUVA is usually given 2-3 times a week and there is progressive clearance in about 6 weeks. It is continued for 2 months after the skin lesions have resolved.
3. Narrow band UVB therapy (311 nm) is a safe and useful therapy in plaque psoriasis. Philips TL-01 fluorescent lamps emit a narrow UVB band at 311 nm. This is found to be superior to conventional broad-band UVB, producing longer remissions. UVB therapy 3 times/week is sufficient. This therapy is particularly useful in plaque psoriasis, guttate psoriasis, sebo psoriasis and psoriasis in a pregnant woman. It is not effective in erythroderma or generalized pustular psoriasis.
4. Retinoids are vitamin A derivatives, particularly useful in pustular psoriasis and plaque psoriasis. Etretinate and recently acitretin (25-50 mg/day) are useful either alone or in combination with PUVA (Re- PUVA). Acitretin is started in a daily dose of 25 mg and gradually increased to 50 mg for 3-4 months, depending on the response and side effects. After good clearance of lesions is achieved, the dose is gradually tapered and stopped.
5. Cyclosporine is an immunosuppressant used in doses of 3-5 mg/kg /day orally and it is highly effective. The

drug is continued till lesions resolve and the dose is slowly tapered. It can cause hypertension and renal toxicity and so monitoring is mandatory.

Recent Advances in the Treatment of Psoriasis

Biological response modifiers (biologics) are a new class of drugs and are likely to revolutionize the treatment of moderate to severe psoriasis. Biologics are proteins derived from recombinant DNA technology, hybridomas and blood and whole human cells. Three main types are used to treat psoriasis and other immune mediated diseases like rheumatoid arthritis or Crohn's disease. They are:

- recombinant cytokines
- monoclonal antibodies and
- fusion proteins

They interfere with T cell activation and effector function and prevent the inflammatory effects. Biologics are large molecules and administration is via injection or infusion. Biologics available to treat moderate to severe psoriasis or psoriatic arthritis are:

1. *Etanercept* is a fusion protein which blocks the TNF- α . It is given subcutaneously in a dose of 50 mg twice a week for 12 weeks and then tapered to 25 mg. Injection site reactions and multiple sclerosis like syndrome are the main side effects.
2. *Alefacept* is a fusion protein and acts by eliminating the pathogenic T cells. Dose is 7.5 mg IV or 15 mg IM weekly for 12 weeks. CD4 suppression is the main side effect and should be monitored.
3. *Efalizumab* is a monoclonal antibody that blocks the T cell activation, co-stimulation and migration. Dose is 1 mg/kg subcutaneously every week. Head ache, nausea and chills are the side effects noted.
4. *Infliximab* is a monoclonal antibody that blocks TNF- α . Side effects include infusion reactions and reactivation of tuberculosis. It is under trial.
5. *Adalimumab* and *oncept* are under trial.

Their major advantage is the low risk for end organ toxicity and drug-drug interactions. Some of these may offer long-term remissions. These are under regular use for only about 5 years. Long-term safety has yet to be determined.

Points to remember

- Topical corticosteroids, coal tar, salicylic acid, dithranol, tacrolimus and tazarotene are used for localized lesions.
- Generalized involvement necessitates systemic treatment with methotrexate, PUVA or retinoids.
- Newer biologics are now approved for the treatment of psoriasis.

Lichen planus

Lichen planus (LP) is an acute or chronic inflammatory dermatosis involving skin and / or mucous membrane. LP is most common between 30-60 years of age.

Etiology: It is idiopathic in most cases, but it is evident that cell mediated immunity (CMI) plays a major role. Majority of the infiltrate contains CD 8+ and CD 45 RO+ memory cells. Drugs such as beta blockers, antimalarials, thiazides, gold and mercury salts and infection with hepatitis C virus result in altered cell mediated immunity. All these have been implicated as triggering factors for LP.

Pathology is quite characteristic. There is epidermal hyperkeratosis, hyper granulosis, acanthosis, basal cell degeneration and a band like lymphohistiocytic infiltrate in the upper dermis.

Clinical Features

The onset is usually insidious with the classical violaceous, polygonal, flat topped extremely pruritic shiny papules (Fig. 208.6) distributed symmetrically over the flexor aspect of forearms, wrists, lower parts of legs and genitalia. The initial lesions may be erythematous. Some lesions show a white lacy network (*Wickham's striae*) on the surface. Koebner phenomenon (spread of lesions along the lines of trauma) is seen. In two thirds of cases, the buccal mucosa is involved.

Sometimes the onset may be acute and generalized. Scalp involvement leads to scarring alopecia. Nails become dystrophic with longitudinal splintering.

Several clinical variants may occur. These include **hypertrophic lichen planus** that presents as hyperkeratotic verrucous plaques especially on the lower parts of legs. **Annular** lesions occur commonly on the glans penis. **Linear** violaceous papules of lichen planus occur on the limbs and trunk and **follicular** lesions on the scalp. **Graham Little syndrome** is the occurrence of follicular lesions and scarring alopecia of scalp with classical LP. In **lichen planus actinicus**, the lesions are on the sites exposed to sunlight. **Ulcerative lesions** are common on the soles and are resistant to therapy.

Diagnosis: Diagnosis is usually clinical. It can be confirmed by histopathology.

Differential diagnosis includes pityriasis rosacea, psoriasis, cutaneous lupus erythematosus and contact dermatitis. Hypertrophic lichen planus should be differentiated from lichen simplex chronicus and prurigo nodularis.

Course: The lesions usually subside within 9-18 months. Remissions and relapses are common. Resolving plaques may leave a post inflammatory hyperpigmentation.

Treatment: Classic LP can be treated with potent topical steroids such as clobetasol propionate 0.05% twice daily for 2-3 weeks, if there are few lesions. Liquid paraffin or petroleum jelly should be applied 4-5 times daily in one direction, from above downwards on the limbs in order to avoid folliculitis. In acute generalized LP, oral corticosteroids such as prednisolone 30-40 mg/day tapered over 1-3 months halt the rapid progression. Intra lesional injection of 0.1 ml of triamcinolone (10 mg/ml) is effective in hypertrophic LP. Cyclosporine in a dose of 3-5 mg/kg orally for chronic LP induces long lasting remission.

Points to remember

- Characterized clinically by pruritic violaceous flat topped papules with flexor distribution. Resolves mostly within 18 months.
- Lichenoid reactions occur due to drugs like gold, chloroquine and chlorothiazides.
- Responds to topical steroids and emollients.

Pityriasis Rosea

Pityriasis Rosea (PR) is an acute self limiting disorder of unknown etiology, probably infective in origin, affecting mainly children and young adults. Recently Herpes virus type 7 has been incriminated to play a role in the pathogenesis.

Clinical features: PR is characterized by the onset of herald patch in 80% of patients. "*Herald patch*" is an oval plaque, 2-5 cm in size, erythematous, with fine collarette of scales at the periphery. The scales are attached at the periphery and free towards the center of the lesion. After an interval of 1-2 weeks, a generalized eruption appears in crops, mainly over the trunk and proximal limbs. The characteristic lesion is a small oval papule with a crinkly surface and a rim of fine scales (Fig. 208.7). The long axis of the lesions are oriented in the planes of cleavage, running parallel to the ribs and classically form a 'fir-tree' or 'christmas tree' like pattern. Pityriasis rosea is asymptomatic in 50% of patients. The others get pruritus of varying severity. Atypical presentations may occur. This includes (1) lesions occurring only on the face and neck (2) localized (3) unilateral (4) vesicular (5) inverse PR- (PR occurring in the flexures of the axillae and groins)

Fig. 208.6: Violaceous papules of lichen planus

Fig. 208.7: Herald patch and oval papules of pityriasis rosea on the abdomen

(6) erythroderma. The lesions undergo spontaneous remission in 6-12 weeks. Recurrence is uncommon.

Treatment is mainly symptomatic with oral antihistamines such as cetirizine 10 mg or levocetirizine 5 mg once at night for 2-3 weeks depending on the severity of itching. If asymptomatic, emollients like petrolatum alone would suffice. Topical steroid creams like fluticasone 0.05%, mometasone 0.1% or betamethasone dipropionate 0.05% applied once at night over severely pruritic lesions alleviate the itching. However topical steroids should not be applied over large areas. Oral erythromycin 250 mg qid for 2 weeks may allay the condition in 74% of patients.

Reiter's Syndrome

Reiter's syndrome consists of polyarthropathy, urethritis, iritis and a psoriasiform eruption. It invariably affects males and is preceded by genitourinary or gastrointestinal infection. There is a strong association with HLA- B 27.

The main skin lesions are keratoderma blennorrhagicum which are brownish red papules or macules sometimes with a central vesicle seen mainly on the palms and soles. Center of lesions become pustular or hyperkeratotic and crusted. Circinate balanitis is another classic feature of Reiter's and presents as shallow erosions with serpiginous micropustular borders on the glans, if uncircumcised. Only 30% develop the complete triad of arthritis, urethritis and conjunctivitis. Majority have a self limited course and resolves in 3-12 months. Treatment is similar to psoriasis. Methotrexate and retinoids are needed in severe cases (See chapter 111).

Exfoliative Dermatitis (Erythroderma)

Exfoliative dermatitis includes any inflammatory dermatosis which involves more than 90% of the body surface area. It is a dermatological emergency as the systemic side effects are potentially fatal. Exfoliative dermatitis is a

secondary process and represents the generalized spread of a dermatosis or a systemic disease.

Common causes are eczemas (atopic, contact, photo dermatitis), psoriasis, lymphoma or Sezary syndrome, drug eruption (sulfonamides, barbiturates, NSAIDs and phenytoin are the common drugs), pityriasis rubra pilaris and ichthyosis. In about 23% of cases the cause is unknown.

Clinical features: It is commonly seen in middle aged and elderly males. The onset is often acute. It is characterized by generalized erythema and scaling. Temperature regulation is altered. Large amounts of warm blood are present in the skin due to dilatation of capillaries and there is considerable heat dissipation through insensible fluid loss and by convection. So the patient shivers. Scalp and body hair is lost and nails may be thickened or shed. Generalized lymphadenopathy which is a secondary response to severe skin inflammation is common.

Complications: In exfoliative dermatitis, there is skin failure, and so all the normal functions of the skin are affected. Edema, cutaneous and respiratory infection, cardiac failure, hypo albuminemia due to protein loss through scales, dehydration and metabolic derangement, impaired temperature regulation and dermatopathic lymphadenopathy are the major complications.

Diagnosis: History, pathognomonic signs and symptoms of the pre-existing dermatosis, if present, help in the diagnosis.

Course and prognosis depends upon the underlying cause. In most patients, the problem subsides in weeks to months though recurrence is possible. Death rate ranges from 11-30%. Common causes of death are pneumonia, sepsis, high output cardiac failure and other cardiac complications and lymphoma.

Management: Patient needs to be hospitalized. A warm environment and good nursing care are needed. Pulse, blood pressure, temperature and fluid balance are monitored. Emollients and topical steroids are the mainstay of treatment. Adequate nutrition is maintained. The primary cause is treated. Cardiac failure and infections should be corrected.

Points to remember

- Exfoliative dermatitis is a dermatological emergency.
- Uncommon, but potentially fatal, often sudden in onset.
- Psoriasis and eczema are the common causes.
- Characterized by generalized erythema, edema and scaling
- Skin failure leads to complications such as cardiac failure, hypothermia, infection and lymphadenopathy.
- Inpatient management is needed to correct the nutrition, electrolyte imbalance, secondary infection and other complications.
- Treatment of the underlying cause and emollients are essential.

Chapter Summary

- General Considerations 1368
- Atopic Dermatitis 1368
- Seborrheic Dermatitis 1370
- Nummular Eczema 1371
- Stasis Eczema 1371
- Pompholyx 1371
- Contact Dermatitis 1371
- Photosensitive Dermatitis 1373
- Asteatotic Eczema 1373
- Lichen Simplex Chronicus 1373
- Infective Eczema 1374

General Considerations

Eczema is a polymorphic inflammatory reaction pattern of the skin involving the epidermis and dermis. The term ‘eczema’ literally means to ‘boil over’ (Greek). The terms eczema and dermatitis are used interchangeably. Dermatosi s is a general term which denotes any skin disorder.

The etiology of most eczema is not known. It is classified into endogenous (due to internal or constitutional factors) and exogenous (due to external agents). However, in clinical practice these distinctions are often blurred.

Depending on the morphology of the eruption, eczema can be divided into (1) Acute eczema characterized by pruritus, erythema, edema, vesiculation, oozing, crusting and scaling. (2) Chronic eczema characterized by pruritus, lichenification (thickened with prominent skin markings), excoriation and either hypo- or hyperpigmentation.

Microscopic changes in the early stages (acute eczema) show inter cellular and intracellular edema with resultant vesicle formation and associated dermal vasodilatation and infiltration with chronic inflammatory cells.

In chronic eczema, there is thickening of the epidermis (acanthosis, hyperkeratosis) and retention of nuclei by

some corneocytes (parakeratosis). Rete ridges are elongated, dermal vessels dilated and inflammatory mononuclear cells infiltrate the skin.

Eczema is classified into

Endogenous	Exogenous	Unclassified
1. Atopic dermatitis	1. Allergic contact dermatitis	1. Asteatotic eczema
2. Seborrheic dermatitis	2. Irritant contact dermatitis	2. Lichen simplex chronicus
3. Nummular eczema	3. Photodermatitis	
4. Stasis eczema		
5. Pompholyx		

General Principles in the Management of Eczema

1. Acute eczema is managed with wet dressings or compresses. Normal saline, 1 in 8000 dilution of potassium permanganate solution or 1% boric acid can be used. This removes the crusts, stops oozing and provides comfort.
2. Topical creams, particularly combination of glucocorticoid and antibiotic creams (e.g.)Fucidic acid and betamethasone/hydrocortisone, or mupirocin and fluticasone, are preferred.
3. Severe secondary infection needs treatment with systemic antibiotics. Erythromycin 250 mg qid for 5 days is cheap and effective.
4. Ointments should not be used over oozing eczema as it would cause occlusion and worsen the oozing.
5. Creams are preferred in the acute and sub acute stage and ointments in chronic stage.

Endogenous Eczemas

ATOPIC DERMATITIS

Atopic dermatitis (AD) is an acute, subacute or chronic relapsing skin disorder that usually begins within the first 6 months of life, though it can begin at any age. Approximately 70% of patients have a family history of atopy.

Etiopathogenesis

There is a complex interaction between skin barrier, genetic, environmental, pharmacologic and immunologic factors. Triggering factors include

1. Inhalants- dust mites, pollens
2. Microbial agents- exotoxins of *Staph aureus* act as super antigens and stimulate T cells and macrophages.
3. Autoallergens are released from damaged tissue.
4. Foods- eggs, milk, peanuts, fish, wheat.

These allergens are taken up by the antigen presenting cells in the skin and processed and presented to the CD 4 T cells along with class II MHC antigens. The activated T cells secrete many cytokines, especially Interleukin-4 (IL-4), (Th 2 type of response). There is a relative reduction in the number of CD 4 + T cells that secrete IL-2 and γ -interferon and also a decrease in CD8 + T cells. IL-4 activates the B lymphocyte to produce excess of IgE. IgE interacts with the antigen and sensitizes the mast cells and basophils, and causes degranulation. Inflammatory mediators are liberated and cause intense itching and eczema. The damaged skin provides a good environment for the *Staph aureus* population to grow and the exotoxins further worsen the eczema, by acting as super antigens.

Exacerbating Factors

1. Skin barrier function is disrupted causing dehydration. Xerosis of the skin is the most important aggravating factor.
2. Infection with *Staph aureus*.
3. Seasonal variation- atopic dermatitis usually improves in hot season and flares in the cold season.
4. Clothing- wool and fur aggravate the condition.
5. Emotional stress.

CLINICAL FEATURES

Pruritus is the main symptom. It is the itch that rashes rather than the rash that itches. The constant scratch leads to a vicious cycle of itch → scratch → rash → itch. Itching is severe and often interferes with sleep. The skin becomes very dry.

The clinical picture of eczema varies with age.

Infantile phase: Lesions of acute eczema first occur on the cheeks, forehead and scalp and later the trunk and extremities. When the infant begins to crawl, the extensor aspects of knees are involved (Fig. 209.1). Secondary infection with *Staph aureus* is common. In more than half the patients, the eczema resolves by 18 months.

Childhood phase: Papules, lichenified plaques, erosions and crusts are seen mainly on the ante cubital and popliteal fossa (Fig. 209.2), neck, wrists and ankles. There is erythema on the face with infra orbital folds. Periorbital pigmentation and loss of eyebrows on the lateral one third

Fig. 209.1: Atopic dermatitis in an infant

Fig. 209.2: Atopic dermatitis in a child

may occur due to rubbing. Palmar markings may be exaggerated (hyperlinearity of the palms).

Adult phase: Lichenification and excoriations in a flexor distribution is the characteristic feature in this phase. Irritant dermatitis of the hands is common.

Other features:

1. Stroking leads to blanching and not redness as in normal skin. This unique feature of AD is called **white dermographism**.
2. Chelitis, conjunctivitis, facial palor, ichthyosis and nipple eczema are the minor features of AD.
3. Extensive skin involvement may cause exfoliative dermatitis.

Diagnosis: Diagnosis is based on clinical findings such as onset in infancy, severe pruritus, typical distribution, morphology of lesions, personal or family history of atopic dermatitis, allergic rhinitis or asthma.

Differential diagnosis: Seborrheic dermatitis, irritant and allergic contact dermatitis, psoriasis, nummular eczema and dermatophytosis should be differentiated from atopic dermatitis.

Prognosis: Spontaneous and complete remission occurs during childhood. 30-50% of patients may develop asthma or hay fever later in life. Adult onset AD often runs a severe course.

Management

The patient is advised to avoid any predisposing factors like dust, infection or any particular food which aggravates the condition. Dry skin management is the most important. The child should be given a quick bath with luke warm water. Soap substitutes like cleansers containing cetyl and stearyl alcohol or super fatted soaps used for bathing, prevents drying of the skin. Moisturizers and emollients should be applied immediately after bath and repeated many times to prevent drying. Moisturizers should be applied along the direction of hair follicles to avoid folliculitis. Creams are preferred in an acute eczema and petrolatum for dry eczema. Wet compresses with saline or dilute potassium permanganate solution reduce the oozing associated with acute eczema. Oral and topical antibiotics to eliminate the *Staph aureus* infection promote healing. Cotton clothes are preferred. Cool and comfortable environment prevents itching. Antihistamines such as hydroxyzine should be used without hesitation because it is the 'itch that rashes'.

Topical steroids like fluticasone, desonide or mometasone applied once or twice daily till the lesions resolve reduces inflammation and itching. Tacrolimus (0.03%, 0.1%) and pimecrolimus creams are also widely used now. Severe and resistant forms are managed by phototherapy and systemic steroids like prednisolone 1 mg/kg body weight till the acute symptoms are controlled. Oral cyclosporine is very effective but the side effects and cost restricts its use.

Points to remember

- Usually begins in infancy
- Immunologically mediated, environmental factors also play a role
- Clinical features include acute eczema in infancy affecting face and hands, subacute eczema in childhood affecting antecubital fossa and popliteal fossa, neck, wrists and ankles and chronic lichenified eczema in flexor distribution in adults.
- Itch scratch cycle is predominant
- Infection, heat, wool, stress, inhalants (dust) and certain foods are the exacerbating factors. Treatment includes emollients, topical steroids, antihistamines and antibiotics.

Fig. 209.3: Seborrheic dermatitis of the scalp

more common in males and occurs after puberty and the incidence increases with age. Onset in infancy is also common (cradle cap). HIV infected individuals have an increased incidence of SD that is often severe and intractable.

Etiology: is unknown. *Malassezia furfur* is said to play a role. Abnormalities in sebaceous gland activity and zinc, niacin and pyridoxine deficiencies are also implicated.

Clinical features: The common clinical patterns are

1. Scalp and face involvement: greasy or dry scaling, erythematous macules and papules often cause a diffuse involvement of the scalp (Fig. 209.3). Other classical sites are eyebrows, eyelashes, beard, malar region, scalp hairline (corona seborrheica), naso labial folds, retroauricular and meatal region.
2. Petaloid: Lesions simulating pityriasis rosacea, occur over the presternal area.
3. Flexural: In the axillae, groins, anogenital and submammary areas, SD presents as diffuse, sharply marginated erythema with erosions and fissuring. Common in the elderly.
4. *Pityrosporum folliculitis*: is an erythematous follicular eruption with papules or pustules over the back.

Course and prognosis: Seborrheic dermatitis affects majority of individuals at sometime during life. Recurrences and remissions are common. Infantile and adolescent seborrheic dermatitis disappears with age.

Management: As the condition is chronic, initial therapy followed by long term maintenance therapy is required.

Scalp: Shampoos containing selenium sulphide (2.5%), zinc pyrithione (1-2%), ketoconazole 2%, flucinolone acetonide, applied twice a week (the frequency can be reduced later), are effective. Salicylic acid and coal tar shampoos are useful in reducing thick greasy scales.

Face and trunk: Topical glucocorticoid creams (1-2.5% hydrocortisone), ketoconazole 2% cream, tacrolimus 0.03%, pimecrolimus 1% are all effective.

Seborrheic dermatitis (SD) is a very common, chronic inflammatory dermatosis characterized by erythema and scaling in regions where the sebaceous glands are most active. Mild scalp SD causes flaking (dandruff). SD is

Fig. 209.4: Coin shaped lesions of nummular eczema on the leg

Cradle cap: Removal of crusts with warm oil (olive) compresses is needed, followed by creams or shampoos.

Nummular Eczema (Discoïd Eczema)

Nummular eczema is a chronic pruritic inflammatory dermatitis, typically affects middle aged or elderly, clinically characterized by coin shaped erythematous plaques with exudation and crusting (Fig. 209.4). It is severely pruritic, with excoriations. Sometimes dry scaly lichenified plaque may be seen. Lesions may be clustered on the lower parts of the legs or trunk in males and hands or fingers in females. It may be generalized and scattered. It has a chronic course from weeks to months and tends to recur. Secondary bacterial infection is common.

Management: Moderate to high potency topical steroid combined with antibiotics (fucidic acid and betamethasone), moisturizers and anti histamines like hydroxyzine or cetirizine are the mainstay of treatment. Systemic antibiotics may be needed if secondary infection is severe. Photochemotherapy (PUVA) or narrow band UVB (311 nm) are very effective in severe cases with extensive involvement.

Stasis Eczema

Chronic venous insufficiency leads to stasis eczema (varicose eczema) in the lower parts of the legs and feet.

Pathogenesis: Incompetence of the deep perforating veins increases the hydrostatic pressure in dermal capillaries. Pericapillary fibrin deposition leads to the pathological and clinical changes.

Clinical features: Inflammatory edema, papules, scaling, crusting, erosions, pigmentation stippled with recent and old hemorrhages and dermal sclerosis are the characteristic features. There may be concomitant irritant contact

Fig. 209.5: Pompholyx. Note the vesicles on the sides of fingers

dermatitis due to secretion from stasis ulcer and allergic contact dermatitis secondary to topical medications and bacterial colonization.

Management: Emollients and topical steroids are needed. Venous insufficiency should be managed.

Pompholyx

Pompholyx is an acute, chronic or recurrent dermatosis of the lateral aspects of the fingers, palms and soles characterized by symmetrical deep seated pruritic, clear vesicles (Fig. 209.5) and later by scaling, fissures, and lichenification. Spontaneous remissions can occur in 2-3 weeks. Recurrence is the rule. Secondary infection may occur. Hyper hidrosis is common.

Management: wet compresses with saline, topical steroids and in severe cases, a short course of systemic steroids are needed. Topical PUVA (as soaks) are also useful in severe cases.

Points to remember

- Seborrheic dermatitis affects the scalp and face. Treated with combination creams of steroids and antifungals.
- Nummular eczema presents as coin shaped lesions on the limbs of the elderly.
- Stasis eczema, associated with venous insufficiency is treated with emollients and low or moderate potency topical steroids.

Exogenous Eczema

CONTACT DERMATITIS

Contact dermatitis (CD) is a term applied to acute or chronic inflammatory reaction to substances that come in contact with the skin. There are two types of CD. Irritant contact dermatitis (ICD) caused by a chemical irritant and

allergic CD (ACD) caused by an allergen (antigen), which elicits a type IV hypersensitivity reaction.

Irritant Contact Dermatitis

ICD is caused by exposure of the skin to chemical or physical agents that are capable of producing cell damage, acutely or chronically. It is dependent on the concentration of the offending agent and occurs in all those who are exposed, depending on the penetrability and thickness of the stratum corneum. There is a threshold concentration for these substances above which they cause acute dermatitis and below which they do not.

ICD may occur minutes after exposure or may be delayed up to 24 hours. Acute ICD can occur due to strong irritants like acids, chloroform, methanol, phenol or propylene glycol and cause toxic reactions after a short exposure. The spectrum of changes ranges from erythema to vesiculation. Erosion, crusting and scaling follows. Papules are not seen. In chemical burns, necrosis of tissues leads to ulceration. Lesions are sharply demarcated to the site of contact with the irritant. Configuration is often bizarre.

Most cases however, are caused by cumulative exposure to one or more mild irritants like water, soaps and detergents. This causes a chronic disturbance of the barrier function that allows even subtoxic concentrations of the offending agents to penetrate into the skin and elicit a chronic inflammatory response. Hands are most commonly affected. There is dryness, chapping, erythema, scaling, fissuring, and crusting. Stinging and itching are the main symptoms.

Allergic Contact Dermatitis

Allergic contact dermatitis is dependent on sensitization and thus occurs only in sensitized individuals. Depending on the degree of sensitization, even minute amounts of allergen may elicit a reaction.

The eruption starts in a sensitized individual 48 hours or a few days after contact with the allergen. The eruption worsens on repeated exposures (crescendo reaction). There is intense pruritus. Lesions are initially confined to the area of contact with the allergen and later spread to the surrounding areas. Generalized involvement can also occur, if sensitization is strong. In the acute stage (Fig. 209.6) there is erythema, papules, vesicles, erosions, scaling and crusting and in the chronic stage (Fig. 209.7) there is lichenification, fissuring, scaling and crusting.

Patch test: In ACD, sensitization is present on all parts of the skin as it is immunologically mediated. Therefore, application of the allergen to any area of normal skin provokes an eczematous reaction. It should be performed

Fig. 209.6: Allergic contact dermatitis to diclofenac spray

Fig. 209.7: Allergic contact dermatitis to rubber

Fig. 209.8: Patch test allergens pasted on the back

on a previously uninvolved skin after the dermatitis has subsided (Fig. 209.8).

Management of Contact Dermatitis

1. Avoidance of irritants/allergens.
2. Wet dressings and topical steroids for acute reaction and if severe, systemic glucocorticoids are indicated.
3. In chronic CD, protective/lubricating creams and high potency topical steroids are necessary.

Points to remember

- ICD is more common than ACD. Atopics are more susceptible to irritants.
- Common irritants are water, abrasives, chemicals (alkalis) and detergents.
- Common allergens are nickel (jewellery, zips, instruments), chromates (cement, primer), cobalt (paint, ink), colophony (glue, adhesive tape), preservatives, perfumes and paraphenylenediamine (dye).
- * Avoidance of allergens and irritants are important in the prevention of CD.

Photosensitive Dermatitis

In normal persons pigmentation of the skin increases with exposure to sunlight, depending on its intensity, duration of exposure and type of skin. Photosensitivity is an abnormal response to sunlight and affects the sun exposed parts of the body like the forehead, malar region, nose, rim of ears, sides and back of neck, 'V' area of the chest and extensor aspect of distal extremities. Ultra violet A (UVA 320-400 nm) and ultra violet B (UVB 290-320 nm) are the primary inducers of most photosensitivity reactions. The photon energy is absorbed by molecules such as skin cells (chromophores) and then either dispersed harmlessly or results in clinical disease. The chromophore can be a) exogenous (topical or systemic), b) endogenous (DNA is the most important skin chromophore), c) endogenous or exogenous allergen causing an immune reaction activated by photo radiation.

Photo dermatosis is broadly classified into

1. Photo toxicity- sunburn, drug/chemical induced, plant induced (phyto photo dermatitis)
2. Photo allergy- drug/chemical, chronic actinic dermatitis, solar urticaria
3. Idiopathic- Polymorphous light eruption, actinic prurigo, hydroa vacciniforme
4. Miscellaneous- Metabolic, nutritional, genetic, photo aggravated dermatosis, chronic photo damage.

Sunburn is a transient inflammatory response of normal skin due to exposure to UVB rays. It is common in fair skinned individuals. There is uniform erythema, edema, vesicles and bullae strictly confined to the sun exposed areas. Erythema is visible 2-6 hours following exposure and reaches a maximum at 24-72 hours and fades in 3-5 days, followed by pigmentation.

Drug / chemical induced photo toxic reactions: In this condition interaction occurs between drugs /chemical with ultra violet rays in the skin and manifests like an ICD (e.g. dyes, coal tar derivatives, psoralens, tetracyclines, phenothiazines, thiazides, sulfonamides and others).

Photo allergic reactions: A photo allergen such as fragrances like musk ambrette, PABA, phenothiazines and

halogenated salicylanilides in deodorant soaps, formed in the skin initiates a type IV hypersensitivity reaction and manifests like an ACD.

Idiopathic- Polymorphous light eruption: Polymorphous light eruption (PMLE) is the most common photodermatosis. This is common in women. UVA and UVB can evoke PMLE, UVA being more common. Lesions are papular, papulovesicular or urticarial plaques that begin within 24 hours of exposure. In the individual patient, usually one type of lesion predominates. Recurrences are common. Spontaneous improvement occurs after years.

Management: Strict avoidance of sunlight is necessary. Sun block creams like zinc oxide or titanium dioxide, broad spectrum sunscreens, topical glucocorticoids and antihistamines are used in the treatment of PMLE. Severe eruption may necessitate systemic steroids.

Points to remember

- Sunlight can cause tanning, sun burn and photo ageing in normal skin.
- Important idiopathic photodermatoses are PMLE and chronic actinic dermatitis.
- Some conditions like lupus erythematosus, porphyria and rosacea are worsened by sunlight.
- Treatment includes avoidance of sun exposure, irritants and allergens, use of sun screens and topical steroids.

Asteatotic Eczema (Eczema Craquele)

Asteatotic eczema is a dry eczema with fissuring and cracking of the skin, often affecting the limbs in the elderly. The skin is dry, erythematous and itchy and shows a crazy-paving pattern of fissuring. Dry winter climate, over washing and hypothyroidism exacerbates the condition. Topical emollients and bath emollients should be used regularly. Sometimes a mild topical steroid is necessary.

Lichen Simplex Chronicus (LSC)

LSC is a localized form of lichenification due to rubbing or scratching as a habit or due to stress. The skin becomes highly sensitive and hyperexcitable in response to minimal external stimuli. LSC is common in elderly females. It usually occurs as a single plaque of lichenification with exaggerated skin markings and hyper pigmentation (Fig. 209.9), associated with paroxysms of pruritus. Common sites are the lower parts of the legs and back of the neck. Sometimes a nodular lichenification known as *prurigo nodularis* develops on the shins and forearms.

It should be explained to the patient that the rubbing and scratching must be stopped. Potent topical steroids, coal tar and intra lesional triamcinolone are effective.

Fig. 209.9: Lichenified plaques of lichen simplex chronicus

Fig. 209.10: Infective eczema-there is edema vesiculation oozing and crusting

Infective Eczema

Infectious eczematoid dermatitis (IED) or infective eczema is an eczema that occurs secondary to an infection in the skin. It can occur around discharging

wounds, sinuses or ulcers as an acute eczema (Fig. 209.10). This should be differentiated from infected eczema where a primary eczema is complicated by secondary bacterial infection.

TABLE 210.1

Blistering disorders classification	
Genetic	Immunobullous
Epidermolysis bullosa	Pemphigus vulgaris Bullous pemphigoid Dermatitis herpetiformis Linear IgA disease

GENERAL CONSIDERATIONS

Blistering disorders are a heterogeneous group of diseases presenting with vesicles and bullae on the skin and mucous membrane. These groups of disorders cause great morbidity and even mortality in dermatological practice. The basic classification of blistering disorders is given in

Table 210.1. Blistering drug reactions are described in the section on drug reactions.

The genetically transmitted group of blistering disorders like epidermolysis bullosa are mechanobullous disorders where friction and trauma contribute to the formation of blisters. In immunobullous disorders, autoimmune mechanisms contribute to the formation of

blisters. Autoimmune blistering disorders account for 0.49% of the skin disorders in Kerala, pemphigus vulgaris being the commonest.

Pemphigus Vulgaris

The word pemphigus is derived from the Greek word “pemphix” meaning bubble. The usual age group is 40-60 years. Auto antibodies (IgG) are directed against cell surface glycoproteins called pemphigus antigens, especially desmoglein 3. This leads to a loss of the normal cell to cell adhesion in the epidermis (acantholysis). It is clinically characterized by multiple flaccid vesicles and bullae, arising on normal skin, distributed on the flexures, scalp and oral mucous membrane (Figs 210.1 and 210.2). A tangential pressure applied adjacent to a bulla or vesicle will cause the skin to peel away (*Nikolsky sign*), while vertical pressure on the bulla leads to lateral extension of the blister (*Asboe-Hansen or bulla spread sign*). The bulla on rupture leads to large, painful denuded areas which extend without healing. The oral mucosa shows erosions and ulcers. It is invariably fatal if not treated aggressively with immunosuppressive agents.

Fig. 210.1: Pemphigus vulgaris

Fig. 210.2: Flaccid vesicles of pemphigus on axilla

Fig. 210.3: Pemphigus vegetans: Note the vegetating plaques on the back over the erosions of pemphigus vulgaris

Variants

1. **Pemphigus vegetans** presents with granulomatous vegetative purulent plaques on the flexures, trunk and other areas (Fig. 210.3).
2. **Pemphigus foliaceus** presents with superficial pustules, erythema, scaling and crusting distributed on the face, scalp, upper chest and abdomen and may present as exfoliative dermatitis.
3. **Pemphigus erythematosus** (*Senear-Usher syndrome*) is a variant of foliaceus where there is erythema on the malar area and considerable overlap with SLE.

Bullous Pemphigoid

Bullous pemphigoid occurs after 60 years of age. Autoantibodies interact with bullous pemphigoid antigen in the hemidesmosomes of basal keratinocytes and there is complement activation and attraction of neutrophils and eosinophils. These inflammatory cells release various bioactive molecules causing bullous lesions.

Clinical features include multiple tense bullae and vesicles distributed on the lower abdomen, thighs and flexor aspect of forearms. The bulla heals after rupture with no peripheral extension. Nikolsky and bulla spread sign are negative. Oral lesions are rare.

Dermatitis Herpetiformis

The age of onset is 20-40 years. It is associated with gluten sensitive enteropathy and IgA deposits in the skin. Autoantibodies to epidermal transglutaminases probably cross react and bind to transglutaminases in the gut and

Fig. 210.4: Grouped vesicles of dermatitis herpetiformis

circulate as immune complexes and deposits in the skin. IgA activates complement leading to chemotaxis of neutrophils and produces tissue injury. The patient presents with severely pruritic multiple grouped vesicles, papules and urticarial plaques distributed on the upper shoulder, lower back and extremities (Fig. 210.4). Nikolsky sign and bulla spread sign are negative. Oral lesions are uncommon. 70% of the patients may give history of exacerbation of lesions and diarrhea while taking gluten containing food such as wheat, barley and oats.

Linear IgA Disease

Linear IgA disease presents with multiple pruritic tense subepidermal bullae on the extensor surfaces of elbows,

Fig. 210.5: Chronic bullous disease of childhood—annular lesions with peripheral vesicles give a string of pearl appearance

knees, buttocks and trunk. Oral erosions and ulceration are common. The similar disease occurring in children is known as *chronic bullous disease of childhood* (Fig. 210.5). Here the lesions are confined to the perineum, lower abdomen, eyelids and scalp. Annular lesions with vesicles along the edge give a “string of pearl” appearance. Homogenous linear deposits of IgA are present at the basement membrane zone.

Investigations and Treatment

Tzanck test, skin biopsy and immunofluorescence are the investigations done to diagnose vesiculo-bullous disorders. Tzanck test is a cytodiagnostics technique

TABLE 210.2

Investigatory findings and treatment of vesiculo bullous disorders			
Description	<i>Pemphigus vulgaris</i>	<i>Bullous pemphigoid</i>	<i>Dermatitis herpetiformis</i>
Tzanck test	Acantholytic cells ¹	Eosinophils	Neutrophils
Skin biopsy	Suprabasal intraepidermal bulla with acantholytic cells	Subepidermal bulla containing eosinophils	Subepidermal bulla containing neutrophils
Immunofluorescence	IgG against inter cellular cement substance	IgG against basement membrane zone	Granular IgA against upper papillary dermis
Electron microscopy	Antibody against desmoglein – 3	Antibody against bullous pemphigoid antigen in hemidesmosomes	Antibody against epidermal transglutaminases
Treatment	Steroids, dapsone, cyclophosphamide, gold therapy, DCP therapy ² , plasmapheresis	Steroids	Dapsone

2. DCP – Dexamethasone cyclophosphamide pulse therapy.

where a smear is taken from the floor of a de-roofed bulla and stained with Geimsa or Leishman stain. Specific cells are seen in each condition (Table 210.2). Immunofluorescence is the gold standard for diagnosing these disorders.

Treatment consists of oral corticosteroids, dapsone, cyclophosphamide, dexamethasone cyclophosphamide pulse therapy (DCP therapy) in severe cases and also plasmapheresis in life threatening cases. The investigatory findings and treatment are summarized in Table 210.2.

211

Urticaria and Angioedema

S. Pradeep Nair

Chapter Summary

History and Definition 1377
Clinical Features 1377
Treatment 1378

History and Definition

Hippocrates first described urticarial pruritic lesions caused by nettles and mosquitoes which he named “*knidos*”. It was in 1769 that William Cullen coined the term ‘urticaria’. Urticaria (syn. wheals, hives) is defined as transient erythematous papules and plaques occurring in the skin due to plasma leakage. Angioedema (syn. angioneurotic edema) are transient erythematous swellings of the dermis, subcutaneous and submucosal layers. Angioedema usually affects eyelids, lips, larynx and rarely genital mucosa. Laryngeal edema can be life threatening. Urticaria and angioedema can co-exist and occur as part of immunological and inflammatory reactions on the skin. Urticaria of less than 6 weeks duration is acute urticaria and more than 6 weeks duration is called chronic urticaria. The classification and etiological factors for urticaria/angioedema are given in Table 211.1.

Clinical Features

Urticaria presents as severely pruritic, superficial, well defined, erythematous papules and plaques on any part of the skin (Fig. 211.1). The lesions can be round, oval, arciform, annular or serpiginous. These lesions are

TABLE 211.1

Classification and etiology of urticaria	
Classification	Etiology
Acute and chronic urticaria	Infection Infestation
Physical and cholinergic urticaria	Injections Ingestion (food, drugs)
Urticarial vasculitis	Inhalation (pollen grains, dust, smoke)
Contact urticaria	Insect bite (mosquitoes, wasp and bee stings) Implants (dental, orthopedic)

transient lasting not more than 24 hours and then fresh crops of lesions occur. Angioedema presents with ill-defined edema involving the dermis and subcutaneous tissue, commonly of the lips and eyelids. It may involve the upper respiratory tract and the patient may present with dyspnea and runs the risk of impending life-threatening laryngeal edema which is a medical emergency. Meticulous history taking is very important keeping the etiological factors in mind. Acute urticaria is commonly due to drugs or infections. In children, foci of infection especially dental caries, helminthiasis and food are important factors. In most cases of chronic urticaria the cause may be obscure (idiopathic).

Physical and Cholinergic Urticaria

Physical urticaria is caused by external stimuli. *Dermographism* is a type of physical urticaria where stroking the skin elicits the triple response.

Fig. 211.1: Urticaria due to insect bite

Cholinergic urticaria (heat urticaria) is characterized by the presence of wheals when the patient sweats or does exercise. The wheals are very small and sometimes perifollicular.

Cold urticaria: The lesions are confined to the sites exposed to cold and occur within minutes after rewarming.

Aquagenic urticaria occurs when the patient comes in contact with water, irrespective of its temperature.

Solar urticaria occurs on exposure to sun light (290-500 nm of the electromagnetic spectrum).

Urticarial Vasculitis

This type of urticaria is a Type III hypersensitivity reaction and occurs in autoimmune disorders. Here the wheals will

persist for more than 24 hours and may be painful. Bullous lesions may also occur and investigations have to be done to find out systemic disorders.

Contact Urticaria

Contact urticaria may be immune mediated or non-immune mediated. Immunologic contact urticaria occurs in individuals sensitized to contact with external allergens like latex rubber gloves. This is also commonly seen in atopic children. Non immunologic contact urticaria is due to the direct effects of exogenous urticants penetrating into the skin or blood vessels e.g. benzoic acid in eye solutions and foods, cinnamic aldehyde in cosmetics and serotonin in nettle stings. The wheals may occur within 2 hours of contact.

Treatment of Urticaria

In most cases, if the cause is identified and removed the urticaria subsides. The treatment protocol of urticaria is given in Flow chart 211.1.

Angioedema with impending laryngeal edema is a medical emergency as it is life threatening. The treatment protocol is given in Table 211.2.

TABLE 211.2
Treatment of angioedema
1. Inj. Adrenaline 0.5 mL SC or IM
2. Inj. Hydrocortisone 100 mg IV
3. Inj. Pheniramine maleate 22.75 mg IM

 Exfoliative Drug Eruption 1380
 Urticarial Drug Reactions 1381
 Acneiform Eruptions 1381
 Lichenoid Eruptions 1381
 Photosensitive Drug Reaction 1381
 Hyperpigmentation 1381

A drug reaction is defined as an undesirable clinical manifestation resulting from the administration of a particular drug. Cutaneous drug reactions constitute 2.85% of the dermatological conditions seen in Kerala. The clinical manifestations of drug reactions are protean and can mimic many dermatoses. The classification of drug reactions is given in Table 212.1.

TABLE 212.1**Common drug eruptions**

Maculo-papular
Vesiculo-bullous
Exfoliative dermatitis
Fixed drug reaction
Urticarial
Acneiform
Lichenoid
Photosensitive
Hyperpigmentation

Maculo-papular

Maculo-papular reaction (syn. exanthematous drug reaction) is the commonest type of drug reaction. They are usually caused by penicillin and related antibiotics, allopurinol, gold salts and carbamazepine. Initial reaction usually occurs less than 14 days after drug intake. These

**Fig. 212.1:** Maculo-papular rash due to ampicillin

eruptions present with symmetrical, pruritic erythematous macules and papules on the trunk and limbs (Fig. 212.1). Buccal mucosa may be involved. The treatment is to stop the incriminated drug. Antihistamines and topical calamine lotion relieve the symptoms.

Vesiculo-bullous

Vesiculo-bullous drug reactions are commonly due to drugs like naproxyn, nalidixic acid, furosemide and piroxicam. They can mimic pemphigus, pemphigoid, porphyria or linear IgA disease.

Erythema Multiforme

This type of drug reaction presents with vesicles or bullae, papules, plaques, urticaria and the characteristic 'iris' or 'target' lesion. The iris lesion presents with a central area of vesicle or purpura, a mid zone of edema and an outer ring of erythema. The lesions are usually distributed on

TABLE 212.2

Penicillins
Sulphonamides
INH
Piroxicam
Allopurinol

the dorsum of the hands, palms and extensor aspect of extremities. The oral mucous membrane and the eyes can also be affected. Penicillins, sulphonamides, anti convulsants and NSAID'S are the usual culprits. Other than drugs, a wide variety of etiological factors can cause erythema multiforme, especially infections like herpes simplex and mycoplasma. Systemic steroids have to be given in severe drug reactions.

Stevens Johnson Syndrome (SJS)

This is a serious drug reaction characterized by constitutional symptoms like fever followed by maculo-papular rash, vesicles and bullae involving the trunk and limbs. The bullae rupture to form areas of extensive erosions. The eyes, oral cavity and genitals are invariably involved. The lips and oral cavity shows erosions and ulcers covered by hemorrhagic crusts (Fig. 212.2). The eyes may show purulent conjunctivitis and later corneal ulcers. The drugs commonly causing SJS in the state of Kerala is given in Table 212.2. Treatment is with high dose prednisolone (40-60 mg/day), antibiotics and antihistamines. Intravenous immunoglobulin (IVIG) in doses of 0.4 g/kg/day given for 3-4 days is life saving and therefore should be considered in severe cases. The care of the eye is very important. Frequent sterile saline irrigation for the eyes, topical eye antibiotics like tobramycin or quinolones, topical betamethasone or prednisolone eye drops are necessary. Eye should be managed by the ophthalmologists. Frequent rinsing of the oral cavity with chlorhexidine or dilute potassium permanganate mouth washes is essential.

Toxic Epidermal Necrolysis (TEN)

TEN is a dermatological emergency with a very high mortality. The drugs causing TEN in Kerala are given in Table 212.2. The patient first presents with high grade fever and severe toxemia followed by purpuric macules on the trunk and limbs with a 'charred' appearance involving more than 30% of the body area (Fig. 212.3).

Fig. 212.2: SJS-oral cavity shows ulceration and crusting

Fig. 212.3: Toxic epidermal necrolysis due to ampicillin carbamazepine

These lesions are soon followed by blistering and large areas of the skin sloughs off leading to extensive areas of erosions. There is severe oral, eye and genital mucosal involvement. Hepatitis and acute renal tubular necrosis are the systemic complications. Loss of large areas of skin leads to electrolyte imbalance, septicemia and temperature dysregulation which may lead to death. High dose systemic steroids, antibiotics and intravenous immunoglobulin have to be given. Barrier nursing and proper skin and eye care is essential for the patient.

Exfoliative Drug Eruption

Heavy metals like gold, phenytoin, INH, ayurvedic and homeopathic preparations are notorious to cause exfoliative type of drug reaction. Emollients like liquid

Fig. 212.4: Bullous lesion of FDE

Fig. 212.5: Fixed drug eruption due to sulphonamide—
Note the post-inflammatory hyperpigmentation

paraffin, systemic steroids and antihistamines have to be given (refer erythroderma).

Fixed Drug Eruption (FDE)

This is a localized type of drug reaction caused by paracetamol, sulphonamides, dapsone and tetracyclines. 30 minutes to 8 hours after taking the drug, the patient may develop sharply demarcated macules, initially erythematous, then dusky red to violaceous and then become oedemaous which may evolve to a bulla and erosion (Fig. 212.4). Common sites are the limbs, face or trunk. Sometimes there may be painful blisters and erosions on the oral or genital mucosa. The lesions heal by themselves with post inflammatory hyperpigmentation, but on subsequent exposure to the same drug the lesions recur at the same sites or other sites (Fig. 212.5).

Urticarial Drug Reactions

Urticaria and angioedema are usually caused by penicillins, cephalosporins and sulphonamides. Urticarial drug reactions can also occur as a part of anaphylaxis where the patient will have bronchospasm and vasomotor collapse. Adrenaline (0.5 mL SC), hydrocortisone (100 mg) and pheniramine maleate (10-20 mg) injections are life saving.

Acneiform Eruptions

Steroids, INH and phenytoin are the drugs causing acneiform eruptions. It is characterized by monomorphic, acne like lesions distributed on the face, limbs and trunk. Comedones are absent. Stopping the drug will clear the lesions.

Lichenoid Eruptions

It presents as pruritic violaceous papules resembling lichen planus on the trunk and upper limbs. Oral lesions are absent. Gold salts, captopril, antimalarials and beta-blockers may produce lichenoid eruption.

Photosensitive Drug Reaction

Photosensitising drugs like psoralens, sulphonamides, tetracyclines, retinoids, chlorpromazine and thiazide diuretics cause this type of reaction. Erythema, papules and sometimes vesiculation occurs on the face and extensor aspect of upper limbs (sun exposed areas).

Hyperpigmentation

Clofazimine, chlorpromazine, minocycline and antimalarials are the common drugs which cause diffuse hyperpigmentation of the face and trunk.

Chapter Summary

- Disorders of Blood Vessels 1382
- Vasculitis 1382
- Stasis Ulcer 1382
- Neuropathic Ulcers 1383
- Disorders of Lymphatics 1383
- Lymphedema 1383
- Lymphangioma Circumscriptum 1383

Disorders of Blood Vessels

Diseases of arteries and veins contribute to a large variety of dermatoses, leg ulcers being the most common. The common causes of leg ulcers in India are given in Table 213.1.

Vasculitis

Vasculitis is the inflammation of small and large blood vessels. The blood vessel is infiltrated by polymorpho-nuclear cells, lymphocytes or granulomas. It presents with well defined painful punched out ulcers on the lower aspect of the legs (Fig. 213.1). It can also be a manifes-

Fig. 213.1: Vasculitic ulcer
Note indolent ulcer—no sign of healing

tation of systemic disorders like SLE. *Pyoderma gangrenosum* is a type of vasculitis that presents with single or multiple well defined painful ulcers with undermined edges and a violaceous border on the trunk and lower extremities. It may be associated with systemic disorders, especially inflammatory bowel disease. Treatment of the primary cause leads to healing of ulcers.

TABLE 213.1 Common causes of leg ulcers	
1. Traumatic	
2. Arterial occlusion	Atherosclerosis Thromboembolism Thromboangitis obliterans
3. Vasculitis	SLE, Rheumatoid arthritis Pyoderma gangrenosum
4. Venous	Stasis ulcers
5. Infections	Fungal, Parasitic
6. Neuropathic	Leprosy Diabetes mellitus Tabes dorsalis
7. Malignancies	Squamous cell carcinoma Kaposi's sarcoma

Stasis Ulcer (Varicose Ulcer)

Chronic venous insufficiency of the deep veins of the legs leads to edema and later ulceration. It presents as chronic non-healing ulcers on the lower medial aspect of the legs along with stasis eczema. The lesions in the veins can be demonstrated by Doppler studies of the venous system. Foot end elevation, pressure stockings, and management of eczema by regular use of emollients and topical steroids and antibiotics are helpful in mild cases. Regular foot exercises help to allay progression of the lesion. Surgical treatment of the varicose veins may be required in intractable cases.

Fig. 213.2: Leprosy with neuropathic ulcer

Fig. 213.3: Maggots in the neuropathic ulcer

Neuropathic Ulcers

Neuropathic ulcers complicate sensory and autonomic neuropathy occurring in several diseases such as diabetes mellitus, leprosy and other forms of sensory neuropathies, syringomyelia and others. Leprosy is a very common cause for plantar ulcers in India (Fig. 213.2). Anesthesia, defective walking mechanism due to collapse of arches of feet and autonomic neuropathy leading to fissuring of soles contribute to the formation of the ulcers. Ball of the big toe, head of metatarsals and heel are the common sites for ulcers. The ulcers can also be complicated by infestation with maggots (Fig. 213.3). The patient should be advised bed rest. Antibiotics and potassium permanganate foot baths help to resolve the ulcers. Once

	Lymphangitis
	Proximal lymphatic obstruction

the ulcer has become clean a plaster of Paris cast may be applied to help healing. Use of footwear with micro-cellular rubber (MCR) helps to prevent relapse. The primary condition should receive simultaneous treatment.

Disorders of Lymphatics

LYMPHEDEMA

Accumulation of lymph in the soft tissues due to obstruction leads to lymphedema. The common causes of lymphedema are given in Table 213.2.

Lymphedema presents with erythema and edema of the lower limbs, upper limbs or external genitals depending upon the cause. In chronic cases the edema becomes non-pitting. Recurrent fever with rigor and chills and streptococcal cellulitis complicates lymphedema caused by filariasis. Chronic lymphatic obstruction is common in malignant metastasis in the lymph nodes, in surgical removal and irradiation of the lymphatic system. Chronic lymphedema may be complicated by verrucous nodules and plaques on the skin surface known as *elephantiasis verrucosa nostra*. This may be rarely complicated by lymphangiosarcoma. There is no specific treatment. Cellulitis and lymphangitis should be treated with penicillin. Surgery may be required in some cases. See also Chapter 70.

LYMPHANGIOMA CIRCUMSCRIPTUM

This is a localized congenital lymphatic malformation characterized by confluent vesicles resembling “frog spawn”, distributed on the axillary folds, proximal part of limbs, perineum and tongue. Treatment is by surgical excision or ablation by CO₂ laser.

Chapter Summary

- Disorders of Hypermelanosis 1384
- Freckles 1384
- Lentigines 1384
- Melasma (Chloasma) 1384
- Incontinentia Pigmenti 1385
- Disorders of Hypomelanosis 1385
- Vitiligo 1385

Normal skin color is determined by the amount and distribution of melanin in the skin. Increase or decrease of melanin in the epidermis results in hyper or hypomelanosis respectively.

Disorders of Hypermelanosis

Dermatoses and systemic disorders that present with hypermelanosis are given in Table 214.1.

Freckles

Also known as ephelides, this autosomal dominant condition presents with hyperpigmented macules on the face and other sun exposed areas. This disorder is more common on the white caucasoid skin. Treatment is by applying sunblocks like zinc oxide or sunscreens containing avobenzones, oxybenzone, anthranilates, cinnamates or octyl salicylates, avoiding excessive

sunlight and cosmetic chemical peeling by phenol, solid CO₂ and glycolic acid.

Lentigines

Lentigines are hyperpigmented macules arising due to increased melanocytes at the dermo-epidermal junction. They may be single, segmental or multiple. Multiple lentigines can occur as part of syndromes like ‘LEOPARD’ syndrome consisting of L- lentigines, E- ECG abnormalities, O- ocular hypertelorism, P- pulmonary stenosis, A- abnormal genitalia (infantilism, cryptorchidism), R- retardation of growth, D- deafness. Lentigines can affect any area of the skin and mucous membrane. There is no specific treatment.

Melasma (Chloasma)

This disorder mainly affects women and presents with hyperpigmented macules and patches on the cheeks and forehead (Fig. 214.1). It results from exposure to sunlight. Pregnancy and use of oral contraceptives predispose to the condition, indicating a hormonal relationship. Treatment is by a combination of topical depigmenting agents like hydroquinone 2-4%, tretinoin 0.025-0.05% and hydrocortisone 1%. Chemical peeling with

Fig. 214.1: Hyperpigmented patches of melasma on the malar region

TABLE 214.1

Disorders of hypermelanosis	
Dermatoses	Systemic disorders
Freckles	Incontinentia pigmenti
Lentigines	Peutz-Jeghers syndrome
Melasma	Albright syndrome
Café-au-lait macules	Fanconi's anemia
	Endocrine disorders

trichloroacetic acid or glycolic acid is useful. Sunblock creams such as zinc oxide are essential in the prevention of melasma.

Incontinentia Pigmenti

This X-linked dominant genodermatoses presents with bullous lesions at birth evolving into warty plaques and later healing with hyperpigmented macules and patches with a bizarre pattern resembling “Chinese figures” distributed on the trunk and limbs. There may be associated ocular defects like cataracts, papillitis, congenital retinal folds and optic atrophy and dental defects like delayed dentition, impacted and missing teeth, pegged teeth and malformed crowns. There is no definite treatment. Genetic counselling is a must.

Peutz-Jeghers Syndrome

It is characterized by intestinal polyposis with periorificial lentigines. They are prone to develop intestinal malignancy.

Disorders of Hypomelanosis

Disorders presenting with hypopigmentation and depigmentation are given in Table 214.2.

Vitiligo

This is a primary autoimmune depigmentary disorder. Vitiligo accounts for 3.12% of the skin disorders in Kerala. Secondary post-inflammatory depigmentation is called leukoderma. In a vitiligo patch melanocytes are absent and hence no melanin production. Vitiligo presents with multiple depigmented macules and patches on any area of the skin including oral and genital mucosa (Fig. 214.2). They may be localized, segmental or generalized. Sometimes the hair on a vitiligo patch may also be depigmented known as leukotrichia. Vitiligo may be associated with other autoimmune disorders.

TABLE 214.2		
Disorders of hypomelanosis		
Genetic	Systemic disorders	Dermatoses
Albinism	Hypopituitarism	Leprosy

Tuberous sclerosis	Pernicious anemia	Pityriasis versicolor
Vitiligo	Other autoimmune diseases	Syphilis
		Sarcoidosis

Fig. 214.2: Vitiligo-depigmented patches on the shin

Treatment: PUVA (Psoralens + UVA) is very effective. 8-methoxy psoralen is given in a dose of 0.03 mg/kg (20 mg for an adult) orally. Two hours later the lesions are exposed to ultraviolet light repeatedly for increasing duration till repigmentation, which usually occurs in 12-18 months. Alternatively sunlight can be employed as the source of ultraviolet light (PUVA- SOL) for 15-30 minutes. This procedure is done 2-3 times/week. Eye protection with UVA blocking glasses is necessary during and after treatment. Extensive and acutely occurring vitiligo responds satisfactorily to systemic steroids and these drugs have to be used with caution.

- Onychomycosis 1387
- Nail Psoriasis 1388
- Miscellaneous Conditions affecting the Nails 1388

Disorders of Hair

The hair is a skin appendage. It develops from the primary epithelial germ at the third month of gestation. The hair growth is cyclic. The growing phase of the hair is known as anagen, the involutionary stage catagen and the shedding stage is telogen. Hair disorders account for 1.89% of the skin disorders seen in Kerala. The common hair disorders encountered are given in Table 215.1.

ALOPECIA AREATA

This is an autoimmune disease characterized by localized reversible loss of hair usually involving the scalp, mustache and beard area, even though any hair bearing area can be affected. The involved area will resemble a

Fig. 215.1: Alopecia areata

Fig. 215.2: Alopecia universalis

TABLE 215.1

Hirsutism
Canities

bald patch and at the periphery the typical “exclamatory” hairs can be seen (Fig. 215.1). Exclamation mark hairs are broken off stubby hairs where the distal ends are broader than the proximal ends. Alopecia totalis is denoted when the entire scalp hair is lost and alopecia universalis, when the entire body hair is lost (Fig. 215.2). Treatment is by topical irritants like salicylic acid, topical steroids

and intralesional steroids. The patient should be reassured of its benign nature and spontaneous recovery.

CICATRICIAL ALOPECIA

This is scarring alopecia and the hair does not regrow. Scarring alopecia is caused by trauma, infections, follicular lichen planus of scalp, discoid lupus erythematosus and malignancies. Hair transplantation or the use of artificial hair is indicated to relieve psychological distress and social disability.

ANDROGENIC ALOPECIA

This is male pattern baldness and is an androgen dependent condition with a strong familial background. The commonest type of clinical presentation is frontoparietal hair recession. Hamilton’s scale is used for grading the degree of hair loss. Treatment is with topical minoxidil 2-5% and/or systemic anti-androgen drugs like finasteride (1 mg/day). Female pattern alopecia may have to be treated with anti androgens like cyproterone acetate (100 mg/day), flutamide (250 mg/day) and spironolactone (200 mg/day). Unresponsive patients may require hair transplantation.

HYPERTRICHOSIS

Increased hair growth in areas of normal growth is called hypertrichosis. It can be congenital, acquired or iatrogenic. Congenital *hypertrichosis lanuginosa* is a condition where the infant’s skin is covered by lanugo hair. The hair will be silky and the entire body, excepting the palms and soles will be affected. Acquired hypertrichosis lanuginosa is paraneoplastic manifestation. Steroids, phenytoin, minoxidil and diazoxide are the drugs causing hypertrichosis.

HIRSUTISM

This is male pattern hair occurring in females. Terminal hairs develop on the androgen-dependent areas like the mustache and beard area in a female. Endocrine abnormalities may play a role. Polycystic ovary syndrome is an important cause for hirsutism. Medical treatment includes anti-androgens like finasteride, flutamide and spiranolactone. Electrolysis and laser epilation are the new modalities of therapy.

CANITIES

Graying of hair is known as canities and premature graying of hair is denoted when graying occurs below 20 years of age. Genetics may play a role in premature graying. Calcium pantothenate may be beneficial in some patients.

Onychomycosis
Nail psoriasis
Leuconychia
20 nail dystrophy
Beau's nail
Mee's nail
Terry's nail
Muerhcke's nail
Half and half nail

Diseases of Nails

The finger nails grow approximately 0.1 mm/day and toe nails one-third this rate. The nail lesions may at times reflect serious systemic disorders. The common nail disorders are given in Table 215.2.

PARONYCHIA

Acute paronychia is a staphylococcal infection of the nail folds. The patient presents with painful swelling and erythema of the nail folds. Compression helps to extrude pus. *Chronic paronychia* is seen in domestic workers, fish mongers and canteen workers who frequently come into contact with water. Chronic paronychia is caused by a combination of staphylococcus and candida albicans. There is separation of the cuticle from the nail plate and retraction of the proximal nail fold. It may be associated with swelling, redness and mild tenderness of the proximal nail fold.

Acute paronychia may need incision and drainage, and systemic antibiotics like cloxacillin or cephalosporins. Chronic paronychia is managed by topical anti fungal agents like clotrimazole lotion or a combination with topical steroids like betamethasone twice daily for 3-6 months. Topical amorolfine nail lacquer applied twice weekly is effective in localized distal nail infection. If proximal nail damage occurs, oral antifungal therapy with itraconazole 200-400 mg/day for 6 weeks or pulse therapy with 400 mg/day for 1 week/month, for 3 months, is required. Prevention is by stopping wet work and use of gloves to protect hands.

ONYCHOMYCOSIS

Fungal infection of the nails is called onychomycosis and is caused by dermatophyte species or by *Candida albicans* (Fig. 215.3). One or more nails may be affected. The nails will be discolored, brittle and sometimes total dystrophy

Fig. 215.3: Onychomycosis

may occur. The condition is generally resistant to treatment. Systemic therapy with griseofulvin (500 mg/day) for 3 months for finger nails and 6 months for toe nails is required. Pulsed doses of itraconazole, 200 mg bid for 7 days a month, repeated twice for finger nails and thrice for toe nails are effective. Terbinafine 250 mg/day for 6 weeks is the treatment for dermatophyte infections of the nails. Amorolfine, a nail lacquer applied once or twice a week is effective.

NAIL PSORIASIS

Psoriasis is the most common dermatosis affecting the nails. Fine pitting is the hall mark of psoriasis. Pitting of nail can also occur in alopecia areata. “Oil spot macule” is the most specific nail change seen as a yellowish brown macule on the nail plate. Subungual hyperkeratosis is thickening of the distal end of the nail with retained keratin underneath. Onycholysis is lateral or distal separation of the nail plate from the nail bed which can be seen in fungal infections and eczemas also. Sometimes dystrophy of all the nails can occur (Fig. 215.4).

Fig. 215.4: Nails show onychodystrophy, onycholysis and subungual hyperkeratosis with psoriasis of the adjacent skin

Miscellaneous Conditions affecting the Nails

Leuconychia is whitish discoloration of the nails as a consequence of hypoproteinemia and renal or hepatic disease.

Twenty nail dystrophy is considered to be a manifestation of lichen planus where all the 20 nails are dystrophic.

Beau’s nails are transverse grooves seen on the nail plate sometimes involving all the nails. They may follow severe systemic illnesses like pneumonia and is due to a temporary arrest of nail growth.

Mee’s nails are white transverse bands seen on the nail plate and may be a manifestation of chronic arsenic poisoning or chemotherapy.

The other nail disorders shown in the table are described in the cutaneous manifestations of systemic disorders.

216

Disorders of Elastin and Collagen Fibers

S. Pradeep Nair

Chapter Summary

- Cutis Laxa 1389
- Pseudoxanthoma Elasticum 1389
- Striae Distensae 1389
- Anectoderma (Macular Atrophy) 1389
- Ehlers-Danlos Syndrome 1390
- Keloid and Hypertrophic Scar 1390

The elastin and collagen fibers of the skin give strength and elasticity to the skin. The disorders affecting these fibers are given in Table 216.1.

TABLE 216.1

Disorders of elastin and collagen fibres	
Elastin	Collagen
• Cutis laxa	Ehlers-Danlos syndrome
• Pseudoxanthoma elasticum	Pachydermoperiostosis
• Striae distensae	Keloid/hypertrophic scars
• Anectoderma	
• Marfan's syndrome	

Cutis Laxa

Cutis laxa is a heterogenous group of elastic tissue disorders characterized by skin laxity and involvement of internal organs. It may be inherited or acquired, localized or generalized. Inherited cutis laxa may be autosomal dominant or recessive. Acquired cutis laxa is seen as a sequel of recurrent urticaria, angioedema and SLE in a few cases. Abnormalities of elastic fibers causes the skin to be lax and pendulous, hanging in folds especially on the face and axilla giving the patient a “blood hound” or “old man” facies (Fig. 216.1). The skin loses its elasticity. Pinching the skin causes slow recoiling. Plastic surgery procedures like “face lift” operations may benefit the patient.

Fig. 216.1: Acquired cutis laxa

Pseudoxanthoma Elasticum

This autosomal dominant disorder affects the elastic fibers of the skin, blood vessels and eyes. The skin is soft, lax and wrinkled involving the sides of neck, flexures and abdomen. The skin on the neck may have a “chicken skin” or “cobblestone” appearance. The patient may have cardiac and ocular defects. Angioid streaks of the retina are seen. There is no specific treatment.

Striae Distensae

These are linear scars occurring due to skin stretching in pregnancy, weight lifters and sometimes in Cushing’s syndrome. These present as linear hypopigmented or depigmented scars on the breast, axilla, lower abdomen and thighs. Prolonged topical therapy with potent corticosteroids may also cause striae (Fig. 216.2) in the area of application. Topical retinoids may help to resolve the condition in some patients.

Anectoderma (Macular atrophy)

This represents a localized area of slack skin due to elastic fiber damage. It may be primary, or secondary to syphilis, leprosy or SLE. They present as out pouchings of the skin on the trunk, upper arms and thighs. The surface of the

Fig. 216.2: Steroid induced striae on the right thigh

skin is wrinkled. A finger can be insinuated into the lesions. There is no effective treatment.

Ehlers-Danlos Syndrome

This is an inherited disorder of collagen fibers. There are 11 sub types of this syndrome. Abnormalities of collagen

fibers cause increased fragility of the skin and blood vessels. The skin is hyperextensible and rebounds quickly after pinching in contrast to cutis laxa. There is hypermobility of the joints resulting in joint damage. Ecchymosis is seen in Type V and ocular involvement in Type VI (See Chapter 94).

Keloid and Hypertrophic Scar

These are localized areas of excessive collagen tissue response following injury. Keloids may occur de novo or following injury or acne. It presents as firm skin coloured or hyperpigmented plaques with peripheral pseudopodia like extensions. The commonest site is over the sternum. Extensive keloids are seen following burns. Keloid has to be distinguished from hypertrophic scar. The latter is confined to the original site of injury unlike keloid and it usually undergoes resolution. Treatment is recommended for both conditions. Intralesional triamcinolone up to a maximum of 10 mg per sitting is helpful to favour resolution. Simultaneous use of cryotherapy with liquid nitrogen hastens resolution. Results are better for hypertrophic scars. CO₂ laser ablation therapy is helpful in resistant cases.

217

Cutaneous Manifestations of Systemic Disorders

S. Pradeep Nair

Chapter Summary

- Generalised Pruritus 1390
- Thyroid Disorders 1391
- Diabetes Mellitus 1391
- Liver and Kidney Disorders 1391
- Internal Malignancy 1392

Generalised Pruritus

This is a very common manifestation of systemic disorders. The systemic conditions causing generalized pruritus are given in Table 217.1.

Generalized pruritus associated with systemic disorders is worsened during night. In diabetes mellitus, hepatic disorders and chronic renal failure the dryness (xerosis) of the skin may worsen the pruritus.

Management: Emollients like liquid paraffin and antihistamines like hydroxyzine (10-25 mg thrice daily) alleviate the pruritus. The underlying systemic disorder should be treated appropriately.

Several systemic diseases produce cutaneous manifestations which may be the first indication of the disease. Skin is considered to be the mirror of the body.

TABLE 217.1

Systemic causes of pruritus
Diabetes mellitus
Liver disorders
Chronic renal failure
Hyperthyroidism
Iron deficiency anemia
Polycythemia
Chronic leukemias
Lymphomas

TABLE 217.2

Skin manifestations of thyroid disorders	
Hyperthyroidism	Hypothyroidism
Generalised pruritus	Xerosis
Warm skin	Cold skin
Palmar erythema	Palmoplantar keratoderma
Hyperpigmentation	Decreased sweating
Increased sweating	Edema of hands, face and eyelids
Pretibial myxoedema	Xanthomas
Chronic urticaria	Sparse and coarse hair

Thyroid Disorders

The skin manifestations of thyroid disorders are given in Table 217.2.

Thyroid disorders may also be associated with diabetes and vitiligo. Pretibial myxoedema presents with skin colored or yellowish waxy nodules and plaques on the anterolateral aspect of lower limbs. Treatment is with topical potent steroids or with intralesional triamcinolone. Treatment of the basic thyroid problem may alleviate some of the skin manifestations.

Diabetes Mellitus

Diabetes is associated with a large number of skin manifestations (Table 217.3). Some of the manifestations may be related to poor diabetic control. The autonomic neuropathy of diabetes leads to xeroderma and ichthyosis which in turn leads to generalized pruritus.

Granuloma annulare presents with multiple discrete annular plaques with peripheral pebbling. Treatment is with topical steroids.

Necrobiosis lipoidica is a very specific skin lesion associated with diabetes. The patient presents with erythematous plaques on the shin which later becomes yellowish brown and undergoes central atrophy. The lesions have a glazed appearance and may ulcerate and then heal with scarring. Local treatment consists of the application of a potent glucocorticoid like clobetasol propionate 0.05% ointment.

TABLE 217.3

Skin manifestations of diabetes
Generalised pruritus
Xeroderma/ichthyosis
Granuloma annulare
Necrobiosis lipoidica diabetorum
Infections – bacterial, fungal
Diabeticorum bullosum
Scleredema diabetorum
Eruptive xanthomas
Diabetic dermopathy
Acanthosis nigricans
Diabetic ulcers

Candidal intertrigo is a very common fungal infection seen in diabetes.

Diabeticorum bullosum is the presence of large hemorrhagic bullae on the lower limbs.

Scleredema presents with edema and sclerosis of the skin of the upper back.

Diabetic dermopathy (shin spots) presents with multiple hyperpigmented patches on the lower limbs.

Eruptive xanthomas: The hyperlipidemia seen in diabetes may cause eruptive xanthomas presenting with skin colored to yellow papules on extensor surfaces and buttocks.

Acanthosis nigricans presents as velvety plaques on the nape of the neck and flexures.

Diabetic ulcers: These are common complications of longstanding diabetes. See section on diabetes.

Liver and Kidney Disorders

Liver and kidney disorders present with a wide variety of skin manifestations (Table 217.4).

Liver disorders: Hepatitis B and C infection can present with chronic urticaria. Palmar erythema and spider

TABLE 217.4

Skin manifestations of liver and renal disorders	
Liver disorders	Renal disorders
Generalized pruritus	Generalized pruritus
Xeroderma	Xeroderma
Jaundice	Hyperpigmentation
Hyperpigmentation	Kyrle's disease
Palmar erythema	Half and half nail
Spider angiomas	Calcinosis cutis
Terry's nails, Muerhrcke's nails	

Fig. 217.1: Kyrle's disease

angiomas occur in liver failure. Spider angiomas are usually seen on the upper half of the body. Terry's nails present with proximal white color and distal pink color. They occur in cirrhosis liver. Muehrcke's nails present with white bands and may be due to hypoalbuminemia.

Chronic renal failure: The skin signs are seen in advanced cases and are of limited diagnostic value.

Half and half nail presents with proximal white color and distal pink, red or brown color and is seen in 10% of patients with chronic renal failure.

Kyrle's disease is a perforating collagenosis of the skin and is often associated with diabetic nephropathy and/or retinopathy. It presents with multiple discrete hyperpigmented keratotic papules on the limbs and trunks (Fig. 217.1). The lesions may even precede the renal failure.

Metastatic calcification in the form of *calcinosis cutis* over the joints and flexures may occur.

Fig. 217.2: Plaques and nodules due to Non-Hodgkin's lymphoma

Internal Malignancy

The skin manifestations of internal malignancy may be either in the form of secondaries or as paraneoplastic syndromes. The abdominal skin is the commonest site of cutaneous secondaries in intra abdominal malignancies and occur in the form of papules, plaques or nodules (Fig. 217.2), a classic example being 'Sister Joseph's nodules' which are periumbilical cutaneous secondaries. Secondaries may be seen on the trunk and scalp in lung cancers, and on the scalp or operative scars in hypernephroma. The skin manifestations of paraneoplastic syndromes are given in Table 217.5 (Fig. 217.3).

Malignant acanthosis nigricans presents with diffuse hyperpigmentation of face and flexures. The palms of the hands show increased rugosity and hyperkeratosis (tripe palms). The usual malignancy is carcinoma stomach.

Leser Trelat sign is the occurrence of multiple pruritic seborrheic keratoses in a short duration on the trunk.

TABLE 217.5

Skin manifestations of paraneoplastic syndromes	
Skin manifestation	Malignancy
Generalized pruritus	Leukemia, lymphomas
Exfoliative dermatitis	Leukemia, lymphoma, Ca. rectum, colon, prostate
Acquired ichthyosis	Leukemia, lymphomas
Bullous eruptions	Ca. GIT, breast, lung, thymoma, Castleman tumour
Acanthosis nigricans	Adenocarcinoma of GIT
Leser Trelat sign	Adenocarcinoma of GIT
Pityriasis rotunda	Hepatocellular carcinoma
Erythema gyratum repens	Ca. lungs
Erythema annulare centrifugam	Leukemia, lymphomas
Erythema multiforme	Leukemia, lymphomas
Erythema nodosum	Leukemia, lymphomas
Necrolytic migrating erythema	α - cell tumour of pancreas
Migrating thrombophlebitis	Ca. pancreas, stomach, lungs
Acquired hypertrichosis lanuginosa	Ca. colon, rectum, bladder

Fig. 217.3: Acquired ichthyosis due to Hodgkin's lymphoma

Fig. 217.4: Erythema gyratum repens
Note the concentric plaques with wood-grain appearance

Erythema gyratum repens (Fig. 217.4) is characterized by multiple confluent erythematous scaly concentric and whorled patches on the trunk resembling “wood grain” pattern. These patients have a high incidence of lung carcinoma.

Erythema annulare centrifugum presents with multiple erythematous annular patches on the trunk with peripheral extension.

Necrolytic migratory erythema (glucagonoma syndrome) presents with superficial eroding areas of erythema and

scaling distributed on the lower abdomen, buttocks and thighs.

Migrating thrombophlebitis (Trousseau’s sign) involves the veins of the upper limbs and trunk.

Acquired hypertrichosis lanuginosa presents with excess lanugo or vellus hairs on the face and ears and later other hair bearing areas. This cutaneous manifestation has a very strong relation with internal malignancy.

218

Skin Tumours

S. Pradeep Nair

Chapter Summary

Benign Skin Tumours	1393
Premalignant Skin Conditions	1394

Benign Skin Tumours

This chapter deals with the benign skin tumours and the premalignant skin conditions. They account for 1.98% of

the skin conditions in Kerala. Benign skin tumours can arise from the epidermis, dermis or the skin appendages. They commonly present with asymptomatic papules or nodules. The common benign skin tumours are given in Table 218.1.

Seborrheic Keratoses

This is a pigmented benign skin tumor composed of epidermal keratinocytes. This presents with single or

TABLE 218.1

Benign skin tumors
Seborrheic keratoses
Acrochordon
Keratoacanthoma
Trichoepithelioma
Syringoma

Fig. 218.1: Seborrheic keratosis

multiple hyperpigmented flat papules or plaques on the face, neck and upper trunk with a ‘stuck-on’ appearance (Fig. 218.1). Dermatitis papulosa nigra is a clinical variant presenting with tiny pin head sized hyperpigmented papules on the face and neck. Electro-surgery and cryotherapy are the treatment modalities.

Acrochordon

They are also known as skin tags or Templeton’s tags and are soft skin colored pedunculated papules usually seen on the neck, axilla, back and chest. Histologically they are soft fibromas. Treatment is by electrosurgery or cryotherapy.

Keratoacanthoma

This is a benign tumour originating from the pilo-sebaceous unit containing keratinized squamous cells. It presents as skin colored dome shaped firm papules or nodules with a central crater filled with a keratin plug usually seen on the central part of the face (Fig. 218.2). This has to be differentiated from squamous cell carcinoma. Spontaneous resolution may occur. Surgical excision, electrocautery or topical 5-fluorouracil are the treatment modalities.

Trichoepithelioma

This is a benign skin tumour arising from hair structures. These may be solitary or multiple. Multiple trichoepithelioma may be an autosomal dominant disorder. It presents

Fig. 218.2: Keratoacanthoma of the forearm

with skin colored papules distributed on the face, especially on the eyelids, cheeks and naso-labial folds. Treatment is by excision.

Syringoma

This is a tumour arising from the ductal part of the eccrine sweat glands. It presents with skin colored papules with a crenated edge on the upper and lower eyelids and cheeks. Treatment is by electrosurgery.

Premalignant Skin Conditions

Some common premalignant skin conditions are given in Table 218.2. They usually lead to squamous cell carcinoma.

Actinic Keratoses

This occurs due to chronic exposure to sunlight. It is rare in India, but common in white races. It is characterized by skin coloured or hyperpigmented hyperkeratotic papules and plaques on the sun exposed areas like the face and dorsum of hands. They may lead to squamous cell carcinoma. Small and superficial lesions can be treated with liquid nitrogen cryotherapy and topical

TABLE 218.2

Premalignant conditions
Actinic keratoses
Arsenical keratoses
Bowenoid papulosis
Cutaneous horn
Erythroplasia of Queyrat

5-fluorouracil. Large indurated lesions must be excised and sent for biopsy. Prevention consists of avoidance of direct sunlight and regular use of sunscreens containing avobenzones, oxybenzones and cinnamates.

Arsenical Keratoses

This occurs in individuals who are exposed to chronic arsenic poisoning. It presents as multiple discrete punctate keratotic papules and plaques on the palms and soles. It may be associated with lung carcinoma. Treatment is difficult, but keratolytic agents can be tried.

Bowenoid Papulosis

This is caused by human papilloma virus, HPV-16 and presents with multiple discrete lichenoid papules usually on the shaft of the penis. They may progress to squamous cell carcinoma. Treatment is by electrosurgery, cryotherapy

and topical 5-fluorouracil. Topical immune response modifier, imiquimod is also effective.

Cutaneous Horn

This presents as hard yellowish brown horny plugs or outgrowths on the upper part of the face and ears. Treatment consists of excision. Underlying squamous cell carcinoma should be excluded by histopathology.

Erythroplasia of Queyrat

This presents as red velvety plaques with a moist appearance on the glans penis in people with intact prepuce. It is considered to be a form of squamous cell carcinoma in situ. Treatment is with topical 5 fluorouracil if there is no submucosal invasion. Moh's surgery is the treatment of choice if the condition is invasive.

Chapter Summary

- General Considerations 1398
- Signs and Symptoms of Mental Disorders 1398
- Clinical Examination of a Psychiatric Patient 1402
- Classification of Mental Disorders 1404

GENERAL CONSIDERATIONS

What is Psychiatry? The German Dr. Johann Reil originated the term ‘Psychiatry’ from the Greek root ‘psyche’ (=mind) and *iartos* (=treatment). Psychiatry or psychological medicine can be defined as that branch of medicine concerned with the study, diagnosis, treatment and prevention of disorders of the mind. Psychiatric disorders are termed variously as *insanity*, *mental illness*, *mental disease*, *emotional disorders*, *behavioral disorders*, *functional disorders* and the like in the past. Psychiatry differs from Psychology. *Psychology* deals with scientific study of behavior of normal man and animal.

Evolution of psychiatry: Though in prehistoric times physical and psychological illnesses were treated with contempt, with the renaissance movement the attitude towards the victim of illness came to be one of compassion. The **moral treatment** of insane was initiated by Phillippe Pinel in France in the 18th Century by setting free the lunatics from chains.

Mental hospitals have a long history of evolution. Originally these were called *mad houses*, *lunatic asylums* or *mental asylums* and these were places where the aggressive and violent psychiatric patients could be admitted and kept in isolation under custody along with other criminals. Laws providing for the admission, detention and discharge of lunatics into such lunatic asylums were also formed and these were known as the *Lunacy Acts*. With the passage of time these institutions came to be known as mental hospitals. At present the mentally disordered person are kept in the community and

treated without isolating them into mental hospitals. The modern approach is to consider psychiatric patients also along with the general stream of other patients and to provide treatment facilities for them in general hospitals under especially trained personnel. The mental hospitals are giving way to general hospitals and community psychiatry centers especially with the advent of modern drugs. Custodial care is being discouraged and the family and society are brought more and more to take care of the mentally ill patient who is allowed to remain in the community itself as far as possible. This helps to minimize psychiatric morbidity, facilitate early recovery and remove the social stigma. This practice of community psychiatry is a modern concept.

SIGNS AND SYMPTOMS OF MENTAL DISORDERS

Most of the symptoms are subjective in nature. Often the patients are mocked at and alleged of simply imitating the symptoms. These symptoms are expressed as disturbances in the mental functions. They are best described as disturbances of mood, cognition, and psychomotor activity (conation).

Disturbance of Mood

Laughing, crying, anger and the like are expressions of emotion. Emotion is the subjectively experienced feeling tone of mind. It is commonly noted as affect and mood. Though both are used interchangeably in the clinical setting, there are subtle differences. *Affect* is a momentary accentuation of emotion and *mood* a more sustained emotional state. The normal mood of a person is congruent with the ideas, action and behavior and it is appropriate to the situation. It is stable and adequate in intensity.

Disturbance of Mood

- Pleasant mood states
 - Euphoria
 - Elation

Ecstasy

Exaltation

Unpleasant mood states

Anxiety

Depression

Irritability

Hatred

Other mood states

Apathy

Anhedonia

Blunting

Incongruous.

Disturbance of Thinking*Of Formal thought*

Loosening of association

Flight of ideas

Neologism

Perseveration

Of Stream

Thought block

Pressure of talk

Poverty of thinking

Circumstantiality

Of Abnormal content

Delusions

Obsessions

Phobias

Suicidal ideas

Of Possession

Thought deprivation

Thought insertion

Thought broadcast

The common disturbances of mood include incongruity, anxiety, depression, elation, euphoria, ecstasy, flattening (blunting), lability, apathy and anhedonia. When mood is not in harmony or congruent to the ideas or actions it is called *incongruous affect*. For example, the person may start smiling on hearing the tragic news about a dear one. *Anxiety* refers to an unpleasant fearful mood. *Depression* denotes sadness of mood. Anxiety, depression, irritability, hatred and others are *dysphoric (unpleasant) mood states*. *Elation*, *euphoria* and *ecstasy* are euphoric (pleasant) mood states. Elation is a well sustained cheerful mood. Euphoria is a happy mood with grandiosity and increased physical well-being. Ecstasy is the extreme degree of pleasure (rapture). In *labile affect*, the mood frequency changes without reason (*emotional incontinence*). In *affective blunting* (flattening) the degree of emotional expression is reduced much (constricted). Loss of emotional expression is called *apathy*. The inability to feel or share pleasure is referred as *anhedonia*.

Typically the mood is sad in depressive disorder, elated in manic disorder, anxious in anxiety disorder, incongruous or blunted in schizophrenia and labile in organic disorders.

Disturbance of cognition: Cognition refers to an individual's thoughts, knowledge, interpretation, understanding and ideas about himself and his environment.

Thought (thinking) is the goal directed arousal of symbols, ideas and associations leading to a reality-oriented conclusion. The thought comes to light through the verbalization (talk/speech), writing and gestures. Normally, thinking is coherent (fully understandable) and relevant to the context. It follows logic and contains only relevant matters as contents.

Disturbances in thinking may involve its formation, stream (flow), contents and ownership (possession). Loosening (looseness) of association, flight of ideas, neologism and perseveration, are formal thought disorders. In *loosening of association* the grammatical alliance of talk is lost and no meaningful relation occurs between the ideas. The talk lacks comprehension. Apparently it looks like a flight of ideas. In *flight of ideas* the talk jumps from topic to topic in quick succession, the ideas are related to each other and they are comprehensible. *Neologism* denotes the formation of new words which have no meaning to others (e.g. Hirschsprung, Heboobi). *Perseveration* is the involuntary repetition of the same thought (talk or activity) given in response to a stimulus when a subsequent stimulus is presented. Thought is said to be *irrelevant* when it is not to the context. It is *incoherent* when it is not meaningful. Thought block, pressure of talk, poverty of thinking, tangential thinking and circumstantiality are disturbances of the stream of talk. When the stream of the talk suddenly stops in the midst and fails to proceed further it is termed *thought block*. In *pressure of talk* ideas continue to rush out of the mind due to its richness. On the other hand, in *poverty of thinking* the talk is scanty and flow is slow. In *circumstantiality* the talk is prolonged by lengthy narration of unwanted details before coming to the right point finally. In *tangential thinking* the flow of talk deviates in different directions and a final goal (point) is not reached. The thought may be disturbed by abnormal contents like delusions, obsessions, phobias and suicidal ideas. A **delusion** is an abnormal belief not shared by other people. It is a false, fixed notion which cannot be corrected even by giving evidence to the contrary. Delusion can be corrected by treatment. *The various kinds of delusions are persecutory, paranoid, grandiose, poverty, guilt, nihilistic, infidelity, control, and hypochondriacal/somatic*. In *persecutory delusion*, the patient may have the wrong notion that attempts are being made to harm

or kill him. He believes that secret plots are made against him; he is poisoned, he is spied upon and so on. A news in the media, a gesture observed, and a conversation he heard may be construed as referring to him only, and that they are deliberately done by his enemies (*delusion of reference*). *Paranoid delusion* is synonymous with persecutory delusion though it actually includes grandiose delusions as well. In case of *grandiose delusion* the patient may retain the false notion that he is immensely rich, he is having close contact with people of high caliber, he is very powerful or that he is a big scholar or scientist. In *delusion of poverty* he holds that he is extremely poor having lost everything and he may even start begging. In *delusion of guilt*, the belief is that the patient is a sinner who has done sinful deeds in the past or in the previous birth and attributes guilt to himself. The wrong notion held in *nihilistic delusions* is that part of his body, he himself or the world itself is not existing. In *delusion of infidelity* (amorous delusions, jealous husband's or wife's syndrome, pathological jealousy) the wrong notion is that the spouse is having illicit sexual relations. In *delusions of love (erotomania)* it is wrongly believed that someone is in sincere love with him or her. In *delusions of control* (influence/ passivity feeling) the person's belief is that his thoughts, mood and actions are being controlled by people outside. In *hypochondriacal delusion* the patients may think that he suffers from some incurable illness.

Primary delusion (autochthonous delusion) is the sudden development of delusion without being preceded by any psychological event in the background.

Secondary delusion occurs as a consequence of some psychological events such as mood changes, hallucinations, delusions, or others.

Systematized delusions are a complex set of delusions built one upon another around a single theme or an event.

Obsession denotes recurrent intrusion of unwanted thoughts into mind in spite of the efforts made to stop it. *Phobias* denotes a kind of fear specific to an object or a situation which are normally harmless. *Suicidal* idea is another abnormal content.

The ownership ('my-ness') of thought may be changed. Thought deprivation, thought insertion and thought broadcasting are disturbances in possession of thought. In *thought deprivation* (withdrawal) the patient believes that ideas are stolen or taken away from his mind. In *thought insertion* the belief is that ideas are introduced into his mind from outside agencies. In *thought broadcast* the belief is that his thoughts (unexpressed) are known to others as soon as it occurs to him. He may believe that his actions and thought are being controlled.

Thought disturbance is frequent in schizophrenia. Cognitive decline is the hallmark of dementia. Sad gloomy thought pervades depression.

Clinical importance of delusions		
Types of delusion	Characteristic false belief of	Typical mental disorder
Paranoid		
Persecutory	Persecution – to kill or – to harm	Schizophrenia, Depression (when moved congruent)
Reference	Actions of others have special reference/meaning	-do-
Grandiose	Oneself being high, big, rich	Mania
Poverty	Poverty or loss	Depression
Guilt	Sinful action	Depression
Nihilistic	Non-existence of part or whole of self or the world itself	Depression
Somatic/hypochondriasis	Bodily disease	Depression
Jealousy	Illicit sexual relationship	Delusional disorder, Alcoholism
Love	Being loved	Delusional disorder
Primary		Schizophrenia
Secondary delusions		Mood disorder or any psychosis

Disturbance of perception: Perception is the cognitive process of becoming aware of the objects and the environment around us by way of the sense organs. The various kinds of perceptions include visual (seeing objects), auditory (hearing sounds), tactile or haptic (feeling touch), olfactory (smelling odours) and gustatory (feeling taste), and gustatory phenomena. Hallucinations, illusions, macropsia and micropsia are the common disturbances of perception. *Hallucination* is the vivid sensory (perceptive) experience occurring in the absence of the corresponding external object or stimulus. Thus there can be visual, auditory, tactile, olfactory, and gustatory hallucinations. In *auditory hallucinations* one may hear voices or noises in the absence of the corresponding external stimulus. In *visual hallucination* one may see objects in the absence of such external objects. In a similar way, the hallucination may be olfactory, tactile or gustatory. In *Liliputian hallucinations*, the hallucinatory objects especially the people appear much smaller. Auditory and haptic hallucinations are common in schizophrenia. Visual hallucinations are common in organic disorders. Visual illusions occur in delirium and auditory illusions are common in depression. Hallucinations and illusions are not always pathological. *Hypnagogic hallucinations* occurring as one falls to sleep and *hypnopompic hallucinations* occurring as one

awakens from sleep are common phenomena. This may be a normal phenomenon at times.

Type of hallucinations	Typical disorder
1 Auditory	
a. Third person-running commentary; discussion, arguing, conversation	Schizophrenia
b. Second person-blaming, accusing, prompting suicide	Major depression
c. Hearing one's own thought aloud.	Schizophrenia
2 Visual	
a. Insects-spiders, snakes, and the like	Organic-delirium
b. Lilliputian.	Temporal lobe epilepsy (TLE)
3 Olfactory	
a. Aura-burnt smell	Temporal lobe epilepsy (uncinate fit)
b. Foul odor emanating from the body	Major depression
c. Poisonous, foul smelling gas applied from outside.	Schizophrenia
4 Tactile	
a. Cocaine 'bug'	Cocaine psychosis
b. Bizarre sensation such as radiation, electromagnetic waves, cosmic rays all caused by enemies outside.	Schizophrenia

Illusion: This refers to misrecognition of objects. A rope may be perceived as a snake or a shadow of a tree may be viewed as a ghost. The illusion can be corrected by verifying the truth by closer examination.

Micropsia: In micropsia the real object or figure appear smaller than what they actually are, and in **macropsia** it is the reverse. They are found in temporal lobe epilepsy (TLE).

Disturbance of memory: The function of memory includes *registration*, *retention* and *recollection* of past events and information. Events once registered are retained and stored in the memory centers, and are recalled later according to need. Recollection with the help of a cue is recognition.

The common disturbance of memory is amnesia, which denotes loss of memory. Amnesia may be global and progressive or selective for certain events only. The memory loss may be for immediate events (loss of retention) or for recent or remote events. The gap in memory may be filled up by fabricated and irrelevant events and information. This phenomenon is called **confabulation**.

Disturbance of intelligence: Intelligence is the global capacity of an individual to think rationally, to act swiftly and to adjust adequately to the surroundings. Intelligence grows and develops with physical growth and maturation.

Intelligence is expressed in terms of **Intelligence Quotient (IQ)**. The average IQ is 100 ± 16 . When the intelligence is not proportionately grown and developed **mental retardation** results. In **dementia**, on the other hand the normally acquired intelligence deteriorates. Dementia is an acquired disorder and mental retardation is developmental disorder.

Disturbance of consciousness: These affect the clarity of the sensorium. The disorder of consciousness includes **clouding, confusion, stupor and coma**. Functional psychiatric symptoms develop in a clear conscious setting. On the other hand if the symptoms are found to supervene on an impaired state of consciousness, an organic illness has to be considered. In hysterical fainting there is no real loss of consciousness, and they will be aware of the surroundings.

Disturbance of orientation: Orientation is the appreciations of one's own temporal, personal, and spatial relations at a given moment. **Disorientation** is the disturbance of orientation. Disorientation may pertain to time, place or persons. It may occur in delirium.

Disturbance of attention and concentration: Distractibility is the disorder in which the attention is impaired. Fluctuating levels of attention are found in organic brain syndromes, e.g. delirium. Lack of concentration is seen in depression, schizophrenia, dementia and delirium.

Disturbance of insight: This denotes the abnormalities in the state of awareness of physical or mental health. Psychotic patients believe that they have no illness and so refuse treatment, whereas neurotic patients admit their illness but generally refuse to admit that their illnesses are psychological. They prefer treatment from doctors other than psychiatrists.

Disturbance of conation (motor activity): *Conation* represents the will to carryout an activity. It can be expressed as psychomotor or motor activity. It is different from neurological motor function. The disorder of motor activity may include decreased, increased and repetitive activity and disturbance of posture. The condition is called **psychomotor retardation** when the motor activity is decreased. In **psychological stupor** the motor activity is reduced to a minimum and the patient is fully conscious, unlike as in organic stupor. When motor activity is increased it is termed as **psychomotor overactivity**. Motor activity is increased to a very high degree in states of psychotic excitement. Repetitive motor activity includes stereotypy, mannerism, perseveration, echopraxia and echolalia.

Stereotypy: This term refers to monotonous, purposeless, repetition of an activity. **Mannerism** also is a repetitive

activity but is not monotonously repeated and often goes with normal personality. The repetition of a previous activity in spite of the patient's effort to move on to a new activity is called **perseveration** of activity. **Echopraxia** denotes involuntary repetition or imitation of an activity just seen. **Echolalia** denotes involuntary repetition or imitation of words just heard.

Catatonia: This term refers to widespread rigidity which may manifest as waxy flexibility posturing, negativism and excitement. **Waxy flexibility (flexibilitas cerea/catalepsy)** In this disorder limb can be positioned in any awkward posture for any length of time. **Posturing** refers to maintenance of imposed postures, which may be even bizarre and uncomfortable for long periods of time, however, awkward they may be.

Negativism: This term refers to the resistance to perform an activity, or doing opposite to what is expected for a given stimulus.

Disturbance of behavior: Behavior is a general term. It is any activity either physical or mental, like walking, crying, speaking, eating, writing and the like. This term is broadly used to describe mental function.

Somatic symptoms: Physical symptoms pertaining to any bodily system may be associated with psychiatric disorders and occasionally be the presenting symptom of such disorders.

Clinical Examination of a Psychiatric Patient

Examination of a psychiatric patient in general is similar to that of a medical case. The first part consists of history taking and the next consists of the mental state examination. In addition, a full physical examination is required for all cases. An informant to whom the patient is closely known should be selected for eliciting the history, especially in the case of psychosis and mental retardation. It is important to establish an understanding relationship (rapport) with the patient. A scheme followed in psychiatric examination is given below:

- A. *History*
 - a. Bio-data
 - b. Presenting complaints
 - c. History of the present illness
 - d. History of past medical and psychiatric illness
 - e. Family history
 - f. Personal history
 - g. Premorbid personality
- B. *Mental status examinations*
 - a. Appearance and general behavior
 - b. Motor activity
 - c. Mood (affect)

- d. Thinking
- e. Perception
- f. Consciousness
- g. Orientation
- h. Attention and concentration
- i. Memory
- j. Intelligence
- k. Judgment
- l. Insight
- C. *Physical examination*
 - a. General
 - b. Systemic
- D. *Provisional diagnosis*
- E. *Investigations - biological and psychological*
- F. *Final diagnosis.*

History

Bio-data: The name, address, age, sex, income, education, occupation and marital status are noted.

Presenting complaints: The common presenting complaints include aggression, violence, excessive talk, retarded motor activity, suicidal behavior, insomnia, loss of appetite, body aches and pains, paralysis, loss of memory, poor intelligence, habituation to drugs and intoxicants, and sexual disorders. The presenting complaints are recorded in sequential order.

History of present illness: All details of the illness from its onset to the present state should be vividly described. Precipitating and aggravating factors and daily variation of symptoms are enquired into. Details of treatment have to be recorded. Leading questions may be required to bring out features such as suicidal tendencies, substance abuse, sexual disturbances, obsessions, delusions or hallucinations.

History of past illness: This should include all the past psychiatric problems, medical illness, physical trauma and accidents. Important events from birth (including birth injuries) and milestones of development have to be obtained.

Family history: All details of the family members, their inter-relationship, the family structure, the attitude of other family members towards the patient and the occurrence of psychiatric illness in family have to be elicited. It is always desirable to construct a family tree.

Personal history: All details regarding occupation, work, socio-economic status, sexual activity, addictions, marriage and marital adjustments and details of the children should be recorded. A biographic scheme is to be derived. Intrauterine history; details of delivery, diseases, trauma during childhood, administration of drugs, poor group relations and details of education are

taken. History of physical torture and sexual assault during childhood should also be elicited.

Premorbid personality: This refers to the personality of the individual before developing the illness. This should include the general behavioral pattern, his hobbies, likes and dislikes, character trait, habits, attitude, social relations and others. The patient comes back to premorbid personality level, once he recovers from the mental illness.

Mental Status Examination

General appearance and behavior: The look of the patient, his dressing, hair style, level of co-operation, communication skills and level of activity, are noted.

Psychomotor activity: Note whether the activity is normal, decreased or increased and then look for specific disturbances of motor activity such as stereotypy, stupor, mannerism, negativism and others.

Affect and mood: The mood is assessed objectively and subjectively. The patient is asked to tell about his mood which gives the subjective mood state. Objectively the mood may be assessed by the interviewer. Normally, both subjective and objective mood should be the same (congruent). Abnormalities of mood, if any, are determined.

Thinking: This is brought out by noting the talk, writing and gestures of the patient. Disturbance of thinking manifests as disturbance of the form, stream, content and possession of the thought. Suicidal tendencies, obsessions and sexual matters have to be brought out by specific interrogation. When the patient is mute, gesture or written language is taken for analysis.

Perception: Spontaneous gestures and self-conversation may give clue to hallucinations. Symptoms such as hearing voices or other sensory experiences, in the absence of any real source should suggest hallucinations. In the presence of hallucination, its content, the person (whether first, second or third) and the related mood should be elicited.

Consciousness: The level of consciousness has to be carefully recorded through inspection and interrogation.

Orientation: Orientation in time (day, date, week and year) place and persons should be assessed.

Attention and concentration: Attention can be assessed during interrogation. Normally, attention is prompt and sustained as long as the stimulus continues. Attention and concentration can be tested by:

- *Forward and backward counting test:* The patient is made to count 1 to 20 forwards and then backwards.
- *Serial deduction test:* To deduct serially 3s from 40 or 9s from 100. *The rate of performance and the*

errors committed will give an idea of the state of attention and concentration. These factors also depend to great deal on the level of his education.

- *Digit span test:* In the digit forward test the patient is asked to repeat digits given by the interviewer containing three, four, five, six, seven or eight digits (e.g.: 729, 3194, 27106....). In the backward digit test, the digits given by the examiner have to be repeated in the reverse order (i.e. 8139 as 9318). *7 digits forward and 5 digits backward constitute, normal ability.* It is lowered when the attention or immediate memory is impaired.

Memory: Immediate memory (power of retention), recent memory and remote memory have to be separately assessed.

- *Intelligence:* This can be assessed clinically by knowing his adaptive skills, general knowledge, occupational adjustments, educational achievement, motor skills, management of finance, household and others, during the interview. Intelligence can also be measured by scales of intelligence.

Judgment: This can be assessed by making the patient take decisions when confronted with specific situations. For example, the patient is asked “*what will you do when you see a house on fire?*”, “*What will you do when you get a wound on your finger?*” Answers to these types of questions help to reveal impairment in judgment.

Insight: This is the appreciation of one’s own physical and mental state. To assess the level of insight the patient is just asked whether he is sick or he needs any treatment. Patients who have no insight often answer that they are not ill and that they do not require any treatment in spite of severe symptoms.

Physical Examination

No mental examination is complete without a thorough physical examination.

At the end of the psychiatric and physical examinations, a provisional diagnosis can be arrived at in most cases.

Psychological testing: **Psychometry** is the method of measuring psychological processes, and states. These tests are ancillary to clinical assessment. They measure specific aspects of intelligence, personality and thinking. Neuropsychological tests help to quantify and localize the brain damage.

Intelligence test: The common scales of intelligence are:

- Wechsler Intelligence Scale for adults and for children
- Raven’s progressive matrices test
- Bhatia’s battery of intelligence scale
- Binnet Simon scale of intelligence.

Personality tests: These assess the type of personality, its change or deterioration, if any .The usual tests are:

- Minnesota Multiphasic Personality Inventory(MMPI)
- Rorschach Test by Hermann Rorschach
- Bender Visual Motor Gestalt Test (BVMG).

Memory tests: These quantify the loss of memory, e.g.

- Boston Memory scale
- Wechsler Memory scale
- Bender Visual Motor Gestalt test (BVMG).

Rating scales: These are questionnaires, interviews and checklists that help to quantify behavior, thought and mood. For example:

- Brief psychiatric rating scale (BPRS)
- Hamilton’s rating scales for depression
- Hamilton’s rating scales for anxiety
- Abnormal involuntary movements scales (AIMS).

Classification of Mental Disorders

The terms ‘psychiatric’ and ‘mental’ which are used synonymously, denote disorders pertaining to the mind. A major impediment in the classification of mental disorders is the absence of a specific etiological factor. So, the term disorder is preferred in place of disease or illness. For the same reason an etiological classification may not always be possible. The psychiatric disorders are therefore categorised into diagnostic entities based on sets of symptom patterns having a separate course (categorical classification). The American Psychiatric Association has made a system of classification known as *Diagnostic and Statistical Manual of Mental Disorders* (DSM).The World Health Organisation has made its own system known as *International Classification of Diseases and Related Health Problems(ICD)*. The DSM 1V and ICD –10 are currently in vogue.

ICD –10 is widely followed. The diagnostic categories are give under chapter V(F). Each diagnostic category is given an alphabetic letter code (F) followed by a number code (alpha numerical coding). The disorders range from F-00 to F-99.

Features of psychoses and neuroses are given in Table 219.1.

TABLE 219.1
Features of psychoses and neuroses

Major psychological disturbance with	Minor psychological disturbance with
Loss of contact with reality	No loss of contact with reality
Loss of insight	No loss of insight
Disintegration of personality	No disintegration of personality
Presence of delusions	No delusions
Presence of hallucination e.g. schizophrenia, delirium	Typically no hallucination, except rarely, e.g. anxiety neurosis, hysterical neurosis

A simplified version of the main category of mental disorders

- F00—F09 Organic mental disorders
- F10—F19 Mental disorders due to psychoactive substance use
- F20—F29 Schizophrenia and delusional disorders
- F30—F39 Mood (affective) disorders
- F40—F49 Neurotic stress-related and somatoform disorders
- F50—F59 Behavioral syndromes associated with physiological disturbance
- F60—F69 Personality disorders
- F70—F79 Mental retardation
- F80—F89 Psychological developmental disorders
- F90—F98 Childhood emotional disorders
- F99 Unspecified mental disorders.

The terms such as *psychosis*, *neurosis* and *functional* disorders are not in common use at present. By tradition, a disorder or symptom is said to be functional when there is no demonstrable physical abnormality in any organ system.

Chapter Summary

Delirium 1405

Dementia 1405

Amnesic Disorders 1406

These are a group of psychiatric disorders resulting from diagnosable physical disease. Though there are a large number of physical diseases, the psychiatric manifestations mainly occur as three syndromes. They are *delirium*, *dementia* and *organic amnesic syndromes*.

DELIRIUM

Synonyms: *Acute psycho-organic syndrome*, *acute brain disorder*, *toxic metabolic encephalopathy* and *acute confusional state*.

Delirium is a syndrome and not a disease.

Clinical Features

The clinical features of delirium depend on the degree of severity. It may vary from mild to severe abnormality. Symptoms are rapid in onset, transient in duration and reversible in outcome. These often fluctuate with brief spells of symptom-free intervals (lucidity). Children and old people are more vulnerable. Widespread psychological (cognitive) disturbance is seen. The cardinal feature is impairment of the level of consciousness. The clarity of awareness of sensorium is reduced. It leads to clouding, confusion, stupor or even coma. Orientation in time is lost early, and later to place and even to persons. Attention is fleeting with distractibility. Concentration is poor. Immediate and recent memory is impaired, affecting comprehension and learning. Visual hallucination of insects, reptiles and small objects and visual illusions are characteristic. Disturbed thinking results in irrelevant and incoherent talk and persecutory delusions. Mood becomes irritable, anxious and apprehensive. It may be perplexed, labile or even depressed. Disturbance in motor function produces severe restlessness, excitement or violent and

aggressive behavior. It brings danger to self and to others. Sometimes under-activity is seen. Insomnia is one of the earliest features of delirium. It is typically associated with day time somnolence. Sleep-wake cycle is altered. Insight and judgment are lost. These mental symptoms are accompanied by physical symptoms such as dehydration, tremors, incoordination, aphasia and incontinence. The EEG may show generalised slowing of activity, but in delirium tremens due to alcohol withdrawal, overactivity is more common in the EEG.

Delirium is due to generalised metabolic disturbances. The major neurotransmitter implicated is acetylcholine. Reticular activating system (RAS) is the main seat of pathogenesis. Delirium occurs in a large number of physical conditions as listed in Table 220.1.

- **Diagnosis and management:** Delirium is an emergency. The diagnosis is made from the clinical features and relevant investigations. The identification of the primary medical condition and its management are the goals. Good supporting environment and nursing care play the key role. Mild delirium may clear up with supportive care. In other cases appropriate drugs are needed. These include injection diazepam (5-10 mg) IV or lorazepam 2 mg oral may help to relieve restlessness and anxiety. Injection of haloperidol 2-5 mg IM reduces psychotic features such as delusions, violence and excitement. The drugs may have to be repeated and later changed to oral route and gradually withdrawn.

DEMENTIA

This is a syndrome, not a particular disease. The word dementia in Latin means general mental deterioration. It is a neuro-psychiatric syndrome produced by organic brain diseases. Dementia is characterised by decline of cognition, memory, thinking, intellect and personality. Associated symptoms may develop. The level of consciousness is not altered. Dementia is of insidious onset, and runs a chronic progressive course. Primary dementia is generally irreversible in nature (See Chapter 189).

TABLE 220.1

Common causes of delirium

Metabolic disturbances	Vascular causes
Electrolyte disturbances	Cerebrovascular disorders
Acidosis/alkalosis	Cardiac failure
Hypo/hyperglycemia	Acute myocardial infarction
Hepatic failure	Cerebral edema
Uremia	Hypertensive encephalopathy
Endocrine disturbances	Eclampsia
Hypo/hyperthyroidism	Drugs
Hypo/hyperparathyroidism	Consumption/withdrawal of:
Adrenal dysfunction	alcohol
Pituitary dysfunction	Barbiturates
CNS infections	Anticholinergics
Meningitis	Antipsychotics
Encephalitis	Nutritional Deficiency of
Cerebral abscess	Thiamine, niacin,
Systemic infections	Vitamin B ₁₂ and folates
Pneumonias	Others Epilepsy
Enteric fever	Head trauma
Viral fevers	
Septicemia	

- **The clinical features** of dementia depend on the stage of the disorder. Loss of recent and immediate memory is noted early. It interferes with day-to-day functions. Remote memory is affected only gradually and it leads to disorientation. The gap in memory is filled by irrelevant events and information (confabulation). Other cognitive areas such as thinking, attention, concentration, intelligence, perception and judgment also show decline. Thinking is slow with low word output. Grandiose and persecutory delusions may occur. Attention and concentration are impaired, but the level of consciousness is unaffected. Visual hallucinations, loss of judgment and loss of insight occur. Personality changes are obvious. Lack of personal care, filthy habits, sexual disinhibition, stealing, lying and drug abuse may be there. Mood deteriorates to one of depression, elation or lability. Changes in the motor activity lead to restlessness and wandering, which predispose to accidents. Suicidal thoughts and attempts are not rare. When the patient fails to cope-up with the stress, temper outbursts occur (catastrophic reaction). The patient follows a rigid, stereotyped routine (organic orderliness). Insomnia is common. Aphasia, agnosia, apraxia, tremors, myoclonus, peripheral neuropathy and other neurological signs may appear. All symptoms worsen as the disease progresses. Several diseases may give rise to dementia. These are described in Section: 17 Chapter 189.

Diagnosis and treatment: The typical clinical features and investigations help to identify the condition and detect the cause. Dementia is differentiated from mental retardation which is a developmental disorder, delirium and pseudodementia, which is depression with cognitive impairment. The major aim of treatment is to remove the cause whenever possible, in order to reverse dementia or atleast to arrest its progress. Attention to general health is important. Regular physical exercise, proper nutrition and prevention of accidents are essential. Counselling to the patient and the family is needed. The involvement of community and social agencies can help to reduce the burden of management.

Unmanageable cases need institutional care. Any common psychotropic drug can be used symptomatically to reduce restlessness, wandering, insomnia, delusions and hallucination and depression.

Drugs with minimum anticholinergic side effects are preferred, and they should be given in minimal effective doses.

Lorazepam – 0.5-1 mg (anti-anxiety and hypnotic)
Risperidone drops/tablet – 0.5-1 mg (anti-psychotic)
Olanzapine tab – 2.5-5 mg (anti-psychotic)
Quetiapine – 12.5-25 mg (antipsychotic)
Mirtazapine – 7.5-15 mg (antidepressant)
Citalopram – 5-10 mg (antidepressant)
Fluoxetine – 10-20 mg (antidepressant)

Cognitive enhancers: These are newer drugs tried in Alzheimer's diseases, but they are still experimental.

- a. Memantine—5-15 mg. This drug is a NMDA receptor blocker
- b. Donepesil (5-15 mg)-Acetylcholineesterase inhibitor
- c. Cortisol, oestrogen, vit E, and plant products like *Ginko biloba* are other agents tried from time to time.

Since there is no specific drug for dementia the emphasis should be on prevention.

AMNESTIC DISORDERS

These disorders are characterised by profound impairment in recent memory with minimal impairment of other cognitive functions. Ability to learn new informations (anterograde amnesia) and ability to recall previously learned informations are impaired. Orientation to time and place may be lost, but orientation to person is retained. Visuo-spatial and geographical memory are unaffected. The amnesic gap may be filled by unrelated informations (*confabulation*). Full insight is retained. Lesions are demonstrable in the hippocampus, amygdala, fornix and midline structures like the mamillary bodies and dorso-medial thalamus.

Course: The disorder may be of gradual or sudden onset. It may recover fully or run a chronic course.

The common amnesic disorders include transient global amnesia, alcoholic black out, **Korsakoff's**

syndrome, multiple sclerosis, cerebrovascular diseases and such other conditions.

Treatment: Treatment is directed to the cause. In addition to the supportive psychotherapy, drugs can be used to allay the anxiety.

221

Schizophrenia and Delusional Disorders

N. Krishnan Kutty

Chapter Summary**Schizophrenia** 1407

General Considerations 1407

Clinical Features 1408

Treatment 1409

Persistent Delusional Disorders 1410**Schizophrenia****GENERAL CONSIDERATIONS**

A precise definition of schizophrenia is lacking. It is a mental disorder characterized by specific psychological symptoms which interfere with the thinking, emotion, conation and motor behavior of the patient. Often the disorder runs a chronic deteriorating course. Whether schizophrenia is a single disorder or a group of many disorders is an unsettled riddle. Schizophrenia is a serious psychiatric disorder. The concept of schizophrenia was initially introduced by **Emil Kraepelin** and termed it *dementia praecox* (dementia = intellectual deterioration, praecox = early onset). To him it was an illness among adolescents and young adults which gradually lead to intellectual deterioration. Later, **Eugene Bluler** showed that splitting of emotion, thought and behavior was the essential feature of schizophrenia. Hence, he coined the term **schizophrenia** (Schizo=split; phrenum=mind).

Etiology: The exact etiology is not clear, but several factors play their roles.

- **Heredity:** Genetic factors play a major role in the etiology. The incidence of schizophrenia is about 1%

in the general population. There is higher incidence of the disorder in the family members of schizophrenic patients. About 5% of the parents, 8% of the siblings and 12% of the children of schizophrenics are seen to be affected by the disorder. In twin studies, the concordance rate is 57% in monozygotic twins whereas it is only 12% for dizygotic twins. The mode of transmission may be monogenic or polygenic and the gene may be dominant or recessive. Defects in the long arms of chromosomes 7, 11 and 18 and the short arms of chromosomes 19 and X have been shown in linkage studies.

- **Personality:** Many schizophrenic patients show schizoid personality trait. These individuals are very shy, sensitive and are largely unsocial.

Family background: In many instances there may be disturbances of family background. These include faulty parental attitudes, irrational and incoherent family atmosphere, defects in family communication, broken homes and the like. Emotional instability is found in many families.

- **Social factors:** Schizophrenia is more common in the lower socioeconomic groups. Urbanisation and industrialization are other significant contributory factors.
- **Biochemical:** Dopamine hypothesis—It is hypothesized that schizophrenia is the result of *dopaminergic hyperactivity* in the CNS, especially of D-2 receptor. Hyperactivity of other amines such as serotonin (5HT) and *nor-epinephrine* are also probable. But these findings are not specific to schizophrenia. The GABAergic neuronal loss observed in the hippo-

campus suggests a role for GABA. The role of the excitatory amino acid, glutamine has also been implicated.

- **Neuropathology:** Pathological changes are noted in the frontal lobe, hippocampus and basal ganglia. The size of the hippocampus, para hippocampus and amygdala is reduced on postmortem studies. Cell loss is also seen in the putamen and globus pallidus. Neurodevelopmental disturbance and neurodegenerative changes have also been attributed.
- **Stress:** Schizophrenia may be precipitated by physical stress like infection, injury, general debility, childbirth or several forms of psychological stress. Life events too are important factors.

CLINICAL FEATURES

Schizophrenia is a disease with protean manifestations. The symptoms of the illness include disturbances in thinking, mood, perception and motor behavior. These symptoms occur in a clear conscious setting of the mind.

- **Disturbance in thinking:** Thought disorder is a prominent symptom of schizophrenia. There is loss of meaningful connection in the sequential pattern of ideas (*loosening of associations*) which is a formal thought disorder. So the talk becomes incoherent. The stream of thought is affected. Circumstantiality, stereotypy and perseveration may be observed. New words or phrases may be invented which may not make any sense to others (*neologism*). The patient may detach from reality and live in his own inner world of phantasy (*autism*). Occasionally, the patient may be mute. At times there may be excessive, incoherent and irrelevant talk and activity at a high rate (excitement). They may fail to catch the wider implied meaning of proverbs which are interpreted in a purely literal sense (*concrete thinking*). This is due to the *loss of abstract* thinking. It may be their experience that the feelings, thoughts or activities are being carried out under external control (*passivity*).
- **Delusions** are common. They may arise without an attributable cause. Such primary delusions are characteristic of schizophrenia. It may be of persecutory, grandiose, somatic or religious themes. Secondary delusions also exists. The thoughts may be alienated, i.e. the patient experiences that thoughts are being taken away from his mind (*thought withdrawal*); or that thoughts are being introduced into his mind (*thought insertion*). Another phenomenon is the feeling that thoughts are being known to others as soon as it occurs in their mind (*thought broadcasting*).
- **Disturbances of affect:** All forms of affective changes may be seen in schizophrenia. In the early stages loss of emotional feelings (*anhedonia*) may be present. Usually, the patients show an incongruous or

Schizophrenic thought disorder

Loosening of association
Thought blocking
Neologism
Autism
Loss of abstract
Thinking
Primary delusions
Thought insertion
Thought withdrawal
Thought broadcasting
Passivity

blunted affect. In some cases lability, depression, elation, anxiety or exaltation may be the affective changes.

- **Disturbances of perception:** The most common abnormality is auditory hallucination which occurs in a clear, conscious setting. Hallucinatory voices may pass comments or give orders or pass simple statements about the patient (third person auditory hallucination). Voices may be threatening, accusatory and obscene. Tactile hallucinations in the form of electromagnetic waves, electricity, vibrations or cosmic rays may be experienced. Visual hallucinations are uncommon and other kinds of hallucinations are rare.
- **Motor disturbances:** The patient lacks energy, initiative and drive. The motor activity may be completely blocked-up at times (catatonic stupor). The patient may carry-out all given instructions without any resistance, even if they are harmful (*automatic obedience*). The patient's limbs shows spasm and can be passively moulded to any awkward posture for any length of time (*waxy flexibility /catalepsy*).They may actively resist instructions or may do just the opposite of what is expected normally(negativism). Negativism also causes retention of saliva/urine. Other motor disturbances like repetition of activities such as stereotypy, mannerisms, perseveration or echopraxia are also found. At times they exhibit spells of senseless excitement or states of complete withdrawal from the surroundings. Impulsive, suicidal, and homicidal behavior may occur. These may be in response to delusion or hallucination.
- **Cognitive disturbances:** Attention, concentration and vigilance are impaired in schizophrenia. This adversely affects the immediate memory. In chronic cases intellectual deterioration is also seen.
- **Other clinical features:** Mental functions such as consciousness, orientation, memory and intelligence are fully preserved but reasoning, judgment and insight are impaired.
- **Soft neurological signs:** Certain non-localising neurological signs (soft signs) have been reported in

schizophrenia. They include tics, stereotypies, grimacing, abnormal motor tone, abnormal movements, dysdiadokokinesis, astereognosis, diminished dexterity and the like.

- **Eye signs:** The blink rate may be increased. The patient does not make eye-to-eye contact with others.
- **Fundamental symptoms:** *Eugene Bleuler* classified the clinical features into fundamental symptoms and accessory symptoms. Autism, ambivalence and disturbances in affect and associations (4 A's) are the *fundamental symptoms*. All the other symptoms like delusions hallucinations, etc. are included under *accessory symptoms*. The fundamental symptoms are diagnostic of schizophrenia.
- **Positive and negative symptoms:** All the symptoms of schizophrenia can be grouped into two sets: (i) positive symptoms, and (ii) negative symptoms.

Positive symptoms	Negative symptoms
More acute	More chronic
Productive symptoms	Deficit symptoms
More in acute disease	More in chronic disease
Formal thought disorders	Anhedonia, lack of initiative and poverty of thinking.
Delusions	Incongruity and flattened affect
Hallucinations	Social withdrawal
Inappropriate affect	Impaired attention and concentration
Disturbance in motor activity	
Increase in dopamine in subcortical tissues	Decrease in dopamine in prefrontal cortex

Classification of Schizophrenia

Classically, schizophrenia is divided into four types. These are the *catatonic*, *paranoid hebephrenic* and *simple schizophrenias*. This classification is made on the basis of the dominant clinical features

Schizophrenia-Types (Eugene Bleuler)
Catatonic schizophrenia Paranoid schizophrenia Hebephrenic schizophrenia Simple schizophrenia

In *catatonic* schizophrenia, motor disturbances are very prominent.

In the *paranoid* form, delusions and hallucinations are the prominent features.

In *hebephrenia*, florid thinking disturbances and marked mood changes are predominant.

In *simple* schizophrenia, an insidious onset, lack of interest, and initiative and gradual social withdrawal are the characteristic features.

In addition to these classic forms, many other special varieties have been described.

Drugs used in Schizophrenia
Conventional anti-psychotics Chlorpromazine Trifluoperazine Thioridazine Haloperidol
Atypical anti-psychotics Risperidone Clozapine Olanzapine Quetiapine Aripiprazole
Depot preparations Inj fluphenazine decanoate Inj haloperidol decanoate

Diagnosis

Schizophrenia is diagnosed on the basis of clinical features. The symptoms should be present atleast for a period of one month. Psychometric tests may be helpful. Schizophrenia has to be differentiated from physical disorders like uremia and other organic mental disorders and also from masked depression, mania, hysteria and others.

Course

Some cases of schizophrenia may recover fully. Others show remissions and exacerbations. A few deteriorate gradually and progressively. The prognosis depends on many factors.

TREATMENT

Schizophrenia poses the threat of chronic handicap and therefore treatment should be instituted early. Mainly three modalities of treatment are at hand. These include anti-psychotic drugs, electroconvulsive therapy (ECT) and psychosocial therapy.

Anti-psychotic drugs: Both conventional antipsychotics such as phenothiazines and haloperidol, and newer atypical anti-psychotics such as: Risperidone, clozapine , olanzapine, quetiapine and aripiprazole are currently in use (See Chapter 234).

A suitable drug is to be selected depending upon the efficacy, availability, affordability, side effects, drug compliance and general health of the patient. The starting dose should be small and the dose is increased to the effective range and maintained for symptom control. Drug therapy may have to be continued for at least for 24 to 36 months.

Depot preparations like injections of fluphenazine decanoate 25 mg IM once in 2-4 weeks and inj of haloperidol decanoate are more advantageous than oral preparations in the maintenance phase.

Electroconvulsive Therapy (ECT)

ECT is beneficial in catatonic schizophrenia, acute schizophrenic episodes, and in schizophrenic excitement.

Psychosocial treatment: Steps are taken to keep the patients socialized by means of psychosocial education, close personal contact, group therapy, recreational therapy and occupational therapy so that the patient can readily come back to the social milieu after the treatment. The relatives are counselled regarding the nature of the disorder and the role they have to adopt. Chronically handicapped persons need rehabilitation.

Persistent Delusional Disorders

These are a group of disorders characterised essentially by a single type of long-standing delusion. It was known previously as *paranoia*,

The symptoms do not fit into any other type of mental disorders such as schizophrenia, mood disorders or organic psychosis. The delusions may be of several types:

1. Some important person is strongly in love with the person—*delusion of love (Larabault's syndrome, erotomania)*.
2. The spouse has extramarital relationship (*morbid jealousy, jealous husband/ wife syndrome, delusion of infidelity, Othello syndrome*).
3. Infestation by a parasite or venereal disease or cancer (*paracito-phobia/venereo-phobia , cancer-phobia*).
4. Mis-shapening of body parts such as nose or face (*dysmorphophobia*), or
5. Emanation of foul order from body parts.

The delusion is treated by anti-psychotics and psychosocial therapy.

222

Mood Disorders: Mania, Depression, Dysthymia

N. Krishnan Kutty

Chapter Summary

- General Considerations 1410
- Mania 1411
- Depression 1411
- Dysthymic Disorders 1412

GENERAL CONSIDERATIONS

What was originally described as manic depressive psychosis (MDP) by Emil Kraepelin is presently known as *Mood disorders* (MD). A persistent change in mood is the basic abnormality in this disorder. When the mood remains sad (depressed) the resulting clinical condition is called *depression*. It is called *mania* when the mood remains elevated and cheerful. The disorder usually runs an episodic course with recovery and recurrence. In between, lucid intervals occur in which the patient is

normal. Mood disorders may be unipolar depression, or bipolar mood disorders (BPMD). In unipolar depression only depressive episodes occur but they occur consecutively atleast thrice. In BPMD both depressive and manic episodes occur.

Etiology

The etiological factors for mood disorders fall under two broad groups-biological and psychosocial. The important biological factors may be genetic, biochemical, endocrine or neuro-anatomical.

Genetic factors: The incidence of mood disorders is high among the close relatives of the patients. Children born to affected parents develop the disorders even when the environment is different. In monozygotic twins the prevalence rate is 69% compared to the general population. Non-biological children and dizygotic twins have prevalence rates of only 19%.

- **The central monoamines**, residual sodium and melatonin are the more important biochemical factors implicated. *Norepinephrine*, *serotonin* and *dopamine* are the brain neurotransmitters involved. The concentration, turnover and postsynaptic receptor sensitivity of these neurotransmitters are diminished in depression. The converse is true in mania. Reserpine, which depletes serotonin from its stores, causes depression. *The residual sodium*, both intracellular and bone marrow sodium is increased upto 50% in depression and 200% in mania.
- **Endocrine** disorders such as Cushing's syndrome, hypothyroidism and hyperparathyroidism are known to produce depression. The secretion of cortisol is high in depression due to hyperactivity of the hypothalamic-pituitary-adrenal axis. This secretion is not suppressed by exogenous dexamethasone as occurring in normal persons.
- **Organic disorders** like cerebral atherosclerosis, neurosyphilis, AIDS, Parkinson's disease and frontal lobe injuries may produce depression. PET and SPECT studies have demonstrated reduced cerebral blood flow and reduced oxygen and glucose consumption in the frontal cortex among such patients- (*hypofrontality*). The hypothalamus, the basal ganglia and limbic cortex are probably the anatomical sites affected in depression.

Psychological and social factors are closely linked. The prominent psychosocial factors are recent stressful life events, obsessive and cyclothymic (mood swings) personality traits, loss of maternal affection during childhood, loss of loved objects, loneliness, helplessness, and cognitive distortions. In simple terms cognition simply means thinking. **The cognitive theory** proposes that depression results primarily due to negative cognition, negative view of the self, of the world and of the future. The mood change is secondary.

Mania

CLINICAL FEATURES

- **Elation of mood** is the characteristic disturbance in mania. It is expansive. Generally, the manic patient appears well dressed, often in colorful clothing and is cheerful. He is entertaining and often highly interfering. He forms the focus of attention by his talk and jocularity. In the case of hypomania, the mood is one of euphoria with a generalized feeling of increased well-being. In the case of manic excitement the mood is one of excitement. Occasionally, the mood may be irritable.
- **Thought/talk:** The patient talks excessively and he is rich in ideas. The talk is often coherent, but may

not be relevant. Since the rate of talk is high, too many ideas may be crowded into the mind, giving rise to pressure of talk. Often, the ideas shift from topic to topic giving rise to "*flight of ideas*". The talk may contain typically grandiose delusions or persecutory delusions. The talk is jocular.

- **Disorders of perception** such as illusions may be present during manic excitement. Hallucinations are rare in mania.
- **Motor activity:** Mania is associated with exuberant energy and overactivity. He may get-up very early in the morning and engage himself in various kinds of unwanted activities. The actions are left incomplete. He unnecessarily interferes in the affairs of other people when he is hyperactive, and picks up quarrels. In states of excitement he may turn violent, aggressive, destructive and uncontrollable.
- **Other symptoms:** These include increased sexual urge, extravagance, drug abuse and intoxication. Intelligence is well preserved. There is apparent impairment of memory on account of rapid flight of attention. Insight and judgment are impaired. Insomnia is a regular feature.

Diagnosis: The diagnosis is based on the clinical features. Mania is to be differentiated from schizophrenia, general paralysis of the insane (GPI), alcoholic excitement and delirium.

Features of mania
Elated, expansive mood High motor activity Richness of ideas Flight of ideas Jocularity Grandiose delusions

Treatment: Pharmacotherapy and electroconvulsive therapy (ECT) are employed in the treatment of mania. Antipsychotics and mood stabilisers are the drugs of choice for acute manic symptoms. Excited and violent patients have to be sedated with parental drugs. In some cases mechanical restraint may be needed.

ECT may be necessary to bring down violent excitement rapidly.

Depression (Major Depression)

Depression may be a symptom, a syndrome or a disease entity (depressive illness). Several terms such as *psychotic depression*, *endogenous depression*, *MDP depression*, *agitated depression*, *involutional melancholia* or *masked depression* are used to designate depressive disorder. The symptoms of depression are subject to diurnal variation,

being worse in the morning. Depressive episodes may be mild, moderate or severe.

CLINICAL FEATURES

- **Mood:** The symptoms of depression are centered around the disturbance in mood. The mood is sad. The face appears gloomy with wrinkled forehead, drooping of the eyelids and sagging of the angles of the mouth. They show no interest in pleasurable activities (*anhedonia*). Sometimes the mood is one of irritability and anxiety.
- **Thought and speech:** The speech is slow, and the voice is low. Poverty of thinking and loss of self-confidence are prominent symptoms. They are pessimistic and they lack self-confidence. They may retain ideas or delusions of guilt, worthlessness and hopelessness. Out of such thoughts may spring-up suicidal ideas and attempts. Eighty-percent of suicides are attributable to depression. In most cases of suicide the attempts are well-planned and secretly executed. Nihilistic and hypochondriacal delusions are not uncommon. In severe cases they may remain mute (*depressive mutism*).
- **Disorders of perception:** Auditory hallucinations of accusatory nature may occur.

Features of depression
Sadness of mood Retarded motor activity Poverty of thinking Delusion of guilt Hopelessness Worthlessness Suicidal ideas and attempts Loss of appetite Loss of weight Loss of libido Insomnia Other somatic symptoms

Motor activity is retarded. The movements are slow. The patient tends to stoop while walking or sitting. Depressed patients become self-centered and prefer to be left undisturbed. The routine work may be avoided due to the feeling of general weakness. In the extreme form the patient may develop *depressive stupor* where all the activities are minimal with least response to external stimuli.

- *Their attention* and concentration are impaired.
- *The insight and judgment* may be impaired.

- *Pseudodementia* The sluggishness of mental activity and impairment of attention and concentration may give an apparent impression of dementia.
- *Somatic symptoms:* Loss of appetite, loss of weight, constipation, loss of libido and late insomnia are vital symptoms of depression .Other bodily symptoms such as headache, giddiness, chest pain, backache and amenorrhea are common. Many give history of depressive symptoms preceding myocardial infarction.

Diagnosis: Diagnosis of depression is made on the basis of clinical features. Depression has to be differentiated from organic disorders, schizophrenia, endocrine disorders and substance use disorders.

Course: The symptoms of depression may recover fully but the risk of recurrence is present either as depression or as mania.

Treatment: Pharmacotherapy, psychotherapy and electro-convulsive therapy are effective. Combination therapy brings about more rapid recovery.

- **Inpatient care:** Patients in depressive stupor and those with suicidal ideas require hospitalization.
- **Drugs:** Antidepressants are the drugs of choice. Tricyclic antidepressants (TCA), selective serotonin re-uptake inhibitors (SSRIs), and other atypical antidepressants are in common use. The treatment is initiated with smaller doses and worked upto the optimum level. The drug is maintained for three to six months after recovery and then it is gradually tapered off. Hypnotics, anti-anxiety drugs and other supportive therapy are also indicated.
- **ECT** is indicated in cases of depressive stupor, suicidal ideas and suicidal attempts.
- **Psychotherapy:** Cognitive behavior therapy and supportive psychotherapy are beneficial.

Dysthymic Disorders

This used to be known as neurotic or reactive depression. This is considered as a variant of depression, mild in intensity, chronic in duration and without delusions or hallucinations. Somatic symptoms such as loss of weight, loss of appetite and loss of libido are not marked. Insomnia is early and sleep is fretful. The symptoms are worse in the evenings unlike as in the case of mood disorders.

Treatment: This includes counselling, psychosocial therapy, and pharmacotherapy with antidepressants.

Chapter Summary

Generalised Anxiety Disorders (GAD) 1413
Phobic Anxiety Disorder 1414
Panic Disorder 1414

Anxiety is a subjective unpleasant feeling of fear, tension, impending danger and panic. In normal persons fear or anxiety develops as a result of some known external reasons. Anxiety disorders are a group of conditions characterised by severe anxiety. The fear is usually accompanied by autonomic disturbances. There is no obvious external cause.

Three types of anxiety disorders are seen. These are:

- Generalised anxiety disorder
- Phobic anxiety disorder, and
- Panic disorder

Generalised Anxiety Disorders (GAD)
(Anxiety Neurosis)

In this disorder the anxiety is free floating and the symptoms are experienced all the time. It was previously known as anxiety neurosis.

Etiology: The important causative factors include hereditary predisposition, morbid environment and constitutional defects. Physical factors such as infection, exhaustion and others may precipitate anxiety reaction. According to Sigmund Freud anxiety develops as a result of the conflict in the unconscious mind. The conflict occurs when there is rivalry between the reality and the needs/wish of the individual, sexual or otherwise. The conflict is unpleasant. So it gets repressed into the unconscious part of the mind. When mental energy is diminished, repressed conflict tends to enter into the conscious mind. It is experienced as anxiety. Mental defense mechanisms do not come into play.

Overactivity of the neurotransmitters such as norepinephrine, serotonin and gamma-aminobutyric acid

Features of GAD
Mental Symptoms Severe anxiety Irritability Lack of attention and concentration Worry
Physical Symptoms Motor Restlessness Tremors Tension CNS Headache Dizziness Insomnia CVS Palpitation Tachycardia Preordial pain High systolic BP Respiratory Tachypnea Breathlessness Hyperventilation GIT-dysphagia Dry mouth Diarrhea GU tract Frequency of micturition Menstrual irregularities Sexual dysfunctions Skin Cold and clammy

(GABA) are seen in this disorder. Main pathological lesions are seen in the locus coeruleus.

Clinical Features

The symptomatology can be classified as: (a) mental, and (b) physical.

- **Mental symptoms:** Anxiety is the main symptom. It is generalized and present throughout. It hampers the activities of the individual. Anxiety interferes with the functions of attention and concentration and thereby,

the memory. Anxiety is the common cause of amnesia in students. The person is preoccupied by ‘worries’ and may have many kinds of anxious thoughts and feelings.

- *Physical symptoms:* General features are motor restlessness, fine tremors and generalised muscular tension. This causes aches and pains, especially frontal headache and backache. The pupils are dilated. The mouth is dry due to decreased salivation.
- *Cardiovascular manifestations:* Tachycardia, rise in systolic blood pressure, precordial pain and palpitation are common.
- *Respiratory symptoms:* Patients with GAD complain of breathlessness and tachypnea. Hyperventilation may lead to alkalotic tetany.
- *Gastrointestinal symptoms:* These include dryness of mouth, dysphagia, diarrhea, constipation, vomiting abdominal pain, ‘gas’ and others.
- *Genitourinary symptoms:* Anxiety disorder is associated with increased frequency of micturition. Sexual drive (libido) is often diminished. Menstrual irregularities are found in women.
- *Central nervous symptoms:* Headache is experienced as a tight band around the head. The patient experiences difficulty in getting into sleep. The sleep is light and fretful. The skin is cold and clammy.

Diagnosis: Clinical diagnosis can be made based on the somatic and psychic features. Persistent anxiety with somatic symptoms is the important feature. Careful search to exclude organic disorders such as endocrine abnormalities, ischemic heart disease, asthma and malignancy is absolutely essential. Other psychiatric conditions such as delirium, schizophrenia and agitated depression have also to be differentiated.

Treatment

- *Psychotherapy* is the principal form of treatment. Cases of recent onset may improve with counselling, by giving reassurance and encouragement to make adequate adjustment with the environment. In other cases relaxation therapy and cognitive therapy may be provided.
- *Drug therapy:* Antianxiety drugs are good to give rapid relief. For long term therapy any of the anti-depressants may be preferred.
See Table 223.1.

Phobic Anxiety Disorders

This disorder is characterized by the presence of ‘phobia’. Phobia denotes fear which is specific to an object or situation. The fear is unreasonable and out of proportion to the demand of the situation. The subject avoids the object or situation which evokes the phobia.

TABLE 223.1
Common anti anxiety drugs

<i>Benzodiazepines</i>
Alprazolam
Diazepam
Chlordiazepoxide
Clonazepam
<i>Beta blockers</i>
Propranolol
<i>Azaspirone</i>
Buspirona

Clinical features: The symptoms of phobia are very similar to those of generalised anxiety disorder but these symptoms occur only in the presence of the stimuli which evoke the phobia, either under imagination or in real situation. The patient is symptom-free at other times.

- In *simple phobia*, the fear is usually for harmless objects like pen, match box, spider and the like.
- In *social phobia* the fear is for social situations.
- In *agoraphobia* the fear is experienced on getting away from house or being in situations from which escape seem to be difficult.

Diagnosis: Diagnosis of phobia is based on the clinical features in relation to the phobic stimulus. Phobic disorder should be differentiated from generalized anxiety disorder, schizophrenia, obsessive compulsive disorder, epilepsy and depression.

Treatment: The acute symptom can be managed with anti-anxiety drugs. Behavior therapy which is intended to desensitise the patient to the phobic stimulus, is the treatment of choice. Systematic desensitization, implosion and flooding are the techniques used (See Chapter 235).

Panic Disorder

The characteristic feature is sudden, unexpected episodes of intense anxiety. It is marked by chest pain, breathlessness, palpitation, sweating and a feeling of imminent death or turning mad. The patient may run for help. It may be mistaken for acute myocardial pain. Sometimes it is associated with agoraphobia. Diagnosis is made from the typical features.

Lactate infusion test: Intravenous infusion of sodium lactate precipitates panic reaction and this test can be used for diagnosis.

Treatment: Panic disorder responds well to drugs such as alprazolam, diazepam, SSRIs, tricyclic antidepressants, valproate and cognitive and supportive psychotherapies. (see Chapter 235).

Chapter Summary

General Considerations 1415

Clinical Features 1415

Diagnosis 1415

Treatment 1415

GENERAL CONSIDERATIONS

This disorder is characterised by obsessions and compulsions. Obsessions are unwanted thoughts repeatedly coming to the mind in spite of a strong will to get rid of them. There is the subjective compulsion to act accordingly. Though the patient is fully aware of this absurdity, he is helpless. He is unable to resist this action.

Etiology: Obsessions usually occur among obsessive personalities. Such individuals are usually very meticulous and methodical, and are very particular about cleanliness and orderliness in everything. Many give a family history of obsessive disorder. Obsession may also result as a sequel of head injury and intracranial infections. Neuroimaging studies have revealed bilateral reduction in the size of the caudate nuclei. There is increased activity in the frontal lobe, basal ganglia and cingulum and dysregulation of central serotonin.

CLINICAL FEATURES

The obsessions may take the form of ideas, doubts, phobias, impulses, slowness and rumination. The idea may be of any form. Obsessive doubts may be for an activity that has been just carried out. For example, the patient may go to bed after bolting the door. He may get-up the next moment in doubt whether he had bolted the door or not. This may be continued indefinitely.

- Obsessive phobia is the fear that one may do a harmful thing. For example, a patient may have the fear that he may add poison in the medicine supplied.
- Obsessive compulsions are motor activities which are repeated (*obsessive rituals*). The patient may wash the hand repeatedly, being unsatisfied with the cleanliness. The washing may be continued even to the point of peeling off the skin.
- An impulse may arise to howl or utter obscene words in the church when the mass is on. Obsession may be associated with anxiety or depressive features.

DIAGNOSIS

The premorbid personality, the family history and clinical features help to make a diagnosis. Obsessive compulsive disorder has to be differentiated from schizophrenia, psychotic depression and dementia.

Course: In many cases the illness may recover gradually by itself. In some, the recovery may be sudden even during the early part of the illness. Often wilful efforts to suppress the obsession may tend to aggravate the condition.

TREATMENT

OCD responds well to treatment. A combination of pharmacotherapy and behavioral therapy is most suitable. Clomipramine and SSRIs are the drugs of choice. They are to be given at the higher dose for 2 to 3 weeks.

Exposure and response prevention are the behavioral therapy techniques employed. This itself may be curative. In addition, supportive therapy and counselling to the family are also indicated.

Psychosurgery like cingulotomy may have to be done in intractable cases.

Conversion Disorders, Dissociative Disorders, Somatoform Disorders, Cultural Bond Syndromes, Reaction to Stress and Adjustment Disorders

N. Krishnan Kutty

Chapter Summary

General Considerations 1416
 Conversion Disorders 1416
 Dissociative Disorders 1417
 Somatoform Disorders 1417
 Cultural Bond Syndromes 1418
 Reaction to Stress and Adjustment Disorders 1418
 Acute and Post-traumatic Stress Disorders 1418
 Adjustment Disorders 1418

GENERAL CONSIDERATIONS

For a long time this disorder was known as *hysteria*, the term coined by *Hippocrates*. Later it was known as *hysterical neurosis* manifested as a conversion reaction and dissociative reaction. The disorder is characterised by psychogenic loss or disorder of function. When the symptoms are confined to the sensory, motor or visceral functions it is called conversion disorder. It is called dissociative disorder when the symptoms are psychic in nature.

Etiology: This disorder develops as a result of environmental stress in subjects who possess defective personalities such as hysterical personality. Such individuals are often emotionally immature. They are defensive, dramatic in behavior, demonstrative and demanding. They show tendency to be untruthful. They are seductive and easily suggestible.

Psychogenesis

- Sigmund Freud, the father of psychoanalysis found that hysterical symptom could be produced by suggestion and abolished by persuasion. He stated in his psychodynamic theory that hysterical symptoms develop as a result of psychic (emotional) conflict in the conscious mind. The conflict is repressed into unconscious part of the mind to be forgotten. Later

in life the repressed emotional conflicts try to enter the conscious mind. This produces anxiety which is very unpleasant. The anxiety is made innocuous by the mental defense mechanisms of *conversion* into bodily symptoms and *dissociation* into psychic symptoms.

- **Pathophysiology:** Hypometabolism in the dominant hemisphere, hypermetabolism in the non-dominant hemisphere, and defect in interhemispheric communications have been described.

The relief from anxiety is the *primary gain* in the disorder. The symptoms provide material advantage to the patients. This is the *secondary gain*. The patients are unconcerned about their disability (*La bella indifferenza*). In conversion disorders the emotional abnormality produces physical symptoms pertaining to motor, sensory and visceral systems. It may mimic any disease.

CONVERSION DISORDERS

Syn. Hysterical neurosis

Clinical Features

- **Motor symptoms:** Various types of paresis and paralysis like hemiplegia, monoplegia and paraplegia, bizarre gait, tremors and mutism are common. It is usually a function like movement and not a group of muscles on any nerve distribution that is affected. The proximal parts of the limbs are more affected than the distal parts. The left side is more affected than the right. The paralysed muscles may be used in one movement but not in others. Efforts to produce a particular movement in a paralyzed limb may produce spasm in the opposite group of muscles. Examination reveals generalized muscular rigidity with increased tendon reflexes and flexor plantar response. Disuse atrophy may rarely supervene in long-standing cases.
- **Tremors:** Coarse tremors occurring at rest and exaggerated when attention is drawn to them is suggestive of conversion disorder.
- **Seizures:** The seizures (fits) occur in emotionally charged situations in the presence of onlookers. Fits do not occur when the patient is alone. Consciousness

is not lost during the fits and the sequence of events is bizarre. The movements also are bizarre. They may resemble arching or such other acts. Serious injuries do not occur during these episodes. These features help to distinguish hysterical reactions from epileptic seizures.

- **Sensory symptoms:** These include anesthesia, paresthesia, and hyperesthesia. These sensory disturbances do not correspond to any anatomical pattern. Unlike as in neurological lesions the boundaries are sharply demarcated and the extent changes widely with repeated testing. Symmetrical anesthesia affecting the extremities such as gloves and stockings type may occur.
- **Special senses:** Blindness and deafness may occur. The patient can avoid obstacles in her path even when there is 'total blindness'. Many patients complain of diplopia as well. Diplopia can be complained of even when one eye is shielded.
- **Visceral symptoms:** Common symptoms are vomiting, retention of urine, constipation, loss of appetite and others.

DISSOCIATIVE DISORDERS

Clinical features : In dissociative disorder the symptoms are confined to the psychic field. Amnesia, fugue, somnambulism, multiple personality, and hysterical trance are the common manifestations.

- **Amnesia:** In dissociative amnesia, the loss of memory is confined to a circumscribed event or connected events which are normally tolerable but producing agony to the patient. The amnesia occurs in situations of intolerable stress. The intellectual functions are unaffected, unlike as in dementia.
- **Fugue:** In dissociated fugue the person may wander in the amnesic state with loss of identity. A new identity may be assumed and he may engage in a work quite dissimilar to the previous job. The original identity can be regained under hypnosis, or even spontaneously.
- **Somnambulism:** It is a dissociative state where the individual walks around in sleep. He avoids obstacles on his way. This symptom may also occur in depression and epilepsy.
- **Dual or multiple personality (identity disorder):** The patient is possessed by a different personality, usually by a 'spirit'- good or evil. In dual personality, the second personality may dominate the activities of the patient and he may not be aware of his real personality.
- **Dissociate trance (twilight state or stupor):** In this disorder the patient gets detached from reality and may become almost immobile and immersed in his own self or in some other divine power.

Diagnosis The diagnosis of dissociative disorder (conversion) is made from the clinical picture. Personality tests may be helpful in establishing the diagnosis.

- **Differential diagnosis:** The somatic symptoms may resemble those of physical diseases. Psychiatric disorders like schizophrenia, depression, dementia and mania have to be differentiated.

Treatment: Reassurance and suggestion are the usual modes of treatment adopted. The success depends on identification and removal of the secondary gain and resolution of the emotional conflict. Abreaction, psychotherapy and behavior therapy may be employed. Anti-anxiety drugs have their role to reduce the internal anxiety. It is not uncommon to find fresh symptoms cropping up when the existing symptom is removed by mere suggestions without resolving the conflict.

SOMATOFORM DISORDERS (SFD)

This includes a set of psychiatric disorders presenting with symptoms of a physical illness but with no physical finding either on examination or repeated investigations. *Somatisation disorder*, *hypochondriacal disorder* and *somatoform pain disorders* are the common types of SFDs.

In *somatisation disorder* multiple and often changing symptoms are present. The patient fails to get relief from several doctors. They are eager to get medicines for relief.

In *hypochondriacal disorders* the patients are pre-occupied with physical illness. They demand all kinds of investigations to prove their illness. At the same time they are afraid to take drugs.

Somatoform pain disorder (psychogenic pain disorder) Chronic pain such as headache, low backache, pelvic pain and chest pain are common symptoms. The pain may be symbolic of guilt, demand for affection, suppressed aggression or atonement for perceived sin. It may be rewarding to the patients in that they gain attention and care, and escape from job or unpleasant task. It may also be the manifestation of other psychiatric disorders such as anxiety, depression or schizophrenia.

Factitious disorder: In this disorder the symptoms of mental or physical illness are purposefully adopted in order to remain in the sick role and avoid specific situations. There is no external gain. Dermatitis artefacta, bruising, brittle diabetes, pyrexia of unknown origin, purgation of unknown origin, chronic wounds and self-medication are examples.

Malingering: In this condition symptoms of mental disorder or physical illness may be feigned by the person to get some external gain. The gain may be to get exemption from strenuous work, financial compensation

in accident, to get relieved from police action and the like. The symptoms may be vague and they may not suggest any typical disorder. They resist detailed evaluation and give evasive answers. Investigations give negative result. Constant observation and evaluation may bring-out the truth. It should be tactfully conveyed to the person.

CULTURAL BOND SYNDROMES

Some psychiatric syndromes are specific to different countries and cultures. 'Possession state' and 'Dhatt' syndromes are important members in this group.

Possession states: Individuals are seen talking and acting, not in their own self, but in the role of others, being possessed by phenomena such as the spirit of (a) a dead relative or friend or a person who met with an unnatural death, (b) a god or goddess and (c) a devil.

They bring-out various demands, wishes, orders or warning during the state of possession. These syndromes are more prevalent among young girls especially in rural India. Invocation of the fond deity in trance state is a common religious ritual.

Basically, the syndrome is a dissociative disorder. Major depression, schizophrenia or epilepsy also may appear as possession states. Usually no treatment is required. Counselling and supportive psychotherapy may help to remove the stress which may precipitate the syndrome. Other cases require appropriate pharmacological agents.

Dhatt syndrome: The syndrome is common among young males mostly prevalent in the northern part of India. They complain of losing semen before and after passing urine. This gives rise to mixed picture of anxiety and depression. Muscular weakness, lack of interest and energy, lack of concentration, palpitation, body aches and visual blurring are complained of. The wrong concept behind this syndrome is that semen (dhathu) is a vital bodily element for vigor and health, and its loss is harmful to health. It is to be treated by counselling and anti-anxiety drugs.

REACTION TO STRESS AND ADJUSTMENT DISORDERS

Acute and Post-traumatic Stress Disorders

Severe stress precipitates many kinds of mental disturbances, but stress reaction (disorder) stands out different from others. An exceptionally severe stress may produce characteristic symptoms known as **stress reaction** or disorder in a person with no previous history of mental illness. Such a stressor may be a major road traffic accident, death caused by lightning, earthquake, flood, bomb explosion, murder, rape, assault and similar situations. If the stressor is of a threatening nature the symptoms are more like those of an anxiety disorder.

When the stressor is one of loss or defeat the symptoms are more like those of a depressive disorder. Stress disorders may be acute or late post-traumatic.

Acute Stress Disorder

In *acute stress* disorder (ASD) the symptoms follow within minutes or hours of the trauma. It may last for 2-3 days and recover spontaneously. The main symptoms are a dazed feeling, numbness, inability to understand what is said and answer to questions. Autonomic arousal such as anxiety, restlessness, tachycardia, sweating and insomnia may be seen. Symptoms of dissociation, flash back memory of the traumatic event and nightmares are common. Medical help from a general practitioner may be warranted at times. Anti-anxiety and antidepressant drugs, counselling and other supportive measures offer relief.

Post-traumatic Stress Disorder

In *post-traumatic* stress disorder, (PTSD) the symptoms appear after a latent period ranging from a few weeks to six months. Psychiatric intervention is necessary for relief. The main symptoms are hyper-arousal, painful re-experiencing of the traumatic event, emotional numbness, guilt feeling, rejection, humiliation and a pattern of avoidance behavior. Illusions, hallucinations, dissociative state or panic state may manifest. At times aggression, violence and poor impulse control are also seen. The *treatment* is symptomatic. Counselling, catharsis, direct advice, education to build-up healthy coping skills, cognitive behavior therapy or hypnosis are essential.

Drugs such as tricyclic antidepressants, beta adrenergic blockers, and other antianxiety drugs are indicated.

Adjustment Disorders

Syn: Grief reaction

Psychological disturbances may be precipitated by life changes which may turn-out to be stressful. Bereavement, migration, divorce, detection of a serious illness, retirement, desertion and financial liabilities are but a few examples. It develops within one month to six months, usually not later than six months. The disturbances would not have developed in the absence of the stress. Worrying, poor concentration, anxiety, depression, irritability, nonspecific aches and pains and palpitation are the usual manifestations. Rarely, aggressive behavior, deliberate self harm and abuse of drugs and alcohol may occur. In children it manifests as regressive behavior such as thumb sucking, nail biting, babbling or enuresis.

The treatment is directed to resolve the stressful problem. Counselling is the best method to encourage them to talk-out and discuss their problems. Drugs such as anti-anxiety and antidepressant drugs, and hypnotic may also be used.

Chapter Summary

General Considerations 1419

Clinical Features 1419

Treatment 1419

Prevention 1419

GENERAL CONSIDERATIONS

Torture is the intentional infliction of brutal pain, both physical and mental on a victim with a view to procure information or confession or punishing for committed or suspected crime, or ruining a rival.

Torture is common in several situations in life. It may be present in the family, or inflicted by other agencies or persons including governmental establishments, especially during war or post-war situations, for eliciting evidence in crimes and as part of terrorism. Excluded is the pain or suffering arising only inherent in/or incidental to lawful punishment. Torture scenes occur in military set-up, police custody, refugee camps, dictator governments, the spread of social violence, and also at home (domestic violence). The methods of torture involves all sorts of physical violence such as kicking, beating, crushing, burning, mutilating, application of irritant chemicals, and mental inflictions such as isolating, humiliating, abusing, accusing, horrifying, guilt-inducing, providing false tragic news of dear persons, giving psychoactive chemicals and forcing to utter slogans opposite to their principles, morals and ethics, and sexual violence, especially against women including unwanted pregnancy. There is no intention to murder. As a result the torture victim is totally ruined, physically, mentally, morally and spiritually. His personality gets disintegrated. Doctors and psychologists are often called in to assist the torturers, especially by governmental agencies in many countries.

CLINICAL FEATURES

The symptoms are related to post-traumatic stress disorder (PTSD). Torture-victims present a spectrum of physical

and mental symptoms. These may be akin to post-traumatic stress disorders (PTSD), but the picture varies depending on the measures used to inflict torture. Prominent ones are the symptoms pertaining to musculoskeletal system, though all systems may be affected. Insomnia, nightmare and lability of mood, lack of concentration, loss of memory, social withdrawal, guilt feeling, insecurity and helplessness are the usual mental symptoms. Other symptoms are fears, apprehension, irritability, anxiety, depression, suicidal ideas and change of personality.

TREATMENT

Torture-victims are to be treated and rehabilitated. A holistic approach involving physical, mental, spiritual, legal and cultural measures has to be adopted to give better outcome. The victim is given respect as a human being, his trust and confidence is established. Drugs and psychosocial therapies are given appropriately to relieve symptoms and to rebuild his personality.

PREVENTION

Torture is an inhuman act and unacceptable to democratic principles. The UN convention prohibits the act of torturing and such inhuman acts, since it is a violation of human rights. *The International Rehabilitation Council for Torture Victims* (IRCT) and many such international organizations are active in its prevention and rehabilitation of the victims. Medical profession is often drawn to assist the torturers. Doctors are forced to stay to prevent death of the victim and they may be forced to issue false medical certificates of tissue damage. They have to treat and rehabilitate the victims, once they are freed. The World Medical Association looks down upon torture and makes plea to governments and doctors not to encourage this heinous act.

Disorders of Adult Personality

N. Krishnan Kutty

Chapter Summary

General Considerations 1420
Clinical Features 1420
Treatment 1420

GENERAL CONSIDERATIONS

The term, personality is derived from the Greek word *Persona* = *mask*. Personality is the total characteristic of an individual, i.e. everything that a person is made up of. It includes the physical makeup; behavior in relation to others, the thinking and feeling. The personality is stable, predictable and measurable. It is in harmony with the socio-cultural standards. When the character traits becomes rigid and maladaptable it results in personality disorders. It produces subjective distress to the person as well as to others in the society.

Etiology

Genetic factors, constitutional factors, and disturbance in family environment during childhood have been implicated. Some psychopaths show an extra 'Y' chromosome (XYY) syndrome. Some criminal psychopaths may show abnormal EEG patterns.

This disorder develops from early childhood without any clear-cut onset of time. Personality can be assessed by clinical interview and by psychological test such as Minnesota Multiphasic Personality Inventory (MMPI), Rorschach's test, Thematic Apperception Test (TAT), Personality Assessment Schedule (PAS) and others.

CLINICAL FEATURES

Personality disorder differs from personality changes. Personality changes are the deterioration of personality due to brain damage, chronic alcoholism, chronic schizophrenia, chronic distress or chronic epilepsy. On the other hand personality disorders develop as primary phenomena from early life. Many types of personality disorders are known. Some common types are given below:

Schizoid Personality Disorder

These individuals are shy, over-sensitive, and seclusive, often with autistic (phantasy) thinking and poor emotional relationship with others.

Obsessive Compulsive Personality Disorder (Anankastic Personality)

These subjects show excessive concern with conformity and adherence to standards of behavior. They are rigid, overinhibited, overcautious, and overdutiful and less adaptive.

Anxious (Avoident) Personality Disorder

Persistent feeling of tension and apprehension, avoidance of social interaction and criticism, and extreme sensitivity to rejection are the usual features.

Histrionic (Hysterical) Personality Disorder

It is marked by self suggestibility, attention seeking behavior, shallow or labile affect, self dramatisation, seductiveness, defensiveness and dependency.

Paranoid Personality

They are always suspicious and sensitive. They are stubborn and argumentative. They are pre-occupied with groundless conspirational explanations of events.

Dissocial (Antisocial) Personality Disorders (Asocial, Psychopathic, Sociopathic Personality)

These personalities are characterised by impulsive behavior, lack of guilt, failure to keep sustained affectionate relationship and failure to learn from past experience. They are labelled as heartless, callous, self-centered persons. They are in the habit of making crimes and offences of all sorts including substance abuse.

Treatment

Since these are life-pattern disturbances, treatment modalities are less effective. Individual and group psychotherapy are the method of choice, psychotropic drugs may help during periods of crisis.

228

Psychoactive Substance Use Disorders and Alcohol-related Disorders

N. Krishnan Kutty

Chapter Summary

Psychoactive Substance Use Disorders 1421

Alcohol-related Disorders 1422

These are disorders due to the self-administration of chemical substances for pleasure. These substances have their effect on the mind. They alter the mood, thought, level of consciousness and behavior.

PSYCHOACTIVE SUBSTANCE USE DISORDERS

Drug dependence, drug addiction and habituation were the terms used in the past to denote the same condition. The psychoactive substances (drugs) are of different kinds:

- Alcohol
- Amphetamine and other stimulants
- Cannabis—ganja, charas, bhang, hashish
- Cocaine
- Caffeine—coffee and tea
- Hallucinogens like LSD, mescaline
- Volatile solutions such as petrol, ether, benzene
- Nitrite, nitrous oxide
- Tobacco (nicotine)
- Opioids—morphine, codeine, heroin, pethidine and methadone, pentazocine
- Sedatives and hypnotics – benzodiazepines, e.g. diazepam, lorazepam, and others.
- Tranquilizers—alprazolam, librium and others.

Administration of, or self-medication by these drugs produces several phenomena referable to psychological functions. Most of such drugs lead to drug dependence on repeated administration. Ultimately they lead to changes in personality and behavior. Several syndromes may be produced by such psycho-active drugs.

Etiology: The three major factors involved in substance use disorders include: (1) The personality, (2) The substance and (3) The environment.

They form a closed chain. The personality has to be vulnerable, the drug should be readily available and the social environment has to be favorable.

- **Personality factors:** Family disturbances in early childhood and parental disharmony are important factors. Anxious and depressive personalities get their symptoms apparently relieved by the substance and they continue the abuse. Delinquency and antisocial personality disorders are other common causes. Challenges of day-to-day life and intra and inter personality problems are contributory to drug abuse.
- **Drug availability:** The drug used may be of medicinal nature such as diazepam, pethidine or mood elevators. Drug trafficking is a major and active menace when there is legal restriction. Substances such as tobacco and alcohol are freely available without restriction.
- **Social environment:** Many social factors such as unemployment, peer group relationship and social deprivation play a part. Disturbed family circumstances working environments, marital disharmony, poverty and consumerism are the major social factors.
- **Physiological reward theory:** Release of dopamine in large amounts is noted in the nucleus accumbens in drug dependent individuals. The nucleus gets its innervation from the ventral tegmentum. The dopaminergic response is rewarding since it is associated with the sensation of pleasure, (positive reinforcement).
- **Behavior theory:** The pharmacological effect brings on euphoria and relief. This positively reinforces the behavior to repeat the act of substance abuse. When the effect becomes one of flushing, nausea or tachycardia which is unpleasant, it negatively reinforces the behavior and drug consumption is given up.
- **Acute intoxication:** When the drug use is transient, a picture of acute intoxication results. Abnormal psychic and physical symptoms appear. Symptoms depend upon the drug used. They disappear as the drug is discontinued.
- **Harmful use (abuse):** Heavy substance use may lead to damage to physical health (e.g. alcoholic hepatitis) social health (e.g. disapproval and criticism) and mental health (e.g. depression).
- **Dependence syndrome:** These are altered physiological and mental states, (alteration of mood, behavior

and cognition) due to prolonged use of the drug. Withdrawal symptoms occur when the substance is abruptly discontinued. There is overwhelming desire (compulsion) to continue the drug in order to overcome the unpleasant effects.

- **Tolerance** is another feature. Effect of the drug diminishes with repeated use of the same dose. The dose has to be increased progressively to get the same effect. Interest and pleasure in other useful activities diminish.
- **Withdrawal state:** This develops once the drug is discontinued after prolonged use. Physical symptoms and psychological symptoms are seen.
- **Amnesic syndrome:** Constant impairment in recent memory is the prominent symptom. Events and time sense are confused (confabulation).

Diagnosis: is made from the history, physical examination and laboratory findings.

TREATMENT

- **Detoxification**, psychosocial therapy and rehabilitation are the methods of treatment.

The treatment of substance abuse is not easy. The first step is the motivation of the patient to accept the treatment. The substance is then totally withdrawn. The withdrawal symptoms which may result are treated medically. The abstinence is maintained by psychosocial therapy. Counselling and group therapy may help to resolve personal and interpersonal problems.

- **Rehabilitation** to re-establish their social and economic position is important to prevent relapse. Financial support and social guidance are helpful steps to bring the victim to mainstream life style.

Prevention: Substance abuse can be prevented through mass education, banning the production and distribution of drugs and giving moral education to build up psychic immunity. Since drug addiction starts early in life, the younger population is at risk and therefore the college and school students are to be specially targeted.

ALCOHOL-RELATED DISORDERS

These disorders result from the consumption of ethyl alcohol-containing beverages in quantities large enough to damage the physical, mental and social health of an individual. Wine, beer, toddy, brandy, whisky, rum and arrack are the usual beverages.

Etiology: The role played by genetic factor is important since persons show a genetic and familial predisposition to acquire the habit. Both psychological and environmental factors contribute to the development of alcoholism. Social and family maladjustment, economic

factors and vulnerable personality together promote the dependence on alcohol. Anxious and depressed persons find solace in alcohol to get-over their problems. Anti-social personalities find pleasure in alcohol, especially during periods of crisis.

Alcohol induces euphoria and relief from anxiety. These serve as positive incentives to repeat the consumption of alcohol. This positive reinforcing effect is associated with a high amount of dopamine release in the nucleus accumbens. In some oriental population such as the Japanese a variant of the isoenzyme *aldehyde dehydrogenase* provides them partial immunity to alcohol. They get negatively reinforced by the production of nausea, flushing and tachycardia on consuming alcohol. Several physical and psychological abnormalities can be caused by alcohol depending upon the amount of consumption, its frequency, type of beverage consumed, co-existent physical and psychiatric illnesses and the nutritional status (see Chapter 23).

CLINICAL FEATURES

Alcohol is a cerebral disinhibitant. Acute intoxication causes euphoria or elation, slurred speech, incoordination and gait disturbances. During periods of excitement, irrelevant talk, aggressive and violent activity, illusions and persecutory delusions may be observed. In cases of *chronic alcoholism* many other neuropsychiatric complications may be noted. These include continuous auditory hallucinations (*alcoholic hallucinosis*) and delirium tremens on withdrawal of alcohol. Other manifestations include delusion of infidelity (*alcoholic paranoia*), loss of recent memory with personality change (*amnesic syndrome /Korsakoff's Psychosis*) and intellectual deterioration (alcoholic dementia). Depression, schizophrenia and sexual dysfunction may be aggravated by chronic alcoholism. It is a major cause of suicide. Chronic alcoholism causes damage to several organs such as the stomach, liver, peripheral and central nervous system, heart and others. Consumption of alcohol by drivers is a major contributory factor for road accidents.

Diagnosis of alcoholism is based on the history and clinical features. The severity of intoxication generally correlates with the blood levels of alcohol though there are several exceptions. Blood level can be easily determined, so also the severity of consumption can be rapidly determined by breath tests.

TREATMENT

The treatment of alcoholism includes (i) *the treatment of the dependence*, (ii) *the psychiatric complications*, and (iii) *the physical complications*. Motivation may be required in most of the cases. The patient is initially detoxified. Alcohol is withdrawn. The resulting

withdrawal reaction—delirium tremens is medically managed. The patient is quietened with chlordiazepoxide. Electrolyte imbalance and dehydration are corrected. Anticonvulsants and antipsychotics may be needed. After the detoxification process psychotherapeutic measures are employed. The goal is to improve the environment and personality to maintain sobriety.

Prevention of relapse may be achieved through *behavioral therapy technique* or by *chemical aversion*. For chemical aversion disulfiram (*antabuse*) is chosen. Initially a dose of 0.5 g twice daily for the first day, 0.75g on the second day followed by 0.5 g on the third day and

0.25g on the fourth day onwards. The patient is advised not to take alcohol containing liquids, since they lead to intense discomfort and even life-threatening consequences when receiving antabuse. Relapse can also be prevented by anti-craving drugs such as *acamprosate* (calcium acetyl homotaurinate) a GABA analogue which inhibits the craving for alcohol. It is given in doses of 333 mg-666 mg thrice daily. Naltrexone is an antagonist of endogenous endorphin. This drug is given in the doses of 50 mg. once a day after stopping alcohol for 12 weeks. It helps to maintain abstinence. The neuropsychiatric complications and physical complications are medically managed.

229

Behavioral Syndromes Associated with Physiological Disturbances and Physical Factors

N. Krishnan Kutty

Chapter Summary

Eating Disorders 1423

Anorexia Nervosa 1423

Bulimia Nervosa 1424

Sleep Disorders 1424

Sexual Dysfunction 1425

Erectile Disorder 1425

Premature Ejaculation 1425

Abnormalities of Sexual Preference 1425

Postpartum Psychiatric Disorders 1426

EATING DISORDERS

Eating disorders include anorexia nervosa and bulimia nervosa.

ANOREXIA NERVOSA

This disorder is common in young women. It is a condition characterised by severe resistance to eat or drink articles of food for prolonged periods leading to severe loss of body weight (below 15% of the standard weight). Any attempt to force them to feed may result in vomiting. Vomiting and diarrhea may be deliberately induced for losing weight. Though common among prepubertal

females, males are not exempt. Body image disturbance is the main cause. The fear of becoming obese is the triggering factor. The wish to become a 'lean beauty' is also a factor. Amenorrhea, intolerance to cold, growth of lanugo hair, dry skin and cardiac arrhythmias are the common features in this disorder. Symptoms of depression, obsessive compulsive disorder and sexual maladjustment are associated features. In severe cases cachexia supervenes. The condition is fatal, if untreated.

Treatment: is mainly supportive. Inpatient care may be required. The patient and family members are educated about the disease and better interpersonal relationship should be promoted. The patient is encouraged to bring up body weight by eating and helped by counselling, and drug therapy. At least 1,200-1,500 calories should be supplied per day and gradually increased upto 3,000-4,000 calories. Rarely parenteral feeding may have to be given. In 6% of cases *re-feeding syndrome* may develop. This may give rise to transient pedal edema. Emergency complications include prolongation of Q-T interval in the ECG, hypophosphatemia, weakness, confusion and neuromuscular dysfunction.

No drug is specific for anorexia nervosa. Cyproheptadine, chlorpromazine and pimozide are found to be useful. Modified insulin treatment can be used to bring up weight. Some cases may improve with electroconvulsive therapy.

BULIMIA NERVOSA

This is characterised by episodes of irresistible urge to overeat (binges). Surprisingly, the body weight remains normal. This is usually achieved by the self-induction of vomiting, use of laxatives or diuretics, or strenuous exercise. It is seen more commonly in women. Amenorrhea is not a feature. Stress encourages overeating. Cognitive behavior therapy and other forms of psychotherapy may help to reduce stress and stop this disorder. Drugs such as SSRIs are helpful adjuncts. Complications may develop on account of repeated vomiting or due to side effects of self-administered drugs.

SLEEP DISORDERS

Insomnia, hypersomnia and parasomnias are included under this term.

Insomnia

It is the most common sleep disorder. It may be primary or secondary. The secondary causes are medical and psychiatric. Physical pain, asthma, arthritis, hyperthyroidism, excessive use of caffeine, hunger, use of drugs such as aminophylline and steroids are the common medical causes. Depression, anxiety, mania, obsessive compulsive disorder, dementia and withdrawal from alcohol or drugs are the common psychiatric causes. The treatment depends on alleviation of the primary cause. Hypnotics can be used temporarily.

In primary insomnia no specific cause can be found. It is uncommon. There is difficulty in falling asleep or the patient wakes up frequently. The treatment modalities are conditioning of sleep, adoption of sleep hygiene using the bedroom only for sleeping, change of bedroom, and relaxation techniques and use of hypnotic on a short-term basis.

Hypersomnia

In this condition there is excessive sleep, Narcolepsy is the most common manifestation.

Narcolepsy

Narcolepsy is a disabling sleep disorder characterized by excessive day time sleepiness and abnormal rapid eye movement (REM) sleep. Other associated phenomena include **cataplexy** which is sudden loss of muscle tone triggered by strong emotions, sleep paralysis, and hypnagogic (at the onset of sleep) hallucinations and sleep paralysis. The prevalence in the general population is about 0.05%. The condition shows genetic predisposition strongly associated with a HLA allele. **Sleep paralysis** is the occurrence of inability to move the limbs or the head or to speak and breathe normally either at sleep onset or on waking up mainly from REM sleep, despite being mentally awake. The biochemical basis is the deficiency of *hypocretin-1* peptides which are produced in the

hypothalamus. The level of *hypocretin* in CSF are low. Values of CSF *hypocretin* lower than 110 ng/L or 30% or normal values are highly suggestive of narcolepsy.

Clinical features: Daytime sleepiness is the first symptom to appear. The sleep episodes are irresistible, often short, often associated with dreaming and followed by normal wakefulness lasting for several hours.

Cataplexy which is specific to narcolepsy is a diagnostic marker. It is characterized by sudden drop of muscle tone, often precipitated by positive emotions such as laughter. In most cases all the striated muscles except the diaphragm lose tone and the person collapses. Sometimes the involvement of the muscles may be partial. The attack may last for a few seconds to several minutes. Others associated features are sleep paralysis and automatic behavior.

Diagnostic criteria:

1. Excessive daytime sleep occurring almost daily for at least 3 months, not attributable to other causes
2. Associated cataplexy
3. Diagnostic features on polysomnography
4. Levels of CSF hypocretin—1 below 110 ng/L or less than 30% of normal values are highly suggestive with high sensitivity and moderate specificity.

Treatment: Narcolepsy has no cure and therefore the management is symptomatic. The medications include (1) dopaminergic stimulants for daytime sleepiness and sleep attacks (2) antidepressants (mostly noradrenergic) for cataplexy and (3) hypnotics for disturbed night-time sleep.

Modafinil is a wakefulness promoting agent, given in a dose of 100-200 mg in the morning, repeated after lunch if needed. Methylphenidate and amphetamines are commonly used in doses below 60 mg/day. Other stimulants include sodium oxybate, mazindol, pemoline and selegiline.

Dose of mazindol is 2-3 mg/day.

Sodium oxybate is the approved drug for cataplexy given in doses of 3-9 g at night. It reduces day time sleepiness, narcolepsy, sleep paralysis and hypnagogic hallucinations. Adverse side effects include dizziness, headache, nausea, and less frequently, pain, depressive mood, enuresis and sleepwalking. Antidepressant drugs (especially SSRIs) are effective in treatment of narcolepsy and cataplexy—especially clomipramine in doses of 10-25 mg.

Further reading: Yues Dauvilliers, et al. The Narcolepsy with cataplexy. The Lancet 2007;369:499-511.

Parasomnias: These are abnormal events occurring while asleep. They may be nightmares, night terror, somnambulism (sleep walking) somnolology (sleep talking), bruxism (teeth grinding) and enuresis (bed wetting). These are common in children.

- **Nightmare:** It occurs during rapid eye movement (REM) sleep. The person may get up from sleep with

frightening dreams. Sleep may proceed after it. The content of the dream is recollected the next day. It is always non-pathological. But it is common after a stress experience. Usually no treatment is required. Measures to reduce stress, tricyclic antidepressants to reduce REM sleep and diazepam are the modalities of treatment.

- **Night terror:** The person (often a child) gets up from sleep frightened, terrified, confused, disoriented, screaming aloud, clinging to others around or running for help. After this episode the person falls asleep again. The episode is not remembered the next morning. It occurs during NREM sleep. It can be a manifestation of temporal lobe epilepsy. Treatment is seldom required. Diazepam or antiepileptic drugs may be required if a seizure disorder is diagnosed.
- **Sleep walking:** This occurs during non-rapid eye movement (NREM) sleep. It may be associated with sleep talking. The person may get up while asleep and perform various activities like taking bath, getting dressed up and even going for a walk and returning. He may meet with accidents during this phase. The activity can be terminated by waking him up. The events are not recollected when awake.

SEXUAL DYSFUNCTION

Sexual response is a psychosomatic process. The natural sexual activity in humans is the coital union of man and woman culminating in orgasm in both the partners. Seminal discharge occurs in the male during this state. The causes of sexual disturbances may be physical, psychological or both.

The different disorders include:

1. Reduction or loss of sexual desire and lack of sexual enjoyment.
2. Lack of genital response, which includes impotence in men and absence of sexual arousal in women.
3. Orgasmic dysfunction which includes premature or retarded ejaculation in man and orgasmic failure in women.
4. Vaginismus and dyspareunia in women and painful ejaculation in men.

Erectile Disorder

Impotence: *Impotence* is the inability to get or sustain erection sufficient enough for satisfactory coitus. Impotence may be due to organic diseases or may be due to psychological causes. If erection occurs in the presence of another partner, or during masturbation, it indicates a psychological cause. Presence of spontaneous early morning erection also points to a psychological cause. Psychological causes leading to impotence include venereophobia, lack of privacy, inertia on the part of the partner, fear of castration, and incestuous feelings.

Diseases such as depression, conversion disorders, anxiety disorder are associated with impotence. Many psychotropic drugs impair erection and delay ejaculation on account of autonomic side effects. Drugs such as bromocriptine, yohimbine and cyproheptadine may be useful in such cases.

Phosphodiesterase type-5 inhibitor such as sildenafil, tadalafil, and vardenafil are found very effective. **Sildenafil** is very effective to induce strong erection when given in doses of 25-100 mg. SOS to be taken one-hour before expected intercourse. Only one dose should be taken within 24 hours. Cooperation from the partner is essential for success.

Side effects include vomiting, headache, flushing, dizziness, visual disturbances, raised intraocular pressure, nasal congestion and hypersensitivity reactions. Contraindications include the concurrent use of nitrates, and vasodilators; hypertension, recent stroke, unstable angina, myocardial infarction and hepatic damage.

Premature Ejaculation

This is the occurrence of ejaculation early during the sexual intercourse before penetration or soon after that. This leads to a sense of frustration in the male and the female partner does not get orgasm. Physical methods such as the 'stop and start technique' and 'squeeze technique' in which the glans penis is squeezed when ejaculation is imminent, may succeed in some cases. Drugs such as fluoxetine and tricyclic antidepressants are helpful to delay ejaculation.

- **Female orgasmic disorder:** Many women may fail to get orgasm or it may be obtained only after undue delay.

Abnormalities of Sexual Preference Syn. Paraphilias

- *Fetishism, transvestic fetishism, pedophilia, exhibitionism, sexual sadism, sexual masochism and voyeurism* are some of the important disorders.
- **Fetishism:** Libido gratification from contact with articles such as dress, hair and others of the opposite sex.
- **Pedophilia:** An unnatural urge and desire to have sexual relationship with children of pre-pubertal age
- **Exhibitionism:** Tendency to exhibit his/her genitals to members of the opposite sex in public for sexual pleasure.
- **Sexual sadism:** Sexual pleasure derived from inflicting mental or physical pain on the sexual partner.
- **Sexual masochism:** Sexual pleasure derived by being abused or being acted cruelly by the opposite partner.
- **Voyeurism:** This is the phenomenon in which a person derives sexual pleasure by observing sexual activity of others.

- *Scopophilia*: This is sexual pleasure uptake from visual sources such as nudity in the opposite sex and obscene pictures.

**POSTPARTUM PSYCHIATRIC DISORDERS
(PUERPERAL PSYCHOSIS)**

These are the psychiatric disturbances which are precipitated by the stress of child birth.

- **“Postpartum Blues”** “(Maternity Blues)” is a mild disturbance of short duration. The main symptoms are irritability, crying spells, labile mood, agitation and confusion. It may disappear by itself within 2-3

days. To hasten recovery anti-anxiety drugs may be used.

- **Postpartum Psychosis** is a severe kind of disturbance. The symptoms in the majority of cases are those of mood disorders - either of mania or depression with agitation. Schizophrenia and delirium-like picture do occur at times. The life of the infant is always at risk, because of the delusions involving the baby. So the baby has to be protected.

The diagnosis is to be made after exclusion of any intracranial pathology. The treatment depends upon the clinical presentations. Antidepressants, antipsychotics, anti-anxiety and hypnotic drugs may be selected.

**Psychological Factors
Affecting Systemic
Medical Disorders**

N. Krishnan Kutty

Chapter Summary

Psychosomatic Disorders 1426
Psychiatric Disorders Caused by General
Medical Disorders 1427

PSYCHOSOMATIC DISORDERS

The body and mind interact both in health and illness. The mind plays a major role in many physical illnesses. A physical illness may be precipitated, aggravated or prolonged by psychological factors. This paved the way for the concept of psychosomatic disorders. This term has now been replaced by the new terminology “Psychological factors affecting medical conditions”.

The psychological factors are many:

1. It may be a primary mental disorder which affects the course of a medical disease, e.g. major depression delays recovery from stroke; myocardial infarction.
2. It can also be a psychological symptom that adversely affects the disease, e.g. anxiety worsens bronchial asthma. Depressive symptoms delay recovery from surgery.

3. It may be a personality factor that precipitates a disease, e.g. Type A personality in coronary artery disease.
4. It may be severe stress.

There are many physical disorders where psychological factors play a major role. The common physical disorders are:

Respiratory disorders: Bronchial asthma, hay fever vasomotor rhinitis.

Gastrointestinal disorders: Peptic ulcer, irritable, bowel syndrome, ulcerative colitis, anorexia nervosa.

Cardiovascular disorders: Hypertension, paroxysmal tachycardia, coronary artery disease.

Nervous system: Migraine, headaches.

Endocrine and metabolic disorders: Hyperthyroidism, diabetes mellitus, menstrual disturbances, obesity.

Dermatologic disorders: Eczema, psoriasis, neurodermatitis.

Bones and joints: Rheumatoid arthritis, backache.

Maladaptive health behavior affecting a general medical condition, e.g. avoidance of physical exercise, over-eating, unsafe sex practices and others.

TABLE 230.1

List of important medical conditions which give rise to mental symptoms	
General medical conditions	Psychiatric symptoms/syndromes
Endocrine disorders Hyperthyroidism Hypothyroidism Hyperparathyroidism Cushing's disease Addison's disease Pheochromocytoma	Psychotic symptoms Delusions, hallucinations, agitation, insomnia
Metabolic Conditions Hypoglycemia	Mood symptoms Depression – persistent sadness, gloomy thought, motor retardation, suicidal intent, ideas and attempts
Hepatic encephalopathy Uremia	Mania-elated, expansive mood, hyperactivity, persecutory/ grandiose delusions, muscular rigidity, immobility, catatonic posturing, negativism, mutism, echolalia and echopraxia
CNS Conditions Encephalitis sequelae, GPI, post-stroke, post-traumatic, Alzheimer's disease, Huntington's chorea, Wilson's disease, tuberous sclerosis, parkinsonism, frontal and temporal lobe tumours	Anxiety symptoms Generalized anxiety, restlessness panic episodes, obsessive compulsive symptoms, amnesia, dementia
Drugs Propranolol, anti-psychotics, steriods sympathomimetics, ranitidine, L-dopa, oral contraceptives	Personality Change A persistant change in behavior from the previous state and character trait
Other conditions Vitamin B ₁₂ deficiency, pellagra, leukemia Systemic lupus erythematosus (SLE)	————Do————
Note: All the psychiatric symptoms may develop in any of the general medical conditions, nonspecifically.	

- **Management:** Medical treatment is the more important modality of management. It should be supplemented with measures to allay and counteract the psychological impacts caused by the underlying disease. Psychotherapeutic measures include counselling, general behavior therapy techniques such as muscle relaxation, biofeedback, controlled breathing exercises as practiced in yoga and other measures such as hypnosis.

Psychiatric Disorders Caused by General Medical Disorders

Several primary psychiatric disorders are accompanied by somatic manifestations. Similarly psychiatric symptoms

develop in several medical conditions such as cerebral infarction, encephalitis, drug toxicities and others. These are evident from the history, physical examination and laboratory findings. The Psychiatric symptoms are not specific or any particular medical disorder and vice versa. They are not reactions or sequelae of primary medical conditions. There are several medical and surgical conditions which give rise to psychiatric manifestations as part of the disease process. The psychiatric abnormality also clears up when the underlying condition is treated. These are described along with such disorders in the different sections.

The Table 230.1 gives a list of important medical conditions which give rise to mental symptoms.

Chapter Summary

General Considerations 1428
Down's Syndrome 1428

General Considerations

Syn:Mental subnormality /mental handicap/ idiocy/amentia/mentally challenged/ oligophrenia

Mental retardation (MR) is a state of sub-average intellectual functioning resulting in or associated with impairment in adaptive behavior and manifested during the developmental period before the age of eighteen years. Normal persons adapt sufficiently to various needs of the society and the environment. Adaptive behavior can be measured using *Vineland Adaptive Behavior Scale* (VABS). The retardation is graded on the basis of *intelligence quotient* (IQ) into four grades.

Causes of mental retardation: Mental retardation can occur with or without any obvious mental or physical disorder. Several etiological factors are known. A few of them include:

Grades of MR				
Grade of MR	IQ range	Mental age	Occurrence rate	Most common cause
Mild/moron or feeble mindedness	50-69	under 9	85%	Psychosocial
Moderate-(Imbecility)	35-49	under 6	10%	Down's syndrome, fragile X syndrome, Phenylketonuria
Severe	20-34	> 3< 6	3-4%	Microcephaly, cretinism, cerebralpalsy
Profound-Idiocy	below 20	below 3	1-2%	-Do-

Chromosome abnormality—For example, Down's syndrome, fragile X-syndrome, Inborn errors of metabolism, e.g. phenylketonuria.

Congenital brain abnormalities—For example, microcephaly hydrocephalus, tuberous sclerosis, cretinism, cerebral palsy.

Prenatal causes—For example, maternal rubella, syphilis, lead poisoning, alcohol.

Perinatal—For example, birth asphyxia, kernicterus.

Postnatal—For example, hypothyroidism, injury, intoxication with lead and mercury, autism, encephalitis, meningitis.

Down's Syndrome (Mongolism)

This condition is the most common chromosomal abnormality causing mental retardation (MR). It was described by **Landon Down** in 1886. The incidence is one in thirty live births occurring in children born to mothers aged 45 and above. The risk in the second child is 1 in 100.

Pathology: The 21st chromosome occurs as triple (trisomy) instead of the normal two alleles. About 95% of *trisomy* is due to non-disjunction which happens during meiosis. The rest 5% is due to translocation and *mosaicism*. In mosaicism the non-disjunction occurs during cell division after fertilization.

Clinical Features: Clinical features are characteristic. The face is round with small mouth and pegged teeth, furrowed protruding tongue and high arched palate. The eyes show oblique palpebral fissures and epicanthic folds. The occiput is flat. The hand is short and broad with a single palmar crease and short curved little finger. Hypotonia and hypermobility of joints may occur. Other less common features are congenital heart disease, especially septal defects, duodenal obstruction, impaired immune responses, higher incidence of leukemia, hypothyroidism and atlanto-axial dislocation.

Diagnosis: Is by the clinical findings and IQ measurement. IQ below 70 favors M.R. Mental retardation can be

predicted during infancy by the presence of clinical features such as microcephaly, mongoloid features, cerebral palsy and others. During early childhood, delay in the developmental milestones, academic backwardness, peer group maladjustment, and absenting from school or house may suggest mental retardation. Later in life such cases present as inability to bear responsibilities and failure in adaptation to life situations. Some of them require supervision even in routine work.

Management and care of mental retardation: The main objectives are provision of educational and psycho-social care. It depends on the age of the retarded person and type of retardation. Fostering, boarding, schooling in special schools and accommodation are their social needs. A team

approach including doctors, nurses, occupational therapists, psychologists, physiotherapists and speech therapists, is most rewarding. Persons with mild handicap can live independently though supervision may be needed in special situations.

Normalization is the modern concept, widely practiced in the USA. The mentally retarded person is made to live in the community and given the chance to experience and participate in social activities. Retarded children are preferably brought up in their own homes. Training and accommodation are provided in the proximity of the family. As in the case of normal persons, the mentally retarded are also prone to develop various psychiatric disorders. Drugs and behaviour therapy are given accordingly.

232

Behavioral and Emotional Disorders Occurring in Childhood and Adolescence

(Syn. Psychiatric Disorders in Childhood and Adolescence)

N. Krishnan Kutty

Chapter Summary

Disorders of Psychological Development 1429
Pervasive Developmental Disorders 1429
Childhood Autism 1429
Attention Deficit Hyperactivity Disorder 1430
Conduct Disorders 1430
Enuresis 1430

Children also suffer from common psychiatric disorders as other age groups. Some of the disorders are seen exclusively in children. The important ones are described below.

Disorders of Psychological Development

Children may lag behind in the development of learning of certain psychological skills specifically.

Examples:

- Specific reading disorders.
- Specific spelling disorders.

- Specific mathematics disorders.
- Understanding and articulation of spoken language.
- Impairment of motor coordination.

Lack of self-esteem and delay in brain maturation may be the cause in many. The disorders may disappear as the child grows. Emotional support and instilling confidence may enhance recovery.

Pervasive Developmental Disorders

The symptoms of these disorders are pervasive impairment of social skills, communication skills and behaviors. Childhood autism and Attention Deficit Hyperactivity Disorders (hyperkinetic syndrome) are the common disorders.

CHILDHOOD AUTISM (INFANTILE AUTISM)

The term autism denotes a state of absorption into ones own world of phantasy with loss of contact with the reality. Reported incidence of childhood autism is 2-5/10,000 live births.

Childhood autism was originally described by **Leo Kanner** in 1943 as Early Infantile Autism. Autistic

aloneness, language abnormality and restricted and compulsive behavior are the main three features of this disorder. Boys are more affected than girls. The disorder is unmasked by the third year of life. The child is abnormally quiet, lacks the usual emotional warmth and likes to be left alone. Eye-to-eye contact is avoided. He does not communicate through conversation. Pronouns are reversed. 'You' is used to mean 'I' Echolalia is common. Words and behavior are stereotypic. The child is fond of sameness in everything. Bizarre behavior such as rocking, whirling the head and flapping of hand may be present. Impulsive violence is common. The arithmetic skill is relatively high. IQ may be around 70 in most cases. Some have normal IQ. Many cases may be attributable to birth trauma. Autism is strongly a genetic disorder, and probably arises from multiple genetic defects. Recurrence within families with one affected child is high.

There is no specific treatment. Antipsychotics are given to control violence and hyperactivity. Behavior therapy may be helpful. Parents are to be counselled regarding management of the child at home. Many improve spontaneously and may be able to attend normal school. A few may require training in special schools. Some require special residential care.

Attention Deficit Hyperactivity Disorder-ADHD (Hyperkinetic syndrome)

This disorder is more common in boys. Persistent inattention, hyperactivity and impulsivity are the cardinal features. These affect their scholastic performance. Impulsive and reckless behavior are common. Brain damage due to birth trauma, allergy to food containing tartrazine, toxicity to lead and overactivity of peripheral adrenergic system are some of the recognized causes.

Treatment: Stimulant drugs such as dextroamphetamine 2.5-5 mg twice a day, clonidine, tricyclic antidepressants and monoamine oxidase inhibitors are beneficial. Many children become normal as they reach adolescence. Atomoxetine HCl is a recently introduced drug for this condition.

CONDUCT DISORDERS

These are the most common disorders of childhood. Persistent dis-social, aggressive, or defiant behavior are the presenting features. It is manifested as quarrelsomeness, disobedience, lying, cruelty to people and animals, destructiveness, stealing, absenting from school, fire setting, temper tantrums, running away from home and the like. The disorder may be the outcome of unsatisfactory family environment, poor academic performance and such other psychosocial adversities.

Treatment: Some may improve spontaneously. Drugs are of little value. Psychosocial therapy is important. The child is given insight-oriented psychotherapy to bring up problem solving skills. Adverse domestic factors are identified and removed. The child's behavior is rectified through rewards, praise and approval (*contingency management*).

Drugs: In selected cases anti-psychotics, SSRIs, mood stabilizers and anxiolytics may be helpful.

ENURESIS (BED WETTING)

Almost all children get bladder control by the age of five years. Enuresis is the voiding of urine during sleep persisting after the age of five years. In primary enuresis the child has never attained bladder control after birth. In secondary enuresis the child has attained bladder control which is subsequently lost. Delay in brain maturation, emotional factors such as school problems, birth of a younger child, loss of parental affection and other stressful factors may be the underlying causes. Local causes include low volume capacity of the urinary bladder, urinary tract infection, congenital abnormalities of the lower urinary tract and others.

Treatment: Behavior therapy techniques using *mattress alarm (bell or buzzer and pad)*, bladder training exercises and reassurance are the therapeutic modalities. Drugs such as imipramine 25-50 mg at night are useful. Intranasal administration of synthetic antidiuretic hormone is effective.

Chapter Summary

Suicide, Attempted Suicide and Deliberate Self-harm 1431

Violent and Aggressive Behavior 1432

Acute Anxiety and Panic Episode 1432

Stupor 1432

Acute Psychological Reactions to Physical Diseases 1432

A psychiatric emergency can be defined as a sudden disturbance in behavior, thoughts or feelings for which immediate intervention is necessary to avoid danger to the patient, other people or both. The common psychiatric emergencies are:

1. Suicide and attempted suicide
2. Violent or aggressive behavior
3. Acute anxiety and panic episode
4. Stupor
5. Acute psychological reactions to physical illness
6. Abnormal reaction to drugs.

Suicide, Attempted Suicide and Deliberate Self-harm

‘Suicide is an expression of personal agony’. It is a deliberate act or an attempt to kill by oneself (*sui*=self, *cide*=murder). Some of these persons may not be actually bent upon causing death but may only be trying to seek attention or help when they are in distress through *self injurious behavior*. Hence, the term ‘*deliberate self harm (DSH)*’ is commonly used at present to denote such self-destructive actions including suicide.

Suicide can be due to many causes

- **Psychiatric disorders:** Major depression is the most common condition leading to suicide. It can also occur in schizophrenia, personality disorders, alcoholism, and drug addiction. Less serious suicidal attempts may be made by patients with dissociation/conversion

disorders, immature personality and antisocial tendencies.

- **Physical diseases:** Chronic or serious physical illness like malignancies and degenerative or disfiguring diseases or surgery may lead to a feeling of hopelessness and some may attempt or commit suicide.
- **Social factors:** Suicidal behavior is high among socially isolated individuals as shown by the French sociologist Emil Durkheim. Persons with broken families, disturbed marriages and stressful occupations are more vulnerable. Though both sexes make suicidal attempts more serious ones are made by males. Similarly, suicidal behavior is more common among adolescents and elderly subjects.
- **Psychological factors:** Acute psychological stresses of a severe degree may often lead to suicidal behavior. Loss of job, financial crisis, marital stresses, interpersonal problems in the family, death or serious illness of beloved ones, accidents, failure in examinations, humiliating or painful experiences and other similar factors may predispose to suicidal behavior.

Management: In attempted suicide emergency medical management is required to prevent deterioration and death. The modalities depend on the type of attempt and substances used as poisons. These are described in Section-4. Once the emergency is tided over, the next step is to identify the pre-disposing factors and arrange suitable measures to prevent recurrence. In suicidal risk the first step is to arrange a safe environment where they can be closely observed. The seriousness of suicidal risk is to be evaluated by taking all relevant factors into consideration. The presence of depression, previous history of suicidal attempts, young age, history of alcohol and drug addiction, presence of serious physical diseases, severe psychological stresses, social isolation and an immature maladjusted personality contribute to increase the suicidal risk. Such patients require psychological support in the form of counselling and psychotherapy. Drugs are needed to relieve depression, anxiety or psychosis, if they are present. Hospitalization is better when the risk is high.

Violent and Aggressive Behavior

This may result from psychoses like schizophrenia, mania, delirium and intoxication with drugs and alcohol. The patients are briefly evaluated. They should be kept in safe custody to avoid danger to themselves and others. Some of these patients may respond to supportive environment and reassurance. Physical restraints may be necessary in others. Injections of diazepam 10-20 mg IV slowly, Lorazepam 2 mg IM or haloperidol 5 mg IM can be given to quieten the patient. The basic disorder is to be identified and managed subsequently.

Acute Anxiety and Panic Episode

This may be secondary to unidentifiable stresses. The patient comes in severe tension, restlessness and with impending feeling of death or disaster accompanied by marked autonomic arousal. After proper evaluation, provision of supportive environment, reassurance and parenteral administration of anti-anxiety drugs serve to overcome the anxiety. The causative factors need exploration and further management.

Stupor

Stupor is a state of minimal psychomotor activity. These patients may refuse to eat and may not cooperate in maintaining proper hygiene. The causes of stupor include

catatonic schizophrenia, depressive illness and organic conditions. The general management is similar to that of a comatose patient. Further treatment depends on the underlying cause.

Acute Psychological Reactions to Physical Disease

Commonly in the medical and surgical wards, one encounters patients who present with acute anxiety, tension, depression, fear, agitation or even aggression occurring during acute physical disorders such as ischemic heart disease, stroke, accidents, burns, malignancy and postoperative pain. These manifestations are secondary to their anxiety and emotional stress. Such patients need sympathetic communication, education, reassurance and encouragement. Drugs may be used to control anxiety and depression. *The attending physician should extend psychological help as well as appropriate treatment for the basic physical condition.* Other situations where acute psychological stress occurs include the following:

- 1. When breaking the news of a serious illness such as AIDS, cancer or leukemia in the patient and
- 2. When giving the first information of death of a close relative.

In such cases proper empathy from the physician and a supportive attitude towards the persons help to ease the situation.

234

General Principles of Management of Psychiatric Disorders

N. Krishnan Kutty

Chapter Summary

- Electroconvulsive Therapy 1433
- Pharmacological Methods 1433
- Anti-psychotic Drugs 1433
- Antidepressants 1435
- Anti-anxiety Drugs 1436
- Antiparkinsonism Drugs 1437

Therapeutic modalities in psychiatric medicine fall into three major groups.

These are:

- 1. Physical methods
- 2. Pharmacological methods and
- 3. Psychological methods

Psychiatric cases can be managed in the regular outpatients department, but inpatient care is

needed in cases of violence, stupor, suicidal threat, delirium and feeding problem.

Combination of therapies is much better than a single mode.

PHYSICAL METHODS OF TREATMENT

These are electroconvulsive therapy (ECT) and psychosurgery.

ELECTROCONVULSIVE THERAPY (ECT)

Convulsive Therapy was introduced by **Von Meduna** in 1934 as a treatment for schizophrenia. He observed that schizophrenia and epilepsy seldom occurred together. So his idea was to produce convulsions to drive away schizophrenia. First he used injection of camphor oil and later injections of leptazol to induce the convulsions. In 1938 **Cerletti** and **Bini** in Italy found that electricity could produce convulsions and they devised a machine. Thus, electro-shock treatment (EST) came into being and later used the terminology, electro-convulsive therapy (ECT). ECT became very popular because of its efficacy in the management of depression, mania and schizophrenia.

- **ECT technique:** In ECT an electric current is applied over the brain in the temporal regions, so as to induce a seizure. The seizure so produced, resembles a typical grand mal epilepsy. Two types of techniques are followed - direct ECT and modified ECT. At present modified ECT is the method of choice.
- **Modified ECT:** ECT is administered after giving a muscle relaxant in order to minimize the muscular convulsion. For practical purposes the ECT is comparable to a major surgical procedure. Informed consent should be obtained and the procedure should be undertaken by a specialist, only in places with facilities for emergency care.
- **Indications of ECT:** ECT is still considered as a very effective therapeutic procedure for the following conditions.
 1. Major depression with suicidal intent.
 2. Depressive stupor
 3. Resistant depression
 4. Catatonic schizophrenia
 5. Acute schizophrenic excitement
 6. Manic excitement
 7. Schizo-affective disorder.
- **Contraindications:** There is no absolute contraindication except for the anesthesia. The contraindications include acute coronary heart disease, acute febrile illnesses, hypertension, acute respiratory illness and intracranial space occupying lesions. Pregnancy is not a contraindication.
- **Complications:** Mortality is 3 to 4 per 100,000. It parallels the risk of anesthesia. The other complications include injuries to tongue, skeletal muscles,

ligaments and bones, aspiration pneumonia, cardiac arrest, respiratory arrest and post-ictal anterograde and retrograde amnesia. The amnesia disappears within 1 to 4 weeks.

Psychosurgery

It was introduced by **Egas Moniz**. These are neurosurgical operations to control intractable mental disorders. Nerve tracts or nuclei concerned with mental functions are severed or destroyed. Proton beams, radioactive implants such as yttrium-90, ultrasonic beams and electrical coagulation are employed for this operation. *Stereotactic tractomy* severs the connection between the orbital part of the frontal lobe and the limbic area. *Stereotactic limbic leucotomy* interrupts the frontal lobe pathways and cingulate gyrus and amygdala.

Indications for surgery include intractable conditions not responding to medical treatment such as:

- Obsessive compulsive disorder
- Anxiety disorders
- Depression
- Paranoid schizophrenia, and
- Pain disorders.

The outcome is unpredictable. Some may improve remarkably and others deteriorate, even to the level of vegetative existence.

PHARMACOLOGICAL METHODS (DRUG THERAPY)

The discovery of drugs that can rectify disturbed mental function was a major revolution in psychiatry. These drugs which have affinity towards the mind are collectively called *psychotropic* drugs. Such drugs are generally used in the treatment of mental disorders. They can be classified into:

- i. *Anti-psychotics*
- ii. *Antidepressants*
- iii. *Mood stabilizers*
- iv. *Anti-anxiety drugs*
- v. *Hypnotics*
- vi. *Psychostimulants*
- vii. *Cognitive enhancers*
- viii. *Antiparkinsonism drugs*

ANTI-PSYCHOTIC DRUGS (NEUROLEPTICS / MAJOR TRANQUILIZERS)

These drugs are capable of eliminating psychotic symptoms such as delusions, hallucinations, psychomotor excitement and the associated symptoms. Most of these drugs act by blocking dopamine receptors (D_2) or the serotonin ($5HT_2$) receptors in the CNS at the mesocortical and mesolimbic tracts. In addition they also block the histaminic (H_1) cholinergic and adrenergic receptors and

TABLE 234.1

Showing the common anti-psychotic drugs

Kind of drugs	Starting dose (mg) oral	Max. daily dose (mg)	Prominent side effect
<i>Conventional anti-psychotics</i>	<i>Common S/E</i>		
Phenothiazines			
Chlorpromazine	50-100 tid 50-100	1500 IM	Sedation Hypotension
Thioridazine	50-100 tid	800	extrapyramidal
Trifluoperazine	5 tid	60	symptoms (EPS) and others
Fluphenazine decanoate	12.5-50 once in 2-4 weeks	IM	EPS
Butyrophenones			
Haloperidol	5-20 mg tid oral 5-10 IM	100	Severe EPS; non-cardiotoxic
Haloperidol decanote	25-250 once in 2-4 weeks	IM	EPS
Diphenyl butyl piperidine			
Pimozide	2-4 mg od	20	EPS
<i>Atypical anti-psychotics</i>			
Benzisoxazoles			
Risperidone	1-2 mg bd oral	16	Sedation EPS
Dibenzodiazapines			
Clozapine	25-50 mg bd	900	Convulsion leucopenia sedation
Thienobenzodiazemine			
Olazepine	5-10 mg od HS	20	Sedation weight gain
Dibenzothiazepine			
Quetiapine	25-50 mg tid	500	Sedation
Aripiprazol	10-15 od	30	Insomnia

these account for their side effects. These drugs are readily absorbed from the gut and are bound to plasma proteins. They are metabolized mostly by hepatic microsomal oxidase system (Table 234.1).

• **Conventional Vs. atypical anti-psychotics**

Phenothiazines are the first group of antipsychotics that came into popular use. Butyrophenone came later. These drugs produced extrapyramidal side effects (EPS) which were very troublesome. The search for EPS-free drugs lead to the discovery of newer antipsychotics. These newer antipsychotics are relatively free of EPS and are called *atypical anti-psychotics* (second generation anti-psychotics). The original group of drugs, (first generation anti-psychotics) are also known as *conventional anti-psychotics*.

• **Indications**

These drugs are used to control psychotic behavior in disorders like schizophrenia, mania, delirium, depression with agitation, aggressive and violent behavior, delusions, hallucinations and others.

• **Dosage and administration**

Anti-psychotics have a wide dosage range with individual variations. Treatment is initiated with small doses. The optimum dose is built up to get symptom control. Maintenance dose is required in disorders like schizophrenia and manic disorders. Drugs which have long half-life need to be administered once daily and those with shorter half-life are given more frequently.

• **Side effects of anti-psychotics**

Extra pyramidal symptoms (EPS)

These result from antidopaminergic activity at the basal ganglia.

Drug induced parkinsonism - Tremor, rigidity, akinesia, dysarthria and 'mask like face'. These respond well to trihexyl phenedyl HCl, promethazine, diazepam and other antiparkinsonian agents. *Acute dystonia*: Acute spasms of muscles of neck, tongue, face, glottis and other parts—These respond well to antiparkinsonism agents.

Akathisia - Motor restlessness and a drive to move, which is not due to anxiety or agitation. The treatment is by reducing the dose and using drugs like diazepam or propranolol.

Tardive dyskinesia: (perioral tremors/oro-facial dyskinesia/rabbit syndrome), wide spread choreoathetosis and dystonia. Prevention is better, since it is not easy to treat. Diazepam, propranolol and antiparkinsonism agents are effective.

Anticholinergic (antimuscarinic) symptoms: Blurred vision, dry mouth, hesitancy of micturition, urinary retention, constipation, precipitation or aggravation of glaucoma.

Antihistaminic symptoms: Sedation and weight gain which are due to H₁ receptor blockade.

Antiadrenergic symptoms: Posturalhypotension, tachycardia, erectile dysfunction.

ECG changes: Prolongation of Q-T interval and T wave changes.

Malignant neuroleptic syndrome (MNS): It is a rare but very serious side effect mostly seen with high potency drugs. It is characterised by generalized muscular rigidity (catatonia), hyperpyrexia, unstable blood pressure, tachycardia, excessive sweating, myoglobinuria, urinary incontinence and impaired sensorium. Serum creatine phosphokinase (CPK) is elevated to very high levels. The treatment is symptomatic. The anti-psychotic is stopped immediately. Drugs like diazepam, dantrolene, bromocriptine, amantadine and L-dopa help to relieve symptoms. MNS is a medical emergency.

Endocrine side effects: Elevation of prolactin level leading to gynecomastia, galactorrhea, amenorrhea and weight gain.

Hematological: Agranulocytosis.

Allergic: Photosensitivity, skin rashes, itching, exfoliation of skin.

Gastrointestinal: Gastritis, hepatitis, constipation.

Antidepressant Drugs

Syn: Mood elevators / Thymoleptics

These are drugs which elevate the depressed mood by increasing the neurotransmitter levels of norepinephrine and serotonin at CNS synapses. The common antidepressant drugs are given in Table 234.2.

Tricyclic Antidepressants (TCAs)

- **TCAs** are the first group of drugs which became popular because of their proven efficacy. These are absorbed well from the GIT and are highly protein bound. They are metabolised in the liver.

Dosage is 25 mg bd or tds and raised to 50 mg tds. It is maintained for 3-6 months and gradually tapered off. Weight gain and cardiac toxicity are major disadvantages. ECG changes include prolongation of PR and QT intervals, ST segment depression, blunting of T wave and arrhythmias.

Selective Serotonin Re-uptake Inhibitors (SSRIs)

- **SSRIs** have recently become more popular because of their ease of administration and lack of cardiotoxicity. They produce GIT disturbances like nausea, and bloating sensations, diarrhea and CNS disturbances like day time sleepiness, headache, agitation, irritability, seizure and some times, EPS. Allergic reaction may occur giving rise to skin rashes.

Monoamine Oxidase Inhibitors (MAOIs)

- **MAOIs** were the first antidepressants discovered which lead to the discovery of TCAs. These drugs are rarely prescribed, because of lack of potency and serious side effects like 'cheese reaction', i.e. a patient on MAOIs goes into a state of fatal hypertensive crisis on consumption of tyramine containing foods like cheese.

Mood Stabilizers

These drugs are primarily meant for the prophylaxis of bipolar mood disorders (BPMD), but they are also effective in the treatment of acute mania. The common mood stabilizers are lithium, carbamazepine, oxcarbazepine, valproate, lamotrigine, topiramate and gabapentine.

- **Lithium**: The anti-manic effect of lithium was discovered by **Cade** in 1949. The carbonate and citrate salts are used.

Dosage: Lithium is given orally. It is absorbed well and excreted through the kidneys. 600-800 mg is given daily in 2-3 divided doses to obtain a serum lithium level of 0.8 to 1.2mEq/ L for treatment of acute mania. For prophylaxis the level can be 0.4 - 7 mEq/ L and this may be continued for 3 to 5 years. The level is adjusted by periodic estimation of the level of lithium after a 12-hour fast.

Side effects: 1) Diuresis, tremors, weightgain, hypothyroidism, GI-disturbances, widening of QRS complex in ECG, teratogenicity and others.

Serum levels above 1.4 mEq/ L produce toxicity, which includes nausea, vomiting, slurred speech, toxic tremors, seizures, and confusion. If, untreated this may end fatally.

- **Carbamazepine**: It is basically an anticonvulsant. **Dose**- 400-1600 mg given orally in two divided doses. For prophylaxis it is continued for 3-5 years, though

TABLE 234.2

Common antidepressant drugs				
Name	Starting dose mgs	Max. daily dose	Amine effect	Usual side effect (SE)
Tricyclic Antidepressant Drugs (TCA)				
Amitriptyline	25 tds od or bd	150	Norepinephrine (NE) 5 Hydroxytryptamine	Sedation anticholinergic action, sexual dysfunction, cardiac toxicity, Hypotension
Imipramine	25 tds	200	NE, 5HT	Same as above
Clomipramine	25 tds	300	NE, 5HT	Same as above
Selective serotonin reuptake inhibitors (SSRIs)				
Fluoxetine	20 OD	80	5HT	GI disturbances nausea, vomiting, anorexia, dry mouth
Sertraline	25 OD	200	5HT	Sexual dysfunction - delayed orgasm, anorgasmia,
Paroxetine	10-20 OD	60	5HT	CNS disturbances
Citalopram	10-20 OD	60	5HT	headache, somnolence
Escitalopram	10-20 OD	60	5HT	insomnia, agitation EPS, mania
Venlafaxine	37.5 bd	375	5HT, NE	
Monoamine oxidase inhibitors (MAOIs)				
Phenelzine	15	90		Cheese reaction
Tranylcypromine	30	60		CNS - confusion insomnia, headache
Isocarboxazid	10	30		ANS - Blurred vision, drymouth
Moclobemide	150 bd	600		Other S/E - hypotension, sexual disturbance (No cheese reaction with Moclobemide)
Atypical antidepressants				
Bupropion	100 bd	450	Dopamine (DA) NE	Agitation, headache insomnia hypotension
Trazadon	50 bd	600	5HT	Sedation, dry mouth constipation,
Mirtazapine	15 od Bed Time	45	5HT, NE	increased appetite sedation weight gain
* OD - Once daily, bd - twice a day, tds - thrice a day				

in smaller doses. It induces hepatic micro-somal enzymes.

Side effects: Diplopia, drowsiness, agranulocytosis, fatal skin reactions such as exfoliative dermatitis, Stevens-Johnson syndrome and toxic epidermal necrolysis. The drug is teratogenic.

- **Oxcarbazepine:** It is an analogue of carbamazepine. Dose 150-300 mg bd.
- **Valproate** - It is also basically an anticonvulsant. *Dose* - This drug is started with a dose of 400-600 mg in divided doses and increased to a maximum of 1-2 g daily. Serum levels of 50-100 µg/L are optimal. The drug is teratogenic. *Side effects:* GI disturbances, leucopenia and weight gain. Acute pancreatitis and hepatotoxicity are rare serious complications which could be fatal.

Lamotrigene, Topiramate and Gabapentin are being used recently as adjuncts; but they have not come into common use.

**Anti-anxiety Drugs
(Anxiolytics / Minor Tranquillizers)**

These are drugs which relieve anxiety symptoms and therefore, used in anxiety disorders. The common anti anxiety drugs are the following:

The Benzodiazepines are the most commonly used drugs. They can be given orally or parenterally, especially IV. They bind to the GABA receptors and thereby enhance GABA activity. Sedation, ataxia, confusion drug dependence and withdrawal syndrome are the common adverse effects.

General Principles of Management of Psychiatric Disorders

Drugs	Dose- oral and parenteral	Remarks
Benzodiazepines		
Lorazepam	1-2 mg once or twice daily 2 mg IM/IV	Short acting
Oxazepam	15-30 mg thrice daily	Short acting
Alprazolam	0.25 to 0.5 mg 2-3 times daily	Potent drug, long acting
Diazepam	5 mg twice daily 5-10 mg IV	Poorly absorbed when given IM- hence IV dose is preferred Long acting
Chlordiazepoxide	10-20 mg two to three times daily	
Clonazepam	0.5 to 2 mg once or twice daily	Long acting
Nitrazepam	5-10 mg at bed time	Hypnotic
Flurazepam	5-10 mg at bed time	Hypnotics
B-Adrenoreceptor blocker		
Propranolol	10-40 mg twice or thrice daily	Effective against peripheral manifestations of anxiety
Azapiron		
Buspiron	5-10 mg, twice or thrice daily	No sedation No dependence

Flumazenil is a Beta 2 receptor antagonist which antagonises the action of benzodiazepine and can be used as an antidote to treat acute toxicity of benzodiazepine.

Hypnotics: These are sleep promoting agents. The drugs in common use are listed below:

Benzodiazepines	Oral dose
Nitrazepam	5-30 mg bed time
Clonazepam	2-4 mg bed time
Lorazepam	2 mg bed time
Flurazepam	30-60 mg bed time
Oxazepam	15-30 mg bed time
Non-benzodiazepines	
Zolpidem	5-20 mg bed time
Zopiclone	3.75-7.5 mg bed time

Psycho-stimulant drugs: These include amphetamine, methyl phenidate, cocaine and caffeine. These drugs

release dopamine and prevent its re-uptake. They may lead to drug dependence and development of psychosis.

Amphetamine is used in the treatment of narcolepsy.

Methyl phenidate is used in the treatment of attention deficit hyper activity disorders.

Cocaine is used as a local anesthetic to mucus membranes. Recently it is being tried for therapeutic purposes as well. Being highly habit forming, this drug has to be used with caution.

Cognitive enhancers: Recently a few drugs have been introduced to improve memory and other cognitive functions in cases of dementia, especially in Alzheimer's disease. These drugs are:

Drugs	Dosage	Remarks
Choline esterase inhibitors		
Tacrine	30-40 mg qid	Treatment is initiated with small doses and gradually increased to the optimum level.
Donepezil	5-10 mg qid	
Rivastigmine	3-6 mg tid	GI disturbances may develop
Galantamine	8-12 mg bid	
NMDA antagonist		
Memantine	5-10 mg bid	
MAOIs (beta)		
Selegiline	5-10 mg bd	
Other nonspecific drugs		
Vitamin-E, calcium channel blockers		May be useful in some situations, especially as adjuvant drugs.
Ginkgo biloba, estrogens		

Antiparkinsonism Drugs: These drugs are very useful in the management of drug induced extra pyramidal symptoms. Commonly used drugs are:

Drug	Dosage
1. Trihexyphenedyl HCL	1-2 mg bid or tid
2. Procyclidine HCL	2.5-5 mg bid or tid 2.5-5 mg IM
3. Promethazine HCL	10-25 mg bid or tid 25-50 mg IM
4. Diazepam	2-5 mg bid or tid 10-20 mg IV slowly
5. L-Dopa is not recommended as it worsens or induces psychosis.	

Psychological Methods of Treatment (Psychotherapy)

N. Krishnan Kutty

Chapter summary

Psychoanalytic Psychotherapy 1438

Narcoanalysis 1439

Abreaction 1439

Supportive Psychotherapy 1439

Group Psychotherapy 1439

Behavior Therapy 1439

PSYCHOANALYTIC PSYCHOTHERAPY

Psychotherapy is also known as ‘*talking cure*’. It is based on the communication taking place between the therapist and the patient. The therapist is a trained person. Removing or modifying symptoms or promoting positive personality growth is the goal of the therapy. Over hundred types of psychotherapies are in vogue. All of them follow a few fundamental principles.

The therapist should be a trained person. He should establish therapeutic relationship with the patient. Listening and talking takes place between them.

This results in release of pent up emotions in the patient. The patient is given information and explanations of symptoms, guidance, suggestions and advice to restore his lost morale.

What is Psychoanalysis

- *Psychoanalysis* is not merely a form of psychotherapy. It also refers to the process of exploring (analysing) the mind **Sigmund Freud** (1856-1939) is the father of psychoanalysis. He was a Viennese physician. In his classic work “The Interpretation of Dreams”, he gave a model of the mind called the ‘*Topographical Theory*’ of the mind. The mind is formed of three regions—the unconscious, pre conscious and conscious regions.
- *The unconscious* part of the mind contains all the repressed (forgotten) ideas and affects. It is the seat of neurotic conflict and influences the conscious mind.

- *The preconscious* part is the region which is in between the conscious and unconscious regions and it can access both these parts. It contains the events and processes that can be brought to the conscious part, at will.

- *The conscious* mind is that part which becomes aware of the external and internal world through the senses.

In later years Freud proposed another model of the mind called the ‘*Structural Theory*’ of the mind. The mind is formed of three provinces—the id, ego and super ego.

- *The Id* – This is present at birth. It is unconscious and is the reservoir of basic drives and instinct for sex aggression and survival.
- *The Ego* - It is the conscious part. It is the organized portion of the id and includes perception, voluntary movement, memory, judgment, and adaptation to reality. It registers sensations from the outside world and internal sources. It is the organ that reconciliates between id and super ego.
- *The Super Ego* – It is formed from id and ego. It consists of ethical values, and moral principles. It imposes restrictions and prohibitions. It invokes guilt and self punishment.

The psychotherapy introduced by Sigmund Freud is called *psychoanalytic psychotherapy*. *Supportive psychotherapy*, group psychotherapy, suggestions, hypnosis, narcoanalysis, abreaction, exposure and response prevention and thought stopping, are some of the other common methodologies of psychotherapy employed.

The classical psychotherapy introduced by **Sigmund Freud** is psychoanalysis. He devised a technique known as ‘*free association*’. The patient is made to rest comfortably on a couch. He is allowed to talk freely, uninhibited, whatever comes to his mind, in sessions lasting for about 45 minutes. Repeated sessions are required. Block in the flow of talk may occur during the sessions. This indicates *resistance*. Resistance is indicative of unconscious painful experiences (conflict). As the psychotherapy proceeds the patient may develop an

emotional relationship (love, liking, hatred) with the therapist. This phenomenon is called *transference*. As a result, neurotic manifestations may develop in the treatment setting. This is known as *transference neurosis*.

The actual neurotic conflict is reflected in this transference neurosis, during the therapeutic sessions. This neurosis is *analyzed and interpreted*. It will help to resolve the neurotic conflict and thereby eliminate the symptoms. The patients also regain insight. The main idea of psychoanalytic psychotherapy is uncovering of the unconscious to resolve the neurotic conflict, the root of neurotic disorder.

Indications

Psychoanalytic psychotherapy is indicated in anxiety disorders, phobic disorders, conversion and dissociative disorders and personality disorders.

NARCOANALYSIS

The unconscious mind can be reached through the help of narcotic drugs such as short-acting barbiturates like thiopentone sodium and sodium amytal. Usually a 2.5% solution of thiopentone sodium is slowly administered intravenously to produce a state of cerebral disinhibition. The patient is then allowed to talk freely and uninhibited. Suggestions are given if needed.

Narcoanalysis is employed in the following conditions:

- Dissociate and conversion disorders
- Anxiety disorder and
- Differential diagnosis of catatonic schizophrenia from depressive and organic stupors.

ABREACTION

Abreaction is the secret of religious healing. Abreaction refers to the process of letting out of pent up emotions very freely. It may be done through verbal suggestions or by use of drugs like short-acting barbiturates or stimulant drugs. It is used to bring into conscious mind the unconscious (forgotten) traumatic events and thereby to remove symptoms and disability.

SUPPORTIVE PSYCHOTHERAPY

In this form of therapy the patient gets support from the therapist, who may be perceived as an authority figure. The patient is given acceptance and he is listened to. The unexpressed emotions are ventilated. It helps to release the inner tensions and strengthens the defense mechanism. The patient is helped to tackle his problem of guilt, shame, anxiety and frustration. The goal is achieved through the process of guidance, persuasion and environmental support. Finally, he may get self-confidence and better outlook of the environment and of himself.

Group psychotherapy: In this form of therapy a group of patients are getting the benefit of psychotherapy simultaneously. A group is formed of 6-10 selected patients and the therapists. The group forms a social environment for each patient and that forms the therapeutic agent. Uninhibited free talk is encouraged between members. Each one shares the experiences and problems of others. The group may focus on activities of problem solving and provision of support. Each session may last for 90-120 minutes. The group may meet once or twice a week. Group therapy is indicated in neurotic disorders, psychotic disorders, substance abuse, sexual deviations and personality disorders.

BEHAVIOR THERAPY

Behavior therapy works on the principle of ‘learning theory’. The neurosis is regarded as a maladaptive behavior learned by the patient and the symptoms as conditioned maladaptive pattern of behavior. The patient can be made to unlearn it. Systematic desensitization, implosion (flooding), aversion, exposure and response prevention, and thought stopping are some of the common techniques used in behavior therapy.

Cognitive Therapy (Cognitive Behavior Therapy-CBT)

This therapy is developed by **Aron Beck** based upon experimental psychology with respect to depression, but later applied to other disorders as well. It is a short-term psychotherapy where the patient and the therapist actively participate (collaborate). It is focused on current problems and finding their solutions. CBT is employed in the management of depressive disorder, anxiety disorders, phobic disorders, panic disorder, obsessive compulsive disorder (OCD) and others. The concept is that behavior and emotions are determined by the patient’s cognition. Patient’s emotions may be the result of *cognitive errors*. Beck found that symptoms of depression were due to disordered ways of thinking (*cognitive distortions*) and not primarily due to downing of the mood. If the errors in thinking are corrected the rest of the symptoms ought to change and the depression should disappear. In the initial stage of cognitive therapy the cognitive distortions are elicited by repeated interviews and daily monitoring of the thought process. These are analyzed. The patient is made to understand the errors. Correction of the irrational ideas and distortions are then brought out by verbal and behavioral technique.

Systematic Desensitization: It is employed in the treatment of phobic disorders. The subject is gradually deconditioned to the phobic stimulus which is thus made innocuous. Initially, the phobic stimulus or object is identified. A graded list (hierarchy) of the anxiety

provoking situations is charted out with minimum anxiety at one end and maximum at the other end. The patient is trained to relax. He is then exposed to the phobic stimulus at the minimum end of the hierarchy. Any anxiety that may develop is got over by relaxation. This process is worked upwards serially till the maximum anxiety-arousing situation is got over. This treatment is good for simple phobia.

Implosion (flooding): In this technique the patient is suddenly exposed to the phobic stimulus. The patient is made to tackle the resulting anxiety manifestations by relaxation and, if necessary, with the help of drugs. He is not allowed to escape from the situation. By a series of such exposures the patient is deconditioned to the phobic stimulus. This kind of treatment is effective in phobic neurosis. If desensitization is done in real situation it is called *flooding* and if it is done in imagination it is called *implosion*.

Aversion therapy: This is used in the treatment of alcoholism, drug dependence, sexual deviations, tics,

mannerisms, and certain dissociative symptoms. The principle is to associate a noxious stimulus with the maladaptive habit and this helps to eliminate the abnormality by negative reinforcement, e.g. In the case of alcohol dependence a strong painful electric shock can be applied on the arm as soon as the patient starts to gulp alcohol in a therapeutic setting. This aversive stimulus may help him to get rid of the habit. The pain produces aversive conditioning.

Exposure and response prevention: It is a good treatment technique for obsessions with ritualistic practice, i.e. when obsessions are accompanied by compulsive rituals. The patient is trained to withdraw from carrying out the act in spite of strong urge to do so. The anxiety may mount up, but lyses gradually within an hour. Slowly the patient gets confidence. His behaviour is modified in this way.

Thought stopping: It is a process of distraction of attention from the obsessive thought when it intrudes into the mind by specific techniques, e.g. snapping an elastic band tied around the wrist at the moment.

Psychiatric Disorders Special to Childhood

N. Krishnan Kutty

Chapter Summary

- Childhood Autism (Infantile Autism) 1440
- Attention Deficit Hyperactivity Disorder 1441
- Conduct Disorders 1441
- Enuresis 1441

Children also suffer frequently from psychiatric disorders affecting adults. But a few disorders such as childhood autism, attention deficit hyperactivity disorders, conduct disorders and enuresis are peculiar to them. These disorders are briefly outlined.

reality. Childhood autism was originally described by **Leo Kanner** in 1943 as *Early infantile autism*. Autistic aloneness, language abnormality and restricted and compulsive behavior are the symptom triad of this disorder. Boys are more affected than girls. The disorder is unmasked by the third year of life. The child is abnormally quiet. He lacks the usual emotional warmth and likes to be left alone. Eye-to-eye contact is avoided. He does not communicate through conversation. Pronouns are reversed. 'You' is used to mean 'I'. Echolalia is common. Words and behavior are stereotypic. The child is fond of sameness in everything. Bizarre behavior such as rocking, whirling the head and flapping of hand may be present. Impulsive violence is common. The arithmetic skill is relatively high. Intelligence quotient (IQ) may be around 70 in most cases. Birth trauma is probably the common cause in many cases.

The term autism denotes a state of absorption into ones own world of phantasy with loss of contact with the

Two gene defects are recently reported. One is in an unknown gene in chromosome 11. Another is in a protein called neurexin-1 which is closely associated with brain glutamate which enhances the communication between neighbouring neurons.

There is no specific treatment. Anti-psychotics are given to control violence and hyperactivity. Behavior therapy may be helpful. Parents are to be counselled regarding management of the child at home.

A small percentage may improve spontaneously and may be able to attend normal school. A few may require training in special schools. The majority require special residential care.

Attention Deficit Hyperactivity Disorder (ADHD)

Syn: Attention Deficit Hyperkinetic Syndrome (ADHS)

This disorder is more common in boys. Persistent inattention and hyperactivity are the cardinal features. These affect their scholastic performance. Impulsive and reckless activity are common. Brain damage due to birth trauma, allergy to food containing tartrazine, toxicity to lead and overactivity of peripheral adrenergic system are some of the recognized causes.

Treatment

Stimulant drugs such as dextroamphetamine 2.5-5 mg twice a day, clonidine, tricyclic antidepressants and monoamine oxidase inhibitors are beneficial. Many children become normal as they reach adolescence. Atomoxetine HCl is a recently introduced drug for the condition.

Conduct Disorders

This is the most common disorder of childhood. Persistent dissocial, aggressive or defiant behavior are the presenting features. It is manifested as quarrelsomeness, dis-

obedience, lying, cruelty to people and animals, destructiveness, stealing, lying, absenting from school, fire setting, temper tantrums, running away from home and the like. The disorder may be the outcome of unsatisfactory family environment, poor academic performance and such other psychosocial adversities.

Treatment

Some may improve spontaneously. Drugs are of little value. Psychosocial therapy is important. The child is given insight oriented psychotherapy to bring up problem solving skills. Adverse domestic factors are identified and removed. The child's behavior is rectified through rewards, praise and approval (contingency management).

Enuresis (Bed wetting)

Almost all children get bladder control by the age of five years. Enuresis is the voiding of urine during sleep persisting after the age of five years. In primary enuresis the child has never attained bladder control after birth. In secondary enuresis the child attained bladder control, which is subsequently lost. Delay in brain maturation, emotional factors such as school problems, birth of a younger child, loss of parental affection and other stressful factors may be the underlying cause. Local causes include low volume capacity of the urinary bladder, urinary tract infection, congenital abnormalities of the lower urinary tract and others.

Treatment

Behavior therapy techniques using mattress alarm (bell or buzzer and pad) bladder training exercises and reassurance are the therapeutic modalities. Drugs such as imipramine 25-50 mg at night are useful. Intranasal administration of synthetic antidiuretic hormone (ADH) is effective in many cases.
