Physical examination may reveal tenderness in the epigastric region or a mass in advanced cases. A gastric mass has to be distinguished from hepatic enlargement and other organs in the epigastrium. Barium meal examination helps to demonstrate the tumour. Final diagnosis can be made by endoscopy and biopsy, or exfoliative cytology. Routine upper gastrointestinal endoscopy and cytology helps in diagnosing the lesion before the tumour is demonstrable radiologically. Treatment of the tumour at this stage gives considerably better results. Gastroscopy, therefore, should be performed without delay in all cases of persistent upper abdominal symptoms. When endoscopy is available this is the investigation of choice for early and definitive diagnosis. Time should not be lost for radiological diagnosis since the false-negative rate is quite high and only moderately advanced lesions can be demonstrated by barium meal examination (Fig. 78.1).

Prompt surgical removal of the tumour early in the course of the disease offers the only chance of cure. Metastases have to be excluded by detailed investigation. If the lesion is resected at a very early stage the 5-year survival exceeds 90%. If the lesion does not involve the serosa or lymph nodes, the 5-year survival rate is around 50%. If the nodes are affected, survival falls to 10% or less. In advanced cases, chemotherapy using 5-fluorouracil in combination with methyl CCNU and adriamycin may

Fig. 78.1: Carcinoma stomach.
Note: the cauliflower growth (arrow)

induce temporary remission. Chemotherapy is generally used as an adjunct to surgery in such cases.

Gastric Outlet Obstruction

Syn: Pyloric obstruction

This is a common condition seen in clinical practice. Cicatrization due to peptic ulcers, antral carcinoma, pancreatic carcinoma, foreign bodies, and lymphomas may lead to pyloric obstruction. Rare causes are postsurgical stenosis, pyloric and duodenal diaphragm, adult hypertrophic pyloric stenosis, annular pancreas and acute pancreatitis.

Gastric outlet obstruction produces colicky pain, visible peristalsis and vomiting of stale food. The general condition of the patient rapidly deteriorates. Gastric peristalsis has to be distinguished from small-intestinal peristalsis. Gastric peristalsis is always from left to right, while intestinal peristalsis follows a stepladder pattern without any fixed direction. Another physical sign is succussion splash which is elicitable from the stomach even after several hours of ingesting food or fluids. Normally, the stomach is emptied within three hours after food. On gastric aspiration, a residue greater than 300 mL four hours after a meal, or overnight fasting gastric residue greater than 200 mL is suggestive of gastric outlet obstruction. Barium meal studies and endoscopy with biopsy or cytology can confirm the diagnosis.

Conservative treatment consists of fluid and electrolyte replacement, gastric aspiration, stomach wash, antacids and anticholinergics. The definitive treatment is surgical.

A common cause of gastric outlet obstruction in babies is *congenital pyloric stenosis* which is a familial disorder affecting more often males. In them the circular muscle coat of the pylorus is hypertrophied and this may become palpable. Pyloromyotomy relieves the obstruction.

Hematemesis

Hematemesis or vomiting of blood occurs when bleeding arises from the gastrointestinal tract proximal to the duodeno jejunal flexure (ligament of Treitz). The concentration of hydrochloric acid in the stomach and the amount of food present, determine the colour of the vomited blood. Action of the acid makes the blood brownish so that if vomiting occurs briskly after extravasation, the vomitus is bright blood, otherwise it is dark brown. A bout of hematemesis is often followed by melaena which may last for up to 5 days. The common causes of hematemesis are peptic ulcer, erosive gastritis, rupture of esophageal varices and carcinoma. Drugs such as aspirin, corticosteroids, anti-rheumatics especially NSAIDs and anticoagulants may produce hematemesis in susceptible subjects. Gastric erosions may complicate cerebral and subarachnoid hemorrhage, burns, renal failure, hepatic failure, viper bites and shock and hematemesis may develop in them. Rare causes include Mallory-Weiss syndrome (mucosal laceration of the cardia due to vomiting), gastric polyps, leiomyomas, lymphoma and blood dyscrasias such as purpuras and coagulopathies.

If bleeding from the upper gastrointestinal tract is small, it leads only to melaena. Hematemesis results from more massive bleeding. Hemorrhage leads to hypovolemic shock which depends on the extent and rate of hemorrhage and presence of other diseases. Loss of 20% of the blood volume results in postural hypotension and tachycardia. Shock supervenes if the bleeding continues or recurs.

Management

Emergency management consists of proper assessment, general measures to combat shock and replacement of lost blood.

In many cases the initial bout of bleeding may subside but soon fierce bleeding recurs, and leads to hypovolemic shock. Due to this possibility it is essential to hospitalize all patients with genuine hematemesis, even though the initial episode may be apparently mild. The patient should be monitored in an acute care ward.

1. The patient is sedated with IV diazepam in doses of 5-10 mg given slowly over a period of 3-5 minutes.
2. The pulse, respiration, and blood pressure are charted at 5-min. intervals to assess the condition and detect internal bleeding. The amount of blood lost from the stomach and in feces should be recorded.
3. An intravenous line using a wide-bore needle is established and compatible fresh blood is administered at the same rate as the blood is lost. Blood transfusion has to be continued till the bleeding stops. In an ordinary case, several units of blood may have to be given over the initial few days till the bleeding stops.

Central venous pressure record is a good indicator for monitoring proper volume replacement.

4. Prompt and adequate replacement of blood is the most effective single measure to tide over the crisis, save life and arrest the bleeding. If blood is not readily available normal saline or a plasma volume expander like 6% W/V dextran can be started as intravenous drip till blood is procured.
5. The stomach contents are aspirated at regular intervals through a nasogastric tube which is kept in position. This helps to detect intragastric bleeding promptly and also to administer foods and medications. Through the nasogastric tube ice-cold saline lavage can be instituted. It is beneficial in some cases. Iced milk can be introduced in small quantities at regular intervals when brisk hemorrhage subsides.
6. **Drug therapy:** H_2 receptor antagonists such as cimetidine and ranitidine are effective in controlling bleeding. Dose of cimetidine 200 mg IV 6 h. Dose of ranitidine is 50 mg IV 6 h. Antacids in large doses (aluminium hydroxide gel (30-60 mL every 4 h) is effective in stopping the bleeding in peptic ulcer. Proton pump inhibitor such as pantoprazole is available for slow IV injection in a dose of 40 mg daily.

Elective Endoscopic Management

Attempts must be made to establish the diagnosis. Emergency gastroduodenal endoscopy is indicated if the bleeding does not stop or recurs frequently. The bleeding spot can be visualized and cauterized by modern techniques. These include the use of bipolar electrodes, heater probes, neodymium yttrium-aluminum-garnet lasers, and local injection of vasoconstrictor agents like adrenaline. Esophageal varices can be occluded by injecting sclerosing solutions or banding. In the case of esophageal varices, compression with Sengstaken tube is an effective temporary measure in trained hands.

Indications for Emergency Surgery

1. Recurrent and profuse bleeding not amenable to conservative measures even after 12 h of admission. This period may be extended if modern facilities for intervention and adequate supply of blood are available.
2. In elderly subjects due to arteriosclerosis and hypertension the bleeding tends to persist. Moreover, bleeding is poorly tolerated by such subjects. They go into metabolic complications like uremia and vascular complications like shock and disseminated intravascular coagulation. Hence surgery should be

considered early. Large ulcers and posterior ulcers in the duodenum may require early surgery.

3. Presence of other medical conditions which are aggravated by blood loss.

Surgical techniques consist of ligation of bleeding vessels, undersewing the ulcer bed, or excision of the bleeding area in intractable cases.

MELENA

This term denotes the visible presence of altered blood in feces. Bleeding from any part of the gastrointestinal tract proximal to the middle of the colon can give rise to melena, if the bleeding is gradual and the blood gets partially digested during its downward passage. After a single isolated episode of bleeding the blood may be detectable in feces for upto five days. At least 60 mL of blood should be present to produce this symptom. The black colour and tarry consistency are caused by partial digestion of the blood. When bleeding in the upper gastrointestinal tract is brisk, the blood may pass down rapidly without allowing time for digestion and in this condition the stools may contain fresh blood. Melena occurring in a patient with obstructive jaundice imparts a silvery colour to the feces.

FRESH BLOOD IN STOOLS

Syn: Hematochezia

Bleeding lesions of the large intestine or rectum generally give rise to fresh blood in stools. Conditions which produce serious bleeding per rectum are ulcerative colitis, diverticulitis, typhoid ulceration, carcinomas, polyps, Henoch-Schonlein purpura, fulminant bacterial dysentery, and ischemic colitis. Bleeding from diverticulitis, ulcerative colitis, typhoid ulceration, fulminant bacterial dysentery, Henoch-Schonlein purpura and ischemic colitis can be massive. Polyps, carcinomas and other lesions such as angiodysplasia give rise to bleeding of variable severity. They are usually recurrent.

Hemorrhoids is probably the most frequent cause for the presence of fresh blood in stools, in all parts of the world. The blood is passed either along with the passage of stools or in drops after defecation. When the whole stool is collected in a pan, the blood will be seen on the surface of the stool or apart from the main stool mass. Proctoscopy reveals the lesion.

Presence of fresh blood in stools is an urgent indication for full investigation. The investigation should include the following.

1. Examination of the whole stools passed at one time, collected in a bed pan, while defecating. This will help to settle whether the bleeding is from hemorrhoids or from higher up in the colon.

- Digital examination of the rectum, proctoscopy and sigmoidoscopy.
- Colonoscopy if the lesions are beyond the reach of the sigmoidoscope.
- Contrast studies—barium enema.
- Isotope studies and selective angiography.
- Investigations to diagnose hemorrhagic disorders.

Management of Lower Gastrointestinal Tract Bleeding

This depends upon the cause. General measures include blood transfusion and attention to the primary cause.

If the lesions can be visualized by endoscopy, procedures to arrest bleeding such as cauterization, or ligation may be undertaken. Systemic diseases such as typhoid and Henoch-Schonlein purpura have to be managed on their own merits.

Chapter Summary

Malabsorption States

- General Considerations 473
- Celiac Disease 476
- Tropical Sprue 476
- Carbohydrate Intolerance 477
- Intraluminal Bacterial Proliferation in the Intestines 477
- Parenteral Nutrition 478
- Irritable Bowel Syndrome (IBS) 478
- Crohn's Disease 480
- Abdominal Tuberculosis 481
- Intestinal Polyposis 482
- Vascular Disorders Affecting the Small Intestine 483
- Carcinoid Tumours and the Carcinoid Syndrome 483

Malabsorption States

GENERAL CONSIDERATIONS

This term includes several conditions where intraluminal digestion of food and/or its subsequent absorption are defective. The processes that are impaired may be: (i) intraluminal digestion, (ii) transfer across the mucosal

lining, or (iii) transport from the mucosa to the circulation and to the target organs. In some cases the pathological mechanism is well-defined and evident, e.g. lactase deficiency. In others several mechanisms may be involved, e.g. blind loop syndrome in which there is bacterial overgrowth, short circuiting of intestinal contents and also mucosal abnormality.

Malabsorption state is quite common in India and this may result from a number of different conditions. The clinical picture is the total outcome of: (i) nonabsorption of ingested materials resulting in steatorrhea and creatorrhea, (ii) malnutrition manifesting as loss of weight and specific deficiencies, and (iii) symptoms of the underlying disease such as tropical sprue, tuberculous enterocolitis or chronic pancreatitis.

Causes of Malabsorption

- Abnormalities of the stomach:* These are (i) partial or total gastrectomy, (ii) gastrocolic fistula, (iii) hypertrophic gastritis (this leads to excessive protein loss in feces), and (iv) Zollinger-Ellison syndrome.
- Pancreatic disorders:* These include chronic pancreatitis, cystic fibrosis and carcinoma.
- Biliary disorders*
 - Long-standing obstructive jaundice leads to defective digestion and absorption of fat and fat soluble vitamins.
 - Deficiency of bile acids which may occur in two groups of conditions.

Interruption of the enterohepatic circulation of bile acids: Bile acids, which are normally absorbed from the distal ileum, cannot be absorbed if the distal ileum is diseased or removed. Bile acids pass into the colon and are lost in the feces. They stimulate secretion of water and electrolytes in the colon. Since the bile salts are not secreted in the bile through the enterohepatic circulation, they are not available in the proximal jejunum and, therefore, fat digestion and absorption become defective, leading to diarrhea.

When the upper small intestine is colonized by bacteria, the bile salts are deconjugated, micelle formation is inadequate, fat absorption is impaired, and steatorrhea results.

4. **Intestinal diseases:** These lead to defective transport across the gut mucosa. The mucosa may show gross pathological lesions or may be histologically normal. Mucosal damage occurs in intestinal tuberculosis, tropical sprue, celiac disease, Crohn's disease, Whipple's disease and intestinal lymphoma.

Parasitic infections like giardiasis, strongyloidiasis, schistosomiasis, trichuriasis, ascariasis, coccidiosis and cryptosporidiosis and intestinal capillariasis may interfere with absorption. The tape worm *Diphyllobothrium latum* uses up vitamin B₁₂ from the small intestine and deprives its host of this nutrient. Soil transmitted helminths such as *Ascaris lumbricoides* may lead to lactose intolerance in some cases. Heavy infestation by *Trichuris trichura* can lead on to inflammatory and motility changes and result in malabsorption.

The mucosa is histologically normal in specific enzyme defects like lactase deficiency. In pernicious anemia where absence of intrinsic factor results in the malabsorption of vitamin B₁₂ the intestine is normal histologically.

5. **Impairment of transport from the small intestine:** Blockage of lymphatics draining the small intestine prevents the discharge of absorbed chylomicrons into the systemic circulation. This occurs in intestinal lymphomas, intestinal and mesenteric tuberculosis and primary lymphangiectasia of the mesenteric lymphatics.

Though diarrhea is the prominent symptom in the vast majority of cases, rarely selective malabsorption (e.g. vitamin B₁₂) may be encountered even in the presence of constipation. Since different nutrients are processed at different regions of the gastrointestinal tract, the severity and type of malabsorption vary with the site of lesion. Absorption of fat and fat soluble vitamins is affected much earlier than that of the water-soluble vitamins. Loss of blood and exudates from the ulcerated mucosa further aggravates the condition in disorders like tuberculous enterocolitis and Crohn's disease.

Fig. 79.1: Malabsorption state—male 40—intestinal resection. Note: loss of weight and glossitis

The onset may be insidious as in sprue and intestinal tuberculosis and many patients seek medical help only several months after the onset. The onset can be explosive in conditions like giardiasis.

Clinical Features

Gastrointestinal: In most of the cases gastrointestinal symptoms predominate. Common presentations are diarrhea, especially steatorrhea, distension of the abdomen, abdominal discomfort and increased amounts of flatus which may be very foul-smelling, especially when digestion is impaired.

Diarrhea is more prominent during the early part of the day, with relief in the later part. Nutritional inadequacy results from general malabsorption. It manifests as weight loss, fatigue, lethargy, and failure of growth and development in children. Anemia occurs due to deficiency of iron, folate and/or B₁₂. Rickets, osteomalacia and tetany may develop due to defective absorption of vitamin D and calcium. Nutritional edema develops due to impairment of protein absorption. Glossitis, angulostomatitis, peripheral neuropathy and pellagra develop due to malabsorption of B complex factors (Fig. 79.1). Bleeding tendency results from vitamin K deficiency. Vitamin A deficiency leads to night blindness and other ocular manifestations.

Psychiatric symptoms such as anxiety, loss of confidence, irritability and depression are very common, especially when diarrhea is the prominent symptom.

Investigations

Examination of feces: The stools are large, bulky, greasy, and pale. There is a tendency to froth and stick to the toilet. In normal persons the stool fat is below 6-7 g per day on a diet which contains up to 100 g of fat. In malabsorption states the fat content is increased and this is referred to as steatorrhea. If the pancreatic digestion is

unaffected, the fat is present as fatty acids. If the pancreatic function is defective, the fat is present as neutral fat. Microscopic examination reveals fat globules.

Fecal nitrogen should be less than 2.5 g per day in normal subjects. Values above this level suggest malabsorption. Presence of intact muscle fibres in stools, demonstrable microscopically is called *creatorrhea*.

Blood examination: Serum albumin may be reduced in severe cases and they may show dependent edema. Serum iron, folate, vitamin B₁₂, carotene and cholesterol are lowered depending on the severity and duration of the malabsorption state. Vitamin K-dependent coagulation factors are deficient and this results in prolongation of the prothrombin time. Blood picture may be microcytic or macrocytic depending on the predominant deficiency.

Studies of Intestinal Absorption

Xylose absorption test: In this study, 5 g of xylose is given orally and the urinary excretion over the next 5 h and the serum levels are determined. Normal persons excrete at least 1 g in urine in 5 hours and the blood levels reach 25 mg/dL 2 h after the oral dose. In malabsorption due to mucosal disease affecting the upper small intestine, urinary elimination is lowered. This test is not foolproof since delayed gastric emptying, renal disease and sequestration of D-xylose in muscles and edema fluid reduce the urinary excretion.

Lactose absorption: This will be defective in lactase deficiency. Normal subjects absorb lactose and the blood level of glucose should increase 20-30 mg/dL 2 h after oral administration of 50-100 g of lactose. The blood levels will be deficient in subjects with lactase deficiency. The specific test for lactase deficiency is demonstration of diminished amount of the enzyme by biochemical estimation in biopsy specimens of intestinal mucosa.

Vitamin B₁₂ absorption (Schilling test): Radioactive vitamin B₁₂ is administered orally and the fecal loss and urinary elimination are estimated. Normally, more than 7% of administered vitamin B₁₂ is eliminated in urine in 12 hours. Vitamin B₁₂ absorption is impaired in lesions affecting the distal ileum.

Fecal fat estimation: Generally feces is collected for three days for the estimation of fat. Absorption studies employing radiolabeled fat (¹⁴C-triolein test) reveals excessive loss of ingested fat which appears in feces.

Fecal protein loss: Fecal nitrogen is grossly increased in protein-losing enteropathy. This is diagnosed by labeling serum protein with radioactive chromium and detecting its appearance in feces.

Radiology: Radiological study of the gastrointestinal tract after ingestion of barium-meal reveals reduction in transit

time of the intestinal contents and segmentation and flocculation of barium in the small intestine. Anatomical abnormalities such as ulceration, strictures, tumours, fistulae, and blind loops are demonstrated.

Sampling of the intestinal contents: Using special tubes which can be passed under fluoroscopic control, the intestinal contents can be sampled from different levels. Endoscopic aspiration can be performed from sites accessible to the endoscope. Aliquots obtained by aspiration are examined for enzyme content and nutrients, and also microbiologically. The effect of secretory stimulants like secretin, and pancreozymin can also be studied.

Biopsy studies: Using the Crosby capsule, peroral biopsies used to be obtained from various sites. This is seldom used to at present. Endoscopic biopsies can be obtained when facilities are available. The mucosa can be examined under the dissecting microscope to assess the villus pattern. Further histopathological and histochemical studies can be undertaken. In malabsorption, intestinal villi show blunting, confluence, atrophy, and varying degrees of round cell infiltration.

Since minor degrees of villus atrophy and cellular infiltration may be found in normal individuals, mucosal biopsy alone cannot be considered pathognomonic, especially if the abnormalities are mild. It gives valuable information when considered in the light of other investigations. Biopsy is the mainstay of diagnosis in conditions like tuberculosis, Crohn's disease and Whipple's disease.

Breath tests: They are useful in the diagnosis of steatorrhea, bacterial overgrowth of the intestines, lactase deficiency, and ileal disease. ¹⁴C-labeled triolein is given with a lipid meal and breath ¹⁴CO₂ is estimated. Level of ¹⁴CO₂ in breath correlates with the capacity for fat absorption. ¹⁴C-cholyglycine breath test is a screening test for bacterial overgrowth in the intestine and impaired ileal absorption of conjugated bile salts.

Estimation of breath hydrogen levels after an oral dose of 12.5-25 g of lactose gives an indication of the capacity to absorb lactose. In malabsorption states the unabsorbed lactose is acted upon by bacteria in the colon to produce excess hydrogen which appears in blood and is eliminated in the breath. Increased levels of breath hydrogen indicate bacterial overgrowth in the intestine. Lactulose can be given instead of lactose for the same purpose.

Treatment

Dietary management: The diet has to be modified depending upon the type and severity of malabsorption. Since fats, and to a lesser extent carbohydrates cause diarrhea, these have to be restricted. Proteins do not cause diarrhea and they should be given in the usual form or as

predigested proteins to avoid negative nitrogen balance. All vitamins have to be supplemented. Parenteral supplementation of nutrients has to be resorted to if oral feeding is not tolerated or is ineffective. Vitamins and minerals have to be given parenterally regularly.

Specific management: This depends upon the cause. Several diseases leading to malabsorption are curable, e.g. giardiasis, lactase deficiency, tuberculous enteritis. Many conditions which may not be curable ultimately, can be treated symptomatically and normal health restored, e.g. pernicious anemia. Such conditions should be looked for and treated appropriately.

CELIAC DISEASE

Syn: Gluten-induced enteropathy

This disease is produced by immunologically mediated or direct inflammatory response initiated by gliadin which is present in gluten which is a component of wheat, rye, barley and oats. Pathological changes are seen in the mucosa from the duodenojejunal junction to variable lengths distally. Circulating antibodies to gluten are demonstrable in many cases. The disease is less common in India compared to the West. In the west the prevalence of celiac disease in the general population is 1/266. HLA associations include HLA-DQ₂ (DOA 1-*05/DOB₁*0₂) or HLA DQ₈ (DOA1* 0301/DQBI*0302).

Gluten triggers the production of certain IgA class antibodies called R1 type reticulins and endomysial antibodies. These include IgA anti-endomysial AB, anti-tissue transglutaminase AB (tTG), and IgA anti-gliadin AB. Their presence is pathognomonic. The reticulins and endomysial antibodies are directed against fibroblast derived extracellular matrix-proteins known as celiac diseases autoantigen proteins. The disease is self perpetuating unless the trigger gliadin is removed.

CLINICAL FEATURES

The disease is more prevalent in young persons. Symptoms start between the ages of 1 and 3 when cereals are introduced into the diet. The child fails to thrive, becomes irritable and develops characteristic steatorrhea. The symptoms show periodic remissions and exacerbations over the years. There is increased incidence of intestinal lymphoma in these subjects.

Adult celiac disease may occur at any age. It is characterized by anemia, loss of weight, diarrhea and varying degrees of malabsorption.

Dermatitis herpetiformis: This is a frequent association of celiac disease. Skin shows blistering subepidermal eruptions. This is a classic nongastrointestinal manifestation of celiac disease. Histology shows granular IgA

deposit in the affected sites. Withdrawal of gliadin clears the skin lesion also.

Avoidance of gluten in the diet relieves the skin lesions as well. In intractable cases dapsone given orally in a dose of 50-200 mg/day helps to clear the lesions.

Diagnosis

It is made from the history, demonstration of malabsorption, and characteristic histology. Improvement on withdrawal of wheat or rye and aggravation on reintroduction suggest the diagnosis. Histologically the mucosal atrophy during the active stages of the disease and its clearance during abstinence from gluten containing diet can be demonstrated.

Serologic Diagnosis of Celiac Disease

The serologic tests available are IgA EMA (endomysial antibodies), IgA tTG (tissue transglutaminase), IgA AGA (anti-gliadin antibodies) and IgGAGA. AGA has lower sensitivity. EMA are directed against the connective tissue surrounding the smooth muscles. It is sensitive and specific, but expensive. The epitope against which EMA is directed is identified as tTG. IgA tTG is more specific and sensitive. It is also cheaper. In low-prevalence areas a negative tTG test virtually rules out celiac disease.

Treatment

Avoidance of wheat, barley, rye and oats in all forms brings about dramatic relief within weeks. Full recovery takes a few months to years. Apparent failure of therapy is due to inadvertent inclusion of the offending cereals in the diet.

TROPICAL SPRUE

This is a syndrome which occurs exclusively in the tropics. It is characterized by morphological abnormalities of the small intestine associated with malabsorption of two or more unrelated substances without any detectable cause. This disease has been reported from various parts of Asia, Africa and South America. In India the disease is present sporadically in all regions, but maximum number of cases have been reported from Vellore, Tamilnadu. Foreigners who have resided for varying periods in India and other neighbouring countries may be affected. In the indigenous population sprue is more common among poor malnourished young adults. Folate deficiency precipitated by pregnancy and severe malnutrition can aggravate the disease. More cases are seen during the hot humid months. The disease occurs sporadically though several small outbreaks have also been recorded.

The *etiology* of tropical sprue is not clearly understood. The prevalence of the disease in residents of certain localities, occurrence of several cases in the same household (sprue houses), seasonal prevalence, and the favorable response to antibiotics suggest an infective etiology. The onset is insidious. The clinical features are mainly steatorrhea and the sequelae of generalized malabsorption.

The jejunal histology is variable. The changes seen are epithelial cell damage, lengthening of the crypts, broadening and shortening of the villi, and varying degrees of chronic inflammatory cell infiltration. A normal jejunal mucosal biopsy rules out tropical sprue.

Treatment

Many patients improve with hospitalization and correction of malnutrition. In addition to general treatment, administration of tetracycline 1 g daily in divided doses for 3–4 weeks results in clinical improvement, reduction of jejunal bacterial counts, and correction of the histological abnormality. Folic acid 10 mg orally four times daily is given for 6 months. In cases of severe malabsorption, folic acid in intramuscular dose of 10 mg may have to be given for the initial few days. The condition is likely to recur in many cases if proper dietary care is not followed.

Carbohydrate Intolerance

Disaccharidase Deficiency

This is a common condition which is often missed. Carbohydrate intolerance may result from: 1. Deficiency of specific disaccharidase, 2. Impairment of transport of monosaccharides in the intestine or 3. Diffuse mucosal disease resulting in deficiency of disaccharidases and impairment of monosaccharide transport.

The *symptoms* are vague and they consist of bloated feeling, gaseous distension, belching, colicky pain, borborygmi, and diarrhea following ingestion of lactose or other carbohydrates. Diarrhea results from the osmotic effect caused by unabsorbed low molecular weight carbohydrates. Flatulence is produced by fermentation of carbohydrate in the intestines.

Most widespread enzyme deficiency is that of lactase. This may be acquired or congenital. The former manifests in later years whereas the latter is present from birth. Causes of acquired deficiency include diarrheal states, intestinal parasitism, and primary intestinal diseases. These tend to be transient and are relieved when the underlying condition is corrected.

Diagnosis is suggested by lactose absorption tests and breath tests showing excessive hydrogen after oral lactose challenge.

Treatment

Many patients learn to avoid symptoms by omitting the offending articles of diet. Exclusion of lactose (milk and dairy products and baked foods containing dairy products) from the diet gives relief.

Intraluminal Bacterial Proliferation in the Intestines

Normally the jejunal contents show only less than 10^5 bacteria per mL. Most of these are derived from swallowed bacteria. Gastric acidity and intestinal motility help to keep down the bacterial counts. Impairment of these functions results in bacterial overgrowth. The bacteria hydrolyze conjugated bile salts in the jejunum and this leads to defective micelle formation and absorption of fat. Deconjugated bile salts also damage the mucosa directly. In addition, proliferating bacteria use up essential vitamins like vitamin B₁₂ from the proximal small intestine before they reach the ileum and thus deprive the host of these vitamins. Paradoxically folate levels may be high since the bacteria produce folate.

1. **Structural lesions:** Diverticula, blind loops, fistulae, strictures occurring in intestinal tuberculosis, vascular lesions, radiation enteritis and Crohn's disease, post-operative or traumatic adhesions, and afferent loop stasis after gastric operations.
2. **Fistulae:** Gastrocolic, jejunocolic, jejunoileal and others.
3. **Hypochlorhydria and achlorhydria:** Post gastric-surgery mucosal atrophy, total gastrectomy, vagotomy, atrophic gastritis, pernicious anemia and severe malnutrition including iron deficiency anemia.
4. **Abnormalities of intestinal motility:** Systemic sclerosis, amyloidosis, diabetic and other autonomic neuropathies, paralytic ileus, pseudo-obstruction, and post-vagotomy ileus.
5. **Hypo- or agammaglobulinemia.**

Symptoms of the primary disease may be present. In addition, those due to malabsorption may also be present.

The condition is diagnosed by quantitative culture of the intestinal contents. Breath tests using lactulose or ¹⁴C-labelled cholyglycine are helpful. Appropriate investigations are indicated to detect the underlying cause and plan definitive therapy.

Treatment

Administration of tetracycline in a dose of 1 g/day in divided dosage for 3–4 weeks relieves the symptoms temporarily. Surgical treatment for the anatomical abnormality should be advised if the lesion is correctable.

PARENTERAL NUTRITION

Parenteral alimentation is necessary when ingestion and absorption of nutrients are inadequate, impossible over long periods of time or contraindicated. In several situations such as organ transplantation, postoperative states, post-traumatic states, burns and others where ingestion of food is not possible or excess have to be given to overcome hypercatabolic states, parenteral alimentation becomes mandatory. If excess of calories are administered this is called hyperalimentation. When the process has to be continued over several days or weeks, a central venous line is necessary. Proprietary preparations are available. These are highly expensive. It is preferable to use an infusion pump and monitor the rate of nutrient delivery.

Nutrient Solutions

Carbohydrates and fats form the two main sources of calories. Supply of 200-250 g of glucose daily is adequate to prevent starvation ketosis. Adequate calorie supply can be achieved by the administration of 600-700 g glucose given as a 20-30% solution through a central venous catheter. Administration of glucose in this concentration into peripheral veins causes damage to the venous walls and leads to thrombophlebitis.

Lipids can be given as a 10% emulsion intravenously. Fat emulsions being isotonic, can be infused into peripheral veins. Addition of amino acids and glucose to the fat emulsion provides all the proximate principles. The source of fat is soyabean or cottonseed oil and the fatty acid is oleic or linoleic acid. The common source of nitrogen is crystalline amino acids and the equivalent of 8-16 g is to be supplied daily. Amino acids are supplied as mixture of essential and nonessential amino acids in the ratio of 1:1.5. Amino acids will be used for anabolic activity only if 150-250 carbohydrate calories are also supplied simultaneously for each gram of nitrogen.

Vitamins, minerals and other electrolytes have to be supplied, their quantity is to be determined by biochemical estimations. Optimal quantities of electrolytes have to be supplied to ensure complete metabolic utilization of the nutrients in solution.

In general, for every 1000 Cal, NaCl 10 mmol; K⁺ 20 mmol; PO₄ 30 mmol; Mg²⁺ 8 mmol and Ca²⁺ 5 mmol are to be supplied in addition to daily losses. Several solutions are available commercially for parenteral nutrition.

When nutrients are administered into a peripheral vein without recourse to a central venous catheter, it is referred to as peripheral parenteral nutrition.

In the commercially available parenteral solutions energy is provided by glucose and long chain triglycerides in almost equal proportions. 150-250 cals should be provided with 1g of nitrogen which is provided mainly

as amino acids. For providing nutritional balance, energy supply should be 25-40 Cal/kg bw/hour. Nitrogen should be provided at the rate of 0.2-0.3 g/kg bw/hour. Complications include sepsis, blockage of the catheter and other mechanical problems. After initial hospitalization to set up parenteral nutrition, subsequent treatment can be continued at home. The solutions are prohibitively expensive for routine use.

Irritable Bowel Syndrome (IBS)

This condition has been known by several synonyms such as mucous colitis, spastic colon, irritable colon and colonic neurosis. In the west 20-30% of gastrointestinal disorders is constituted by IBS. In India this is very common and many cases used to be diagnosed as chronic amebiasis in the past. Irritable bowel syndrome is a functional disorder to the intestine characterized by alteration of the bowel habits and abdominal pain in the absence of any detectable organic pathology.

There is no morphologic, histologic, microbiologic or biochemical abnormality in IBS. Changes in gut motility are observed in several studies though they poorly correlate with the symptoms. In the constipated variety the frequency of high altitude peristaltic contractions is less whereas nonpropulsive segmentation contractions are more. Moreover food induced hypermotility of the colon occurring normally about one hour after the meal is reduced in many patients. This may account for their postprandial symptoms. Emotional stress is seen to aggravate the motility disorder.

Normally gut has two types of myoelectrical activity—the basic electric rhythm (BER) and spike activity (SA). The BER is in the continuous wave form at the rate of 6 cycles per minute. The SA is the form of electrical bursts superimposed on BER and this is responsible for the mechanical contraction of the gut. IBS patients have a slow BER at the rate of 3 cycles per minute. In normal people, feeding induces SA immediately which peaks in 30 minutes and lasts for about 50 minutes. But in IBS patients the feeding induced SA is dampened in the first 50 minutes, but it becomes stronger later on.

Clinical Features

In India the female to male ratio is 1:3, though in the West, females suffer more. The clinical spectrum is wide. The presentations include (i) painless functional diarrhea, (ii) painless simple constipation, (iii) alternating diarrhea and constipation, (iv) bloating of abdomen, and (v) pain due to spasm of colon and small intestine. The common age group is 20-40 years. Symptoms are vague and these include abnormal bowel habits ranging from constipation to diarrhea (often alternating irregularly), pellet like stools, increased gastrocolic reflex, vague abdominal pain

ranging from dull ache to severe colic, flatulence relieved by belching, capricious appetite, and insomnia. Around 20% of subjects complain of weight loss. All patients are emotionally tense and they tend to exaggerate the disability.

Examination does not reveal any abnormality except for vague tenderness over the abdomen, palpable cecum and sigmoid, increased bowel sounds, and signs of anxiety. The majority of these patients go from doctor to doctor getting repeated prescriptions such as amebicides, antibiotics, sedatives, tranquilisers, and massive doses of vitamins. Most of them are wrongly diagnosed as amebiasis, neurosis or other colonic disorders.

Clinical examination should always be followed by macroscopic examination of a total stool, passed in a clean container. The feces is large in volume, the consistency may vary from hard to semisolid, it may froth, and mucus may be present, but, there is no blood. Microscopy helps to exclude dysentery, amebiasis and other intestinal parasites. IBS seriously reduces the quality of life of the affected individuals and is an important medical cause of reduced work output. Investigations such as colonoscopy and tests for malabsorption need be done only in those patients with alarm symptoms.

Diagnosis

This condition (IBS) should be diagnosed clinically and other similar conditions should be excluded by investigations. Amebiasis, giardiasis, malabsorption states, tuberculous enterocolitis, ulcerative colitis, diverticulitis, purgative abuse and heavy helminthic infestations should be excluded. Till recently IBS remained a diagnosis arrived at by exclusion of similar conditions. At present diagnostic criteria have been laid down. These include:

1. Continuous or recurrent symptoms for at least three months.
2. Abdominal pain relieved by defecation or associated with a change in frequency and consistency of stool.
3. Disturbance in defecation on at least 25% of times with any three of the following features.
 - a. Altered stool frequency,
 - b. Altered stool form—hard, loose or watery,
 - c. Altered stool passage—straining, urgency, tenesmus,
 - d. Passage of mucus, and
 - e. Abdominal distension.

A slightly modified Rome II criteria is also in vogue at present.

Investigations

The blood picture in IBS is usually normal. Stool examination repeated thrice including one concentration smear helps to exclude amebiasis and other intestinal

parasites. All IBS patients do not require extensive investigation. Routine investigations may be done in all patients. Investigations such as colonoscopy, small bowel barium studies and tests for malabsorption are required only in a limited number in whom the diagnosis is not clear. Presence of blood in stools at any time, loss of weight, presence of constitutional symptoms and family history of colonic neoplasms are indications for full systematic investigation.

Sigmoidoscopy and colonoscopy reveal only hyperemia and normal nonfriable mucosa with excess of mucus. This helps to differentiate IBS from ulcerative colitis and amebiasis. Intestinal biopsy is normal. Barium enema is not diagnostic and may show only non-specific changes. It is ideal to reassure the patient only after excluding more serious underlying disease.

Management

Reassurance and psychological support is most important in allaying anxiety and this is very effective in the majority of cases. Even if the diagnosis of IBS seems to be the most likely one, it is advisable to follow up the patient at frequent intervals for at least one year to detect weight loss, development of anemia, presence of blood in stools and other systemic disturbances, which all should raise the possibility of more serious colonic diseases.

Diet

All offending articles of diet which aggravate symptoms should be avoided. In general, a moderate-roughage diet is advisable. The use of high fiber diets has been advocated in spastic colon but the results are not uniformly encouraging.

Substances that increase stool bulk like methylcellulose (*Isogel*, *ispagula husk*) or bran generally improve stool consistency and give relief. **Several drugs are in vogue for management of IBS. In practice, the ideal drug regimen has to be determined by trial and error since no drug may act predictably.** As a rule of the thumb, the following drugs may be tried first depending on the symptoms.

1. **Diarrhea—predominant**—Loperamide 4 mg, diphenoxylate 5 mg, anticholinergics, codeine phosphate 30 mg.
The 5-hydroxytryptamine (5HT₃) antagonists such as alosetran have proved effective in preventing urgency for defecation. Alosetran taken prophylactically helps to avoid embarrassment during travel and social functions.
2. **Constipation predominant**—Dietary fiber, osmotic laxatives, stool softeners like liquid paraffin, cisapride and enemata.
Tegaserod which is a 5 HT₄ antagonist helps to relieve constipation.

3. Pain, gas, bloating, etc. Anticholinergics, anti-gas preparations such as methyl siloxylene or activated charcoal, and antidepressant drugs.

Tranquilizers are indicated if there is severe anxiety. Psychiatric counseling helps in the majority of cases. Amitriptyline 10-25 mg given at night may benefit a few who have depression and despair.

CROHN'S DISEASE

Syn: Regional enteritis, Granulomatous colitis

This rare disorder is mainly characterized by localized areas of granulomatous inflammation of the small intestine. Rarely all other parts of the gastrointestinal tract may be affected. The etiology is unknown. It is more common in west especially among Jews, and it is rare in India. There is evidence that the incidence is increasing in India.

Etiology

Though the exact cause is not known, factors such as genetic predisposition, infective agents and autoimmune phenomena have been implicated.

Pathology

The role of disturbances in gut flora is being investigated. Viable *Mycobacterium avium paratuberculosis* has been detected in a substantial proportion of cases. Specific genes related to the development of Crohn's disease include CARD 15/NO D₂. This gene is expressed in monocytes, macrophages, dendrite cells and also intestinal epithelial cells including Paneth cells. Lesions are maximal in the terminal ileum. The bowel is edematous, swollen, and narrowed. Later the mucosa appears nodular and ulcerated. Classically normal and abnormal segments alternate and this is referred to as *skip lesions*. The mesentery and lymph nodes are involved. Histologically lesions are characterized by chronic granulomatous inflammation containing lymphocytes and plasma cells extending through all the layers of the intestinal wall. In 50% cases there are well-defined noncaseating granulomas containing multinucleate giant cells.

Clinical Features

The disease affects persons aged 15-35 years more, and it is characterized by remissions and relapses. Presenting symptoms include fatigue, weight loss, right lower quadrant pain, and diarrhea. The pain is continuous and localized but may be colicky. Moderate diarrhea follows. The feces is not visibly mixed with blood.

Physical Examination

Physical examination reveals a tender mass in the right lower quadrant made up of inflamed loops of bowel. Acute ileitis may resemble acute appendicitis and

Fig. 79.2: Crohn's disease—Fistulous track endoscopic view

sometimes the diagnosis is made on laparotomy. Rarely the disease may present as prolonged pyrexia, intestinal obstruction, fistulization, and malabsorption syndrome. Enteropathic arthritis is a frequent complication.

Diagnosis

Diagnosis should be suspected clinically. Laboratory investigations are non-specific and are of little value. The ESR may be moderately raised. There may be leukocytosis, anemia, and presence of occult blood in stools.

A barium examination of the small bowel reveals loss of mucosal pattern, rigidity and narrowing of the affected segments, and a "cobble stone" appearance. The characteristic radiological feature is the "string sign" which is produced by the narrowing of the diseased segment with dilatation of the normal intestine on either side. Fistulous tracts, strictures, and fibrosis may be demonstrable in advanced cases. Stomach and duodenum may be involved and the picture may resemble an infiltrative tumour. Barium enema reveals colonic lesions. Endoscopy reveals the lesions, strictures, fistulae and other complications. Endoscopic biopsy is also confirmatory (Fig. 79.2).

Differential Diagnosis

Crohn's disease may be mistaken for tuberculosis of the ileocecal region, lymphoma, appendicular abscess, amebiasis, carcinoma cecum and ulcerative colitis.

Prognosis

In acute regional enteritis the prognosis is good since in two-third of the cases the condition subsides without recurrence. In chronic regional enteritis the disease tends to be recurrent and chronic.

Principles of Treatment

Low residue diet containing adequate calories and protein should be instituted. Diarrhea is relieved by drugs like diphenoxylate (Lomotil) 2-5 mg/day or codeine 30-60 mg orally 2 to 3 times a day.

Sulfasalazine 2-6 g/day is moderately effective. This drug is less effective in this condition than in ulcerative colitis. Corticosteroids are given if active disease persists. Prednisolone 40-60 mg/day is started and reduced over a few months. Budesonide which is a topically active glucocorticoid is effective in relieving symptoms, when given orally in a dose of 8 mg/day. Methotrexate, azothioprine, ciprofloxacin in combination with metronidazole have all been tried with benefit.

Acute exacerbation of Crohn's disease is difficult to treat. Remission can be induced with parenteral steroids, parenteral alimentation and intravenous antibiotics such as metronidazole and ciprofloxacin. *Infliximab* which is a monoclonal antibody to TNF- α may be useful in resistant cases and in complications such as fistulae. It can also be used as a primary modality in severe and complicated cases. *Sargramostim* which is a recombinant human GM-CSF has been found to be beneficial in reducing inflammation and improving the quality of life.

Surgery is reserved for complications like obstruction, fistulae or abscesses.

ABDOMINAL TUBERCULOSIS

Abdominal tuberculosis may be divided into: (i) *intestinal tuberculosis*, (ii) *tuberculosis of mesenteric lymph nodes*, and (iii) *tuberculous peritonitis*.

Intestinal Tuberculosis

This is the most common granulomatous disease of the bowel in India. The lesions may be secondary to a focus in the lung or they may develop primarily within the intestinal tract. The latter is fairly common. Highest incidence is in young adults in their second and third decades and women are more affected than men.

Pathogenesis and Pathology

Human and bovine strains of *Mycobacterium tuberculosis* produce intestinal lesions but human strain is more common. The infection may reach the intestine by four different routes—enterogenous, hematogenous, through the lymph channels, and by direct extension from tuberculous lesions in the female genital tract.

The most common site is the ileocecal region (85% cases). Stasis of the intestinal contents and the close contact of tubercle bacilli with the mucosal surface in this region make this part vulnerable. Ileum, cecum, colon, jejunum, and duodenum may be involved in that order of frequency. The lesion may be ulcerative, hypertrophic or ulcerohypertrophic. Pathological picture depends on the reaction of the host and virulence of the invading bacilli.

The bacilli infiltrate through the lymphatics into the submucosa. Tubercles are formed and intense inflamma-

tion with caseous necrosis occurs around the lymphatic channels. Enderteritis and lymphangitis lead to the formation of shallow mucosal ulceration. The ulcers are typically triangular running circumferentially (napkin ulcers). They heal by fibrosis leading to short segment strictures. Mesenteric lymph nodes are enlarged initially, later they may caseate and calcify.

Recurrent localized infection leads to the hypertrophic form. In this form there is increased fibrosis and fat. Ulcerohypertrophic type shows large stellate ulcers with necrosis. The abdominal mass is made up of adherent mesenteric lymph nodes, fat and fibrous tissue.

Clinical Features

The clinical manifestation may be classified into five following groups.

1. *Constitutional symptoms*, e.g. fever, weakness, anorexia, night sweats, and weight loss.
2. *Ulceration of the intestine* leading to abdominal discomfort, diarrhea, malabsorption, perforation, and rarely hemorrhage.
3. *Hypertrophic and ulcerohypertrophic forms* present with features of subacute intestinal obstruction, e.g. postprandial distress and distension, nausea, vomiting, constipation, colicky pain, borborygmi, and visible peristalsis. A tender lump may be palpable in the right iliac fossa.
4. *Involvement of adjacent tissues like peritoneum and lymph nodes* lead to the formation of localized or free ascites. Single or multiple masses in the abdomen, enlarged lymph nodes, and matted intestinal loops may be present. Extension of the disease to the pelvic adnexa gives rise to the formation of tubo-ovarian masses.
5. *Symptoms produced by tuberculosis in other parts of the body.*

Complications

Intestinal tuberculosis leads to complications such as intestinal obstruction, perforation, malabsorption state, and rarely massive hemorrhage. Malabsorption is the result of reduction in the absorptive surface, blind loop syndrome, and obstruction to lymphatics. Abdominal pain, weight loss and diarrhea form the symptom-triad of intestinal tuberculosis.

Diagnosis

Clinically abdominal tuberculosis should be suspected in all cases of vague dyspepsia associated with malabsorption. Presence of obstructive symptoms, ascites, and palpable masses strengthen the clinical suspicion. Evidence of tuberculosis elsewhere in the body strengthens the possibility further. Increased erythrocyte sedimentation rate and anemia occur in the majority.

A plain film of the abdomen may reveal dilated small bowel loops with fluid levels. Calcified lymph nodes may be seen.

In the barium meal study small intestinal loops show irregular widening of mucosal folds and irregularity and upward displacement of the cecum. Constricted segments with proximal dilatation may give rise to the “string sign” as in the case of Crohn’s disease. The ascending colon may be shortened.

Other investigations like ascitic fluid analysis, peritoneal biopsy, and peritoneoscopy may be helpful in arriving at a diagnosis. Endoscopic biopsy of the lesion is confirmatory. Adenosine diaminase (ADA) test in ascitic fluid is specific for tuberculosis and it is a useful and reliable test. PCR is useful to detect tubercle bacilli in peritoneal fluid and in endoscopic biopsy materials. The test is very sensitive, but too expensive for routine clinical use at present.

Treatment

General chemotherapy is given on the same lines as for the pulmonary tuberculosis. A low residue diet is advocated when there are obstructive symptoms. Most of the cases respond fully to antituberculosis treatment. Surgery may be very rarely required under the following conditions:

1. Intestinal obstruction
2. Perforation and hemorrhage
3. If there is doubt of malignancy and
4. When the diagnosis is uncertain, laparoscopy or laparotomy may be required.

Tuberculosis of the Mesenteric Lymph Nodes Syn: *Tabes mesenterica*

In most cases it is secondary to intestinal tuberculosis, single or multiple lymph nodes may be affected. Caseation is followed by calcification and the nodes are visible in X-rays. The presentation is variable. Some patients present with general symptoms like anorexia, loss of weight, and irregular pyrexia. Central abdominal pain with palpable abdominal lymph nodes should raise the possibility of mesenteric tuberculous adenitis.

Intestinal Polyposis

Polyps arise from the mucosal surface and project into the lumen. They may be benign or malignant.

Adenomatous Polyps

These are the most common. They may be sessile or pedunculated, solitary or multiple. The rectum and sigmoid colon are the most common sites accounting for more than 80% of the total. Majority of the polyps are silent, but at times they produce bleeding and intermittent

obstruction due to intussusception. Some polyps become malignant, especially if the diameter exceeds 1 cm, the smaller ones are benign. Polyps can be visualized by barium studies and endoscopy. Endoscopic removal of polyps within reach is feasible. Since recurrence occurs in 50% cases, all subjects must be followed up regularly.

Villous Adenoma

This occurs usually in the rectum or sigmoid. This is sessile, soft and friable, and it tends to bleed on mild trauma. Around 40-60% turn malignant in due course. Watery diarrhea and hypokalemia may develop rarely. Management consists of surgical excision and prolonged follow-up.

Familial Colonic Polyposis

This is a rare, autosomal dominant disorder characterized by the presence of numerous adenomatous polyps in the entire colon, especially the rectum and sigmoid, starting to appear from childhood and adolescence. These patients may present with lower abdominal pain, weight loss, diarrhea, tenesmus, and presence of blood and mucus in stools. There is almost a complete tendency to develop malignancy and hence prophylactic colectomy is indicated. Systematic follow-up of the patient and his family members is necessary (Fig. 79.3).

Juvenile Polyposis

This condition occurs in infants and children and is familial. Polyps are seen mainly in the colon and only sometimes in the small bowel. It presents with rectal bleeding and growth retardation. Histologically, inflammatory changes are seen in addition to columnar epithelium and mucus cysts. Therefore, these are also known as inflammatory polyps. There is no risk of malignancy and only symptomatic polyps should be removed. Prophylactic colectomy is not advised.

Fig. 79.3: Polyp colon: endoscopic view often polyps are precancerous

Peutz-Jeghers' syndrome: In this condition multiple hamartomatous polyps occur in the small intestine and colon along with spotted melanin pigmentation in the buccal mucosa, lips, and skin around the mouth, palms, and soles. Malignant change is less common. Treatment is required only if the polyps become symptomatic.

Vascular Disorders Affecting the Small Intestine

Arterial supply to the small intestine is derived from the celiac and superior mesenteric which are extensively connected to provide adequate collateral circulation. The distal transverse colon, the splenic flexure, and the junction of the superior and middle portions of the rectum are vulnerable to ischemia.

The causes of ischemic bowel disease are given in the Table 79.1.

TABLE 79.1
Causes of ischemic bowel disease
1. <i>Arterial occlusion</i> i. Atherosclerosis ii. Thrombosis iii. Embolism iv. Aorto-arteritis v. External compression (e.g. median arcuate ligament of the diaphragm) vi. Trauma
2. <i>Small vessel disease</i> i. Vasculitis ii. Connective tissue disorders iii. Anaphylactoid purpura iv. Radiation enteritis
3. <i>Venous occlusion</i> i. Primary ii. Secondary iii. Thrombophiliac states
4. <i>Non-occlusive mesenteric infarction</i>
5. <i>Steal syndromes</i>

The clinical features of arterial insufficiency depend on the site and degree of obstruction and the rapidity of onset. Clinical presentation ranges from transient malabsorption to frank infarction of extensive areas of the gut (Table 79.2).

Infarction of the Bowel

This may occur acutely or subacutely. It presents with severe colicky pain around the umbilicus which later leads to peritonitis, gastrointestinal bleeding, toxemia and hypovolemic shock. Fever indicates definite infarction. Stools contain frank or altered blood. Management is surgical if infarction has occurred. Gangrenous bowel is resected and vascular reconstruction is attempted.

TABLE 79.2
Clinical manifestations of ischemic bowel disease
1. <i>Acute intestinal ischemic syndromes</i> i. Infarction of the bowel ii. Ischemic colitis and enteritis
2. <i>Chronic intestinal ischemic syndromes</i> i. Intestinal angina ii. Stricture iii. Local ulcer iv. Celiac axis obstruction (median arcuate ligament syndrome) v. Intramucosal or intramural bleeding ("thumb printing" on X-ray) vi. Malabsorption syndrome

Intestinal angina occurs in partial obstruction of the superior mesenteric artery, especially when the other blood vessels are also diseased. The blood supply is inadequate to meet the demands of intestinal muscles after intake of food.

Twenty to thirty minutes after a heavy meal the patient develops severe crampy or colicky abdominal pain around the umbilicus lasting for 2-4 hours. The patient is afraid of taking food and, therefore, he loses weight. Often intestinal angina is a forerunner to intestinal infarction. Auscultation may reveal arterial bruit in the abdomen. Abdominal aortography or selective mesenteric angiography helps in locating the obstruction.

Treatment

The diet should consist of small quantities of easily digestible or predigested food given at short intervals. Surgical measures to revascularize the ischemic segments should be considered. Thrombophiliac states should be excluded by investigations and managed appropriately.

Carcinoid Tumours and the Carcinoid Syndrome

Carcinoid tumours arise from the endocrine argentaffin cells in the small intestinal mucosa. Argentaffin cells are most abundant in the cecum and appendix and these are the most common sites for carcinoid tumours. Carcinoid tumours may be associated with multiple endocrine adenomas. The tumours may arise singly or multifocally in 20% of cases. They vary in size from a few millimeters to a few centimeters. Those larger than 2 cm in diameter are malignant and they may spread to the liver, lungs, bones and local lymph nodes. The degree of malignancy is low and even with metastases about one-third of cases survive for more than 5 years. Atypical sites for carcinoids are the stomach and the bronchi. Extensive lesions produce metabolic abnormalities due to the production of large amounts of serotonin (5-hydroxytryptamine, 5 HT)

by the tumours and their secondaries. Several other substances like kallikrein, bradykinin, other kinin peptides, prostaglandins, and histamine have also been identified. The substrate for the production of 5-HT is tryptophan; 5-HT is deaminated by amine oxidase to 5-hydroxy-indole acetic acid (5-HIAA) which is excreted in urine in excess, i.e. more than 30 mg in 24 h.

Carcinoid Syndrome

This is produced by excessive production of 5-HT.

Clinical Features

Carcinoid syndrome is characterized by frequent episodes of flushing and watery diarrhea. Repeated flushing may give rise to facial edema and the development of telangiectasia. Asthmatic symptoms are prominent due to bronchospasm. Severe abdominal colic associated with borborygmi may occur. These attacks are precipitated by emotional upset, alcohol, and excessive foods. Right-sided heart lesions like pulmonary and tricuspid stenosis, tricuspid incompetence and right-sided heart failure may develop in long-standing cases. Death is due to intractable right-sided cardiac failure. Since tryptophan, which is the precursor of niacin, is used up for the formation of 5-HT, conditioned deficiency of niacin (pellagra) may develop. Carcinoid tumours arising from the intestines are late to produce symptoms. In gut carcinoid tumours the 5-HT

and other vasoactive molecules are released into portal system. They are metabolised in the liver first pass and hence such tumours will have no systemic symptoms early in the diseases. Later when hepatic metastases develop the vasoactive substance are released into systemic circulation. Thus typical carcinoid symptoms are late and often indicate hepatic metastases.

Diagnosis

Clinically carcinoid syndrome should be suspected in all cases of severe abdominal colic associated with hypermotility of the bowel, flushing, and palpable mass in the ileocecal region. Demonstration of excessive urinary 5-HIAA and raised serum levels of 5-HT will confirm the diagnosis. Foods like pineapples, bananas and walnuts, and drugs like phenothiazines, mandelamine, and glyceryl guaiacolate which increase urinary levels of 5-HIAA should be avoided for 3 days before undertaking the tests.

Treatment

Surgical excision of the primary tumour and the metastases, is undertaken. The results are dramatic in most cases. Another method is to perfuse the tumour with cytotoxic drugs through the hepatic artery. The diarrhea is controlled by methysergide 4 mg given four times daily. The flush is resistant to medical treatment. Treatment is given on usual lines when cardiac failure occurs.

Diseases of the Colon

K.R. Vinaya Kumar, K.V. Krishna Das

Chapter Summary

Idiopathic Ulcerative Colitis	484
Diverticulitis	487
Carcinoma of Colon	488

Idiopathic Ulcerative Colitis

Ulcerative colitis is the idiopathic inflammation affecting the mucosa of the large intestine. Some patients have extra intestinal manifestations also.

This disease is present in all parts of the world and it is not uncommon in India. It is characterized by repeated bouts of diarrhea with blood and mucus, produced by inflammation and ulceration of the colon.

Many authors consider ulcerative colitis and Crohn's disease together under the term inflammatory bowel disease. The former affects only the large intestine, whereas the latter can affect all parts of the alimentary tract, though the predominant and most frequent involvement is in the distal part of the small intestine. Clinically and histologically the two conditions show overlap.

Ulcerative colitis results from environmental factors triggering loss of tolerance for normal intestinal flora in genetically susceptible individuals. Cigarette smoking confers a protective effect against this disease. The role of alteration in the normal protective gut flora in the causation of inflammatory bowel disease is established.

Etiology

The etiology is unknown. Psychological factors such as emotional stress, anxiety, or bereavement are evident in many cases. Since ulcerative colitis may be associated with diseases like arthritis, uveitis, erythema nodosum, hepatitis, and autoimmune hemolytic anemia, an autoimmune basis has been suggested. Other postulations include transmissible viruses, bacteria, allergy to milk proteins and genetic factors.

Pathogenesis

The disease usually starts from the rectum which is involved in 95% of cases. Whole of the colon up to the cecum may be affected with extension to the terminal ileum. In the ordinary case the inflammation is confined to the mucosa and submucosa. Initially the mucosa is hyperemic, swollen, roughened, and easily bleeding on contact. Superficial ulcers are seen which show diffuse infiltration of lamina propria and submucosa by chronic inflammatory cells. Crypt abscesses (cryptitis) may develop in 40% of the cases. The damage to mucosal epithelium is compensated by hyperplasia of regenerating mucosa which appears as pseudopolyps. Extension of the inflammatory process deeper into the muscularis and other structures causes strictures and shortening of the bowel in chronic cases.

Clinical Features

Moderately Severe Form

Majority of cases occur between 20 and 40 years. In the west, males and females are equally affected, but in India, the male to female ratio is 2 : 1. The disease starts with looseness of the bowel with blood and mucus, abdominal pain, weight loss and fever. The severity varies. The condition tends to be prolonged, unlike bacterial dysentery. In the majority of cases the condition is mild with less than 4 stools per day and the patient is afebrile. In the moderately severe form, there are disabling constitutional symptoms and the number of stools varies from 6-12/day.

In a few cases the disease takes a fulminant form and may be mistaken for severe bacterial dysentery. It is characterized by fever, bloody diarrhea, dehydration and electrolyte disturbances. Toxic megacolon occurs in a few cases in whom the inflammatory process affects all the layers of the bowel and mortality is high in such cases.

Diagnosis

The diagnosis should be suspected in all patients with a history suggestive of dysentery, but not relieved by the usual antiamebic and antibacterial drugs. Examination of the feces, colonoscopy and barium enema help in establishing the diagnosis. The feces is mixed with blood and mucus. Microscopy shows erythrocytes, neutrophils, and macrophages. These findings are similar to those found in bacillary dysentery.

Sigmoidoscopy/Colonoscopy

The mucosa is friable, granular, and it is covered with a thick inflammatory exudate consisting of pus, mucus, and blood. Frank ulcerations, pseudopolyps, and strictures may be seen in advanced cases. A rectal biopsy confirms the diagnosis. Microscopic examination of the fresh exudate helps in excluding amebiasis.

Colonoscopic Grading of Severity

1. Normal mucosa
2. Loss of vascular pattern
3. Granular non-friable mucosa
4. Friability of mucosa
5. Spontaneous bleeding with ulceration.

Barium Enema

This investigation helps to assess the extent and severity of the disease and its complications. Barium enema should not be done during the acute phase. In early cases no abnormality may be detectable or may show only loss of haustrations. Later, the mucosal surface is serrated or spiculated due to shallow ulceration. The picture reveals pseudopolyps and strictures in advanced stages of the disease. The presacral space is widened in the lateral view.

Colonoscopy

This should be done to assess the state of the disease and its extent. During follow-up, repetition of colonoscopy at 2-yearly intervals helps to detect the development of cancer early, in cases with duration above 10 years (Fig. 80.1).

Differential Diagnosis

Acute bacillary dysentery: This forms the most important differential diagnosis. The diagnosis is made on stool culture, since microscopic examination of the feces and sigmoidoscopic appearance are indistinguishable.

Amebiasis is to be differentiated by examination of the feces, sigmoidoscopy, and biopsy.

Other conditions such as inflamed hemorrhoids, ulcerating growths of the colon, tuberculosis of the colon,

Fig. 80.1: Ulcerative colitis: endoscopy
Early stage: Note hyperemia and bleeding tendency

Fig. 80.2: Ischemic colitis: endoscopy. Note: mucosal ulceration and bleeding (arrow)

ischemic colitis, irritable bowel syndrome, and Crohn's disease have to be differentiated by appropriate investigations. Gonococcal proctitis and AIDS-related bowel disease have to be excluded in susceptible individuals (Fig. 80.2).

Complications

These may be local or systemic.

The local complications are:

1. **Toxic megacolon:** It is seen in 1-1.5% of cases, especially in fulminant colitis. This is characterized by acute dilatation of the whole or part of the colon to a diameter greater than 6 cm, usually measured at the midtransverse level. The symptoms include fever, tachycardia, prostration, and abdominal distension with diminished or absent bowel sounds. Plain X-ray of abdomen reveals dilated transverse colon. Perforation is identified by the presence of air under the diaphragm. In toxic megacolon the mortality is 12-30%.
2. **Colonic stricture.**
3. **Carcinoma of the colon** is 7-11 times more frequent if subjects with ulcerative colitis than in controls, and

more so in the chronic continuous form with extensive involvement. Risk of cancer is associated with the extent and duration of the disease. It is 1.7% for those with disease localized to the rectum, 2.8% for those with disease extending beyond the rectum to the hepatic flexure and 14.8% for those with disease extending proximal to the hepatic flexure.

The extraintestinal complications are:

1. **Liver disease:** Liver involvement occurs in the form of fatty liver, pericholangitis, sclerosing cholangitis, chronic hepatitis, and cirrhosis.
2. **Arthritis:** Sacroilits and seronegative monoarticular or polyarticular arthritis may develop.
3. **Ocular lesions:** Iritis (uveitis), episcleritis, superficial keratitis with blepharitis, retinitis, and retrobulbar neuritis occur rarely.
4. **The complications involving skin** are pyoderma gangrenosum and erythema nodosum which may occur in 1-3% of cases. Several other systemic complications have been described. Secondary amyloidosis may develop in a few.

Course and Prognosis

The course and severity of ulcerative colitis are variable. In the majority of cases symptoms are recurrent with complete symptomatic remission between attacks. In 5-10% of cases there are no recurrences after the initial attack; 5-15% follow a chronic continuous course without any remission.

Factors that determine the prognosis are: (i) severity of initial attack, (ii) extent of colitis, (iii) duration of illness prior to hospitalization, and (iv) age of the patient at the onset. Total involvement of the colon, severe disease, short fulminant course and elderly age are adverse prognostic factors. About 4-6% of patients will be dead within one year of the onset of illness and 13-20% within 5 years. Complications like toxic megacolon, associated liver disease, hypokalemia, and hypoalbuminemia also worsen the prognosis.

Management

Management of ulcerative colitis depends upon its severity and extent of the involvement. Patients with mild disease confined to the rectum and sigmoid respond to treatment satisfactorily. In moderate and extensive disease, relapses occur in 75% of cases.

Treatment of Moderately Ill Patients

The diet should be bland, low residue type, and with a high protein content. In patients with mild or moderately severe disease, initial therapy consists of sulfasalazine or analgesics. Salazopyrine has a sulfa moiety and an aminosalicilate moiety. The colonic bacteria split it into

5-amino salicylate (5ASA) which enters the mucosa to exert its antiinflammatory action. The beneficial action is due to the amino salicylate whereas the side effects are mainly due to sulfa moiety. The newer drugs which also deliver 5ASA are mesalazine and olsalazine. They do not contain the sulfa moiety and hence side effects are considerably less. Sulfasalazine (*salazopyrin*) is started in a dose of 500 mg thrice daily after food and then increased to 1 g three to four times daily, depending on the tolerance. Side effects include headache, malaise, skin rashes, hemolytic anemia, and very rarely, agranulocytosis. Mesalazine is effective in doses of 400-1200 mg thrice a day. Olsalazine is another drug with similar action. It is not freely available in India.

Corticosteroids form the mainstay of therapy in acute exacerbations of severe ulcerative colitis. They may be given intravenously, orally or as retention enemas depending on the condition. Prednisolone is given in the dose of 1-1.5 mg/kg bw daily (40-60 mg) for a week and then tapered off in 4-8 weeks. Steroids can be administered through rectal route as retention enema containing hydrocortisone 100 mg in 200 mL normal saline or as rectal suppositories which produce a foam inside. Beclomethasone, budesonide and prednisolone, metasulfobenzoate are topical steroids which produce good results. They are especially useful for severe ulcerative proctitis.

In some patients prednisolone may be ineffective and corticotrophin gel given in a single daily intramuscular dose of 60-120 units is effective.

Antibiotics are not normally indicated for the colonic lesions, unless systemic symptoms like fever or toxemia develop. Diarrhea may be partially allayed by drugs like codeine phosphate. General management includes reassurance by the physician, anxiolytic drugs such as chlordiazapoxide 10 mg, attention to nutrition especially supplements of proteins, iron and vitamins, and regular follow-up.

Treatment of Seriously Ill Patients

Features which indicate severity include:

1. Bowel movement > 9/day
2. Pulse > 100 minute
3. Body temperature > 38°C
4. Serum albumin < 3 g/dL
5. Plain X-ray abdomen showing intestinal dilation
6. Profuse hemorrhage with systemic effects.

Note: These patients may require surgery.

Such cases should be managed by the physician and surgeon jointly. At the outset an intensive regimen is started and continued for five days.

Only sips of water should be allowed by mouth. Hydrocortisone hemisuccinate is given intravenously in

a dose of 300 mg in 24 h. As an alternative, corticotrophin gel is given in a dose of 60-120 units administered intramuscularly or intravenously. Hydrocortisone retention enemas are given twice a day. Proper maintenance of fluid and electrolyte balance and replacement of blood form the essential supportive measures. In successful cases the temperature falls rapidly with return of the appetite and feeling of well-being. It takes a few days for the bowel frequency to return to normal. Surgical treatment has to be considered if the condition of the patient does not improve with conservative treatment in three to four days.

The onset of toxic megacolon is indicated by the presence of air filled colon with abnormal haustral pattern and irregular margins in plain X-ray of the abdomen. Since late surgery is associated with high mortality and morbidity, decision for undertaking surgery should not be unduly delayed. Surgical measures include total colectomy and ileostomy. Other indications for emergency surgery are colonic perforation and uncontrollable bleeding.

Surgery may also be required electively for the management of complications such as carcinoma, strictures, rectovaginal fistulae and frequent and severe relapses.

Long-term Management

Once the acute attack is controlled, the next step is to prevent relapses. Sulfasalazine given orally in doses of 2-4 g daily, continuously over a prolonged period exerts a suppressive effect to prevent relapse and maintain a symptom-free state. This drug is widely used. Small doses of corticosteroids orally or as topical applications have been used to prevent relapses but their value is still not firmly established.

Immunosuppressants like azathioprine can be used singly or together with corticosteroids for maintenance treatment in severe cases.

Cancer Prophylaxis

Since the risk of colon cancer is high in ulcerative colitis of long duration, there should be periodic evaluation for cancer detection. This is best achieved by colonoscopy every 1-3 years. Starting 10 years after the initial diagnosis, suspicious areas in the mucosa are biopsied to detect even dysplastic changes. Prophylactic total colectomy is indicated in high grade dysplasias.

Diverticulitis

The colonic mucosa may herniate through the muscularis mucosa to form diverticula. These small hernial sacs follow the course of the blood vessels on the mesenteric side and their wall consists of only mucosa and serosa. Many asymptomatic persons have colonic diverticula demonstrable by barium enema. This condition is referred

to as diverticulosis. The most common site is the sigmoid colon. Only rarely is the proximal colon affected. Inflammation of these diverticula leads to diverticulitis. Diverticula are reported in 20-50% of the western population over the age of 50. In India, though large population surveys are not available, the condition seems to be distinctly less common.

Pathogenesis

Diverticula are more common in people consuming low residue diets, which tend to lower the bulk of feces. Rise in intraluminal pressure required to move the colonic contents is probably responsible for diverticula formation in such persons. Inflammation sets in when fecoliths get impacted in the diverticula and cause reduction in blood supply and secondary infection. Intramural or pericolic abscesses may develop. It is, however, rare to produce generalized peritonitis. Sometimes the inflamed mucosa may bleed.

Clinical Features

8

The disease may present in several ways and clinical severity varies widely. The pain of acute diverticulitis may resemble that of acute appendicitis, but it is left-sided and worsened by defecation. Signs of peritoneal inflammation may be present. The subacute form presents with alteration in bowel habits or as discomfort and tenderness in the left iliac fossa. Though in 25% of cases occult blood can be detected in feces, gross bleeding is rare. Rarely dysenteric symptoms may occur. In chronic cases narrowing of the colon may lead to subacute obstruction. Physical examination may reveal palpable and tender sigmoid colon.

Diagnosis

Diverticulitis should be considered when an elderly person presents with subacute or chronic colonic pain associated with alteration in bowel habits. Diagnosis is confirmed by barium enema examination. The diverticula are seen as outpouchings of the colon. They are brought out better in films made with air insufflation into the rectum after voiding the barium. Rigidity, narrowing, and loss of haustrations of the affected segment should suggest the presence of inflammation. Sometimes differentiation from carcinoma is difficult. Contrast radiography should not be undertaken in the acute stage since it may lead to rupture of an inflamed sac.

Differential Diagnosis

Diarrhea and pain have to be differentiated from other forms of colitis. Severe hemorrhage may resemble that occurring in carcinoma, polyps, angiodysplasia or hemorrhoids. The subacute form with obstruction may resemble carcinoma.

Complications

These include free perforation, fistula formation, fibrosis, strictures and massive hemorrhage.

Treatment

In mild cases conservative management consisting of bed rest, stool softeners, and broad-spectrum oral antibiotics like tetracycline or ampicillin serve to tide over the acute phase. Introduction of high residue diet helps to regularise the bowel movements. Antispasmodics have to be given to relieve pain. Administration of ispaggol husk in a dose of 5-10 g after the evening meal helps to produce satisfactory bowel movement and relieve symptoms.

Complications like intestinal obstruction, perforation, abscess formation or massive hemorrhage are indications for surgical intervention. Surgery consists of a diverting colostomy and resection of the involved colon with subsequent reanastomosis.

Carcinoma of Colon

Carcinoma of the colon is common in India. The etiology is unknown. Villus adenoma, familial polyposis of the colon, chronic ulcerative colitis, and rarely adenomatous polyps may develop into malignant lesions. The peak incidence is between the fifth and the seventh decades.

Colorectal cancer is the third leading cause of death among malignancies all over the world. The incidence begins to increase after the age of 50 years and it doubles with each decade. Incidence is higher in the western world. In India this form of malignancy is quite common.

Genetics of Colon Cancer

Genetics of colon cancer has been extensively studied. Changes can be generally classified into three classes.

- Changes in proto-oncogenes:** They play a role normally in signal transduction in cell proliferation. Abnormal activation of these genes lead to tumour formation. Three human genes (ras genes) are identified in this category K-ras, N-ras and H-ras.
- Loss of tumour suppressor activity:** APC gene is a classic example. It is a tumour suppressor gene which is detected in familial adenomatous polyposis (FAP).
- Abnormalities in genes involved in DNA mismatch repair:** Classic example is gene mutation in hereditary non-polyposis colon cancer (HNPCC).

Amsterdam criteria for diagnosis of HNPCC

- At least three relations with colon cancer, one must be the first degree relative of the other two.
- Colorectal cancer involving at least two generations.
- At least one colon cancer occurring before the age of 50 years.

TABLE 80.1

Common inherited polyposis syndromes and the risk of developing cancer

Syndromes	Inheritance	Cancer risk	Distribution of polyps
1. Familial adenomatous polyposis	Autosomal dominant	Near 100%	Colon 100% Stomach 30-50% Duodenum over 90% Small bowel about 50%
2. Gardner's syndrome	Autosomal dominant	Near 100%	Colon 100%
3. Peutz-Jeghers syndrome	Autosomal dominant	About 50%	Small bowel > 90%

Note: In 1 and 2 polyps are adenomatous. In 3, they are hamartomas. Gardner's syndrome is also associated with other abnormalities such as osteomas, epidermoid cysts, fibromas, dental abnormalities, desmoid tumours and retinal lesions.

Germ line mutations in the mismatch repair genes MLH₁, MSH₂, MSH₆ and PMS₂ lead to the development of the Lynch syndromes which are strongly associated with the risk of colon cancer. Demonstration of this genetic abnormality in relatives of patients with colon cancer is an indication for prophylactic measures.

Genetics play a major role in colorectal cancer. Several forms of intestinal polyposis lead to cancer. Hereditary nonpolyposis colorectal cancer syndromes are also described. These include site specific colorectal cancer (Lynch syndrome I) and cancer family syndrome (Lynch syndrome II). Both these show autosomal dominant inheritance. In the latter condition other extraintestinal malignancies are also present, particularly in the ovaries, endometrium, stomach, small intestine, pancreas, urinary tract and larynx.

Risk of developing colorectal cancer is higher in persons who have first-degree relatives with colon cancer.

Number of first-degree relative with colon cancer	Risk of developing colon cancer in a lifetime
1	18%
2	33%
3	50%

In adenomatous polyps the cancer risk increases with the size of the polyp. Histological pattern also influences the cancer risk (Table 80.1).

Pathology

These tumours grow from the epithelial cells of crypts of Lieberkuhn. The lesion may be annular, tubular, ulcerative, or papilliferous. The annular type produces obstructive symptoms early. About 75% of tumours are seen in the descending colon, rectosigmoid, and rectum. Cecum and ascending colon are affected in 15% and the transverse colon is affected in 10% cases. Rectal examination and sigmoidoscopy are able to detect 50% of colonic cancers. Metastases occur initially by lymphatic spread to the

lymph nodes, and later through the bloodstream to the liver.

Clinical Features

Symptoms vary depending on the site of the growth. Growths in the cecum or ascending colon are usually flat or polypoid and they remain silent for long periods. Nonspecific symptoms like anemia, weight loss, anorexia or malaise may be the presenting features in some cases. Blood stained stool is the presenting complaint in 25% of right-sided lesions.

Left-sided lesions cause obstruction early since the contents are solid. Common symptoms are recent changes in the bowel habits and diarrhea alternating with constipation. Growths of the sigmoid colon may present with tenesmus. Colicky pain is often present. Rectal bleeding occurs in 70% of left-sided growths.

Diagnosis

The diagnosis is difficult when the symptoms are nonspecific. Digital examination of the rectum and sigmoidoscopy can pick up more than 50% of cases. Presence of occult blood in feces is suggestive of ulcerated growths.

Barium enema brings out the lesions in many cases. A growth may be seen as a filling defect or distortion of the colonic mucosa or as an ulcer. Post-evacuation air insufflated film is very useful for outlining colonic mucosal lesions.

In lesions beyond the reach of the sigmoidoscope, colonoscopy is diagnostic. Even when the barium enema is not definite, colonoscopic examination and biopsy serve to establish the diagnosis. Wherever possible histological diagnosis by endoscopic biopsy should be made before radical surgery since granulomas and ameboma may clinically resemble neoplasm (Fig. 80.3).

When secondaries occur in the liver, serum alkaline phosphatase, and 5-nucleotidase are elevated. Carcino-

Fig. 80.3: Carcinoma colon advanced: endoscopy
Note: cauliflower growth

embryonic antigen (CEA) is elevated in colonic cancer. Though this is not specific for colonic carcinoma, its use is mainly in following up patients who have undergone surgery. Rise in the level of CEA indicates recurrence of the growth or development of metastases.

8

Differential Diagnosis

Carcinoma of the colon should be differentiated from all other conditions which cause dysenteric symptoms and recent change in bowel habits, such as ulcerative colitis, polyps, diverticulitis and intestinal tuberculosis. In chronic amebiasis, granulomatous masses (ameboma) may develop and these have to be differentiated. Lymphoma, lymphogranuloma venereum, and endometriosis may also cause difficulty in diagnosis. It should be remembered that carcinoma may coexist with other lesions.

Complications

These include metastases, obstruction, intussusception, volvulus, bowel perforation, local peritonitis, massive

hemorrhage and spread to neighbouring organs like the ureters, bladder and uterus.

Treatment

In early cases colonic resection with colostomy is the treatment of choice. Preoperative radiation is advocated in rectal cancer. Even when the tumour is not removable, palliative surgery to overcome the obstruction may be required. Adjuvant chemotherapy with 5-fluorouracil and levamisole has good survival advantage. Even a few metastases in the liver are not a contraindication for surgery, since the liver metastases can also be removed.

Prognosis

Surgery offers almost cure, if colon cancer is detected early. Since most cases are detected late either when the growth is fixed or has metastasized, the prognosis is poor. In large series, overall five-year survival for patients undergoing radical surgery is about 50%. When the tumour is confined to the bowel wall, the five-year survival is 75-80%, whereas in those with lymph node metastases the survival is only 25%.

Prophylaxis

Carcinoma of the colon is largely preventable if premalignant conditions such as ulcerative colitis and colonic polyposis are regularly followed up with annual endoscopic examination. Colectomy should be undertaken early if malignancy supervenes.

It has been observed that regular use of statins have shown reduction of colon cancer. Regular use of NSAIDs such as sulindac and celecoxib has been shown to be associated with suppression of adenomatous polyps and regression of familial adenomatous polyposis and reduction of colon cancers. The therapeutic role of these observations is not fully evaluated.

81

Diseases of the Peritoneum

K.R. Vinaya Kumar, K.V. Krishna Das

Chapter Summary

Ascites	491
Peritonitis	493
Malignant Lesions of the Peritoneum	493
Retroperitoneal Fibrosis	494
Pseudomyxoma Peritonei	494

ASCITES

Collection of excess of free fluid in the peritoneal cavity is called ascites. A small quantity of fluid resembling lymph is normally present in the peritoneum. Increase in the hydrostatic pressure in the portal capillaries and the colloid osmotic pressure of the ascitic fluid favour further transudation into the peritoneum. Return of the ascitic fluid into the capillaries is brought about by the osmotic pressure of the plasma and the hydrostatic pressure in the peritoneum. The rate of formation and amount of fluid collecting in the peritoneum are determined by these two opposing forces. The peritoneal fluid is in dynamic equilibrium with blood and about 50% of the fluid enters and leaves the peritoneal cavity every hour. The extensive visceral peritoneum and its subjacent capillaries account for this free exchange. In all conditions where the ascitic fluid is a transudate, several factors operate simultaneously.

Cirrhosis of the liver accounts for the majority of cases of ascites in India. In cirrhosis of the liver, in addition to rise of portal venous pressure other factors also operate which help the accumulation of fluid in the peritoneum. These are hypoalbuminemia, secondary hyperaldosteronism which results in the retention of sodium, and increased secretion of antidiuretic hormone which favours the retention of water. Splanchnic arterial vasodilation caused by nitric oxide produced locally acts as a major factor in the development of ascites. Portal hypertension leads to the production of nitric oxide locally. Combination of portal hypertension and splanchnic arterial vasodilatation increases intestinal capillary pressure and

permeability resulting in the accumulation of fluid within the peritoneal cavity. As the disease progresses marked impairment of renal excretion of free water and renal vasoconstriction develop. The former leads to dilutional hyponatremia and the latter to hepato-renal syndrome respectively.

On the other hand, ascites in peritonitis is mainly the result of local inflammation and exudation. Table 81.1 lists the main causes of ascites.

Hemorrhagic fluid occurs in malignancy, acute pancreatitis or infarction of organs like the spleen or gut. The fluid is milky due to presence of fat (chylous fluid) in lymphatic obstruction and rarely in nephrotic syndrome. Meig's syndrome is a rare condition in which a fibroma of the ovary is associated with ascites and pleural effusion. It is a clinical curiosity often mentioned, but seldom encountered. Mucinous fluid accumulates in pseudomyxoma peritonei and in colloid carcinoma of the stomach. Pancreatic ascites develops as a complication of pancreatitis when a fistulous communication develops between the pancreatic duct and the peritoneal cavity. In this condition the ascitic fluid shows high levels of amylase and proteins.

Clinical Features

The onset may be acute as in the case of inflammatory exudates or insidious as in cirrhosis liver. The common symptom is progressive distension of the abdomen. The abdomen is uniformly distended and the flanks are full. In the early stages fluid may be detectable only in the flanks, later as accumulation proceeds the whole of the abdomen is filled. Due to rise in intra-abdominal pressure, the umbilicus becomes everted as a result of the development of an umbilical hernia. Inguinal, femoral or incisional hernias may develop. Striae develop due to stretching of the abdominal wall. **Free fluid in the peritoneum can be demonstrated by eliciting shifting dullness on percussion with changing positions of the patient.** For this sign to manifest, the fluid should be free so as to shift in the peritoneal cavity and the mesentery

TABLE 81.1

Causes of ascites	
<i>Transudate</i> Peritoneum is not actively involved	1. Due to combination of hypoalbuminemia and rise in portal venous pressure, e.g. cirrhosis 2. Hypoalbuminemia, e.g. protein malnutrition, nephrotic syndrome. 3. Increased flow of lymph from the hepatic surface. In hepatic venous obstruction, superficial hepatic veins distend and lymph transudes into the peritoneum, thus adding to the ascites and rise of portal pressure, e.g. Budd-Chiari syndrome. In this condition protein content of the fluid is high. 4. As part of generalized edema, e.g. congestive heart failure, myxedema.
<i>Exudate</i> Peritoneum is actively involved	1. Inflammations a. Infections-chronic peritonitis, e.g. tuberculosis and acute peritonitis. b. Dyscollagenosis, e.g. systemic lupus, polyarteritis nodosa. c. Acute pancreatitis, splenic infarct. 2. Malignancies a. Secondary carcinomatosis from liver, stomach, breast, colon, etc. b. Primary mesotheliomas of the peritoneum. c. Pseudomyxoma peritonei due to rupture of mucocoele of appendix or ovarian cyst.
<i>Miscellaneous</i> Peritoneum may or may not be involved	a. Perforation of hollow viscus, e.g. stomach, appendix, small intestine. b. Fibroma of the ovary (Meig's syndrome). c. Lymphatic obstruction-filariasis, secondary carcinoma, lymphoma.

should be free so as to allow the intestines to float up and give the hyper-resonant note. When the fluid is very tense or when the intestines are fixed due to involvement of the mesentery, shifting dullness may not be elicitable.

When the quantity of fluid is less than 200 mL, it can be detected only by eliciting dullness to percussion around the umbilicus, the patient being examined in the knee elbow position—"puddle sign". Fluid thrill can be elicited over the abdomen when the fluid is large in amount and under tension. In obese individuals the abdominal fat transmits "thrill" in the transverse direction and this should not be mistaken for fluid thrill.

Associated Findings

Ascites and pleural effusion may coexist. Fluid from the peritoneum may pass into the pleural cavities through defects in the diaphragm or lymphatic channels. The raised intra-abdominal pressure pushes up the diaphragm, resulting in the diminution of the respiratory excursions of the lower portion of the chest. The cardiac apex may be displaced upwards. Elevation of the diaphragm also leads to secondary rise in intrapleural and right atrial pressure. The jugular vein may be full due to this reason.

Differential Diagnosis

Free fluid in the peritoneum has to be differentiated from localized fluid collections such as abscesses, cysts, hydramnios and large hydronephrosis. Rarely a very much distended bladder may give rise to doubt. Localized fluid does not give rise to shifting dullness. Solid organs like

enlarged uterus and ovarian tumours do not produce fullness of the flanks.

Diagnosis

Presence of fluid is readily detectable by ultrasonography and this is the investigation of choice. In addition to fluid, solid masses and metastases can also be detected. The diagnosis should be confirmed by paracentesis, which is necessary to determine the etiology. Even when a major cause such as cirrhosis liver is evident, it is still advisable to do a diagnostic paracentesis to exclude other coexisting lesions like tuberculous peritonitis or hepatoma. The ascitic fluid is examined microscopically, biochemically and microbiologically.

Microscopic Examination

A fresh specimen of uncentrifuged fluid should be examined after adding one drop of methylene blue. This brings out the cells clearly. Further identification of cells can be done by examining the stained deposit or by Papanicolaou's technique. When parasites such as micro-filaria are suspected, the deposit should be examined after centrifugation. Presence of inflammatory cells is characteristic of exudates. Lymphocytes predominate in tuberculosis, malignancy and pancreatic ascites. In pyogenic infections like acute peritonitis, neutrophils predominate. Malignant cells are identifiable in wet stained preparations but they are better identified by Papanicolaou's technique. Bacterial organisms can be identified by Gram stain and Ziehl-Neelsen's stain.

Biochemical Tests

Protein content of the ascitic fluid is high in exudates. In transudates, the protein level seldom exceeds 2.5 g/dL. Higher values suggest infection, malignancy or infarction. Determination of serum albumin/ascitic fluid gradient (SAAG) is helpful in deciding upon the cause of ascites. Increase in alpha-fetoprotein suggests the presence of hepatoma. Rise in amylase levels above 100 units/L together with higher protein content suggests pancreatic ascites.

Laparoscopy

It helps to visualize the peritoneum and abdominal organs and also aids in the selection of suitable sites for biopsy.

Closed biopsy of the peritoneum can be performed using special (*Cope's or Abrams*) needles if facilities for laparoscopy are not available. This is helpful in the diagnosis of extensive diseases such as tuberculous peritonitis and disseminated malignancy.

Course and Prognosis of Ascites

These depend upon the cause. In hepatic cirrhosis the ultimate prognosis depends upon the state of liver function. If the liver function is considerably reduced, 40% cases die within 2 years of onset of ascites.

In peritonitis, the outcome depends on early diagnosis and prompt treatment. Ascites occurring in malignancy generally denotes advanced disease and this has a poor prognosis. Ascites secondary to hypoproteinemia, nephrotic syndrome, and cardiac failure clears up with improvement of the underlying condition.

Treatment

In all cases where the ascites is secondary to a treatable disease, cure of the primary disorder relieves the ascites as well. When the underlying cause is irreversible such as cirrhosis of liver, measures to relieve the ascites are undertaken.

PERITONITIS

The peritoneum is an extensive serous cavity lined by flattened epithelium. It is generally resistant to infection and in healthy subjects infection is promptly localized.

Peritonitis is inflammation of the peritoneum. It may be acute or chronic and localized or generalized. Acute peritonitis presents as a surgical emergency with severe pain, toxemia, and shock. Physical examination reveals extreme tenderness, board-like rigidity, and absence of peristaltic sounds because of intestinal paresis. If exudation develops into the peritoneal cavity, signs of ascites become evident. Chronic peritonitis presents with ascites.

Acute Peritonitis

Common causes of this condition include appendicitis, perforation of viscera occurring in peptic ulcer, typhoid fever, cholecystitis, Crohn's disease, ulcerative colitis, dysentery, diverticulitis, gangrene, strangulated internal hernias, and injury by foreign bodies. Gonococci and pneumococci may cause localized or generalized peritonitis as a primary infection or by spread from other foci.

Diagnosis

Examination of the ascitic fluid shows the presence of intestinal contents, organisms and large number of neutrophils. Plain X-ray of the abdomen may reveal dilated loops of intestines and subdiaphragmatic gas in the case of perforation. Ultrasonography is very helpful.

Acute peritonitis is a surgical emergency. Principles of management consist of correction of fluid and electrolytes, antibiotic therapy, measures to combat shock, and surgical measures. All cases should be managed under the combined care of the surgeon and physician without delay.

Chronic Peritonitis

This condition is commonly caused by tuberculosis, malignancy or chemical causes, e.g. peritoneal dialysis. It presents as progressive ascites or peritoneal adhesions with intermittent subacute intestinal obstruction. Diagnosis is established by examining the ascitic fluid which shows increase in protein and chronic inflammatory cells. Treatment for the underlying causes relieves the condition.

Malignant Lesions of the Peritoneum

Many neoplasms metastasize into the peritoneum early and, therefore, secondary tumours are much more common. The primary may be abdominal neoplasms from the stomach, liver, or ovaries or extra-abdominal sites like carcinoma of the breast and lungs. These patients present with rapidly developing ascites and cachexia and they run a downhill course. Examination may reveal nodular masses in the abdomen, presence of **Virchow's glands** and periumbilical subcutaneous tumour deposits (**Sister-Joseph's nodules**).

Sister Mary Joseph (1856-1939) surgical assistant to Dr. William Mayo, noted the association between para-umbilical nodules and metastatic intra-abdominal cancer. Ascitic fluid may be hemorrhagic in many cases and microscopy reveals tumour cells. Chemotherapy may be palliative in some cases.

Primary tumours are rare. Histologically these are mesotheliomas. In many cases there is association with exposure to asbestos.

RETROPERITONEAL FIBROSIS

Retroperitoneal fibrosis may develop as an adverse side effect of therapy with drugs like methysergide. Other recognized causes are retroperitoneal lymphoma, carcinomatous secondaries, and post-irradiation fibrosis.

The etiology is unknown in many cases. The disease is more common in middle-aged males. Progressive fibrosis of the peritoneum on the posterior abdominal wall leads to constriction of the ureters and bilateral obstructive uropathy. Surgical measures are required to relieve ureteric obstruction. Clinical features include malaise, back pain, normochromic anemia and raised ESR. Contrast urogram shows the obstruction at the level of the pelvic brim with distension proximally, often the distension is

asymmetrical. CT scan may show the fibrosis as a para-aortic mass.

Treatment is to relieve the obstruction surgically. Withdrawal of methysergide early during the course of the illness arrests further progress, and the fibrosis may even regress.

Pseudomyxoma Peritonei

It is a rare metastatic peritoneal disease the primary being in the ovary or the appendix. This is characterized by the accumulation of a jelly like material in the peritoneal cavity. The condition is very indolent and many patients survive more than five years after diagnosis. Surgical debulking of the tumour and local drugs administered intraperitoneally may be beneficial.

Hepatobiliary System:
General Considerations

K.R. Vinaya Kumar, K.V. Krishna Das

Chapter Summary

Anatomy 496

Physiological Considerations 497

ANATOMY

The liver weighs 1.2 to 1.5 kg in the adult. It is comparatively bigger in infants, weighing around 6% of the birth weight. It is held in its place by the general intra-abdominal pressure and also by its peritoneal and vascular attachments.

Anatomically, falciform ligament divides the liver into a large right lobe, which is six times the size of the left, and the left lobe. The right lobe has two other lesser segments—the quadrate lobe in its inferior aspect and the caudate lobe located posteriorly. A portion of the left lobe is felt in the epigastrium in normal subjects. Based on its vascular supply and biliary drainage, the liver can be divided into physiological right and left lobes. The line of functional division lies to the right of the falciform ligament.

Structure of the Liver

The basic architecture of the liver is formed by the hepatic lobules which measure about 1 mm in diameter and are polyhedral in shape. Clearcut demarcation between lobules is not present in the human liver as is seen in the pig. Traditionally, the central hepatic vein was thought to be at the center of the lobule and portal triad at the periphery. The portal triad contains the radicles of the portal vein, hepatic artery and the bile duct, a few round cells and some connective tissue. A limiting plate of hepatic cells surrounds the portal tract.

Rappaport gave the acinar concept with the central vein at the periphery and the portal tracts at the center. An acinus is made up of a group of liver cells which is supplied by the terminal branches of the hepatic artery, portal vein, and bile duct. The acinus is the functional unit of the liver. A group of acini forms a complex acinus.

The liver cells are arranged in the form of sheets (hepatic laminae) which are connected by interlaminar bridges. In between the sheets of liver cells are vascular spaces—the sinusoids. The liver tissue is pervaded by two systems of tunnels formed by the portal tract and by the hepatic venous radicles. These two systems interlace in such a way that they do not come in contact. They are separated in the terminal portions only by a few liver cells that extend from the central vein to the portal triad.

The sinusoids are lined by a layer of endothelial cells. In between the hepatocyte and the endothelial cells is a narrow space—the *space of Disse*—which contains lymph. The hepatocytes account for 60% of the weight of the organ. They are polygonal, 30μ in size and show a central nucleus 8-10μ in diameter. Life span of the hepatocyte is 150 days. The bile canaliculi are found between adjoining liver cells. The hepatocyte has several complex metabolic functions to perform.

The phagocytic cells in the liver are the *Kupffer's cells* which belong to the reticuloendothelial system. They are situated in the walls of the sinusoids. In addition to Kupffer's cells, the sinusoidal walls contain endothelial cells, fat storing cells known as lipocytes or *Ito cells* and *pit cells* which have probably an endocrine function.

Under the electron microscope, hepatocytes reveal desmosomes which are anchoring pegs on the sides of contact of the cells. Microvilli project into the bile canaliculi. In the sinusoidal border, microvilli project into the perisinusoidal tissue space of Disse. The mitochondria contain several enzymes concerned with various metabolic activities including beta-oxidation of fatty acids. The rough endoplasmic reticulum (RER) synthesizes several proteins, including albumin, clotting factors and enzymes, and the smooth endoplasmic reticulum (SER) is the site of bilirubin conjugation, detoxification of many drugs and steroid synthesis. Adjacent to the bile canaliculi dense pericanalicular bodies are seen and these lysosomes contain many hydrolytic enzymes. Some of the pericanalicular dense bodies are termed microbodies. Golgi apparatus lies near the bile canaliculi. Lysosomes, microbodies, and Golgi apparatus are concerned with the

sequestration and elimination of ingested materials and this system is deranged in cholestasis. The hyaloplasm contains granules of glycogen, lipids, and fine fibrils. The cytoskeleton is formed by microtubules and micro-filaments.

Blood Supply

The liver receives a dual blood supply; 1500 mL of blood perfuses the liver every minute. The arterial blood supply is from hepatic artery which supplies 20% of blood. The remaining 70-80% of blood (1000 to 1200 mL) come from the portal vein. More than 70% of the oxygen supply to the liver is derived from the portal vein. When the portal venous oxygen tension is low during digestion, the major source of oxygen supply is the hepatic artery. The portal blood also contains some hepatotrophic factors which are essential for hepatic regeneration. The normal portal pressure is 7 mm Hg (90-120 mm water). The blood is drained into the inferior vena cava by three or more hepatic veins which are formed by radicles which commence in the intralobular veins which drain the sinusoids. The intralobular veins join to form sublobular veins and then the hepatic veins. Lymphatic channels from the liver drain into groups of nodes in the porta hepatis and thence into the nodes around the celiac axis. The mediastinal lymph nodes and those around the thoracic portion of the inferior vena cava also receive some lymphatics from the liver.

Bile secreted into the bile canaliculi by the hepatocytes drains into the intralobular cholangioles which join to form the larger interlobular bile ducts in the portal tracts. From each physiological lobe the interlobular bile ducts join to form the right and left hepatic ducts which join to form the common hepatic duct. The common bile duct is formed by the union of the cystic duct from the gallbladder with the common hepatic duct. It travels behind the head of the pancreas to open into the second part of the duodenum at the ampulla of Vater. Bile is secreted continuously and stored in the gallbladder which is a pear-shaped sac with a capacity of 50 mL. Normally this organ is not palpable, but when it enlarges it becomes palpable under the edge of the liver. The neck of the gallbladder shows a sacculation (*Hartmann's pouch*) which is a common site for lodgement of gall stones. The gallbladder contracts to release bile into the duodenum and this is related to the passage of food. The bile contains secretory and excretory products. The normal composition of bile is given in Table 82.1

PHYSIOLOGICAL CONSIDERATIONS

The liver plays a key role in the metabolism of carbohydrates, proteins, lipids, hormones, bilirubin,

TABLE 82.1

Normal composition of bile	
	(%)
Water	97.62
Total solids	2.38
Bile salts	0.90
Mucin and pigments	0.50
Lipids	0.25
Inorganic salts	0.73

porphyrin, bile salts and many drugs. It is only natural, therefore, that liver diseases lead to a wide variety of systemic manifestations. Because the liver has tremendous reserve capacity, the manifestations of disease occur only when the liver disease is advanced. Regardless of the etiology, the systemic features of liver disease are fairly similar.

Glucose Metabolism

One of the major functions of the liver is to maintain normal blood glucose level. Even though man is an intermittent feeder, the liver acts to dampen the effects of absorption and prevents surges in the blood glucose level and maintains blood glucose levels in the normal range. A fairly steady blood sugar level is maintained by the processes of glycolysis, glycogenolysis, glycogenesis and gluconeogenesis. Liver disease can lead to hypo- or hyperglycemia. Fulminant hepatitis and hepatomas can induce even fatal hypoglycemia due to reduction of gluconeogenesis and reduction of glycogen stores. Hyperglycemia may occur in chronic liver disease, especially cirrhosis. Reduced glucose uptake and glyco-genesis by the liver, coupled with hepatic resistance to insulin, are responsible for this feature.

Protein Metabolism

The liver is the major site of amino acid metabolism. The enzymes responsible for transamination and oxidative deamination are found in very high quantities in hepatocytes. Except for branched chain amino acids, the majority of amino acids entering the liver are catabolized. Levels of aromatic amino acids normally metabolized in the liver are increased and branched chain amino acids metabolized by the skeletal muscle are depressed in liver disease. The alteration of the ratio between the two types of amino acids has been incriminated in the pathogenesis of hepatic encephalopathy.

The liver synthesizes not only the protein it needs but also many export proteins (all plasma proteins except immunoglobulins), the most important of which is albumin. Albumin contributes significantly to the plasma oncotic pressure.

Coagulation Factors

Many of the blood clotting factors such as I, II, V, VII, VIII, IX and X are synthesized in the liver. The vitamin K dependent factors are synthesized in the liver and are made functionally active by the vitamin (See also Ch. 30). In addition to coagulation factors, intrinsic antithrombotic proteins such as protein C and proteins S are also synthesized in the liver. The capacity of the liver to produce coagulation factors is limited. Therefore, in hepatic failure coagulation function is deranged early.

Lipid Metabolism

Fatty acids produced by lipolysis of adipose tissue and those absorbed from the intestine reach the liver. Some fatty acids may be esterified with cholesterol, conjugated to phospholipids or converted to triglycerides. The triglycerides are cleared from the liver as lipoproteins by combination with apoproteins. Disturbances in these — either increased entry of fatty acids into the liver or decreased clearance — can lead to fatty liver.

Alterations in cholesterol and lipoprotein metabolism are seen in patients with cholestatic liver disease. The liver contains an enzyme lecithin-cholesterol acyltransferase (LCAT). A decrease in the production of LCAT is responsible for the increase in free cholesterol in serum. The reduced level of LCAT is also correlated with the appearance of lipoprotein-X (LP-X) in patients with cholestasis. Lipoprotein-X has a high concentration of free cholesterol and triglycerides.

Hormonal Metabolism

The metabolism of various hormones is affected in liver disease, e.g. insulin, glucagon, thyroxine, steroids, and sex hormones. Abnormalities of sex hormone metabolism account for spider angioma, loss of axillary and pubic hair, testicular atrophy and gynecomastia seen in patients with chronic liver disease. In addition to the hepatic dysfunction, the factors which lead to liver injury also directly impair gonadal function, e.g. alcohol, hemochromatosis.

Chapter Summary

Biochemical Abnormalities in Jaundice and Classification 498
Diagnosis 500
Complications due to Jaundice 502
Management of Jaundice 503

Definition

Jaundice is yellow discoloration of skin, sclera, mucous membranes, and other tissues due to excess of bilirubin in the blood. The normal level is 0.5-1.0 mg/dL. Clinically, jaundice is manifest when serum bilirubin rises above 3 mg/dL (50 μ mol/liter). The term 'latent jaundice' is used when the level is between 1-2 mg/dL. Examination in bright daylight is absolutely essential to detect mild jaundice (Fig. 83.1).

Biochemical Abnormalities in Jaundice and Classification

Approximately 30 mg of bilirubin is formed in the body every day of which 80% is derived from senescent erythrocytes and 20% from other sources. Bilirubin combines with albumin and this product being insoluble in water does not appear in urine. In hemolytic jaundice in which most of the bilirubin is unconjugated, urine does not contain bilirubin. Three main phases are recognized in the metabolism of bilirubin. These are: (i) entry into the liver cell, (ii) conjugation, and (iii) excretion into the bile. After uptake, bilirubin is conjugated with glucuronic acid in the endoplasmic reticulum of hepatocytes with the help of glucuronyl transferase. Reduced levels of this enzyme are responsible for certain forms of congenital hyperbilirubinemias like *Crigler-Najjar syndrome*. Conjugated

Fig. 83.1: Obstructive jaundice male aged 55: Carcinoma head of pancreas. Note: dark yellow pigmentation of sclera and skin

bilirubin is water-soluble and it freely passes into urine. *Bilirubin* diglucuronide in the gut is acted upon by bacteria present in the distal small intestine and the colon and is converted into urobilinogen. Urobilinogen is reabsorbed mainly from the small intestine and to a small extent from the large intestine into the portal blood. It is subjected to enterohepatic circulation. The portion that is present in stool without being absorbed is called *stercobilinogen*.

Both unconjugated and conjugated bilirubin stain tissues. Collagenous and elastic tissues have the maximum

affinity for bilirubin and, therefore, tissues rich in these are stained early and most deeply.

In adults, bilirubin does not cross the blood-brain barrier and the brain is not stained. In neonates the blood-brain barrier is not well developed and it is disturbed in inflammations (e.g. Weil’s disease). In such situations the brain and CSF are also stained. Presence of bilirubin in ocular fluids may lead to yellow vision-xanthopsia which is extremely rare. Sweat, milk, semen, and synovial fluid may contain bilirubin in most cases, but tears, saliva and pancreatic juice are discolored only if the jaundice is severe. In long-standing jaundice the skin shows a greenish tinge due to the formation of biliverdin, an oxidation product of bilirubin.

Jaundice can be classified in different ways (Table 83.1).

Classification based on pathophysiological mechanism:

- 1. *Overproduction of bilirubin*—hemolytic.
- 2. *Decreased hepatic uptake* — hepatocellular dysfunction.
- 3. *Decreased hepatic conjugation* and release into biliary canaliculi—hepatocellular dysfunction.
- 4. *Obstruction to the biliary passages*—cholestasis with regurgitation of bile into blood.

TABLE 83.1	
Classification of jaundice based on the type of pigment	
I. Predominantly unconjugated hyperbilirubinemia	
A. Overproduction of bilirubin	
1. Hemolysis—intra- or extracorpuscular causes	
2. Ineffective erythropoiesis	
B. Impaired hepatic uptake	
1. Drugs-rifampicin, cholecystographic dye	
2. Familial-Gilbert’s syndrome	
C. Impaired bilirubin conjugation (decreased glycoronyl transferase activity)	
1. Hereditary absence or deficiency of transferase—Crigler-Najjar syndrome—Type I and Type II	
2. Immaturity of transferase (neonatal jaundice)	
3. Acquired transferase deficiency	
a. Drug effect-chloramphenicol, novobiocin	
b. Hepatocellular disease—hepatitis and cirrhosis	
II. Predominantly conjugated hyperbilirubinemia	
A. Impaired hepatic excretion (intrahepatic defects)	
1. Acquired disorders of the liver cells—Viral hepatitis, leprospirosis, drug-induced hepatitis, e.g. INH, methyl dopa, alcohol	
2. Hereditary disorders—Dubin-Johnson syndrome, Rotor’s syndrome	
B. Intrahepatic cholestasis	
1. Viral hepatitis	
2. Drug induced cholestasis, e.g. oral contraceptives, anabolic steroids methyl testosterone, sulfadiazine, chlorpromazine, thiouracil, PAS	
3. Primary biliary cirrhosis	
4. Extensive involvement of liver by malignant secondaries, Hodgkin’s diseases, etc.	
5. Intrahepatic biliary atresia	
C. Extrahepatic causes for cholestasis (surgical jaundice): Gall stones, carcinoma head of the pancreas, biliary stricture, carcinoma of the ampulla of Vater, obstruction of masses in the porta hepatis	

Based on the pathology, jaundice may be classified into *hemolytic*, *hepatocellular* or *obstructive*. Though in the majority of cases the jaundice runs true to type, in many instances more than one factor may be operative and this tends to make the biochemical picture more complex. For example in long-standing hemolytic jaundice, biliary calculi may develop and produce obstructive jaundice as well.

Differentiation of the types of jaundice: Differentiation between *medical*, i.e. *prehepatic* and *hepatic* types or *surgical*, i.e. *extrahepatic cholestasis*, is crucial in deciding upon the management. The investigations have to be planned suitably. Medical jaundice is to be treated mainly with drugs whereas surgical jaundice demands invasive investigations and surgery.

Diagnosis

Majority of cases can be diagnosed by the history, physical examination and simple biochemical tests. Preliminary tests include urinalysis, examination of feces and biochemical and immunological tests of the serum. More definitive diagnostic tests to delineate the anatomy of the biliary tree are ultrasonography, radiological studies, liver biopsy, isotopic investigations, endoscopic investigations, CT scan, MRI and laparotomy.

Table 83.2 gives the clinical differentiation of the types of jaundice.

Biochemical Tests

Preliminary investigations: Laboratory investigations are necessary to determine the type of jaundice and its etiology.

Detection of Bile Pigments and Urobilinogen in Urine

	Hemolytic	Hepatocellular	Obstructive
Bile pigment	Absent	Present	Excessive
Urobilinogen	Excess	Present, may be in excess	Absent

Examination of feces: The stools are dark coloured in hemolytic jaundice due to excessive bile pigment, whereas it is pale and chalky white (clay coloured) in obstructive jaundice due to absence of bile. Ulcerating malignant lesions give rise to occult blood in stools. Silvery colour of feces occurring in obstructive jaundice indicates the presence of altered blood.

Serum bilirubin: The total, conjugated and unconjugated fractions can be estimated. This helps in assessing the severity of jaundice and also in identifying the type. *Van den Bergh reaction* is a qualitative test used in detecting the type of bile pigment in the serum. Direct positive test is given by conjugated bilirubin, unconjugated bilirubin gives rise to the indirect reaction. When both pigments are present the reaction is biphasic.

Enzyme Determination

- a. **Increased levels of SGOT** (serum glutamic oxaloacetic transaminase, aspartate transaminase, AST), and **SGPT** (serum glutamic pyruvic transaminase, alanine transaminase — ALT): Liver cells are rich in transaminases SGPT and SGOT. In the normal state these enzymes are present in serum (10-40 U/L), but when hepatic cells undergo necrosis large amounts are released into circulation. The serum levels of these enzymes are raised in all forms of hepatocellular necrosis, irrespective of the etiology. Though these enzymes are not specific to the liver, when taken in conjunction with other tests of hepatic function, raised levels give a semiquantitative idea of the extent of liver cell necrosis in most cases. In fulminant hepatic failure where most of the liver cells have been lost the amount of enzyme released falls and so transaminase levels may fall despite very severe hepatic necrosis. In such a situation the enzyme levels may be misleadingly low.
- b. **Serum alkaline phosphatase** levels above 30 KA units/dL (210 IU/L) indicate cholestasis, if bone disease can be excluded. In extrahepatic biliary

TABLE 83.2				
Clinical differentiation of the types of jaundice				
Clinical features	Hemolytic	Hepatocellular	Obstructive (Cholestatic)	
*1. Depth of jaundice	Usually mild	Variable	Usually deep	
2. Pruritus	Absent	Variable	Present	
3. Bradycardia	Absent	Absent	Present	
4. Anemia	Present	Absent	Absent	
5. Splenomegaly	Present	Variable	Absent	
6. Palpable gallbladder	Absent	Absent	May be present	
7. Bleeding tendency	Absent	Present	Present in the late stages	
8. Features of hepatocellular failure	Absent	Present early in the disease	Present often late	
* Not a reliable sign.				
Note: The depth of jaundice is not a reliable parameter to differentiate the types				

obstruction, it is disproportionately increased compared to plasma bilirubin. The raised levels are brought about by overproduction of hepatic alkaline phosphatase. Rise in serum alkaline phosphatase is even a more reliable parameter of biliary obstruction than serum bilirubin levels.

- c. **Other enzymes such as gammaglutamyl transpeptidase and 5'-nucleotidase** are helpful in some cases when alkaline phosphatase levels are equivocal.

Serum cholesterol: It is markedly elevated in obstructive jaundice, especially primary biliary cirrhosis. Several other disorders lead to elevation of serum cholesterol and, therefore, this test is not specific.

Serum albumin: It is lowered in hepatocellular failure. In hepatocellular disease gammaglobulin is elevated whereas in chronic biliary obstruction alpha-2 and betaglobulins are elevated.

Prothrombin time: In obstructive and hepatocellular jaundice prothrombin time is prolonged. Shortening of the prothrombin time with parenteral administration of vitamin K₁ suggests that the jaundice is mainly obstructive. Total lack of response indicates gross liver cell damage.

Immunological Tests

Many hepatocellular disorders are immunologically mediated and so several antibodies can be demonstrated. Among them the most useful is the *antimitochondrial antibody* which is present in primary biliary cirrhosis. High titers of *antinuclear and smooth-muscle antibodies* suggest chronic active hepatitis. The different *serological markers of hepatitis B infection* such as HBsAg, HBeAg and their respective antibodies are most helpful in making specific diagnosis. Other viruses producing hepatitis give rise to specific diagnostic immunological markers (See Chapter 55).

Ultrasonography

It is perhaps the most useful noninvasive method to delineate dilated bile ducts, dilated portal vein, pancreatic cysts and tumours, the gallbladder, and the liver. This should be done as the initial imaging procedure to visualize the liver, gallbladder, biliary passage and the venous systems since this can confirm the diagnosis in many cases and further expensive and invasive tests can be avoided.

Liver biopsy: This may be necessary in long-standing jaundice when noninvasive investigations are unrewarding. In the presence of bleeding tendency, as revealed by prolonged prothrombin time, liver biopsy has to be undertaken with care. Percutaneous liver biopsies are now done with Trucut needles or biopsy guns. In liver

failure with severe coagulation disturbances, only transjugular biopsy can be done. In focal lesions of the liver, guided biopsies are required, either ultrasound or CT guided biopsies.

Radiological Studies

Plain X-ray of the abdomen may reveal radiopaque biliary calculi in a minority of cases. Plain radiograph of the abdomen may show gall stones as a chance finding. Contrast radiography such as oral cholecystography, intravenous cholangiography and percutaneous transhepatic cholangiography (PTC) are seldom done now. But selective hepatic arteriography is useful for the diagnosis of focal lesions in the liver, planning hepatic resections and interventions such as embolization and local chemotherapy. For these, more elegant and non-invasive procedures employing ultrasound, CT and MRI principles are adopted at present.

Computed Tomography

CT scan is a very reliable method to demonstrate hepatic lesions. This should be employed when ultrasonography is not fully diagnostic. Structural lesions in the liver such as tumours, abscesses, vascular malformations, parasites, cirrhosis and others can be demonstrated by CT. When ultrasonography and CT scan are used in conjunction the diagnostic yield is much higher. Both these modalities can be employed for guided biopsies and aspirations.

Magnetic Resonance Imaging (MRI)

This gives more information than CT in the following conditions:

1. Infiltrative disorders, especially fatty liver.
2. Accumulation of heavy metals such as copper and iron.
3. When hemangioma and metastatic deposits are suspected, and
4. To determine the patency of blood vessels in the abdomen.

CT cholangiopancreatogram (CTCP) and MR cholangiopancreatogram (MRCP) are useful non-invasive imaging modalities to delineate biliary and pancreatic ductular systems. They are equally informative compared to ERCP.

Isotopic Liver Scan

⁹⁹Tc labelled biliary analogues such as disopropylimino-diacetate (HIDA) and para-isopropyl iminodiacetic acid (Pipida) when given IV are taken up by liver cells and excreted into bile. In obstructive jaundice this is delayed. These tests help to detect the cause of obstructive jaundice due to mechanical cholestasis (Table 83.3).

TABLE 83.3

Differential diagnosis of jaundice

	Hepatocellular jaundice	Intrahepatic cholestasis	Extrahepatic obstruction
Common causes	Viral hepatitis spirochetal jaundice	Viral hepatitis, drugs biliary cirrhosis	Biliary stones, carcinoma of pancreas, carcinoma bile duct
Age	More in the young	Any age	Above 40 years
Duration of jaundice	Less than 3 months	Usually less than 3 months	Often more than 3 months
Itching	May be present	Common	Common
Color of feces	Slightly pale	Pale	Very pale (clay-coloured)
Jaundice	Mild to moderate	Mild to moderate or deep	Very deep in the later stages
Pain	Mild discomfort	Nil	characteristic pain in gall stones; constant radiating pain in pancreatic carcinoma
Liver	Tender and slightly enlarged	Variable	Enlarged and firm in long-standing jaundice
Gallbladder	Not palpable	Not palpable	Palpable in many cases of carcinoma head of pancreas and in some cases of bile duct obstruction
Bilirubin	Total and direct high	Total and direct high	Total and direct very high
Serum cholesterol	Normal	Raised	Markedly raised
Cephalin cholesterol flocculation	2 to 4+	1 to 2+	1+ in the early stages
Alkaline phosphatase (KA units)	10 to 15/dL	Over 15/dL	Over 30/dL
Transaminases	Markedly increases	Moderately increased	Only slightly increased in early stages
Obstruction to major bile ducts	Nil	Nil	Present

Note: Alkaline phosphatase—Normal value 3 to 13 KA unit/dL or 21 to 91 IU/L

Endoscopy

Esophago-gastroscopy: This gives indirect evidence of portal hypertension. Presence of varices in the esophagus and stomach is due to rise in portal pressure, persisting over long periods.

Presence of spider nevi in the oesophagus and/or stomach is suggestive of hepatic failure.

Endoscopic retrograde cholangiopancreatography (ERCP): This procedure helps in visualizing the biliary and pancreatic duct systems. In addition to diagnosis, the same method may be employed to dislodge obstructing stones or relieve a stricture (Fig. 83.2).

Peritoneoscopy: (Syn : Laparoscopy) Direct inspection of the liver and gallbladder through the laparoscope and biopsies under vision from suspicious areas improve diagnostic accuracy considerably.

Surgery

If the diagnosis is not clear by all these tests, laparotomy may have to be performed for initiating the treatment without further delay. Moreover, even in incurable malignant obstruction, drainage of bile through a cholecystojejunostomy helps to relieve symptoms and

Fig. 83.2: Hemobilia. Note: The presence of blood in the opening of the bile duct ERCP

allay misery for considerable periods. At present less traumatic procedures such as laparoscopic surgery are adopted.

Complications due to Jaundice

Jaundice may give rise to further complications, apart from those caused by the primary disease.

a. Obstructive Jaundice

Skin: Skin changes include melanotic pigmentation, chronic pruritus, thickening, and excoriation. Xanthomas develop due to hypercholesterolemia. Bleeding tendency manifests as purpura and bruises.

Malabsorption: Since bile does not reach the intestine, absorption of fat and fat soluble vitamins is defective. This leads to steatorrhea and deficiencies of vitamins A, D, E and K and calcium.

Accumulation of copper: Copper is normally excreted in bile. In chronic obstructive jaundice copper accumulates in the liver and may reach high values. Unlike as in Wilson's disease in which copper is deposited in the lysosomes, in biliary cirrhosis the copper is present in the cytosol.

Hepatocellular failure: Back pressure of bile and prolonged obstruction leads to hepatocellular necrosis, secondary biliary cirrhosis, and hepatic failure. Elderly subjects are more prone to develop these complications.

Renal failure: This may develop during the icteric stage or after surgical relief of the obstruction.

b. Hemolytic Jaundice

Damage to nervous system: In the newborn the blood-brain barrier for unconjugated bile pigment is not developed. The bilirubin is bound to albumin, but when the level exceeds 20 mg/dL, the binding capacity. The binding capacity of albumin is exceeded. Bilirubin passes into the nervous tissues and gets fixed to the mitochondria whose function is impaired resulting in neuronal death. The basal ganglia are affected most but no part of the CNS is totally free. This used to be dreaded complication of hemolytic diseases of the newborn. The CNS of the newborn is most susceptible to this damage.

Pigment gall stones: Presence of excess of bilirubin in bile results in its precipitation and formation of pigment gall stones. Though asymptomatic in many cases, rarely they may become symptomatic and lead to obstructive jaundice.

MANAGEMENT OF JAUNDICE

Definitive management depends upon the cause, but symptomatic treatment is necessary when the cause cannot be corrected.

Hemolytic jaundice: Treatment of the underlying disorder relieves the jaundice in most cases. In severe hemolytic disease of the newborn, measures such as exchange transfusion are necessary to lower serum bilirubin urgently and prevent neurological damage. Phototherapy (exposure to UV rays) benefits mild cases. Early detection of blood group incompatibility of the pregnant women with her husband and appropriate therapy helps to avoid severe hemolytic disease in the newborn.

Obstructive jaundice: Troublesome pruritus may be relieved by antihistamines like diphenhydramine in a dose of 50 mg twice daily. External application of calamine lotion gives relief. In intractable cases, the anion binding resin cholestyramine has to be given in a dose of 4-16 g/day orally in divided doses to lower the bile acid levels in the body. It binds the bile acids in the intestine, prevents their absorption, and facilitate their elimination. The main dose (4-8 g) is mixed in water or fruit juice and given in the morning with breakfast, since this is the time when bile salt concentration in the duodenum is the highest. Since cholestyramine also binds other ingested drugs, such drugs should be given at least one hour before administering cholestyramine. Cholestyramine is of no avail if bile does not reach the intestine as in complete obstruction. In such cases analogues of sex hormones may be effective. Methyltestosterone 25 mg is given sublingually for men and norethandrolone 10 mg is given orally for women. The antipruritic effect of these drugs will be manifested within a week of starting the drug.

Ursodexychoic acid (UDCA) promotes biliary flow and is useful in intrahepatic cholestasis.

Steatorrhea occurs in obstructive jaundice and this can be troublesome. This can be minimised by reducing the fat intake below 40 g/day. Since medium chain triglycerides are absorbed even without the help of bile acids, administration of such fats helps to avoid steatorrhea. Parenteral injection of vitamin K (10 mg) and vitamin D (2.5 mg) should be given monthly. Calcium gluconate given in a dose of 2-4 g orally helps to prevent negative calcium balance.

Endoscopic Management

Interventional endoscopic procedures such as endoscopic cholangiopancreatography are the methods of choice for relieving biliary obstruction and these have eliminated the need for surgery to a great extent. Endoscopic interventions can be done by special instruments during the procedure. These include extraction of stones, division of strictures, and stenting of the pancreatic and bile ducts. Stones can be extracted from the common bile duct, hepatic duct or even from intrahepatic portions of the smaller biliary ducts using baskets or balloons. Benign and malignant strictures can be dilated and stents deployed to restore the lumen (Fig. 83.2).

Surgical treatment: This should be undertaken immediately in cases of extrahepatic obstruction not amenable to endoscopic methods. Even in incurable lesions, palliative surgical procedures to overcome the biliary obstruction such as cholecystojejunostomy, help in relieving the symptoms, especially the intractable pruritus and steatorrhea. Surgical decompression of the biliary tree also helps in arresting the progress of hepatocellular damage. Many years of symptom-free life can be achieved and hence such procedures should be considered in suitable cases without delay.

Cirrhosis: General Considerations

Among the chronic parenchymal liver diseases seen in India, cirrhosis is most common. It is characterized by diffuse fibrosis and conversion of normal architecture into structurally abnormal nodules. At all times during the pathological process, there is evidence of liver cell necrosis, fibrosis, and the development of regenerative nodules which do not conform to normal anatomical pattern. The diffuse lesion involves the major portion of the liver. In many cases hepatocellular necrosis resulting from different pathological lesions initiate the process. In India the common identifiable causes are hepatitis B and C virus infections, alcoholism and chronic ingestion of toxic substances contaminating diet, or as drugs. Protein deficiency may act as an aggravating factor in the presence of other causes.

PATHOGENESIS

When liver cells undergo necrosis, the hepatic lobules collapse and this leads to the formation of diffuse fibrous septa. As a compensatory mechanism nodular regeneration of hepatocytes occurs. When the necrosis is associated with collapse of the reticulin framework cirrhosis results. If the reticulin framework is not collapsed but preserved, hepatocytes regrow and reproduce the normal histological pattern. Damage to the reticulin framework results in the

formation of abnormal nodules which derive nourishment from the hepatic artery, but without portal and biliary connections. The nodules vary in size from a few millimeters to several centimeters. The liver surface becomes nodular. Hepatic vascular bed is distorted, truncated and obstructed, the obstruction being maximal at the level of sinusoids.

Several vascular abnormalities develop. These include:

1. Generalized arterialisation of the liver.
2. Formation of shunts between the branches of the hepatic artery, portal vein and hepatic vein.
3. Formation of arteriovenous shunts also in the pulmonary circulation.
4. Development of a hyperdynamic circulatory state with increased cardiac output and reduced peripheral vascular resistance.

Obstruction to portal venous flow results in the development of portal hypertension. As the nodules grow, their centers are rendered ischemic. Once the disease process is initiated, other factors such as autoimmunity, continuing necrosis, and chronic effect of toxins lead to the progression of the pathological lesions.

Basement membrane forms in the Disse's space and this interferes with the metabolic functions of the liver. The necrotic foci stimulate the proliferation of fibroblasts and collagen and fibrous septae develop in the portal zones and hepatic lobules. Hepatic fibrosis is a common sequel to chronic liver injury from various causes such as alcoholism.

Etiological classification: Cirrhosis may be the end result of several unrelated conditions persistent viral and helminthic infections and hereditary copper or iron overload. In all these conditions the mechanism of fibrosis is similar, but the location varies. In chronic alcohol injury the fibrosis is pericentral whereas in viral hepatitis it is periportal. The perisinusoidal *Ito cells* may also transform into fibroblasts and produce intralobular collagen. Though these cells produce at least five types of collagen, only types I and III are found in the final scar tissue.

Etiological Factors in Cirrhosis

1. Infections	: Hepatitis B, C, D, <i>Schistosomiasis mansoni</i> , congenital syphilis
2. Drugs and toxins	: Alcoholism, methotrexate, arsenic, methyldopa, isoniazid, and several others
3. Metabolic causes	: Galactosemia, glycogen storage disease type IV, alpha-1-antitrypsin deficiency, hemochromatosis, Wilson's disease, urea cycle enzyme defects, tyrosinosis
4. Primary immunological disorders	: Autoimmune hepatitis (lupoid) and primary biliary cirrhosis
5. Vascular causes	: Hepatic venous obstruction, chronic congestive cardiac failure, constrictive pericarditis, veno-occlusive disease
6. Miscellaneous	: Indian childhood cirrhosis
7. Biliary obstruction	: Gall stones, biliary atresia, biliary strictures, mucoviscidosis and non-alcoholic steatohepatitis
8. Cryptogenic	: No cause is detectable even after full investigations. The majority of cases are cryptogenic.

Fibronectin, which is a soluble glycoprotein present in plasma, is rendered insoluble and deposited on the surface of the liver cells. Fibronectin binds collagen to form the extracellular matrix which replaces areas of liver cell necrosis. The matrix consists of proteoglycans, fibronectin and hyaluronic acid.

Cytokines initiate and perpetuate fibrogenesis. Among them platelet derived growth factor (PDGF) is most important. In the early stages fibrogenesis is reversible, but once established, it is not so.

Morphological Classification

The morphological types are:

- micronodular*,
- macronodular*, and
- mixed*.

In micronodular cirrhosis, the nodules are less than 3 mm in diameter, uniform, and these are seen involving the whole liver. The fibrous bands are indistinct and fine. In macronodular cirrhosis the nodules are coarse, irregular, and may grow up to several centimeters. The liver surface is grossly distorted. The mixed type is a combination of the two. In some cases at least the morphology may suggest the cause, though to a large extent this is decided by the extent of necrosis and other aggravating factors as well. In all types of cirrhosis in the later stages when fibrosis predominates the organ shrinks.

CLINICAL FEATURES

Early stages of the disease are asymptomatic. Vague illhealth, anorexia, loss of weight, loss of libido, impotence, abdominal distention, and dependent edema may bring the patient to the doctor. Night blindness is a common symptom in many and this results from the impairment of metabolism of vitamin A. Ascites is probably the most prominent feature which draws attention to the hepatic problem (Fig. 84.1).

Fig. 84.1: Male 60 years—cirrhosis liver with gross ascites and edema. Note: The pale nails and shiny abdomen

The major clinical features depend on the two main pathological processes, **hepatocellular failure and portal hypertension**. These processes often develop simultaneously in the majority of cases but independent of each other. The liver is enlarged in the early stage due to infiltration but in the later stage it shrinks and becomes harder in consistency. The spleen enlarges in size due to portal hypertension and reticuloendothelial hyperplasia. **Clubbing of fingers** may develop in a few. **Dupuytren's contracture** has been found to be associated with cirrhosis, but this association is not strong in Indian subjects (Figs 84.2 and 84.3).

Diagnosis

Cirrhosis has to be suspected clinically by the firm nodular feel of the liver, splenomegaly, signs of portal hypertension and hepatocellular insufficiency. The biochemical tests reflect parenchymal cell damage. Serum albumin is

Fig. 84.2: Male 50 years alcoholic cirrhosis, hepatic failure
Note: Spider nevi on the chest arrows

Fig. 84.3: Cirrhosis liver abdomen showing caput medusae
Note: The prominent veins on the abdominal wall, arrows point to the direction a blood flow

lowered with rise in gammaglobulin. *Bromsulphthalein (BSP) retention* is high. Transaminase levels are elevated if active necrosis is present. In all cases of doubt liver biopsy should be performed for establishing the diagnosis and identifying the morphological pattern, since the diagnosis is based on hepatic morphology.

Since removal of the underlying cause is necessary to arrest progression of the disease, etiological diagnosis should be attempted. In conditions like Wilson's disease, hemochromatosis and autoimmune chronic hepatitis, specific measures can be employed for reversing the lesions.

MANAGEMENT OF HEPATIC CIRRHOSIS

All cases of cirrhosis should be carefully managed. Considerable symptomatic and functional improvement can be achieved and useful life prolonged.

Uncomplicated Cases

Removal of the primary cause: If treatment is started early, the lesions can be reversed, as in alcoholism, HBV and HCV infection, drug toxicity, biliary obstruction and schistosomiasis.

Diet: The diet should contain 2500-2800 Cal/day. Protein intake of 1.25-1.5 g/kg of body weight should be attempted, if possible. The limiting factor is the development of hepatic encephalopathy. Vitamin and mineral supplements are indicated if there are overt or latent deficiencies.

Avoidance of precipitating factors: Factors that precipitate upper gastrointestinal bleeding and hepatic failure should be strictly avoided. Drugs should be administered to cirrhotics only after taking into consideration these potential complications.

Management of Ascites

General Measures

1. Bed rest helps the functional recovery of the liver and prevents deterioration of ascites. Low sodium diet-60-90 mmol/day of sodium (1500-2000 mg of sodium chloride) is ideal. If the serum sodium is < 130 mmol/L in the presence of ascites or edema, it suggests dilutional hyponatremia, due to impairment of water elimination by kidney, caused by syndrome of inappropriate secretion of antidiuretic hormone (SIADH).
2. In many advanced cases of cirrhosis the urinary loss of sodium is generally less than 2 g/day. Therefore, dietary sodium has to be drastically restricted. Apart from added salt at table, several articles of diet contain considerable amounts of sodium. These include pickles, bread, biscuits, salted canned food, milk (if more than 300 mL/day), and salted butter. The diet should contain moderate protein (50-70 g) and adequate calories. Since vegetable proteins are better tolerated than animal protein by patients with hepatic failure, these should be preferred. Failure to conform to a low salt diet is the most important cause of therapeutic failure. Fluid intake should be restricted to one liter a day.
3. **Diuretics** are indicated if salt-restricted diet alone is not effective in clearing the edema and ascites. Loss of weight of at least 1 kg in 4 days is ideal. The diuretic has to be chosen depending on the severity and response to therapy. Powerful diuretics like furosemide, thiazides, ethacrynic acid, and bumetanide cause loss of sodium and potassium. Potassium should be supplemented in a dose of 2 g/8h. Combination of potassium sparing diuretics like spironolactone, triamterine or amiloride, and the powerful diuretics enhances effectiveness and reduces the need for potassium replacement. An effective combination is furosemide with spironolactone or amiloride. Excessive diuresis may lead to hepatic failure, hypotension and uremia in 30-40% of cases and this should be avoided.

When potassium sparing diuretics are given, potassium intake should not exceed 50 mmol/day (3.75 g of KCl). Diuretic therapy may have to be continued over prolonged periods to get sustained benefits.

A convenient and popular regimen is to give spironolactone 25-100 mg thrice a day with frusemide 20-40 mg once a day. This can be continued for several months under supervision.

Frequent determination of serum levels of sodium, potassium and bicarbonate is necessary to avoid electrolyte disturbances.

Some of the resistant cases in whom the serum albumin level is below 2 g/dL respond to intravenous infusion of salt-free human albumin, dextran or ascitic fluid itself. This temporarily raises the colloid osmotic pressure.

As the hepatic function improves and the ascites clears up, dietary intake of salt can be increased and diuretics can be withdrawn in stages. 5-10% of patients with ascites become resistant to treatment. They do not respond even to high doses of diuretics (100-200 mg of spiranolactone and 40-160 mg of frusemide/day). In some others complications such as hepatic encephalopathy, hyponatremia, hyperkalemia or azotemia preclude further increase in diuretic dosage. Risk of hepatorenal syndrome (HRS) occurs in 10% of cases of hepatic failure with ascites.

Resistant Ascites

If the ascites tends to persist despite intensive general measures, fluid should be removed by paracentesis.

Paracentesis: This is a short-term measure and the fluid reaccumulates rapidly. The loss of protein and electrolytes from the body may worsen hepatic function further. Paracentesis is indicated when the ascites increases rapidly despite adequate general measures and causes severe embarrassment and pain. Only the minimum amount of fluid should be removed to relieve these symptoms. If the abdominal distention is severe and accompanied by dyspnea, removal of 4-5 liters of fluid in 12-16 hours brings about temporary relief. Complications of paracentesis include shock, bleeding into the peritoneum, infection and precipitation of hepatic coma. Recently interest in this procedure has increased and controlled paracentesis is being employed more frequently. Regular removal of fluid by paracentesis helps to reduce the dose of diuretic. It is advisable to give albumin infusion to prevent hemodynamic alterations when the paracentesis exceeds 5L of fluid (large volume paracentesis).

It is possible to maintain patients for long periods in reasonable comfort with judicious abdominal tapping repeated at regular intervals.

Spontaneous Bacterial Peritonitis (SBP)

In advanced liver cirrhosis bacterial translocation of the gut microbes into the ascitic fluid occurs. This condition is called spontaneous bacterial peritonitis which is seen in about 50% of patients with cirrhosis and ascites. The ascitic fluid protein is typically low but more than 250 polymorphs/cmm occur. Culture is positive for gram negative enterobacteriaceae, usually a single type. The presentation is with mild fever or abdominal pain. Sometimes rapid worsening of cirrhosis may be the presenting feature. Untreated, the mortality is high with worsening of ascites, hepatorenal syndrome and encephalopathy. Treatment is with cefotaxime 2g tid for 5 days. These patients also require secondary prophylaxis with norfloxacin.

Other forms of peritonitis in cirrhosis are

1. **Culture negative-neutrocytic ascites** where the polymorph count is > 250/cmm; but culture is negative.
2. **Monomicrobial non-neutrocytic ascites.** In this the culture is positive for single type of microbial species; but polymorphonuclear count is less than 250/cmm
3. **Polymicrobial bacterial ascites.** In this condition culture is positive for multiple species of microbes. This usually results from needle puncture of the bowel while attempting paracentesis.
4. **Secondary peritonitis.** In this condition polymorph count is very high, usually > 10000/cmm. This is a serious condition resulting from lesions such as bowel perforation, cholecystitis, appendicitis, diverticulitis, duodenal ulcer and others. Often surgical management is required.

Ascitic fluid ultrafiltration and re-infusion: Using an automated ultrafiltration apparatus (Rhodiascit) proteins of the ascitic fluid can be concentrated and infused intravenously. The equipment is expensive and the procedure demands special skills.

Le veen peritoneovenous shunt: This surgical procedure establishes intermittent drainage of the peritoneal fluid into the superior vena cava through a valve. The respiratory movements of the diaphragm and the reciprocal pressure changes within the abdomen and thorax serve to operate the valve. Limited success has been reported in some cases.

The treatment of complications like hematemesis and hepatic failure is described in Chapters 85 and 86 respectively.

Intercurrent infections: These are common and early treatment is essential to prevent hepatic failure. Ampicillin and amoxycillin are safe. Tuberculosis occurs more frequently in cirrhotics (4-6%). The lesions include pulmonary, lymph nodular or peritoneal tuberculosis. Such patients require standard chemotherapy.

Development of primary carcinoma: Cirrhosis predisposes to the development of primary carcinoma (hepatoma). Rapid enlargement of the liver, fever, pain, rapid loss of weight, development of massive hemorrhagic ascites or sudden hepatic or portal vein obstruction should suggest this possibility.

Prevention: Prevention of viral hepatitis, abstinence from alcohol, enforcement of laws on food adulteration, and proper food hygiene to avoid contamination by toxins, serve to reduce the incidence of cirrhosis on a long-term basis. Widespread vaccination against hepatitis B has brought down the incidence of cirrhosis and carcinoma in many South East Asian countries.

Special forms of Cirrhosis

ALCOHOLIC CIRRHOSIS

The final phase of alcoholic liver disease is alcoholic or Laennec's cirrhosis. This may result from repeated bouts of acute alcoholic hepatitis which is the more likely mechanism in most cases (50%). Presence of hepatic encephalopathy, deep jaundice with bilirubin above 20 mg/dL, prolongation of prothrombin time more than 5 sec. above normal, azotemia and severe hypoalbuminemia are associated with a higher risk of developing cirrhosis. The cirrhosis is micronodular and the liver is moderately enlarged, except in a few cases in whom it is shrunken.

Ascites, esophageal varices, muscle wasting and renal failure are common complications in alcoholic cirrhosis. Continued intake of alcohol leads to persistence of alcoholic hepatitis, progressive deterioration of liver function and death. Withdrawal of alcohol may arrest progress of the disease and in many cases even lead to regression. The inactive stage is compatible with prolonged survival.

NON-ALCOHOLIC FATTY LIVER DISEASE

This was initially recognized in women with diabetes with insulin resistance. Histology shows cytolytic changes in hepatocytes such as ballooning degeneration, Mallory hyaline, and lobular inflammation. Variable degrees of fibrosis may be present. This condition is not caused by alcoholism. This condition may be mistaken for alcoholic liver disease. Increase in liver enzymes may occur. Diet control and exercise to reduce weight and improve insulin sensitivity brings about relief. Drugs like ursodeoxycholic acid, metformin, vitamin E and others are tried with varying degrees of success.

BILIARY CIRRHOSIS

This results from prolonged obstruction to the biliary passages anywhere between the canaliculi and the ampulla of Vater. This may be primary or more commonly secondary.

Secondary Biliary Cirrhosis

Obstruction to the larger bile passages by stones, strictures, growths or extrinsic pressure, is the primary mechanism. Cirrhosis develops after a prolonged latent period. Biliary cirrhosis should be looked for if recurrent fever, chills, tender hepatomegaly, leukocytosis, and features of obstructive jaundice develop.

Treatment

Early removal of the primary cause leads to regression. Secondary biliary cirrhosis is prevented by prompt relief of biliary obstruction. Elderly subjects are more prone to develop cirrhosis as a result of biliary obstruction and therefore in them, procedures to relieve obstruction should be undertaken without undue delay.

PRIMARY BILIARY CIRRHOSIS (PBC)

Recent reports from the west suggest that this disease is quite frequent in middle-aged and elderly women. The disease is still considered to be rare in India accounting for 0.6 to 2% of all cirrhosis. Primary biliary cirrhosis is characterized by chronic cholestasis, pigmentation, xanthomatous eruptions, and histological features of chronic nonsuppurative, destructive cholangiohepatitis. The disease is immunologically mediated. There is a familial tendency, the incidence among close relatives is 1000 times more than in the general population.

Pathology

The liver is enlarged in the early stages, later it shrinks, portal hypertension develops late, and the spleen enlarges. 40% show stones in the gallbladder. The pathology is one of lymphocytic cholangitis involving small intralobular bile ducts within the liver. The first step in pathogenesis is immunological attack on biliary radicles, the next step is hepatotoxicity caused by retention of toxic bile acids secondary to cholestasis and loss of bile ducts.

Histologically the smaller bile ducts show epithelial damage and necrosis surrounded by granulomas consisting of histiocytes, CD8 + lymphocytes, plasma cells, eosinophils and giant cells. Fibrosis of the portal tracts progress (stage III) and give rise to frank cirrhosis (stage IV). The larger bile passages are normal. Antimitochondrial antibodies directed against a family of enzymes, especially pyruvate dehydrogenase complex which are inhibited *in vitro* are characteristic and are present in over 95% of cases.

Clinical Features

Classically, the disease affects middle-aged women and starts with fatigue, pruritus and jaundice. Male to female ratio is 1:9. Complications include malabsorption of fat-

soluble vitamins, especially vitamin D, osteoporosis, progressive hepatic failure, and portal hypertension. Copper accumulates in the liver. Unlike Wilson's disease in which copper accumulates in the lysosomes, in primary biliary cirrhosis it is in the cytosol. The disease progresses to end fatally within 5-7 years because of complications like hepatic failure or portal hypertension.

Diagnosis

Clinical suspicion is important in making a diagnosis. Conditions like chronic biliary tract disease, viral hepatitis, other causes of intra and extrahepatic biliary obstruction, toxic damage to the liver, systemic lupus erythematosus and other forms of cirrhosis have to be excluded. Some cases are associated with other autoimmune disorders such as CREST syndrome (calcinosis, Raynaud's phenomena, sclerodactyly, and telangiectasia), Sjögren's syndrome, thyroid diseases and esophageal dysmotility.

In some cases anti-mitochondrial antibodies may not be present; but all other clinical features resemble PBC. In prognosis and response to ursodeoxy cholic acid (UDCA) it is similar to that in classic PBC. Such cases are known as autoimmune cholangitis. It may lead to metabolic bone disease and hepatocellular carcinoma.

Laboratory Diagnosis

Features of obstructive jaundice such as raised alkaline phosphatase and increased serum bilirubin may be obvious. Alanine transaminase (SGPT) may be elevated to different levels, sometimes it may be normal. Serum cholesterol is elevated. Since the HDL fraction is also considerably elevated, the risk of atherosclerosis is relatively less.

Specific test is the demonstration of **antimitochondrial antibodies** in the serum in titers above 1080 in over 95% of the cases. Titers above 1/40 are suggestive.

Other immunological phenomena such as presence of immune complexes (raised levels of IgG and IgM) and abnormalities of complement may be present, but are nonspecific. Around 70% of cases of primary biliary cirrhosis have raised levels of IgM.

Liver biopsy is confirmatory. Serum cholesterol may be high and xanthomas may develop. Median survival after diagnosis varies from 10-16 years.

Treatment

General measures include relief of pruritus by antihistaminics such as diphenhydramine 50 mg given twice daily or cholestyramine 4-8 g/day with breakfast. The diet is adjusted to contain less than 40 g fat per day, supplied as medium chain fatty acids, e.g. coconut. Monthly injection of vitamin D 2.5 mg and vitamin K 10 mg and oral supplementation of calcium gluconate 2-4 g/day serve to

compensate for the malabsorption state. Rifampicin in doses of 150-600 mg/day helps to allay pruritus.

Specific measures are directed:

1. Towards the primary disease, and
2. Towards the complications.

Attempts to treat the liver lesion with corticosteroids have given equivocal results and in many centers this drug is no longer given due to its tendency to worsen osteoporosis. D-penicillamine has shown promise in recent years. In addition to its copper chelating effect, it relieves inflammation in the liver. Dose ranges from 250-900 mg/day. An alternate drug is colchicine given in a dose of 0.6 mg twice daily. Cyclosporine has been employed with partial success. Ursodeoxycholic acid, given in a daily dose of 12-15 mg/kg bw has been reported to arrest progress and bring about relief. Methotrexate given in a dose of 0.25 mg/kg twice a week orally produces resolution of lesions over a period of 6-12 months. The drug is toxic. Interstitial pneumonitis is one of the serious ill-effects. Portal hypertension, if already established, does not respond to medical therapy. This has to be treated on its own merits—if necessary by shunt surgery. If the condition is advanced, hepatic transplantation is indicated.

PRIMARY SCLEROSING CHOLANGITIS

Definition

Primary sclerosing cholangitis (PSC) is an idiopathic inflammatory disorder affecting the intra and extrahepatic biliary system resulting in fibrosis and stricture formation. 80% of cases are associated with inflammatory bowel disease, especially ulcerative colitis. Despite the association between inflammatory bowel disease and PSC, the latter appears to progress independent of each other.

Etiopathogenesis

The etiology and pathogenesis of PSC are unknown. A variety of causative mechanisms have been proposed, including toxins, infectious processes, ischemia, and genetic and autoimmune factors.

Clinical Features

The median age of diagnosis of PSC is 39, males are affected more. The most common symptoms at the time of diagnosis are jaundice, pruritis, and abdominal pain. The onset and progression of symptoms are usually insidious; rarely the disease can present as acute hepatitis like- illness. Loss of weight can occur at an alarming rate. Patients often experience chronic fatigue. Febrile episodes can occur, usually a manifestation of acute cholangitis. Symptoms and signs such as jaundice, pruritis, abdominal pain and fever may remit spontaneously and for prolonged periods. Rarely the initial presentation may be with

complications such as cirrhosis and portal hypertension. About 20-40% of patients are asymptomatic. Jaundice and hepatomegaly are the most common abnormal physical findings, and the spleen is enlarged in about one-third of patients.

Investigations

Typically, the serum alkaline phosphatase (SAP) level is increased three- to five-folds in PSC. Elevation in the SAP level is usually matched by increase in *serum gamma glutamyl transpeptidase* and *5'-nucleotidase levels*. Serum aminotransferases levels are usually elevated. Levels of conjugated bilirubin are increased in jaundiced patients. In others it may be normal. Serum albumin may be low and prothrombin time may be prolonged. Levels of immunoglobulin in the serum are often elevated. About 97% of patients with PSC have at least one autoantibody. The most common antibody is antineutrophil cytoplasmic antibody (ANCA). Other antibodies include anticardiolipin antibodies and antinuclear antibodies. Non-specific markers of cholestasis such as increased serum cholesterol and lipoprotein X may also develop.

The most common characteristic histopathologic changes is “onion skin” fibrosis, which describes the appearance of periductal concentric fibrosis around the interlobular and septal bile ducts. Ludwig has developed a histologic classification for PSC.

1. In stage I: portal hepatitis with or without bile duct abnormalities and cholangitis
2. In stage II: periportal fibrosis or hepatitis may develop.
3. Stage III : characterized by septal fibrosis or bridging necrosis and stage
4. Stage IV: biliary cirrhosis.

Non-invasive abdominal imaging can be suggestive but not diagnostic of PSC. Ultrasonography and CT may detect extrahepatic and intrahepatic ductal dilation, lymphadenopathy and evidence of cirrhosis or mass lesion. MRI cholangiopancreatography is a useful investigation for PSC. ERCP is considered the gold standard for diagnosis. ERCP not only confirms the diagnosis of sclerosing cholangitis, but also provides information about the distribution of the disease and the presence of dominant strictures that may be amenable to interventional therapy.

Complications

The chronic cholestasis of PSC leads to malabsorption of fat and fat-soluble vitamins and secondary biliary cirrhosis, biliary tract calculi, pancreatic disease, and possibly, cholangiocarcinoma.

MANAGEMENT

There is no definite medical, endoscopic, or surgical therapy, except for liver transplantation, which improves

the general health and well being. Though several drugs including antibiotics, glucocorticoids and immunosuppressants have been used from time to time, none showed any survival benefit. Results with ursodeoxycholic acid (UDCA) are encouraging. Intervention such as balloon dilatation and stent placement for strictures are palliative and safe. This can allay acute exacerbations of jaundice, pruritis and cholangitis and improve the quality of life.

Liver transplantation is indicated for patients with the complications of portal hypertension, hepatic failure, worsening cholestasis with cirrhosis, and recurrent cholangitis, refractory to medical or interventional therapy.

The median survival from diagnosis to death or liver transplantation has been estimated to be 12 years. A number of mathematical models have been developed to predict survival and optimal timing of liver transplantation. These are CTP score, Modified Mayo natural history model, Cox regression model and Swedish prognostic index, which may be referred to as further reading.

Liver Transplantation

First performed in 1963, this has become a standard therapeutic modality in several developed countries. In India this facility is available in a few centres only.

Indications

As a curative therapy it is employed in cirrhosis, hepatobiliary neoplasms, biliary atresia, metabolic disorders such as glycogen storage disease (type II), Wilson's disease, alpha-1 antitrypsin deficiency, homozygous familial hypercholesterolemia, sclerosing cholangitis, hepatic vein occlusion and fulminant hepatic failure. In advanced centers the one-year survival is about 70% and around 45% at 2 years. The perioperative mortality (within 30 days) is 30%. Best results are obtained in subjects with primary biliary cirrhosis, sclerosing cholangitis and cryptogenic cirrhosis.

Contraindications include the presence of extrahepatic malignant disease, active replication of HBV despite treatment, presence of irreversible disease in other organs and age above 55 years. The cost of hepatic transplantation is above \$ 70,000.

Liver in Wilson's Disease

Syn: Hepatolenticular degeneration

(see also Chapter 93 pp 591).

Wilson's disease (WD) is named after the British neurologist Samuel Kinnier Wilson who described the familial syndrome of cirrhosis liver with lenticular degeneration in the brain. WD is an autosomal recessive

disorder and a gene for WD has been mapped to chromosome 13 (13q 14). About 200 mutations in the WD gene have been identified.

The fundamental abnormality is impairment of biliary excretion of copper which is the main mechanism to regulate body content of copper. Accumulation of copper in cells leads to cellular damage by free radicals, oxidative stress and depletion of glutathione. Though the metabolic defect is congenital, symptoms occur only after 5 years of age.

Pathology

Hepatic cirrhosis predominates in young subjects, while in older subjects neurological lesions predominate. The liver shows a variety of pathological changes such as periportal fibrosis, submassive necrosis, and macronodular cirrhosis. Liver cells show fatty change, glycogen vacuolation, and multinuclearity. Copper is deposited in the periportal regions in a patchy manner and this is demonstrable by staining with rubianic acid or rhodamine. Wilson's disease is not rare among many communities in India and, therefore, all young subjects presenting with chronic parenchymal liver disease should be screened for this disorder.

Clinical features resemble those of cirrhosis, chronic active hepatitis, fulminant hepatitis, or chronic hepatic failure. Presence of *Kayser-Fleischer ring* is diagnostic.

Serum ceruloplasmin is low (< 20 mg/dL), urinary excretion of copper exceeds $100 \mu\text{g/day}$. Liver biopsy and estimation of hepatic copper are diagnostic. Hepatic

copper $> 250 \mu\text{g/g}$ of dry weight of liver tissue (normal $< 35 \mu\text{g/g}$ liver tissue) is diagnostic.

Course of the disease is steadily downhill ending with cirrhosis, portal hypertension and hepatic failure. Early treatment arrests the progress and prolongs survival. Dietary articles rich in copper such as nuts, liver, shell fish and chocolates should be avoided. Severe cases may require liver transplantation.

Note: Management is described in Chapter 93 pp 592.

Hemochromatosis

(see also Chapter 93 pp 590).

This results from iron overload and the deposition of iron in several organs. The liver is enlarged, firm and tender. Histologically, deposits of iron can be demonstrated in the periportal liver cells. Fibrosis of the portal zone develops. Kupffer's cells are filled with iron. Macronodular cirrhosis develops if the condition proceeds. There is a high risk of developing primary carcinoma. Removal of iron can be achieved by repeated venesection and use of iron chelating agents such as desferrioxamine.

Indian Childhood Cirrhosis

This term was used to describe symptoms of peevishness, anorexia, abdominal distension, failure to thrive, ascites, hepatosplenomegaly and jaundice occurring in children aged 1 to 4 years. With adequate nutritional supplementation most of them recovered without sequelae. At present this entity is not considered as a primary liver disease.

85

Hepatic Failure

K.R. Vinaya Kumar, K.V. Krishna Das

Chapter Summary

Chronic Hepatic Failure 511

Acute Hepatic Failure 515

Hepatic failure is a syndrome characterised by functional failure of hepatic parenchymal cells. It can result from

various liver diseases with different pathological processes. Hepatic failure may be acute and fulminant or subacute and chronic.

CHRONIC HEPATIC FAILURE

This may result from liver cirrhosis, carcinoma, drug toxicity, cholestatic jaundice and surgical obstruction of

the biliary tree. Factors like high protein diet, hypotension, gastrointestinal bleeding, infections, and overdose of sedatives like morphine precipitate the onset of symptoms. Portal-systemic collateral circulation contributes to the development of encephalopathy. The clinical features differ in the acute and chronic forms.

Biochemical Disturbances in Hepatic Failure

In general, the biochemical abnormalities are more marked in acute fulminant hepatic failure than in the chronic form.

The failing liver is unable to convert ammonia into urea and hence ammonia accumulates. Glutamine is synthesized from ammonia and this is the major detoxification pathway to dispose ammonia. Glutamine is synthesized in astrocytes and this causes brain swelling. The degree of brain swelling correlates with the neuropsychiatric abnormalities. Since amino acids are not further metabolized, aminoaciduria occurs. Synthesis of albumin is impaired. Hypoalbuminemia leads to ascites and dependent edema in chronic liver disease. Vitamin K-dependent coagulation factors (especially prothrombin) are reduced or not made functional, and this leads to generalized bleeding tendency.

9

Causes of Chronic Hepatocellular Failure

- 1. *Predisposing factors*
 - a. Cirrhosis—all types.
 - b. Cholestatic jaundice.
 - c. Drug toxicity.
 - d. Surgical obstruction of biliary tract.
 - e. Carcinoma—primary and metastatic.
- 2. *Precipitating factors*
 - a. High protein diet.
 - b. Gastrointestinal bleeding, hypotension.
 - c. Hepatotoxic drugs or alcohol.
 - d. Intense diuretic regimen leading to hypokalemia and hyponatremia.
 - e. Infections.
 - f. Surgical intervention and trauma.

Hepatic Encephalopathy

This is a neuropsychiatric syndrome that occurs in the presence of significant hepatocellular dysfunction and which has a full potential for reversal. The condition may be full-fledged or mild or even subclinical, occurring in 30-40% of cirrhotic patients.

This is associated with portal systemic shunting of blood. The blood is diverted through preformed collateral channels in portal hypertension. In acute hepatic failure, the liver cells do not metabolize the contents of the portal blood and hence these pass unaltered into the hepatic veins and further to the systemic circulation, thereby in effect producing a functional shunt. The nitrogenous products absorbed from the colon which reach the brain unaltered by hepatic metabolism lead to neurological dysfunction. The toxic products include ammonia and

several pharmacologically active amines produced in the intestines by bacterial action and other products of protein digestion. Several of them have been implicated. The blood brain barrier is deranged. As a consequence these products reach the brain.

GABA and Endogenous Benzodiazepines

Gamma amino benzoic acid (GABA) and endogenous benzodiazepines probably play their roles in the pathogenesis of this disorder. GABA and benzodiazepines are synthesized by the gut bacteria. The former has no major role in hepatic encephalopathy. It is possible that endogenous benzodiazepines which accumulate in hepatic encephalopathy play a major role in neuroinhibition.

The ill-effects of ammonia and other amines are further aggravated by alkalosis, hypoxia, hypokalemia, hypoglycemia and increase in the concentration of fatty acids in serum. Even though several biochemical abnormalities have been identified, the exact pathogenesis is still not clearly known. The blood levels of ammonia or other possible toxic metabolites do not correlate with the mental state, but serial estimations of blood ammonia can be used to monitor the effect of treatment. These metabolites do not cause neurological dysfunction in normal subjects. This fact suggests that an abnormal susceptibility of the brain to toxic metabolites is an important factor in leading to the clinical picture. The CSF is initially normal, but late in the disease, protein, glutamic acid, and glutamine may be increased.

CLINICAL FEATURES

The onset is insidious with general loss of health, fatigue and weight loss. Jaundice may occur, but this is not constant. The early stage may be missed if clinical suspicion is not high.

Hyperkinetic circulation occurs which manifests as high volume pulse, warm extremities, tachycardia, and ejection systolic murmur over the pulmonary area. It is likely that the circulatory disturbances are due to opening up of arteriovenous shunts and the effect of circulating vasodilator substances.

Neurological Manifestations Predominate

- 1. **Alteration of consciousness** ranging from confusion to coma may develop. Sleep rhythm is altered early, with sleep during day and insomnia at night. Personality changes may be marked and these could be mistaken for primary psychiatric disorders.
- 2. **Parkinsonian features**, especially akinesia may develop. Constructional apraxia develops which can be demonstrated by making the patient to draw along the Reitan number chart (Fig. 85.1).
- 3. **A diagnostic physical sign is flapping tremor (asterixis)** elicited by holding the hands outstretched

Fig. 85.1: Reitan number chart for trail making test

with extension of the wrist. The fingers and wrist show coarse tremors comparable to the flap of a bird's wing. In early cases the tremor (flap) is confined to the extremities but later on it extends to the proximal joints of the limbs, trunk, jaw, neck, and tongue. Flapping tremors are bilateral, asynchronous on both sides and absent at rest. The tremors fluctuate in severity with changes in hepatic function.

3. **Electroencephalogram:** The EEG mainly shows slowing of rhythm from alpha (8-13 cps) to the delta (4 cps) range. Other abnormalities may also occur. Diffuse bilateral high voltage slow waves occur.

The EEG changes closely reflect hepatic functional impairment. The EEG abnormalities can be precipitated by giving a high protein diet. As hepatic function deteriorates, coma sets in.

MRI show hyperintensity of globus pallidus on T₁ weighted imaging.

Vascular phenomena Cyanosis occurs in one-third of patients due to hypoxia. Intrapulmonary arteriovenous shunts develop. The diffusing capacity of the lung is also impaired.

Finger clubbing, palmar erythema and spider nevi are common. Erythematous patches may occur over several parts of the body, especially the chest wall and supraclavicular regions. Arterial spiders are quite suggestive of chronic hepatic failure, though they can occur less commonly in other conditions such as pregnancy and estrogen therapy. A few may occur even in normal subjects. The upper limbs, and the mucous membranes of the nose, mouth and gastrointestinal tract are the sites of predilection. An arteriole comes to the surface and breaks up into capillaries which radiate like the legs of a spider. The central arteriole may pulsate in large nevi. Pressure over this vessel blanches the whole spider and on releasing the pressure blood fills from the center to the periphery. Liver disease should be suspected

Fig. 85.2: Male 50 years alcoholic cirrhosis, hepatic failure
Note spider nevi on the chest arrows

when they are numerous, and fresh spiders are appearing. The vascular phenomena of liver failure have been attributed to hyperestrogenism (Fig. 85.2).

Other features: Fotor hepaticus develops in some patients with severe hepatic failure. It is a slightly fecal odor attributed to the presence of methyl mercaptan and dimethyl sulfoxide in breath. This is present more often in acute hepatic failure. However, this sign is not prominent in Indian subjects when compared to those from the west.

Low grade fever attributable primarily to the liver disease may be present. Gram-negative bacteremia and low grade septicemia are common due to shunting of the blood through collateral channels. Spontaneous bacterial peritonitis and endocarditis may occur with atypical presentations.

Skin changes occur in long-standing cases. They include the appearance of white spots, white nails (leuconychia), loss of hair and pigmentation.

Endocrine disturbances: Males develop hypogonadism which presents as loss of libido and impotence and feminization manifested by gynecomastia and loss of facial hair. In females endocrine symptoms are less pronounced. The cause of feminization is still not fully understood.

Ascites: In chronic hepatic failure due to cirrhosis, when hypoalbuminemia and portal hypertension develop, ascites invariably occurs. The kidney plays a part in the development of ascites. Cirrhosis leads to a spectrum of renal abnormalities ranging from retention of sodium to full fledged hepatorenal syndrome.

Drug metabolism: The detoxification function of the liver is impaired and elimination of drugs becomes defective. Even small doses of morphine produce profound sedation and tip the patient into hepatic coma. Several other drugs such as tetracycline may reach toxic levels in these patients. As the coma deepens, signs of upper motor

neurone lesion, such as exaggeration of deep reflexes, patellar and ankle clonus and Babinaski's sign develop.

Hepatic encephalopathy has been graded into four grades.

Grade	Characteristics
1.	Altered sleep patterns, altered mood, irritability, inability to maintain attention
2.	Lethargy, altered speech, increased memory loss, dysarthria
3.	Progressive stupor, decreased level of consciousness but responsive to stimuli
4.	Coma, unresponsive to painful stimuli

Prognosis

The prognosis depends upon the underlying condition, the presence of precipitating factors, and the management of the case.

Precipitating factors: Following are the precipitating factors:

1. High protein diet.
2. Gastrointestinal or other hemorrhage, extravasated blood in the gastrointestinal tract acts as a source of nitrogenous products and is more harmful in this regard than other proteins on a weight for weight basis.
3. Hepatotoxic drugs like morphine, ammonium salts and alcohol.
4. Intense diuretic regimen which produces hypokalemia and hyponatremia.
5. Infections.
6. Minor or major surgery including liver biopsy and abdominal paracentesis, and
7. Progressive deterioration of hepatic function.

If the precipitating factors are avoided and the patient is properly managed, satisfactory physical and mental state can be maintained for prolonged periods. Cases with a removable precipitating factor do better than those in whom the hepatic failure is the result of advanced liver disease.

MANAGEMENT

The aim of treatment is to improve hepatic function, relieve symptoms, and prolong useful life.

Symptomatic treatment: The patient should be put to bed rest in the acute and subacute stages.

Diet: The total dietary intake should be 2000-2500 Cal. and the amount of protein has to be adjusted so as to give the maximum possible nourishment without precipitating portal systemic encephalopathy. This has to be determined by trial and error. Vegetable proteins are tolerated better than animal proteins and they may be preferred. On an average, many patients tolerate about 40 g proteins daily.

Considerable persuasion may be necessary to make the patient eat despite the anorexia. Adequate intake of food definitely brings about improvement. Hematinics such as iron, folate, and other vitamins should be given. The hemoglobin level has to be maintained above 10 g/dL, if necessary by transfusion.

Sedatives like morphine and paraldehyde precipitate coma and these should be avoided. While long-acting barbiturates like phenobarbitone which are mainly excreted by the kidney are tolerated, the short-acting ones like pentobarbitone and thiobarbitone which are mainly metabolized by the liver should be avoided. Oxazepam and diazepam may be used.

Treatment of Hepatic Precoma and Coma

Diet: Proteins should be totally withdrawn. Carbohydrates are given orally or parenterally to supply 1500-1600 CAL in 24 h. As the condition improves proteins are added to the diet.

Antibiotics: Broad spectrum antibiotics which sterilize the intestinal flora prevent bacterial breakdown of the products of protein digestion and the formation of toxic products. The ideal drug is neomycin 4-6 g/day given in divided doses. Being nonabsorbable, it reaches the colon in adequate concentrations to exert its effect. Ampicillin in a dose of 2 g/day in four divided doses is a suitable alternative.

Lactulose: This unabsorbable disaccharide is broken down by bacterial flora into lactic acid and small amounts of acetic acid when it reaches the ileum and cecum. The pH value of the colonic contents is lowered. At this low pH the lactose splitting organisms overgrow, suppressing the protein splitting organisms like *bacteroides* which produce ammonia. At a dose of 10-30 mL given thrice daily, lactulose is very effective in relieving chronic portal systemic encephalopathy. *Lactitol*, which is a derivative of lactulose, has a better taste and is more acceptable.

Purgatives: Proper evacuation of bowels helps in improving the mental state whereas constipation tends to worsen it. Purgation is achieved by the administration of magnesium sulfate 15-30 g orally. Lactulose itself acts as purgative. Enemas are employed to clear the bowels when purgation is contraindicated. The enemas should be at mildly acidic or neutral pH to prevent the absorption of ammonia. Bowel wash with saline or 1% dextran solution twice a day helps to clear the colon and this measure is effective in improving the mental state.

Attention to Precipitating Factors

1. *Intestinal blood loss* should be treated by quantitative replacement of fresh blood. Blood should be removed from the intestines by aspiration and purgation. Oral broad spectrum antibiotics should be given to prevent the formation of ammoniacal products.

- If the coma has been precipitated by the use of sedatives, the *appropriate antidote* should be used, e.g. nalorphine in the case of morphine.
- Electrolyte imbalance* should be corrected. Potassium deficiency can be prevented and mild cases treated by the use of copious administration of fruit juices, and oral potassium chloride 2 g every 6 h. Intravenous administration of potassium is done if serum potassium is below 3.5 mmol/L.

Dopamine agonists: In some patients levodopa given in a dose of 0.5 g 6 h brings about benefit. Similar effect has been seen with bromocriptine in a dose of 15 mg/day.

Flumazenil

Flumazenil is a GABA benzodiazepine receptor antagonist. In controlled trials it is found to improve hepatic encephalopathy significantly.

Follow-up: Improvement should be monitored clinically and by objective evaluation with EEG, trail-making test and blood ammonia levels. Irreversible hepatic failure is an indication for hepatic transplantation.

Subclinical Hepatic Encephalopathy

Clinically there is no change in the level of consciousness; but abnormality is detected during psychomotor testing such as trail making test. The reaction time is prolonged and visual evoked potentials may be delayed. Such patients are unfit for handling fast mechanisms and for jobs such as driving vehicles and piloting aircraft.

ACUTE HEPATIC FAILURE (AHF)

Syn: Fulminant hepatic failure

Definition

Altered mental status with coagulopathy occurring in the setting of acute liver disease unaccountable by other obvious causes should suggest the possibility of acute hepatic failure (AHF). Encephalopathy is an essential feature for diagnosis. The term fulminant liver failure denotes the occurrence of hepatic encephalopathy developing within eight weeks of onset of liver disease. If the condition develops later on in the illness (even up to 26 weeks) it is called sub-fulminant or late onset hepatic failure. AHF is a serious clinical state with mortality reaching upto 80%.

Pathology

Massive necrosis of liver cells leads to sudden impairment of liver function. Cerebral symptoms are caused by hepatic encephalopathy as well as development of cerebral edema which occurs in upto 80% of cases. Coning of brainstem may occur.

Causes of Acute Hepatic Failure

- Viral hepatitis**—B, D, E and A and other viruses can cause AHF. Over 70% of cases of AHF are caused by viral infections. Overall incidence of AHF in viral hepatitis is around 1%. Frequency of AHF in different types of viral hepatitis is given below:

HAV	0.35%. AHF is more common in the elderly and drug users. Prognosis is relatively better with survival over 60%.
HBV	1%.
HCV	By itself, it is rare to produce AHF. In combination with HBV, it predisposes to AHF.
HDV	In combination with HBV it increases the frequency and severity of AHF.
HEV	This is likely to cause AHF, especially in pregnant women

 Other viruses such as CMV, EBV and herpes viruses 1, 2 and 6 cause AHF especially in immunocompromised subjects.
- Drugs**—halothane, monoamine oxidase-inhibitors such as iproniazid and phenelzin, isoniazid.
- Poisoning**—paracetamol, mushrooms, weedicides, copper sulfate, alcohol, organic solvents.
- Shock**—surgical shock or gram-negative toxic shock.
- Occlusion of major hepatic veins** (Budd-Chiari syndrome)
- Acute fulminant biliary tract infection with obstruction.
- Other Causes**
 - Disseminated malignant deposits obstructing sinusoidal blood flow, e.g., Cancer of stomach and breast, oat cell tumour of lung, myeloblastic leukemia, and carcinoids.
 - Miscellaneous causes: Acute veno-occlusive disease, bone marrow transplantation, Wilson's disease, acute fatty liver of pregnancy.

Clinical Features

Neurological manifestations predominate in this disorder. They are much more varied than in chronic hepatic failure. Flapping tremors, headache, change of personality and behavior, delirium, decerebrate rigidity, convulsions, abnormalities of ocular movements and coma occur in varying combinations. Finally the majority of cases go into coma. For clinical purposes the coma is graded from I to V.

Grading of Coma (Sherlock S)

Grades

I	Confused, altered mood or behaviour, psychometric defects
II	Drowsy, inappropriate behaviour
III	Stuporous, but able to speak and obey simple commands, inarticulate speech, marked confusion
IV	Coma
V	Deep coma and no response to painful stimuli

The light reflex and the plantar response are unaffected till late in the disease.

The patient is often jaundiced. Brainstem function is impaired and this manifests as irregularity of respiration, **515**

circulatory disturbances and hypotension. Generalized bleeding tendency occurs in most cases. This manifests as bleeding from the mucous membranes, gastrointestinal tract, skin and injection sites. Prothrombin time is prolonged. Factors II, V, VIII, IX, and X are reduced. Thrombocytopenia may develop in some. Other complications include pancreatitis, shock and circulatory failure.

Renal symptoms: Oliguric renal failure occurs as a result of hepatorenal syndrome in upto 50% cases.

Other general symptoms: Due to the increasing intracranial pressure there is reflex hypertension and bradycardia (Cushing's reflex). Hypoglycemia is a common accompaniment. Superadded infections develop if the coma persists for a few days or more.

Depending on the duration, AHF can be subdivided into hyperacute, acute and subacute (Table 85.1).

TABLE 85.1

Clinical feature	Hyperacute AHF	Acute AHF	Subacute AHF
Encephalopathy	+	+	+
Duration of acute disease	0-7 days	8-28 days	29-72 days
Cerebral edema	Common	Common	Infrequent
Prolongation of prothrombin time	+++	++	+
Rise in serum bilirubin	++	+±	+
Prognosis for recovery with treatment	moderate	poor	poor

Biochemical changes: Urine may show bile pigments, increased urobilinogen and amino acid crystals such as leucine and tyrosine.

The blood sugar is lowered. Serum bilirubin is increased. Serum albumin may be lowered as the disease progresses. Elevation of aspartate and alanine transaminases occurs in the early phase. As hepatic necrosis advances, the levels of these enzymes may even fall. Prothrombin time is prolonged. Blood ammonia level may be raised.

Complications

These include cerebral edema, renal failure, bacterial infections, circulatory failure, hemorrhage and hypoglycemia.

Course and Prognosis

If the coma is of grade IV or V, mortality is 75-80%. The prognosis is worse in females, older subjects and those with longer duration of coma. In those that recover, cirrhosis liver does not usually develop. It is essential to

TABLE 85.2

Adverse prognostic factors in AHF

Prothrombin time exceeding 100 secs, irrespective of the grade of encephalopathy or any three of the following:

1. Age below 10 and above 40 years.
2. AHF caused by non-A non-B hepatitis, halothane or allergic drug reactions.
3. Duration of jaundice before onset of encephalopathy, more than 7 days.
4. Prothrombin time over 50 secs and
5. Serum bilirubin level over 17.5 mg/dL.

Death is usually due to shock, respiratory failure, bleeding, renal failure, cerebral edema or infection.

assess the prognosis early in the disease, in order to decide the need for liver transplantation (Table 85.2).

MANAGEMENT

1. The precipitating causes should be looked for and eliminated. Proteins are totally withdrawn from the diet. Neomycin, lactulose, magnesium sulfate and bowel washes should be started.
2. The patient should be nursed as a case in deep coma. Nutrition is supplied parenterally. Continuous infusion of 10% glucose or intermittent administration of 50% glucose is necessary to prevent hypoglycemia. Sedation must be avoided, if possible. If the patient becomes restless, a sedative antihistaminic like diphenhydramine or buclizine may be used. Barbitone sodium has to be given parenterally if a patient becomes violent and unmanageable. Measures to avoid rise in intracranial tension include artificial hyperventilation, infusion of intravenous mannitol 0.5 g/kg bw as a 20% solution within 10-15 minutes, hemodialysis and hemoperfusion.
3. Infection has to be diagnosed early and treated with broad spectrum antibiotics like third generation cephalosporins such as cephalexime, ceftriaxone, ceftazidime and others.
4. **Electrolytes:** Generally serum sodium and potassium are low. Hyponatremia may become severe as a preterminal phenomenon. Excess sodium should not be supplemented unless there is evidence of sodium loss, but potassium should be supplemented orally or parenterally. Serum calcium tends to be low and this is attributable to coexistent hypoalbuminemia and pancreatitis. Intravenous calcium gluconate (10%) is administered to make up the serum calcium levels to normal.
5. Renal failure may require dialysis.
6. Bleeding due to vitamin K deficiency may be allayed by the intramuscular administration of vitamin K 10 mg daily, but if the bleeding is due to hepatic functional impairment vitamin K is not beneficial. Such cases have a poor outcome. Fresh blood, coagulation factor concentrates or fresh plasma may be required at times.

7. The principles employed in the management of chronic hepatic failure have to be followed as the condition improves and the patient's chances of survival become brighter.

Artificial Liver Support

The principle is similar to hemodialysis in renal failure. The aim is to maintain or support liver function artificially till the patient's liver recovers or a donor liver is available for transplantation. The most effective bioartificial liver (BAL) model is based on the principle that viable hepatocytes are maintained in a chamber through which blood is passed through permeable artificial capillaries (to favour exchange of plasma components). Several of such extracorporeal devices are under trial with encouraging results.

Charcoal hemoperfusion (charcoal removes water soluble toxic metabolites) and Rhone-Poulenc hemodialysis system using special polyacrylonitrile membrane which removes middle molecules up to a molecular weight of 5000 KD.

Hepatocyte Transplantation

This is another procedure under trial with favourable results. Unlike liver transplantation, donor hepatocytes can be obtained more readily and the procedure is technically easier.

In experienced hands and advanced centres all these have shown temporary benefit but none has been accepted universally. At present these are of value in tiding over a crisis in a patient with reversible hepatic disease and also for the preoperative preparation before hepatic transplantation. *Hepatic transplantation* should be considered as an emergency procedure if a donor organ and facilities for surgery are available.

Prognostication in cirrhosis liver which helps to determine the priority for liver transplantation.

Conventionally Child Pugh Turcotte classification is used where 1-3 scores are given to five parameters-serum bilirubin, serum albumin, ascites, encephalopathy and

prothrombin time. A score of 5 and 6 is classified as child's A, 7,8 and 9 as child's B and 10 or more as child C. The prognosis for survival worsens as the class moves from A to C. It has the disadvantage of lack of proper discrimination in later stages of liver disease for which another scoring system has been recently introduced. The modified end stage liver disease, (MELD) score is based on serum bilirubin, prothrombin time (INR) and serum creatinine for which different weightages are given. The system is currently under validation.

In the case of hepatic cancer, additional points are given to facilitate early transplantation. Over the previous decade liver transplantation is being done in India with successful results. Upto the end of 2003, 37 liver transplants were done; in Delhi, Chennai, Vellore, Hyderabad and Bangalore. At present this surgery is being done with greater success. Liver transplantation can be done with liver obtained from cadavers or living donors. In the latter case part of the donor's liver from the right lobe is removed for transplantation. Postoperatively the donor's liver re-grows and makes up the volume of the organ.

Major Indications for Liver Transplantation

1. End stage liver disease
2. Acute fulminant liver failure
3. Hepatocellular carcinoma
4. Large benign tumours such as hemangioma
5. Biliary cirrhosis with intractable pruritus, and
6. Metabolic disorders

HLA haplotyping and detailed immunological testing are not required. Blood group compatibility and physical factors such as size of the transplant are of importance in cross matching. Post transplantation immunosuppressant regimen consists of tacrolimus, cyclosporine, azathioprine or mycophenolate mofetil with or without corticosteroids. Operative mortality is around 5% and one year survival exceeds 80% in most centers. In the presence of renal failure concomitant renal transplantation is also needed. The long term survival depends also upon the primary condition for which transplantation was done.

Portal Hypertension

K.R. Vinaya Kumar, K.V. Krishna Das

Chapter Summary

General Considerations 518
 Portal Hypertension in Cirrhosis 518
 Porto-pulmonic Syndrome 522
 Extrahepatic Portal Hypertension (EHPH) 522
 Noncirrhotic Portal Fibrosis 522

General Considerations

9

The superior mesenteric and splenic veins join to form the portal vein which divides initially into the left and right branches and thereafter, in a dichotomous fashion. The portal blood is drained into the hepatic sinusoids. Major branches of the portal vein do not have valves. The abdominal parts of the alimentary tract, spleen, pancreas, and gallbladder drain into the portal system. The portal venous flow is 1000-1200 mL of blood/minute. In the normal liver the whole of the portal blood passes through the sinusoids and is drained by the hepatic veins into the inferior vena cava. When onward flow of blood is obstructed, portal vein radicles develop extensive collaterals with systemic veins so that even more than 80% of its blood can be drained into the systemic circulation without passing through the liver. Normal pressure in the portal vein is 7 mm Hg. Portal hypertension results from obstruction to onward flow of portal blood. The term “portal hypertension” is applied when the portal venous pressure exceeds 12 mm Hg.

Classification

Portal hypertension can be classified in different ways. Depending on the site of obstruction in relation to the hepatic sinusoids, it may be divided into two types—*presinusoidal* and *postsinusoidal*.

Presinusoidal Extrahepatic: Portal venous obstruction due to any cause or splenic vein occlusion. Intrahepatic: All types of cirrhosis, noncirrhotic portal fibrosis, schistosomiasis, myelofibrosis.

Postsinusoidal Major hepatic vein obstruction (Budd-Chiari syndrome).

Obstruction to small radicles of hepatic vein—veno-occlusive disease.

Generalized rise in inferior vena caval pressure, e.g. right-sided heart failure, constrictive pericarditis and pericardial effusion.

The two most common causes of portal hypertension are mechanical obstruction to venous outflow in the liver by nodules developing in hepatic cirrhosis and extrahepatic occlusion of the portal vein. In many cases portal hypertension remains silent till complications become visible. The portal blood normally carries oxygen and hepatotrophic factors into the liver. When portal blood is shunted away, the liver depends more and more on hepatic arterial blood for oxygen supply and it undergoes functional impairment and atrophy. Bacteremias develop since the portal blood passes into the systemic circulation without being filtered by the hepatic macrophage barrier. Entry of the products of digestion directly into the systemic circulation without being metabolized by the liver hastens the onset of portal systemic encephalopathy.

Rise in portal pressure tends to favour ascites when other factors like hypoproteinemia and sodium retention also develop.

PORTAL HYPERTENSION IN CIRRHOSIS

In cirrhosis the development of portal hypertension is the result of different complex mechanisms. The regenerating nodules of cirrhosis distort, obstruct and reduce the vascular bed. Obstruction occurs at all levels from the portal zones through the sinusoids to the hepatic venous outflow. The regenerating nodules derive their nourishment from the hepatic artery since they have no portal blood supply. Direct communications between the hepatic artery and portal radicles develop in cirrhosis and these serve to transmit arterial pressure to the portal venous system.

Clinical Features

Signs of portal hypertension include asymptomatic splenomegaly, gradual development of portal systemic

Fig. 86.1: Portal hypertension—barium swallow X-ray showing esophageal varices. Note the longitudinal filling defects caused by the dilated veins

collateral veins and bouts of hematemesis or melena. In some cases chronic blood loss due to oozing of blood leads to iron deficiency anemia.

The Common Sites for Portal-systemic Collaterals

- In the lower end of esophagus and gastric fundus, left gastric and short gastric veins communicate with esophageal veins. These form esophageal and gastric varices and are responsible for fatal hematemesis.
- The veins of the abdominal wall become prominent and they radiate from the umbilicus. Rarely they may form a “*caput medusae*” around the umbilicus. The direction of blood flow is the same as in the normal veins of the abdominal wall, but the flow is considerably increased. Blood from the portal vein is brought to the abdominal wall through the paraumbilical veins and other veins in the falciform ligament and these are drained by the abdominal veins (see Fig. 84.3 on pp 506).
- Communication between the inferior mesenteric veins and the hemorrhoidal veins results in the formation of varices in the rectum. These varices are distinct from hemorrhoids. The former may regress when the portal hypertension is relieved.
- Hepatic veins communicate with diaphragmatic veins, veins in the leinorenal ligament and omentum, and venous collaterals developing in the scars of previous laparotomies.
- Portal blood may be drained to the left renal vein from the splenic vein directly or through collaterals in the diaphragm, pancreas, stomach, or left adrenal. This blood passes mainly into the superior vena cava through the azygos and hemiazygos systems. A small

Fig. 86.2: Esophageal varix endoscopic view. Note: dilated veins in the esophagus (arrow)

quantity of blood enters the inferior vena cava and even into the pulmonary veins.

In addition to the classic sites, other venous collaterals may also develop in extrahepatic portal obstruction.

The severity of portal hypertension and its cause have to be determined by investigations.

The portal pressure can be measured by the following methods:

- Intrasplenic pressure* can be directly measured by a needle introduced percutaneously or during surgery into the spleen.
- By *umbilical vein catheterization*.
- By *transhepatic portal vein puncture*.
- Wegged hepatic venous pressure* can be measured by a catheter introduced through a hepatic venous radicle until it gets arrested. This pressure represents the sinusoidal venous pressure. Normal wedged hepatic pressure is 5-6 mm Hg which may go up to 20 mm Hg in portal hypertension.

The portal systemic blood flow can be estimated by radio-isotopic methods.

Demonstration of the Collaterals

- Esophageal varices:** These stand out prominently in a properly made barium swallow picture. These can be seen directly by endoscopy. Rectal varices can be visualized by proctoscopy (Figs 86.1 and 86.2).
- Percutaneous trans-splenic portal venography:** Radio-opaque dye is injected into the splenic pulp. This visualizes splenic and portal veins and their collaterals. The dye can be traced up by proper timing of the pictures. Deep jaundice and prolongation of the prothrombin time are contraindications for this procedure since the risk of bleeding is high.
- Scinti-photo splenoportography:** This is an isotopic method by which serial scans are made using a gamma camera after injection of ^{133}Xe (Xenon) or $^{99\text{m}}\text{TcO}_4$ (technetium) into the spleen. The venous flow pattern can be traced.

4. **Selective visceral angiography:** The celiac axis is catheterized and dye injected. The contrast material flowing into the splenic artery returns through the portal vein which is visualized. Similarly superior mesenteric artery can be catheterized.
5. **Selective venous catheterization:** Umbilical vein catheterization and injection of contrast material visualizes the portal venous system.
6. **Transhepatic portography:** The portal vein is visualized by injecting dye through a cannula introduced through the liver.
7. **Ultrasound study, Doppler and CT scan:** These are elegant methods which delineate the portal vein and its major branches. Dilatation, occlusion and deformity can be made out but the results are poorer in comparison to direct visualization by phlebography. In the ordinary case all these advanced procedures are not necessary for diagnosis, but proper evaluation is essential when surgery is contemplated.

BLEEDING ESOPHAGEAL VARICES

Causes which precipitate bleeding are not clearly known but in some cases ingestion of aspirin or similar drugs and upper respiratory infections are responsible. The bleeding may be dramatic and fatal if left untreated, or more often, it may be a continuous ooze. This is followed by ascites, hepatic coma, and hepatocellular failure. Immediate effects of blood loss are shock and rapid deterioration of liver function. Reduction in hepatic arterial flow results in necrosis of liver cells which depend upon the hepatic arterial supply. Blood in the gastrointestinal tract acts as a source of toxic nitrogenous products and this precipitates hepatic coma. The common site for rupture of the varices is within 7 cm of the lower end of the esophagus. Rupture is mostly caused by rise in the intravariceal pressure and disruption of the venous walls. Even in patients with esophageal varices, in about a third, bleeding may be from other sites such as peptic ulcers, gastric erosions and esophageal tears (**Mallory-Weiss syndrome**). These have to be identified in order to institute effective therapy.

Portal hypertensive gastropathy: This is a change brought about in the gastric mucosa as a result of ectasia of submucous capillaries and veins, without any inflammatory change. Relief of portal hypertension leads to regression of this condition as well (Fig. 86.3).

Management of Variceal Bleeding

Variceal bleeding is a medical emergency and carries a mortality of about 35%. It is best managed in the intensive care units of a tertiary level hospital. Oxygen inhalation through an airway is started. The patient should be given first aid as for any major upper gastrointestinal bleed in order to stabilize his condition. This consists of IV

Fig. 86.3: Stomach bleeding portal gastropathy

fluids and fresh blood replacement, sedatives to allay anxiety and IV injection of H_2 receptor antagonist such as ranitidine 50 mg, or a proton pump inhibitor such as pantoprazole 40 mg, over a period of 2-5 minutes. Large doses of oral antacids such as aluminium hydroxide and magnesium trisilicate 1-2g initially and repeated hourly to reduce bleeding from co-existing ulcers, in the esophagus and stomach. The patient should be transported to a medical centre with facilities for specialized care, as soon as possible, preferably with the blood transfusion in place.

Principles of Management

1. To stabilize the patient's vital functions
2. To diagnose the site of bleeding
3. To arrest the bleeding
4. To prevent re-bleeding and
5. Secondary prevention

Stabilizing the Patient

The patient requires rapid intravenous fluids, blood transfusion and oxygen inhalation to stabilize the vital functions. CVP monitoring is essential. A moderate or severe bleed usually requires three units of fresh blood transfusion. Over-transfusion increases the risk of bleeding further. Systemic diseases such as diabetes, infections, electrolyte abnormalities and abnormalities of coagulation also require attention.

Identifying the Site of Bleeding

After stabilizing, the patient should be taken up for emergency esophagogastrosocopy. This is technically difficult during the emergency and should be done by a skilled endoscopist in a well equipped center with therapeutic facilities. The bleeding sites may be single, multiple or diffuse.

Arrest of Bleeding

Methods include

1. Pharmacotherapy
2. Balloon tamponade

3. Endoscopic interventions and
4. Surgery.

Pharmacotherapy

Somatostatin: It is given as an initial intravenous infusion for 3-5 days at the rate of 250 mcg/hr. It controls bleeding in 80-85% of patients and prevents the re-bleeding also.

Octreotide, which is the analogue of somatostatin is equally effective. The initial bolus dose is 50 mcg followed by continuous infusion at the rate of 50 mcg/hr. Vasopressin given in an IV bolus dose of 20 units over a period of 10-15 minutes at 4 hour intervals used to be the drug of choice prior to the use of somatostatin, which is more effective. Vasopressin also reduces portal pressure but troublesome side effects such as angina, bowel ischemia and gangrene of the toes may develop at times. **Terlipressin** (Triglycyl lysine vasopressin) is a vasopressin analogue which is more effective and has less of side effects.

Vapreotide and **lanreotide** are newer analogues of somatostatin which have also been introduced. The dose is 250 µg as bolus followed by 250 µg hourly as continuous infusion for upto five days.

Balloon Tamponade

Sengstaken Blackmore or Linton Nechlon tube may be useful for temporary tamponade while the patient is being transported to a higher centre. It is not as effective as somatostatin or endoscopic interventions. It is not used unless there are exceptional circumstances.

Endoscopic Interventions

Endoscopic sclerotherapy (EST) can arrest 85 to 90% of active bleeding. The common sclerosants used for esophageal varices are sodium tetradecyl sulfate (STD), polydocenol and alcohol. The gastric varices require cyanoacrylate for injection. Endoscopic variceal ligation (EVL) is a better procedure than EST to prevent variceal bleeding (Figs 86.4 and 86.5).

In this procedure the varices are sucked into a hood attached to the distal end of the endoscope and a rubber band applied at its base. Transjugular intrahepatic portal systemic shunt is a catheter intervention procedure that may be undertaken to reduce portal venous pressure as an emergency measure.

Surgery

The emergency surgical procedures to stop variceal bleeding carry high mortality. The same result can be achieved with endoscopic procedures. Hence the role of surgery is limited.

Long-term Prophylaxis

Large varices and varices which have bleed previously require obliteration with EVL or EST. Drug therapy can lower portal pressure on a long-term basis. The drugs useful for prophylaxis are nonselective beta-blockers such

Fig. 86.4: Technique of sclerotherapy for esophageal varices A—Esophageal varix, B—Intra-variceal injection, C—Para-variceal injection

Fig. 86.5: Technique of variceal ligation of esophageal varices. B—varix sucked into the housing cylinder

as propranolol 80 to 160 mg/oral daily or nadolol 80 mg oral daily and long acting nitrates such as isosorbide mononitrate 20-40 mg/day. Portacaval shunt surgery may be useful in selected cases of extrahepatic portal hypertension and noncirrhotic portal fibrosis. This surgery is not done as a first line procedure at present.

Indications for Portacaval Anastomosis

1. At least one episode of severe hemorrhage in subjects in whom esophageal varices have been demonstrated endoscopically and portal hypertension, recorded.
2. Preferably below 40 years of age, since survival rates are lower in cases above 50 years.
3. Adequate hepatocellular function indicated by serum bilirubin below 2.5 mg/dL, serum albumin above 3 g/ dL, and absence of established ascites and even transient encephalopathy.
4. Presence of stable and nonprogressive hepatic lesion.

In ideal cases over 50% survive in reasonable health at the end of 5 years. Relative contraindications include moderate or advanced hepatic failure and congenital or other acquired abnormalities of the portal vein. Portacaval shunting should not be undertaken if future liver transplantation is to be undertaken.

Long-term complications of portacaval anastomosis include deterioration of hepatic function, portal systemic encephalopathy, occlusion of the shunt, shunt myelopathy (paraplegia due to demyelination of the pyramidal tracts), chronic extrapyramidal and cerebellar syndromes and hemosiderosis.

Porto-pulmonic Syndrome

Significant pulmonary hypertension is seen in about 4-6% of cirrhosis patients with portal hypertension. Pulmonic vasculature shows medial hypertrophy, endothelial hyperplasia and luminal thrombosis. The changes may be due to the vasoconstrictors escaping hepatic metabolism in cirrhosis with porta-systemic anastomosis. Thromboembolism from the dilated and tortuous paraesophageal and mediastinal varices to the pulmonic vascular bed may be another mechanism.

Development of PPS seriously shortens the life span in cirrhosis patients. There is no effective treatment. Epoprostanol (prostacyclin) and nitric oxide inhalations show some clinical benefit. Portosystemic shunts are also tried. Severe PPS is a contraindication for liver transplantation.

9

Portal hypertensive enteropathy is a recently identified manifestation of portal hypertensive intestinal vasculopathy. Endoscopic findings include bleeding vascular ectasias, ulceration and small bowel varices. The stomach, small intestine and colon can be affected (Fig. 86.6). Cirrhosis liver is the most frequent cause and the lesion is mainly related to the level of portal hypertension. The patients present with continuous gastrointestinal blood loss, requiring repeated blood transfusions. Wireless capsule endoscopy is the investigative modality of choice to detect the bleeding lesions all along the GI tract. Treatment consists of trans jugular intrahepatic porto-systemic shunting which promptly reduces the portal hypertension and arrests the bleeding (Fig. 86.7).

Fig. 86.6: Portal colopathy. Note: The dilated submucosal blood vessels. These may bleed colonoscopy

Fig. 86.7: Portal colopathy colonoscopy. Note: Active bleeding (arrow)

Extrahepatic Portal Hypertension (EHPH)

Extrahepatic portal hypertension is caused by portal or splenic vein thrombosis. This is a common cause of portal hypertension in India. The liver is normal. The disease starts in childhood and present for the first time between 11-25 years but sometimes symptoms may manifest even as early as 3 to 4 years.

Etiology

1. Portal vein thrombosis secondary to neonatal umbilical sepsis.
 2. Intra-abdominal infections like acute appendicitis and peritonitis.
 3. Abdominal trauma.
 4. Malignant tumours of the pancreas, stomach, colon or periportal lymph nodes.
 5. Acute pancreatitis and pancreatic cysts.
 6. Hematological disorders like polycythemia, thrombocythemia and thrombophilic conditions such as deficiency of protein C and S and antithrombin may be present in a third of these cases.
 7. Congenital anomalies of the portal veins.
 8. Vascular lesions such as arteriovenous fistulae in the spleen or hepatic artery-portal vein fistula in the liver.
- Hematemesis is the presenting symptom in the majority.

Management: It consists of emergency medical treatment of variceal bleeding followed by appropriate shunt surgery depending on the availability of suitable veins. Since the liver function is good, long-term prognosis is bright.

Noncirrhotic Portal Fibrosis

Syn: Idiopathic portal hypertension

This disorder is frequently seen in India and the neighbouring countries. It is characterized by gross splenomegaly and portal hypertension with patent extrahepatic

portal veins. Hepatic function is normal. Histological and clinical features do not suggest cirrhosis. Liver biopsy may be normal or varying degrees of portal fibrosis and cellular infiltration may occur. Studies from Punjab suggest chronic arsenic intoxication as a probable cause.

The condition is most common in the third and fourth decades. Many patients complain of several attacks of

hematemesis which are better tolerated by these patients than those with hepatic cirrhosis. Ascites and jaundice are uncommon.

Management: Since this condition may present with severe hematemesis, the treatment is that of bleeding esophageal varices.

HEPATORENAL SYNDROME

Syn: Syndrome of functional failure

Definition

Hepatorenal syndrome (HRS) is defined as functional renal failure occurring in the setting of advanced liver disease but in the absence of intrinsic renal disease. The HRS is characterized by intense constriction of renal cortical vasculature with resultant diversion of blood flow from the renal cortex. As a result GFR comes down, plasma renin level increases, urine output decreases and sodium is avidly reabsorbed in the distal nephron. Histologically, the kidneys are normal. Such kidneys can perform normally when transplanted into subjects without portal hypertension. In the same individual correction of

portal hypertension and liver failure by transplantation restores renal function too.

Functional renal failure occurs in 18% of decompensated cirrhosis and portal hypertension within 1 year. The three most important risk factors of HRS are low sodium concentration, high plasma renin activity and absence of hepatomegaly. Other risk factors include ascites, poor nutritional status, and esophageal varices.

Pathogenesis

HRS is characterized by sodium retention, water retention, and renal vasoconstriction. It is associated with decrease in renal blood flow, glomerular filtration rate and urine output. These lead to azotemia. However the pathophysiological mechanisms are not fully defined, though several propositions are made.

Diagnostic criteria

HRS should be suspected in any patient with acute or chronic liver disease and portal hypertension, when there is a rise in serum creatinine to above 1.5 mg/dL. The criteria are divided into major criteria, which must be present in all patients for diagnosis, and minor criteria, which provide support for diagnosis.

Major criteria:

1. Chronic or acute liver disease with advanced hepatic failure and portal hypertension.
2. Low glomerular filtration rate, with creatinine clearance < 40 mL/min and blood serum creatinine > 1.5mg/dL
3. No history of treatment with nephrotoxic drugs, shock, infection, or significant recent fluid losses.

4. Absence of sustained improvement in renal function following diuretic withdrawal and volume expansion with 1.5 L isotonic saline.
5. Proteinuria < 500 mg/dL, and absence of ultrasonographic evidence of urinary obstruction or parenchymal renal disease.

Minor criteria:

1. Urine volume < 500 mL/day
2. Urine sodium < 10 mmol/L
3. Urine osmolality greater than plasma osmolality.
4. Urine red blood cells < 50 per high power field.
5. Serum sodium concentration < 130 mmol/L.

Clinical Types

HRS is divided into 2 types. *Type 1 HRS* is rapid in onset and rapid and progressive in course. Impairment of renal function, defined as a doubling of the initial serum creatinine to a level higher than 2.5 mg/dL, or a 50% reduction of the initial 24-hour creatinine clearance to a level lower than 20 mL/min occurs in less than 2 weeks. Patients with type 1 HRS are usually very sick, with signs of advanced liver failure.

Type 2 HRS is defined as the impairment in renal function evidenced by S creatinine level more than 1.5 mg/dL, which does not meet the criteria for type 1 HRS. Commonly it manifests as refractory ascites.

Untreated, the median survival time for patients with type 1 HRS is less than 2 weeks.

Management of HRS

Currently liver transplantation remains the definitive treatment of choice for hepatorenal syndrome. According to the *Model of End stage Liver Disease scoring system*, (MELD) which is a new scoring system which sets priorities for liver transplantation, patients with impaired renal function get priority for transplantation. Other measures can only be used as a bridge to transplantation.

Hemodialysis is frequently used to control azotemia and maintain electrolyte balance before liver transplantation. Continuous veno-venous hemofiltration causes less hypotension but requires the continuous services of a dialysis nurse. Usefulness of combination of various vasoconstrictors such as octreotide and midodine, epinephrine, terlipressin and albumin is under current investigation. Transjugular intrahepatic portal systemic shunt (TIPS) may also be beneficial and life saving during the waiting period before transplantation.

Alcoholic Liver Disease

Alcohol-related liver injury is common in places where alcohol consumption is high. Severe forms of injury usually occur when the intake is above 150 g ethanol per day for a few years. The three recognizable syndromes are *fatty liver*, *alcoholic hepatitis* and *Laennec's cirrhosis*.

Alcoholic fatty liver is the most benign one. Infiltration of the liver with triglyceride is extremely common in men consuming alcohol regularly. The most frequent physical finding in such patients is hepatomegaly without any evidence of cirrhosis. Abstinence from alcohol at this stage leads to rapid regression within weeks.

Alcoholic Hepatitis

Approximately 25% of chronic alcoholics develop histological evidence of alcoholic hepatitis. This is characterized by hepatocellular necrosis affecting mainly the centrilobular zone. Remaining hepatocytes are often distorted and enlarged. In addition, inflammatory exudate consisting of polymorphs and perisinusoidal and perivenular fibrosis is usually present. Cytoplasmic inclusions known as alcoholic hyaline or *Mallory bodies* are seen. These changes may occur alone, but are usually accompanied by significant fatty infiltration and often by cirrhosis.

Clinically, alcoholic hepatitis tends to be more serious than fatty liver, although a few are asymptomatic. Anorexia, nausea, upper abdominal pain, weakness, vomiting, fever, jaundice, and diarrhea may occur in various combinations. The pain may be in the right upper quadrant and closely resembles cholecystitis.

Biochemical abnormalities include elevation of transaminases, hyperbilirubinemia, hypoalbuminemia, and prolongation of prothrombin time. The ratio of SGOT/SGPT is usually >2/1 in alcoholic liver disease. Ratios >3/1 is more suggestive and significant. Alkaline phosphatase is elevated in approximately 30% of such patients. Neutrophil leukocytosis is common (12000-20000 cmm).

These are non-specific changes, but in an alcoholic, these strongly suggest hepatitis. The diagnosis can be confirmed only by liver biopsy. It is to be remembered that the entire histological picture of alcoholic hepatitis may appear in conditions other than alcoholism, such as obesity, diabetes, short bowel syndrome, Indian childhood cirrhosis, and drug toxicity. The outcome in patients with alcoholic hepatitis is not nearly as benign as in those with alcoholic fatty liver alone. The reported overall acute mortality is 15-20% and approximately 50% cases develop alcoholic (Laennec's) cirrhosis.

Management: There is no specific therapy. Abstinence from alcohol is essential. Nutritional support, corticosteroids, propylthiouracil, glucagon, insulin, intravenous amino acids, pentoxifylline and colchicine have been tried with inconclusive results. Some of these agents seem promising but none has yet been established as an effective therapy.

Course: The healing of alcoholic hepatitis in survivors is slow, despite good nutrition, rest, and abstinence from alcohol. Most patients show activity of the disease even

after 3 to 4 months. The final phase of alcoholic liver disease is alcoholic cirrhosis. Alcoholic cirrhosis is described in Chapter 84 pp 508.

Chronic Hepatitis

Definition

It is defined as chronic inflammatory activity in the liver continuing without improvement for more than six months. In asymptomatic patients estimation of the duration may be difficult. Features such as spider angioma, firm irregular hepatomegaly and splenomegaly suggest a chronic process. Fibrosis seen in liver biopsy also would suggest chronicity. The terms chronic persistent hepatitis and chronic active hepatitis are replaced by the term 'chronic hepatitis' at present.

Etiology

1. Hepatitis B and C are the most common
2. HDV +ve in 5-10% of HBV + cases
3. Autoimmune hepatitis
4. Wilson's disease
5. Drug toxicity—several drugs
6. Chronic alcoholic hepatitis
7. A third of the cases are idiopathic, since no causative factor can be identified. They form a heterogenous group.

Natural History

It depends on various factors such as the degree of necro-inflammatory activity, stage of the disease, etiology and the host response to treatment. Most of patients are asymptomatic and progress towards cirrhosis liver. The risk of hepatocellular carcinoma (HCC) is increased in HBV and HCV related chronic hepatitis. Some patients with high inflammatory activity present with jaundice and even liver failure.

CHRONIC HBV HEPATITIS

Clinical Features

Most of the patients are asymptomatic and present with elevation of aspartate transaminase (AST) and alanine transaminase (ALT) or viral markers detected during routine check-up especially during blood donation. Sometimes asymptomatic hepatomegaly is detected clinically or on ultrasonography for some other purposes. Rarely they may present with acute hepatitis and the jaundice fails to clear within six months. In some cases the presentation is with acute onset of jaundice, but symptoms persist and the ALT and AST may remain high. Liver biopsy may reveal chronic hepatitis.

Pathogenesis

After an acute attack of hepatitis B more than 95% of adults clear the virus completely. If the host immune response is inadequate, the virus tends to persist. Causes of poor immune defence response include (i) poor expression of HLA class I antigens on the hepatocyte membrane, (ii) increased suppressor T-cell function (iii) defective cytotoxic (K) lymphocyte function and (iv) presence of blocking antibodies on the liver cell membrane.

Pathology

The entire disease activity spectrum caused by HBV has to be labeled as 'chronic hepatitis B infection' and further classification should be based on histology. Necroinflammatory activity and fibrosis form the basis of histological classification.

Modified Knodell's classification scores the necro-inflammatory activity which is the histologic activity index scored on a scale 0 to 18 and this forms the basis of Knodell's classification. Presence of fibrosis is scored on a scale of 0 to 4 and this forms the basis of grading (see box).

Diagnosis

The viral etiology is established by viral markers—HBsAg, HBeAg, HBcAg and their antibodies. HBV virus can exist in the liver in a replicating stage or integrated stage. In the replicating stage, the virus multiplies actively. It is present in blood and the disease can spread. The Histologic Activity Index is high and the patients require antiviral treatment.

<i>Knodell's Histologic Activity Index (HAI)</i>		
Component		Score
Periportal necrosis with or without bridging necrosis		0-10
Intralobular necrosis		0-4
Portal Inflammation		0-4
<i>Staging (Fibrosis)</i>		
		Score
Fibrosis	none	0
Portal expansion	+	1
Portal to portal tract fibrosis	+	2
Bridging fibrosis	+	3
Cirrhosis	+	4

The viral genome integrates with host hepatocyte DNA and there is no independent viral replication or viremia in the integrated phase. Hepatic necrosis is minimal at this stage and the benefit of antiviral treatment is probably only slight.

Clinical feature	Replicating stage	Integrated stage
Infectivity	High	Low
HBsAg	Positive	Positive
HBeAg	Positive	Negative
Anti-HBe	Negative	Positive
HBV DNA	Positive	Negative

Treatment

Interferon alpha (IFN- α) is the preferred drug which is given in the dose of 5-10 million units thrice a week for 4-6 months. HBeAg clears and HBV DNA disappears in 40-60% of cases. IFN therapy should be closely supervised. It is costly (Rs. 1500/dose) and side effects are seen in up to 30% of cases. The common side effects are flu like syndrome myalgia, anorexia and alopecia. Bone marrow suppression, thyroiditis and depressive state with suicidal tendency may occur. A flare up of inflammatory activity is usually seen with conversion (i.e.) HBeAg +ve to Anti-HBe + ve status. Newer drugs such as lamivudine, adefovir and thymosin- α are also effective.

CHRONIC HEPATITIS C

60-90% hepatitis caused by HCV tend to become chronic. It is the most common cause of post-transfusion chronic hepatitis and cirrhosis. There is increased incidence of hepatocellular carcinoma.

CLINICAL FEATURES

Most of the patients are asymptomatic or have only mild symptoms like anorexia and fatigue. The ALT and AST levels are often elevated. Periods of normal transaminase levels are characteristic of HCV infection. They may also present with extrahepatic manifestations such as lichen planus, thyroiditis or membranous glomerulonephritis. Mixed cryoglobulinemia may develop and lead to symptoms see chapter 55.

The course of the illness is slower compared to chronic HBV infection. Cirrhosis liver and liver failure develop only after 10 years or more.

Diagnosis

Third generation anti-HCV test (ELIZA) is useful for screening. Radioimmunoassay (RIBA) is confirmatory. HCV-RNA can be detected by PCR and can be quantified. Tests are available for genotyping also. Genotyping is helpful in predicting treatment response. PCR test done in reliable laboratories only should be accepted since several factors vitiate the test results.

Liver biopsy helps to assess the activity and the results are expressed according to Metavir scoring system. Lymphoid aggregation, fatty changes and bile duct injury are features of HCV infection.

Treatment

For HCV also IFN- α is the mainstay of therapy. Pegylated interferon with ribavirin is the treatment of choice. Interferon is given in doses of 3 million units thrice weekly for six months. HCV-RNA disappears and transaminases return to normal in more than 50% of patients. Reappearance HCV-RNA occurs in half of the responders. Response rate, (i.e.) HCV-RNA negative and transaminases returning to normal levels after one year of therapy can be enhanced by increasing the dose of IFN and duration of therapy. Adjuvants such as ribavirin and ursodeoxycholic acid also enhance the response. In chronic liver disease there is a general tendency to accumulate iron in the liver. Increased hepatic iron content is associated with poorer outcome. In such cases phlebotomy and regular removal of blood improves the outcome if done along with IFN treatment.

Factors which predict a favourable therapeutic outcome in chronic HCV hepatitis	
Young age Females Non-obese Short duration of infection Hepatic iron content not raised	Non-alcoholics Low viral load Less fibrosis Elevated transaminases Virus genotype II or III

AUTOIMMUNE HEPATITIS

The definite diagnosis of autoimmune hepatitis requires not only periportal hepatitis, hypergammaglobulinemia and auto-antibodies, but also the absence of viral markers, chronic alcoholism, exposure to blood products, hepatotoxic drugs and biliary lesions. The serum gammaglobulin levels are usually more than twice the normal.

Pathogenesis

Hepatitis results from cell mediated cytotoxicity in an susceptible host. There is an aberrant display of class II HLA antigens on the hepatocyte surface which initiates cytotoxic response. The aberrant display may be due to viral infection or exposure to drugs or other environmental factors.

Classification

There are three types of autoimmune hepatitis based on immunoserological markers (Table 87.1).

Treatment

There is good response to steroids. Prednisolone is given initially in the dose of 30 mg which is tapered to 5-15 mg after about 4 weeks. The exact duration of treatment is not clear. Azathioprine can be given in cases where steroids cannot be tapered.

TABLE 87.1

Classification of autoimmune hepatitis			
Features	Type I	Type II	Type III
Diagnostic antibodies	Smooth muscles Antinuclear— actin	Liver/kidney microsome Type I P 450 II D 6	Soluble liver antigen Liver/pancreas
Age	Bimodal	Pediatric	Adults
Female %	78	89	90
Concurrent organ specific antibodies	4%	30%	No data
Gamma globulin elevation	+++	+	++
HLA	B8 DR3 DR4	B14 DR3 C4A-Q8	Uncertain
Steroid response	+++	++	+++
Progression to cirrhosis	45%	82%	75%

DRUG TOXICITY ON THE LIVER

Liver is one of the main organs concerned with drug metabolism. Most of the drugs are converted into more water soluble, inactive, and nontoxic compounds for elimination by the kidneys or through bile. The enzymes required for drug metabolism are present in the microsomes of the endoplasmic reticulum. The enzymatic reactions occur in two steps. The first step includes oxidation, reduction or hydrolysis. The second step reactions are conjugation and excretion. Some drugs are directly conjugated. Though majority of the metabolites are harmless, some are toxic, e.g. acetaminophen and INH. Some drugs induce enzymes which accelerate the metabolism of the same drug as well as others, e.g., barbiturates, alcohol, anesthetics, oral hypoglycemic drugs, anticonvulsants, griseofulvin, rifampicin, phenylbutazone, meprobamate and warfarin. Protein deficiency and pregnancy make the liver more vulnerable to toxic damage.

Drug injury to the liver is of two types: The injury is predictable and dose-dependent in one; the other type, which is due to idiosyncrasy to the drug, is unpredictable and independent of the dose. Hypersensitivity reaction is triggered off by the drug or its metabolites which act as complete antigens or haptens. The patterns of adverse reactions of the liver to drugs are limited. The general pattern of injury to the liver caused by some of the common drugs is listed in Table 87.2.

Peliosis hepatis is a rare ill-defined lesion, the cause of which is unknown. The liver appears mottled blue and the section shows numerous small blood filled lacunar spaces which may arise from sinusoids or portal or hepatic veins. Sometimes this may be a chance finding at autopsy in patients dying of tuberculosis (Table 87.2).

HEPATIC VENO-OCCLUSIVE DISEASE (VOD)

Though originally described from West Indies, it is reported from several parts of the world. In India small outbreaks have occurred in Punjab, Rajasthan, and Madhya Pradesh. Though the exact etiology is unknown, it is most likely caused by toxic phlebitis produced by *pyrrolizidine alkaloids* found in plants like *senecio*, *heliotropium* and *crotolaria*, consumed as local herbal remedies or accidentally in contaminated cereals. Pathological changes lead to occlusion and fibrosis of the central and sublobular veins. Cirrhosis may develop in the subacute and chronic forms.

The presentation may be acute, subacute or chronic. In children, it tends to be acute with sudden development of hepatomegaly and ascites. Hepatic failure develops in them and mortality is higher. Those who recover may pass into the subacute or chronic phase. In the subacute variety, ascites and hepatosplenomegaly tend to persist. The chronic form leads to cirrhosis of liver with portal hypertension.

Treatment

In the acute phase general nutritional support, maintenance of fluid and electrolyte balance, and symptomatic measures help in tiding over the crisis. There is no specific treatment (see also Section 4, Chapter 24).

BUDD-CHIARI SYNDROME

Budd-Chiari syndrome (BCS) is caused by thrombotic obstruction of the hepatic venous outflow, usually at the level of inferior vena cava or the major hepatic veins. Most of the cases are idiopathic. A membrane is seen in the IVC in some cases. This may be congenital or acquired.

TABLE 87.2

Liver injury caused by drugs	
Types of reactions	Causative drugs
1. Chronic hepatitis	Acetaminophen, tetracycline, acetylsalicylic acid, INH, alpha methyl dopa, sulfonamides, nitrofurans, phenylbutazone aspirin
2. Cholestasis	INH, methyltestosterone, chlorpromazine, thiouracil, para-aminosalicylic acid
3. Granuloma formation	Phenylbutazone, long-acting sulfonamides, allopurinol, dilantin, diazepam, (granulomatous hepatitis) chlorpropamide, hydralazine, halothane, methyl dopa, procainamide
4. Fulminant hepatitis	Acetaminophen, combination of INH and rifampicin
5. Hepatic vein thrombosis (Budd-Chiari syndrome)	Oral contraceptives
6. Peliosis hepatitis	Anabolic steroids, oral contraceptives
7. Acute intermittent porphyria	Barbiturates
8. Cholelithiasis	Clofibrate
9. Cirrhosis	Oral antidiabetic drugs, alcohol
10. Tumour formation	Oral contraceptives, anabolic steroids
Several types of hepatic tumours have been associated with drug administration	
a. Hepatocellular adenoma	Oral contraceptives, anabolic steroids
b. Focal nodular hyperplasia	Oral contraceptives
c. Hepatocellular carcinoma	Oral contraceptives, anabolic steroids, methotrexate, androgens
d. Angiosarcoma	Diethyl stilbesterol, vinyl chloride
e. Peliosis hepatitis	Azathioprine, corticosteroids, diethyl stilbesterol, fluoxymesterone, methyl testosterone, oxymetholone

In 75% of cases there is a pro-thrombotic state. Myeloproliferative diseases, especially polycythemia vera and essential thrombocythemia account for over 50% of cases. Thrombophilic states predispose to this syndrome (Table 87.3) (see also Chapter 160).

CLINICAL FEATURES

Budd-Chiari syndrome may present in three forms

1. **Acute form:** This constitutes 20%. The onset is acute with sudden onset presenting with occlusion of all the hepatic veins, characterized by abdominal pain, ascites and even fulminant hepatic failure.
2. **Subacute form** occurs in 40%. The onset is slow and the signs and symptoms persist for over 6 months. Ascites is mild. Hepatic necrosis is minimal due to the development of collateral circulation.
3. **Chronic form** This constitutes 40%. Duration exceeds 6 months. Cirrhosis may be associated. Compression to inferior vena cava by enlarged caudate lobe leads to BCS.

The hepatojugular reflux is abolished and this should raise the possibility of obstruction to hepatic veins.

Diagnosis

Budd-Chiari syndrome has to be distinguished from occlusion of the portal vein and inferior vena cava. In

portal vein thrombosis, ascites is rare and there is no tender hepatomegaly. Inferior vena caval occlusion leads to edema of lower limbs and distention of abdominal veins without ascites. Often hepatic veins and the inferior vena cava may both be occluded by the same process. Doppler studies, CT and MRI demonstrate the lesion. Direct venography using transjugular techniques can confirm the diagnosis. The transaminases may show moderate elevation upto 4-5 times the normal levels. Ascitic fluid

TABLE 87.3

Pro-thrombotic conditions pre-disposing to BCS
1. Factor V. Leyden mutation
2. Prothrombin mutation G20210A
3. Antiphospholipid antibody syndrome
4. Paroxysmal nocturnal hemoglobinuria
5. Deficiency of protein C,S and AT.111
6. Cancers such as hepatocellular carcinoma, adrenal and renal cancer, retroperitoneal sarcoma and thrombophlebitis migrans complicating distant neoplasms.
7. Oral contraceptives, Behcet's syndrome
8. Local conditions such as liver abscess and echinococcal cysts.
9. 20% seem to be idiopathic, but many of them prove to be occult myeloproliferative diseases, on follow-up.
Latent myeloproliferative diseases can be identified by demonstrating mutations in the Janus Kinase 2 (JK2) gene.

in BCS shows high serum/ascitic fluid albumin gradient with high ascitic fluid protein, often $< 2.5\text{g/dL}$.

Prognosis is generally poor and to a great extent it depends on the primary condition. Acute cases terminate in hepatic coma. Only a few patients survive more than a year. Survivors may develop portal hypertension later.

Treatment

This consists of removing local causes if any, fibrinolytics and long term anticoagulation. Stenting the hepatic veins and insertion of transjugular porto-systemic shunts (TPS) help to prevent further occlusion. In severe cases liver transplantation may be required.

LIVER DYSFUNCTION IN CIRCULATORY IMPAIRMENT

Acute circulatory failure: Hepatic cells are very susceptible to anoxia caused by cardiac failure or fall in hepatic artery perfusing pressure as in shock. These reflect as functional derangement. The left lobe is more affected than the right. Microscopically, central veins and central zones show congestion. These zones show hemorrhage, focal necrosis, hydropic changes, and polymorphonuclear infiltration. The reticulin network is usually preserved.

Chronic congestive heart failure: The liver is enlarged, congested, and dark purplish in colour with rounded edges. The central vein is dilated and congested and the sinusoids are distended. Liver cell necrosis occurs, but there is no marked cellular infiltration. The degenerating cells may show pigmentary disturbance. Fibrous bridges form between central veins, leaving the portal zones relatively unaffected. The ill effects of hypoxia and back pressure are felt maximally in the central zones. A complex micronodular cirrhotic picture develops (**cardiac cirrhosis**).

Jaundice may occur in chronic congestive heart failure, due to hepatic necrosis and release of bilirubin from multiple foci of infarction such as the lungs. Ascites may develop. The ascitic fluid is highly proteinaceous. Mild grades of hepatic dysfunction develop. Mild portal hypertension occurs in many. Though mild splenomegaly may occur, other features like esophageal varices are uncommon. Treatment of cardiac failure in long-standing cases partially reverses the functional derangement but the structural abnormalities persist.

PYOGENIC ABSCESS OF THE LIVER

Liver is a common site for pyemic abscesses. In gram-negative septicemia microscopic abscesses are common and tender hepatomegaly is a common event. However, liver may be the seat of focal collection of pus which may be more often multiple. Bacteria can reach the liver

through the portal vein, hepatic artery and bile ducts, or by direct extension from contiguous organs and through penetrating injuries. Secondary infection of an amebic abscess or hydatid cyst converts it into pyogenic abscesses.

The organismal flora is mixed, containing *E. coli*, *Staph. aureus*, *Str. fecalis*, *Pr. vulgaris*, *Pseudomonas*, *Bacteroides* and anaerobic streptococci. Continuous pain, high fever, chills, jaundice, toxemia, neutrophil leukocytosis, and tender hepatomegaly should draw attention to the possibility of pyemic abscess. Aspiration of the pus and microbiological examination confirm the diagnosis. Treatment consists of appropriate antibiotic therapy and supportive care. Needle aspiration and rarely surgical drainage is required. Surgical drainage of the pus is required if medical measures alone are inadequate. The source of infection should be removed to prevent recurrence.

Carcinoma of the Liver

PRIMARY CARCINOMA

Syn: Hepatoma

Primary carcinoma of the liver is a common neoplasm seen in India, South Africa, Malaysia and China. It is less common in Caucasians. Hepatocellular carcinomas form 75% of the primary tumours while cholangiocarcinomas form 20%.

Etiology

The etiological factors vary in different geographical regions. Carcinoma supervening on cirrhosis accounts for 20% of the total. The regenerating nodules in macronodular cirrhosis may become malignant. Hepatitis B and C and aflatoxins from *Aspergillus flavus*, alcoholism, hemochromatosis, and clonorchiasis predispose to carcinoma. In many cases the tumour arises *de novo*.

Though the majority are unicentric, some are multiple. The right lobe is more affected. The hepatocytes show hyperchromatic nuclei and mitotic figures with only scanty stroma. The tumour spreads throughout the liver, involves the peritoneal surface and spreads to the peritoneum. It spreads locally through the portal vein, inferior vena cava and bile ducts causing obstruction to these channels. Distant metastasis is rare. Nodes in the porta hepatis, mediastinum, and cervical chains may also be affected.

Clinical Features

In India younger subjects (second and third decades) suffer more, though any age group can be affected. Vertical transmission of hepatitis B from mother to offspring and development of B hepatitis early in life accounts for this phenomenon. Males are four to five times

more affected than females. The presenting complaints are pain, fullness in the right hypochondrium, feeling of a mass, fever or jaundice. Auscultation may reveal arterial bruit and venous hum along the porta hepatis. This venous hum is referred to as **Cruveilhier-Baumgarten syndrome**. This may occur in cirrhosis liver with portal hypertension also. Portal hypertension and intraperitoneal hemorrhage are late features. Left supraclavicular nodes may be enlarged due to metastases. Liver function is maintained till late in the disease. Pleural effusion and atelectasis of the right lower lobe can occur. Occlusion of the portal vein or hepatic vein may present with acute symptoms of portal hypertension.

Diagnosis

Carcinoma should be suspected if massive enlargement of the liver occurs with fever, cachexia and hemorrhagic ascites. Jaundice is usually a late manifestation in hepatoma whereas it occurs early in cholangioma. Rarely secondary polycythemia may develop.

Diagnosis of Hepatocellular Carcinoma (HCC)

Imaging techniques such as ultrasonography (USS), CT and MRI are very useful. A lesion more than 2cms has high sensitivity and specificity for diagnosing HCC. Triple phasic helical CT is diagnostic. The unenhanced phase, enhanced phase and arterial and portal venous phases can be studied. *Alfa fetoprotein* (AFP) values above 200 ng/mL (normal 0-8.5ng/mL) are also diagnostic. If the diagnosis is not possible by imaging and AFP levels USS guided FNAC is useful. Complications include hemoperitoneum, dissemination of the lesion and needle track seeding.

Liver biopsy confirms the diagnosis, if the selection of the site is proper. Celiac axis angiography reveals the abnormal branches of the hepatic artery feeding the tumour. Angiography is necessary if surgical excision is planned.

MANAGEMENT

It may be curative or palliative. Curative modalities may be surgical or interventional. Surgical resection and liver transplantation are the surgical procedures. Unfortunately only around 15% of HCC are rescetable at the time of diagnosis. Local resection has the advantage that transplantation is not needed. Liver transplantation is the surgical procedure of choice in the western world. It is especially useful for HCC with cirrhosis and hepatic failure.

Interventions

Trans arterial chemoembolization (TACE): The hepatic artery is selectively catheterized and the chemotherapeutic

agent is directly delivered into the tumour followed by gel occlusion. Occlusion of the artery will lead to necrosis of the tumour which is mainly dependent on arterial blood supply, whereas the normal liver parenchyma is supplied by the portal vein.

Radiofrequency ablation (RFA) and alcohol injection into the tumour are the other interventions which are effective.

Operability

To be operable single lesions should be less than 5cms in diameter and multiple lesions should be less than 3 in number and less than 3 cms in diameter. The rest of the liver parenchyma should be normal.

Surveillance for HCC in cirrhosis: Cirrhotic patients are at higher risk for developing HCC and hence they have to be followed up. The current practice is to screen them with USS and AFP at 6 month intervals. Operability is high in HCC detected by surveillance.

SECONDARY CARCINOMA OF THE LIVER

Liver is a very common site for metastasis. These are thirty times more common than primary carcinoma. The usual primary sites are stomach, esophagus, other parts of the gastrointestinal tract, bronchus, breast, thyroid, kidney, adrenal, or melanoma of the skin. Biopsy from the secondaries may give clue regarding the primary.

Clinical examination reveals the irregular enlargement of the liver (**hob-nail liver**). The nodules show umbilication due to necrosis in the center. Jaundice occurs early if any of the major biliary passage is obstructed. The secondaries are generally less vascular than primary tumours and, therefore, arterial bruit is not heard. Splenomegaly may be present. Secondaries may lead to hypoglycemia. Ascites develops in due course. Ascitic fluid shows increase in proteins. Carcinoembryonic antigen may be detectable in the fluid. Lactic dehydrogenase is elevated to thrice the normal value. Cytology of the fluid shows malignant cells. Liver biopsy confirms the diagnosis. The progress is rapidly downhill and death occurs within weeks or months. Causes of death include malignant cachexia, hepatic failure and bleeding esophageal varices.

Therapy is at best only palliative. 5-fluorouracil given singly or as a combination regimen given either systemically or by local infusion into the hepatic artery is beneficial in some cases.

Benign tumours, which are rare, include adenoma and hemangioma.

Hepatic Adenoma

This may be associated with the administration of sex hormones and oral contraceptives. This may present as

local tumours or with peritoneal hemorrhage. Treatment is surgical resection.

Hemangioma Liver

It is the most common benign tumour. Two types are seen— cavernomas and the true hemangiomas. Some of them are associated with regular use of oral contraceptives. These tumours may sequester platelets and lead to consumption coagulopathy especially disseminated intravascular coagulation (**Kasabach-Merritt syndrome**). X-ray may show calcification. The ultrasound scan appearance is characteristic and in doubtful cases contrast CT may be diagnostic.

Treatment is largely aimed to reassure the patient and prevent injuries and bleeding. Definitive management includes surgery or angiographic embolization. Very large lesions which lead to consumption coagulopathy may have to be resected with liver transplantation, if needed.

Reye's Syndrome

During the course of viral infections like influenza A and B, varicella and probably others, toxic damage to the liver occurs. The condition is more common in children, especially if given aspirin. The liver shows fatty infiltration. Clinically it presents with hepatic failure, encephalopathy and rise in intracranial tension. Jaundice is usually absent. The mortality is high, if untreated (see chapter 52).

88

Diseases of the Gallbladder and the Major Bile Ducts

9

K.R. Vinaya Kumar, K.V. Krishna Das

Chapter Summary

General Considerations 531
Investigation of the Gallbladder and Bile Ducts 532
Cholecystitis 532
Carcinoma of the Gallbladder 534

General Considerations

The right and left hepatic ducts join to form the common hepatic duct. It joins the cystic duct to form the common bile duct which ranges in length from 2-9 cm. It passes behind the duodenum through the head of the pancreas to join the pancreatic duct and opens into the second part of the duodenum at the ampulla of Vater.

The gallbladder, situated below and in close contact with the liver, is pear-shaped, and has a capacity of 50 mL. Its fundus lies beneath the tip of the right ninth costal cartilage. In 10% of people the gallbladder has a mesentery (floating gallbladder) and it is freely movable.

The liver secretes 600 to 700 mL of bile in 24 hours at a pressure of 15-25 cm of water. The gallbladder concentrates the bile ten-fold by absorption of water and electrolytes. Bile secretion is inhibited when the pressure in the common bile duct exceeds 30 cm water. Vagus, which is the motor nerve, probably maintains the tone of the gallbladder. Gallbladder contracts in response to cholecystikinin (CCK) secreted by the duodenal mucosa. Cholecystikinin also causes relaxation of the sphincter. Drugs like morphine and pethidine cause spasm of the sphincter of Oddi and glyceryl trinitrate relaxes it.

Symptomatology of Biliary Tract Disease

The most obvious sign is jaundice which may be constant and progressive or fluctuating. This may or may not be associated with pain. Acute inflammatory lesions cause severe pain in the right hypochondrium, referred to the right shoulder. Obstruction to the cystic duct or common bile duct causes colicky pain with periodic waxing and waning. Unlike as in renal colic, mild constant pain persists between spasms. Persistence of continuous pain

for more than five hours should suggest complications such as infection or perforation of the gallbladder.

The fundus of an enlarged gallbladder can be palpated at the lateral border of the right rectus abdominis as a globular firm mass. Sometimes an elongated or floating gallbladder may reach as low as the right iliac fossa. Obstruction of the common bile duct due to external pressure as in carcinoma of the head of the pancreas causes enlargement of the gallbladder (*Courvoisier's law*). Since the gallbladder may enlarge only intermittently, repeated examinations may be necessary to detect it. Gall stones lead to chronic infection and thickening of the gallbladder, and this restricts enlargement. Tenderness over the gallbladder is elicited over the right hypochondrium. *Murphy's sign* is sudden catching pain felt on inspiration when the palpating finger exerts gentle pressure below the liver edge at the right border of the right rectus abdominis. The *Boas's sign* is tenderness, sometimes elicited over the region of the right scapula. Gallbladder pain may occasionally radiate to the chest and this may be mistaken for anginal pain. Gallbladder disease and ischemic heart disease coexist in many instances.

Investigation of the Gallbladder and Bile Ducts

Radiographs: Plain radiograph taken in the antero-posterior and right lateral positions may reveal radiopaque calculi. Only 10% of biliary calculi are radiopaque. Opacities due to renal calculi, calcified lymph nodes and fecoliths have to be differentiated from gall stones. An enlarged gallbladder may throw a soft tissue shadow. Gas in the biliary tree and pancreatic calculi are also seen at times.

Ultrasonography: It is the most useful noninvasive method to detect dilated biliary passages, gallbladder and calculi. This is the investigations of first choice.

CT scan: It demonstrates dilated biliary passages, intra and extrahepatic lesions and the gallbladder. The neighboring organs can also be well-visualized.

Contrast radiography: With the advent of noninvasive procedures such as ultrasound, CT scan and MRI which are much more effective in bringing out the abnormalities, the cumbersome and less precise investigations such as oral cholecystogram, intravenous cholangiography and blind percutaneous transhepatic cholangiography are seldom performed at present. Still in particular situations, USS guided or CT guided needling procedures and biopsies are done.

Endoscopic retrograde cholangiopancreatography (ERCP): This is an elegant method for visualizing the biliary and pancreatic duct systems. It utilizes endoscopy and radiography simultaneously. The ampulla of Vater is

cannulated through a side-viewing duodenoscope and the contrast is injected. The pancreatic duct, bile duct, and their tributaries are visualized in over 80% of cases. The ERCP also facilitates the collection of specimens for biopsy, cytology, and analysis of the juices. Therapeutically, ERCP has been employed to remove stones from the ducts and relieve strictures and even malignant obstructions. Endoscopic ultrasound scan (EUS) is a very sensitive imaging modality for terminal CBD lesions.

Operative cholangiography: The bile duct can be opacified during surgery by injecting contrast medium and its progress is followed.

Choledochoscopy: Visualization of the intra- and extrahepatic biliary system intraoperatively is possible by the choledochoscope which is introduced into the common bile duct. Stones and lesions missed by other investigations can be detected.

Barium meal: A properly conducted barium meal examination may give valuable clues in hepatobiliary disease. Distortion of the stomach and duodenum, abnormalities of the duodenum produced by ampullary carcinoma or pancreatic tumours, presence of fistulae, and regurgitation of the barium through the incompetent biliary sphincter are all useful diagnostic findings. This is seldom done at present since direct visualization is possible by endoscopy.

Radionuclide imaging: Scintiscans using ^{131}I rose-bengal or $^{99\text{m}}\text{Tc}$ -pyridoxylidene iminodiacetic acid derivative (HIDA) when given intravenously is taken up by the liver and excreted in bile. The biliary tree can be visualized.

Duodenal biliary drainage: Bile can be collected for examination through a duodenal tube after injecting cholecystokinin.

CHOLECYSTITIS

This may be acute or chronic.

ACUTE CHOLECYSTITIS

Obstruction to the gallbladder neck or cystic duct by gall stones, mucus plugs, neoplasms or other foreign bodies leads to stasis and infection. Initially the lesion is sterile but soon infection by *E. coli* and *Streptococcus fecalis* supervenes. Anaerobes such as *fusobacteria* and *Bacteroides* are also common. Inflammation may be mild or fulminant. The gallbladder may become filled with pus (**empyema of the gallbladder**) and the organ may burst after perforation, leading to severe biliary peritonitis and shock. Invasion by gas-forming organisms leads to the presence of gas in the wall of the gallbladder (emphysematous gallbladder) or in its cavity.

CLINICAL FEATURES

The disease is more common in middle-aged women. Sudden severe pain in the epigastrium and right hypochondrium referred to right shoulder, fever, vomiting and restlessness should suggest acute cholecystitis. Deep jaundice is rare unless the biliary tree is diffusely involved or the common bile duct is blocked. Heavy fatty meals at night, violent exercise, travel or even abdominal palpation in some cases may precipitate the attack. Pain may be colicky or continuous. The abdomen may be rigid. In some cases the gallbladder may be enlarged and palpable but local tenderness and rigidity preclude proper palpation. **Murphy's sign** and **Boas's sign** may be positive. General features of infection like fever, rigor, and neutrophil leukocytosis accompany these attacks. The condition subsides with treatment but recurs after varying intervals. Perforation of the gallbladder, ascending cholangitis, and shock occur in severe cases.

Differential diagnosis of acute cholecystitis includes hepatitis, cholangitis, gastric perforation, pancreatitis, appendicitis, acute intermittent porphyria and peritonitis. Pain may radiate to the chest, which could be mistaken for angina pectoris.

Diagnosis

The condition should be suspected clinically. Polymorphonuclear leukocytosis with a shift to the left is usually seen. The ultrasound scan may demonstrate stones in more than 90% of cases. Radionuclide scan (HIDA) is typical. It may demonstrate the bile ducts without visualizing the gallbladder.

Treatment

Conservative treatment consists of bed rest, analgesics and intravenous fluids to give symptomatic relief. Antibiotics like penicillin, cephalosporins and cotrimoxazole reach the bile in adequate amounts and these have to be employed judiciously. Metronidazole is to be given if anaerobic infection is suspected. In more than 90% of cases the condition subsides with conservative treatment within 3-4 days.

Surgical Management

Elective cholecystectomy can be done within three months after the acute phase subsides. The surgical mortality is about 0.5 to 1%. With the advent of laparoscopic cholecystectomy the operation has become more simple and less traumatizing.

Acute gangrenous cholecystitis is seen in the elderly and immunosuppressed individuals. The gallbladder may rupture at the fundus giving rise to local peritonitis, adhesions with other viscera or formation of internal biliary fistula. Acute gangrenous cholecystitis should be

suspected in any individual if the pain and toxemia increase despite treatment, and shock supervenes. The mortality is 15-20%. Initial treatment consists of massive antibiotic therapy and supportive measures. Emergency cholecystectomy or cholecystostomy and drainage of abscesses are indicated if the condition deteriorates in spite of adequate conservative measures.

CHRONIC CHOLECYSTITIS

This is the most common medical lesion affecting the gallbladder, and it is invariably due to cholelithiasis. The gallbladder is thickened and fibrotic and the mucosa may be destroyed by scarring.

CLINICAL FEATURES

Vague upper abdominal pain, colic, gaseous distension after fatty meal or recurrent episodes of acute cholecystitis should suggest the possibility of chronic cholecystitis. Peptic ulcer, hiatus hernia, and chronic pancreatitis have to be excluded by investigations. Murphy's sign may be positive and in the absence of hepatic disease it is very suggestive of cholecystitis. Calculi may be seen in plain radiographs of the abdomen. Oral cholecystogram, cholangiogram, ultrasonography and ERCP help to localize the lesion.

Course and Prognosis

The condition persists for several years with exacerbations and remissions. There is increased risk of malignancy.

Treatment

Medical treatment consists of dietary adjustment, reduction of weight, antispasmodics, antacids, and antibiotics. Early cases may subside completely. Drugs which dissolve cholesterol gall stones are worth a trial. *Chenodeoxycholic acid* in a dose of 13-15 mg per kg body weight given orally at bed time is effective in dissolving these stones in a period of 6-24 months. Recurrence may occur on stopping therapy. Side effects include mild diarrhea and elevation of serum cholesterol. *Ursodeoxycholic acid* is a better drug in this class and in a dose of 10 mg/kg given twice daily, it acts faster. Troublesome diarrhea does not occur. Rowachol is a mixture of essential fatty acids capable of dissolving gall stones. Medical treatment is generally not preferred on long term basis.

Shock wave lithotripsy disintegrates the stones. This helps in quicker resolution. Surgical removal of the gallbladder is indicated if medical treatment fails. With the availability of laparoscopic cholecystectomy in many centers in India at reasonable cost, this has become more popular as the definitive long-term treatment.

Typhoid cholecystitis: The biliary tract may be colonized by *Salmonella typhi*. More commonly chronic cholecystitis may occur in typhoid carriers.

Typhoid bacilli form a nidus around which calculi may form. The gallbladder becomes chronically infected with *Salmonella* and this perpetuates the fecal carrier state. Cholecystectomy helps in clearing the focus of infection and the carrier state.

Carcinoma of the Gallbladder

It is a rare condition in South India, but is more common in the Gangetic belt of India. It is seen more in people

above the age of 50 years. Around 90% cases are adenocarcinomas. It presents with progressive biliary obstruction. Chronic calculous cholecystitis predisposes to malignancy.

Cholangiocarcinoma

This is a rare slow-growing adenocarcinoma arising from any part of the biliary tree from the bile canaliculi to the sphincter of Oddi. Progressive jaundice occurs depending on the site of obstruction.

Diseases of the Pancreas

K.R. Vinaya Kumar, K.V. Krishna Das

Chapter Summary

- General Considerations 534
- Pancreatitis 536
- Cystic Fibrosis of the Pancreas 539
- Carcinoma of the Pancreas 540
- Endocrine Tumours of the Pancreas 541

General Considerations

Applied Anatomy

Pancreas is situated posteriorly in the upper abdomen. It contains both exocrine and endocrine cells. Since the head of the pancreas lies within the duodenal loop in close approximation, enlarging lesions of the head of the pancreas produce radiologically demonstrable changes in the inner margin of the duodenum. The common bile duct passes through the head of the pancreas and tumours of this region compress the common bile duct to produce obstructive jaundice. Being deeply placed, lesions of the pancreas may remain without producing clinically demonstrable local physical signs for long periods.

The pancreas is made up of large lobules, each made up of smaller lobules containing acini. Each acinus

contains two types of cells. The zymogen-containing cells secrete the digestive enzymes and these predominate. Cells situated near the center of the acini secrete water and bicarbonate. The main pancreatic duct is formed by the confluence of smaller ducts. It opens into the second part of the duodenum along with the common bile duct at the ampulla of Vater. The islets of Langerhans which are made up of four types of cells known as alpha, beta, gamma and delta, are scattered throughout the organ. These cells secrete glucagon, insulin, and other peptide hormones. Endocrine tumours may arise from them.

Applied Physiology

The pancreas secretes 1.5-3 liters of juice daily. It is alkaline with the pH 8-8.3. Trypsin, chymotrypsin, amylase and lipase form the main enzymes. Sodium bicarbonate, which is the major electrolyte, renders alkalinity to the secretion. Potassium, calcium, zinc, chloride, phosphate, and sulfate are also present in smaller amounts. The secretion is under hormonal and neural control, the former being more important. When acidic gastric contents enter the duodenum and the pH goes down to 4.5, the duodenal and jejunal mucosa release secretin. Cholecystokinin (pancreozymin) is also secreted from the duodenal and jejunal mucosa when long-chain

fatty acids, amino acids (especially tryptophan, phenylalanine, valine and methionine) and acidic gastric contents enter. Copious amounts of alkaline juice are produced in response to secretin. Cholecystokinin stimulates the production of thick juice which is rich in enzymes. Gastrin is also a weak stimulus for pancreatic secretion. Vasoactive intestinal peptide (VIP) antagonizes the effect of secretin. Bile acids in the intestinal lumen also stimulate pancreatic secretion.

Neural control is through the vagus which exerts direct effect on the acinar cells. Indirectly, it influences pancreatic secretion through the mechanism of gastrin.

Actions of pancreatic juice: Amylase secreted in the active form digests starches into oligosaccharides and to the disaccharide maltose. The lipolytic enzymes (*lipase* and *co-lipase*) breakdown fat into glycerol and fatty acids.

The proteolytic enzymes are *trypsin*, *chymotrypsin*, *carboxypeptidases*, *aminopeptidases*, *elastase*, *ribonuclease*, and *deoxyribonuclease*. They are secreted as inactive precursors (zymogens) which are activated later. *Trypsinogen* is activated by *enterokinase* found in the intestinal mucosa to *trypsin*. Trypsin further activates the other proteolytic enzymes sequentially.

Pancreatic Function Tests

Enzyme levels in blood and urine: Amylase, *trypsin*, and *lipase* are present in normal serum in small amounts. In acute pancreatitis, within a short interval, the amylase reaches very high levels and this rise is suggestive of the diagnosis. Normal value of amylase is about 60-180 Somogyi units/dL (or 150-340 IU/L). The serum levels come down within a few days.

Since serum amylase levels are not specific for pancreatic disease, measurement of renal clearance of amylase from blood has been suggested as a more reliable test for diagnosis of acute pancreatitis. The clearance ratio is calculated by simultaneous estimation of amylase and creatinine in serum and urine. Normal amylase/creatinine clearance ratio is around 3.1. Value of more than 5 suggests the diagnosis of acute pancreatitis. The value of this test is also doubtful.

Analysis of feces: Steatorrhea and creatorrhea are seen commonly in pancreatic disease. Fecal fat estimation done on feces collected for 3 days on a high fat diet (about 75 g/day) helps in confirming the presence of steatorrhea. Normal subjects do not lose more than 6 g of fat in feces daily. Higher values suggest pancreatitis or malabsorption. In pancreatitis, feces contains neutral fat, whereas in malabsorption states it contains mainly fatty acids.

Estimation of fecal trypsin and chymotrypsin is useful in the diagnosis of chronic pancreatic insufficiency, particularly cystic fibrosis.

Tests for exocrine function: Pancreatic juice can be collected by duodenal aspiration or by endoscopy. Exocrine function may be tested directly (secretin pancreozymin test) or indirectly (Lundh test). The ability to produce enzymes and bicarbonate is tested after giving secretin 1 unit/kg I.V and pancreozymin 4 units/kg. This test is the gold standard for exocrine pancreatic function.

Normal Values

1. Volume output should be more than 2 mL/min and amylase more than 6 units/kg.
2. Bicarbonate concentration should be more than 80 mmol/L.
3. Bicarbonate output should be more than 10 mmol in 30 min.

Enzymes are also estimated and compared with the norms for the population studied.

Lundh test: This test is based on the effect of fatty acids and amino acids on the endogenous release of cholecystokinin which in turn stimulates secretion of pancreatic enzymes. This is an indirect test of pancreatic function since it depends on the endogenous release of pancreozymin from duodenal mucosa. The test may be misleading in the presence of duodenal mucosal disease. Normal value of tryptic activity by this test is 19.6 ± 3.5 mEq/mL per min.

Tubeless pancreatic function tests: The principle is to estimate the urinary elimination of digestion products of substances given orally. This indirectly estimates the digestive function. The two tests in this group are the 'benteromide test' and pancrealauryl test.

Benteromide test: N Benzyl-L-tyrosyl P-aminobenzoic acid is administered orally and its urinary elimination product para-amino benzoic acid is estimated. Chymotrypsin is the enzyme concerned. In the pancrealauryl test fluorescein laurate is given and the fluorescein eliminated in urine is estimated. Pancreatic esterases are the enzymes responsible.

Cytology of duodenal aspirate: Cytological examination may reveal the presence of neoplastic cells.

Isotopic scanning of pancreas: The isotopic scanning of pancreas can be done by using radioactive selenomethionine using ^{75}Se which is taken up by the pancreas.

Assessment of endocrine function: Studies of glucose homeostasis and determination of serum levels of insulin, glucagon, cholecystokinin and other peptide hormones help to assess the hormonal activity of the pancreas.

Radiography: Pancreatic calculi and calcification can be demonstrated in plain radiographs. In acute pancreatitis indirect evidences like dilatation of small bowel loops due to ileus may be present.

Ultrasound and CT scan: These are very helpful non-invasive methods for demonstrating deep-seated lesions. Ordinary method of ultrasonography is less reliable since the pancreas does not lend itself to proper imaging and, therefore, small lesions may be missed.

Endoscopic ultrasonography is a more reliable method to detect lesions even as small as 1 cm or less. It is helpful in staging pancreatic cancers, differentiating benign from malignant cystic lesions, obtaining FNAC from pancreatic mass lesions and guiding endoscopic drainage of pseudocysts.

Hypotonic duodenography and barium meal reveal the changes produced in duodenum and intestines by pancreatic lesions.

Endoscopic retrograde cholangiopancreatography (ERCP) is a very valuable tool in investigating the pancreas directly. ERCP shows ductal abnormalities such as dilation, obstruction and stones. It is the gold standard for the diagnosis and staging of chronic pancreatitis, with sensitivity of 75-95% and specificity of over 90%. Morbidity caused by ERCP is 3-4% and mortality 0.1 to 1%.

MRI cholangiopancreatography is a recently developed imaging modality with about 96-100% sensitivity to detect ductal stages in the pancreatic duct.

Pancreatitis

Pancreatitis may be acute or chronic. The incidence varies in different ethnic groups. Acute pancreatitis is seen infrequently as a medical or surgical emergency in India. Chronic pancreatitis accounts for a significant proportion of malabsorption syndrome. Chronic calcific pancreatitis with secondary diabetes is seen in some endemic areas, especially in Kerala. Pancreatitis is closely associated with alcoholism and biliary tract disease.

ACUTE PANCREATITIS

Pathogenesis: Acute pancreatitis results from auto-digestion of the pancreas by its own enzymes. The inactive precursors of proteolytic enzymes are activated by regurgitated bile, viral infections, ischemia, anoxia, trauma or toxins, within the pancreas. Digestion of the tissues results in edema, hemorrhage, vascular damage, coagulation necrosis, and fat necrosis. Secondary factors like liberation of activated enzymes, bradykinin and histamine-like substances into the pancreas result in vasodilation, exudation, and disseminated intravascular coagulation. These factors lead to further damage.

Acute pancreatitis has been defined as an acute inflammatory process of the pancreas with variable involvement of other regional tissues or remote organ

systems. In mild disease when organ dysfunction is minimal prognosis for recovery is good. In severe disease there are local lesions such as necrosis, abscess or pseudocyst formation and systemic complications such as respiratory distress, shock, gastrointestinal bleeding, renal failure and others. The extent of severity has been semiquantified by using clinicopathological criteria such as Ranson's criteria or Apache II scores (see Chapter 36).

Causes

1. *Alcoholic bouts.*
2. *Biliary tract disease*, especially cholelithiasis in the common bile duct.
3. *Trauma*—blunt abdominal injuries, surgical trauma, post-ERCP reaction.
4. *Metabolic causes*—hyperlipidemia, diabetes, renal failure, hypothermia.
5. *Endocrine causes*—hyperparathyroidism, corticosteroid therapy, oral contraceptives.
6. *Infections*—mumps, viral hepatitis, coxsackie and echo-viruses, mycoplasma.
7. *Pancreatic ductal obstruction* due to migration of *Ascaris lumbricoides* and other causes.
8. *Inflammation spreading from neighboring tissues*, e.g. penetrating peptic ulcer.
9. *Connective tissue diseases*, e.g. systemic lupus erythematosus.
10. *Drug-induced pancreatitis* caused by diuretics, anti-inflammatory drugs, azathioprine, 6-mercaptopurine, L-asparaginase, isoniazid, rifampicin, tetracycline, phenformin.

In many cases there may not be any identifiable cause.

Clinical features: Onset is sudden with acute upper abdominal pain which may radiate to the chest, precordium, back or lower abdomen. An alcoholic bout or heavy eating may precipitate the attack. The patient adopts a stooping posture with pressure on the abdomen to get relief. Nausea, vomiting, dehydration, and signs of shock occur in severe cases. Mild jaundice may be present in a few cases. Erythematous skin nodules may form due to fat necrosis. Secondary pleural effusion may develop on the left side.

Examination of the abdomen shows rigidity, marked tenderness, mild distension due to ileus of the intestines, and absence of peristaltic sounds. A bluish discoloration may be seen in the flanks (**Turner's sign**) or around the umbilicus (**Cullen's sign**) due to extravasation of blood into the abdominal wall. When present, these signs strongly suggest acute necrotising pancreatitis. Ascites may develop as a complication (*pancreatic ascites*).

Course and Prognosis: The acute phase subsides within a week but recurrence may occur. In general the mortality

is 10-20%. In hemorrhagic pancreatitis with profound shock the mortality is high. Adverse factors include elderly age, severe shock, respiratory failure, fall of serum calcium below 8 mg/dL, azotemia and high fluid requirements.

Laboratory features: Serum amylase is increased early during the stage of acinar necrosis and it comes down in 3-4 days. Amylase levels may reach even 2000 Somogyi units/dL. Urinary amylase is raised initially during the illness and it remains so for 4-7 days. In acute pancreatitis the renal clearance of amylase is higher than that of creatinine. The amylase/creatinine clearance ratio (Cam/Ccr) is increased in acute pancreatitis and this is a diagnostic feature. Serum amylase levels are elevated in other conditions such as cholecystitis, intestinal infarction, perforation and obstruction, and mumps. Amylase level is increased in the ascitic fluid of pancreatic ascites.

Moderate neutrophil leukocytosis is common. Blood glucose is increased and calcium is lowered. Serum bilirubin may be transiently elevated, up to 4 mg/dL in a few cases. Electrocardiogram abnormalities such as ST-T-wave changes may develop in some cases and this may resemble myocardial ischemia.

DIAGNOSIS

Radiology: Calculi in the biliary and pancreatic duct systems may be seen in the plain radiograph of the abdomen. Loops of duodenum and jejunum are distended (**sentinel loop**) due to ileus. The inner wall of the duodenal loop may show pressure effects and widening on barium meal and hypotonic duodenography.

Ultrasonography and CT scan help to assess the morphological abnormality in the pancreato-biliary system. Endoscopic retrograde cholangiopancreatography performed after subsidence of the acute phase helps to demonstrate the underlying abnormality.

Contrast enhanced CT is a very good imaging modality to reveal morphological changes in the pancreas. MRI scan gives additional information.

Differential diagnosis: Acute emergencies like gastric or duodenal ulcer perforation, acute cholecystitis, renal colic, hepatitis, peritonitis, acute myocardial infarction and pleurisy have to be considered in the differential diagnosis.

General complications: These include shock, hyperglycemia, hypertriglyceridemia, hypocalcemia, and disseminated intravascular coagulation. Infection generally supervenes on the necrotic tissue in 40-60% of cases. 10-15% of patients develop systemic inflammatory response syndrome (SIRS) leading to a fulminant course and multi-organ failure. SIRS is the result of activation of the inflammatory cascade mediated by cytokines, immunocytes and the complement system.

Local Complications

1. **Pancreatic phlegmon:** A solid mass composed of inflammatory tissue and fat necrosis develops and this may persist for 1-2 weeks.
2. **Pancreatic abscess.**
3. **Pancreatic pseudocyst:** Fluid and tissue debris collect in the lesser sac of peritoneum over a period of 1-4 weeks after the acute attack. Pseudocysts, in contrast to true cysts, lack epithelial lining on their walls. Wall of the pseudocyst is made up of necrotic material, granulation, and fibrous tissue around. Pseudocysts present like mass lesions, giving rise to local pressure effects.
Treatment consists of endoscopic or surgical drainage into the stomach or the small intestine.
4. **Pancreatic ascites** develops due to the rupture of pancreatic duct into the peritoneum. Massive intraperitoneal hemorrhage may develop.
5. **Intestinal infarction.**
6. **Obstructive jaundice.**

The terms hemorrhagic pancreatitis, phlegmon and pseudocyst which were in vogue, are seldom used at present.

Systemic Complications

Respiratory system: Atelectasis, left-sided pleural effusion, mediastinal abscess, adult respiratory distress syndrome.

Cardiovascular system: Myocarditis, pericardial effusion, sudden death.

Renal failure

Central nervous system: Fat embolism, psychosis.

Fat necrosis in several organs: This may involve skin, central nervous system, bones, and other organs.

TREATMENT

Mild cases require only symptomatic measures.

Medical management: Analgesics like methadone 10 mg or pethidine 100 mg are used to relieve pain. In severe cases, morphine 10-20 mg may be required. Since morphine causes spasm of the sphincter of Oddi, it may be combined with atropine 0.5 mg or propantheline bromide 15-30 mg. Oral feeding is avoided in the acute stages. Food is gradually introduced when the condition subsides.

Shock: It is managed on general lines by replacing fluids and electrolytes and the use of pressor agents when required. Intravenous administration of glucose and electrolytes has to be continued till the ileus disappears. Hypocalcemia is corrected by the administration of calcium gluconate intravenously. If diabetic state

develops, insulin has to be administered. Broad spectrum antibiotics are indicated to treat secondary infection.

If there is troublesome abdominal distension, continuous nasogastric aspiration may help. Necrotic lesions and local fluid collections should be evacuated by guided needle aspiration.

Surgery may be indicated at times in acute pancreatitis.

Indications

1. Excision of necrotic tissue (necrosectomy) is needed if there is extensive necrosis as demonstrated by helical CT with pancreatic protocol.
2. Drainage of pus is required if there is evidence of infection and abscess formation. Gram staining of FNAC specimen may reveal organisms.
3. Pancreatic ascites may have to be drained at times.
4. Relief of biliary obstruction if medical treatment by itself is not successful.

In the presence of biliary stones or other obstructive lesions, surgery is undertaken electively to prevent relapse of pancreatitis. Necrotic lesions and local fluid collections should be evaluated by guided needle aspiration. The material should be submitted for microbiological tests. Surgical debridement is indicated if there is infection and also in sterile abscesses which fail to improve with medical therapy.

Sometimes biliary obstruction may have to be relieved in the acute phase of pancreatitis itself if conservative measures fail to resolve the condition.

CHRONIC PANCREATITIS

Chronic pancreatitis is of two types—**relapsing** and **non-relapsing**. In this condition the pancreatic tissue is progressively destroyed and replaced by fibrosis.

Pathology: The pancreas is firm to hard, fibrotic, and distorted. Calculi may develop inside the distorted ductal system. Acinar tissue may also become calcified. Exocrine pancreatic function suffers when 80-90% of the acini are destroyed. Though the islets are relatively spared, they are also affected finally, resulting in diabetes. In chronic relapsing pancreatitis seen in India, diabetes mellitus is a prominent feature.

CLINICAL FEATURES

Chronic pancreatitis is more common in the fourth and fifth decades. It presents with recurrent upper abdominal pain following alcoholic bouts or dietary excesses. The pain may be referred to the back between T₁₀ and T₁₂ segments. These patients adopt a characteristic squatting posture with pressure applied to the abdomen. When present, this feature may suggest the diagnosis. Overt diabetes develops in one-fifth of the cases. Except for vague tenderness over the epigastrium, physical

examination may not reveal much. Less commonly, enlarged pancreas, pseudocyst or pancreatic abscess may be palpable.

Course and prognosis: Chronic pancreatitis tends to be persistent or recurrent, especially if accompanied by biliary tract disease. Complications include malabsorption state, malnutrition, obstructive jaundice, diabetes mellitus and higher risk of malignancy. Chronic pancreatitis carries a mortality of 50% in 20-25 years. Malabsorption develops when the exocrine function falls by 80%.

Diagnosis: Chronic pancreatitis should be suspected clinically in any alcoholic patient complaining of epigastric pain referred to the back.

Investigations: Plain X-ray of the abdomen may reveal pancreatic calculi and calcification of the substance of the gland in 30-40% of cases. Ultrasonography reveals enlargement, cysts, abscesses, and ductal abnormalities. Functional impairment can be assessed by undertaking exocrine function tests. The ERCP helps to delineate the biliary and pancreatic duct system and also in obtaining biopsies and to carry out procedures to relieve obstruction. Glucose tolerance test brings out the diabetic state. Serum amylase is not constantly elevated in chronic pancreatitis but its level may increase during acute exacerbations. Stool fat is increased (above 7 g in 24 h), this is made up of neutral fat. This helps to distinguish the condition from intestinal malabsorption in which the lipids are in the form of fatty acids. Vitamin B₁₂ malabsorption occurs since the vitamin is bound in the gut by proteins other than intrinsic factor and thus, rendered unabsorbable.

Treatment: Abstinence from alcohol and smoking and reduction of weight help to reduce exacerbations. Analgesics and antispasmodics may be necessary to relieve pain. Reduction of dietary fat to 20-30 g/day helps to reduce the abdominal discomfort and relieve steatorrhea in mild cases. Fat soluble vitamins have to be supplemented orally or parenterally as required.

Digestion can be aided by the administration of pancreatic enzymes or enzymes derived from fungal or other plant sources given orally after food. Pancreatic extract (Pankreon, Pancreatin) is available commercially. Four to six tablets (2-3 g) have to be given with meals or more frequently. This measure helps in digestion, corrects the steatorrhea, and also ameliorates pain. Vitamin B₁₂ malabsorption is also corrected. Though this is generally safe, excessive use of pancreatic extracts leads to hyperuricemia. In moderate and severe cases H₂ receptor blocker drugs such as ranitidine 150 mg bd or a proton pump inhibitor such as omeprazole 20 mg bd are given orally to reduce gastric acidity and thereby limit the inactivation of pancreatic enzymes in the intestine.

Medium chain triglycerides are useful to reduce diarrhea. They require only small amounts of pancreatic

enzymes for digestion. Moreover bile salts are not required for their absorption. Medium chain triglycerides are contained in oils such as coconut oil. Diabetes has to be treated on its own merits.

Surgery: Intractable pain, pancreatic cysts, pseudocysts and neoplasms are indications for surgery. In many cases, relief of obstruction and withdrawal of alcohol results in improvement of pancreatic function. In some cases removal of the affected portion of the pancreas may be required.

AUTOIMMUNE PANCREATITIS (AIP)

Syn: Autoimmune related pancreatitis

This was first described in 1955 by Yoshida et al to describe the form of pancreatitis that is associated with autoimmune manifestations revealed by clinical and laboratory parameters. AIP is a form of chronic pancreatitis caused by autoimmune inflammation. This leads to lymphocytic infiltration with associated fibrosis of the pancreas leading to organ dysfunction. AIP forms 5-11% of the total cases of chronic pancreatitis. Male to female ratio is 2:1 the disease is present in India and formed 1% of a serious from Vellore.

Ref: Etiology and clinical profile of chronic pancreatitis the CMC Vellore experience. Ashok Chacko and Shajan Peter in chronic pancreatitis and pancreatic diabetes in India. Edited by V. Balakrishnan and others published by The Indian Pancreatitis Study Group 2006.

Some cases show association with other autoimmune diseases such as rheumatoid arthritis, Sjögren's syndrome and inflammatory bowel disease.

Clinical features: A wide variety of symptoms may occur. Jaundice and mild to moderate abdominal pain are frequent. Imaging studies shows biliary duct strictures which may resemble those of primary sclerosing cholangitis. Histology helps to confirm the diagnosis.

Diagnosis: The CT scan image is characteristic. Endoscopic ultrasonography is an important tool to diagnose AIP. AIP has to be differentiated from alcohol induced pancreatitis and pancreatic cancer.

Treatment: Corticosteroids form the mainstay of treatment. Prednisolone in a dose of 40 mg/day/should be started orally and continued for a week, before tapering the dose.

TROPICAL PANCREATITIS

This is described under Section 10 chapter 92.

CYSTIC FIBROSIS OF THE PANCREAS

Syn: Fibrocystic disease of pancreas, Mucoviscidosis

Cystic fibrosis (CF) of the pancreas which was thought to be rare in India, is now reported to be present, though

infrequently. The incidence in orientals is 1/90000 of population, compared to 1/20000 in caucasians and 1/17000 in negroid races. CF is an autosomal recessive disease. The defective gene is located in the long arm of chromosome 7. Normally this gene encodes for a 1480-amino acid protein called cystic fibrosis transmembrane regulator (CFTR). The CFTR is a protein that regulates and participates in the transport of electrolytes across epithelial cell membranes and probably across intracellular membranes as well. At least more than 1000 mutations in the CFTR has been identified. Several molecular abnormalities in the gene give rise to a wide spectrum of clinical features.

CFTR mutations can be classified into six groups

1. CFTR is not synthesized
2. The processing is defective
3. Defective regulation
4. Defective conductance.
5. Partially defective production and processing and
6. Defective regulation of other channels

The primary defect in CF is one of disordered ion-transport in epithelial cells. This abnormality is manifested in almost all secretory glands particularly the sweat glands and mucus secreting organs such as pancreas, liver, lungs, intestines, salivary glands, prostate, testes and others.

Normally sweat is formed in the secretory coil of the sweat glands as an ultrafiltrate of plasma containing 135 and 100 mmol/L of sodium and chloride respectively. These ions are reabsorbed by the ductal epithelium and normal sweat contains only less than 50 mmol/L of Na^+ and Cl^+ , when the flow rate is 10 nanoliter/gland/minute. One of the main abnormality which is highly diagnostic, is the increase in chloride in the sweat to levels above 60 mmol/L.

Bicarbonate content of pancreatic juice is less than normal. The mucus secreted by mucous glands in all organs is abnormally viscid. This is responsible for blocking the smaller duct system and impairing ciliary activity.

Pathology: Pancreatic ducts are occluded and dilated to form cysts. Acini undergo atrophy. There is interstitial fibrosis. Islets of Langerhans are relatively unaffected. Intrahepatic bile ducts may show obstruction in 10% of cases. Cirrhosis with portal hypertension may develop. Lungs which are normal at birth, soon develop purulent bronchitis, bronchiectasis, and cystic changes. Other glands which develop ductal obstructions are the sublingual salivary glands, prostate, and testes.

Non-classic forms of CF occur in which milder mutation of the CFTR gene occurs, with partial preservation of pancreatic function. In this form malabsorption is rare.

Clinical Features

Earliest manifestation in the newborn is meconium ileus in which the meconium which is abnormally thick leads to intestinal obstruction. As the child grows the intestinal symptoms take the form of recurrent subacute or acute intestinal obstruction, ileocolic intussusception and rectal prolapse.

Pancreatic lesion leads to varying degrees of pancreatitis and malabsorption. Glucose tolerance may be impaired, frank diabetes is less common. If diabetes occurs, it shows features of both types 1 and 2.

In comparison to the respiratory morbidity, pancreatic dysfunction is milder.

Respiratory Infection

Occurrence of respiratory infection and sinusitis is also genetically related. The age of onset and severity of the lesions vary, depending on the genetic abnormality. Respiratory tract lesions include chronic sinusitis, nasal polyps, chronic otitis media and conductive deafness. Deafness is due to blockage of eustachian tubes. Respiratory findings include bronchiectasis, recurrent purulent infection, hemoptysis and pneumothorax. Main infective agents are *Staph. aureus* and *Ps. aeruginosa*. The latter is more serious and often drug resistant. Infection by *Ps. aeruginosa* marks the onset of a progressive downhill course. Death is normally due to respiratory failure. CF is one of the causes of chronic obstructive pulmonary disease and pancreatic insufficiency occurring before the age of 30 years. Congenital absence of vas deferens is almost universal.

Azoospermia occurs in 80-90% of males, and almost all males are infertile. Women can bear children. The degree of sub fertility is also related to the genetic mutation.

Diagnosis

This is established by determining sweat electrolytes. Sweat is collected by stimulating diaphoresis with pilocarpine iontophoresis. Major and minor diagnostic criteria are given below. Normal sweat chloride level is <40 mmol/L. In the non-classic form it may be 40-59 mmol/L.

Sweat chloride may rarely be increased in heavy tobacco smoking, chronic bronchitis, malnutrition, hereditary nephrogenic diabetes insipidus, adrenal insufficiency and ectodermal dysplasia. When sweat tests are inconclusive estimation of electrical potential difference between the nasal mucosa and forearm skin is helpful. Genotyping the CFTR gene helps to make more precise diagnosis.

Course and prognosis: If untreated, 80% of cases die in the first year of life. With treatment, median survival has

Criteria for diagnosis of cystic fibrosis

Major criteria

1. Sweat chloride exceeding 60 mmol/L in children and 80 mmol/L in adults.
2. Evidence of pulmonary involvement.
3. Obstructive azoospermia.

Minor criteria

1. Sweat chloride 40 mmol/L in children and 60 mmol/L in adults.
2. Family history of cystic fibrosis or azoospermia.

Definite diagnosis is made if two major criteria, or a combination of one major and one minor criterion from two different organ systems are present.

gone up to about 30 years. Death is due to respiratory complications.

MANAGEMENT

Digestive enzyme replacement therapy and nutritional support help to reduce the ill-effects of chronic pancreatitis.

Respiratory problems are treated with antibiotics, respiratory physiotherapy, bronchodilators and expectorants. Attempts are being made to deliver the aminoglycoside tobramycin, as aerosol, with partial success. Advances in therapy include the use of inhaled glucocorticoids in selected cases, NSAIDs like ibuprofen and the interleukin r.IL₁₀.

Intractable cases have to undergo lung-transplantation. Attempts to institute gene therapy are in progress. Relatives of CF patients should undergo genetic tests and sweat tests to enable diagnosis early.

PANCREATIC ASCITES

Pancreatic ascites is due to leakage of pancreatic juice into the peritoneum from a ruptured duct or pseudocyst. The fluid is rich in proteins and enzymes. The fluid may leak into the pleura causing a pancreaticopleural fistula. 50% of these cases can be managed nonsurgically by paracentesis, diuretics, carbonic anhydrase inhibitors or octreotide, and parenteral nutrition. If these fail, surgical measures aimed at diversion of the pancreatic juice to jejunum or using stents in the pancreatic duct may be needed.

CARCINOMA OF THE PANCREAS

This neoplasm is seen in all parts of India not uncommonly. It is more common in women of the age group 55-70 years, but both sexes may be affected. Histologically, they are adenocarcinomas arising from the ductal epithelium and occasionally from the acini. In some cases ductal carcinomas arise multicentrically.

Genetic analysis has revealed that several germline mutations of P16, BRCA1, BRCA2, Rb and APC genes are associated with increased incidence of pancreatic cancer. Cigarette smoking, hereditary pancreatitis and hereditary non-polyposis colorectal cancers are associated with higher risk of cancer pancreas.

Clinical features: Pancreatic carcinomas may remain asymptomatic for long periods. The lesion is generally advanced by the time it becomes symptomatic. Early symptoms are vague such as nonspecific dyspepsia, epigastric pain, and vomiting. Thrombophlebitis migrans (recurrent venous thrombosis occurring in different parts) may develop in carcinomas of the body and tail of the pancreas.

Many cases may be misdiagnosed as hysteria or other neurotic disorders, before the actual diagnosis reveals itself.

Growths arising from the head of the pancreas cause painless progressive obstructive jaundice because of pressure on the common bile duct. The gallbladder enlarges and becomes palpable. The tumour may become palpable in the epigastrium on rare occasions. Lesions affecting the body and tail do not produce jaundice but diabetes may develop when the lesion is extensive. Cachexia sets in late. Severe boring pain referred to the back develops when the nerves are affected. Death follows within 6 months of the onset of obstructive jaundice in untreated cases. Only 10% survive one year.

In carcinoma of the ampulla of Vater, obstructive jaundice is an early symptom. Ulceration and bleeding from the growth give rise to melena or a silvery colour to feces.

Investigations: Carcinoma of the pancreas should be suspected when elderly persons complain of vague upper abdominal symptoms, painless progressive obstructive jaundice with a palpable gallbladder, migrating thrombophlebitis or progressive cachexia. Ultrasonography, CT scan, and ERCP give diagnostic information. Pancreatic juice collected endoscopically may reveal malignant cells. Angiography helps to visualize the mass and its blood supply.

Spiral CT, MRI, cholangiopancreatography, and endoscopic ultrasonography help to bring out even small tumours better.

Treatment: Operable tumours of the ampulla of Vater are treated by excision of the duodenum and head of the pancreas. In inoperable cases biliary obstruction is relieved by cholecystojejunostomy or choledochojejunostomy. This drainage procedure gives immense symptomatic

relief. Effective palliation of jaundice can be achieved with endoscopic stenting of bile duct.

Endocrine Tumours of the Pancreas

These are rare, but characteristic clinical features develop when they occur.

Islet cell tumours: Benign adenomas are rare. They secrete insulin and give rise to spontaneous hypoglycemia, which develops in the morning on a fasting stomach or after heavy exercise. This condition is relieved by food.

Zollinger-Ellison syndrome: This is due to gastrin-secreting tumours arising from the islets of Langerhans.

They are more common in the body and tail of the pancreas. Sometimes they may be multicentric. They may form part of multiple endocrine adenomatosis (MEN type I-Werner's syndrome), the other lesion being parathyroid adenoma. Excessive gastrin leads to the secretion of large amounts of gastric acid and aggressive gastric ulceration. (Refer section 8, Chapter 78, pp 470).

Other Non-beta Cell Pancreatic Tumours

Glucagonoma: This arises from the alpha cells which grow to form adenomas or carcinomas and secrete excessive glucagon. These patients present with diabetes mellitus, severe weight loss and a skin rash termed as necrolytic migratory erythema seen particularly over the face, buttocks, abdomen, perineum, and distal parts of the limbs. Treatment involves surgical removal of the tumour.

Watery diarrhea, hypokalemia achlorhydria (WDHA) syndrome, Verner-Morrison syndrome, Pancreatic cholera: This condition is caused by a non-beta cell pancreatic islet neoplasm which produces excessive quantities of vasoactive intestinal peptide (VIP). In comparison to the other endocrine tumours, these are larger. The severe watery diarrhea gives rise to shock, renal shut down, fatal hypokalemia, and metabolic acidosis. The VIP also causes hyperglycemia and hypercalcemia. When located, treatment is surgical removal.

Somatostatinoma: Tumours producing somatostatin have been described in a few cases. Somatostatinomas are associated with hyperglycemia, loss of weight, hypochlorhydria, steatorrhea, and gallbladder disease.

Tumours secreting adrenocorticotrophic hormone: These may arise from pancreatic islets. Cushing's syndrome produced by these tumours is milder than the classical types. In many of the cases several hormones may be produced, e.g., insulin, gastrin, serotonin, etc.

General Considerations

Diabetes mellitus is a chronic metabolic disorder characterized by hyperglycemia with or without glycosuria, resulting from an absolute or relative deficiency of insulin. This is brought about by an impairment of insulin production or its release by the beta cells of the islets of Langerhans. More often it is due to a resistance to the action of insulin either due to a receptor/post receptor defect or an imbalance between insulin and its counter regulatory hormones. Clinically diabetes is characterized by a wide spectrum of disorders ranging from asymptomatic hyperglycemia to abnormalities in the various organs.

PANCREAS

The endocrine component of the pancreas consists of different types of cells: α -cells, β -cells, δ -cells and PP cells contained in the islets of Langerhans which constitute 1% of its weight. There are 100,000 islets in the pancreas, and each islet contains 1000-3000 cells. Thus altogether there are 100-300 million β -cells in the pancreas.

Pancreatic beta cells can store 200 units of insulin and can release 30-50 units of insulin per day.

95% of cells of the pancreas have exocrine function and 5% have endocrine function. The beta cells produce insulin, alpha cells produce glucagon, delta cells produce somatostatin and the PP cells produce pancreatic polypeptide.

Epidemiology

Diabetes is a major public health problem all over the world. Its prevalence varies in different populations, being very high to the extent of 40% of all those above the age of 15 years in Pima Indians, 34% in Micronesians particularly of Naura, and in migrant Indians in S. Africa, Fiji, UK and USA. It is low in Eskimos, tribes in India and primitive populations of Africa. The prevalence of diabetes is likely to double itself during the next few years. By the year 2025, the number of people suffering from diabetes in the world is estimated to be 350 million, of which 70 million will be in India (Table 90.1). *The previously used terms insulin dependent diabetes mellitus (IDDM) and non-insulin dependent diabetes mellitus (NIDDM) are now termed as type 1 and type 2 diabetes mellitus.*

The Multicenter ICMR study done in 1972 reported prevalence rates 2.3% in urban and 1.5% in rural populations. More recent studies have shown that the prevalence is increasing with rates of 10-13% in urban and 2.4% in rural areas.

Type 2 diabetes is by far the most common type of diabetes encountered in India, accounting for more than 95% of the total. It generally starts between the age 30-40 years. The incidence increases with age, males are more commonly affected and 58% of the Indian diabetics have a positive family history of diabetes. The incidence of type 1 DM in India is very low (Tables 90.2 and 90.3).

Type 1 diabetes or IDDM is more common among the Caucasian populations of Finland, Sweden, USA and the UK accounting for 25-150 per 100,000 populations. Its prevalence in India is less than 1% of all diabetics.

A survey conducted in Neyyatinkara taluk of Trivandrum district under the auspices of Health Action by People on 83,00 persons revealed the overall prevalence of type 2 diabetes mellitus in persons aged 20 and above was 6.7% with higher prevalence in males. When adjusted to an internationally comparable population, the prevalence in those aged 30-64 worked out to be 8.2%. The demographic pattern of type 2 diabetes is also changing with a shift to start in younger persons. In the USA, where the overall prevalence increased by 33% between 1990 and 1998, the prevalence in the age group 30-39 years rose by 70%.

CLASSIFICATION

The Classification suggested by American Diabetes Association (ADA) is called as the etiological classification of diabetes and has the two main types of diabetes labeled as type 1 and type 2, along with gestational diabetes mellitus and the other specific types where a precise etiological factor is identified.

The revised diagnostic criteria give equal importance to the fasting and 2 hours post glucose load plasma

Break up of types of diabetes mellitus seen in a tertiary care hospital in Trivandrum 2005-2007

Type 2 DM	96%
Type 1 DM	0.8%
Gestation DM	1.2%
DM secondary to drugs, pancreatic disease and viral infections	± 2%

glucose (2h PG) for the diagnosis of diabetes, thereby eliminating the need for a routine oral glucose tolerance test (OGTT) for the diagnosis of diabetes. The cut-off level of fasting plasma glucose (FPG) for diagnosis of diabetes has been fixed as 126 mg/dl, since this reflects the same degree of hyperglycemia as a 2hr-PG of 200 mg/dl in terms of susceptibility for the development of micro-vascular and macrovascular complications. These criteria are expected to rationalize and simplify the diagnosis of diabetes and a larger number of people could be screened due to the simplification of the procedure of doing only fasting plasma glucose rather than an OGTT.

An intermediate group of subjects are recognized whose glucose levels, although not meeting the criteria for diabetes, are nevertheless too high to be considered altogether normal. This group is defined as having FPG levels above 100 mg/dL (6.1mmol/L) but below 126 mg/dL (7.0 mmol/L) and/or 2-hour values in the OGTT of 140 mg/dL (7.8 mmol/L or above, but below 200 mg/dL (11.1 mmol/L) (Table 90.4).

TABLE 90.4

Criteria for diagnosis of prediabetes		
Category	Fasting plasma glucose	2-hr post-prandial
1. Normal	< 100 mg/dL	< 140 mg/dL
2. Impaired fasting glucose (IFG)	100-125 mg/dL	<140 mg/dL
3. Impaired glucose tolerance (IGT)	<100 mg/dL	140-200 mg/dL

Etiopathogenesis

Type 1Diabetes: Type-1 diabetes mellitus has been classified into type-1A in which cell-mediated autoimmune attack on the beta cells is more prominent and type-1B in which the mechanism is less clear. Type1B is less frequent of the two. In Asians and Africans type-1B is seen more frequently than in the whites. HLADR / DQ confer 50% susceptibility whereas other genes confer 15%.

Classification of type-1 diabetes mellitus

- 1. Preclinical
 - a. Autoantibodies + / OGTT normal.

- b. Autoantibodies + / OGTT abnormal.
- c. Autoantibodies + / fasting hyperglycemia
- 2. Clinical – with diabetes
 - 1a. Autoantibodies present (autoimmune)
 - 1b. Autoantibodies absent (idiopathic)
- 3. Explosive onset / fulminant onset
- 4. Rapid onset
- 5. Late onset (LADA).

HLA Associations

Type 1 diabetes is a heterogeneous disorder in which several factors may play a role. These are the HLA system, viral infections, and autoimmune processes. Type 1 tends to be a familial disorder and there is a 25-fold increase in the risk amongst the siblings than the general population. Its inheritance is related to HLA loci on chromosome 6. It is seen that HLA B8, B15, B6, B21, BW3, DR3 and DR4 are associated with a higher risk of diabetes mellitus. On the other hand, a negative association has also been noted with HLA B7. In Asian Indians and Japanese, Type 2 appears to be associated more with HLA BW21 and BW 54 than with B8. HLA DR 4 is associated with two alleles of the DQB1 locus— DQW8 and DQW7 and five alleles of DRB1 locus. 96% of type 2 diabetes are homozygous for the amino acid aspartate at position 57 of the DQB chain, compared with only 19% of the general population. Both DQW8 (DR 3 associated) and DQW2 (DR4 associated) have a neutral amino acid at position 57 rather than aspartate. DR3 and DR4 (DQW 8 and DQW2) heterozygous individuals in the general population can now be identified who have an 8% risk of developing type 1 diabetes. DR2 and DQPi afford strong protection. Among identical twins only 50% show concordance for type 1 diabetes as against 100% for type 2 diabetes.

Despite current emphasis on genes within the major histocompatibility complex it is likely that genetic susceptibility to type 1 DM in humans will be influenced by multiple genes. Genetic heterogeneity will not only influence the probability of autoimmune-beta cell destruction but also the rate of damage and age of onset of type 1 DM. The DQB 1 allele is associated with high levels of anti-GAD (glutamic acid decarboxylase) antibodies and the DR4 alleles are associated with elevated levels of anti-insulin antibodies. For the development of type 1 DM, 50% susceptibility is conferred by HLA. Other genetic factors confer 15%. In the west, only 50-60% of type 1 diabetes are below the age of 18 years. The situation in India is not very clearly known.

The immunological and metabolic changes occur long before the development of symptoms of hyperglycemia. This period preceding the development of diabetes, is known as prediabetes during which there is increase in the levels of pancreatic islets cell antibodies (PICA) and impaired first phase insulin release (FPIR) and this is the stage where preventive strategies are being aimed at in interventional trials (Tables 90.5 to 90.7).

TABLE 90.5

Etiological classification of diabetes mellitus (ADA)

1. Type 1 diabetes (cell destruction, usually leading to absolute insulin deficiency)
 - Immune mediated
 - Idiopathic
2. Type 2 diabetes (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance)
3. Other specific types
 - A. Genetic defects of cell function
 - Chromosome 12, HNF-1 (MODY 3)
 - Chromosome 7, glucokinase (MODY 2)
 - Chromosome 20, HNF-4 (MODY 1)
 - Mitochondrial DNA
 - Others.
 - B. Genetic defects in insulin action
 - Type A insulin resistance
 - Leprechaunism
 - Rabson-Mendenhall syndrome
 - Lipotrophic diabetes
 - Other
 - C. Diseases of the exocrine pancreas
 - Pancreatitis, Trauma, Pancreatectomy
 - Neoplasia
 - Cystic-Fibrosis, Hemochromatosis
 - Fibrocalculous pancreatopathy
 - Others
 - D. Endocrinopathy
 - Acromegaly/Cushing's syndrome
 - Glucagonoma, pheochromocytoma
 - Hyperthyroidism, somatostatinoma
 - Aldosteronoma
 - Others
 - E. Drug or chemical induced
 - Pentamidine
 - Nicotinic acid
 - Glucocorticoids
 - Thyroid hormone, diazoxide
 - Adrenergic agonists
 - Thiazides, phenytoin
 - Interferons
 - Others. Immunosuppressive drugs, steroids, tacrolimus, cyclosporin
 - F. Infections
 - Congenital rubella
 - Cytomegalovirus
 - Others
 - G. Uncommon forms of immune mediated diabetes
 - Stiff man syndrome
 - Anti-insulin receptor antibodies
 - Others
 - H. Genetic syndromes associated with diabetes
 - Down's syndrome, Turner's syndrome
 - Klinefelter's syndrome
 - Wolfram's syndrome, Friedreich's ataxia
 - Huntington's chorea
 - Laurence-Moon-Biedl syndrome
 - Myotonic dystrophy, porphyria
 - Prader-Willi syndrome
 - Others
4. Gestational diabetes mellitus

TABLE 90.6

Criteria for diagnosis of diabetes mellitus (ADA 1997) – accepted all the world over

- 1. Symptoms of diabetes plus casual plasma glucose 200 mg/dl (Casual is defined as any part of the day without regard to time since the last meal. The classic symptoms of diabetes include polyuria, polydipsia and unexplained weight loss)
OR
- 2. Fasting plasma glucose (FPG) 126 mg/dl (fasting is defined as no caloric intake for 8 hours)
OR
- 3. A 2-hour post-glucose-load plasma glucose (2 hr PGBS) 200 mg/dL during oral glucose tolerance test (OGTT).

Note: The test should be performed as described by the WHO using a glucose load containing the equivalent of 75g of anhydrous glucose dissolved in water. In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day.

The expert committee on the diagnosis and classification of diabetes mellitus (American Medical Association) has defined normal plasma glucose as 100mg/dL. Values between 100 and 126 are classified as impaired fasting plasma glucose (FPG).

Infections

Coxsackie B4 has been incriminated to play a causal role in the pathogenesis of type 1 DM. The other viruses known to play a role are mumps, CMV, EBV, varicella and the viruses causing infective hepatitis. An autoimmune etiology is suggested by its association with other autoimmune disorders such as Hashimoto’s thyroiditis, pernicious anemia and Addison’s disease. Pancreatic islet cell antibodies (PICA) and cell surface antibodies are demonstrable in several patients with recent onset type 1 DM. It is possible that all the three factors namely HLA status, viral infections and autoimmunity interact to produce the disease. In type 1 DM there is progressive loss of beta cell and in severe forms they may be totally absent. Insulin secretion progressively decreases to almost nil when the disease is fully established.

Autoantibodies in Type 1 DM

These are the antibodies produced against certain antigens of the beta cells. They have not been found to have any etiological role in type 1 diabetes, but mainly serve as markers of type 1 diabetes. These antigens are glutamic acid decarboxylase (GAD), insulin, islet cells etc. Based on the pathogenesis, type 1 DM has been divided into type 1A and type 1B. In the former there is cell mediated autoimmune attack on beta cells. Type 1B is less frequent. The cause is not clearly known. Type 1B is more seen in Asians and Africans.

TABLE 90.7

HLA antigens and the effects they confer on Type 1 diabetes susceptibility

HLA antigen	Effect on diabetes susceptibility
DQ2	Predisposes
DQ8	Predisposes
DQ7	Neutral/protects
DQ6	Protects
DQ18	Protects

Latent Autoimmune Diabetes in the Adult (LADA)

A slow onset form of type 1 diabetes has been described. In this subtype, subjects are initially well controlled with oral drugs (mimicking type 2 diabetes) but have a rapid acceleration of beta cell failure, leading to a frank autoimmune beta cell failure and long-term dependence on insulin in later years.

Type 2 DM

Type 2 DM (previously known as NIDDM) is considered as a ‘multifactorial’ or ‘complex’ disease due to the complex interaction between various genetic and environmental factors in its pathogenesis. Multiple evidence suggests that genetic factors play a major role in this condition. A genetic predisposition running through families is evident. Identical twins invariably develop type 2 diabetes when exposed to the same environmental factors. In genetically predisposed individuals several environmental factors precipitate the onset of diabetes. Important among these are obesity, physical inactivity, repeated pregnancies, infections, physical or psychological stress and *diabetogenic* drugs. Birth of large babies weighing above 4 kg is a strong pointer to the subsequent development of diabetes in the mother.

Obesity

The current obesity epidemic due to the modern sedentary life and caloric abundance is a major factor that predisposes to type 2 diabetes. Hence it is invariably seen that type 2 diabetes is closely related to obesity. Obese subjects show a relative resistance to the action of insulin due to a reduction in the number of insulin receptors on the target cells. The full complement of receptors is restored on shedding the excess weight.

There is an association between low birth weight in infancy and occurrence of IGT or DM in young adulthood. Increase in the body mass index (BMI) after the age of 2 years is also associated with the chance to develop DM.

Physical Inactivity

It seems to act as a factor favoring the onset of type 2 diabetes. Many of the diabetics are physically inactive. Physical exercise improves their exercise tolerance.

Role of Insulin antagonists: Glucose metabolism is delicately balanced by the coordinated effects of insulin antagonist hormones like glucagon, cortisol, catecholamines and growth hormone. Several other hormones also take part in the metabolism of carbohydrates. Imbalance of this hormonal profile results in carbohydrate intolerance.

Other antagonists to insulin: Antibodies to insulin may develop in individuals who are on treatment with insulins especially the animal insulins. The antibodies inactivate endogenous as well as administered insulin. Such patients show progressive insulin resistance. Fatty acids which compete with carbohydrate for metabolism in muscle lead to insulin resistance. In hyperlipidemia insulin dependent carbohydrate metabolism suffers and a relative insulin resistance develops.

Thus it would seem that persons are predisposed to develop type 2 diabetes by genetically. However lifestyle factors will determine the onset, age of onset, severity of the metabolic defect and further course. The interplay of genetic and environmental factors is well brought out by the studies on migrant Indians who have settled in affluent countries. These studies show that although the prevalence of diabetes in India is about 6-7%, it increases sharply to 10- 12% in Indians who have migrated to the developed countries.

10

Amylin

The role of amylin, a 37-amino acid protein in the pathogenesis of type 2 diabetes has been established. Amylin is normally produced by the beta cells and co-secreted with insulin. This amylin has favorable metabolic effects in normal healthy individuals. But due to several reasons it gets deposited as insoluble fibers in the islets of patients with type 2 diabetes. This islet amyloidosis which is the main pathological hallmark seen in 90% of patients with type 2 diabetes at autopsy studies is considered to be one of the factors responsible for beta cell failure in addition to glucotoxicity and lipotoxicity.

INSULIN

This is the hormone produced by the beta cells of the islets of Langerhans and is composed of two polypeptide chains A and B linked together by two disulfide bonds. The precursor of insulin is proinsulin (big insulin) from which C-Peptide is broken off to form insulin with a molecular weight of 6000 D. Insulin is stored in the granules of the beta cells to be discharged into the interstitial fluid under appropriate stimulus. The proinsulin cross-reacts with insulin antibodies but has none of the metabolic effects of insulin. Insulin secreted by the beta cells enters the portal circulation and the liver traps 50-60%. The remaining portion enters the peripheral circulation. This

can be estimated as immunoreactive insulin (IRI). Basal value of IRI in health is 2-20 μ U/ml. Since C-peptide is secreted in equimolar quantities with insulin its level can be estimated to assess the functioning beta cell reserve.

The main stimulus for insulin formation and release is hyperglycemia caused by ingestion of carbohydrates. Other stimuli include rise in amino acids produced by protein digestion, growth hormone, glucagons, gastrin, pancreozymin, secretin and several other gut hormones especially gastric inhibitory polypeptide (now called glucose dependent insulinotropic polypeptide - GIP and neurohormones such as enkephalin and endorphins. Glucagon like peptide (GLP-1) is a potent insulin-releasing hormone, which triggers insulin release in response to postprandial hyperglycemia. Substances having this property are listed as **incretins**. Insulin reaches its target cells through blood. Levels of circulating insulin vary during the different periods of the day, being lowest in the fasting state. Immunoreactive insulin level ranges from 5-50 IU/mL in fasting normal subjects. On the target cell insulin binds to specific surface receptors and then initiates further biochemical events within the cell. The insulin receptors are large molecular weight proteins (500,000 D), which mediate insulin action. The metabolic actions are together known as post-receptor effect. Sensitivity of insulin depends upon the number of unbound receptors. The number of receptors varies inversely with the levels of circulatory insulin. The sensitivity of the receptors to insulin has a major role to play in the causation of diabetes mellitus. The genetic locus for insulin is on chromosome 11 and that for the receptors is on chromosome 19. Alteration of the cell membrane by insulin favors the entry of glucose, potassium and amino acids into muscles, liver and fat cells. Insulin retards gluconeogenesis in the liver. Excess glucose entering the skeletal muscle is converted into glycogen. Insulin helps to build up adipose tissue by aiding the conversion of glucose into fat and blocks the escape of fatty acids from fat cells. In conjunction with growth hormone, insulin enhances the incorporation of amino acids into peptides in the liver and skeletal muscles.

Insulin activates a series of lipid and protein kinase enzymes linked to the translocation of glucose transporters to the cell surface, synthesis of glycogen, proteins, messenger RNAs (mRNAs) and nuclear DNA which affect cell survival and proliferation.

Pathological Changes

Pancreas: In **type 1** diabetes the beta cells of the islets of Langerhans show reduction in number, degranulation and hyalinization. In recent onset type 1 DM lymphocytic infiltration of the islets occurs and this may be caused by viral infection. Inflammation is seen particularly around the beta cells only and not around the other types of cells.

In type 2 DM during the early phase the beta cells are normal in number or only slightly reduced. The beta cells lose their sensitivity to the hyperglycemic stimulus for releasing insulin. As a result insulin secretion loses its smooth and fine relationship with glucose level. It tends to be erratic. In the early stages of evolution of type 2 DM—the reduction in the sensitivity of the receptors is compensated by overproduction of insulin and accompanying hyperinsulinemia. Frank diabetes results when beta cells starts failing and insulin production comes down.

Insulin resistance in muscle develops early in persons who would develop type 2 diabetes later. Beta cell function starts deteriorating about 10 years before the onset of DM, by which time the beta cell function has fallen to 30% or less.

Acanthosis nigricans is a cutaneous marker of hyperinsulinemia. Both impaired fasting glucose (IFG) and impaired glucose tolerance (IGT) lead to type 2 diabetes in a variable proportion of patients.

Several factors account for the frequency and time of onset of complications in diabetes. These include the abnormalities of glucose levels, genetic factors, smoking, obesity, hypertension, hyperlipidemia and others.

Vascular Changes

Diabetics show a predisposition to develop vascular lesions affecting both small and large blood vessels. In microangiopathy, there is specific involvement of the small blood vessels. Venules, capillaries and arterioles are affected in this process. There is deposition of PAS (periodic acid Schiff) positive material in the capillary basement membrane. Glycosylation of several proteins in the vessel wall results in increased permeability. The basement membrane is thickened. Ultimately there is vascular occlusion.

Microangiopathy is most marked in type 1, developing early in life but also occurs in type 2. Various factors like endothelial damage, increased plasma viscosity, erythrocyte aggregation, reduced red cell deformability and increased platelet adhesion lead to microangiopathy. The problem is more complex and the entire process is still not fully understood. Microangiopathy affects several organ systems. The main lesions are seen in the retina; kidneys, peripheral nerves and heart giving rise to diabetic retinopathy, nephropathy, many forms of diabetic neuropathy and cardiomyopathy.

Macroangiopathy

The diabetic is prone to develop occlusive vascular disease in medium sized arteries such as the coronary, cerebral and peripheral limb vessels. The process is one of atheroma which sets in at younger ages and is more extensive than that occurring in non diabetics. These lesions lead to increased risk of ischemic heart disease, cerebrovascular accidents and ischemia to the limbs with

intermittent claudication and peripheral gangrene. Macroangiopathy largely accounts for the steep rise in mortality in middle-aged diabetics.

Retinopathy

Diabetes mellitus produces a classical retinopathy. A specific change occurs in the vessels leading to loss of mural cells (pericytes) and the formation of micro aneurysms. The occurrence of retinopathy is related more to the duration of the disease than to the severity. Once initiated the fundus changes are usually progressive. The early changes are venous dilation and the appearance of small dot like micro aneurysms in the perimacular area. Arterial blood is shunted and this leads to ischemia of the retina. Increased vascular permeability accounts for the formation of exudates. In the next stage dot and blot hemorrhages predominate. Large subhyaloid hemorrhages and vitreous hemorrhages may develop and vision is seriously impaired. Such hemorrhages are due to rupture of newly formed blood vessels. As these hemorrhages are absorbed, organization by fibrous tissue results and multiple bands of retinitis proliferans develop. These lead to permanent visual impairment. The fibrous bands may contract giving rise to retinal detachment. Leaking vessels in the retina can be demonstrated by fluorescein angiography. Retinopathy is usually associated with advanced nephropathy. Sometimes in diabetic ketoacidosis with severe hyperlipidemia the fat gives a milky white appearance to the retinal arteries called “lipemia retinalis”.

Renal Lesions

These are commonly seen in subjects who have had diabetes for over 15-20 years. Vascular changes include (i) arteriosclerosis of the renal artery, (ii) sclerosis of the arterioles and (iii) glomerulosclerosis. Glomerulosclerosis may be nodular (Kimmelstiel-wilson lesion) or diffuse. There is accumulation of PAS positive eosinophilic material within the mesangium. There is thickening of the glomerular capillary basement membrane. The establishment of glomerulosclerosis is indicated by the presence of proteinuria. Further damage to the glomeruli results in the development of chronic renal failure.

Distinct stages can be defined in the evolution of diabetic nephropathy. In the initial stages, asymptomatic microalbuminuria in which up to 200 mcg/minute of albumin may be lost in the urine. Normal subjects do not lose more than 20 mcg/min or 300 mg of protein in 24 hours. Microalbuminuria is not detectable by the ordinary laboratory tests. In type 1 DM there is elevation of systolic BP during sleep preceding micro albuminuria. This rise in BP is an important contributory factor in the development of structural changes in the kidneys. It is absolutely necessary to control blood pressure also along with blood sugar to prevent deterioration.

In the early stage the kidneys are enlarged, more vascular and the glomerular filtration rate (GFR) is

increased. *In the second stage*, there is microalbuminuria and in *third stage* the proteinuria is more pronounced and easily detectable by routine tests. Loss of 3.5g or more of protein in 24 hours may lead to the development of nephrotic syndrome. Hypertension develops during this stage. In the fourth stage further structural changes develop and the glomerular filtration rate comes down with gradual increase in the blood levels of metabolic waste products such as creatinine and urea. The fifth stage is one of gross reduction of glomerular filtration and overt renal failure with azotemia, severe hypertension and complications such as cardiac failure and end stage renal failure. Autonomic neuropathy may lead to functional obstruction of the bladder, retention with over flow, urinary infection and further deterioration of renal functions. Another system of classification is based on creatinine clearance.

The diabetic patient is predisposed to develop urinary infection and therefore acute and chronic pyelonephritis are very common. Fulminant urinary infection leads to ischemic necrosis of the renal papillae. This presents as acute anuric renal failure. Fleshy masses may be passed in the urine. These are the necrosed papillae and the condition is called papillitis necroticans ulcerans. Emphysematous pyelonephritis is another serious complication.

Peripheral Nerves

In the myelinated nerve fibers, axonal atrophy was considered to be the primary lesion, secondary to ineffective axonal transport. Axoglial dysfunction, and abnormalities of paranodal connections between the terminal myelin loops and the axonal membrane have also been described. This could explain the reduction in nerve conduction velocity. This improves with therapeutic inhibition of aldose reductase. More recent studies, however provide evidence for the presence of demyelination and hence Schwann's cell involvement is the primary lesion. As the myelinated fibers degenerate, there is an attempt to regenerate, which manifests in the form of regeneration clusters. With progress of the neuropathy the density of the regeneration clusters also comes down.

Structural abnormalities have also been found in the vessels supplying the nerve fibers. The epineural vessels show arteriolar attenuation, venous distension, arterio-venous shunting and new vessel formation along with intimal hyperplasia and hypertrophy, denervation and reduction in neuropeptide expression. The perineural vessels also demonstrate basement membrane thickening and endothelial cell hypertrophy and hyperplasia. There is also a reduction in capillary density and occurrence of pericyte loss with reduction of endoneural oxygen tension and blood flow to the nerves. In a large series from south India overall prevalence of diabetic neuropathy was 19.1% among a group of 1000 consecutive diabetic patients. Age and the duration of diabetes were important risk factors.

CLINICAL FEATURES

The clinical manifestations of diabetes are protean. Though the symptoms are similar in both types of diabetes, in type 1 they develop acutely whereas in the majority of the type 2 the onset is insidious. Type 1 patients are usually below the age of 30, thin and emaciated and unless promptly treated with insulin, they would develop ketoacidosis.

Clinical features	Type 1	Type 2
Usual age at onset (yrs)	5-30 years	35-65 years
Sex	M:F 1:1	F>M (in India)
Prevalence Among diabetes	15-18% in Caucasians 1% in Indians	95-98% of Indians
Genetic	Heredity+ Strong HLA association	Heredity +++ No HLA association
Nutrition	Lean	Often obese
Usual onset	Rapid with classic symptoms	Slow, insidious, often with only mild symptoms
Ketosis	Prone	Not prone
Islet cell antibodies	May be present within 1 year of onset	Absent
Treatment modality	Almost all require insulin for control of sugar	Majority can be controlled by oral hypoglycemic drugs (OHAs)

Due to the high prevalence of obesity, type 2 diabetes is occurring at earlier ages as a global phenomenon, especially in developed countries.

Type 2 patients are generally above the age of 30, obese, usually asymptomatic and may present directly with the vascular complications of diabetes. **Around 50% of the cases present with the classical symptoms of polyuria, polyphagia and weight loss.** These symptoms can be directly correlated with hyperglycemia and glycosuria. Other clinical presentations which warrant full investigation to exclude diabetes are (i) non-healing ulcers (ii) recurrent respiratory or urinary tract infections (iii) Rapid changes in refraction of the eyes (iv) steady and unexplained rapid weight loss (v) increased tendency for fungal infections like moniliasis, balanoposthitis and vulvitis; (vi) unexplained peripheral neuropathy (vii) premature onset of ischemic heart disease, stroke or vascular occlusions (viii) history of overweight babies and recurrent fetal loss in women (ix) premature cataract often below the age of 50 years and retinopathy

(x) impotence in males, and (xi) any vague ill-health. In some cases, diabetics may present to the doctor for the first time with any of the major emergencies, without any apparent illness previously.

Malnutrition Related Diabetes Mellitus (MRDM)

Syn: type 2 lean diabetes

The latest classification proposed by WHO has deleted the term MRDM and replaced it by the title “type 2 lean diabetics.” There patients may require insulin for control. A significant proportion of young people with diabetes in developing tropical countries present with certain characteristics symptoms and metabolic profile rendering their categorization into either type 1 or type 2 difficult. Previously this subset has been classified separately by the WHO study group as malnutrition related diabetes mellitus (MRDM). MRDM has been further subclassified into (a) fibrocalculous pancreatic diabetes (FCPD) and (b) protein deficient diabetes mellitus.

Clinical characteristics of MRDM are as follows: Age of onset between 10 and 30 years, body mass index <19, moderate to severe hyperglycemia, requirement of large doses of insulin for control, ketosis resistance and history of malnutrition in childhood. The subgroup of FCPD shows evidence of pancreatic calcification, often demonstrable in plain x-ray of the abdomen.

Maturity Onset Diabetes of the Young (MODY)

The incidence of type 2 DM is increasing in the younger age groups all over the world. In India there is 54% increase in the prevalence of type 2 DM in the 15-19 years old adolescents. Many risk factors are associated with this increase in prevalence during childhood. These include obesity which increases insulin resistance, racial factors, puberty and gender characteristics. In addition there is

decrease in physical activity, unhealthy food habits including excessive consumption of calories and trans-fatty acids, and faster ways of life.

The different types of diabetes that can be seen in the young are:

- 1. Type 1 DM
- 2. Type 2 DM
- 3. Malnutrition related DM (MRDM) and
- 4. Maturity onset diabetes of the young (MODY).

MODY accounts for about 2-3% of all type 2 DM and about 27% of all diabetes in the young below 30 years in India. The clinical picture of type 2 DM and MODY are almost similar. Both are insidious in onset and non-ketotic, but the latter develops at a much younger age. Family history is very prominent in MODY. BMI may be high in more than 40% of MODY cases. It may be low in 13%. Features of the metabolic syndrome such as acanthosis nigricans, hypertension and abdominal obesity are absent in MODY. Strong family history running into three generations with autosomal dominant inheritance is the most characteristic feature of MODY.

Although six different forms of MODY have been identified MODY-1 to MODY- 6, each involving mutation of a different gene located in a different chromosome, only three are considered more important. The first MODY gene to be recognized was a glucokinase gene (GCKI) followed by hepatocyte nuclear factors (HNF 1α, 4 α, 1β).

HNFs are transcription factors that regulate the expression of several genes in the liver and beta cells of pancreas.

In all types of MODY, there is defect in insulin secretion by the beta cells, but the clinical presentation may be different. Some may respond to OHAs, but others require insulin (Tables 90.8 and 90.9).

Prediabetes: Some patients show borderline values of glucose on oral glucose tolerance test (OGTT), not completely fulfilling the criteria for diagnosis of diabetes.

Genetic and clinical features of MODY			
Type	Gene defects	Prevalence	Signs
1. MODY 1	HNF 4 α Chromosome-20q12, 13 involved	5%	Severe hyperglycemia, microvascular complications, they may need insulin
2. MODY 2	Glucokinase chromosome 7p 15	10%	Mild, microvascular complications are mild. Diet control alone may be sufficient
3. MODY 3	HNF 1 α commonest type chromosome 12q.24	70%	Symptoms as in MODY 1
4. MODY 4	IPFI mutation (insulin promoter factor 1) chromosome 13q. 12	Rare	Like MODY 3
5. MODY 5	HNF 1B mutation chromosome 17q 12-21	Rare	Microvascular complications and renal failure are common
6. MODY 6	Chromosome 2q. 32	Very rare	

TABLE 90.9

Clinical differences between type 1 and type 2 DM

	Type 1 DM	Type 2 DM
Insulin deficiency	++++	+
Insulin resistance	Rare	+++ common
Insulin requirement	Low to moderate	Variable
Sulphonylurea drugs	Unresponsive	Responsive
Common cause of death	Nephropathy CHD, DKA	CHD, nephropathy, stroke and gangrene
CHD – coronary heart disease; DKA- diabetic ketoacidosis.		

This group has been delineated as a separate entity- prediabetes. This includes (1) impaired fasting glucose (IFG) and (2) impaired glucose tolerance (IGT) based on data from several epidemiological studies (Table 90.4). IGT progresses to diabetes in many subjects, usually at a rate of about 2% per year if not managed early. Some patients with IGT continue to remain in the same category or may revert to normal glucose tolerance. Treatment with oral hypoglycemic agents does not influence the subsequent outcome. There is increased frequency of morbidity and mortality from macroangiopathy and cardiovascular disease, while specific diabetic microangiopathy is rare. Hypertension and coronary artery disease (CAD) are also common in IGT patients as in classic type 2 DM patients. Prevalence of IGT is also increasing and a recent study from Chennai (MV diabetic centre) revealed that 16% of the adult population had IGT. Therefore it is obvious that the diagnosis of IGT warrants careful follow-up of the subjects, with appropriate advice in lifestyle modifications- diet, exercise and cessation of smoking.

DIAGNOSIS

Diabetics with classic symptoms can be diagnosed clinically, but since many cases may be asymptomatic, diabetes should be suspected even in the absence of symptoms. The clinical symptoms and the biochemical alterations do not go hand in hand in many cases. Diabetes being mainly a biochemical disease with several different but inter-related biochemical and molecular abnormalities, should always be diagnosed and managed with biochemical monitoring along with clinical examination. Fasting plasma glucose levels above 126 mg/dL (6.7 mmol/L) or postprandial plasma glucose levels above 200 mg/dL are diagnostic. It is always better to do both estimations to confirm the diagnosis.

Estimation of FBS and PPBS has become mandatory investigations in all health check up examinations.

Urine tests: These tests can be used for initial screening and follow-up of cases under treatment. Urinary glucose

does not always directly reflect the blood glucose level. The value of urine examination cannot be underestimated since proteinuria, ketonuria and the microscopic abnormalities can be detected only by examining the urine.

Glucose in urine is tested by the Benedict's test and Clinitest (Chemtab), which detect reducing substances non-specifically. While glucose is by far the most common reducing substance in urine, the possibility of other reducing substance should be kept in mind and the enzyme methods (employing glucose oxidase) which are specific for glucose (Clinistix, Diastix) should be employed.

If the Benedict's test is positive and the glucose oxidase is negative, the presence of other reducing substances such as ascorbic acid, aspirin and lactose should be suspected.

Blood glucose estimation: Various methods are employed to estimate the blood glucose. The methods using copper reduction (Folin-Wu or Nelson Somogyi) also detect the reducing substances like uric acid, creatinine and hence their values are 20-30 mg/dL higher than those obtained by the glucose oxidase method which gives the true glucose values. Highly accurate and rapid (1-2 min) devices are now available based on immobilized glucose oxidase electrodes. Hexokinase and glucose dehydrogenase methods are used for reference. Blood sugar estimations are mandatory for confirming the diagnosis of diabetes. Both fasting and postprandial values should be estimated. In mild diabetes the fasting blood sugar values may be below 126 mg /dL and therefore the diagnosis is likely to be missed if only the fasting blood sugar is estimated.

Glucose tolerance test (GTT): The oral glucose tolerance test (OGTT) is mainly used for diagnosis of diabetes when blood glucose levels are equivocal, during pregnancy, or in an epidemiological setting to screen for diabetes and impaired glucose tolerance.

The OGTT should be administered in the morning after at least 3 days of unrestricted diet (greater than 150 g of carbohydrate daily) and usual physical activity. The test should be preceded by an overnight fast of 8-14 h. during which period only water may be drunk. Smoking is not permitted during the test. The presence of factors such as medications, inactivity and infection that influence interpretation of the results of the test must be recorded.

After collection of the fasting blood sample, the subject should drink 75 g of anhydrous glucose dissolved in 250-300 mL of water over the course of 5 minutes. For children, the test load should be 1.75g of glucose per kg of body weight, up to a maximum of 75g of glucose. Blood samples should be once again collected 2 hr after the test load.

If there is delay in estimation of glucose the blood samples should be collected in a tube containing sodium fluoride (6 mg/mL of whole blood) and immediately

centrifuged to separate the plasma. In subjects having symptoms of diabetes, a single fasting value above 126 mg/dL or a 2-hour blood glucose value above 200 mg/dL after 75 g of glucose oral may be taken to be diagnostic. In asymptomatic subjects at least two abnormal blood glucose values should be insisted upon to confirm the clinical diagnosis.

The glucose tolerance test may be abnormal in conditions other than diabetes mellitus. These include cirrhosis of the liver, chronic renal failure, starvation and under nutrition, stressful situations, hypokalemia and use of diabetogenic drugs.

Glucometers: these are instruments which can be used at home for self monitoring of blood glucose and is freely available in India for prices ranging from Rs. 1500-3500. The blood glucose can be estimated within 5 seconds using a special paper strip and blood from finger prick. Usually the values are higher by 10-15 mg/dL as compared to laboratory values, since laboratory values denote venous blood glucose while glucometers use capillary blood.

Glycosylated hemoglobin: Glycosylation is an irreversible non-enzymic process. It depends directly on the blood levels of glucose. Once the hemoglobin is glycosylated it remains in circulation as such till the erythrocyte completes its life span. The percentage of glycosylated hemoglobin has been used as a guide to the presence and level of hyperglycemia during the past 3 months. Glycosylated hemoglobin is termed HbA1c. This particular fraction is measured and expressed as the percentage of the total hemoglobin content. A diabetic is considered to be well controlled if the HbA1c is below 6.5%. As the life of an RBC is about 120 days, HbA1c is an index of the average sugar levels over the previous 3 months.

Even at the time of first consultation, major complications may be present in the patient. Patients with hypertension, microalbuminuria, early sensory neuropathy and retinopathy may be completely asymptomatic, and hence these may be missed, if not looked for. Many patients go around with the disease without being diagnosed till they get major complications.

In addition, lipid profile, urine examination for microalbuminuria, ophthalmic examination, exercise ECG, neuropathy tests using biothesiometer and Doppler studies should be done routinely at the first examination in those with duration above 5 years.

Prognosis

Once diabetes is established, it tends to be life long. Proper management can achieve euglycemia during most part of the day and thereby confer clinical normalcy and prevent complications. Prognosis in the diabetic depends largely on the presence or absence of chronic vascular

complications. Present day treatment has served to prevent or successfully overcome acute complications like ketoacidosis, infections, hypoglycemia and lactic acidosis. The long-term complications affecting the kidneys, nerves and blood vessels also depend on a great deal on hyperglycemia. Other parameters such as lipid abnormalities, microalbuminuria and hypertension influence the prognosis adversely.

These complications can also be prevented to a great extent by rigid diet control, exercise and regular therapy. Once established the degenerative complications progress relentlessly and lead to damage of vital organs like the kidneys, heart and brain unless properly managed. Death is mainly due to complications like myocardial infarction, cerebrovascular accidents, end stage renal failure or acute diabetic complications such as diabetic coma, hypoglycemia and infections. Cumulative morbidity occurs due to blindness, peripheral vascular disease and peripheral neuropathy which cripple the long term survivors. Proper therapy also arrests the progression of established complications. Cardiovascular complications can be reduced further by elimination of other risk factors like hypertension, cigarette smoking, obesity and hyperlipidemia.

The Diabetes control and Complications Trial (DCCT) (1991-95) which was carried out at 14 different centers in the USA and Canada had enrolled 1441 patients with type 1 diabetes with the objective of assessing the role of intensive insulin therapy in the primary prevention of microangiopathic complications as well as in arresting the progression of these complications. The data has convincingly brought out the importance of tight metabolic control in preventing the development of microangiopathy and arresting its progression. The risk reduction of various measured outcomes ranged from 35-75%. A beneficial effect on the macroangiopathy was also demonstrated.

The United Kingdom Prospective Diabetes Study (UKPDS), a large study carried out in 23 centers all over the United Kingdom, followed 5102 patients with newly diagnosed type 2 diabetes over 5 years (1987-91) and reported a significant decline in the incidence of macrovascular disease with strict glycemic control. Additional benefits were also obtained with control of blood pressure. Strict control of blood pressure also brought down the incidence of stroke and heart failure. Both these trials and several other reports emphasize the role of strict biochemical control of all forms of diabetes mellitus in reducing the incidence of complications. Follow-up of patients included in the DCCT 1993 trial has shown that the benefits of strict control of the diabetic state continued even four years after the termination of the study. With proper motivation and education of the patient, considerable improvement in glycemic control can be achieved in almost all patients at relatively low cost.

TREATMENT

The aim of treatment is to achieve normal blood glucose levels throughout day and night, to alleviate symptoms and to prevent complications. The four pillars of diabetic management are diet, exercise, drugs and patient education, backed up by regular monitoring of glycemic control and early detection and treatment of complications.

Dietary Management
(Medical Nutrition Therapy)

Diet is the corner stone in the management of diabetes. The objective of dietary therapy is the optimization of glycemic control and to provide a nutritious and balanced diet. In type 1 DM patients the total energy input has to be relatively higher in order to regain ideal weight and growth. In type 2 patients the calories need to be restricted in order to avoid obesity. Dietary articles such as saturated fats, excess salt and cholesterol which promote vascular complications have to be avoided.

Goals of Medical Nutrition Therapy

1. To achieve and maintain near normal glycemia (euglycemia).
2. To achieve and maintain optimal lipid profile. (total cholesterol < 150, triglyceride $\pm$ 120, HDL>50 and LDL<100/mg/dL).
3. To achieve and maintain normal blood pressure levels around 120 to 130 / 80 to 85 mmHg.
4. To adjust the nutrient intake to restore and maintain ideal body weight to avoid dyslipidemia, cardiovascular disease, hypertension and nephropathy. During childhood and pregnancy adjustment for growth also should be provided.
5. For elderly patients, provision for proper nutrition and psychosocial needs.

In type 2 diabetic patients the first step would be dietary therapy alone along with exercise. They should be given a trial of dietary therapy for 4-8 weeks. About 50% of the patients come under control with diet alone. Proper patient education helps to improve adherence to treatment.

The following points have to be considered while prescribing a diet for a diabetic-

1. The type of diabetes- type 1 or type 2
2. The weight of the individual in comparison with his ideal body weight (BMI)
3. His occupation and activities and to assess his caloric requirements
4. The presence of any complications

An appropriate assessment of the caloric needs of each diabetic individual should be done.

TABLE 90.10

Optimum daily needs in calorie intake per kg of desirable body weight			
Body weight	Activity		
	Sedentary	Moderate	Heavy
Obese	20	25	30
Standard weight	30	35	40
Underweight	35	40	45
(Additional allowances are required in case of pregnancy, lactation and growing children.)			

Total Caloric Intake

This is the most important step while prescribing a diet. Total caloric intake depends on the patient's body weight, degree of physical activity and the presence of any other comorbid illnesses. Obesity is an important factor in terms of target cell resistance to insulin action.

The body mass index (BMI) will help to determine the total caloric requirement.

BMI = Weight (in Kg) / Height in m². It is desirable to keep the BMI between 22 and 25.

Ideal body weight can be readily calculated by the formula:

ideal body weight = height in cm – 100.

The recommended daily allowance is 30 Kcal/kg of desirable body weight to patients with average activity except in the case of obesity where appropriate changes have to be made as given in the Table 90.10.

Having calculated the number of calories required, they are distributed into at least three principal meals and one or two small snacks. These calories are derived from three principal sources—carbohydrates, protein and fats. Each fraction has its own importance and should provide 60% of the calories from carbohydrates and 20% each from proteins and fats.

When instructing on the diet regime the following points should be stressed.

1. ***It is not a reduction in the diet; on the other hand it is a modulation to suit the particular need of the individual.*** This concept will help to reduce the psychological resistance in accepting the diet.
2. The patient and his spouse should be counseled together, so that the latter will understand the principles and help to provide the diet appropriately.
3. Whenever possible, the dietary articles should be prescribed in terms of weight so that at least on a few occasions the actual quantities would be determined and adopted.
4. It is better to prescribe the diet in terms of the primary food articles such as rice, meat, fish and others so that the patient can determine the various items of the menu in relation to the allowed foodstuff.

5. Many patients are under the wrong impression that reducing the food further than what is prescribed may be beneficial and this should be avoided.
6. Both the quantity to diet and its timing are important since other aspects of management such as medication and exercise are timed in relation to the diet. As far as possible the diet should conform to the cultural habits and socioeconomic condition of the patient.
7. Vast majority of treatment failure can be avoided by proper dietary instructions.
8. At all follow-up visits enquiry on the diet should be made and the need for strict adherence stressed.
9. As far as possible the patient should be involved in the formulation of the diet and such a participatory instruction assures better compliance.

Carbohydrates

The amount of carbohydrates to be permitted in diet of diabetic patients has been an area of controversy. Till recently most people recommended restriction of carbohydrates in the diet to provide only 30-40% of the calories. Our diets in India are cereal based and have a high carbohydrate component (about 70%). Several studies in India have shown that good metabolic control can be achieved with high carbohydrate diets, provided the caloric intake is optimized. Such diets provided better patient compliance and had no adverse effect on the long-term complications.

The American Diabetic Association and the European Diabetic Association study groups have also altered their dietary recommendations. In an attempt to reduce cardiovascular morbidity and mortality, they now recommend a liberalized use of carbohydrates in the diet up to 50-60% of the calories. This also helps to reduce the intake of saturated fats. Modification in the type of carbohydrate can be achieved by increasing the intake of legumes and pulses, green leafy vegetables and other vegetables, which will increase the content of complex carbohydrates and fiber.

Fats

The fat content of diet should be 20-25% of the total calories. The distribution of the type of fat should be equal, i.e. saturated fats and mono and polyunsaturated fats should be equally distributed to make up the total fat intake. The dietary cholesterol should be less than 300 mg/day. Invisible fat is derived in a fair amount from cereals, legumes and seeds and contributes to 5-10% of the total energy intake. Milk and Milk products contribute approximately to 40-45% of the total fat content in vegetarian diets. Milk fat is a saturated fat.

Proteins

Protein intake has been recommended as 0.8 g/kg body weight and should contribute to 12–20% of the total caloric intake. Vegetable proteins derived from cereals and lentils, do not contain cholesterol. They have high fiber content. Animal protein is rich in saturated fats and tends to increase cholesterol and triglycerides. Lean meat and fish are to be preferred to fatty meat in order to minimize the risk. When renal failure occurs, strict-protein restriction is instituted.

The dietary salt should be less than 6 g/day. In the presence of hypertension or renal failure it should be reduced to around 3 g/day.

Alcohol should be avoided as far as possible. Alcohol intake will increase the risk of hypoglycemia by inhibiting gluconeogenesis. It may induce ketoacidosis, lactic acidosis and may contribute to peripheral neuropathy. Alcohol also induces hypertriglyceridemia and hyperuricemia. Alcohol is an additional source of calories, without any further nutritional values each mL providing 7 calories. If consumed it should be taken only in moderate quantities (1-2 drinks/day i.e. 20-40 mL/day).

Exercise

In type 2 diabetes, regular exercise forms an important component of therapy along with dietary regulation and oral hypoglycemic agents. However a careful assessment of the expected benefits and associated risks of exercise in individual patients should be made while incorporating an exercise program in the treatment. Appropriate monitoring should be done to avoid complications. Exercise should not be recommended indiscriminately in all type 1 diabetic patients but efforts should be made, to make it possible for those who want to exercise to do so as safely as possible.

Endocrine/Physiological Responses during Exercise

1. Suppression of insulin release – directly as well as through epinephrine.
2. Sympathetic system activation – which inhibits insulin release (by alpha-receptor stimulation) and stimulates lipolysis.
3. Non-insulin dependent glucose uptake in the periphery.

In both type 1 and type 2 diabetic patients who are under good control the response to exercise will be normal. In untreated type 1 patients there is an increased production of FFA from adipocyte lipolysis, which leads to decreased glucose uptake in the periphery. This can even precipitate diabetic ketoacidosis in some patients. In the well-controlled patients this does not occur (Tables 90.11 and 90.12).

TABLE 90.11

Exercise in diabetes: benefits exceed the risks

Benefits of Exercise:

1. It lowers blood glucose concentration.
2. It improves insulin sensitivity.
3. Decreases triglyceride, increases HDL cholesterol and decreases LDL cholesterol.
4. It lowers blood pressure in mild to moderate hypertension.
5. It causes weight reduction by metabolizing adipose tissue.
6. It helps in cardiovascular conditioning.
7. It improves sense of well-being and quality of life.

Risks of unsupervised exercise in uncontrolled diabetic

1. Hypoglycemia
2. Hyperglycemia after very strenuous exercise, particularly in poorly controlled diabetes.
3. Precipitation or exacerbation of cardiovascular disease and acute cardiac events like arrhythmias, sudden death and cardiac failure.
4. Worsening of long term diabetic complications – particularly proliferative retinopathy, nephropathy (increases proteinuria), peripheral neuropathy risk of soft tissue and joint injuries. Autonomic neuropathy (causes reduced exercise tolerance, impaired response to dehydration and postural hypotension).

While prescribing exercise, it should suit the social and economic condition of the patient and his work schedule. Regular exercise as part of the therapeutic intervention should be taken by all diabetics, irrespective of the physical activity entailed in their regular occupation. Maximum benefit is achieved by exercises such as brisk walking (4-5 km/hour), swimming, cycling and such other aerobic exercises. At least five sessions a week should be performed in order to achieve optimal benefit. While starting the exercise program in persons above the age of 35 years clinical assessment of their cardiovascular status should be done and introduction of the exercise regimen should be gradual, so as not to precipitate any acute cardiovascular events.

For the average middle-aged Indian diabetic the following exercise regimen is adequate.

- Walk 3 km on level ground over a period of 45 minutes
- Swim for 30 minutes at average speed without cardiovascular distress.
- Cycle on level ground at 8 km/hour for 30 minutes.

Regular sports and games activities can be undertaken and should be encouraged by those who desire to do them, with special provision made for the diet and medications. Since such sport activities are likely to be intermittent rather than regular, in practice walking or cycling is more regularly available.

Before an exercise program is initiated, a fair control of blood glucose is to be ensured and a thorough clinical evaluation of the patient should be made particularly in regard to complications of diabetes such as hypertension, coronary artery disease, peripheral vascular disease, retinopathy and nephropathy.

Yoga exercises Recently several well-planned studies have demonstrated the beneficial effects of yogic practices in diabetics. Patients with diabetes demonstrated a significant fall in fasting and postprandial blood glucose values and HbA1c, with reduction in the requirements of OHA and insulin. Type 1 diabetic patients with brittle diabetes showed marked improvement with the practice of yoga. There was a salutary effect on the lipid profile, with a fall in serum cholesterol, triglycerides and an increase in HDL- cholesterol fraction. Certain *Asanas* (specific postural manipulations which have to be learnt under supervision) have been identified as useful in the control of diabetes. Thus yogic practices have a useful role in the control of diabetes and prevention of its long-term complications.

ORAL HYPOGLYCEMIC AGENTS (OHAs)

The oral hypoglycemic agents are indicated in type 2 diabetes when diet and exercise fail to achieve euglycemia. The two major groups of drugs in use are a) Insulin

TABLE 90.12

Pre-exercise checklist for diabetic patients

1. Correct planning of exercise program (which includes duration and intensity of exercise).
2. Review diabetic medications (need to alter dosage, timing/site of insulin injection).
3. Perform necessary tests to rule out any long-standing, silent diabetic complications that may need a change in exercise pattern:
 - a. Treadmill test/Stress Echo – to rule out coronary artery disease and also to know the individual's exercise tolerance capacity.
 - b. Ophthalmic fundoscopy – to rule out proliferative retinopathy; if present, anaerobic exercise has to be avoided.
 - c. Biothesiometry. This is the method to determine any impairment of vibratory sensation in the extremities accurately in order to assess the extent and severity of sensory loss.
The patients should be advised on appropriate footwear which will ensure protection to the feet and avoid localized pressure and trauma.
4. The blood glucose should be checked before the exercise.

Plasma glucose levels:

- a. If < 100 mg/dL – advise pre-exercise snacks.
- b. If 100-250 mg/dL – can proceed with exercise.
- c. If > 250 mg/dl – check urinary ketones – if positive, insulin should be started. Resume exercise only after correction of ketosis.

secretagogues (sulfonyl urea compounds) and b) insulin sensitizers (glitazones).

Contraindications to the use of OHA

- 1. Type 1 diabetes
- 2. Type 2 diabetes patients during episodes of infections
- 3. Other stressful situations like myocardial infarction stroke
- 4. During pregnancy
- 5. On patients who have to undergo surgery and
- 6. In renal and hepatic insufficiency. Lean type 2 diabetes patients with a postprandial blood sugar of >400 mg/dl and MRDM patients will also require insulin therapy.

Sulphonylurea (SU) Compounds
(Tables 90.13 and 90.14)

Actions and Indications

The SU compounds stimulate the beta cells of the pancreas to release insulin, as evidenced by an increase in the plasma levels of both basal and postprandial insulin in Type-2 diabetes mellitus patients. A minimum of 30% of beta cells is required for their optimal action. They improve the sensitivity of beta cells to glucose and other secretagogues. They have a beta cytotropic action. They also have extra pancreatic actions and reduce neoglucogenesis and glycogenolysis. They improve the receptor binding of insulin and also act on the post receptor sites. Both these actions help in decreasing the peripheral insulin resistance – a key factor in the pathogenesis of type-2 DM. This action leads to improvement in the response to exogenous insulin as well. There is no evidence that SU cause beta cell exhaustion. However continuous exposure to maximum doses may result in desensitization of beta cells.

Therapy should be initiated with the smallest dose, taken 15-30 minutes before breakfast and small increments should be made at weekly intervals till the optimum dose is reached. The sulphonylureas are similar in effectiveness in equipotent doses and in the absence of any specific reason such as adverse side effects, cost or nonavailability, there is no need to change the medication in patients who are adequately controlled. So

TABLE 90.13 Classification of OHAs	
Mode of action	Drugs
1. Insulin secretagogues	a. Sulphonylureas b. Meglitinides c. GLP-1 agonists d. Amylin
2. Insulin sensitizers	a. Biguanides b. Thiazolidenidiones
3. Inhibitors of GI glucose absorption	a. Alpha-Glucosidase Inhibitors

also there is no advantage in combining two or more sulphonylurea drugs.

Choice of compound: Tolbutamide and chlorpropamide which were among the initial sulphonylurea drugs have been almost replaced by the newer derivatives which are easier to administer, safer and predictable in action. **Glibenclamide** has a better effect on fasting plasma glucose than glipizide as it causes greater suppression of hepatic glucose production. **Glipizide** and **gliclazide** induces greater insulin levels in the postprandial state.

Glimepiride is the recently developed sulphonylurea, which is referred to as the third generation sulphonylurea, because it differs from all other preceding members of its class in several important attributes. It has the *highest weight for weight potency*, and long duration of action requiring once daily dosage. Its onset of action is very rapid. It has no pharmacokinetic or pharmacodynamic interaction with beta-blockers, calcium channel blockers, H₂ receptor blockers, ACE inhibitors or anticoagulants. It does not require dose adjustment in hepatic or renal impairment. The effective dose is 1-8 mg/day.

On the pancreatic beta cells, glimepiride binds to a different receptor site as compared to the other sulphonylurea compounds. It also acts as an insulin sensitizer by promoting glucose utilization by peripheral tissues, by increasing the availability of the glucose transporters GLUT 1 and GLUT 4 in the cell membranes. It brings about a comparable reduction of blood glucose levels as other sulphonylureas, with lower insulin and C-peptide levels.

On long-term treatment about 40-50% of patients develop resistance to the action of the particular sulphonylurea-(secondary sulphonylurea failure). In this situation

TABLE 90.14 Dosage of sulphonylureas						
Drug	Relative potency	Dosage mg/day	Duration	Peak action hours	Half-life (hours)	Significant effect (hours)
Glibenclamide	150	2.5-30	Medium	3-4	10-16	Up to 24
Glipizide	100	2.5-20	Short	1	3-7	Up to 24
Gliclazide	80	80-320	Medium	4	10-12	Up to 24
Glimepiride	450	1-8	Long	1	12-16	Up to 24

other sulphonylureas may be tried. If found ineffective, biguanides or insulin may be needed.

Adverse effects of SU: The most common adverse side effect is the development of hypoglycemia coinciding with the peak action of the drugs. Some people are more susceptible to this type of reaction. Depending upon type of SU and the dose, the duration and severity of hypoglycemia varies. In otherwise well stabilized subjects, factors such as avoidance of meal, vomiting or increased physical activity may bring on hypoglycemia. If undiagnosed in time, SU induced hypoglycemia can be even fatal.

Non-specific gastrointestinal symptoms ranging from dyspepsia to diarrhea can occur with SUs in 3-5% of patients. Minor skin reactions occur which readily resolve on stopping the drugs. However occasionally severe reactions like exfoliative dermatitis or Stevens-Johnson syndrome may occur. Cholestatic type of jaundice and bone marrow depression are rare complications.

Occasionally water retention with dilutional hyponatremia may occur with sulfonylureas. Hypoglycemia occurs when there is an absolute or relative overdose.

Non-sulphonylurea Secretagogues: Meglitinides (Table 90.15)

This group includes repaglinide and nateglinide. These act through separate receptors on β -cell membrane, compared to SUs.

1. **Repaglinide:** It is a benzoic acid derivative. It was the first meglitinide analogue to become available. It initiates insulin secretion by closing the K^+ATP channels. It induces rapid postprandial insulin response. The drug's short half-life ensures that insulin concentrations peak at 1-2 hours, by 6 hours they are back at fasting concentrations. It does not have the risk of severe or prolonged hypoglycemia. It is given in doses of 0.5-4.0 mg/day in divided doses taken 15 minutes before meal.
2. **Nateglinide:** It is a d-phenylalanine derivative. This drug has a unique property of fast association and dissociation kinetics at the pancreatic beta cell. The other unique property of this drug is that it doesn't inhibit the KATP in the presence of low sugars. This glucose sensitizing property explains the low incidence of hypoglycemia associated with nateglinide. It is given in dose of 60-240 mg/day in three divided doses, 10-15 minutes before the meal.

Insulin Sensitizers

Biguanides: Actions and Indications

Mode of action: The biguanides lower the blood glucose levels in diabetics through their extra pancreatic effects, but do not reduce the blood glucose levels in

normal individuals, unless they are starved. They do not stimulate endogenous insulin secretion and do not cause hypoglycemia. The glucose lowering effect of these compounds has been shown to occur through three main mechanisms: i) inhibition of intestinal glucose absorption, ii) increase in utilization of glucose by peripheral tissues and iii) stimulation of anaerobic glycolysis in the liver, which inhibits hepatic gluconeogenesis and increases production of lactate. The biguanides are rapidly and almost completely absorbed from the GI tract. Occurrence of drug induced gastric side effects can be reduced by giving the drug after food.

Metformin

This biguanides is the most widely used since the longest duration. Metformin is neither metabolized by the liver nor bound to serum proteins. It is excreted unchanged by the kidneys. Its plasma half-life of 1.5-2.8 hours is much shorter than that of phenformin. Daily dosage of metformin is 500-2500 mg. Studies have shown that metformin can delay the onset diabetes in high risk groups. Effects of metformin are potentiated by other hypoglycemic agents, such as sulfonylureas and salicylates.

Insulin receptor effects: Metformin may help to improve insulin sensitivity in diabetic subjects by increasing insulin receptor binding in individuals with a reduced number of insulin receptors. The effects of metformin on the post receptor sites is of much greater importance for the potentiation of insulin action.

Lipid metabolism: Circulating triglyceride concentrations are decreased by metformin in both normal and type-2 diabetes patients. This is largely due to reduction in VLDL. A small increase in HDL has been observed in patients treated with metformin.

Other indications for metformin: This drug has been used for conditions other than diabetic mellitus. e.g. Polycystic ovarian syndrome (PCOS) in women, which is an insulin resistance state and metformin is the first line of drug to be used in such patients. Since metformin passes the placental barrier, it is not approved for use in pregnancy. Recent studies have shown that metformin reduces the risk of spontaneous abortion during the first trimester and reduce the incidence of fetal anomalies. It effectively reduces the development of gestational diabetes mellitus.

Phenformin: This was popular before the introduction of metformin. It is very effective. Adverse effects include severe lactic acidosis. Due to this adverse side effect phenformin is not generally used at present.

Biguanide and sulphonylurea combination: The addition of biguanide in cases where sulfonylurea alone cannot normalize blood sugar levels has allowed the continuation of oral therapy in many patients.

Sulfonylurea increase insulin release and cause greater suppression of hepatic glycolysis whereas metformin increases peripheral insulin mediated glucose disposal. Many diabetologists in India prefer to initiate treatment with combination of a sulfonylurea and metformin.

Metformin-insulin combination: Addition of metformin decreased the daily insulin requirement by 16% in a group of insulin requiring type 1 diabetes patients. Due to their insulin potentiating effects the biguanides have also been used as adjuvants of insulin therapy in both type 2 and type 1 diabetes patients. Metformin monotherapy is not effective in type 1 diabetes patients.

The adverse effects of biguanides: These are usually mild and limited to the gastrointestinal tract. Side effect includes a bitter or metallic taste in the mouth, anorexia, nausea, occasional vomiting and intermittent diarrhea. These are usually dose related and can be minimized by the use of timed disintegrating tablets or by very slowly increasing the dosage. Less frequent toxic effects include stress reactions and malabsorption of B12 and folic acid with resultant macrocytic anemia. Pancreatitis had been reported with the use of phenformin. Undoubtedly the most serious side effect associated with the use of biguanides is lactic acidosis. This is more commonly encountered with phenformin therapy and led to its ban in the USA. Metformin is a less lipophilic drug than phenformin and it is not metabolized in the body but excreted unchanged in the urine. On the other hand, phenformin is metabolized in the liver, so the chances of lactic acidosis increase with phenformin. The risk of developing lactic acidosis increases if the metformin level builds up in the blood. Since metformin is cleared primarily by the kidneys, patients with impaired kidney function (serum creatinine > 1.4 mg/dL in women and > 1.5 mg/dL in men) should not be treated with metformin.

Metformin is also employed as a primary mode of therapy in obese type 2 diabetic patients without complications.

Thiazolidinediones: The thiazolidinediones currently in use are **pioglitazone** and **rosiglitazone**. These drugs act by improving insulin sensitivity by binding to the peroxisome proliferator activated receptor gamma (PPAR γ), a molecule implicated in the transcription of numerous genes controlling carbohydrate and lipid metabolism. PPAR γ is the target for thiazolidinediones. They reduce insulin resistance thereby acting as hypoglycemic agents on their own, as well as insulin sparing agents. In addition they improve the lipid profile, lower blood pressure in hypertension and reduce cardiovascular risk factors. They promote fatty acid uptake and storage in adipose tissue, thereby increasing body fat and weight gain. They lead to fluid retention and cardiac failure in susceptible subjects, especially if combined with insulin.

These can also be used to treat PCOS like metformin, however they should be stopped if the women with PCOS becomes pregnant. These drugs are not approved for use in pregnancy because they pass the placental barrier and affect fetal growth and development. Unlike metformin, these drugs cause modest weight gain of approximately 1-3 kg. This is due to increased subcutaneous adipose tissue in the periphery and fluid retention.

Dose: Pioglitazone – 15-45 mg /day as a single daily dose.

Rosiglitazone – 2-8 mg/day in two divided doses.

Contraindications for the use of thiazolidinediones:

1. Congestive heart failure
2. Hepatic dysfunction with alanine transaminase (ALT) > 2 times the normal
3. Obesity.

Alpha-glucosidase inhibitors: **Acarbose** and **miglitol** belong to this group. They competitively inhibit the enzyme alpha-glucosidase, which is present in the brush border of small intestine. This enzyme breaks down complex carbohydrates into glucose and favours its absorption. Use of **acarbose** or **miglitol** as a supplement to sulfonylurea therapy reduces postprandial hyperglycemia. Use of acarbose permits slightly liberal use of complex carbohydrates in the diets without causing hyperglycemia.

Acarbose or miglitol is to be administered orally with the first bite of each meal. The currently recommended initial dose is 25 mg three times daily with the dose increased slowly, every 4 weeks to a maximum of 100 mg three times/day. Only 2% of the administered acarbose gets absorbed into systemic circulation. Acarbose is metabolized exclusively by the kidneys. Its use is contraindicated in the presence of hypersensitivity to the drug, severe renal failure, diabetic ketoacidosis, inflammatory bowel disease, colonic ulcers, partial bowel obstruction, chronic intestinal disease associated with impaired digestion or absorption and other disorders that may deteriorate with intestinal gas formation. These drugs are to be avoided in pregnancy.

Miglitol has less side effects than acarbose in doses of 25-50 mg tds. Another recently introduced drug is **voglibose** 0.2 to 0.3 mg at a time which is more potent in action with less of side effects (Tables 90.15 and 90.16).

INSULIN THERAPY

The discovery of insulin at the University of Toronto in 1921 by Sir Frederick Banting and Charles Herbert Best revolutionized the treatment of diabetes, extending the life expectancy of insulin dependent diabetics. The early commercial preparations of insulin were from bovine and porcine pancreas. They were impure and of variable quality, still they dramatically improved the prospects of

TABLE 90.15

Commonly used non-SUs oral hypoglycemic agents				
Class	Name	Duration of action hrs	Daily dose	Type of action
a. <i>Non-sulphonyl Urea secretagogues</i>	Nateglenide	8 hours	180-240 mg	(1)
	Repaglinide	8 hours	8-16 mg	(1)
b. <i>Biguanides</i>	Metformin	8 hours	500-2500 mg	(2 and 3)
c. <i>Thiazolidinediones</i>	Rosiglitazone	6-8 hours	6-12 mg	(2)
	Pioglitazone	18-24 hours	15-45 mg	(2)
d. <i>Alfa glucosidase inhibitors</i>	Acarbose	6-8 hours	50-100 mg with each meal	(4)
	Miglitol	6-8 hours	25-50 mg "	(4)
	Voglibose	6-8 hours	0.2-0.3 mg "	(4)

Key:
 (1) Insulin secretagogue (2) Insulin sensitizer (3) Diminishes hepatic glucose production (4) Inhibits alfa glucosidase and absorption of glucose.

TABLE 90.16

Approximate glucose lowering potential of type-2 diabetes therapies		
Drug	FPG reduction	HbA _{1c} reduction
1. Sulphonylurea	50-60 mg/dL	1-2%
2. Metformin	50-60 mg/dL	1-2%
3. Meglitinide	≤ 70 mg/dL	1-2%
4. Thiazolidinediones	50-60 mg/dL	1-2%
5. Alpha-glucosidase inhibitors	15-30 mg/dL	0.5-1%
6. Combination of 1 and 2	100-120 mg/dL	3-4%

TABLE 90.17

Differences between insulins from three species			
Species	A chain A ₈	A ₁₀	B chain B ₃₀
Bovine	Alanine	Valine	Alanine
Porcine	Threonine	Isoleucine	Alanine
Human	Threonine	Isoleucine	Threonine

Note: Bovine insulin is more different from human insulin, compared to the porcine variety.
 At present both bovine and porcine insulin are not manufactured, and all available insulin is of the human variety (Table 90.17).

10

life in several thousand diabetics. Banting was awarded the Nobel Prize in 1923 along with Mcleod, professor of physiology in whose laboratory Banting and Best conducted their study.

During the past five decades several developments have taken place in insulin production, purification and formulation, aimed at improving metabolic control, safety and convenience of its use. Improvement in insulin purity was the first challenge and has been the goal ever since. This resulted in the production of chromatographically purified insulin and later, insulin with the chemical and molecular composition of human insulin referred to as **human insulin**. Similarly attempts to retard the subcutaneous absorption of insulin to spare diabetics the discomfort of multiple daily injections resulted in the development of intermediate and long-acting insulins. The preparations such as lente insulin, NPH (neutral protamine Hagedorn) insulin and protamine zinc insulin have longer duration of action.

Human insulin has a molecular weight of 5807 Daltons and contains 51 amino acids arranged in two polypeptide chains. The A chain contains 21 amino acids and is linked to the B chain by 2 disulfide bridges. Pre-pro-insulin and proinsulin are the precursors of insulin. Human insulin differs structurally from bovine and porcine insulin as shows below:

Insulin is relatively soluble at pH below 4 or above 7; the addition of Zinc broadens the pH in which precipitation occurs.

Like other proteins, insulin is also unstable and it is susceptible to chemical degradation and inter- and intra-molecular transformations. The presence of contaminants and immunogenicity of bovine and porcine insulins used to give rise to problems such as:-

- Immunogenic insulin resistance
- Insulin allergy
- Insulin-induced lipo-atrophy and lipo-hypertrophy and
- Insulin—insulin antibody complex mediated complications.

Human insulin is produced by recombinant DNA technology, the composition of the final product being identical to that of natural human insulin chemically and in molecular configuration. Being synthetic, the supply can be modified to meet the need, without shortage. It is more rapidly absorbed and has a somewhat shorter duration of action when compared with insulin of animal origin.

Therapeutics of Insulin

Insulin therapy aims at providing ideal physiological insulin profiles with peaks at meal times and maintenance

TABLE 90.18

Indications for insulin therapy

- 1. All type 1 diabetes patients.
- 2. In type 2 diabetes patients
 - a. During episodes of metabolic complications like diabetic ketoacidosis, hyperosmolar non ketotic coma and lactic acidosis.
 - b. During infections, myocardial infarction, stress, surgery, renal insufficiency or infective hepatitis.
 - c. During pregnancy
 - d. When diet, exercise and oral hypoglycemic agents fail to achieve euglycemia (primary and secondary sulfonylurea failure)
 - e. Lean type 2 diabetes patients with very high blood glucose levels at onset
 - f. Pancreatic calculi patients most of whom require insulin and
 - g. Even in non-diabetics, when the blood glucose level rises under stress such as myocardial infarction or septic shock, insulin is used to lower blood glucose.

of basal levels between meals and at night. This can be achieved by administering soluble insulin before each meal and adding a dose of intermediate acting insulin at bed time. The alternative regimes would be; (i) a split dose of soluble and intermediate acting insulin before breakfast and dinner, (ii). a single dose of soluble and intermediate acting insulin before breakfast, (iii) a single dose of intermediate acting insulin before breakfast. With the introduction of premixed insulin it is easier for the patients to adopt these regimes. As in the case of other hypoglycemic agents, diet control and exercise should be instituted along with insulin therapy (Table 90.18).

Dosage of Insulin

There are no hard and fast rules to assess the initial dose of insulin. It is ideal to start with a small dose and gradually increase at intervals of 2-3 days till the optimum dose is achieved as judged by the plasma glucose levels. The initial dose required can be calculated at the rate of 0.5 units/kg/day for type 1 and 0.2 units/kg/day for type 2 diabetes. If the patient is not symptomatic 50% of the calculated dose can be given initially and the dose can be gradually increased by 4 units every 4th day. If the patient is symptomatic, the calculated dose can be given in full at the start and adjusted subsequently.

Duration of action of insulin depends on the route of administration as well. There is no upper limit for insulin dose. The half-life of soluble insulin is 4-6 hours when given subcutaneously and 1-2 hours when given intramuscularly but it is only 5-10 minutes when the I V route. **For simplicity one can assume that the half-life of IV insulin, I M insulin and SC insulin are 4 minutes, 40 minutes and 4 hours respectively** (Table 90.19).

Site of Insulin Injection

Subcutaneous insulin can be given at one of the following sites: anterior abdominal wall, lateral aspect of the thighs and arms. Intramuscularly it can be administered over the deltoid or other regions. **The rate of absorption of insulin from the injected site varies.** More rapid absorption occurs from the abdominal wall compared to the deltoid region and the thighs when given SC. Intramuscular injections are more rapidly absorbed and duration of action is only for several minutes. Intravenous injections produce immediate effect, but only for a few minutes.

TABLE 90.19

Insulin preparations

Insulin preparation	Onset of action	Peak action	Total duration
Short acting (regular, or soluble)	0.5-1 hour	2-4 hour	4-6 hours
Intermediate acting			
NPH	2-4 hours	10-16 hours	20-24 hours
Lente	2-4 hours	10-16 hours	20-24 hours
Long acting			
Ultralente	6-8 hours	14-20 hours	24-32 hours
PZI	6-8 hours	14-20 hours	24-32 hours
Premixed insulins containing regular and NPH 30:70 and 50:50	0.5 hours	2-10 hours	12-18 hours
Note: Insulin manufacturers supply different-formulations of insulin separately or in the premixed form containing regular and longer-acting preparations.			
Newer insulins/insulin analogues			
Insulin Lispro	-	Short acting	
Insulin Aspart	-	Short acting, also long acting preparations combined with protamine.	
Insulin Detemir	-	Long acting, given twice a day	
Insulin Glargine	-	Long acting- 24 hours action	
Insulin glulisine	-	Short acting	

Storage

It should preferably be stored at 4-8°C. However it is stable at room temperature for 3-4 weeks.

Intensive Insulin Therapy

Awareness of the significance of tight metabolic control in the prevention of long-term complications of diabetes has led to the development of newer insulin delivery systems and different types of insulin therapy. Intensive insulin therapy of type 1 diabetes uses either 3-4 injections daily or a continuous subcutaneous insulin infusion from an insulin infusion pump. Blood glucose determinations done prior to each meal and at bedtime helps to determine the dose of soluble insulin to be administered based on an adjustment schedule algorithm.

Self Injection

This can be done using conventional disposable syringes specially calibrated for insulin. **Insulin pens using specially made insulin cartridges are available which are disposable or suitable for permanent use.** Availability of insulin pen facilitates the injection of insulin and also ensures the availability of the injection at the exact time, irrespective of the activity of the patient. The insulin pen with its insulin cartridge should be stored at room temperature. The cost of the insulin pen is around Rs. 700. Insulin available in cartridge is 25% more expensive than insulin available in multi-dose vials.

Insulin pump therapy or continuous subcutaneous insulin infusion (CSII), delivers insulin continuously into the subcutaneous tissue through a subcutaneous needle. The system is driven by a battery powered pump. By delivering insulin in the physiological basal-bolus pattern, it can mimic the body's insulin secretory pattern and is an excellent form of insulin delivery, provided patient selection is ideal. Artificial pancreas is a self-adjusting continuous infusion device which the patient can wear. The glucose sensor activates the pump and automatically adjusts the dosage to maintain euglycemia. This sensor-cum-delivery device is still not approved for commercial use (Table 90.20).

Insulin analogues: Insulin analogues are molecules which differ from insulin in their molecular structure, but produce the same biological response as insulin. Two types of insulin analogues are available, short-acting and long-acting analogues.

The short-acting insulin analogues start action within 5-10 minutes after administration, and the duration of action is only for 4 to 5 hours thereby, mimicking the normal physiological insulin response to meals. The rapid acting insulin analogues in use are *insulin Lispro*, *insulin aspart* and *Glulisine*. They are produced by recombinant DNA technology and they differ in structure from human

TABLE 90.20

Newer insulin delivery systems

- i. Insulin pump
- ii. Inhaled insulin
- iii. Intranasal insulin
- iv. Jet injectors (transdermal insulin)
- v. Oral insulin
- vi. Rectal insulin
- vii. Insulin administration via liposomes

insulin in the transposition of amino acids in the B chain. The sequence of amino acids at B 28 and 29 in human insulin is proline and lysine and in lispro it is lysine and proline. This transposition reduces the capacity for self-association of insulin, thereby keeping it in monomeric state and resulting in more rapid absorption after subcutaneous injection and shorter duration of action. Lispro insulin is used with advantage in the control of postprandial hyperglycemia. It is given by injection immediately before a meal.

Insulin aspart which is short acting has the proline in position B28 replaced by aspartic acid.

Glulisine is another new rapid-acting analogue which differs from human insulin by the replacement of asparagine by lysine at position B3 and lysine by glutamic acid at position B29. All these insulins can be given during pregnancy.

Among the *long-acting insulin analogues*, **glargine** is the widely used one. In glargine, there is addition of two arginine molecules at position B 30 and a substitution of glycine for asparagine at position A21. This analogue is widely used for basal supplementation. It does not produce peaking of insulin levels and therefore the risk of nocturnal hypoglycemia is negligible. Because of its long duration of action, once daily administration is sufficient. Since this insulin has acidic pH, it should not be mixed with any other insulin.

The other newer long-acting insulin analogue which is ideal for basal insulin supplementation is **Detemir**. In this, threonine at B30 is removed and lysine at position B 29 is acylated with myristic acid (C14 fatty acid chain). This allows insulin detemir to reversibly bind to the human albumin, which delays its absorption from the site of injection. This insulin is given twice daily.

Insulin analogues provide the therapeutic tools for finer adjustments of insulin dosage.

These are given by SC injection in doses of 0.1 to 0.2 unit/kg bw (Table 90.21).

INSULIN RESISTANCE

This may be due to genetic factor, development of antibodies to insulin or the receptor, and interaction of counter regulatory hormones. This can be managed by:

1. Increasing the dose of insulin and adjusting the frequency of injections

TABLE 90.21

Duration of action of insulin analogues			
Type	Onset of action	Peak action	Effective duration
Lispro	5-15 mts	30-90 mts	4-6 hours
Aspart	5-15 mts	30-90 mts	4-6 hours
Glargine	2-4 hours	None	20-24 hours

Note: Rapid acting analogues are available in premixed form with lispro and protamine crystalline aspart so that the action of insulin can be prolonged.

- 2. Changing the brand of insulin
- 3. Use of immunosuppressants such as cyclosporine and tacrolimus, or newer insulin analogues
- 4. Use of insulin- like growth factor, if available.

Emerging Therapies: Making Use of the Incretin Pathway

Several newer drugs are emerging in the therapy of diabetes. They mimic the actions of incretins like GLP-1 which are gut-derived peptides with beneficial effects on insulin action, insulin secretion, gut emptying and satiety.

Exenatide, a drug that is derived from the salivary secretion (venom) of a lizard called the Gila monster, and liraglutide, a synthetic molecule, are designed to mimic the actions of GLPI. This is given parenterally.

Dipeptidyl peptidase IV (DPPIV) inhibitors which inhibit the GLPI degrading enzyme (DPPIV) and enhance the action of GLPI are also available at present. They can be given orally.

Amylin agonists: Amylin, secreted by the beta cells, stomach and small intestine enhances insulin secretion. Inhibitors of gastric emptying are also emerging as antidiabetic drugs. Pramlintide is an amylin agonist which can be given parenterally.

Monitoring Control of Diabetes (Table 90.22)

Whole blood or plasma glucose estimation is the best available index of diabetic control. Blood glucose estimation should be done in the fasting and postprandial states. Usual diet and medication should be continued on the day of the tests.

Frequency of blood sugar studies varies with the type of diabetes and its severity. In type-1 DM patients it should be done as frequently as possible. If the patient is doing self-blood glucose-monitoring (SBG) the results have to be cross-checked at monthly intervals. In well controlled type-2 DM patients the blood glucose levels should be done once in 4-6 weeks. Those on insulin therapy and during periods of stress the patients need closer follow up as in type 1 DM. It is preferable to do both fasting and postprandial blood glucose.

TABLE 90.22

Targets for control of diabetes
Fasting blood glucose – 90-130 mg/dL
2-hr postprandial blood glucose — < 180 mg/dL
HbA ₁ C — < 6.5%.

Glycosylated hemoglobin: In normals hemoglobin is glycosylated (HbA1c) and the level is 6%. Levels above 8% indicate the existence of higher levels of plasma glucose. Once glycosylated, the level of HbA1c is maintained as such till the erythrocytes disintegrate. Glycosylated hemoglobin estimation gives the time-related measure of the prevailing average blood glucose concentrations to which RBC's are exposed. Since the RBC life span is 120 days, the levels of HbA1c indicate the glycemic state of the past 2-3 months. This is in contrast to the fasting and post-prandial blood glucose levels which are indicative of diabetic control on that particular day. HbA1c level can not be manipulated by the patient, unlike blood glucose levels.

Glycosylated fructosamine is a marker of medium term control of glycemia over the preceding 2-3 weeks. It is a useful test for monitoring during pregnancy.

Monitoring the progress of complications: Factors other than glycemic control also determine the complication rate. These include the genetic make-up, tobacco smoking, obesity, hypertension, hyperlipidemia and presence of other precipitating factors. All these should be taken into account while monitoring complications.

Renal function tests should be performed every 3-6 months. Lipid profile and estimation of urinary micro-albumin, ECG, X-ray chest, biothesiometry and ophthalmic examination should be carried out annually. Biothesiometry is based on the pattern of electrical response of different region of the feet to electric current. Typical abnormalities develop along with the development of neuropathy. Biothesiometry helps to quantify the severity, extent and progress of neuropathy.

Education of the Diabetic

In a chronic disorder like diabetes mellitus the patient's co-operation and participation are of utmost importance

TABLE 90.23

Components of diabetes education
i. Since diabetes lasts lifelong, it has to be kept under control with diet, exercise and drugs.
ii. The aim of therapy is to provide relief from symptoms, and prevent the long-term complications of diabetes.
iii. Recognition of hypoglycemia early and its prompt correction so as to prevent further consequences.
iv. The importance of foot care in preventing infections.

in the management. Education regarding the various aspects of diabetes helps to achieve better compliance from the patients (Table 90.23).

BRITTLE DIABETES

Syn: Unstable diabetes, labile diabetes

This term is used to denote patients who have wide swings in blood glucose levels after the institution of appropriate treatment. These patients undergo frequent disturbing episodes of hypo- and hyperglycemia. The severity and frequency varies.

Type A: Incapacitated by glucose excursion. This may be primarily hyperglycemia, hypoglycemia or mixed.

Type B: Incapacitated, but lifestyle disturbed by decompensation of glucose control more than thrice a week.

Causes

1. Disorders of glucose regulations.
2. Disturbances in other hormones, which influence glucose levels.
3. Disorders of insulin pharmacokinetics
 - a. Insulin antibodies
 - b. Insulin receptor antibodies
 - c. Renal insufficiency
 - d. Hepatic cirrhosis
 - e. Erratic absorption from subcutaneous injection of insulin
4. Gastrointestinal disorders
 - a. Gastro paresis diabeticorum
 - b. Malabsorption state
5. Coexistent systemic illnesses
6. Psychological problems
 - a. Self-induced therapeutic problem
 - b. Bulimia (eating disorder)
 - c. Depression
 - d. Alcohol abuse
 - e. Communication gap between the doctor and the patients.

Management

Empirical therapy: Frequent small doses of insulin or employing as insulin pump which will self-regulate its action.

Specific therapy aims at tracking the cause.

DIABETES DURING PREGNANCY

Diabetes mellitus encountered during pregnancy may be gestational or pregestational. It should be determined whether the woman had type 1 or type 2 diabetes even before the onset of pregnancy.

Diabetes mellitus leads to serious complications during pregnancy. Not only the complications of the disease may get worse in the mother, but the fetus and neonate are also placed at a risk, leading to increased perinatal morbidity and mortality. Gestational diabetes, defined as carbohydrate intolerance of variable severity with the onset or first recognition during the present pregnancy and which clears up spontaneously after delivery.

Tissue sensitivity to insulin is slightly increased between 12 and 14 weeks of pregnancy and thereafter it declines through out the rest of the pregnancy. It returns to normal immediately after delivery.

In normal pregnancy, development of insulin resistance is a mechanism to provide higher energy substrate to the baby. Blood glucose and free fatty acid levels increase. This, in turn leads to higher insulin secretion. In 2-4% of women the pancreatic insulin response is inadequate and gestational diabetes ensues.

If perinatal morbidity and mortality are to be reduced, gestational diabetes mellitus (GDM) must be detected as early as possible and treatment instituted promptly. Screening of all pregnant women for gestational diabetes between 24-28 weeks gestation with a 50 g oral glucose challenge is the most widely used method. Women showing whole blood glucose value more than 140 mg/dL at 1hour are given a 100 g OGTT. The criteria of O' Sullivan and Mahan remains the most commonly used standard for the diagnosis of GDM (Table 90.24). Diagnosis of GDM is made if any two values are above the normals.

Maternal complications: The most common obstetric complications include hydramnios, pre-eclamptic toxemia, urinary tract infections, vaginal moniliasis and premature labour. Hyperemesis gravidarum and infections are associated with higher risk of ketosis in diabetic women. Diabetic retinopathy may worsen during pregnancy.

Fetal Complications: These include intrauterine death, prematurity, congenital anomalies, respiratory distress syndrome, hypoglycemia, hypercalcemia and hyperbilirubinemia. Prenatal mortality is increased due to placental

TABLE 90.24

O' Sullivan and Mahan's criteria (ADA recommendation) for diagnosis of gestational diabetes mellitus after a 100 g glucose load

Plasma glucose (mg/dL)	
Fasting	95
1 hr	180
2 hr	155
3 hr	140

Note: 2 or more values must be abnormal to make a diagnosis of GDM

insufficiency, prematurity, or trauma during birth. The risk to fetus increases as the pregnancy advances and intrauterine death of fetus is more frequent towards the later stages. Incidence of intrauterine fetal death can be reduced by proper control of the diabetic state.

The management of diabetes during pregnancy is a demanding task and can be best achieved through a team work approach involving the obstetrician, diabetologist, pediatrician and dietician. The management of pregnancy complicated by diabetes should begin before pregnancy is contemplated. Information about the potential complications of pregnancy for the mother and offspring should be explained to the couple. The importance of good stable metabolic control before conception should be highlighted. The aim of therapy should be to maintain the post-prandial blood glucose levels below 120 mg/dL. The insulin requirements may fall during the first trimester, then there is a progressive increase in the requirements until about 34-36 weeks of pregnancy. The requirements come down soon after delivery. It is better to put on 3 doses of short acting human insulin or 2 split doses of soluble and intermediate acting insulin.

Dietary management: A meal plan is made to maintain euglycemia and to provide sufficient calories to sustain adequate nutrition for the mother and the fetus without excessive weight gain. Addition of 150 calories during the first trimester and 300 calories in the second and third trimesters above the basal requirements is adequate. Protein intake should be increased to 1.5-2 g/kg body weight. Exercise should be advised as is compatible with the obstetric condition.

Monitoring control of Diabetes: Preferably plasma glucose levels should be done by the patient before the main meals and also post-prandially at least twice a day. Present day glucometers (available at Rs.1500) enable self monitoring. The advent of glucometer and home blood glucose monitoring helps to achieve good glycemic control. Measurements of HbA1c at 4-6 week intervals help to confirm the status of long term glycemic control. Urine examination for glucose does not give proper assessment of control, since renal threshold for glucose is lowered during pregnancy.

Fetal monitoring techniques: Ultrasound examination for evaluating fetal growth, estimating fetal weight, detecting hydramnios and malformations should be repeated at 4-6 week intervals. Determination of maternal serum alphafetoprotein at 16 weeks along with ultrasound at 18 weeks helps to detect neural tube defects and other anomalies. Fetal echocardiography at 20-22 weeks reveals

cardiac defects. Amniocentesis is performed before elective delivery to document fetal pulmonary maturity.

Timing of delivery: Delivery should be timed when fetal maturation is achieved. Maternal diabetes should be controlled meticulously. The route of delivery for the diabetic patient has to be decided individually. Diabetes as such is not an indication for caesarean section. The decision for caesarian section should be based on the obstetric indications. Termination of pregnancy at the optimum time is a combined decision of the team of doctors based on the degree of control of diabetes, fetal growth, maturity and viability; general condition of the mother, outcome of previous pregnancies and the neonatal services available. In many instances induction of labour and delivery are done by about 36-38 weeks by which time the risk of hyaline membrane disease of the lung is low. On long-term follow-up more than 30% of gestational diabetes patients develop type 2 diabetes.

NEONATAL DIABETES MELLITUS (NDM)

This is defined as insulin-requiring hyperglycemia that is diagnosed within the first three months of life. It may be transient; subsiding by three months, or may continue for longer periods.

Neonatal diabetes mellitus (NDM) is different from other forms of diabetes. It is caused by activating mutations of genes KCNJ 11 which encodes kir 6, 2-a subunit of the ATP sensitive potassium channel (KATP) of the beta cell.

The disease is rare with an incidence of 1/50000 to 1/100000 live births. Such children show intrauterine growth retardation. The disease manifests in the first 3-6 months of life with glucosuria, polyuria, dehydration, failure to thrive and frank diabetic ketoacidosis.

Serum levels of insulin and insulin-like growth factor are low. Treatment with insulin results in dramatic catch up growth and improvement. In 50% of cases insulin can be discontinued, but DM may recur in the second to third decade of life. 50% of cases of NDM develop permanent DM. Interestingly these cases respond to oral hypoglycemic agents such as glyburide. These are the cases which have mutations in the SUR1 regulatory subunit of KATP or Kirb 2 genes. Identification of these genetic mutations can predict cases which will respond to oral sulfonylurea. This response may result from the closing of mutant KATP channels, thereby increasing insulin secretion in response to incretins and glucose metabolism.

 Other Complications 580
 Prevention of Diabetes Mellitus 581

10

Diabetes mellitus is associated with several complications throughout the course of the disease. At present short-term control of diabetes can be achieved in almost all cases by the use of dietary regimen, exercise and drugs. On long-term basis, majority of the patients fail to comply with the strenuous therapeutic regimen and the ideal control of blood sugar during day and night is compromised. Postprandial hyperglycemia is recognized to be an important factor contributing to vascular complications and increased mortality. Diabetes is more dreaded for complications, which invariably set in as the diabetic state continues. Though the DCCT and UKPDS trials have demonstrated that the incidence and severity of all complications can be brought down, complete prevention cannot still be guaranteed in any particular case. On account of this, long-standing diabetic patients constitute a sizeable proportion of chronic morbidity requiring regular and expensive therapeutic interventions. In many diabetics the disease may be first detected when the patient presents with a complication.

A. Acute Complications

1. Metabolic derangements
 - a. Diabetic ketoacidosis and coma.
 - b. Hypoglycemia
 - c. Hyperosmolar nonketotic coma
 - d. Lactic acidosis
2. Infections
 - a. Medical: Acute infections such as skin infections, respiratory tract infections, urinary tract infections, genital infections such as balanoposthitis, vulvovaginitis, and rhinocerebral mucormycosis.
 - b. Surgical: Boils, carbuncles, cellulitis, superficial and deep abscesses, gangrene, foot infections, necrotizing fasciitis.
3. Acute events occurring as a result of the long-term complications
 - a. Ischemic heart disease-acute
 - b. Renal failure
 - c. Peripheral vascular occlusion
 - d. Loss of vision
4. Obstetric Complications
 - a. Intrauterine fetal death
 - b. Hydramnios, more frequent
 - c. Higher frequency of pre-eclampsic toxemia
 - d. Large baby (> 4 kg) giving rise to complications during delivery and perinatally
 - e. Infections of the genital tract
 - f. Worsening of the diabetic state during pregnancy and postpartum.

B. Long-term Complications

1. **Cardiovascular:** Earlier onset of atheroma, ischemic heart disease, cerebrovascular accidents, high incidence of hypertension (about 30% of diabetes have hypertension).
2. **Neurological:** Peripheral neuropathy, autonomic neuropathy and mononeuritis multiplex including cranial nerve palsies, urinary retention and incontinence, diabetic autonomic diarrhea.
3. **Peripheral occlusive vascular diseases.**

TABLE 91.1

Major associated complications seen in long standing diabetic subjects at the time of first examination in a tertiary care hospital at Trivandrum

Complication	%
Nephropathy	70
Hypertension (> 140/90)	50
Carotid artery disease	18
Peripheral vascular disease	21
Retinopathy	20
Coronary artery disease (ECG criteria)	12
Elevated LDL (> 150 mg%)	12
Hypertriglyceridemia (> 200 mg%)	18

Ref: Poulouse K.P. Personal communication (2004)

- Renal:** Recurrent urinary infections, chronic pyelonephritis, papillitis necrotians, diabetic glomerulosclerosis, end stage renal failure.
- Ocular:** Cataract, retinopathy, iridocyclitis, glaucoma, refractive changes induced by treatment
- Respiratory:** Pulmonary tuberculosis, other infections.
- Alimentary:** Xerostomia, stomatitis, gingivitis, dental sepsis, loosening of teeth, halitosis, hepatomegaly, gastric dilataion, nocturnal diarrhea, and paralytic ileus
- Bone and joints:** Osteoporosis, osteoarthritis, and neuropathic joints (Charcot's joint).
- Skin:** Chronic fungal infections of skin, moniliasis of the mucous membranes of the genitalia and mouth, pruritus vulvae, necrobiosis lipidica diabetorum, trophic ulcers of the feet, scleredema
- Drug induced complications:** Hypoglycemia, drug allergy, toxicity to liver and bone marrow.

Even though the major long term complications produces clinical deterioration in the patient, sometimes they may be ignored and the patient may not seek medical attention, as shown in Table 91.1.

Metabolic Emergencies in Diabetes

All these situations are life-threatening. Hence awareness; early diagnosis and appropriate management are necessary to cut down the morbidity and mortality. Metabolic emergencies in a diabetic can be classified as:

1. Diabetic ketoacidosis and coma
2. Hypoglycemia
3. Hyperosmolar nonketotic coma and
4. Lactic acidosis

HYPOLYCEMIA

Hypoglycemia is the fall of blood glucose levels below 50-60 mg/dL at which level symptoms occur in normal persons. However the development of symptoms also

depends on the prevailing blood glucose levels and individual susceptibility. Factors such as age, medication and co-morbid conditions influence the clinical manifestations. In those who have chronically elevated blood glucose levels, even reduction of glucose to normal values may precipitate symptoms. Clinically it is characterized by a varying degree of neurological dysfunction and is responsive to the administration of glucose. The clinical manifestations are extremely varied and depend upon the rate of fall of blood glucose levels and the release of counter regulatory hormones.

Early recognition of the condition is essential since severe forms of hypoglycemia are life-threatening and delay in instituting therapy can result in permanent brain damage or loss of life. In many instances slow onset hypoglycemia is recognized by the patient from his past experiences.

Recent onset of episodes of hypoglycemia in a patient on therapy may be a pointer to renal insufficiency. The insulin requirements go down and necessary changes in dose have to be made. The excretion of oral hypoglycemic drugs is impaired and such drugs are better avoided in a diabetic with renal insufficiency.

CLINICAL FEATURE

This varies from patient-to-patient and the circumstances in which an attack is provoked, generally depending on the rate of fall of blood glucose and the individual endocrine status. The hypoglycemic episodes with insulin usually occur at predictable time intervals in relation to their peak action. Hypoglycemia due to oral drugs can occur any time 30-60 minutes after ingestion. Unlike insulin induced hypoglycemia, it may present with bizarre symptoms and elude recognition. The presentation may mimic cerebrovascular accident at times. Persistence of hypoglycemia over prolonged periods is another feature which should be borne in mind. Recurrence after initial correction is also common.

With a rapid fall in the blood glucose as happens during insulin therapy manifestations due to epinephrine release are prominent, while with a gradual fall in blood glucose the picture is predominantly due to decreased cerebral function presenting with varying neurological deficits (Table 91.2).

Symptoms of Hypoglycemia

1. Adrenergic symptoms: Palpitation, sweating, tremors, anxiety.
2. Neuroglycopenic symptoms: Tiredness, dizziness, drowsiness, seizures, coma.

Hypoglycemia usually manifests abruptly, unlike hyperglycemia which is more gradual in onset.

Physical examination reveals cold extremities, excessive sweating, tachycardia, elevated blood pressure and mental agitation. As the condition proceeds the patient

TABLE 91.2

Precipitating factors for hypoglycemia

- I. Meal-medicine mismatch:
 - a. Decreased food intake, missing a meal or its delay, diarrhea, vomiting.
 - b. Increased physical activity (unplanned, excessive strenuous physical activity) without reduction of the dose of drugs or adjustments in food intake.
 - c. Increased dose of either insulin or oral hypoglycemic agents
- II. Decrease in insulin requirements, which can occur when a juvenile diabetic goes into remission (*honeymoon phase in type-1 diabetes*), or soon after delivery in a pregnant woman (due to the drop in the placental hormones) or with the elimination of stress and control of infection.
- III. Renal and hepatic insufficiency which decrease the insulin requirements.
- IV. Drug interactions e.g. quinine, newer quinolones.
- V. Excessive alcohol consumption

becomes drowsy and comatose. Generalized convulsions may occur. The pupils are dilated and plantar response is extensor. Atypical features may occur at times.

At the suspicion of hypoglycemia, glucose should be administered after taking blood for glucose estimation. Venous blood glucose below 60 mg/dL suggests hypoglycemia. In severe cases the value may be below 40 mg/dL and at times glucose may be undetectable. In any doubtful situation, the response to glucose can be taken as a reliable test for the diagnosis of hypoglycemia.

Symptoms of hypoglycemia vs blood glucose levels

Plasma glucose (1 mmol/L = 18 mg/dL)	mg/dL	mmol/L	
	66	3.9	Counter regulation starts
	60	3.3	Autonomic symptoms
	50	2.8	Neuroglycopenic symptoms such as difficulty to concentrate, confusion, weakness, drowsiness, blurring of vision, dizziness and dysphasia
	40	2.2	Lethargy
	31	1.7	Coma
	20	1.1	Convulsions
	11	0.6	Permanent brain damage
	0	0	Death

The persistence of hypoglycemia for over six hours may lead to permanent CNS damage. Recurrent attacks may also contribute to impairment of mental faculties in children and the elderly. Hypoglycemia impairs the quality of life. Sudden death due to cardiac arrhythmias ('dead in bed' syndrome) may occur due to the abrupt

catecholamine surge associated with falling serum potassium levels, which can precipitate fatal arrhythmias. ECG may show QTc prolongation.

Management of Hypoglycemia

Management consists of emergency measures to correct the blood glucose levels and maintenance to avoid recurrence. If the patient can swallow, 50 g of glucose dissolved in 200 mL water should be given orally. Symptoms start improving within 5-7 minutes and patient becomes normal within 20-40 minutes. If glucose is not ready at hand, sucrose, sweet articles of food or even cereal foods can be given. Mild cases respond successfully. This method should be advised to all diabetic patients so as to avoid more serious consequences.

If the patient is unconscious, parenteral glucose should be administered. About 15-20 g. of glucose is usually needed. This is best administered by I V infusion of 200-250 mL of 10% dextrose, which is safe and effective.

An alternative is to give **glucagon** given IM in a dose of 1.0 mg and repeated 15 minutes later. It is effective in raising blood sugar. This is a useful method if the drug is available and in conditions, where IV injections are not possible due to technical reasons. Glucagon may be repeated after 15 min if response is poor. Glucagon injections are ineffective in cases of alcohol-induced hypoglycemia.

After initial correction of hypoglycemia, the patient is kept under observation for 3 to 4 hours, till he recovers completely and is fit for discharge. This is particularly important for those who are on long acting sulphonyl-ureas. Follow up action consists of detecting the precipitating cause for hypoglycemia and avoiding these factors.

Prevention

All patients should be informed about the clinical picture of hypoglycemia and taught how to recognize an impending attack and take corrective steps. They should be given identity cards indicating the disease, medication received and the address of the personal physician.

Hypoglycemic episodes are frightening to the patients and therefore, unless the warning symptoms are explained to them and corrective measures advised, many of them fail to comply with the prescribed regimen thereafter.

Recurrent Severe Hypoglycemia

Severe recurrent hypoglycemia is common among type-1 diabetes patients as well as among those with late stage of type 2 diabetes. The most frequent cause is exogenous insulin, which, unlike endogenous insulin does not get

suppressed when the blood glucose starts falling. The other reason is the failure of the counter regulatory hormone response. The hypoglycemia is not recognized by the patient at its onset. This state is called as 'hypoglycemic unawareness'. A vicious circle develops and episodes of hypoglycemia recur.

Hypoglycemia Unrelated to Diabetes Mellitus

In resting adults, over 60% of glucose is used by the CNS and the remainder by other tissues such as muscles, bone marrow and kidneys. Fasting hypoglycemia may result from reduction in hepatic gluconeogenesis and/or excessive glucose utilization. The former is due to hepatic diseases. The latter is due to tumours, which use up large amounts of glucose or non-beta cell tumors, which produce one or other insulin like growth factors.

Test

Plasma insulin is measured when blood sugar level is less than 45mg/dL. In those in whom insulin levels are high, the probabilities are insulinoma, factitious hypoglycemia, ingestion of sulphonylurea drugs and the presence of anti-insulin antibodies. These can be differentiated by determining C-peptide, proinsulin, and insulin antibody concentration. Insulinomas produce insulin and also proinsulin. The hallmark of Insulinoma is failure to suppress insulin production in the presence of hypoglycemia.

Anti-insulin antibody is more commonly seen in SLE, rheumatoid arthritis, Graves' disease and benign monoclonal gammopathy. Rarely it may be an isolated disorder.

Antibody induced hypoglycemia: Autoimmune insulin syndrome is a rare cause of hypoglycemia. This is characterized by late postprandial hypoglycemia and polyclonal insulin-binding antibodies. The antibodies trap insulin and release it after varying intervals, giving rise to hypoglycemia.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) is caused by gross derangement of carbohydrate and fat metabolism brought on by severe deficiency of insulin. This is characterized by hyperglycemia, presence of excess ketone bodies in blood and urine, and metabolic acidosis. In the early stages, the ketosis may be mild and easily correctable, but later it becomes clinically pronounced and resistant to therapy. Diabetic ketoacidosis is a common medical emergency encountered in the medical casualties of all major general hospitals in India. The term diabetic coma was used to denote extreme ketoacidosis. This term is not commonly in vogue at present.

Pathogenesis

Insulin deficiency may be absolute or it may be a conditioned deficiency brought on by the precipitating factors. Severe insulin deficiency results in hyperglycemia. Hyperglycemia leads to hyperosmolarity of the plasma, which causes a shift of intracellular fluid to the extracellular compartment with consequent cellular dehydration. Osmotic diuresis leads to loss of water and sodium from the extracellular compartment. Severe loss of water and electrolytes result in the shrinkage of extracellular fluid volume and hypotension. Reduction of renal blood flow impairs renal function.

In the presence of insulin deficiency fat cells undergo lipolysis. This releases excess of fatty acids which reach the liver but they are only incompletely metabolized. Due to this, large amounts of ketone bodies are formed.

Apart from insulin deficiency, other concomitant metabolic derangements also contribute to the severity of ketosis. Growth hormone and glucocorticoids which antagonize the action of insulin are produced in excess. These enhance gluconeogenesis, lipolysis, and ketogenesis in the liver. Lipolysis leads to production of free fatty acids (FFA). Glucagon directs the FFA to enter the mitochondria for beta-oxidation leading to excess production of ketone bodies such as acetone, acetoacetic acid and β -hydroxy butyrate. All the ketone bodies are excreted in urine. Acetone being volatile is present in the expired air and this imparts a fruity smell to the breath. Acidosis gives rise to peripheral vasodilatation which aggravates hypotension and leads to shock. The plasma bicarbonate level is reduced progressively as ketosis worsens.

Body potassium: Another serious metabolic consequence is the abnormal shift of potassium. Potassium moves out of the cells into the extracellular compartments leading to hyperkalemia. Potassium is lost in urine, resulting in the net loss of potassium from the body even in the presence of hyperkalemia. When the metabolic abnormality gets corrected with insulin, fluids and electrolytes, the glucose and potassium re-enter the cells. This leads to severe hypokalemia, which may be fatal, if undetected and treated promptly.

The anion gap is increased. Serum magnesium concentration falls. Total body phosphorus is also lowered. The erythrocyte 2,3- diphosphoglycerate levels are also lowered and as a consequence the oxygen dissociation curve is shifted to the left. This leads to tissue anoxia. Once ketosis develops, if left untreated, it proceeds leading to diabetic coma.

Causes of diabetic Ketoacidosis: All diabetics are predisposed to ketoacidosis, especially those with type-1 DM. In a few cases the diagnosis of diabetes may be made for the first time when the patient presents in coma, especially in children.

Precipitating Factors

1. Withdrawal or reduction in insulin dosage.
 2. Infections.
 3. Trauma or surgery
 4. Medical emergencies like acute myocardial infarction and cerebrovascular accidents.
 5. Large carbohydrate intake.
 6. Drugs which aggravate the diabetic state, e.g. corticosteroids.
 7. Psychological stress.
- In the majority of cases, the condition is precipitated by sudden withdrawal of insulin in the presence of an offending factor.

CLINICAL FEATURES

Since the metabolic derangement takes time to develop, the onset of ketosis is gradual over a few days, but in some young diabetics it may occur more rapidly. The early symptoms are those of uncontrolled diabetes such as extreme fatigue, polyuria, vomiting, and insomnia. Drowsiness and altered behavior should draw attention to the possibility of ketoacidosis. The clinical state steadily deteriorates. Some cases present with abdominal symptoms like severe pain and distension, which may be mistaken for surgical emergencies.

The fully established case presents a characteristic picture. The patient is dehydrated, drowsy, or deeply comatose. The respiration is deep and sighing and this is known as **Kussmaul's respiration**.

(Adolf Kussmaul (1822-1902) was a German physician. He has described three important clinical phenomena-pulsus paradoxus, Kussmaul's sign in pericardial tamponade and Kussmaul's respiration in metabolic acidosis).

A fruity smell of acetone may be detectable in the breath. Eyeball tension is low and blood pressure is low. The limbs are flaccid and deep reflexes are sluggish. Plantar response is upgoing. The abdomen may be distended due to gastric dilation or paralytic ileus, which results from autonomic neuropathy. Initially the pupils are normal, but they may dilate, when the coma becomes deep. In some cases fundal examination may reveal lipemia retinalis (milky plasma in the retinal vessels).

Diagnosis

Any deterioration of the general condition, loss of control of the diabetic state, bizarre symptoms, fatigue, vomiting and altered behavior occurring in a diabetic should be investigated for ketoacidosis.

The diagnosis should be established by urine examination and blood biochemistry. Urine shows sugar and acetone. Acetoacetic acid and acetone can be detected by *Rothera's test* or *Acetest tablets* or Ketostix. The tests can be semi-quantitated by noting the speed of development and depth of colour and also testing the urine in progressive dilutions. Acetone disappears on boiling.

Plasma ketones can also be detected by Ketostix or chemical methods. Acetoacetic acid can be tested also by the Gerhardt's test (ferric chloride test). Drugs like captopril which are eliminated in urine, give rise to false positive tests for acetone. Blood sugar is considerably elevated in most cases, but in some the elevation may be only moderate. Serum triglycerides are elevated (Table 91.3).

Differential Diagnosis

The diagnosis is easily suspected if coma occurs in a known case of diabetes, but the previous history may not be forthcoming always. So also the diabetic may develop other disorders leading to coma e.g. cerebrovascular accident. Diabetic coma has to be differentiated from hypoglycemic coma, cerebrovascular accidents, other causes of metabolic coma, head injuries, poisoning, and intracranial infections like meningitis and encephalitis. In cerebrovascular accident, diabetic ketosis may also develop as a complication. Another point to be remembered is that in cerebral hemorrhage and subarachnoid hemorrhage temporary glycosuria may develop even in non-diabetics, but this passes off when the acute stage is over. Moreover, this is not usually associated with ketonuria and acidosis. Other common causes of ketoacidosis are starvation and severe vomiting. In this glycosuria does not occur and blood glucose levels are low. Other causes of metabolic acidosis such as renal failure, lactic acidosis, poisoning by acids and salicylates and circulatory shock has to be excluded.

Hypersmolar nonketotic coma is rare in comparison to diabetic coma. The former is characterized by dehydration, hypotension, and disturbances of higher functions, ending in coma. This is more frequent in subjects with type 2 DM. In this condition the blood glucose is very high, often above 400 mg%. Ketonuria and metabolic acidosis are not present.

MANAGEMENT

- The principles of management include;
1. Correction of dehydration
 2. Control of hyperglycemia.
 3. Correction of electrolyte disturbances and acidosis.
 4. Attention to precipitating factors like infection, injury or stress
 5. Supportive measures.
 6. Long-term management.

Diabetic ketoacidosis is a medical emergency requiring hospitalization for treatment. In comatose patients, nasogastric tube is introduced to aspirate the stomach contents. In many cases the stomach may contain large amounts of fluid due to gastroparesis and therefore it is advisable to empty the stomach. Oral feeds are not permitted due to the possibility of aspiration pneumonia. Milder forms of ketoacidosis can be treated by

TABLE 91.3

Clinical and biochemical data to assess the severity of diabetic ketoacidosis

	Mild	Moderate	Severe
Symptoms	Increasing polyuria, thirst, weakness, tiredness	Severe polyuria, polydipsia, rapid breathing, smell of acetone in breath, weakness; somnolence, vomiting	Symptoms of moderate ketosis with drowsiness progressing to stupor and coma
Signs	Flushed face and skin tachycardia, slight smell of acetone in breath	Kussmaul's breathing, loss of skin turgor, soft eyeballs small pulse volume, heavy odour of acetone in breath, drowsiness, and weakness	Severe dehydration, hypotension, extreme tachycardia, air hunger, coma
Urine			
Glucose	2%	Above 2%	Above 2%
Acetone	+++	+++ in 1:4 dilution	+++ in 1:8 dilution
Serum			
Acetoacetate	Positive in undiluted serum (3-6 mmol/L)	Positive in 2-3 fold dilution (6-12 mmol/L)	Positive in 1:4 dilution (above 12 mmol/L)
Plasma bicarbonate	Above 18 mEq/L	10-18 mEq/L	Below 10 mEq/L
Potassium	Normal	Often elevated	Usually elevated
Sodium	Normal	Normal	Normal
Hematocrit	Normal	Elevated	Elevated
pH	Normal	7.2	7.1 or less
Approximate water deficit	1-2 liters	3-4 liters	5-8 liters
Approximate sodium deficit	Less than 100 mmol	100-250 mmol	250-480 mmol

conservative measures and if the patients can tolerate oral food and fluids, this route can be employed for correction.

Correction of dehydration: Fluid and electrolytes should be replenished by I V normal saline as early as possible and this is the most effective single step to arrest further deterioration and bring about recovery. The approximate fluid deficit ranges from 2-8 liters depending on the severity of the condition. The speed of administration of isotonic saline for a moderately severe case is given below:

1st liter	30 min
2nd liter	1 hour
3rd liter	1 hour
4th liter	2 hours
5th liter	3 hours
6th liter	4 hours (Total infusion of 6 liters in 11-12 hours)

Blood glucose and plasma bicarbonate are estimated at 2-hourly intervals. When the blood glucose falls below 250 mg/dL, 5% glucose solution may be given instead of saline. This helps to prevent hypoglycemia and also provide water for correcting cellular dehydration. By this time oral intake is increased and intravenous administration, tapered off.

A serious complication that may develop during fluid and electrolyte replacement is cerebral edema which may

even go on to coning of the brainstem. This is more frequent in children and newly diagnosed diabetics. Symptoms of increased intracranial tension usher in after the initial period of recovery. Unless this complication is kept in mind and promptly managed by the use of intravenous mannitol and other measures, mortality will be high.

Insulin: Diabetic coma is the most urgent indication for soluble insulin. Insulin has to be given intravenously in moderate and severe cases. In mild cases insulin may be given intramuscularly.

Dose: Since large intermittent doses may lead to complications such as late hypoglycemia, hypokalemia, hyperlactatemia and osmotic disequilibrium, the present trend is to use smaller doses, 2-10 units per hour continuously as slow intravenous infusion. In some cases higher bolus doses may be required. Action of insulin lasts only for few minutes if given intravenously. In mild cases the same dose can be given I M hourly.

Soluble insulin is diluted with saline to give 0.1unit/mL and administered in the drip or by intermittent injections in a dose of 6 units/hour (0.1 unit/kg/h for children) till the blood glucose comes down to 180 mg/dL. Thereafter the dose of insulin is reduced to 3 units/h. It is ideal to reduce the blood glucose to 90 mg/dL (5 mmol/L). In insulin-resistant cases as detected by blood

sugar estimation at 1 hr and 2-hr intervals, larger doses should be started without delay. It should be the aim to correct the metabolic abnormality within the shortest period, since prolongation of the coma may give rise to irreversible cellular damage. Insulin infusion is continued till the patient is able to take oral feeds and is fit for subcutaneous insulin.

If intramuscular injections of insulin are used the dose is 20 units as loading dose and 6 units every hour to be reduced to 6 units every 2 hours when the blood glucose falls below 180 mg/dL. Once the emergency is tided over, the patient should be put back on his regular insulin regimen.

Electrolyte disturbances: In addition to severe loss of sodium, there is also gross potassium deficit. The serum potassium level does not reflect the total body content since there is shift of intracellular potassium to the extracellular compartment. In the early phases the serum potassium level is high. With the normalization of metabolism with insulin and fluid replacement, potassium re-enters the cells. At this stage serious hypokalemia may supervene. Administration of potassium early in the regimen prevents this complication. If serum potassium is above 4-5 mmol/liter, potassium chloride administration is not started till the potassium falls with therapy. The dose and frequency are adjusted by 2-hourly serum potassium estimations. It is desirable to maintain the serum potassium levels between 4 and 5 mmol/L. Potassium replacement is crucial to prevent death due to hypokalemia during recovery. In a severe case, approximately 100-200 mmol of potassium may be necessary in the first 24 hours. Electrocardiogram monitoring is a helpful bedside method to indicate the effects of hypo- and hyperkalemia on the heart.

Administration of bicarbonate: There is considerable controversy regarding the use of bicarbonates in DKA. It need not be given as a routine. Its use results in a fall of serum potassium, shift of oxygen dissociation curve to the left resulting in tissue hypoxia and CSF disequilibrium. The indications for use of bicarbonates are

1. severe acidosis with plasma bicarbonate level less than 10 mmol/L
2. patients with DKA complicating AMI and
3. in patients with associated lactic acidosis.

Sodium bicarbonate is given slowly in doses of 55-100 mmol (200-300 mL of 2.74% NaHCO_3 solution). As the condition improves, the dose is reduced. Foci of infection, which may act as the precipitating factor should receive attention from the beginning.

Other supportive measures include proper care of the mouth, attention to the bladder and bowels, maintenance of fluid balance charts, and prevention of decubitus ulcers. When the patient improves, he is rehabilitated and his

usual antidiabetic regimen is restored. With modern lines of therapy almost all cases of diabetic coma can be saved if the condition has not advanced too far. Many of the deaths may be accountable to the underlying conditions, which have precipitated diabetic coma, such as myocardial infarction, stroke or infections.

Mild forms of DKA if detected early, can be managed at home using soluble insulin and, if needed, the insulin analogues such as insulin lispro, which are more prompt and predictable in action.

Prevention of Recurrence

The patient should be advised on the regular use of insulin and other anti-diabetes drugs. The fact that insulin should be continued during intercurrent illness has to be stressed. Frequent monitoring of blood glucose levels and urine examination for acetone should be done when the diabetic gets stressful situations, particularly infections.

HYPEROSMOLAR NON-KETOTIC COMA

Syn: Hyperosmolar hyperglycemic non-ketotic state (HHNKS)

This is a serious emergency seen occasionally in the elderly diabetics. It is commonly precipitated by infections, myocardial infarction, burns, trauma, surgical stress, renal failure, pancreatitis and the use of drugs like thiazide diuretics, steroids, phenytoin and propranolol. In this condition probably small amounts of endogenous insulin are present so that lipolysis does not occur, but glucose metabolism is greatly deranged. Blood glucose levels often exceed 300 mg/dL and go up above 600 mg/dL. Ketosis is absent and this distinguishes HHNKS from diabetic coma. Normal osmolality of the plasma is ± 290 mOsm/L. In hyperosmolar non-ketotic state the plasma osmolality rises above 300 and in severe cases, may exceed 370 mOsm/L. There is profound cellular dehydration. The hematocrit is high. When the fluid loss becomes severe, hypernatremia develops. Sodium ions are critically important in determining plasma osmolality. Body potassium is lost and a total deficit of 200-300 mmols may occur.

Clinical Features

The condition starts with extreme weakness and drowsiness and the patient gradually sinks into coma. Other neurological manifestations such as seizures, ataxia, hemiparesis, aphasia and mental disturbances may be present. Though thirst is present in the early stages, it disappears later. Respiration is normal or depressed. Apart from these features, the picture may resemble diabetic coma.

Diagnosis

Hyperosmolar non-ketotic coma should be suspected in all cases of coma occurring in diabetics, without demonstrable ketosis. Plasma osmolarity can be calculated from the plasma levels of sodium, potassium, glucose and urea using the following formula:

Plasma Osmolarity in mOsm/L= 2 (Na⁺ + K⁺) +

$$\frac{\text{Glucose in mg/dL}}{18} + \frac{\text{urea in mg/dL}}{5.6}$$

Some authors do not include K in the calculation.

Treatment

Principles of management include correction of the extreme fluid depletion and the hyperosmolar state. Insulin is administered in small doses as soon as the condition is recognized. Small doses are preferable since these patients are very sensitive to even small doses of insulin. Soluble insulin is given in doses of 5-10 units per hour intravenously as an infusion till the blood sugar comes to normal. Alternatively, 20 units of soluble insulin may be given intramuscularly, followed by, small doses of 5-10 units every second hour intramuscularly.

Hypotonic fluids are administered to lower the osmolarity. Half normal saline is the fluid of choice. About 6-8 liters may have to be given over 24 hours. Monitoring of central venous pressure is essential in the elderly to avoid fluid overload and cardiac failure. In patients with shock isotonic saline should be infused till the central venous pressure begins to rise.

Potassium should be replaced early during the treatment and it should be monitored with serum potassium estimations.

The prognosis is grave and mortality may be 20-40%. Prompt and early treatment results in recovery.

LACTIC ACIDOSIS (LA)

Normal level of serum lactate is between 0.4 and 1mmol/L in the fasting state and it may go up to 2 mmol/L after

meals (5 to 18 mg/dL). This is maintained by the balance between the production and utilization of lactate. Though lactate is produced in all the tissues, the brain, red blood cells and skeletal muscles account for the major part of this metabolite. Lactate is used for energy metabolism by several tissues under different circumstances. 70% of the lactate is cleared by the liver and 30% by the kidneys. Lactic acidosis has been divided into types A and B. In type A there is hypotension and tissue anoxia. Type B is further subdivided into types β_1 , β_2 and β_3 depending upon the etiology. LA may be primary when tissue perfusion is poor as in shock states. It may occur secondary to metabolic derangements as in uncontrolled diabetes, especially when treated with phenformin.

In diabetic lactic acidosis the blood lactate level is increased above 5 mmol/L and the arterial pH is below 7.25 (Table 91.4).

DIABETIC LACTIC ACIDOSIS

The hypoxic state produced by aberration in tissue metabolism probably contributes to the lactic acidosis associated with severe diabetes. Biguanides, especially phenformin aggravate this condition by inhibiting gluconeogenesis and mitochondrial electron transport chain. Due to this complication, phenformin is not routinely used at present. Metformin can also rarely produce lactic acidosis in patients with renal failure but the risk is quite low in normal subjects.

Clinical Features

In 80% of the patients the condition starts with gastrointestinal problems, followed by sudden alteration in the sensorium leading to loss of consciousness, hypotension, Kussmaul's breathing, hypothermia, severe dehydration and circulatory collapse. Diagnosis should be confirmed by estimating plasma lactate which is above 5 mmol/L. The lactate pyruvate ratio would be above 15. Arterial pH falls below 7.25 and plasma bicarbonate falls below 18 mmol/L. The anion gap which measures the

TABLE 91.4 Classification of lactic acidosis (Cohen and Woods, 1976)			
Type A (Tissue hypoxia)	Type B (without tissue hypoxia)		
	β_1 (Common disorders)	β_2 (Drugs and toxins)	β_3 (Hereditary form)
Cardiogenic shock	Diabetes mellitus	Biguanides	Type 1 glycogen storage disease
Endotoxic shock	Renal failure	Sorbitol	Fructose 1-6 diphosphatase deficiency
Severe anemia	Liver disease	Xylitol	Methylmalonic acidemia
Left ventricular failure			(Leigh's syndrome)
	Infections	Salicylates	
	Leukemia	Methanol	

unmeasured anions in blood would be above the normal range of 8-12 mmol/L.

In the absence of ketonuria, an increased anion gap in a diabetic is almost diagnostic of lactic acidosis. Mortality exceeds 50% in most series, if untreated.

Treatment

The principles of treatment comprise correction of shock, tissue hypoxia and acidosis. Toxic metabolites may be removed by hemodialysis. Insulin therapy speeds up recovery from lactic acidosis. Thiamine has been used with benefits especially in alcohol induced lactic acidosis. However its value remains doubtful. Sodium bicarbonate is given to counteract acidosis (buffer action). It should be used with great caution since volume overload, worsening of acidosis and rebound alkalosis may develop. The total dose of bicarbonate can be calculated from the formula.

Total requirement of bicarbonate (mmol) = (25- plasma bicarbonate) $\times$ body weight in kg $\times$ 0.3

Note: Carbicarb (a mixture of sodium carbonate and sodium bicarbonate) can also be used as a buffering solution IV. It is seldom used in practice.

OTHER ACUTE PROBLEMS IN THE DIABETIC

Somogyi effect (Posthypoglycemic hyperglycemia): Insulin treated patients may show wide fluctuation in blood glucose levels, especially hyperglycemic episodes following periods of hypoglycemic episodes. The counter regulatory hormones that are secreted abruptly give rise to this phenomenon.

Dawn phenomenon: This is hyperglycemia occurring around 3-4 am, which is due to partial insulin resistance caused by release of growth hormone. An additional bed time dose of insulin controls the hyperglycemia.

Rhinocerebral mucormycosis: This presents as a fulminant infection of the nasal cavity and paranasal sinuses with extension into the cranial cavity. This is seen more commonly in association with diabetic ketoacidosis. It gives rise to facial edema, cranial nerve palsies and coma. The organism belongs to the order mucorales in the class zygomycetes. Unless detected early and treated promptly the condition is fatal. Strong clinical suspicion and demonstration of the fungus helps to make early diagnosis. Amphoterecin B is the drug of choice.

Necrotising Fasciitis is fulminant infection in the fascial compartments of the limbs caused by mixed bacterial flora. It presents as acute painful infection of the limb or other sites, rapidly leading to suppuration. The rise in pressure in the fascial compartments may lead to vascular occlusion and extensive gangrene if not attended to early

with antibiotic therapy and surgical decompression of the fascial compartment.

Long-term Complications of Diabetes Mellitus

The chronic complications of diabetes have been classified into microvascular and macrovascular complications. The microvascular complications are specific for diabetes and they constitute diabetic nephropathy, retinopathy neuropathy and also the dilated cardiomyopathy. The macrovascular complications on the other hand, are not exclusive to diabetes. They tend to start even before the onset of florid diabetes. These include coronary artery disease, cerebrovascular disease and the peripheral vascular disease. Diabetes accelerates their progression and extent considerably.

Pathogenesis of diabetic complications: Several factors contribute to the total picture. These include:

Hyperglycemia: Hyperglycemia raises the intracellular glucose concentration in insulin independent tissues such as nerves, glomeruli, lens and retina. Aldose reductase, the rate-limiting enzyme in the polyol pathway catalyzes the reduction of glucose to sorbitol, which is subsequently converted to fructose. Sorbitol does not easily cross the cell membranes. It accumulates intracellularly and leads to cellular damage through its osmotic effects (e.g. in the lens): by altering the redox state of pyridine nucleotides (by increasing the NADH/NAD ratio); and by depleting the intracellular myoinositol levels.

Glycosylation of Proteins: The attachment of glucose to amino groups of protein leads to the formation of Schiff base products or early glycation products. The glycation of proteins leads to alteration in the functions of proteins. It is also responsible for the free-radical mediated damage to the tissues. The early glycosylation products undergo 'Amdori rearrangement' to form stable products termed **the advanced glycosylation end products (AGE)**. Specific AGE receptors are found in several cells such as the macrophages and endothelial cells where they mediate the release of cytokines and reactive oxygen species leading to cellular damage.

The other important factors which are involved in the pathogenesis of both the microvascular and macrovascular complications of diabetes are hypertension, hyperlipidemia, smoking and hypercoagulability.

CARDIOVASCULAR SYSTEM

Atherosclerosis sets in early and it tends to be diffuse and extensive. Ischemic heart disease is common. Ischemic heart disease in the diabetic differs from that in the non-diabetic by the involvement of both the sexes in the same

proportion and the occurrence of painless infarction. Some diabetics develop congestive cardiac failure in the absence of hypertension and demonstrable coronary artery disease. Such cases may be termed diabetic cardiomyopathy. Mortality from cardiovascular disease is 2-3 times more common in the diabetics as compared with normal. The target levels for control of blood pressure and lipids in the diabetics are lower than those in non-diabetics. The ideal levels to be achieved are: BP 130/80, LDL < 100 mg/dL, HDL > 40 mg/dL and HbA_{1c} < 7%.

Management of acute myocardial infarction in the diabetic is the same as in the nondiabetic. Since ketoacidosis may be precipitated by myocardial infarction, strict control of diabetes using insulin is needed in the acute phase. Hypoglycemia should be avoided since it may lead to extension of infarct. Diabetes is not a contraindication for angiography, angioplasty or bypass grafting.

Peripheral Vascular disease: Peripheral vascular disease occurs in 20% of the chronic diabetics. Affection of the upper limb is rare and the reasons for this not clear. Occlusion of the femoral artery and its branches may occur. The foot becomes ischemic. Intermittent claudication may develop. Associated sensory neuropathy predisposes to minor trauma leading to fulminant infection and gangrene. Calcification of the arteries in the legs and feet may be demonstrable in X-ray. Monkeberg's sclerosis affects several arteries.

Strict measures to control blood glucose and lipid levels and regulated exercise programmes help to give symptom relief in the early stages. Cessation of smoking is absolutely necessary for recovery. Lipid lowering drugs such as atorvastatin 10 to 20 mg or more at bed time and gemfibrosil normalize the lipid levels. Regression of the arterial narrowing does occur. Surgical measures include balloon angioplasty and bypass grafting. Once gangrene supervenes the management of the local condition is essentially surgical.

CEREBROVASCULAR DISEASE

In India 8-32% of stroke patients have diabetes and cerebrovascular disease is encountered in about 10% of all diabetic patients. The most common age group for strokes in diabetics is the sixth decade. Study by Poulouse K.P from Trivandrum showed that carotid artery atherosclerosis was present in 18% of patients with type 2 DM above the age of 55 years. It was 6 times more common in diabetes compared to non-diabetes (Int J: Diab. in developing countries 2002, vol 22). The presence of hypertension increases the risk of development of stroke. Thrombotic strokes are more common. The severity of neurological deficit is greater and the rate of recovery is poorer in a diabetic. The risk of a second episode within six months is very high and prophylactic use of antiplatelet agents is indicated.

DIABETIC RETINOPATHY

Diabetic retinopathy is now becoming the leading cause of blindness in most of the developing countries. The risk 8% developing diabetic retinopathy is directly related to the duration of the disease. In type 1 diabetes of 15 years or more duration the chance of having any form of retinopathy is 98% and about one-third of such patients have proliferative disease. In type 2 DM of 15 years duration the prevalence is 78%. A third have macular edema and a 6th have proliferative retinopathy. Insulin requiring diabetes have higher incidence of retinopathy compared to those controlled on diet and exercise without drugs.

Recent introduction of corneal confocal microscopy has helped to study the morphology of structures in the cornea including the nerves. The corneal structures are highly magnified up to a resolution of 1-2μ. The lesions can be quantitated and followed up.

The lesions of diabetic retinopathy can be divided into two broad categories namely background or nonproliferative (NPDR) and proliferative diabetic retinopathy (PDR) (Table 91.5).

Fluorescein angiography is a reliable method to delineate retinal lesions. The earliest sign of retinal change is increased capillary permeability that is evidenced by the leakage of dye into the vitreous humor after fluorescein injection. Occlusion of the retinal capillaries follows, with subsequent formation of sacular and fusiform aneurysms. Arteriovenous shunts also occur. There is proliferation of the lining endothelial cells with loss of pericytes that supports the vessels. Hemorrhages in the inner retinal areas are dot shaped, while bleeding in the more superficial nerve fibre layers appear flame shaped, blot shaped or linear. Preretinal hemorrhages are boat shaped. The exudates are of two types. The cotton-wool spots are microinfarcts. Non-perfused areas surrounded by a ring of dilated capillaries and hard exudates represent leakage of proteins and lipids from damaged capillaries which can best be assessed by fluorescein angiography (Figs 91.1 to 91.4).

TABLE 91.5	
Lesions in diabetic retinopathy	
Background (NPDR)	Proliferative (PDR)
Increased capillary permeability	New vessels
Capillary closure and dilatation	Scar (retinitis proliferans)
Microaneurysms	Vitrear hemorrhage
Arteriovenous shunts	Retinal detachment
Dilated veins	
Hemorrhages (dot and blot)	
Cotton-wool spots	
Hard exudates	

Figs 91.1A and B: Preproliferative retinopathy. Fundus—note: hard exudates (arrow)

Figs 91.2A and B: Preproliferative retinopathy (A) note: cotton wool patches (arrow) (B) more advanced stage note: neovascularisation from veins (arrow)

The increased capillary permeability leads to development of retinal edema and is often associated with hard exudates. If the edema involves the macular region visual acuity may be affected severely and sometimes even permanently. The fundamental characteristic of proliferative retinopathy is new vessel formation and scarring. The stimulus for new vessel formation is retinal hypoxia secondary to capillary occlusion. Vascular endothelial growth factor (VEGF) plays a major role. Two serious complications of proliferative retinopathy are vitreal hemorrhage and retinal detachment, which can cause sudden loss of vision (Figs 91.1A to 91.2B).

The treatment of diabetic retinopathy: This consists of retarding its progression by strict glycemic control, control of blood pressure, cessation of smoking and correction of hyperlipidemia. Laser photocoagulation is used for decreasing the incidence of hemorrhage and scarring when new vessel formation occurs. Pan retinal photocoagulation is often used to diminish the retinal demands for oxygen in the hope that the stimulus for neovascularization may

Fig. 91.3: Proliferative retinopathy. Note: regular looped vessels arising from the disc and normal vessels (arrow)

Figs 91.4A and B: (A) Preretinal hemorrhage—note: horizontal upper border (B) advanced diabetic retinopathy with laser scars (arrow). Also note absorbed pre-retinal hemorrhage (arrow head)

be decreased. Definite guidelines are available for the prevention and management of diabetic retinopathy. Persons who have no retinopathy as detected by fluorescein angiography should be screened by an ophthalmologist at intervals of three years. Those with retinopathy should be screened at intervals of 6-12 months for prophylactic and therapeutic photocoagulation of lesions.

(Ref. Navced Younis et al The Lancet: 2003; 361: 195-200)

Surgical techniques used for treatment of non-resolving vitreal hemorrhage and retinal detachment include pars plana vitrectomy. Newer, but experimental approaches include PKC-beta inhibitors like ruboxistaurin, which block the hyperglycemia-induced toxic PKC (protein kinase C) pathways.

Other Complications Affecting the Eye

Refractive errors are common due to changes in osmolarity of the aqueous humor altering the convexity of the

lens when the blood glucose levels change widely. This is a common phenomenon when an uncontrolled diabetic undergoes proper therapy, especially with insulin. This is called *insulin presbyopia*. When the lens adjusts to the normal glucose levels, the vision corrects itself.

Cataract: Senile cataract is preponed by 10 years or more in the uncontrolled diabetic. Posterior capsular cataract is more common. Management is similar to that of cataract in the non-diabetic.

In type 1 diabetic patients, snowflake opacities may develop in the lens due to severe hyperglycemia.

Diabetic Nephropathy

Renal complications of diabetes mellitus have been studied extensively in both types of diabetes by close follow-up over prolonged periods. Five distinct phases in the course of the disease have been identified (see also Chapter 174).

Stage I (Hyper filtration-hypertrophy stage): This stage is characterized by 20-40% increase in glomerular filtration rate (GFR) compared to normal age-matched controls, elevated renal plasma flow and an increase in kidney size by 30%. There is increase in the glomerular size and volume with elevated intraglomerular pressure. These changes are reversible with good glycemic control.

Stage II (Stage with structural glomerular lesions): The hemodynamic changes of the earlier stage and structural glomerular changes begin to appear during this stage in the form of basement membrane thickening and mesangial expansion. During the later part of this stage urinary albumin excretion may also increase transiently (normal < 7 µg/min) during periods of poor glycemic control and exercise.

Stage III (Stage of microalbuminuria): This stage is characterized by the appearance of microalbuminuria. i.e. albumin excretion is in the range of 30-299 mg/day or 20-200 µg/minute. Estimation of urinary albumin/creatinine ratio is emerging as the best way to assess microalbuminuria since this will eliminate fallacies due to urinary dilution or concentration. Microalbuminuria appears primarily due to decreased concentration of anionic heparan sulfate proteoglycans in the glomerular basement membrane. The urinary albumin excretion varies greatly depending upon the time of the day, exercise, posture, and glycemic control. Hence it should be measured at least 2-3 times before microalbuminuria is confirmed. At this stage the blood pressure starts to rise. The risk of overt nephropathy increases 25-30 times once this threshold of albumin excretion is crossed. However, interventions such as strict glycemic control, aggressive antihypertensive therapy and dietary protein restriction have been shown to retard the progress. Microalbuminuria

is an independent marker of cardiovascular risk of ischemic heart disease.

Stage IV (Overt nephropathy): This stage is characterized by the appearance of dip stick positive proteinuria (>550 mg/day). Hypertension is invariably present and retinopathy is also present in over 90% of the patients. Absence of retinopathy should alert the physician towards a nondiabetic cause for the renal disease. Once the overt proteinuric phase begins, there is a steady decline in renal functions with the GFR falling on an average by about 1 ml/min/month. A plot of the reciprocal of serum creatinine against time usually yields a straight line and allows the prediction of the rate of deterioration. Development of nephrotic range proteinuria portends a poor outcome.

Stage V (End stage renal disease): This stage is characterized by the presence of uremic symptoms, fluid retention and edema. At this stage abnormalities of several other organ systems may be obvious. Cardiac insufficiency, peripheral neuropathy, gastroparesis, cystopathy and other extra renal vascular disease may occur. Median survival in untreated patients is less than a year. Such patients require renal replacement therapy in the form of repeated hemodialysis, continuous ambulatory peritoneal dialysis or renal transplantation.

In type 2 diabetes, since the onset of the disease is not acute and since the diabetes can remain unrecognized for a long period of time many patients may present with nephropathy even at the time of first diagnosis. The presence of other disorder such as essential hypertension, urinary tract infection and other forms of kidney diseases hasten the progression of nephropathy.

Management

Even though there is no specific treatment for diabetic nephropathy, early detection and meticulous control of diabetes can reverse microalbuminuria and the progression of nephropathy can be slowed. Hypertension should be treated aggressively with the target blood pressure being <130/85 mm Hg. ACE inhibitors and angiotensin receptor blockers (ARBs) have been shown to slow the progression of nephropathy. They may also be useful in normotensive subjects with microalbuminuria. ACE inhibitors include captopril 12.5-75 mg, lisinopril 2.5-20 mg, Ramipril 1.25-5 mg or perindopril 2-4 mg given daily. Angiotensin receptor blockers (ARBs) like losartan (25-100 mg), Irbesartan (150-300 mg), Candesartan 8-12 mg, Valsartan 80-160 mg or telmisartan 40-80 mg are equally effective in retarding renal lesions. These drugs have been found to be useful to retard diabetic nephropathy also in normotensives. While administering them, renal function should be monitored in the initial phases to avoid hypotension and deterioration of renal function. There is risk of hyperkalemia which should also be monitored. Restriction

of dietary protein helps to retard the progression of renal failure.

URINARY TRACT INFECTIONS

Urinary tract infections are very common in diabetics since glucosuria predisposes to recurrent urinary infection. All common organisms causing urinary infection in non-diabetics are seen in the diabetics as well. In addition, candida may also become invasive. Severe urinary infection may give rise to pyelitis, pyonephritis and perinephric abscess. Papillitis necroticans is the condition in which the renal papillae undergo necrosis in the presence of fulminant infection. Fleshy bits are passed in the urine. At times these may give rise to urinary obstruction and reflex anuria.

Balanoposthitis: This is acute or chronic infection of the glans penis (balanitis) and prepuce (posthitis) occurring commonly in diabetics with glycosuria. This condition gives rise to secondary phimosis. In addition to local cleaning and application of nystatin ointment, strict control of glycosuria is required for full recovery. In many cases the first indication of the loss of control of the diabetic state may be the occurrence of balanoposthitis.

NEUROPATHY

The most common neurological complication is peripheral neuropathy. Metabolic neuropathy may develop because of hyperglycemia and this subsides with proper control of diabetes. The other type is mononeuritis multiplex which is produced by occlusion of the vasa nervorum of the nerve trunks. This does not clear up promptly with treatment. Clinical presentation may be varied. Symmetrical distal sensory neuropathy with pain, numbness, paresthesia, glove and stockings sensory loss and areflexia is the common pattern seen in diabetics.

Motor paralysis leads to foot drop, weakness and wasting of the quadriceps, wasting of small muscles of hands and feet and clawing of the feet. Entrapment neuropathies are also not uncommon. Patients may develop carpal tunnel syndrome. As a result of sensory motor neuropathy, pressure sores may develop over the metatarsal heads.

In chronic cases, with loss of sensation, the mid-tarsal and ankle joints may undergo degeneration (Charcot's joints). The third or sixth cranial nerves may be paralyzed (cranial neuritis). Pupillary abnormalities and disturbances of accommodation may also occur.

Sometimes diabetics develop lancinating pain, motor weakness, sensory ataxia and bladder derangements as in the case of tabes dorsalis (**diabetic pseudotabes**) (Table 91.6).

Diabetic amyotrophy consists of gross weakness and wasting of the proximal groups of muscles of the pelvic girdle, quadriceps and the ilio-psoas. Clinical features are

TABLE 91.6

Classification of diabetic neuropathy

2. Radiculopathy/plexopathy
3. Entrapment neuropathy
4. Asymmetric lower limb motor neuropathy

pain, paresthesia and loss of tendon jerks without any objective sensory loss. This is seen more commonly in elderly subjects. Diabetic amyotrophy has to be differentiated from a primary myopathy and neuropathy. With proper control of the diabetic state; amyotrophy clears off completely unlike myopathy and neuropathy. Diabetic amyotrophy is probably due to microvasculitis in the lumbosacral plexus.

The gold standard to detect and quantify the severity of diabetic neuropathy includes electrophysiological tests and quantitative sensory tests of thermal and pain perception by small fibres. Sural nerve biopsy and electron microscopy helps to demonstrate the morphological changes.

Autonomic neuropathy is common in diabetes. Presence of autonomic neuropathy should be looked for since the warning signs of hypoglycemia may not develop in such patients. Common manifestations of autonomic neuropathy are impotence in males, orthostatic hypotension, nocturnal diarrhea, disorder of sweating and atonia of the bladder. There is impairment of autonomic control of the heart. Absence of sinus arrhythmia and loss of normal response to Valsalva's maneuver clinically indicate autonomic dysfunction of the heart. Subjects with cardiac autonomic neuropathy are under high risk of sudden cardiac death.

Once established, diabetic neuropathy tends to persist. Meticulous control of diabetes is of definite benefit. Analgesics, antidepressants and antiepileptic drugs such as carbamazepine help to relieve the pain and insomnia. Empirically high dose of vitamins B₁, B₁₂ and B₆ have been widely used based on clinical impression without much objective evidence. Electrical stimulation of the site of pain using a cutaneous nerve stimulator helps to relieve pain in some cases. More recently local application of capsaicin has been used with some benefit. Several drugs such as antioxidants, neurotropic peptides, nerve growth factor, prosaposin, memantine, gabapentin, frisiium,

Fig. 91.5: Trophic ulcer R foot—note the indolent deep ulcer

duloexitine, pregabalin and erythropoietin have been employed from time to time with marginal benefit.

Diabetic Foot

Foot problems give rise to severe morbidity in diabetic patients. Diabetes accounts for up to 50-80% of non-traumatic amputations. The life time risk of developing foot lesions in the diabetic is 12-25%. The factors contributing to the foot problems are:

1. neuropathy – sensory, motor and autonomic
2. ischemia and
3. trauma – physical, mechanical, thermal, continuous mechanical stress, uneven weight bearing.
4. infection

Ulceration of the foot in a diabetic usually results from the combination of neuropathic damage, tissue ischemia and excessive pressure loading, often with superimposed infections (Fig. 91.5).

Neuropathy predisposes to ulceration by reducing perception of pain and trauma inflicted by foreign bodies and walking with tight or ill-fitting shoes. Motor neuropathy leads to involvement of the small muscles of the feet altering the posture of the feet and leading to abnormal pressure distribution on to vulnerable areas, particularly over the metatarsal heads and heels. This leads to formation of callus which can breakdown and lead to ulceration. The other factors which contribute to abnormal distribution of foot pressure, in addition to motor neuropathy are limited joint mobility and local deformities, including Charcot's arthropathy. Removal of callus redistributes the pressure and reduces the risk of subsequent ulceration.

Ischemia: Tissue ischemia is a very important factor in the development of foot ulcers in the presence of neuropathy. Apart from major vascular occlusions, defects

Fig. 91.6: X-ray diabetic foot—note the resorption of the phalanges and distal parts of the metatarsals

in microcirculation which occur in diabetes, contribute to the development of ulceration and failure of established ulcers to heal.

Infections: Infection in diabetic foot ulcers is commonly due to mixed pyogenic anaerobic organisms, some of which may be gas forming. Infection of the deeper tissue may lead to thrombosis in the vessels. Abscess formation may also occur which may compress the plantar arch and reduce blood supply to the forefoot and toes. This may lead to gangrene of the toes and osteomyelitis of the bones, necessitating amputation. Systemic signs such as fever may be absent even with deep-seated infections. X-ray may show resorption of bones (Fig. 91.6).

MANAGEMENT

Prevention of foot ulcers is very important and meticulous care has to be taken. The foot has to be inspected everyday for any evidence of injury, washed clean, wiped dry and powdered. Walking on barefoot should be avoided. Footwear has to be well fitting and specially designed in case of deformity. Callosities or fissures in the skin have to be taken care of. Use of hot water, heating pads, or corn plasters is to be avoided. Smoking should be stopped and meticulous control of hyperglycemia and hyperlipidemia is to be achieved.

If ulcers are present, specimens from the depth of the ulcer should be sent for bacterial culture and sensitivity. Parenteral antibiotics are to be administered based on the organisms isolated. Local antibiotics are not very helpful. Delay in treatment will also cause rapid spread of infection leading to necrotising myofasciitis resulting in large ulcers. X-ray of the foot is necessary to assess the

involvement of the bones and joints. Deep abscesses may need drainage. Full debridement of ulcers is required till granulation tissue is seen and they should be packed with gauze soaked in antiseptic cream. Deep infections with osteomyelitis and gangrene may require amputation.

Other Complications

Puritus vulvae and **recurrent vaginitis** are distressing conditions associated with glycosuria. The common organism is *Candida albicans*. Strict control of diabetes and use of antifungal creams or tablets help to relieve the condition.

Tuberculosis

Diabetics are more susceptible to develop tuberculosis, especially pulmonary and pleural forms. Successful treatment should aim at simultaneous attention to both the diabetes and tuberculosis. The therapy for tuberculosis is the same as for non-diabetics.

Autonomic disturbances take the form of gastroparesis and paralytic ileus which give rise to bloating of the abdomen and this may mimic a surgical emergency. Correction of the diabetic state, especially ketoacidosis may relieve the condition. Prokinetic drugs such as domperidone may be of help at times.

Nocturnal diarrhea may occur in the uncontrolled diabetic and may be mistaken for infective diarrhea. Control of the diabetic state and antidiarrheal drugs such as codeine phosphate given in a dose of 30–40 mg oral bedtime may give relief. Loperamide which is an opiod derivative also reduces intestinal motility and this may be used as a short-term measure. Toxic megacolon is a serious side effect. Non-pharmacological measures such as dietary regulation and timing of the diet may help in some cases.

Dawn Phenomenon: This is hyperglycemia occurring around 3–4am which is due to partial insulin resistance caused by release of growth hormone. An additional bed time dose of insulin controls the hyperglycemia.

Necrobiosis lipoidica diabetorum: This is a skin condition associated with diabetes mellitus. It may occur only in less than 1% of diabetics, but above 80% of patients with necrobiosis may have diabetes. These lesions appear as shiny yellow plaques over the shin. There may be underlying telangiectasia. These lesions are susceptible to chronic ulceration as a result of repeated trauma.

Acanthosis nigricans, a velvety pigmentation of the nape of the neck, axilla and flexural zones may be associated with insulin resistance and diabetes, especially in the obese. Indirectly it indicates excess insulin secretion.

Scleredema diabetorum diffuse non-pitting induration of skin over the nape of the neck and Dupuytren's contracture may develop in some.

Rhinocerebral mucormycosis: This presents as a fulminant infection of the nasal cavity and paranasal sinuses, with extension into the cranial cavity. This is seen more commonly in association with diabetic ketoacidosis. It gives rise to facial edema, cranial nerve palsies and coma. The organism belongs to the order mucorales in the class zygomycetes. Unless detected early and treated promptly the condition is fatal. Amphotericin B is the drug of choice. The newer antifungals such as voriconazole are also effective.

Necrotising fasciitis is the fulminant infection in the fascial compartments of the limbs caused by mixed bacterial flora. It presents as an acute painful infection of the limbs or other sites, rapidly leading to suppuration. The rise in pressure in the fascial compartments may lead to vascular occlusion and extensive gangrene, if not attended to early.

Prevention of Diabetes Mellitus

The prevalence of diabetes, especially type 2 has increased considerably and reached epidemic proportions and is likely to quadruple itself by the turn of the century. Such a situation demands that we should contain this problem by concentrating on preventive strategies. Since the two types of diabetes are different entities, the approach to their prevention would also be different.

Type 1: Several advances have taken place in the understanding of the pathogenesis and natural history of type 1 diabetes, particularly in its preclinical phase. Coupled with this, the advances in the field of immunology and the development of the concept of immunomodulation and immunosuppression in autoimmune disorders have opened up newer vistas in its prevention. Recent experimental work on mice shows that autoimmune type 1 diabetes can be corrected by the transplantation of islet cells along with splenic cells and immunomodulator adjuvants. Stem cells of the spleen can home to the pancreas and develop into mature functioning islet cells. These landmark studies show promise for cure of type 1 diabetes in future.

(Ref. Douglas A Melton- Reversal of type 1 diabetes in mice. N. Eng. J Med 2006; 355: 89-90)

Type 2: The potential for primary prevention of type-2 DM exists in the high risk groups such as (i) persons with a family history of diabetes, (ii) obese individuals (iii) women with bad obstetric history and (iv) hypertensive patients. In these populations, screening for IGT should

be repeated at regular intervals. Enormous benefits could be achieved from preventive programs aimed at a balanced nutrition, avoidance of obesity, promotion of physical activity and reduction of smoking. Though studies have shown that administration of metformin, acarbose and thiazolidinediones during the stage of impaired glucose tolerance (IGT) and impaired fasting glucose IFG can all prevent the onset of florid diabetes, drugs are not generally recommended for this purpose as lifestyle modifications have been shown to be as effective and cheaper. Cases of pre-diabetes have to be managed on individual levels as the condition warrants.

Pancreatic transplants have been carried out in diabetics since 1966. It provides euglycemia and an insulin independent state. Such a state is achieved and maintained along with the use of immunosuppressant drugs. It is done in most cases simultaneously along with a renal transplant. The three main types of pancreas transplant are:

1. Simultaneous kidney pancreas transplant
2. Pancreas after kidney transplant
3. Pancreas transplant only

The choice of the type of transplantation depends upon the patients' kidney status. Simultaneous kidney pancreas transplant is the commonly performed procedure.

Islet Cell Transplantation

In this, cadaver pancreas is removed enbloc and their islets are separated out using collagenases. These isolated islets are then injected into the portal vein by percutaneous transhepatic procedure under fluoroscopic guidance. These injected islets get trapped in the hepatic sinusoids where they establish vascularity. This is associated with risks of liver failure, portal vein thrombosis and portal hypertension. Major indications for islet cell transplantation are cases of type-1 diabetes with any one of the following indications: 1. unawareness of hypoglycemia 2. brittle diabetes with frequent episodes of hypoglycemia and/or ketoacidosis and 3. progressive diabetic complications such as retinopathy, nephropathy and neuropathy. Today most islet transplants are done in conjunction with renal transplants, although people are focusing on solitary islet cell transplants. $2-7 \times 10^8$ islet cell are required to make effective transplantation. About 50% continue to have functioning pancreas without insulin dependence 5 years after transplantation. The immunosuppressive drugs used for renal transplants are not effective in suppressing the immune response against islet cells.

R.V. Jayakumar, A.G. Unnikrishnan

Chapter Summary

Geographical Distribution 582
Etiology and Pathogenesis 582
Clinical Features 582
Treatment 584
Other Causes of Melliturias 584
Lactosuria 584
Fructosuria 584
Galactosemia 584
Pentosuria 585

Pathology

The pancreas shows intra- and interacinar fibrosis with moderate round cell infiltration. The acini and islets undergo total atrophy and replacement by fat. The ducts are dilated and numerous intraductal calculi made up of calcium carbonate and traces of phosphate are seen to occupy the head and body of the organ. The calculi show a protein core with deposition of calcium in the interstices. The beta cells of the islets are reduced and this accounts for the diabetic state. The liver shows mainly glycogen infiltration and rarely fatty changes and cirrhosis. In long-standing cases the kidneys, retina, and peripheral nerves show lesions similar to those seen in maturity onset diabetes. The parotid glands are prominent and they show ductal dilation and round cell infiltration.

Syn: Calcific pancreatitis, Chronic relapsing pancreatitis, Pancreatic disease of the tropics, Fibrocalculeous pancreatic disease (FCPD).

Geographical Distribution

Chronic relapsing pancreatitis is confined almost exclusively to the tropics, mainly Africa, India, Indonesia and Malaysia. In India most of the cases have been reported from the midland and the hilly tracts of the southern districts of Kerala and Tamil Nadu. Smaller numbers have been reported from many other parts, especially Karnataka and Orissa. The incidence of FCPD seems to have come down in Kerala in recent years.

Etiology and Pathogenesis

Almost all cases belong to the poor socioeconomic groups, which consume cassava as the staple food. The cyanide present in cassava is thought to be responsible for its toxic effects. However some groups who did not consume cassava also had increased incidence of FCPD. This finding made the cassava theory unpopular. Currently, several genes are thought to be responsible for FCPD. The main gene incriminated is the SPINK-1 (Serine protease inhibitor ksazal-1) gene.

Clinical Features

The disease affects children and young adults in the age groups of 15-35 years. Both sexes are equally affected. In one-third cases, previous history of painful episodes of recurrent pancreatitis may be available. The pain is of a colicky or gnawing nature felt over the epigastrium. This differs from that of peptic ulcers in having no relation to food and not being relieved by antacids. Pressure over the epigastrium gives prompt relief. The physical appearance of these subjects is diagnostic. They show extreme emaciation, distension of the upper abdomen, cyanotic hue of the lips, and bilateral painless parotid enlargement. Growth and development are reared. Women develop secondary amenorrhea. Urinary bladder is grossly distended and atonic. The patients generally seek treatment for diabetes or its complications (Figs 92.1 to 92.3).

The diabetic state is often severe, requiring high doses of soluble insulin for control. In the majority of cases the fasting and postprandial blood glucose levels are high. With the passage of time, the diabetes becomes brittle in many cases.

Fig. 92.1: Pancreatic diabetes—male aged 24 years

Fig. 92.2: Pancreatic diabetics a group from a village

Laboratory features: Fasting and postprandial blood glucose levels are in the ranges of type 1 diabetes. Pancreatic enzymes are lowered. Plasma immunoreactive insulin is reduced.

Diagnosis: The disease should be suspected when a young individual presents with abdominal pain and juvenile diabetes. Plain X-ray of the abdomen reveals radio-opaque calculi in the pancreas. CT scan of the abdomen confirms the diagnosis. The calculi are found mainly in the head and body of the organ. They are of varying size and shape and may show translucent centers (Fig. 92.4).

Complications: Complications are due to diabetes, pancreatic calculi, and pancreatic exocrine dysfunction.

Fig. 92.3: Pancreatic diabetes with cataract

Fig. 92.4: Pancreatic diabetes—plain X-ray of abdomen (Note calculi across L1-L2 vertebrae)

1. Diabetic complications are similar to the complications seen in maturity onset diabetes.
2. Complications due to calculi and exocrine dysfunction include obstructive jaundice, recurrent attacks of pancreatitis, and malabsorption state. Steatorrhea manifests if the diet contains normal amounts of fat or excess fat.
3. Carcinoma pancreas.

Prognosis: With adequate control of diabetes by diet and insulin many cases survive up to the fifth or sixth decade. With proper control of the disease, women resume menstruation. Pregnancy and normal childbirths can be achieved with proper management. The children born to such parents do not have predisposition to develop the same disease. Early onset of microangiopathy shortens life

considerably. Some develop pancreatic cancer on follow-up.

Treatment

The treatment is only symptomatic. Control of the diabetic state is similar to the other forms of juvenile diabetes. Since they are mostly insulin-dependent, oral hypoglycemic drugs are ineffective. Generally, the insulin requirement is high and proper control can be achieved only by giving repeated doses of soluble insulin.

Abdominal pain of recurrent pancreatitis is very disabling and response to common antispasmodics like atropine and propantheline bromide is unsatisfactory. During acute attacks the cases have to be managed on the same lines as acute pancreatitis. In intractable cases with demonstrable calculi, surgical removal of the stones and dilation of the sphincter of Oddi have been beneficial in many cases. When signs of malabsorption are present, dietary management and administration of pancreatic enzymes are indicated.

Other Causes of Melliturias

Though glucose is the most common sugar present in urine, other sugars may be encountered at times. Some are present due to inborn metabolic errors whereas others are of the 'overflow' type. In the latter type, sugars appear in urine whenever the blood levels rise above the renal threshold even in the absence of metabolic abnormalities.

Identification of the sugar is important since many cases of innocent melliturias may be wrongly treated as diabetes mellitus with disastrous consequences. A positive Benedict's test with negative diastix should suggest the possibility of non-glucose reducing substances in urine. These include sugars like lactose, fructose, galactose, pentose, and other substances like ascorbic acid, aspirin, and PAS. The final identification of these substances is by chemical methods or chromatography.

LACTOSURIA

Newborn babies ingesting milk may develop lactosuria. The urinary level of lactose increases with the quantity ingested. Lactosuria is common in women during pregnancy and lactation. All these are nonpathological.

FRUCTOSURIA

After intake of large amounts of fructose-containing foods like berries, grapes, and honey even normal persons develop fructosuria, the alimentary fructosuria.

Rarely fructosuria is due to deficiency of the specific enzyme, fructokinase in the liver. This is called essential fructosuria. This condition is benign since most of the

ingested fructose can be utilized by other metabolic pathways.

Hereditary fructose intolerance is a more serious metabolic error caused by the deficiency of *hepatic fructose-1-phosphate aldolase*. This is transmitted as an autosomal recessive. These subjects develop postprandial hypoglycemia. The clinical picture varies with age. The severe form presents in infancy. The baby is normal when breastfed, but vomiting and diarrhea occur when fructose-containing foods, or sucrose and sorbitol (which yield fructose on digestion) are introduced into the diet. The baby fails to thrive. Other accompaniments of the condition are hepatomegaly, jaundice, evidence of hepatic dysfunction, postprandial hypoglycemia, renal tubular acidosis, aminoacidurias and lactic acidosis. If left untreated, the condition proceeds to portal or biliary cirrhosis. If the abnormality is recognized early and fructose is avoided, all the lesions clear up. In older children and adults the disease presents with nausea, abdominal pain, distension, and diarrhea. Since sugar and sweets precipitate these attacks; such persons learn to avoid these items. Hepatic involvement is less marked, but uricosuria and renal stones are more common.

Diagnosis: This should be suspected clinically from the history. Precipitation of hypoglycemia by small doses of fructose (0.25 g/kg body weight in adults or 3 g/m² body surface in children) establishes the diagnosis. In normal subjects hypoglycemia is induced only by large doses of fructose.

Hereditary fructosuria has to be distinguished from other metabolic disorders like galactosemia and tyrosinosis.

GALACTOSEMIA

Normally lactose present in milk is converted into glucose and galactose by intestinal lactase. Galactose is absorbed and converted to glucose in the liver. Conversion into glucose is defective in galactosemia and hence the concentration of galactose-1-phosphate and galactose increase in blood and tissues such as liver, brain, kidneys, intestines, and lens.

Galactosemia is transmitted as an autosomal recessive trait. In the fully developed form classical galactosemia presents with cataract, mental retardation, hepatic cirrhosis, and death in early life. The enzyme galactose-1-phosphate uridyl transferase is deficient. The severe form manifests within a few days of birth with intolerance to milk, vomiting, refusal to feed, and failure to thrive. Jaundice, hepatomegaly, and hepatic dysfunction develop early. Cataracts develop within weeks or months. As the child grows up, mental deficiency becomes evident. Recurrent bacterial infections (*E. coli*) are common and may be fatal.

In the atypical form of galactosemia, the enzyme galactokinase is deficient. Galactokinase is required to convert galactose into galactose-1-phosphate and in its absence galactose accumulates in blood and tissues. The only complication in this disorder is cataract formation.

Diagnosis: Urine shows galactose. Diagnosis is established by demonstrating the deficiency of galactose-1-phosphate uridyl transferase in erythrocytes.

Treatment consists of dietary measures to avoid milk and milk products, and this results in dramatic improvement. Even in advanced cases dietary management leads to regression of symptoms except the cataract.

PENTOSURIA

Pentosuria can be due to ingestion of excessive pentoses found in grapes, cherries, plums, etc. and this is known as alimentary pentosuria. The pentoses are arabinose, apiose, rhamnose, ribose, and xylose. Essential pentosuria is an inherited disorder transmitted as an autosomal recessive trait and the urinary pentose is 1-xylulose. It is caused by the deficiency of xylitol dehydrogenase. This condition is clinically silent and no treatment is required. The pentosuria is controlled by avoiding fruits.

INBORN ERRORS OF METABOLISM: GENERAL CONSIDERATIONS

Inborn errors of metabolism (IEM) are genetically determined interruptions of one or several related metabolic pathways. Clinical symptoms result from several abnormal metabolic processes. These include:

1. Deficiency of an enzyme required for normal metabolism.

2. Toxicity due to accumulation of intermediary compounds due to defective metabolism, including acute intoxication.
3. Energy deficiency
4. Organomegaly
5. Profound central hypotonia and
6. Malformations

Inborn errors of metabolism are mostly recessive disorders with clinical symptoms occurring in homozygous individuals. The genetic defects involve homozygous (autosomal) or hemizygous (X-linked) mutations in genes encoding proteins with single enzymatic function. Other abnormalities include interruption in other biochemical pathways.

Though individually the inborn metabolic disorders are rare, when considered collectively, their incidence is higher. The mode of presentation may give a clue to the metabolic disorder. Positive family history helps in diagnosis. Parental consanguinity and neonatal death of siblings or maternally related male members are factors which favour a diagnosis of IEM.

At present several types of IEM are correctable by therapeutic measures or by bone marrow or stem cell

transplantation. Acute presentations of IEM in neonates fall into one of the following five syndromes:

1. The baby is intoxicated:- During the prenatal period it is apparently normal, but soon after birth it starts deteriorating, especially when external feeding is established.
2. Energy deficient conditions:- These results from recurrent hypoglycemia and/or lactic acidosis.
3. Prominent visceral involvement (i.e.) isolated hepatic, or cardiac failure
4. Floppy baby from the birth often, with seizures
5. Multiple malformations

Metabolic defect should be suspected when an infant which is normal at birth fails to thrive, or develops metabolic acidosis and features such as persistent vomiting, organomegaly, developmental abnormalities, convulsions and urinary abnormalities such as peculiar odour, colour change and others. In some instances, the defect occurs in several children in the same family. It is important to make early diagnosis since in many cases dietary modification and supplementation with the missing cofactor help to overcome the defect and prevent permanent damage.

With the development of methods to detect enzymic defects and more advanced biochemical techniques, several metabolic disorders have been brought to light. Though many of these disorders are rare, their investigation has helped in improving the understanding of several metabolic pathways. Many of these metabolic defects are genetically inherited and, therefore, genetic counseling is important in their prevention. Diagnosis of these metabolic disorders early in life and avoidance of the offending articles in diet or biochemical correction of the abnormality helps to restore normalcy.

Table 93.1 gives a list of the important metabolic disorders. For full description, the student may consult larger textbooks on the subject.

It is now possible to identify the abnormal gene and its product which leads to the clinical abnormality.

Many of the inherited metabolic disorders are correctable by bone marrow or stem cell transplantation. In some cases replacement of the missing enzyme therapy using recombinant enzyme is possible but such treatment is expensive. In Hurler's syndrome, stem cell transplantation using cord blood alters the natural history of the disease, if undertaken early in life.

The Metabolic Syndrome

Syn: Reavens syndrome, Syndrome X

This condition has gained prominence in modern times since it is a common forerunner of ischemic heart disease, diabetes mellitus and atherosclerosis. This condition is amenable to life style modifications and has been extensively studied and criteria for early diagnosis have

TABLE 93.1

Some important inherited metabolic disorders

1. Abnormalities of glycogen metabolism
Glycogenoses
Glycogen storage disease
Type I (von Gierke's)
Type II (Pompe's)
Type III (Cori's, Forbe's)
Type IV (Andersen's)
Type V (McArdle's)
Type VI (Her's)
Type VI a
2. Abnormalities of purine metabolism:
Gout, Lesch-Nyhan syndrome, myopathy, and combined immunodeficiency
3. Abnormalities of pyrimidine metabolism:
Orotic aciduria
4. Lysosomal storage diseases:
 - a. Mucopolysaccharidoses (MPS):
MPS IH-Hurler' syndrome (Gargoylism)
MPS IS (Scheic's syndrome)
MPS II (Hunter's syndrome)
MPS III (Sanfilippo-A, B, and C)
MPS IV (Morquio)
MPS VI (Maroteaux-Lamy)
MPS VII (Sly)
 - b. Mucolipidoses (ML): Mucolipidoses types I, II, III, and IV, mannosidosis, fucosidosis, and aspartyl glucosaminuria.
5. Lipid storage disorders:
Gaucher's disease
Neimann-Pick disease
Farber's lipogranulomatosis
Krabbe's disease
Metachromatic leucodystrophy
Multiple sulfatase deficiency
Fabry's disease
GM1 gangliosidosis
GM2 gangliosidosis infantile
Tay-Sachs disease
Juvenile Tay-Sachs diseases (Sandoff's)
6. Disorders of amino acid metabolism:
Hyperphenylalaninemia (phenylketonuria-PKU)
Tyrosinemia
Histidinemia
Disorders of enzymes concerned with the urea cycle leading to increase in citrulline, argininosuccinic acid, and ornithine in blood.
Disorders of lysine metabolism: Periodic hyperlysinemia, persistent hyperlysinemia, and hyperpipecolatemia.
Disorders of branched-chain amino acid metabolism: Maple-syrup-urine disease, isovaleric acidemia, propionic acidemia, methyl malonic aciduria and biotin responsive multiple carboxylase deficiency.
Disorders of sulfur-containing amino acids: Homocystinuria, cystinosis, and alkaptonuria.
Disorders of fat metabolism: Hyperlipidemias-Fredrickson's types 1, 2a, 2b, 3, 4, and 5.
Hemochromatosis
Wilson's disease
Disorders of heme metabolism.
Porphyrias

TABLE 93.2

Criteria for diagnosis of the metabolic syndrome

1. Impaired fasting plasma glucose (FPG) ≥ 100 mg/dL
2. Obesity with the waist circumference > 102 cms in males and 88 cms in females
3. Plasma triglycerides > 150 mg/dL
4. HDL cholesterol < 40 mg/dL in men and < 50 mg/dL in women
5. Blood pressure $> 130/85$ mm Hg

been laid out. The occurrence of the metabolic syndrome is very common, and it is estimated that 22-39% of the adult population in developed countries have this condition. Prevalence varies depending on the definition used and on ethnicity.

Several criteria for the diagnosis of metabolic syndrome have been put forward by WHO, International Diabetes Federation (IDF) and American Association of Endocrinologists (Table 93.2).

The combination of

1. Abnormal glucose tolerance
2. Abdominal obesity
3. Dyslipidemia
4. Hypertension and
5. Coronary artery disease, is together referred to as the *metabolic syndrome* or the *insulin resistance syndrome*. Indians express this syndrome in an exaggerated manner, and this is probably one of the reasons for the increasing prevalence of type 2 diabetes and coronary artery disease in the Indian subcontinent and especially those who have settled in more affluent countries. The exact genesis of the syndrome is not well understood. Inheritance of polygenic predisposition, abnormal intrauterine programming and sedentary life style are but some of the hypotheses put forward to explain the syndrome. The central underlying feature of this syndrome is insulin resistance.

The major components are obesity, hypertension, dyslipidemia and glucose intolerance (the deadly quartets) and coronary artery disease. The diagnosis requires the presence of at least 3 of the 5 major criteria. Individuals with metabolic syndrome are at increased risk of developing diabetes, cardiovascular events (accelerated atherosclerosis) hypercoagulability and endothelial dysfunction.

The association between the metabolic syndrome and abdominal obesity is well proven. It is possible that in the metabolic syndrome the various endocrine secretions of the adipocytes could play a role in the pathogenesis. Recent reports also reveal a link between both high birth weight as well as low birth weight amongst infants as pre disposing factors for the development of metabolic syndrome and type 2 diabetes in adulthood.

Several other manifestations are linked to insulin resistance. These include: 1. polycystic ovarian syndrome 2. fatty liver 3. hyperuricemia 4. microalbuminuria 5. markers of reduced fibrinolysis such as plasminogen activator inhibitor-1 and 6. endothelial damage.

In subjects who have any one component of this syndrome, it is important to look for other components also since they cluster together. Management consists of full investigations for all the component abnormalities, dietary regulation, physical exercise, control of lipid abnormalities and regular monitoring.

HYPERLIPIDEMIAS

General Considerations

The exogenous lipids: A liberal diet supplies about 100 g of triglycerides and 1 g of cholesterol daily. After absorption they circulate in blood as chylomicrons from which the fatty acids pass to muscle cells and fat cells where they are utilized for energy or re-esterified into triglycerides. The remaining portion of the chylomicron which is rich in cholesterol esters is taken up by the liver for the formation of bile acids and the rest passes unaltered in bile. Free fatty acids liberated from fat depots are also metabolized in the liver to form triglycerides, phospholipids, and cholesterol which circulate in blood as lipoproteins.

The endogenous lipids: The liver synthesizes triglycerides from surplus carbohydrates obtained from diet. The triglycerides are esterified and released into circulation as very low density lipoproteins (VLDL). The triglyceride is split off and it enters the adipocytes. The VLDL remnant which contains mainly cholesterol esters gets physically transformed into low density lipoprotein (LDL). Around 75% of circulating cholesterol is present in the form of LDL, and this is the form in which cholesterol is supplied to extrahepatic tissues like the adrenal cortex, muscle cells, renal cells, and lymphocytes for the formation of cell membranes, and hormones. Unesterified cholesterol which is liberated into plasma from disintegrating hepatic parenchymal and phagocytic cells constitutes high density lipoproteins (HDL). The levels of cholesterol and triglycerides in plasma show considerable variation in health. Cholesterol levels above 200 mg/dL and triglyceride levels above 150 mg/dL indicate hyperlipidemia in adults. The cholesterol of atheromatous lesion is derived principally from plasma.

HDL is protective against atheroma, whereas LDL favours atherogenesis. Lipoprotein abnormalities are particularly marked in the metabolic syndrome (syndrome X) in which the HDL level is reduced. In the presence of hypertriglyceridemia, a decrease in cholesterol content of HDL results from decrease in the cholesteryl-ester content of HDL lipoprotein core making the particle small and

TABLE 93.3

Properties of the major lipoprotein fractions

Lipoprotein	Major lipid	Major apoproteins	Sp. gr.	Electrophoretic mobility
Chylomicron	Dietary triglyceride	AI, AII, BI, CI, CII, CIII	Below 1.006	No movement
VLDL	Endogenous triglyceride	B, CI, CII, CIII, E	Below 1.006	Pre-beta
LDL	Cholesterol esters	B	1.019 to 1.063	Beta
HDL	Cholesterol esters	AI, AII	1.063 to 1.210	Alpha
Remnants and triglyceride	Cholesterol esters	B, CIII, E	Less than 1.019	Slow pre-beta

dense. This leads to increase in the clearance of HDL from the circulation and the serum level of HDL falls.

Small dense LDL: This form of LDL increases when the triglyceride levels rise. This leads to depletion of unesterified cholesterol and phospholipids with either no change or an increase in LDL triglyceride.

Small dense LDL is more atherogenic than buoyant LDL due to the following reasons.

1. It is more toxic to the endothelium
2. It is able to pass more easily through the endothelial basement membrane
3. It adheres to glycosaminoglycans
4. It has increased susceptibility to oxidation
5. It is more selectively bound to scavenger receptors on monocyte derived macrophages. Presence of small dense LDL is common in syndrome X (Table 93.3).

CLINICAL CONSIDERATIONS

The blood levels of cholesterol and triglycerides give valuable information for the assessment of errors of lipid metabolism. LDL and HDL together account for 90% of the cholesterol in the plasma. Lipids are present in circulation as lipoproteins and free fatty acids (non-esterified fatty acids) bound to albumin. The lipoproteins are formed by the combination of the lipids, triglycerides, phospholipid, and cholesterol with specific apoproteins. These have been classified as very low density lipoproteins (VLDL, pre-beta) low density lipoproteins (LDL, beta lipoproteins), or high density lipoproteins (HDL, alpha lipoproteins) based on ultracentrifugal studies and electrophoretic patterns. The LDL and HDL particles are heterogeneous. The terms “pre-beta”, “beta”, and “alpha” refer to the bands seen on electrophoresis.

The role of HDL is probably to transport cholesterol and remove lipids from the arterial walls. The HDL reduces uptake of LDL by cells. Increase in levels of LDL and VLDL and decrease of HDL are associated with higher incidence of atheroma and its complications. Specific subclasses are selectively related to coronary heart disease. HDL has a protective role against atherogenesis. In coronary heart disease the concentration of HDL fraction is particularly low. Raised concentration of

LDL is readily decreased by controlled diet and appropriate drugs. Reduction of saturated fats in the diet and increase in the proportion of mono- and polyunsaturated fats help to lower LDL levels.

Trans-saturated fats produced by hydrogenation of vegetable oils are particularly atherogenic. These fats, prepared in large amounts commercially are used for the production of margarines, artificial butter, bakery products, deep fried fast foods and others. Regular physical exercise helps to lower LDL cholesterol and raise HDL cholesterol to a limited extent.

High levels of LDL (above 500-700 mg/dL) lead to acute pancreatitis.

Lipoprotein (a) [LP (a)] is a genetically determined fraction, with less of environmental influences. In Asian Indians it is a very powerful predictor of coronary artery disease. Concurrent high levels of triglycerides and LDL increase the risk. LP(a) is highly thrombogenic, atherogenic and antifibrinolytic. Its atherogenic risk is 10 times that of LDL. Due to this high risk, LP(a) is called the “**deadly cholesterol**”. Measurement of LP(a) is advisable for all persons with family history of premature atherosclerosis.

Hyperlipidemias may be primary or secondary. In the primary hyperlipidemias genetic factors may be prominent. Environmental factors such as obesity, high saturated fat diet, and smoking aggravate the disorder. Primary hyperlipidemias may be further classified into three groups.

Primary Hyperlipidemias

Group I: This consists of hypercholesterolemia (280-400 mg/dL, 7-10 mmol/L) with a clear serum, normal triglyceride levels, and increase in LDL (beta lipoproteins). In the majority of cases environmental factors like high saturated fat diet and smoking are seen to aggravate the condition. For a long time the condition is asymptomatic, but 50% develop ischemic heart disease by the age of 50 years.

The condition occurs as an autosomally dominant inherited disorder in 5% of subjects. They show very high serum cholesterol levels (320-640 mg per dL in

heterozygotes and 640-1280 mg/dL in homozygotes). Xanthomas and arthritis are common. Xanthomas are deposits of cholesterol seen as yellowish nodular masses which vary in size from a few millimeters to several centimeters. They develop insidiously and are painless. The common types are *xanthoma tendinosum* (over the tendo-Achilles, extensor tendons of the hand, etc), *xanthoma tuberosum* over the bony prominences (around the elbow, knees, iliac crest, etc), *xanthoma planum* (plaque-like), striate xanthoma along the palmar creases, or as papular eruptions (*eruptive xanthoma*). Sometimes they ulcerate and discharge greasy material. Some may be calcified. Histology shows collections of lipid-laden cells.

Many subjects may show *xanthelasma*. These are yellowish plaque-like lesions seen on the medial aspects of the upper and lower eyelids. Though these show a strong association with hypercholesterolemia, they may also be seen in persons with normal cholesterol levels.

Corneal arcus occurs as a greyish ring along the periphery of the cornea. A clear zone of cornea can be seen outside the arcus and this feature distinguishes corneal arcus from other lesions like *Kayser-Fleischer ring*. Corneal arcus is seen to develop in the majority of persons with age, but premature occurrence of arcus has been associated with the presence of hypercholesterolemia, especially LDL cholesterol, but in several reports from India this association has not been seen.

Group II: In this type of disorder there is predominantly hypertriglyceridemia. The serum is cloudy, triglycerides and pre-beta lipoproteins are increased but cholesterol is normal or only moderately increased. Common associations are obesity, diabetes mellitus, and gout. There is a strong tendency to develop ischemic heart disease.

Group III: Consists of chylomicronemia and this results from the deficiency of extrahepatic lipoprotein lipase. This is rare.

Frederickson's classification: Frederickson has suggested a classification of hyperlipidemia which includes six groups based on the serum levels of lipids and lipoproteins, estimated in the fasting state.

Management of primary hyperlipidemias: Many cases can be controlled by dietary management. Excess weight should be reduced. Groups I and II benefit by the avoidance of dietary cholesterol and restriction of fat to supply less than 15% of the total calories. Lipids should be supplied as polyunsaturated fats. Foods such as egg yolk, butter, margarine, hydrogenated oils, lard, suet, cakes and biscuits made with these fats, whole milk, cream, fatty meat, chocolates, coconut oil and foods fried in saturated fats should be avoided. Some cases show an abnormal elevation of serum lipids with the intake of alcohol and refined carbohydrates. Such cases benefit by restriction of alcohol and refined carbohydrates. Group III

Frederickson's classification		
Types	Lipoproteins	Groups
Type 1	Chylomicron	Group III
Type 2a	LDL	Group I
Type 2b	LDL and VLDL	Group II
Type 3	Remnants	
Type 4	VLDL	
Type 5	VLDL and chylomicrons	

hyperlipidemias respond to reduction of fat below 15% of their dietary intake.

As important as the diet are exercise programs. Weight reduction and aerobic exercises help to normalize several of the hyperlipidemias. Proper exercise regimen and avoidance of smoking reduce the coronary risk further.

The desirable level of total cholesterol for Indians is ideally 150-200 mg/dL. Decreased level of HDL below 35 mg/dL is an independent risk factor for atherosclerosis. Presence of low HDL levels is an indication for active lowering of total cholesterol and LDL. Levels of triglycerides above 200 mg/dL especially when accompanied by a low HDL/LDL ratio increases the risk of coronary atheroma six fold. The LDL particle size also influence the risk factor, smaller size being more harmful.

Drug therapy: Drugs are employed when dietary measures alone are inadequate. Cholestyramine, which is an anion exchange resin, in a daily dose of 16-32 g in 3-4 divided doses helps to control the hyperlipidemia in group I. It acts by inhibiting the absorption of bile acids and cholesterol. It is very effective in type 2 hyperlipidemia, but is contraindicated in types 3, 4, and 5.

Clofibrate, which is a branched chain fatty acid, reduces VLDL and it is effective in lowering plasma triglycerides in types 3 and 4, when given in doses of 0.5 g 3-4 times a day. Clofibrate is indicated in severe hyperlipidemia where the risk of atheromatous occlusions, xanthomatosis and pancreatitis is high (Frederickson's types III, IV, and V). Adverse side-effects of clofibrate include gastrointestinal upsets, increased incidence of cholelithiasis, and increased frequency of malignant neoplasms. Nicotinic acid in a dose of 0.5 to 1 g or more thrice daily augments the lipid lowering effects of other drugs in groups I and II hyperlipidemias. Gemfibrosil in a dose of 0.8 g bd is an effective lipid lowering agent.

Exercise and cessation of smoking help to increase HDL cholesterol, and reduce triglycerides and VLDL. High fiber diet, guar gum powder, fenugreek seeds and bittergourd (Karela) are known to lower serum LDL levels.

The statins: These are inhibitors of HMG (hydroxymethyl glutaryl) coenzyme reductase. They inhibit cholesterol biosynthesis in the liver thereby reducing LDL cholesterol. Other actions of statins include modulation of macrophage activity, changing immune functions of lymphocytes,

reduction of inflammatory activity and improvement in hemorrheological factors. There are several members in this group—lovastatin, simvastatin, pravastatin, Rosavastatin, atorvastatin and others. The newer members have got greater clinical activity. The dose range from 10-40 mg once a day. Effective lowering of cholesterol and LDL reduce the risk of thromboembolic occlusions of coronary and cerebral arteries. Maintenance of serum lipids at lower normal levels has also been shown to lead to regression of atheroma. Statins are indicated to normalize lipid levels in both genetic and secondary hyperlipidemias. It is better to start with lower doses and work up the dose to adjust the lipid levels depending upon the clinical condition and changes in serum lipids. Several large clinical trials have established the beneficial role of statins in reducing the incidence of coronary artery disease, cerebrovascular disease and major acute cardiac events such as myocardial infarction and sudden death. The evidence base for regular use of statins for secondary and primary prevention of atheroma is strong. There are reports of the use of large doses of statins (up to 80 mg daily) in the metabolic syndrome improving the results and prognosis. Side effects include reversible myositis, headache, rise in hepatic enzymes, abdominal pain and others.

Probucol

This drug lowers LDL predominantly. It is an alternate drug in those whose response to statins is inadequate or those who cannot tolerate statins. The dose is 500 mg bd oral.

Probucol has no effect on triglycerides. It may lower HDL slightly. Side effects are mild, mainly gastrointestinal. Rarely, prolongation of the Q-T interval and cardiac arrhythmias may develop. Therefore regular ECG monitoring is required.

Cholesterol Absorption Inhibitor

EZETIMIBE selectively inhibits the absorption of cholesterol by the brush border of the small intestinal epithelium. Triglycerides, fatty acids and fat soluble vitamins are not affected. Its main use is in combination with statins when their effect is suboptimal.

Omega-3 fatty acids: Eicosa pentaenoic acid (EPA) and docosahexaenoic acid (DHA), 2-7 g/day given orally reduces blood levels of triglycerides and cholesterol and thereby lower the coronary risk. Fish oils and fish produce similar beneficial effects.

Secondary Hyperlipidemias

Secondary hyperlipoproteinemias outnumber the primary type. In the majority of cases LDL cholesterol is increased in the serum. The risks of coronary, cerebral, renal and peripheral arterial disease are high irrespective of the primary cause and this risk can be brought down by appropriate therapy.

Causes: The secondary types are seen in diabetes mellitus, hypothyroidism, nephrotic syndrome, biliary obstruction, pancreatitis or as a side effect of drugs such as estrogens and corticosteroids.

In all subjects with hyperlipidemias primary causes should be looked for and attended to.

HEMOCHROMATOSIS

Syn: Bronzed diabetes

This is a metabolic disorder associated with marked increase in iron store in the body. Two forms are known 1. genetic 2. acquired. The genetic hemochromatosis is an autosomal recessive disorder showing varied phenotype manifestations and varying expressivity in different families. Homozygous disease occurs in 3-5/1000. Carrier frequency is 1/10 to 1/5 among the Caucasian population and this is one among the more common genetic abnormality in them. HLA-A3 and B14 are more frequently associated with genetic hemochromatosis.

Underlying defect is the pronounced increase in intestinal absorption of iron through an up regulation of the duodenal metal transporter gene caused by mutation of HFE gene, which is located on chromosome 6 near the HLA locus. Its product is widely expressed in several tissues. More than 80% of affected subjects show a homozygous point mutation (G-A at nucleotide 845) in HFE gene. This results in a cytosine to tyrosine replacement at amino acid 282 (c 282 y). This abnormality can be demonstrated in the laboratory and is used for genetic screening. The HFE product binds to transferrin receptor. Several mutations are known to produce hemochromatosis. Mainly four types of hereditary hemochromatosis are identified. These include:

- a. HFE related
- b. Juvenile type
- c. Transferrin receptor 2 (TfR₂) related and
- d. ferroportin related iron overload

Normal iron absorption is 1-2 mg/day. In hemochromatosis it goes up to 6 mg/day and the body stores may reach up to 60 g against the upper limit of normal of 4 g.

The secondary type is due to iron overload.

Pathogenesis

The main defect is loss of regulation of intestinal absorption of iron resulting in increased absorption of dietary iron. This iron is taken up by several parenchymal tissues and macrophages which results in toxic damage. The pathological changes include cellular dysfunction, necrosis, and fibrosis. Liver and pancreas are most severely affected. The skin, myocardium, and endocrine glands like the adrenal cortex, testes, pituitary and thyroid are affected with varying severity. The condition remains asymptomatic till the total body stores of iron reach 15-20 g.

The liver is enlarged, firm to hard in consistency, and the cut section is brown. The hepatocytes and Kupffer's cells show stainable iron. Eventually, portal cirrhosis develops. Cirrhosis develops when the hepatic iron content exceeds 400 $\mu\text{mol/g}$, i.e. 22.4 mg/g of dry liver tissue. Acinar cells of the pancreas and less frequently the islet cells show hemosiderin. Diabetes may develop. There is increase in iron in several organs. Skin shows increased pigmentation due to deposition of melanin.

Clinical Features

Males are affected five times more frequently than females. Symptoms generally start in the fourth and fifth decades. These include lethargy, loss of libido and impotence, pigmentation, hepatomegaly, and diabetes. The combination of pigmentation and diabetes is referred to as **bronzed diabetes**. Cirrhosis of liver and testicular atrophy occur in advanced cases. Severity of the diabetes is variable. Cardiac enlargement, cardiac failure, heart block and arrhythmias occur in 10-15% of cases. Arthropathy develops due to deposition of calcium pyrophosphate and hemosiderin in the synovium. In long-standing cases hepatocellular carcinoma may develop.

Course and Prognosis

Mean survival in untreated cases is 5 years after diagnosis. Death is caused by infection, cardiac failure, hepatic failure, hepatic carcinoma or diabetic complications. Modern treatment has improved the outcome considerably.

Diagnosis

Hemochromatosis should be considered in all patients presenting with hepatic cirrhosis, diabetes, skin pigmentation, and cardiac abnormalities. In hepatic cirrhosis due to any cause there is accumulation of iron in the liver and this should be distinguished from primary hemochromatosis.

Serum iron is usually above 175 $\mu\text{g/dL}$, TIBC is 200 $\mu\text{g/dL}$ and transferrin saturation is about 60% and often even 100%. Serum ferritin may be increased to 1000 ng/mL in severe cases and in the absence of significant hepatocellular damage, this reflects the enormous iron load.

The 24-hour urinary excretion of more than 2 mg iron following intramuscular injection of 0.5 g of desferrioxamine is suggestive of excessive iron stores. Values greater than 10 mg indicate idiopathic hemochromatosis.

Treatment

Simple venesection to remove 500 mL blood once in two weeks or at shorter intervals help to prolong life by a mean of 8.2 years and improves hepatic function. Venesection is indicated when the serum ferritin level exceeds

1000 ng/mL. The hematocrit is adjusted to around 35% by venesection. Each venesection removes 250 mg of iron. When the iron stores become normal (ferritin drops to 50 ng/mL) progression of cirrhosis may halt. Rarely it may regress and the pigmentation may also come down. There is a general reluctance to do venesection at frequent intervals in them. An established case may require removal of several liters of blood at regular intervals of 5-7 days before the clinical benefits become evident.

The iron chelating agent desferrioxamine has been used when venesection is contraindicated by the presence of anemia, but the drug is less effective. Diabetes is controlled on its own merits. In secondary hemochromatosis desferrioxamine is effective.

WILSON'S DISEASE

Syn: Hepatolenticular degeneration;
Westphal-Strumpell pseudosclerosis

It is an inborn error of metabolism of copper inherited as autosomal recessive. The abnormal gene is present in chromosome 13 and it is identified as ATP7B. This disease is present not uncommonly in many communities in India. Normally copper which is absorbed from the gut is initially bound loosely to albumin, but very soon it binds firmly with ceruloplasmin, which is a globulin produced in the liver.

In Wilson's disease absorption of copper is normal or increased. There is defect in excretion of copper into the bile. Ceruloplasmin in the plasma is absent or considerably reduced. Production of ceruloplasmin is normal but its degradation is accelerated. Therefore the serum copper remains loosely bound to albumin and gets deposited in various organs such as the liver, brain, cornea, kidneys heart, and muscles. This leads to the damage of parenchymal tissues. The most prominent lesions are cirrhosis of the liver and damage to basal ganglia and renal tubules. Cirrhosis of the liver is more common in children.

Clinical Features

The presentation may be predominantly hepatic, neurological or mixed. Hepatic manifestations include recurrent episodes of acute hepatitis like picture, acute liver failure, chronic hepatitis, eventual cirrhosis, portal hypertension and chronic hepatic failure. Hematemesis, portal systemic encephalopathy and coma may follow.

In the brain, copper is deposited mainly in the basal ganglia, cerebellum, and cerebral cortex. This manifests as involuntary movements, extrapyramidal features, dystonias, dementia, cerebellar disturbances, and convulsions. Renal tubular damage results in generalized aminoaciduria. Phosphaturia occurs resulting in osteomalacia and renal rickets. Other renal functions remain unaffected (See also chapters 84 and 191).

Deposition of copper in the Descemet's membrane layer of the cornea appears as a brownish yellow ring (Kayser-Fleischer ring) which merges to the limbus without a clear intervening zone. This has to be distinguished from corneal arcus in which a clear zone of cornea intervenes between the ring and the limbus. Kayser-Fleischer ring is best studied by slit-lamp examination. Presence of Kayser-Fleischer ring is associated with definite neurological damage. At times Wilson's disease may present with acute viral hepatitis like picture.

Diagnosis

Wilson's disease should be suspected in all young patients below the age of 40 years who present with hepatic dysfunction and/or neurological disorder, especially affecting the extrapyramidal system and cerebellum. Presence of Kayser-Fleischer ring is diagnostic. Diagnosis should be confirmed by estimating serum copper and ceruloplasmin and demonstrating high copper content in liver tissue obtained by biopsy.

Serum ceruloplasmin is low. Normal value is 18-65 mg/dL. Total serum copper is below 80 µg/dL. Normal value is 100-200 µg/dL. Amount of copper bound to ceruloplasmin is low whereas the unbound copper is higher than normal. Urinary copper excretion is high—more than 100 µg/24 hours. (Normal 0.32 µg/24 hrs). Hepatic copper is elevated — often above 250 µg/g dry weight. Normal 20-45 µg/g.

CT scan in Wilson's disease shows general cerebral atrophy with basal ganglia having low attenuation signals. MRI is more helpful. Subtle changes in signal activity occur in the basal ganglia in symptomatic and even presymptomatic stages. PET scan shows diffuse reduction of glucose metabolism.

Course and Prognosis

The disease steadily progresses to end fatally in 5-14 years. Hepatic failure, hematemesis, or neurological deterioration account for the majority of deaths.

Treatment

Treatment aims at increasing the elimination of excess copper that is stored in tissues. Elimination is increased by chelating agents like penicillamine (dimethyl cysteine-Distamine, Cuprimine). The dose is 1-4 g daily given orally before food and at bed time. It leads to urinary loss of copper. Adverse side effects include nephrotoxicity, agranulocytosis, arthralgia, lupus-like syndrome, lymphadenopathy, rashes, and thrombocytopenia. These are seen on starting the therapy. Side effects may necessitate temporary withdrawal of the drug. Many toxic effects are dose-related. Interruption of therapy leads to relapse of symptoms and therefore treatment has to be life

long. Even during pregnancy penicillamine can be continued.

Triethylene tetramine (Trientine) dihydrochloride is another chelating agent given in a dose of 400-800 mg orally thrice daily before food. It is not freely available.

Trientine enhances copper excretion and decreases intestinal absorption. Zinc given as zinc acetate blocks intestinal absorption by inducing metallothionein synthesis in intestinal cells. The dose is 150 mg oral daily in divided doses. Zinc is safe and can be given on a long term basis for treatment as well as prevention in susceptible subjects. Potassium sulfide given orally is effective in inhibiting absorption of copper from foods. Therapy can be monitored clinically and by biochemical tests for free copper in the serum, urinary copper, and hepatic transaminases. Another drug is tetrathiomolybdate which prevents absorption of copper and also makes the circulating copper unavailable to be deposited in tissues. Side effects include anemia which is due to overzealous elimination of copper from the body. Liver transplantation may be needed in some cases.

Screening of Relatives

Since asymptomatic siblings show abnormality of copper transport, they have to be investigated with estimation of serum ceruloplasmin and hepatic copper. Early treatment helps to prevent the development of organ damage.

Porphyrrias

These are rare metabolic errors involving enzymes concerned with the heme synthetic pathway. Heme is synthesized in every cell, 85% being in erythroid cells. Out of this 85% is used for the creation of different cytochromes. Most of these disorders are inherited, but porphyria cutanea tarda can be acquired. The synthesis of heme involves 8 steps and each step is enzymically mediated. These are:

Glycine

(1)

Delta-aminolevulinic acid

(2)

Porphobilinogen

(3)

Polypyrrrole

(4)

Uroporphyrinogen III

(5)

Coproporphyrinogen III

(6)

Protoporphyrinogen III

(7)

Protoporphyrin III

(8)

Heme

Fig. 93.1: Congenital erythropoietic porphyria

Note: (1) Ulceration and scarring face, (2) Ulceration and mutilation of ears, (3) Mutilation of hands and fingers

In porphyrias, the skin and nervous system are predominantly involved. Excess porphyrins in the skin induce photosensitization and cause further damage. The pathogenesis of neural lesions is not fully understood.

Porphyrias can be classified in different ways:

1. Depending on the organ in which excess of metabolites are produced.
2. Clinical manifestations, and
3. Specific enzyme defects.

Clinical Classification

1. Cutaneous manifestation without neurological features: Congenital erythropoietic porphyria, erythrohepatic porphyria (erythropoietic protoporphyria), porphyria cutanea tarda.
2. Neurological features without skin lesions: Acute intermittent porphyria.
3. Those that produce either cutaneous or neurological and cutaneous manifestations: Variegate porphyria (porphyria variegata), hereditary coproporphyria.

Among the porphyrias the most commonly encountered one is acute intermittent porphyria.

ACUTE INTERMITTENT PORPHYRIA

It occurs worldwide and in India the condition has been reported from all parts of the country. It is inherited as autosomal dominant. Women suffer more than men. Basic defect is a gross reduction (below 50%) of uroporphyrinogen I synthase which is required for the conversion of

porphobilinogen to polypyrrole (step 3). Urine contains the porphyrin precursors porphobilinogen (PBG) and delta-aminolevulinic acid (ALA) even when the patient is asymptomatic. During an acute attack, levels of porphyrin precursors such as δ -aminolevulinic acid and porphobilinogen increase and these are excreted in large amounts in urine. These precursors are neurotoxic, especially to the autonomic and peripheral nervous systems. In addition, urinary uro- and coproporphyrins also may increase.

Clinical Features

This condition may remain latent for long periods without recognition. Acute episodes are precipitated by several factors. Important among them are:

1. Drugs—barbiturates, sulpha drugs, griseofulvin, phenytoin, female sex hormones and several others.
2. Dietary factors—starvation or excess eating; and
3. Infections.

The acute attack is characterized by neurological phenomena and acute abdominal pain. Excitement, behavioural disturbances, depression, suicidal tendency, delirium, convulsions, and coma are frequent. Peripheral neuropathy and mononeuropathies may be prominent in some cases. Autonomic neuropathy results in gastrointestinal dysfunction, urinary retention, hypertensive crises, disordered sweating, and tachycardia.

Abdominal pain may be so severe as to be mistaken for a surgical emergency. Severe constipation or diarrhea may occur. Gastrointestinal fluid losses lead to hyponatremia and dehydration.

Diagnosis

Acute intermittent porphyria should be considered in the differential diagnosis of all bizarre neurological and neuropsychiatric disorders, severe abdominal pain, and autonomic disturbances.

Diagnosis is established by urine examination. Freshly passed urine is colourless but on standing for a few hours at room temperature it becomes portwine in colour and this should be looked for in all cases. Porphobilinogen (PBG) in urine can be demonstrated by Watson-Schwartz test, i.e. the urine gives a pink colour with Ehrlich's aldehyde reagent just as in the case of urobilinogen. On extracting the pigment with chloroform, PBG is not extractable, whereas urobilinogen is. The amount of PBG can be estimated quantitatively.

Apart from acute intermittent porphyria, PBG may occur in urine in hepatic diseases, drug toxicity, porphyria variegata and hereditary coproporphyria. Specific diagnostic test is the demonstration of diminution of uroporphyrin I synthase in erythrocytes.

Treatment

Symptomatic management during an attack: The offending drugs should be stopped. Phenothiazine (chlorpromazine) administered in a dose of 50 mg intramuscularly relieves abdominal pain and hypertension. Maintenance of fluid and electrolyte balance helps to tide over the crisis. High carbohydrate intake and propranolol give symptomatic relief. Hematin (heme arginate) infusion given IV gives relief in acute attacks. The dose is 3 mg/kg once daily IV $\times$ 4 days (maximum 250 mg/day). This may be repeated if necessary. Aspirin, morphine, guanethidine, reserpine, and penicillin can be safely used for suitable indications.

Prophylaxis should be in the form of avoidance of precipitating factors. Relatives should be screened for the enzyme deficiency and susceptible persons should be warned to avoid the offending drugs.

DISORDERS OF AMINO ACID METABOLISM

These are a heterogeneous group of rare disorders clinically characterized by mental retardation and a shortened life span, generally inherited as autosomal recessive and ranging in severity from mild to very severe forms.

Phenylketonuria (PKU)

Syn. Hyperphenylalaninemia

This is one of the most widespread metabolic errors occurring in infancy. It is an autosomal recessive disorder caused by the deficiency of hepatic phenylalanine hydroxylase which is required for the conversion of phenylalanine into tyrosine. In the well developed case there is severe mental retardation, seizures, microcephaly, hypopigmentation of skin and hair, and eczema. Ingestion of phenylalanine in milk and milk products aggravates the symptoms. Death occurs due to intercurrent infections. Phenylacetic, phenylpyruvic, and phenyllactic acids, which are metabolites of phenylalanine, occur in excessive quantities. These impart a musty odour to the urine and give a green colour with 5% ferric chloride solution within 2-3 min.

Avoidance of milk and other phenylalanine containing diet from the first month of life prevents the development of symptoms. Even in established cases withdrawal of dietary phenylalanine improves the symptoms.

Diagnosis

The urine is screened by ferric chloride test for metabolites of phenylalanine. The Guthrie test which is a filter paper spot test using one drop of blood is done as a screening test for the presence of excess amounts of phenylalanine in blood. In infants with a positive Guthrie test quantitative estimation of amino acids in blood is done.

Fig. 93.2: Ochronosis. Note the dark pigmentation of the hands, face and pinna of the ears

Serum phenylalanine is above 20 mg/dL in severe PKU, whereas normally the levels of phenylalanine and tyrosine do not exceed 1 mg/dL.

Treatment

Dietary measures using diets which are low in phenylalanine (200-800 mg/day) help to keep the serum level below 12 mg/dL. This is continued for the first 8-10 years of life. Tetra hydrobiopterin has been tried as an alternate treatment for mild forms of phenyl ketonuria. Tetrahydrobiopterin is a natural co-factor of aromatic amino acid hydroxylases and nitric oxide synthase. Mild cases may respond but many of the severe cases do not. This depends on the specific genotypes.

Alkaptonuria

This is caused by deficiency of homogentisic acid reductase (homogentisate 1,2 dioxygenase). Homogentisic acid is a metabolic product of tyrosine. The urine turns black on standing due to oxidation of homogentisic acid. **Ochronosis** is dark pigmentation of cartilage tissues.

Clinical features of alkaptonuria include arthralgia, arthropathies, pigmentation of the sclera and cartilages, especially of the pinna of the ear, renal stones, cardiac dysfunction and others. In spondylitis occurring in alkaptonuria, the sacro-iliac joints are not affected. This feature distinguishes the condition from ankylosing spondylitis (Fig. 93.2).

A new drug has been introduced **niticinone**. The dose is 0.7mg/ day for 7 days followed by 2.8 mg/day for 3 days. It reduces the level of homogentisic acid in urine. Long term results are awaited.

Inherited Disorders of Connective Tissue

K.V. Krishna Das

Chapter Summary

General Considerations	595
Osteogenesis Imperfecta	595
Ehlers-Danlos Syndrome	595
Marfan's Syndrome	595
Homocystinuria and Hyperhomocysteinemia	596

General Considerations

The term connective tissue includes cartilage, bone, tendons, fascia, ligaments, and vascular walls. The connective tissue consists mainly of the fibrous proteins—collagen and elastin and the amorphous complex carbohydrates, hyaluronic acid, proteoglycans and glycoproteins, together called the ground substance. Functions of connective tissue include: (i) formation of an elastic covering, e.g. dermis; (ii) protection of vital structures, e.g. skull; (iii) acting as levers for aiding muscular action, e.g. long bones, and (iv) provision of deformable elastic cushions to bear stress and aid in joint movement, e.g. cartilage.

Collagens are a class of proteins, each being determined by a single gene. Two major types are pericellular and interstitial collagens. Pericellular collagen (types IV and V) occurs in basement membranes and intercellular tissues. The major collagen of skin, bones, articular cartilage, tendons, and fascia is interstitial collagen (types I, II, III). The collagens are formed from procollagens by complex enzymatic processes.

Developmental disorders involving the collagens may be hereditarily transmitted. The manifestation and severity differ on account of differences in penetrance and expression of single genes or genetic heterogeneity.

Major Disorders of Collagen

OSTEOGENESIS IMPERFECTA

This disorder is described in section 12, chapter 114.

Ehlers-Danlos Syndrome (EDS)

This is a disorder of types I and III interstitial collagen. Ehlers-Danlos syndrome comprises of at least eleven heritable disorders of connective tissue leading to defects in synthesis or structure of collagen. The abnormality is in the metabolism of fibrillar collagen. Mutations in the type V collagen gene account for up to 50% of classic EDS. Other abnormalities such as defects in tenascins which are extracellular matrix proteins can lead to clinically distinct recessive forms of the syndrome. Clinical features include hyperextensibility of the skin, laxity of joints with tendency to subluxate, purpura, bruises, subcutaneous nodular calcification, and violaceous subcutaneous nodules called molluscoid pseudotumours, delayed wound healing, and kyphoscoliosis. The genetics of this disorder is heterogenous and on this basis EDS may be subclassified into autosomal dominant, autosomal recessive and X-linked types.

Marfan's Syndrome

This name is derived from the first description of the disease by the French pediatrician Antoine Jean-Bernard Marfan (1858-1942). The main pathology is caused by quantitative deficiency of fibrillin-1 which is an extracellular matrix protein. This deficiency sets in motion structural changes in later life and results in multi-system connective tissue abnormalities. The skin texture and elasticity are normal. The basic mechanism is altered regulation of transferring growth factor β , (TGF β)-a family of cytokines that affect cellular performance. The gene is located on chromosome 15q21. More than 500 mutations have been reported. In this disorder a wide spectrum of clinical abnormalities exists. The condition is inherited as autosomal dominant. 25% give a family history and 25% is sporadic.

Clinical Features

Bony abnormalities: These include disproportionately long limbs compared to the trunk (dolichostenomelia),

arachnodactyly (spider fingers), pectus excavatum, pectus carinatum, kyphoscoliosis, increased joint laxity, recurrent dislocations, genu recurvatum and flat feet. The arm span is greater than height by 7.5 cm. Arm span/height ratio is >1.05.

Ocular lesions: The classic feature is ectopia lentis occurring in 60% of cases, the displacement of the lens is upwards, unlike as in traumatic dislocation in which the dislocation is downward. Other features include high myopia and retinal detachment.

Cardiovascular lesions: Dilation of the aortic root, aortic regurgitation, aneurysms of the ascending aorta and sinus of Valsalva, dissecting aneurysms of descending aorta, mitral valve prolapse, mitral regurgitation and cardiac failure may occur. Respiratory manifestations include lung cysts and recurrent pneumothorax.

Differential diagnosis: Marfan's syndrome closely resembles homocystinuria which may present with skeletal and ocular abnormalities similar to those of Marfan's syndrome. The urine shows homocysteine in the latter.

Eunuchoid features: These may be mistaken for marfanoid features. In the former there is no arachnodactyly and other features of hypogonadism are present.

Diagnosis

Strong clinical suspicion is essential for diagnosis. If the terminal phalanx of the thumb projects beyond the medial border of the closed fist, it suggests Marfan's syndrome. The wrist sign is overlap of the thumb and little finger when wrapped around the wrist.

Diagnostic criteria have been postulated. Metacarpal index measured on X-ray of the hand is diagnostic.

Prognosis

Progressive dilation of the aortic root, aortic and mitral incompetence, aneurysm of descending aorta and heart failure account for death.

Treatment

There is no curative treatment. The orthopedic, ocular and cardiovascular lesions demand special attention. Medical treatment consists of beta adrenergic blockers such as atenolol given in doses of 25-50 mg od or bid. This reduces the tension on the aorta and delays dilation.

Enalapril and other antihypertensive drugs may be employed. Patients with Marfan's syndrome should avoid isometric exercises and competitive sports since sudden death may occur.

Surgery on the aortic aneurysm and valves are indicated during the course of the disease. Ectopia lentis has to be treated surgically.

Homocystinuria and Hyperhomocysteinemia

Genetically determined homocystinuria occurs in 1/100000 live births and leads to a 40-fold increase in total serum homocysteine (t Hcy). The total pool is the sum total of all forms of homocysteine.

In the plasma homocysteine occurs in four forms:

1. Free thiol—1%.
2. Disulfide bound to plasma proteins, especially albumin—70-80%.
3. Dimer homocysteine.
4. Combination with other thiols including cysteine to produce homocysteine-cysteine mixed disulphide (20-30%).

During the metabolism of methionine, homocysteine is formed. Homocysteine is metabolised further in two ways.

1. In the liver it is remethylated by betaine-homocysteine methyl transferase. Betaine (trimethyl glycine) acts as the donor of the methyl group.
2. In most other tissues the remethylation is catalysed by methionine synthase and N-methyltetrahydrofolate acts as the donor. The latter depends on dietary folate for its formation. Vitamin B₁₂ is an essential cofactor for methionine synthase activity.

Normal fasting plasma level of t Hcy is 5-15 µmol/L. The arbitrary value for hyperhomocysteinemia is elevation above 15 µmol/L of homocysteine, after methionine loading. The levels in the different grades of hyperhomocysteinemia are:

- Mild—16-30 µmol/L
- Moderate—31-100 µmol/L
- Severe—above 100 µmol/L

The term homocystinuria refers to a group of rare inborn metabolic disorders resulting in high level of circulating homocysteine > 100 mmol/L and urinary homocysteine.

Homocysteine in urine can be detected in many metabolic abnormalities. Most common among them is *cystathionine betasynthase deficiency*, which is an autosomal recessive disorder. This deficiency leads to failure of homocysteine to react with serine to form cystathionine and further conversion to cysteine. Two molecules of homocysteine get converted to homocysteine by disulphide oxidation. Normally homocysteine is not detectable in plasma or urine by ordinary chemical methods. In cystathionine beta-synthase deficiency plasma and urinary levels of homocysteine increase and become detectable. In some genetic variants of homocystinurias the metabolic abnormality can be corrected by administration of large doses of pyridoxine, whereas the others are not correctable. Increased levels of homocysteine interferes with normal cross linking of

collagen and this may be a likely mechanism for the production of the ocular and skeletal abnormalities. Excess homocysteine reacts with cysteine residues thereby disrupting the structure and function of fibrillin 1, the main component of the lens zonules (suspensory ligaments). Four vitamins- Folic acid, vitamin B₁₂, vitamin B₆ and vitamin B₂ are involved in the intermediate metabolism of homocysteine.

Pathological homocystinuria is characterized by disruption of the zonular fibers of the lens, osteoporosis and thromboembolism affecting arteries and veins.

Causes of Hyperhomocysteinemia

- A. Genetic enzyme defects in homocysteine metabolism
- B. Nutritional deficiencies of vitamin cofactors, e.g.: folate, vitamins B₁₂ and B₆.
- C. Diseases—Pernicious anemia, hypothyroidism, renal failure, malignancies such as acute lymphatic leukemia and breast cancer, and severe psoriasis.
- D. Drugs—Folate antagonists such as methotrexate, phenytoin and carbamazepine Vitamin B₆ antagonists such as theophylline, tobacco smoke.
- E. Elderly age.

Measurement of plasma homocysteine is done by high performance liquid chromatography (HPLC).

The patient should fast for at least 12 hours to avoid variations caused by the meal.

In chronic renal disease hyperhomocysteinemia occurs. This acts as an independent risk factor for cardiovascular complications.

Hyperhomocysteinemia leads to a prothrombotic state by the following mechanisms.

1. Increases platelet aggregation
2. Activates factors V, X and XII, and
3. Inhibits protein C.

In addition hyperhomocysteinemia is a strong independent risk factor for osteoporotic fractures in elderly men and women. The exact mechanism is not clear, possibly, homocysteine-related collagen cross-linking in bone may be responsible.

Clinical Features

In some of the western societies hyperhomocysteinemia is reported to be around 5%. Vitamin B₁₂ deficiency leading to hyperhomocysteinemia, venous thrombosis and pulmonary embolism has been reported from India.

(Ref. Dani S J, et al. Hyperhomocysteinemia masquerading as pulmonary embolism; JAPI 2003;51:914-916).

Higher prevalence (13-47%) has been reported among groups of patients having symptomatic atherothrombotic disease. Genetically determined type is characterized by marfanoid body features, subluxation of the lens, and mental retardation. Vascular thrombotic episodes are more frequent.

Acquired hyperhomocysteinemia has assumed great epidemiological importance on account of its association with coronary, cerebral and other vascular thrombotic episodes.

Pyridoxine responsive patients have milder forms of the disease compared to pyridoxine non-responders. Bony abnormalities include osteoporosis of the spine and long bones, scoliosis, marfanoid features, pectus excavatum and pectus carinatum. Some children may develop mental retardation and seizures.

The characteristic feature is premature vascular disease. If the condition remains untreated, 20% die before 30 years of age. The homocysteine levels show relationship with coronary artery disease, peripheral artery disease, stroke or venous thrombosis. The vascular damage is mediated by oxidative injury to the endothelium. The embolic complications predominate over atherosclerotic complications.

Diagnosis is suggested by the presence of homocysteine in urine detected by cyanide-nitroprusside reaction which is a simple way of detecting increased amounts of sulphhydryl compounds. This test is not specific.

Management

Several attempts are being made to reduce the risk of vaso-occlusive diseases by lowering plasma homocysteine levels by dietary supplementation with folic acid, 400 µg/day, vitamin B₁₂ 100 µg/day and vitamin B₆ 25 mg/day. Several studies are at present looking into the effect of this vitamin supplementation on the risk of atherogenesis and stroke in the young.

In genetic homocystinuria dietary restriction of methionine and oral supplementation of folate and pyridoxine are beneficial. Cysteine and betaine are found to lower plasma homocysteine levels.

Food articles such as egg, milk and meat are rich in methionine and these should be avoided.

Low methionine dietary formulas are available for treating affected children.

General Considerations 600
Physiology 600
Hormone Metabolism 601
Hormones Actions 601
Clinical Aspects of Endocrine Disorders 602
Physical Examination 604
Laboratory Investigations 605
Types of Hormones and their Patterns of Secretion 606

General Considerations

Approximately 10% of the population in India suffers from endocrine/metabolic diseases other than diabetes mellitus and the proportion of various endocrine/metabolic diseases is given below.

• Goiter	54%
• Diabetes mellitus	20%
• Hormone related reproductive disorders	10%
• Adrenal/pituitary disorders	4%
• Nutritional/metabolic disorders	10%

Endocrine diseases account for 7-10% of patients admitted in hospitals. The prevalence varies from states to states as well as cities and villages.

Physiology

Endocrine system consists of specialised tissue organised in different anatomical sites in the form of glands such as thyroid and adrenals or distributed diffusely as identifiable cells in various organ systems, such as the gut, brain, kidneys, lungs and others. The latter are called paracrine cells. Hormones secreted by the former group reach the circulation directly since these glands are devoid of ducts. Their main action is at distant sites, and many have generalised systemic effects in addition to specific effects on the target tissues, e.g.

1. Thyroid hormone stimulates general metabolism, growth and maturation.

2. Glucocorticoids act as stress hormones, take part in several immunological functions and also influence the blood sugar level.

Effects of hormones on target tissue are mediated through the action on specific receptors which modulate cellular processes, often through the medium of several chemical messengers.

Hormones from the paracrine cells diffuse out and their action is mainly on the neighbouring cells, but they can also have distant effects. The paracrine tissue consists of amine precursor uptake decarboxylase cells (APUD cells). Some of the hormones produced by this system are listed below:

Gut: Gastrin, cholecystokinin, vasoactive intestinal peptide (VIP), motilin, bombesin, substance P and others.

Kidneys: 1, 25 dihydroxy cholecalciferol, erythropoietin, renin, prostaglandins PGA and PGE, kallikrein, insulin like growth factors and others.

Lungs: Dopamine, substance P, prostaglandins, thromboxanes, adrenocorticotrophic hormone, parathyroid hormone, antidiuretic hormone, melanocyte stimulating hormone and others.

Hormones can be chemically classified as peptides, steroids and amines.

Functions of the endocrine system may be considered under the following headings:

1. Maintenance of cellular constancy of the body.
2. Maintenance of the constancy of body fluids (micro-homeostasis).
3. Control of metabolic processes.
4. Growth and differentiation of tissues.
5. Reproduction and
6. Adaptation to changes in the external environment (fluid, food, and electrolyte availability)

Hormones or chemical messengers which are secreted by endocrine cells are released into circulation in response to specific signals. Endocrine dysfunction may manifest as overt clinical disorders such as Cushing's syndrome and acromegaly or silent biochemical abnormalities like hyperglycemia or failure of control mechanisms as in gonadal disturbances.

Biological responses are also under control of other substances such as the neurotransmitters like catecholamines and acetylcholine, prostaglandins, histamine, kinins, cytokines and several others. Intracellular chemicals like cyclic 3, 5 adenosine monophosphate (cyclic AMP), cyclic 3, 5 – guanosine monophosphate (cyclic GMP) and calcium act as second messengers for exerting the biological activity of hormones on cells.

Developmentally, the origin of the endocrine system can be traced back to all the three germ layers.

The endocrine glands can be broadly grouped into:

The pituitary – thyroid – gonadal – adrenal axis (classical endocrine system). These glands act in unison through feedback control and modulate biological activity of distant target cells and organs.

The neuroendocrine system derived from neurectoderm: This is composed of neurosecretory cells. The central component of this system is formed by the brain-pituitary system and the peripheral component is made up of diffusely scattered paracrine cells in many organs. The paracrine system is seen mainly in the gastrointestinal tract adrenal medulla, and the ‘C’ cells of thyroid. These paracrine cells are amine precursor uptake and decarboxylase (APUD) cells which is necessary for the formation of amine or peptide hormones.

Tissues which produce humoral substances which circulate along with the known hormones, e.g. prostaglandins and kinins: These exert strong physiological responses and tend to modulate hormone effects.

Hormone Metabolism

Synthesis, storage, release, and transport to the site of action are the processes undergone before a hormone activates its target. After exerting their effects, the hormones are metabolized to inactive products or they are continually excreted. The concentration of a hormone in blood is governed by its rate of synthesis, release, metabolism and elimination. Many hormones function in closed loop systems, i.e. rise in level of the hormone in the blood exerts feedback inhibition on its controlling hormone. Many endocrine glands exhibit diurnal rhythmicity (sleep-wake cycle), pulsatility with regular periodicity, and regulation of secretion in response to substrate augmentation. Hormones like steroid hormones and thyroid hormones are bound to carrier proteins of high affinity for transport. The hormone is biologically inactive in the bound form and it has to be split to restore its activity.

Hormone Actions

Hormones modulate both the intracellular and extracellular activities of cells so that the different cells in an organ or tissue behave as a synchronous macrocellular complex. As a general rule, hormones do not initiate biochemical processes primarily, but they only regulate the rate of the reactions in responsive cells. Hormones produce measurable specific effect in organs, cells, cellular organelles, enzymes, genes or membranes. The specificity of hormone response is achieved by three mechanisms such as (i) specific target tissue, (iii) appropriate receptor stimulation, and (ii) the capacity of the cells to respond specifically to receptor activation. Hormone effects are generally brought about by conformational changes in protein molecules of the receptors or enzymes in the target cell. The receptor shows increase and decrease in number (up regulation and down regulation) and alteration in their sensitivity to the hormone. Alteration in number and the sensitivity of the receptor also grossly influence the final result produced by the hormone. In type 2 diabetes the basic abnormality is the resistance of the receptors to secreted insulin. Modification of receptor function to increase the sensitivity to insulin by drugs brings about relief. The hormonal effects often lead to acceleration of some biochemical reactions or metabolic pathways with inhibition of others.

One of the main functions of the endocrine system is communication of information between cells. Polypeptide hormones and catecholamines act on the cell surface through specific receptors and activate intracellular second messengers like cyclic AMP, calcium or enzymes. These in turn regulate the activities of the cell. Peptide hormones bring about rapid responses in tissues within seconds or minutes.

Steroid hormones exert their action within the cell by influencing specific receptors which bind to nuclear chromatin. The hormone receptor complex regulates protein synthesis. Thyroid hormones enter the target cells and bind directly to receptor proteins in the chromatin. Such interactions which affect nuclear processes are relatively slow, taking a few hours at times.

Hormone Receptors

The responsive cells contain specific sites of binding of active hormones. The hormones bring about their effect or response in target cells through the receptors. The binding to receptors takes place very quickly. Loss of cellular receptors leads to unresponsiveness to the hormone. Changes in receptor affinity or number also modify the magnitude of hormone responses. The biological effects of a hormone depend on:

- i. its affinity for receptors,
- ii. intrinsic agonist property,
- iii. its concentration at the site of action, and
- iv. its rate of degradation.

The number of hormone receptors on a cell far exceeds that required for bringing about a response. When 5-10% of available binding sites on the cells are occupied, the hormones exert their maximal effect. The remaining number act as spare receptors. Receptors have strict structural specificity, saturability, high affinity and often tissue specificity for target cell responsiveness. The surface receptors are regulated by metabolites such as cyclic GMP within the cell. At times, the receptors may become antigenic and stimulate the production of antibodies. These antibodies react with the receptors and interfere with their functions.

Hormone agonists (optimal inducers) are substances which directly stimulate hormone action by stabilisation of hormone-receptor complex in an active conformational state. Hormone antagonists (anti-inducers) specifically block the effect of an agonist by binding with hormone receptors.

Endocrine disorders result from excessive or diminished secretion of hormones, or abnormalities in responsiveness of tissues. Progressive rise in hormone levels may reduce tissue sensitivity (negative cooperativity).

Clinical Aspects of Endocrine Disorders

11

Symptomatology

Endocrine disorders may manifest with dysfunction of the gland at fault or secondary disturbances in other endocrine glands. Sometimes the presenting symptom may be a remote effect due to defective regulation of a metabolic process, e.g. secondary amenorrhea in hypopituitarism or Cushing's syndrome. The structural changes in the endocrine glands do not always correlate with the severity of dysfunction. For example, gross functional defects may result form microadenomas of the pituitary whereas large tumours may remain silent.

Abnormalities of growth: The rate of growth may be altered in physiological (e.g. puberty) or pathological conditions. Heredity and environmental factors play a major role in determining growth and development. Abnormalities of growth are common in endocrine disorders. Growth is brought about by increase in number and size of body cells. When considering disorders of growth, rate of growth is a more reliable parameter, than the actual size of an individual. The maturation of organs and systems in the body constitutes development.

Endocrine dwarfism: It may be accompanied by abnormalities of sexual function and secondary sexual characteristics e.g. hypothyroidism, hypopituitarism,

gonadal dysgenesis (XO), pseudohypoparathyroidism and adrenogenital syndrome. Hypothalamic syndromes and Cushing's syndrome are causes of impaired growth. *Disparity between age and height, disparity in bone age, alteration of skeletal proportions and disorder in sexual development* are features which suggest endocrine aetiology. Endocrine causes of dwarfism have to be differentiated from constitutional dwarfism, primary bone diseases, malnutrition, metabolic disorders, and severe systemic diseases like renal and hepatic failure.

Excessive height: It may result from accelerated growth hormone activity or abnormalities of adrenal, ovarian or testicular hormones. Pituitary disorders cause gigantism or acromegaly. Hypogonadism causes abnormal increase in height and is associated with eunuchoidism (arm span considerably greater than height and lower segment longer than upper segment). Disorders like Marfan's syndrome and homocystinuria cause abnormally tall stature with other associated congenital abnormalities. Though gigantism is commonly the result of excessive growth hormone activity occurring in young age, rarely it may be secondary to other cerebral disorders as well.

Obesity: Increase in weight by 10% or more above the ideal weight caused by excessive accumulation of fat is called obesity. Endocrine causes include Cushing's syndrome, hypothalamic syndromes, insulinomas, hypothyroidism, polycystic ovarian syndrome and familial hyperlipidemia (type IV). Obesity is associated with delayed puberty in children. It is now known that many cases of apparently dietary obesity in young persons may have abnormalities of adrenocortical function.

Polyphagia: Polyphagia or increased appetite is a common feature of diabetes mellitus and hyperthyroidism and it is accompanied by loss of weight. Polyphagia leading to gain in weight is seen in acromegaly and insulinomas. Hypothalamic disorders like craniopharyngioma and Laurence-Moon-Biedl syndrome may give rise to polyphagia, galactorrhea, hypogonadism, and somnolence.

Loss of weight: Significant weight loss (>5-6%) inspite of increased intake of food is suggestive of diabetes mellitus, thyrotoxicosis and pheochromocytoma. Loss of weight is accompanied by loss of appetite in disorders like Addison's disease, pan-hypopituitarism, anorexia nervosa and psychiatric illnesses.

Non-specific symptoms: like anorexia, nausea, vomiting, and diarrhoea with considerable weight loss may be the features of metabolic disturbances occurring in diabetic ketoacidosis, adrenal crisis, thyroid storm or hypercalcemia.

Fatigue and weakness: These are the presenting symptoms in diabetes mellitus, Addison's disease, hypothyroidism, hypopituitarism, hyperthyroidism. Cushing's syndrome, hyperparathyroidism, and hypogonadism.

Polyuria: Polyuria of more than 3L/day of recent onset should suggest diabetes mellitus, diabetes insipidus or hypercalcemia. Other rare endocrine causes include primary hyperaldosteronism and hypokalemic nephropathy. Polyuria is generally accompanied by polydipsia. Psychogenic polydipsia (increased thirst) is not an uncommon disorder and this has to be distinguished from a primary endocrine abnormality.

Skin changes: Several endocrine disorders lead to characteristic abnormalities on the skin and mucous membranes. In many cases, these precede the other features of endocrinopathies. *Hyperpigmentation* affecting the skin folds, pressure points, and the oral mucous membranes and gums is seen in Addison's disease. Cushing's syndrome is accompanied by increased pigmentation. Pregnancy, thyrotoxicosis, and use of oral contraceptives lead to spotty brown pigmentation over the face (chloasma). Acanthosis nigricans which appears as velvety hyperpigmented thickened plaques in the flexural areas and nape of the neck occurs in Cushing's syndrome and juvenile myxedema.

Vitiligo (hypopigmentation of the skin): This may occur in many endocrine disorders like Addison's disease, hypothyroidism, and hypopituitarism which have an autoimmune basis. Vitiligo may be localised or generalised.

Pallor of the skin may occur in hypothyroidism or myxedema. Panhypopituitarism also leads to hypodepigmentation and loss of hair and the skin does not tan on exposure to sunlight.

Abnormalities of hair: Hirsutism is excessive hair growth in women and children occurring over the androgen sensitive areas such as face, axilla, and pubis. Hirsutism may be primary (idiopathic) or secondary to endocrine disorders. Growth of hair is determined by genetic, endocrine, and other factors. Hirsutism commonly occurs in women at puberty, pregnancy or menopause. In hyperandrogenism, it is an early symptom. In such cases it may be accompanied by other features like virilism in which there is change of voice, clitoromegaly, baldness, and malodorous perspiration. Secondary hirsutism occurs in hyperfunction of the adrenal cortex, polycystic ovaries (**Stein Leventhal syndrome**), testicular and ovarian tumours and bronchogenic carcinoma with endocrine manifestations. Therapy with glucocorticoids, and other drugs such as phenytoin and diazoxide also gives rise to hirsutism.

Loss of hair (alopecia): Androgenic tumours and hyperfunction of the adrenal cortex give rise to frontal baldness. Generalized loss of hair over the head and eyebrows are suggestive of myxedema. Hypopituitarism and hypogonadism are accompanied by absence, or loss of facial, axillary, and pubic hair. Many non-endocrine

disorders like cirrhosis liver and malnutrition are also characterized by loss of hair.

For descriptions of alopecia see Section 18 Chapter 215.

Gynecomastia: Benign glandular enlargement of male breast is called gynecomastia. The glandular tissue is hypertrophied in true gynecomastia. Accumulation of fat in the region of the breasts is called pseudogynecomastia. Bilateral breast enlargement (usually painless, at times tender) occurs physiologically during adolescence. Pathologically gynecomastia occurs in testicular disorders like dysgenesis, atrophy and tumours, systemic diseases associated with disturbances of gonadal hormones (e.g. hepatic failure) and as adverse side effects of drugs like estrogens, spironolactone, digitalis, reserpine, phenothiazines, cimetidine, ketoconazole, busulfan and several others. In most instances the gynecomastia recedes when the cause is removed, but sometimes it tends to persist.

Galactorrhea: This refers to the condition where there is abnormal (unphysiological) secretion of milk. Normal secretion of milk occurs only during lactation and pregnancy. Galactorrhea is a common finding which may not be disclosed by the patient and, therefore, this has to be specifically looked for. Newborn infants may show galactorrhea at times (witch's milk). Hyperprolactinemia, acromegaly, thyroid disorders (hypothyroidism and rarely thyrotoxicosis), feminizing adrenal tumours, corpus luteum cysts, and rarely choriocarcinoma may present with galactorrhea. Drugs like phenothiazines, metoclopramide, digoxin and many others may give rise to galactorrhea.

Disorders of sexual maturation: Normally boys attain sexual maturity before the age of 18 years and girls do so before the age of 16.

Precocious puberty: Sexual maturation before the age of eight years constitutes precocious puberty. Though rarely this may be a familial trait, more often it is due to some serious organic disease. Hypothalamic disturbances, congenital virilizing adrenal hyperplasia, adrenal tumours, and gonadal neoplasms are commonly associated with sexual precocity. Androgen therapy gives rise to sexual precocity in boys. Juvenile hypothyroidism in boys may be associated with pituitary enlargement and sexual precocity. Precocious puberty leads to premature fusion of the epiphyses and this results in dwarfism.

Delayed puberty (infantilism): When there is failure to attain sexual development by the age of 18 years in boys and 16 years in girls, it is delayed puberty. Though it may be a familial trait in some, often it is a manifestation of genetic or gonadal disturbances. In India, non-endocrine causes like malnutrition or undernutrition are also responsible for delayed puberty. Hypothalamic lesions, pituitary lesions and gonadal dysgenesis (Klinefelter's

syndrome) are the common causes of infantilism in boys. Failure to attain puberty by the age of 18 is seen in girls with gonadal dysgenesis (Turner's syndrome), pituitary and hypothalamic diseases and polycystic ovarian syndrome. Rare causes include congenital absence of uterus and vagina and pseudohermaphroditism.

Disturbance of sexual function: Impotence is the inability to get penile erection sufficient to perform the sexual act. Proper penile erection is a complex processes requiring vascular, neural, and endocrine mechanisms. The sex drive is termed *libido*. Impotence and loss of libido are commonly caused by psychogenic factors, but endocrine disturbances like testicular atrophy, Addison's disease, thyrotoxicosis, and feminizing tumours of the adrenal cortex may be associated with this symptom. Autonomic neuropathy occurring in diabetes mellitus, chronic alcoholism, central nervous system lesions, and therapy with several drugs are the other common causes of impotence.

Skeletal manifestations: Several endocrine disorders give rise to changes in the bones which may be the presenting manifestations. The predominant manifestations of metabolic bone disorders are bone pains and muscular weakness. When patients present with bone pains, bone cysts, pathological fractures, bony deformities or 'X-ray evidence of bony abnormalities, hyperparathyroidism, osteomalacia, rickets and osteoporosis should be looked for. Cushing's syndrome and hyperthyroidism may occasionally manifest with severe osteoporosis.

Urinary calculi: Several metabolic disorders lead to recurrent stone formation in the kidneys or other parts of the urinary tract. Calcium stones are seen in hyperparathyroidism, hypervitaminosis D and sarcoidosis. Idiopathic hypercalcuria is a common cause of recurrent calcium stones in male children.

Metabolic abnormalities such as cystinuria, renal tubular acidosis, gout and oxaluria, may all be associated with urolithiasis.

Tetany: Tetany may occur classically in hypocalcemia and less commonly in hypomagnesemia. It is clinically characterised by *carpopedal spasm*, *Chvostek's sign*, and *Trousseau's sign*. Tetany is commonly seen in hypoparathyroidism, pseudo-hypoparathyroidism, osteomalacia, rickets, alkalosis and acute pancreatitis. Tetany is rapidly correctable by the intravenous administration of 10 mL of 10% calcium gluconate. Tetany unresponsive to the administration of calcium should suggest the possibility of hypomagnesemia.

Psychiatric symptoms: Psychiatric symptoms may be prominent in several endocrine disorders. Confusion, behavioural disturbances, somnolence or coma may be seen in hypoglycemia, diabetic coma, hypopituitarism,

hypothyroidism, Addison's disease, water intoxication, and hypercalcemia. Mental changes are also common in hyperthyroidism, Cushing's syndrome, and hypoparathyroidism. In many cases the higher functions return to normal when the endocrine disorder is controlled, but this need not be so in all cases.

Physical Examination

The total clinical effect produced by an endocrine disturbance is determined by the age of onset, severity of hormone dysfunction, duration of the disorder, compensatory mechanisms, and the behaviour of the target organs. Several other factors like generic behaviour, nutritional status, intercurrent illnesses, and therapy modify the expression of symptoms. Familial incidence is seen in disorders like diabetes mellitus, thyroid disorders, pure gonadal dysgenesis, Kallmann's syndrome, Laurence-Moon-Biedl syndrome and multiple endocrine adenomatosis.

Growth and development: Disorders of growth are common in many endocrine disorders.

Secondary sexual characters: Disorders of sexual development may take the form of sexual precocity, heterosexual signs (appearance of features of the opposite sex), delayed puberty, or regression of secondary sexual characters.

Anthropometry: In addition to height and weight, measurement of skeletal proportions is of great value in diagnosis. At birth the ratio of the upper segment to the lower segment is 1:7:1 with the pubic symphysis taken as the reference point. The two segments become equal by the age of 10 years and this proportion is maintained throughout. The arm span equals the height in adults. The infantile proportion is retained in conditions such as juvenile hypothyroidism and chondrodystrophies which interfere with growth in early age. In hypopituitarism and other causes of generalized short stature, the growth retardation is proportional and the ratio is maintained. The lower segment and arm span are disproportionately increased in eunuchoidism, because of delay in closure of the epiphyses.

Cardiovascular abnormalities: Various grades of hypertension may be present in pheochromocytoma, hyperaldosteronism and congenital adrenal hyperplasia. The hypertension may be paroxysmal as in the case of pheochromocytoma or persistent as in the others. Malignant hypertension occurring in young subjects should raise the possibility of an endocrine cause.

Orthostatic hypotension may be a prominent symptom in Addison's disease, hypopituitarism, and diabetic neuropathy. It may also occur less commonly in

pheochromocytoma. Cardiovascular manifestations may be prominent in thyrotoxicosis and myxedema.

The integument: The texture and pigmentation of the skin should be looked for. Black freckles and ‘café’ au lait’ (Fr. coffee with milk) spots are seen in gonadal dysgenesis, neurofibromatosis, and some types of sexual precocity. Hirsutism is common in virilizing conditions. Presence of acne is a sensitive index of excessive androgen activity.

Breasts: Careful examination of breasts for recent change in size, tenderness, pigmentation and galactorrhea is absolutely essential in all cases. Enlargement and hyperpigmentation of breasts occur in pregnancy, trophoblastic tumours, luteinising tumours, Cushing’s syndrome and estrogen therapy. Though the breasts are large in size in testicular feminization, the nipples and areola are immature. In Sheehan’s syndrome the areola may undergo depigmentation.

Musculoskeletal system: Several endocrine disorders give rise to characteristic abnormalities. Excessive muscle weakness, hypotonia and localised hypertrophy or atrophy are suggestive of diseases of the thyroid or adrenal cortex. In juvenile myxedema, hypertrophy of the calf muscle may be present in a few e.g. **Hoffmann’s syndrome**. **Adrenogenital syndrome** is characterized by hypertrophy of the muscles in children – (**Infant Hercules**). Myopathy is characteristic of thyrotoxicosis.

Periodic paralysis (episodes of paralysis mainly involving peripheral muscles lasting for few minutes to hours) may occur in thyrotoxicosis, hyperaldosteronism and others.

Ocular manifestations: Exophthalmos (abnormal protrusion of eyeball) and ophthalmoplegia may be present in thyrotoxicosis and pituitary tumours. Cataract occurring prematurely may point to diabetes mellitus or hypoparathyroidism. Visual field defects are common in space occupying lesions in the region of the pituitary and hypothalamus.

External genitalia: State of development of the external genitalia gives indication of the hormonal status in the early developmental period. Fusion of the labia and enlargement of the clitoris in female babies with or without formation of a penile urethra at birth, are indicative of excessive androgenic activity during early fetal development. Development of clitoromegaly is the result of androgen overactivity later in life. Pelvic examination is necessary for the assessment of the size of the uterus and ovaries and vaginal development. Examination of vaginal epithelium and cervical mucus gives evidence of activity of the ovarian hormones.

Small penis (less than 2.5 cm in length and flaccid) may be due to abnormalities of testosterone biosynthesis, organ unresponsiveness, gonadal dysgenesis, hypo-

TABLE 95.1

The time of appearance of the ossification centre and its fusion in normal subjects

Bone	Epiphyseal appearance	Fusion with diaphysis
Head of humerus	1st year	18-20th year
Medial epicondyle of humerus	4-6th year	18-20th year
Lower end of radius	End of 1st year	17-19th year
Lower end of ulna	5- 6th year	17-19th year
Head of femur	1st year	14-17th year
Lower end of femur	Before delivery	20th year
Patella	Before 2-6 year	Puberty
Lower end of tibia and fibula	1st year	17th year

thalamopituitary disorders or rarely defective development. Testicular size is objectively assessed by measurement. Normal adult testis measures 5cm in length and its volume is 15 to 25 mL. The testes are small and firm in Klinefelter’s syndrome whereas they are small and soft in acquired testicular atrophy.

Bone age: This is a common parameter used for assessing the maturity of the skeleton. Appearance of the centres of ossification and fusion of epiphyses occur regularly at definite periods during the growth of the individual. These are under hormonal control. Abnormalities in the growth of the skeleton provide evidence of endocrine dysfunction. Radiography of selected bones are routinely done for this purpose. In hypothyroidism occurring in early life, centres of ossification fail to appear. Cushing’s syndrome, hypopituitarism and hypogonadism lead to delay in epiphyseal fusion. The epiphyses appear and fuse prematurely in hyperthyroidism and sexual precocity (Table 95.1).

Laboratory Investigations

The function of any endocrine gland can be assessed by:

- 1. Quantitative estimation of its hormones and their metabolites.
- 2. Biochemical tests which reflect the metabolic abnormality, e.g. blood glucose in diabetes mellitus, serum calcium in parathyroid disorders.
- 3. Imaging procedures which reveal the morphology and function of the endocrine glands and other tissues, and
- 4. Assessment of the functional reserve of the glands by appropriate stimulation and suppression tests.

Estimation of Hormones and their Metabolites in Body Fluids

The levels of hormones in blood and body fluids are very low. Non-peptide hormones are present in body fluids in

microgram (10^{-6} g) concentration whereas peptide hormones are present only in the range of nanogram (10^{-9} g) or picograms (10^{-12} g) per unit volume. Several techniques are used for their estimation. These are:

- a. Bioassay,

b. Spectrophotometric and fluorimetric assay,

c. Radioimmunoassay (RIA),

d. Enzyme – linked immunosorbent assay (ELISA) and

e. Chemoluminiscent assay

Adrenal steroids like plasma cortisol and its metabolites – 17-ketosteroids, 17-ketogenic steroids and 17-hydroxysteroids are estimated by spectrophotometric analysis.

Radioimmunoassay (RIA) which has revolutionised the diagnosis and management of endocrine diseases is the most extensively used method for quantitation of hormones in clinical practice. By this method almost all hormones which exist even at picogram levels can be estimated. This method was devised by Berson and Yalow in 1959 and they were awarded the Nobel Prize in medicine in 1977.

Enzyme-linked immunosorbent assay (ELISA) is used instead of RIA in many cases. Though ELISA has some advantages over RIA, so far ELISA has not been able to achieve the type of exquisite sensitivity required for measuring picogram quantities of substances and, therefore, many hormones cannot be estimated by this technique.

Imaging of endocrine glands is done in several ways. Imaging techniques are employed when surgical or other methods of ablative therapy are contemplated.

Commonly used imaging procedures are as follows:

- a. Radiography – plain and contrast studies

b. Isotope scanning – dynamic* and static studies

c. Ultrasonography of neck, abdomen and pelvis.

d. Computerized tomography.(CT)

e. Magnetic resonance imaging (MRI)

f. Angiography to detect abnormal vascularity

* After the injection of the appropriate isotope, images of the organ are taken at one second or at shorter intervals (perfusion phase or vascular phase) and later, after minutes or hours (static phase). Isotope scans give structural and functional details.

The hormone secretion from these glands can also be estimated by selective catheterisation of their efferent veins.

Stimulation and suppression tests: These are useful to assess the functional reserve and autonomy of the different endocrine glands and integrity of their feedback control.

Acronyms commonly used in endocrinology	
ACTH	- Adrenocorticotrophic hormone
ADH	- Antidiuretic hormone
CRH	- Corticotropin releasing hormone
FSH	- Follicle stimulating hormone
GH	- Growth hormone
GHRH	- Growth hormone releasing hormone
GHRIH	- Growth hormone release inhibiting hormone
GnRH	- Gonadotropin releasing hormone
hCG	- Human chorionic gonadotropin
IGF-1	- Insulin-like growth factor-1
LH	- Leuteinising hormone
PIH	- Prolactin inhibiting hormone
PRH	- Prolactin releasing hormone
TRH	- Thyrotropin releasing hormone
TSH	- Thyroid stimulating hormone
T3	- Tri-iodothyronine
T4	- Tetra-iodothyronine

Types of Hormones and their Patterns of Secretion

Polypeptides	GHRH, GHRIH, TRH, ADH, Oxytocin, GH, IGF-1
Single chain peptide	CRH, ACTH, prolactin
Glycoproteins	LH, FSH, TSH, hCG
Steroids	Cortisol, estrogen and androgens
Amines	Dopamine
Iodinated tyrosine	T3, T4

Pattern of Secretion of Hormones

Continuous secretion	T3,T4
Intermittent pulsatile	LH, FSH, GH, prolactin
Circadian rhythm	
• Highest at early morning	Cortisol
• Highest at midnight	Melatonin
• Low at midnight	ACTH
Variable secretion rate	Stress-related hormones

Hypothalamus, Pituitary and their Disorders

Chapter Summary

Physiological Considerations	607
Pituitary Gland	607
Hypothalamic Hormones	608
Hypothalamic Disorders	609
Diseases of the Posterior Pituitary	609
Diabetes Insipidus	609
Vasopressin Excess	611
Anterior Pituitary and its Disorders	612
General Considerations	612
Pituitary Hyperfunction	615
Hyperprolactinemia	615
Gigantism and Acromegaly	617
Cushing's Disease	620
Hypopituitarism	620
Adult Panhypopituitarism	620
Childhood Hypopituitarism	622
Dwarfism	622
Empty Sella Syndrome	623

Physiological Considerations

The main seat of neuroendocrine coordination is the hypothalamus. The higher neural centres influence it through the monoaminergic pathways. Physical and chemical stimuli also influence the hypothalamus through the blood perfusing it. The supraoptic and paraventricular nuclei respond to these stimuli by the production of hormones vasopressin and oxytocin. These are bound to carrier proteins – neurophysins – and in this form they travel down the pituitary stalk to be stored in the posterior pituitary. The releasing hormones which help to release the tropic hormones of the anterior pituitary are secreted by the hypothalamus. These pass down the hypothalamo-hypophyseal portal circulation to exert their action on the anterior pituitary.

The pituitary gland weighs 0.5 to 1.g. (usually 0.6g)
It consists of two portions. (i) adenohypophysis which is

composed of columns of epithelial cells derived from the primordial foregut and (ii) neurohypophysis which is formed from a diverticulum arising from the floor of the third ventricle. The neurohypophysis (posterior pituitary) stores the secretions of the supraoptic and paraventricular nuclei of the hypothalamus.

Blood supply to the hypothalamus and pituitary is derived from the superior and inferior hypophyseal arteries which are branches of the internal carotid artery. The radicles of these vessels lie in close relation to the axons of the peptidergic neurons of the hypothalamus which transfer their secretions into the blood that perfuse them. From these radicles the hypothalamo-hypophyseal portal system arises and it terminates around the epithelial cells of the anterior pituitary. The releasing and inhibiting hormones secreted by the hypothalamus reach the pituitary through this system and exert their control. Blood returning from the pituitary reaches the hypothalamus and the pituitary secretions are able to influence the hypothalamus through this pathway.

Pituitary Gland

Histology: This consists of three types of cells- acidophils, basophils and chromophobes. The acidophil cells (eosinophilic cells) which form about 60-75% of the total number of epithelial cells are situated in the posterolateral aspect of the gland. They secrete growth hormone (GH) and prolactin (PRL). The basophils secrete follicle stimulating hormone (FSH), luteinising hormone (LH), thyroid stimulating hormone (TSH), adrenocorticotrophic hormone (ACTH) and melanocyte stimulating hormone (MSH). The chromophobe cells are either precursors of secretory cells or are cells which are depleted of their secretions. Based on electron microscopic findings the cells of the pituitary can be classified as somatotrophs, lactotrophs, thyrotrophs, gonadotrophs, corticotrophs, and melanotrophs.

Lactotrophs form 15-20% of the total number of cells and they are distributed throughout the gland. Their number

increases during pregnancy. Somatotrophs make up about 50% of the cells of the anterior pituitary. Corticotrophs form less than 10% of cells and are situated anteromedially. Gonadotrophs which form 10% of cells are mainly distributed in the lateral wings, and thyrotrophs are found mainly in the inferomedial and superior parts of the gland.

Hormones of the Pituitary

Type of cells	Percentage	Secretion
Acidophils (eosinophils)	60-75%	
Lactotrophs	15-20%	Prolactin
Somatotrophs	50%	GH
Basophils	25%	
Corticotrophs	10%	ACTH
Gonadotrophs	10%	FH, LH
Thyrotrophs	5%	TSH
Melanotrophs	—	MSH

Hypothalamic Hormones

Growth hormone releasing hormone (GHRH) stimulates the release of growth hormone from the anterior pituitary.

Corticotropin releasing hormone (CRH) and **vasopressin** stimulate the release of ACTH from the pituitary

Thyrotropin releasing hormone (TRH) is a tripeptide found in the median eminence of the hypothalamus and in several other parts of the nervous system. This stimulates the pituitary to enhance the secretion of TSH

and prolactin (PRL) in normal individuals. Only TRH modulates the release of prolactin.

Gonadotropin releasing hormone (GnRH) is a decapeptide which releases both follicle stimulating hormone (FSH) and luteinising hormone (LH) from the adenohypophysis. This is also referred to as luteinising hormone releasing hormone (LHRH). Sex steroids exert a negative feedback on the hypothalamus and pituitary and influence the secretion of FSH and LH. However, estrogens from the developing graafian follicles exert a positive feedback on the hypothalamus and pituitary and thereby enhance the secretion of GnRH and gonadotropins.

Growth hormone release inhibiting hormone (GHRH) or Somatostatin (SS) is a polypeptide hormone with 14 amino acids. In addition to the hypothalamus, several other cells in other locations like stomach, duodenum, upper jejunum and islets of Langerhans are found to contain SS. The hormone exerts a general inhibiting effect on the surrounding endocrine and exocrine tissues. Somatostatin has a short biological life and hence it is unlikely to exert its effect on distant tissues. The growth hormone response brought about by stimuli like exercise, hypoglycemia, arginine and sleep is inhibited by SS. It also reduces the thyroid stimulating hormone (TSH) response to injected TRH. In the stomach and intestine, the production of gastrin, gastric inhibitory polypeptide, hydrochloric acid and vasoactive intestinal polypeptide is diminished. The secretion of insulin and glucagon from islet cells is reduced. The exocrine pancreatic secretions like bicarbonate and enzymes are inhibited (Table 96.1).

Hypothalamic hormones, their action on the pituitary and the peripheral hormones liberated		
Hypothalamic hormones	Action on pituitary	Peripheral hormones released (or) Peripheral effect
Thyrotropin releasing hormone (TRH) (1)	Thyroid stimulating hormone (TSH) (1)	T3,T4 and prolactin (1)
Gonadotropin releasing hormone (GnRH), (LHRH) (1)	Releases luteinising hormone (LH), and follicle stimulating hormone (FSH) (1)	Estrogens and androgenic steroids (2)
Growth hormone releasing hormone (GHRH)	Growth hormone (1) secreted	Somatomedin (IGH-1) (1)
Growth hormone releasing inhibiting hormone (GHRH-somatostatin) (1)	G H inhibited TSH response to TRH reduced	
Prolactin inhibiting factor (PIF) (3)	Prolactin (PRL) (1) inhibited	Prolactin level kept at normal levels
Corticotropin releasing hormone (CRH) (1)	Adrenocorticotrophic hormone (ACTH) (1)	Cortisol mainly (2)
Vasopressin (antidiuretic hormone ADH) (1)	-	Action on the renal tubules
Oxytocin (1)	-	Uterine contraction
Note: (1) peptide (2) steroids (3) amine		

Antidiuretic hormone (ADH) or Arginine vasopressin:

Arginine vasopressin is the natural ADH in humans, whereas in the pig it is lysine vasopressin. This is stored in the posterior pituitary. The term 'vasopressin' denotes its ability to raise the blood pressure of experimental animals and humans in pharmacological doses. The synthesis and release of vasopressin are regulated by osmotic and non-osmotic stimuli. During periods of fluid deprivation the release of ADH increases 3-5 times the basal levels and this helps to conserve fluid by the kidneys. Half-life of ADH in circulation is 7-20 minutes. Under basal conditions, osmotic mechanisms predominate over non-osmotic mechanisms. Changes in serum osmolality by 1 to 2% lead to alteration in the volume of the osmoreceptors in the anterior hypothalamus and this triggers the supraoptic nucleus. However, under conditions of stress, volume receptors in the atrium and pulmonary veins are also activated. When there is a fall in blood pressure, receptors in the carotid and aortic sinuses are stimulated and they augment the secretion of vasopressin. Other factors which stimulate vasopressin secretion are psychological and physical stresses. Once triggered, the non-osmotic mechanisms are capable of stimulating the synthesis and secretion of vasopressin.

Vasopressin exerts its main effect on the distal convoluted tubules and collecting tubules of the kidney and increases the reabsorption of water. The hormone activates the adenylate cyclase system in the cells lining the tubules and makes them more permeable to water by increasing the size and number of pores. In addition, vasopressin stimulates the smooth muscles of the arterioles in the mesentery, coronary circulation and skin. Intestinal smooth muscle is also stimulated to activity. The main source of vasopressin for therapeutic use is synthetic and the preparation is I-deamino-8 arginine vasopressin (DDAVP). It is used mainly for the treatment of diabetes insipidus. In other conditions like hemophilia, DDAVP is finding increasing use. In conditions of intractable hypotension vasopressin is used with benefit. Vasopressin is also employed to reduce portal hypertension and esophageal variceal bleeding.

Oxytocin: This hormone enhances uterine contraction during labour and also in the postpartum period. This helps in delivery and postpartum hemostasis. Oxytocin also enhances the release of milk from the breast during suckling.

The production of oxytocin is controlled mainly by stimuli arising from the breast during suckling. The impulses reach the hypothalamus through the spinal cord and stimulate the production of oxytocin. Distension of the female genital tract stimulates oxytocin production whereas stress and emotional disturbances inhibit it. Oxytocin is used mainly to induce labour and stimulate uterine contraction after delivery. Estrogens also stimulate the release of oxytocin.

Hypothalamic Disorders

Hypothalamic disorders result from destruction of the neurons which secrete the hormones or from alterations in the afferent impulses from the higher neural centres into the hypothalamus.

Reduction of hypothalamic neurons may either be due to lack of development as in **Kallmann's syndrome** or destruction by disease processes such as encephalitis, meningitis, tumours or ischemia. Hypothalamic disturbances may lead to deficiency of the releasing hormones and consequent hypothyroidism, hypogonadism, hypoadrenocorticism and dwarfism. In general, hypothalamic lesions induce only partial failure of the target glands unlike lesions of the pituitary. Hypothalamus exerts a tonic inhibitory control on prolactin secretion, hypothalamic lesions result in uncontrolled production of prolactin. This may lead to galactorrhea, amenorrhea, and hypogonadism.

Hypothalamic function is regulated by feedback impulses from the target glands and also by impulses from higher neural centres. Other stimuli arising from the osmoreceptors and glucoreceptors situated in hypothalamus and alteration in the physical and chemical characteristics of blood influence hypothalamic activity. Functions such as temperature regulation, eating, satiety, and thirst are controlled by regulatory centres situated in the hypothalamus. Important disorders of the hypothalamus are psychogenic **amenorrhea, anorexia nervosa and deprivation dwarfism** in children. Impairment of inhibitory inputs from other areas of the brain may lead to precocious puberty and excessive secretion of ADH (**the syndrome of inappropriate secretion of ADH-SIADH**) (Fig. 96.1).

Diseases of the Posterior Pituitary

DIABETES INSIPIDUS (CRANIAL DIABETES INSIPIDUS)

Normally, antidiuretic hormone (ADH) is secreted in response to physiological stimuli such as osmolality, hypovolemia, hypotension, and psychological stress. This hormone (ADH) plays a major role in maintaining serum osmolality within a narrow range. Normal blood level of arginine vasopressin is 1-3 IU/mL. Failure of secretion of ADH from the supraoptic nucleus leads to the development of central diabetes insipidus. The clinical abnormality becomes evident only when about 99% of the neurons in this region are lost. Several conditions may lead to diabetes insipidus.

Clinical Features

Diabetes insipidus presents with gross polyuria, thirst and polydipsia. The urine volume may vary from 2.5 to 10 litres or more in 24 h and the osmolality may fall below

Fig. 96.1: Anorexia nervosa. Note emaciation, breast is developed pubic hair is present, refusal to eat

200 mOsm/kg. Majority of those patients have normal thirst mechanisms and they make up the fluid loss by taking adequate quantity of water and salt and thus prevent the development of dehydration and hyponatremia. In this condition plasma osmolality is raised whereas the urinary osmolality is low. When the free intake of water and salt is diminished as in coma or due to other causes, severe dehydration and hypovolemia develop. In moderately

severe cases the osmolality of plasma ranges from 400 to 600 mOsm m/kg. In well compensated patients, apart from the history and the gross polyuria with dilute urine (specific gravity around 1004), no other abnormality may be evident. In those subjects in whom the disease is secondary to other disease processes, the primary abnormality may be evident. In idiopathic cases MRI may reveal evidence of neurohypophysitis.

11

Causes of Pituitary Diabetes Insipidus

Pituitary diabetes insipidus

Head trauma (closed and penetrating)	Vascular
Neoplasms	Sheehan's syndrome
Primary	Aneurysm (internal carotid)
Craniopharyngioma	Aortocoronary bypass
Pituitary-adenoma (suprasellar)	Hypoxic encephalopathy
Dysgerminoma	Pregnancy
Meningioma	Idiopathic
Metastatic deposits (lung, breast)	Congenital malformations
hematological (lymphoma, leukemia)	Septo-optic dysplasia
Granulomas	Midline craniofacial defects
Neurosarcoidosis	Holoprosencephaly
Histiocytosis	Hypogenesis, ectopia of pituitary
Xanthoma disseminatum	Genetic causes
Infections	Autosomal dominant (AVP-neurophysin gene)
Chronic meningitis	Autosomal recessive (AVP-neurophysin gene)
Viral encephalitis	Autosomal recessive-Wolfram-(4p – WFS 1 gene) disease
Toxoplasmosis	X-linked recessive (Xq28)
Inflammatory	Deletion chromosome 7q
Lymphocytic Infundibulo-neurohypophysitis	
Wegener's granulomatosis	
Lupus erythematosus	
Scleroderma	
Chemical toxins	
Tetrodotoxin	
Snake venom	

Diagnosis

Diabetes insipidus should be diagnosed by the history and the presence of polyuria with fall of specific gravity of urine. The urine volume does not fall and the specific gravity does not rise with fluid deprivation. Since fluid restriction may be hazardous in these subjects, it has to be done only under close supervision. Other conditions producing polyuria with low specific gravity of the urine such as nephrogenic diabetes insipidus and psychogenic polydipsia have to be differentiated.

Differential Diagnosis

Nephrogenic diabetes insipidus: The renal tubules are refractory to the action of normal levels of circulating ADH. This may be congenital as in primary nephrogenic diabetes insipidus or secondary to diseases such as chronic renal failure, diabetes mellitus, hypercalcemia, hypokalemia and sickle cell anemia or due to drugs such as lithium and demeclocycline.

Primary polydipsia (psychogenic polydipsia): Compulsory water drinking is a part of complex psychiatric disturbances in which the patient drinks large amounts of water. The disorder may show remission and exacerbation.

Investigations

Cranial or central diabetes insipidus can be distinguished from nephrogenic diabetes insipidus and primary polydipsia by simple laboratory tests.

1. **Measurement of 24 hour urine volume:** If the urine volume is less than 2 litres, diabetes insipidus is unlikely. It is to be remembered that mild cases may present with lower urine volumes, but in times of stress such as diarrhea or excessive sweating, hypovolemia, shock and hyponatremia ensue early.
2. **If the osmolality of early morning urine** exceeds 800 mOsm/kg, it almost rules out diabetes insipidus.
3. **Water deprivation test and vasopressin administration:** Fluid deprivation for 8 hours is done under medical supervision, only dry food is given. Since this is hazardous, it should not be continued if the body weight falls by 5% or 2 kg. Urine osmolality is measured hourly till steady values are obtained in three consecutive samples. Then 5 units of aqueous vasopressin or desmopressin 1 µg is given parentally. Osmolality of plasma and urine is determined hourly for further three hours. In central diabetes insipidus the rise in urine osmolality after vasopressin exceeds 9% whereas in patients with nephrogenic diabetes insipidus the rise is less than 9%. With desmopressin 1µg I.M. or 20 µg intranasal, the increase in urine osmolality exceeds 50% whereas in nephrogenic

diabetes insipidus it is below 45%. Patients with psychogenic polydipsia require longer periods of fluid deprivation for obtaining steady urine osmolality, since they tend to be fluid overloaded. Fluid deprivation results in rise of urine osmolality in this condition.

X-ray of the skull may reveal conditions such as histiocytosis, secondary deposits or hematological malignancies which cause destructive lesions of skull bones. CT or MRI scan will be more specific in delineating the lesion.

The prognosis of diabetes insipidus depends upon the primary cause. As such, diabetes insipidus does not shorten life expectancy, if it is identified and promptly managed.

Treatment

Cases with moderate or severe disease require specific therapy.

Vasopressin analogues: At present the synthetic analogue DDAVP (desmopressin) arginine vasopressin is used. It is given as nasal spray or instillation. It has duration of action for 12 to 24 hours and many cases require only one or two doses daily. Moreover, DDAVP is devoid of the pressor activity. It is absorbed even in the presence of nasal congestion. Parenteral preparations are available for use in more severe cases or in emergencies. Dose of DDAVP is 5-10 µg as nasal installation twice a day.

Several non-hormonal substances which act on the nephrons by different mechanisms effectively reduce the urine volume in pituitary diabetes insipidus. These are listed below:

- a. **Chlorpropamide** (250 to 500 mg/day), clofibrate and carbamazepine bring about reduction in urine volume in mild and moderate cases.
- b. **Thiazide diuretics** are effective in bringing down urine volume.

These drugs, being cheaper and more easily available, are generally used except in rare occasions when hormonal replacement becomes inevitable.

VASOPRESSIN EXCESS

Syn: Syndrome of inappropriate ADH secretion (SIADH)

Normally secretion of ADH depends upon plasma osmolality and blood volume. When this mechanism fails, or ectopic sources secrete ADH, the *syndrome of inappropriate ADH* secretion results. This syndrome is not rare in clinical practice. Adults and children may be affected. This is an important cause of hyponatremia in many chronically ill-patients.

Causes

- **TUMOURS:** carcinoma lung, carcinoid, leukemia, lymphoma and thymoma
- **DRUGS:** vasopressin, chlorpropamide, carbamazepine, clofibrate, vincristine, cyclophosphamide, thiazides, nicotine and demeclocycline
- **PULMONARY DISORDERS:** pneumonia, pleural effusion and tuberculosis
- **NEUROLOGICAL DISORDERS:** meningitis, encephalitis, Guillain-Barré Syndrome
- **METABOLIC** Acute intermittent porphyria
- **ENDOCRINE DISORDERS:** Addison's disease
- AIDS and AIDS related complex.
- **IDIOPATHIC**

Clinical Features

The symptomatology is vague and it is likely to be missed unless the condition is strongly suspected. There is dilutional hyponatremia. When the level of serum sodium falls to 120-125 mmol/L, somnolence, anorexia, confusion, and depression may be observed. These are manifestations of cerebral edema when the serum sodium suddenly falls to 125 mmol/L, or less. When the sodium level falls below 120 mmol/L, coma, convulsions and focal neurological deficits may develop. Severe hyponatremia with serum sodium below 110 mmol/L is usually fatal if undetected, due to brainstem herniation.

Diagnosis is by estimating serum sodium level, which is below 125 mmol/L with high urine sodium level above 20 mmol/L. Plasma osmolality must be less than 270 mOsm/kg with normal renal, adrenal and thyroid functions. Urine osmolality is more than 100 mOsm/kg.

Treatment

The syndrome of inappropriate secretion of ADH is only a manifestation of other serious underlying diseases and, therefore, the problem should receive total attention. Mild hyponatremia responds to fluid restriction of 0.5 to 1L/day in addition to the previous days' urine output. Administration of demethylchlortetracycline (demeclocycline) which produces nephrogenic diabetes insipidus is effective in some cases. The dose is 600-1200 mg/day. In severe cases presenting with convulsions, coma or hemiparesis, urgent infusion of hypertonic saline (3-5%) is indicated. Too rapid a correction results in central pontine myelinolysis. Intravenous saline containing 500 mmol/L is infused slowly till the plasma sodium rises above 125 mmol/L, thereafter oral supplements are continued. 100 mL of 3% saline contains 50 mmol of sodium chloride.

Tolvaptan is a selective non-peptide oral vasopressin V2-receptor antagonist which promotes aquaresis (excretion of electrolyte-free water). This drug is useful in the management of hyponatremia (Na^+ level < 135 mmol/L)

which is a predictor of death in chronic heart failure and cirrhosis liver. The excretion of water is not associated with electrolyte excretion. The dose is 15 mg daily orally to start with and increased up to 60 mg/day. The effect wanes off, if tolvaptan is stopped. Adverse side effects include increased thirst, dryness of mouth and polyuria. Tolvaptan is indicated in SIADH and severe fluid overload states such as chronic heart failure, cirrhosis liver and others.

Anterior Pituitary and its Disorders

GENERAL CONSIDERATIONS

Hormones of the anterior pituitary are polypeptides with one or more chains. They can be grouped into three classes.

1. **Corticotropin group:**
 - a. Corticotropin (Adrenocorticotrophic hormone ACTH)
 - b. Melanocyte stimulating hormone (MSH), lipotropins (LPH)

Corticotropin and lipotropins form the major bulk, MSH is present only in small quantities. Endogenous opioid peptides (endorphins) are derived from the lipotropins. The adenohypophysis can maintain its functional capacity even if 50% of its tissue is lost, but beyond this its function suffers.
2. **Glycoprotein hormones:**
 - a. Follicle stimulating hormone (FSH)
 - b. Luteinizing hormone (LH or Interstitial cell stimulating hormone)
 - c. Thyroid stimulating hormone (TSH)
3. **Somatotropin – mammotropin group:**
 - a. Growth hormone (GH)
 - b. Prolactin (PRL)

Adrenocorticotropin (ACTH)

ACTH is a single chain polypeptide with 39 amino acids. The hormone can be estimated by radioimmunoassay. Blood levels show considerable variation, values being highest early in the morning (40-80 pg/mL). ACTH release is facilitated by the corticotropin releasing factors of the hypothalamus and inhibited by increasing levels of circulating plasma cortisol. ACTH production goes on independent of feedback inhibition and diurnal variation during periods of stress. It exerts action on the adrenal cortex and extra-adrenal tissues. ACTH promotes the synthesis of glucocorticoids and androgens by the adrenal cortex. Aldosterone secretion is only marginally affected.

Other effects of ACTH include lipolysis and increase in pigmentation brought about by stimulation of the melanocytes. Normally these extra-adrenal effects of ACTH are not pronounced, but when ACTH production

is increased as in Addison's disease and Nelson's syndrome, pigmentation becomes prominent. The role played by lipotropins in man is not understood.

Glycoprotein Hormones

The pituitary glycoprotein hormones are *thyroid stimulating hormone* (TSH), *follicle stimulating hormone* (FSH), and *luteinizing hormone* (LH). The placental glycoprotein hormone *human chorionic gonadotropin* (HCG) resembles LH in function. All these hormones act through the adenylate cyclase mechanism.

Thyroid stimulating hormone (TSH) (Syn: Thyrotropin) The TSH acts mainly on the thyroid to increase its vascularity and size. It enhances all aspects of thyroid function such as iodine uptake, synthesis of thyroglobulin, and release of thyroxine. TSH secretion is increased by TRH and inhibited by increasing levels of circulating thyroxine and tri-iodothyronine. The inhibitory effect of circulating thyroid hormones on TSH is stronger than the stimulatory effect of TRH on the pituitary. Plasma TSH level is about 0 to 5 μ U/mL. Basal TSH levels are considerably increased and TSH response to TRH is amplified in primary hypothyroidism. The TSH Levels are very low and often undetectable in primary thyrotoxicosis. Moreover, the TSH response to TRH is also negligible.

Gonadotropins

GnRH produced by the hypothalamus influences the synthesis and secretion of LH and FSH. LH is stimulated to a greater degree than FSH. Secretion of LH and FSH is inhibited by rising levels of estrogens, progesterone and testosterone in blood, except during the preovulatory phase. During the preovulatory phase a high level of estrogens produces a positive feedback on the hypothalamus and pituitary, and this result in excessive production of LH.

Gonadotropins increase the synthesis and secretion of sex steroids and promote gametogenesis. The Pituitary produces FSH and LH, and chorionic gonadotropins (HCG) are produced by the placenta. FSH and LH secretion occurs in spurts in females. FSH facilitates the maturation of graafian follicles by acting on the granulosa cells of the ovary. LH also acts on the granulosa cells to enhance estrogen production. Acting on the interstitial cells of the testes, it increases the secretion of testosterone. Spermatogenesis is stimulated. Increase in LH levels in the mid-cycle phase leads to rupture of the mature follicle and liberation of ovum. In addition, it leads to luteinization of the ruptured follicle. LH is responsible for continued development of the corpus luteum till the placenta takes over this function during pregnancy. LH also maintains the steroidogenic function of the placenta.

Somato-mammotropin Group of Hormones

Growth hormone (GH): GH is a single polypeptide with 191 amino acids. The quantity of GH exceeds that of the other pituitary hormones. Human pituitary contains 6-10 mg of extractable GH. Normal daytime circulating level of growth hormone is $< 0.5 \mu\text{g/L}$.

Post-mortem pituitary was a major source of this hormone used for diagnostic and therapeutic purposes. This has led to the spread of disease such as slow virus infections of the CNS.

Fasting level of GH in the plasma is below 4 ng/mL. Secretion occurs in bursts lasting 1-2 h. Maximal secretion occurs during the stages III and IV of NREM sleep. Factors such as exercise, hypoglycemia and rise in amino acid levels enhance secretion. Secretion of GH by the pituitary is increased by its releasing hormone (GRF) and inhibited by somatostatin secreted by hypothalamus.

GH promotes linear growth in prepubertal children by its anabolic activity and effect in cartilage growth. Another metabolic effect includes lipolysis which leads to the increase of serum free fatty acids, which in turn inhibit glucose uptake by cells. This partly accounts for the anti-insulin activity of GH.

GH acts on the liver and other tissues to stimulate the production of *insulin-like growth factor (IGF-1)*, also known as *Somatomedin-C* which is responsible for growth promoting activity. Serum level of IGF-1 is an indicator of overall GH secretion. Whereas GH secretion occurs in spurts, IGF-1 level does not show marked diurnal variation.

Prolactin (PRL): Prolactin resembles GH closely. Prolactin level can be estimated by radioimmunoassay. This hormone is also secreted in bursts lasting for a few minutes to hours, maximal secretion occurring during sleep. Hypothalamus exerts an inhibitory effect on PRL secretion through *prolactin inhibitory factor (PIF)*. It is most likely that prolactin-releasing factors also exist. Thyrotropin releasing hormone also stimulates release of prolactin. Neuroendocrine reflexes caused by suckling and stimulation of breast in females also help to release PRL. Prolactin exerts its main action on the breast which is primed by the action of estrogens, progesterone, GH, and cortisol. Prolactin stimulates the synthesis of milk proteins. The physiological role of PRL in male is not clearly known.

Basal PRL level is about 10-20 ng/mL in men and non-pregnant women. Towards the end of pregnancy, levels as high as 200 ng/mL are observed. During puerperium, values fall to non-pregnant levels even though lactation is continued. Prolactin is released during suckling and this prepares the breast for the next feeding.

Insulin like Growth Factors (IGFs) (Somatomedin-C)

IGFs are substances which act as intermediaries to exert the action of other hormones like growth hormone and insulin. IGF participates in the growth and functions of almost all organs in the body. The three peptide hormones or growth factors namely insulin, IGF-1 and IGF-2 have approximately 50% of the amino acids in common. Interaction of growth hormone with its hepatic cell receptors stimulates the expression of IGF-1 gene and release of IGF-1. Levels of IGF-1 in the liver and serum inhibit further growth hormone release. The mechanisms of regulation of IGF-2 are not known.

Whereas insulin which is secreted by the beta cells of the islets of Langerhans as a prohormone initially, gets cleaved at the C-peptide, the IGFs which are synthesised primarily in the liver retain the C-peptide moiety. Insulin present in pico molar concentrations in plasma has a half-life of minutes, whereas IGFs circulate in nanomolar concentrations bound to IGF binding proteins secreted by the liver. This binding limits the availability of IGFs to the target cells. They act in an autocrine or paracrine manner.

Physiological Role and Mechanism of Action

Insulin acts primarily on the liver, muscles and adipose tissue. IGF take part in the metabolism of all tissue cells. Both the IGFs are important for embryonic development. After birth IGF-1 seems to have a predominant role in regulating growth. The exact function of IGF-2 is not known. IGFs bind specifically to IGF receptors which are distinct from insulin receptors. Once the insulin receptor or IGF receptor is activated, similar metabolic processes are evoked within the large cells. Insulin regulates metabolic functions whereas IGF-1 regulates growth and differentiation in postnatal life. Mechanisms of action of insulin and IGF-1 differ. Liver and fat express both insulin and IGF-1 receptors. Insulin controls hepatic glucose production and lipolysis by signalling exclusively through insulin receptors. So also insulin stimulated uptake of glucose by cells is solely mediated by insulin receptors.

IGF-1 mediates many, if not most of the metabolic actions of growth hormone. It stimulates bone formation, protein synthesis, glucose uptake in muscle, neuronal survival and myelin synthesis. It also reverses negative balance during starvation and inhibits protein degradation in muscles.

Locally produced IGFs have important actions in several organs. Growth hormone, parathyroid hormones and sex steroids regulate the production of IGFs in bone, whereas sex steroids are the main regulators of IGFs in the reproductive system. The exact role of the locally produced IGFs has not been fully elucidated.

Pathological conditions associated with abnormalities of IGF-1 include **Laron's dwarfism**, Type 2 **diabetes mellitus**, Type 1 **diabetes mellitus**, insulin resistance

states and others. IGF-1 is secreted by some tumours whose growth rate is modified by this hormone.

IGF-1 in Therapy

1. **Dwarfism**

Laron's dwarfism is a growth hormone deficiency syndrome in which insensitiveness to growth hormone exists as a result of unresponsiveness of the receptors. In these subjects IGF-1. 150 mcg/kg body weight per day given S.C. increases height velocity by three times that of normals i.e. 10.8 cm vs. 3 cm/year.

2. **Insulin resistant states**

Type 2 DM: IGF-1 has been proposed as therapy for severe insulin resistance states since its actions resemble those of insulin and may therefore bypass the defects that block the action of insulin. In doses of 100 mcg/kg body weight given subcutaneously, it decreases serum insulin levels by 60-80% and improves glucose utilisation both in diabetes mellitus and impaired glucose tolerance. In Type 2 DM, the resistance is overcome.

In Type 1 DM: IGFs exert their action by:

- Decreasing the secretion of GH.
- Increasing the sensitivity to insulin and
- Decreasing insulin requirements.

3. **Osteoporosis**

IGF-1 which has anabolic activity has been used as an adjunct in the management of osteoporosis.

4. **Regulation of growth of baby after birth** by mediating the metabolic effects of GH.

- Stimulates bone formation
- Protein synthesis
- Glucose uptake in muscle
- Myelin synthesis

Side Effects of IGF-1

Intravenous injection may cause anaphylaxis and cardiovascular problems including asystole and hypertension which are secondary to hypophosphatemia. Multiple subcutaneous doses given for more than 10 days may give rise to temporomandibular pain, facial and hand edema, weight gain, dyspnea, tachycardia, raised intracranial tension, gynecomastia and Bell's palsy. All of these regress on withdrawal of therapy.

Investigations in Hypothalamo-pituitary Disorders

These are designed to detect the morphological and functional abnormalities. Tumours may present as space occupying lesions with pressure effects on neighbouring neural structures. Endocrine disturbances resulting from increased or decreased secretion of hormones are also seen commonly, but these may not be constant. Some tumours

secrete excess of hormones while others compress normal tissue and suppress its function. The investigations may be grouped under three heads – neurological, imaging and hormonal studies (Table 96.2).

1. Neurological investigations:

Perimetry: Pressure of tumours in the region of the pituitary causes compression of the optic chiasma and leads to defects in the visual field. These can be documented by perimeter.

Visual Evoked potential studies will be of further help to record involvement of the optic nerve and its pathway.

2. Imaging studies:

- Lateral view skiagrams of the skull may show enlargement of sella, double flooring, destruction of clinoid processes or suprasellar calcification. More detailed information of this area may be obtained by cone views of the pituitary fossa.
- CT scanning coupled with contrast studies: These studies give definite information in almost all cases.
- Isotope scanning procedures help to reveal regional vascularity and focal lesions.
- MRI with gadolinium contrast is superior to CT to detect smaller lesions especially in the posterior fossa.

3. Hormonal studies:

- Radioimmunoassay: Anterior pituitary hormones and secretion of its target glands can be measured precisely by radio immunoassay.
- Feedback control: Integrity of hypothalamo-hypophyseal system can be assessed by tests involving suppression or stimulation tests.
- Indirect indices of hormonal disorders: When the measurement of hormones in blood is not practical, e.g. ADH, the functions of the target organs are studied. For example in diabetes insipidus, studies of concentrating function of the kidney give valuable information.

Diseases Affecting the Pituitary

PITUITARY HYPERFUNCTION

Excessive activity of pituitary hormones may result from several causes. These are:

- Tumours of the pituitary:** Tumours can arise from the different cellular constituents of the pituitary. Pituitary tumours may be isolated or they may form part of multiple endocrine adenomatosis in which the parathyroid and pancreatic islets may also show tumours.
- Defective regulatory control** by the hypothalamus: Diseases of the hypothalamus may result in increased secretion of the release hormones or decreased

secretion of inhibitory hormones acting on the pituitary.

- Ectopic secretion of pituitary hormones:** Hormones of the pituitary or their analogues may be secreted by malignant neoplasms as a paraneoplastic phenomenon, e.g. chorionic gonadotropin and luteinising hormone may be secreted by hepatoblastoma, and PRL, GH and ACTH may be produced by carcinoma of the bronchus.

Well defined clinical syndromes are common and can occur due to excess of PRL, GH and ACTH. Thyroid stimulating hormone (TSH), FSH and LH are less commonly involved and they may not produce typical clinical syndromes at times.

Hyperprolactinemia

Prolactin (PRL) excess is the most common disorder resulting from over activity of the pituitary. About one-third of women with long-standing menstrual disorders show excessive PRL activity. Hyperprolactinemia is less common in males. Prolactin is released sparingly into circulation, because its secretion is under inhibition by a hypothalamic prolactin inhibitory factor.

Causes

- Prolactinomas arising from the pituitary – the most common pituitary tumour.
- Several lesions of the thoracic wall and conditions which stimulate the breasts lead to over secretion of PRL.
- Tumours and inflammatory lesions of the hypothalamus may result in excessive liberation of PRL by the pituitary. In empty sella syndrome the pituitary stalk is compressed due to cisternal herniation into the pituitary fossa and the inhibitory factor for prolactin secretion falls.
- Several drugs such as chlorpromazine, oral contraceptives, reserpine, haloperidol, and digoxin may lead to the release of excess amounts of prolactin.
- Increased amounts of PRL are seen in other endocrine disorders such as hypothyroidism. Pregnancy may be associated with PRL overactivity.

Clinical Features

About 50% of patients with hyperprolactinemia develop galactorrhea and menstrual irregularities. Hirsutism may develop. Women show an ovulation and infertility.

Signs of local pressure on the neural structures such as the optic chiasma, optic tract and third ventricle lead to focal neurological defects such as visual field defects, obstructive hydrocephalus and others. Generalized increase in intracranial tension gives rise to headache and papilledema. Prolactin suppresses the release of

TABLE 96.2

Tests of pituitary function			
Hormone to be estimated	Test	Blood samples	Interpretation
Growth hormone	Insulin tolerance test: Regular insulin (0.05-0.15 u/Kg IV)	-30, 0, 30, 60 min for glucose and GH	Glucose < 40 mg/dL; GH should be >3 mcg/L
	GHRH test: 1 ug/Kg IV	0, 15, 30, 45, 60, 120 min for GH	Normal response is GH>3 mcg/L
	L-Arginine test:30 g IV over 30 min	0, 30, 60, 120 min for GH	Normal response is GH > 3 mcg/L
	L-dopa test: 500 mg PO	0, 20, and 60 min for TSH and PRL	Normal prolactin is >2 mcg/L and
Prolactin	TRH test: 200-500 mcg IV		Increase > 200% of baseline
ACTH	Insulin tolerance test: Regular insulin (0.05-U/Kg IV)	-30, 0, 30, 60, 90 min for glucose and cortisol	Glucose <40 mg/dL Cortisol should increase by > 7 mcg/L or to > 20 mcg/dL
	CRH test: 1 ug/kg bovine CRH IV at 0800 h	0, 15, 30, 60, 90, 120 min for ACTH and cortisol	Basal ACTH increase 2-to 4-fold and peaks at 20-100 pg/mL Cortisol levels > 20-25 mcg/dL
	Metyrapone test: Metyrapone (30 mg/kg) at midnight	Plasma 11-deoxycortisol and cortisol at 8 AM ACTH can also be measured	Plasma cortisol should be <4 mcg/dL to ensure an adequate response Normal response is 11-deoxycortisol >7.5 mcg/dL or ACTH > 75 pg/mL
	Standard ACTH stimulation test: ACTH 1-24 (Cosyntropin) 0.25 mg IM or IV	0, 30, 60 min for cortisol and aldosterone	Normal response is cortisol > 21 mcg/dL and aldosterone response of >4 ng/dL above baseline
	Low-dose ACTH Test: ACTH 1-24 (Cosyntropin) 1, mcg IV or 3-day ACTH stimulation test consisting of 0.25 mg ACTH 1-24 given IV over 8 h each day	0, 30, 60 min for cortisol 3rd day	Cortisol should be > 21 mcg/dL
Thyroid function test (TFT)	Basal thyroid function tests: T ₄ , T ₃ , TSH, free T ₃ , free T ₄	Basal tests	
	TRH test : 200-500 mcg IV	0, 20, 60 min for TSH and PRL	TSH should increase by >5 mU/L unless thyroid hormone levels are increased
LS, FSH	LH, FSH testosterone, estrogen	Basal tests	Basal LH and FSH should be increased in postmenopausal women Low testosterone levels in the setting of low LH and FSH
	GnRH test: GnRH 100 mcg IV	0, 30, 60 min for LH and FSH	In most adults, LH should increase by 10 IU/L and FSH by 2 IU/L
Multiple hormones	Combined anterior pituitary test: GHRH (1 mcg/kg), CRH (1 mcg/kg) GnRH (100 mcg) TRH (200 mcg) are given IV	-30, 0, 15, 30, 60, 90, 120 min for GH, ACTH, cortisol, LH, FSH and TSH	Normal responses are variable Combined or individual releasing hormone responses must be elevated in the context of basal target gland hormone values and this may not be diagnostic (see text)

luteinising hormone and therefore prolactinomas are associated with loss of libido, impotence and azoospermia in men. 95% of prolactinomas are benign. The ratio of incidence of microadenoma in females and males is about 20:1, while no gender difference is seen with macroadenoma.

Diagnosis

Basal serum PRL levels above 20 ng/mL which fail to increase with the administration of TRH, suggests the possibility of prolactinomas. In moderate or large sized tumours the value may go up above several hundred ng/mL. There is generally a direct relationship with the level of prolactin and tumour size. Serum prolactin levels also help to assess the improvement with therapy. Hyperprolactinemia is often associated with thyroid dysfunction. Hence such cases should also be investigated for abnormalities of thyroid function. Other tests of pituitary function should also be done when macroadenoma bigger than 1 cm in diameter are present, in order to assess the degree of suppression of other hormones by the tumours.

CT and MRI may reveal almost all the macroadenomas. MRI can detect only over 70% of the microadenomas. In patients with clinical features and raised hormonal levels suggesting prolactinoma, about 30% of microadenomas may not be readily demonstrable by direct imaging.

Treatment

Dopamine agonists arrest the growth of the tumour, lower the secretion of prolactin and bring about clinical and biochemical relief in more that 80% of cases. Among the dopamine agonists, **bromocriptine** which is a derivative of ergot is most popular in India.

The drugs have to be given on a long-term basis, often for several years. After 2 years of successful therapy the dose can be reduced on a trial and error basis.

In the case of microadenomas medical treatment may be sufficient, but in the case of macroadenomas if tumour regression is not complete or if local complications develop, surgical or radiation therapy may have to be

undertaken. Irradiation with a dose of 3.5-5 Gy over 4-6 weeks is effective but it is only rarely required.

Other dopamine agonists include **cabergoline**, **quinagolide** and **pergolide** Table 96.3.

If with treatment of the prolactinomas the sexual function does not recover, accompanying hypogonadism or menopause has to be suspected.

Usually medical treatment is very satisfactory. Macroadenomas shrink to a considerable extent in more than 70% of cases. Those who desire pregnancy should be informed that there is a small chance of the tumour enlarging during the early weeks of pregnancy.

When the tumour produces pressure effects and threatens vision, surgical removal is the treatment of choice. The procedure commonly employed is transphenoidal microsurgery.

Even in patients with focal neurological deficits medical treatment can be given a fair trial since dramatic improvement is the rule.

Gigantism and Acromegaly

Effects of excessive amount of growth hormone (GH) depend on the age of onset of the disease. *Onset before closure of the epiphyses leads to gigantism and later onset after closure of epiphyses results in acromegaly.*

Causes: Hyperplasia or adenoma of the pituitary affecting the acidophils, chromophobes or both lead to hypersecretion of GH. In 80% of cases the underlying tumour is a somatotroph adenoma, in 10% it is non-somatotroph adenoma and in 10% it is of mixed type. Rarely may it is due to abnormality of the hypothalamus or ectopic hormone production. The total clinical picture results from the local effects of the tumour and endocrine effects of GH. The tumour compresses the neighbouring cells in the pituitary and leads to suppression of gonadotrophs and thyrotrophs. Mixed acidophil adenoma produces both GH and PRL. Large-sized tumours may present as space occupying lesions.

GIGANTISM

Onset of growth hormone excess before the age of 10 years leads to gigantism. This disorder is caused in the

Dopamine agonist drugs		
Dopamine agonist drugs	Dose orally	Side effects
Bromocriptine	2.5-15 mg/day given in divided doses daily	Gastrointestinal intolerance, fatigue, postural hypotension and nasal blockage
Cabergoline	250-1000 µg/week given as 2 doses in a week, maximum dose up to 3.5 mg/week	This is also an analogue of bromocriptine. Better than bromocriptine with fewer side effects, but more expensive, can be given weekly
Quinagolide ⁴	50-150 mg once daily	This is a non-ergot drug
Pergolide	25-50 µg daily	Long acting ergot derivative with potency 100 times that of bromocriptine, side effects few

majority of cases by hyperplasia of the eosinophilic cells of the pituitary. There is disproportionate growth in height and size. Maximal linear growth occurs in the bones of the extremities so that the arm span exceeds the height and the lower segment exceeds the upper segment. Early during the disease muscular hypertrophy and sexual precocity may be evident. Later, features of acromegaly may also develop. Growth hormone exerts its effect on tissue cells through the medium of insulin like growth factors.

ACROMEGALY

Acromegaly develops when growth hormone excess develops after the fusion of the epiphyses. This is seen in adults, between the ages of 20-50. Both sexes are affected. The hormone level may go above 30 mU/L (normal 2 mU/L) (Figs 96.2 to 96.5).

CLINICAL FEATURES

The onset is insidious. There is enlargement of soft tissues and bones of the hands, feet, and skull. The face is elongated and the features are coarse. Lips, tongue, nose, salivary glands and lacrimal glands are enlarged. The mandible is prominent and prognathic. Growth of the mandible leads to separation of the lower incisors. The larynx is enlarged and the voice becomes husky. Thyroid may enlarge under the influence of GH, but there is no hyperfunction. During the active stage, excessive sweating occurs. Spine may show kyphosis, enlargement of vertebrae and osteoarthritis.

Arthritis with hypertrophy and edema of periarticular tissues may occur around the peripheral joints. Bony prominence and attachments of muscles to bone become hypertrophied. Though the bones increase in thickness, unlike in gigantism, the length does not increase. There is generalized enlargement of all viscera. The changes in

Fig. 96.3: Acromegaly male 45 side view.
Note: The prognathic mandible

Fig. 96.4: Acromegaly large legs and feet
Note: Normal for comparison

Fig. 96.5: Acromegaly large hands
Note: Normal for comparison

the heart include enlargement, specific cardiomyopathy and congestive cardiac failure. The nerves are also thickened which may lead to entrapment neuropathies such as carpal tunnel syndrome. Increase in collagen fibres in the nerves may result in peripheral neuropathy. Though the muscles are hypertrophied, they may be weak due to proximal myopathy. Glucose intolerance develops in 25-30% of cases and many proceed to overt diabetes mellitus. Males complain of loss of libido and impotence. Females develop amenorrhea. Gynecomastia and galactorrhea may be seen in some cases.

Course and Prognosis

The endocrine disturbances and local pressure effects progress in cases with pituitary tumours. Death occurs due to raised intracranial tension, diabetic complications, cardiac failure or infections. The course depends on the nature of the pituitary tumour and its growth. In many cases the conditions may burn out. Factors which contribute to increased mortality include higher prevalence of hypertension, diabetes, cardiomyopathy and sleep apnea.

Diagnosis

Acromegaly should be suspected clinically from the appearance of the patient. The diagnosis has to be established by investigations.

1. Imaging procedures: X-ray of skull reveals enlargement of the sella turcica. AP or transverse diameter of more than 16 mm is diagnostic of pituitary fossa widening. Prominence of the bony points of the skull and enlargement of the frontal air sinuses are suggestive points. X-ray of chest may reveal cardiomegaly. X-ray of mandible reveals separation of teeth especially incisors. Hands and feet show tufting of the phalanges and enlargement of soft tissues.
CT or MRI give definite localization of the lesions. MRI of pituitary with contrast administration is the most sensitive method for diagnosis. Adenomas > 2mm in size can be visualized. More than 75% of patients with acromegaly have macroadenomas >1cm diameter at the time of diagnosis.
2. GH estimation: Basal GH levels in blood are elevated. The diagnostic finding is the failure of suppression of GH levels by a glucose load. The patient undergoes an oral GTT with 75-100 g glucose and blood is collected over 120 minutes. In normal subjects the GH levels fall below 2 µg/L. The blood glucose and GH are estimated simultaneously. Other pituitary hormones may also show alterations like PRL, IGF and TSH.
3. Estimation of insulin like growth factor – 1 (IGF-1) is helpful. IGF-1 levels also correlate with the activity of the disease. Normal levels of IGF-1- range from 0.35-1.9 U/mL in men and 0.45-2.2 U/mL in women.

Treatment

Aim of therapy is to correct the biochemical and morphological abnormalities and remove the tumour if pressure effects are evident.

Surgery is the method of choice if there are no contraindications. Impairment of vision is an indication for urgent surgery. The GH levels fall rapidly after surgery. Transphenoidal surgery is the treatment of choice, the GH level and IGH-1 level falling soon after the surgery. 40-50% attain long-term cure. The rest may get varying degrees of benefit.

Irradiation: The pituitary can be irradiated by implantation of radon seeds or yttrium. Alpha particles and protons have been employed in addition to conventional radiotherapy.

Drug therapy: In cases where surgery is contraindicated, *bromocriptine* reduces GH levels in about 50% of cases. Medication has to be continued in a dose of up to 10 mg/day for several months. Unlike in the case of prolactinomas, drug therapy is less effective than surgery. Hence its main role is in cases unsuitable for surgery or surgical failures.

Several newer modalities of drug therapy have been introduced recently. These include:

Somatostatin Receptor Ligands

1. **Octreotide** which is a synthetic analogue of somatostatin is 45 times more potent than the latter in inhibiting GH release. It is given in doses of 100-200 µg as SC injections 8 hourly. Continuous medication is required. Cholelithiasis is one of the major adverse side effects. The physical abnormalities regress with successful therapy. Though the diabetic state may improve in many cases, it may persist in some. Total blindness may not recover. Complications like cardiomyopathy, diabetes mellitus, and neuropathy can be avoided by early treatment. Other preparations include
2. **Octreotide LAR.** 10-40 mg IM injection once in 4 weeks
3. **Lanreotide 30 mg IM** every 10-14 days or
4. **Lanreotide gel 60-120 mg** deep SC injection once in 4 weeks.

Growth Hormone Receptor Antagonist

Pegvisomant 10-40 mg SC injection daily. This is a pegylated growth hormone analogue.

Dopamine Agonists

Cabergoline 1-4 mg oral weekly

The choice of the preparation and monitoring of therapy are highly specialized procedures to be undertaken by trained endocrinologists.

Ref: Shlomo Melmed. Acromegaly: N. Eng JI Med 2006; 355:2558-73.

CUSHING’S DISEASE

This term is given specifically to the condition in which a pituitary adenoma produces excess ACTH and leads to hypercortisolism.

Harvey Cushing described this condition in 1912 and demonstrated its cause as a primary pituitary tumour responsible for producing adrenal cortical hyperplasia, 20 years later. Cushing’s disease is due to hypersecretion of adrenocorticotropin. Microadenomas of the anterior pituitary secrete ACTH. They do not enlarge the sella turcica. The pathological mechanism is probably the failure of negative feedback exerted by circulating cortisol on the hypothalamus. In most of the cases the lesions start as hyperplasia which passes on to microadenomas which are less than 1 cm in diameter. Normal diurnal rhythm of ACTH secretion is abolished and the ACTH response to stress and hypovolemia is also lost.

Due to stimulation by ACTH, bilateral hyperplasia of the adrenal cortex and Cushing’s syndrome result.

Treatment

The ideal treatment is trans-sphenoidal microadenectomy. An alternative line of therapy is bilateral adrenalectomy followed by pituitary irradiation. When surgery and irradiation of the pituitary are contraindicated, drugs which inhibit cortisol secretion are used (*metyrapone*, *ketoconazole*). Some cases of Cushing’s syndrome due to ACTH secreting tumours of the pituitary may respond to *bromocriptine* or *cypheptide*.

In some cases of Cushing’s disease, bilateral adrenalectomy may be followed by enlargement of the pituitary tumour and associated hyperpigmentation. This is called *Nelson’s syndrome*.

Pituitary incidentalomas – The term incidentaloma refers to an incidentally detected lesion with no symptoms. Autopsy studies show an incidence of 10-20%.

Hypopituitarism

When there is failure of one or more cell types of the pituitary to secrete normally, hypopituitarism results. It is unusual to get deficiencies of single hormones. More often several hormones are deficient. The condition commonly presents as dwarfism in children and as hypogonadism in adults.

Hypopituitarism may result from primary lesions of the pituitary or secondary to lesions of the hypothalamus. Head injury, surgery, irradiation, chronic infections and tumours in the suprasellar region may lead to damage to the hypothalamus. Congenital lesions of the hypothalamus leading to diminution or absence of gonadotropin releasing hormone (GnRH) and growth hormone releasing hormone (GHRH) may occur. *Kallmann’s syndrome* is a

congenital deficiency of LHRH associated with anosmia and demonstrable defects in midline neural structures. Sheehan’s syndrome is the condition of hypopituitarism resulting from infarction of the adenohypophysis, usually precipitated by massive hemorrhage, particularly associated with hemorrhagic complications of pregnancy. Simmond’s disease described by Morris Simmonds a German Physician (1855-1925) is panhypopituitarism caused by complete atrophy of the adenohypophysis.

Adult Panhypopituitarism

Symptoms depend on the type and severity of cell failure, age of the patient and the age of onset of the disease. The condition becomes overt only when more than 75% of cells are destroyed. In panhypopituitarism growth hormone is affected first followed by gonadotropins, TSH and ACTH deficiency and consequent secondary adrenal deficiency occurs only when the pituitary function is grossly affected. Hypoprolactinemia manifests only during the puerperium as failure of lactation.

Etiology of Hypopituitarism

Developmental/Structural causes

- Transcription factor defect, Pituitary dysplasia/aplasia
- Congenital CNS mass, encephalocele
- Primary empty sella syndrome

Congenital hypothalamic disorders (septo-optic dysplasia, Prader-Willi Syndrome, Laurence-Moon-Biedl syndrome, Kallmann’s syndrome)

Traumatic

- Surgical resection,
- Radiation damage,
- Head injuries

Neoplastic

- Pituitary adenoma
- Parasellar masses (meningioma, germinoma, ependyoma and glioma)
- Rathke’s cyst
- Craniopharyngioma
- Hypothalamic hamartoma, gangliocytoma
- Pituitary metastases (breast, lung, colon, carcinoma)
- Lymphoma and leukemia
- Meningioma

Infiltrative/inflammatory diseases

- Hemochromatosis, lymphocytic hypophysitis, sarcoidosis, histiocytosis X, granulomatous hypophysitis

Vascular causes

- Pituitary apoplexy
- Sheehan’s syndrome due to massive intrapartum hemorrhage resulting in pituitary infarction
- Sickle cell disease
- Atrophy of the pituitary-Simmond’s disease

Infections

- Fungal (histoplasmosis)
- Parasitic (toxoplasmosis)
- Tuberculosis
- Pneumocystis carinii
- Miscellaneous causes

Fig. 96.6: Sheehan's syndrome. Note: The absence of hair in the axilla and pubic region

Clinical Features

One of the common modes of presentation is **Sheehan's syndrome** in which the hyperplastic pituitary of pregnancy which is vulnerable for ischemic damage undergoes infarction due to postpartum hemorrhage and shock. The earliest manifestation is failure of lactation. The patient develops amenorrhea, genital atrophy, loss of axillary and pubic hair, and loss of libido. Men with hypopituitarism present with testicular atrophy, loss of libido, and absence of spermatogenesis. Failure of ACTH secretion leads to secondary adrenal cortical failure. As the hypopituitarism advances, thyroid hormone deficiency also manifests. It is rare to get classical myxedema. The symptoms of GH deficiency are usually evident clinically. The symptoms of GH deficiency include lack of strength due to reduction in muscle mass, increased insulin sensitivity and mild refractory anemia (Fig. 96.6).

Differential Diagnosis

Panhypopituitarism has to be differentiated from other causes of dwarfism, general debility and asthenia. In *anorexia nervosa* which affects young women between the age of 15 and 30 may mimic hypopituitarism. In *anorexia nervosa* all the pituitary hormones except GH are decreased. With weight loss of more than 20% amenorrhea may also develop. Unlike hypopituitarism, the pubic and axillary hairs are retained. Moreover, emaciation is more suggestive of *anorexia nervosa* (Fig. 96.1).

Investigations

The diagnosis of panhypopituitarism is established by estimating the pituitary hormones and the hormones of the target glands.

Stimulation tests reveal the functional integrity of the target glands.

- ACTH secretion:** When adrenal response to ACTH is established, insulin induced hypoglycemia may be used to test the pituitary reserve of ACTH. If plasma cortisol rises above 20 mcg/dl following insulin, there is normal reserve of ACTH in pituitary.
- TSH reserve:** This can be easily assessed by administration of TRH. This could also elucidate the PRL secretory status of pituitary.

Management

This consists of replacement of the hormones of the target organs.

Cortisol deficiency is corrected with 12.5-25 mg of cortisol or its equivalent of other synthetic steroids. Glucocorticoids should be replaced before supplementation of thyroxine and gonadotropins in order to avoid the development of adrenal crisis. Glucocorticoid replacement should be increased during periods of acute stress like operations and infections. Mineralocorticoid replacement is not usually needed since this hormone is not markedly deficient in hypopituitarism. Thyroid replacement is best achieved with synthetic thyroxine started in a dose of 50-100 µg/day and raised to a dose of 150-200 µg slowly.

Testosterone replacement improves vigour, vitality, and libido. The oral preparation is methyl testosterone. Alternatively, testosterone can be given intramuscularly as depot injections. Estrogens and progesterone therapy prevent atrophy of the breasts and vaginal mucosa and also osteoporosis.

Gonadotropin therapy: Gonadotropin replacement is essential for return of ovulation and spermatogenesis. Short courses of admixture of FSH and LH (menotropins) followed by human chorionic gonadotropins (HCG) are used to induce ovulation (Table 96.4).

Protracted hypopituitarism can lead to premature atherosclerosis and increase in cardiovascular mortality.

TABLE 96.4

The details of pituitary hormone therapy	
Hormone deficit	Hormone replacement
ACTH	Hydrocortisone (10-20 mg AM; 10 mg PM) Cortisone acetate (25 mg AM; 12.5 mg PM) Prednisone (5 mg AM; 2.5 mg PM)
TSH	L-Thyroxine (0.075-0.15 mg daily)
FSH/LH	Males Testosterone enanthate (200 mg IM every 2 weeks) Testosterone skin patch (5 mg/d) Females Conjugated estrogen (0.65-125 mg qd for 25 days) Progesterone (5-10 mg qd) on days (16-25) Estradiol skin patch (0.5 mg, every other day) For fertility: Menopausal gonadotropins, human Chorionic gonadotropins
GH	Adults: Somatotropin (0.3-1.0 mg SC qd) Children: Somatotropin (0.02-0.05 (mg/kg per day)
Vasopressin	Intranasal desmopressin (5-20 µg twice daily) Oral 300-600 µg qd

(Ref. Kalman Kovaes, Sheehan's syndrome The Lancet 2003;361:520-2).

CHILDHOOD HYPOPITUITARISM

Hypopituitarism starting in childhood presents with a wide spectrum of disorders such as dwarfism (GH deficiency), hypogonadism (LH and FSH deficiency), hypothyroidism (TSH deficiency) or a combination of these.

Etiology

In general the etiological factors operating in adults are seen in children as well. In addition, hypopituitarism may be part of a general abnormality in the CNS like absent septum pellucidum. Growth hormone deficiency may develop as a familial trait transmitted as an autosomal recessive. Vaginal breech delivery may be complicated by growth hormone deficiency in the child as a result of mechanical distortion of the skull and consequent damage to the pituitary stalk.

Clinical Features

The child is normal at birth. Growth retardation is evident at the age of 2 or 3 years when the growth rate falls to 50% of the normal. Such children are obese with abnormal, deposition of body fat. When there is associated hypothyroidism, retardation of bone growth is more severe. In spite of growth retardation, these children have normal intelligence, but they may develop psychological

Fig. 96.7: Dwarf normal age-matched woman for comparison (30 years)

disturbances due to their physical appearance. Hypogonadism leads to delay in the fusion of epiphyses. Such children continue to grow for longer periods, thus attaining taller stature than children whose gonadal function is normal.

Hypopituitarism has to be distinguished from other common causes of growth retardation. Pathological causes of dwarfism include malnutrition, severe systemic illnesses, malabsorption state, skeletal disorders, corticosteroid therapy and deprivation dwarfism. Deprivation dwarfism occurs in children brought up in family circumstances under great stress, especially without maternal care.

Dwarfism

This is defined as shortness of stature that is below the third percentile for children of similar age and ethnic group. Genetic and environmental factors influence growth. This is a common problem in pediatric practice. In many cases short stature is seen in families without any demonstrable pathology. Pathologically dwarfism may result from several groups of conditions (Fig. 96.7).

- A. Major constitutional disorders:** Generalized malnutrition, rickets, malabsorption states, congenital cyanotic heart disease, severe respiratory, hepatic or renal disease, and long-term corticosteroid therapy.
- B. Inherited and genetic disorders:** Achondroplasia, fragilitas ossium, aminoacidurias, other metabolic defects, Turner's syndrome, pseudohypoparathyroidism and renal tubular acidosis.
- C. Endocrine disorders:** Cretinism, juvenile hypothyroidism, adrenogenital syndrome, precocious puberty,

hypopituitarism, hypothalamic disturbances, idiopathic hypoparathyroidism. The term Fröhlich's syndrome (*dystrophia adiposo genitalis*) refers to the combination of dwarfism, obesity, hypogonadism and diabetes insipidus and is produced by craniopharyngioma or chromophobe adenoma.

- D. Psychogenic dwarfism or deprivation dwarfism:** This is probably an emotionally mediated disorder unassociated with malnutrition, in which maternal deprivation leads to a selective deficiency of growth hormone. Provision of maternal care and emotional support improves the growth hormone levels and promotes growth.
- E. Laron dwarfism:** This is an autosomal recessive disorder characterised by small face and mandible, prominent forehead, saddle nose, discoloration of teeth, sparse hair, retarded growth of hair and teeth and small hands and feet. Serum GH levels are increased, but insulin like growth factors (IGF) are lower than normal. Receptor insensitivity is the mechanism underlying this disorder.

Investigation and Treatment

Management of a case of dwarfism depends upon the clinical findings and endocrine investigations.

When dwarfism is due to deficiency of growth hormone, the treatment of choice is human recombinant growth hormone (HGH) given in a dose of 0.02-0.2 IU/kg twice a week or 150-300 ug I.M. injection daily. Growth hormone therapy has different goals in children and adults. In children it increases linear growth, restores body composition and improves the quality of life and self image. In adults the main effects are restoration of body composition, reduction of fat tissue, improvement of muscular and cardiac function, beneficial effects on serum lipids and improvement in the quality of life.

Side effects include arthralgia, myalgia, and edema. Initial spurt of growth is remarkable and a linear growth of 12 to 15 cm may be obtained in one year, but the growth rate slows down later and at this stage higher doses of hormone are needed.

Concurrent use of anabolic steroids helps to improve growth and bring about a positive anabolic response. Commercially available GH is prepared by recombinant DNA technique or synthetic processes.

Empty Sella Syndrome

(Syn: Subdiaphragm cistern, Intracellular-subarachnoid Space, Intracellular cyst)

Definition

This is a rare disorder in which the pituitary fossa is enlarged with accumulation of cerebrospinal fluid at the expense of pituitary tissue, which may be reduced to a small remnant. The condition may be primary in which anatomical defects occur in the diaphragm sellae or secondary to surgery or irradiation on the region of the pituitary. The suprasellar subarachnoid space herniates through defects in the diaphragm sellae. The sella turcica becomes filled with CSF enclosed in an arachnoid-lined sac. This causes pressure effects on the pituitary stalk resulting in hyperprolactinemia and galactorrhea.

Diagnosis

The condition may be associated with normal endocrine profile in 60% of cases. In 40% of cases growth hormone response to stimuli and levels of gonadotropins may be reduced.

X-ray skull may show either a normal sella or an enlarged sella with thinned out dorsum sellae. Bony erosion is absent. The diagnosis is confirmed by air-encephalography which shows absence of diaphragm sellae and presence of CSF in the sella turcica. CT scan with metrizamide cisternography or MRI confirms the diagnosis.

Treatment

Hormonal replacement is undertaken if endocrine deficiency exists.

97

Pineal Gland and its Disorders

K.P. Poulse, B. Jayakumar

Chapter Summary

General Considerations: Pineal Gland 624

Disorders of the Pineal Gland 624

General Considerations: Pineal Gland

(Syn. Pineal body)

Anatomy: The pineal gland which weighs 120 mg lies beneath the posterior border of the corpus callosum and between the superior colliculi. Embryologically it develops from the ependyma lining the roof of the third ventricle.

Two types of cells are found in the pineal gland - the pinealocytes which form the majority and the neuroglial cells. The pinealocytes produce indolamines mainly **melatonin** and peptides such as vasotocin. Melatonin diffuses into the bloodstream. Secretion increases soon after the onset of darkness, peaks between 2 and 4 A.M. and falls off thereafter.

In infancy, melatonin levels are high (325 pg/mL). They fall off with age to 10-60 pg/mL in young adults. Exposure to light inhibits secretion. The effects on tissues are receptor mediated.

Possible physiological effects of melatonin include:

1. Hypnotic: increased propensity to sleep.
2. Control of circadian rhythm, e.g. temperature regulation.
3. Possible role in cyclical mood changes.
4. Sexual activity and reproductive function.
5. Anti-proliferative action in cancer.
6. Enhancement of the immune response.
7. Modulation of aging response and protection of cells and damage.

Diminished levels of melatonin may be associated with acceleration of the aging process.

In addition to melatonin, three hypothalamic hormones (TRH LH-RH and somatostatin) and an octapeptide, arginine vasotocin (vasopressin), -have also been detected in the pineal gland. During infancy, the pineal is relatively large. With age, it involutes.

Disorders of the Pineal Gland

1. **Calcification of the pineal gland:** This occurs in the matrix of ground substance secreted by pinealocytes. Calcification begins in early childhood and is completed by about puberty. Calcification is not associated with any functional disturbance.
2. **Tumours:** The pineal may be the seat of tumours. These may be pinealoma, teratoma, glial tumours or vascular tumours.

Tumours lead to mechanical effects due to pressure and endocrine disturbances. Pressure effects include rise in intracranial tension, internal hydrocephalus due to pressure on the aqueduct of Sylvius, and paralysis of upward gaze due to oculomotor involvement (**Parinaud's syndrome**). Ataxia, visual disturbances and signs of hypopituitarism may occur.

Endocrine disturbances manifest as abnormalities of sexual maturation such as sexual precocity, delayed puberty, and hypogonad states, evidence of hypothalamic involvement like diabetes insipidus, polyphagia, somnolence, obesity or behavioural disturbances are seen in 70% of patients with pinealomas and precocious puberty.

Treatment

Surgical treatment is beneficial in trained hands, though the procedure is difficult. Pineal tumours are partially radiosensitive and irradiation is effective. Chemotherapy with carboplatin, etoposide, vincristine, and bleomycin has also been found to be successful. Prognosis is good with a 5 years survival of 70-85%.

Thyroid and its Disorders

K.P. Poulouse, K.V. Krishna Das

Chapter Summary

General Considerations	625
Goiter	628
Hyperthyroidism	630
Diffuse Toxic Goiter	630
Hypothyroidism	635
Cretinism	636
Myxedema	637
Thyroid Hormone Resistance Syndrome (THRS)	639
Thyroiditis	639
Solitary Thyroid Nodule	640
Tumours of the Thyroid	641

General Considerations

At present thyroid disease from the second most common endocrine disorder in India next only to diabetes mellitus. If asymptomatic endemic goiter is also included, thyroid disease may even rank as the most common endocrine disease. The prevalence of iodine deficiency disorders is very high. With the introduction of iodised salt, the prevalence of iodine deficiency disorders is coming down.

Anatomy: The thyroid gland weighs 15 to 25 g, and it is made up of an isthmus and two lateral lobes. The isthmus lies just below the cricoid cartilage. The gland lies deep to the strap muscles of the neck enclosed in the pretracheal fascia which anchors it to the trachea, so that the thyroid moves up on swallowing. The width and length of isthmus averages 20 mm, thickness 2-6 mm. The lateral lobes from superior to inferior pole measure 40 mm, breadth is 15-20 mm and thickness 20-39 mm. The parathyroid glands which are four in number are embedded in the substance or sheath of the thyroid, behind the lateral lobes. The thyroid develops as early as the third or fourth week of gestation. The thyroid is formed as an outgrowth on the ventral wall of the pharynx in association with the

parathyroids which are derived from the third and fourth branchial arch. The 'C' cells which produce calcitonin are formed from the cells of the ultimobranchial body. Persistence of the remnants of the thyroid stalk may give rise to the pyramidal lobe, which lies just to the left of the midline extending upwards from the isthmus or to thyroglossal cyst. Failure of the thyroid stalk to descend results in the formation of lingual thyroid.

In the fetus the thyroid hormones are synthesized under the influence of TSH only by about the eleventh or twelfth week of gestation. Hence in the first trimester the fetus is totally dependent on maternal thyroxine. For proper development of mental and motor skills, adequate thyroid hormone concentration is necessary, whose synthesis depends on the availability of maternal iodine status. Initially, there is synthesis of T4 only in the fetus (TSH dependent) and inactive T3 (reverse T3) is formed from T4.

Iodine metabolism and hormone synthesis: The average Indian diet contains variable quantities of iodine ranging from very low values to more than 200 µg/day. Ingested iodine is reduced to iodide in the gastrointestinal tract and absorbed throughout the gut, the maximum being in the small intestine. Thyroid traps this iodine.

Daily dietary requirement of iodine varies with age

Children < 5 years of age	90 µg
6-12 years	120 µg
> 12 years	150 µg
Pregnancy and lactation	200 µg

In iodine deficiency the level of iodine in urine is < 100 µg/L

Plasma inorganic iodide level is usually less than 1.0 µg/dL. About 90% of the total body iodine is in the thyroid gland.

Thyroxine (T4) and tri-iodothyronine (T3) are formed by sequential reactions occurring in the thyroglobulin molecule under the control of TSH. The follicular cells synthesize thyroglobulin and store it within the follicles as colloid. This colloid acts as a reservoir of thyroid hormones.

Release of thyroid hormones from thyroglobulin: The follicular cells take up thyroglobulin colloid droplets and release T3 and T4 by their degradation. The thyroglobulin molecule is split by proteases and peptidases into T3 and T4 which are released into circulation and this is controlled by TSH. The total T4 secretion is about 60-120 µg and T3 is 20-30 µg per day. In the peripheral tissues T4 is converted into T3. 80% of circulating T3 is derived from de-iodination of T4 in the peripheral tissues and the rest from the thyroid gland. The turnover of T4 from thyroglobulin is only 1% per day and thus the large store of hormone provides prolonged protection against disorders of thyroid hormone synthesis. Total T4 stored in thyroid gland is about 5 mg, which is adequate for 50 days.

Plasma transport: Around 75% of thyroxine (T4) circulates in blood bound to *thyroxine binding globulin* (TBG) which is an alpha-globulin, 15% is bound to pre-albumin, now called transthyretin and the rest to albumin. Tri-iodothyronine (T3) also remains bound to TBG in the plasma. The plasma level of T4 is 5-10 µg/dL and that of T3 is 150-250 ng/dL. The sum total of T4 and T3 bound to the carrier protein is referred to as plasma protein-bound iodine (PBI). The normal range is 4-8 µg/dL. In serum, the free T4 is 0.03% of total T4 and free T3 is 0.3% total T3. The levels of T4 and T3 are regulated by the TSH from the anterior pituitary and TRH from hypothalamus. Rising levels of thyroid hormones inhibit TSH secretion. Both T4 and T3 are de-iodinated in the cells by the microsomal enzymes (deiodinases types 1, 2 and 3) and the iodides are excreted in urine (70 µg/day). T3 is bound to specific nuclear DNA thyroid hormone receptors and it is carried by cytosolic binding proteins into the cell nucleus.

Deiodinases are expressed in liver, kidney, pituitary and thyroid. The metabolic effects of thyroid hormone are initiated by the binding of T3 to the nuclear receptors. T3 has 15 fold higher binding affinity to intranuclear receptors compared to T4.

Actions of Thyroid Hormones

1. Increases cellular oxidation in all tissues.
2. Increase of protein breakdown.
3. Increases the turnover of carbohydrates and lipids.
4. Calcium is mobilized from bone.
5. The cardiovascular effects consist mainly of increase in heart rate and cardiac output.

Calcitonin: Calcitonin is a 32 amino acid peptide hormone formed in the parafollicular cells (C cells) of the thyroid. Calcitonin inhibits bone resorption and release of calcium from bone, thereby helping to lower calcium levels in blood. Catabolism of bone is significantly reduced. Levels of calcitonin increase during hypercal-

cemia and the secretion stops when the calcium levels fall. High levels of calcitonin are seen in patients with medullary carcinoma of the thyroid, however, in this condition there is no hypocalcemia. Human calcitonin gene is located in the short arm of chromosome 11. Glucocorticoids, glucagon and gastrin increase calcitonin secretion. It is also secreted by insulinomas, vasoactive intestinal polypeptide secreting tumours (VIPomas) and some lung tumours. Calcitonin has therapeutic use in the management of acute hypercalcemia, osteoporosis, and Paget's disease of bone.

Calcitonin Gene Related Peptide (CGRP)

This is a 37 amino acid peptide formed from the pre-procalcitonin gene located on chromosome 11. Final targets of action of this peptide are the C-cells of the thyroid and neural tissue. In the C-cells the product is calcitonin, whereas in neural tissue the product is pro-CGRP, which is a neurotransmitter influencing the sensory system. It is also a very powerful vasodilator which is concerned with the regulation of regional blood flow.

ASSESSMENT OF THYROID FUNCTION

Clinical examination is most valuable in all cases. Though several classic features such as lid lag and thyroid bruit specifically point to florid hyperthyroidism, in marginal cases the clinical symptomatology shows considerable overlap with normals or other non-thyroid disorders. Many tests are available to assess thyroid function but no single test is totally satisfactory.

THYROID FUNCTION TESTS

Isotopic Tests

- a. Estimation of T3, T4 and TSH by radioimmunoassay or ELISA
- b. Estimation of free T3 and T4
- c. TRH stimulation test
- d. Thyroid scan
- e. ¹³¹I uptake studies, TSH stimulation and T3 suppression tests. These are seldom done at present.

Non-isotopic Tests

- a. Demonstration of thyroid autoantibodies.
- b. Imaging procedures of the neck. USS, CT and MRI
- c. Biopsy of thyroid—fine-needle aspiration cytology (FNAC) or open biopsy.

Radioactive iodine uptake test: The amount of radioactivity concentrated by the thyroid following oral administration of ¹³¹I, after 2 and 24 hours is measured. In Indians, the normal ranges are 10 ± 5% at 2 h and 42 ± 7% at 24 h. The uptake values are high in hyperthyroidism and are low in hypothyroidism. Since this test is likely to

Alteration of T3, T4 and TSH values in common thyroid disorders			
(Total or free)	T3	T4	TSH
Graves' disease	High	High	Low
T3-toxicosis	High	Normal	Low
Primary hypothyroidism	Low	Low	Very high
Secondary and tertiary hypothyroidism	Low	Low	Low

be altered in several non-thyroidal diseases, and by drugs containing iodides, this is not routinely done except under special circumstances. These include:

- 1. Factitious hyperthyroidism
- 2. Acute and subacute thyroiditis
- 3. Hashitoxicosis and
- 4. For calculating the therapeutic dose of ¹³¹I in thyrotoxicosis.

Normally iodine uptake is suppressed by exogenous administration of T3 or T4. In Graves' disease (primary hyperthyroidism) T3 and T4 fail to suppress iodine uptake. In hypothyroidism, in order to identify the site of lesion as the thyroid, pituitary or hypothalamus, the effect of TSH or TRH respectively on iodine uptake by the thyroid is studied. In primary hypothyroidism the values do not change, whereas in pituitary or hypothalamic disease, the iodine uptake is increased by TSH or TRH respectively.

Estimation of T4, T3 and TSH: These hormones can be directly estimated by radioimmunoassay or ELISA. The total plasma level of T4 is 4-8 µg/dL and T3 is 150-250 ng/dL. Normal range of TSH is upto 5 µU/mL (Table 98.1).

Free T3/T4 estimation: The values of total serum T3 and T4 may be altered by many drugs, which interfere with TBG binding (estrogen increases, androgen decreases) and in conditions like pregnancy and hypoproteinemic states. In these situations free hormone concentrations correlate better with the metabolic state than the total hormone concentrations because they are unaffected by changes in

binding protein concentration or affinity. Free T3/T4 is the preferred test now and can be measured by RIA/ELISA.

TRH stimulation test: 100-200 µg of TRH is injected intravenously after estimation of basal TSH level in the serum. At 20, 40 and 60 minutes post-injection, TSH levels are estimated. Normally there is a two-fold rise. In Graves' disease the TSH response to TRH is minimal. In hypothalamic hypothyroidism, the basal level of TSH is low, but TRH causes more release of TSH. In pituitary disease, the basal as well as post-injection level of TSH remains the same at a low level.

Thyroid scintiscanning: Scanning offers a visual display of the size and shape of the thyroid gland. It is employed in different situations (Table 98.2).

- 1. It provides an objective assessment of the morphology of the gland.
- 2. It locates ectopic foci of thyroid tissue.
- 3. The functional activity of thyroid nodules can be evaluated (hot or cold nodules).
- 4. In the investigation of masses in the neck or mediastinum, scintiscanning is useful to detect their nature (e.g. retrosternal thyroid).
- 5. Metastasis from thyroid carcinoma can be visualized.

Originally ¹³¹I was used for visualizing the thyroid, the scan being done after 24 hours of administration. At present technetium pertechnetate which has a half-life of 6 hours is used for this purpose. With technetium scanning can be done soon after the injection of the radioisotope.

Additional laboratory investigations include haematological tests and estimation of the levels of serum calcium, sodium, CPK and proteins.

Fine-needle aspiration biopsy is a very valuable preoperative procedure done routinely. A correct diagnosis can be obtained in over 80% of cases. False negative results occur more frequently than false positive ones. The diagnostic accuracy of FNAC is about 95%, specificity 92% and sensitivity is around 83%.

Results of various isotopic tests in thyroid disorders				
Disease	RAIU	T4 (RIA)	T3 (RIA)	TSH
Graves' disease	H	H	H	L
Iodine deficiency goiter	H	N	N/M	N
Primary hypothyroidism	L	L	L	H
Suprathyroidal hypothyroidism	L	L	L	L
Subacute thyroiditis	L	N/H	N/H	N/L
Factitious hyperthyroidism	L	H	H if T3 is taken	L

Key: N : normal, H: high, M: marginal change, L: low

Ultrasound/ CT/ MRI Scanning US scanning provides an accurate indication of the size and is useful for differentiating cystic from solid lesions. CT and MRI are useful in the evaluation of retrosternal and retrotracheal extension of the gland, so also compression of trachea, extent of intrathoracic extension of thyroid malignancy and infiltration to adjacent structures. MRI gives better delineation of soft tissue involvement like infiltration of nerves.

Demonstration of thyroid auto-antibodies: Different types of antibodies are demonstrable in patients with thyroid diseases. These include antibodies against thyroglobulin, intracellular microsomal antigen (thyroid peroxidase) and nuclear components. Their presence is diagnostic in many disorders, especially chronic lymphocytic thyroiditis (Hashimoto's disease) and *postpartum thyroiditis*.

All autoantibodies against thyroid cells are IgG. Some antibodies are stimulatory, whereas others are inhibitory with reference to thyroid function.

1. Stimulating - TSH receptor antibodies (Thyroid stimulating immunoglobulin)
2. Destructive
 - a. Thyroid peroxidase (TPO) or antimicrosomal antibodies – the antigen is the thyroid peroxidase enzyme.
 - b. Antithyroglobulin antibodies

TPO antibodies may be present in normal elderly women in upto 20% of cases.

Thyroid stimulating immunoglobulins are TSH receptor antibodies (TSH R Ab).

Since low levels of antibodies are present in normal individuals, the absolute concentration becomes more important. Antibodies are estimated by various methods—immunofluorescence, hemagglutination, radioimmuno assay (more precise) and ELISA techniques. Antibodies are produced due to a secondary response to thyroid injury. The thyroid antibodies most frequently estimated are those directed against thyroglobulin and against thyroid peroxidase. The latter correlates better with thyroid dysfunction and its presence tends to correlate with damage to thyroid tissue and lymphocytic infiltration. The mechanisms of autoimmune destruction of the thyroid probably involve both cellular and humoral components (Table 98.3).

Goiter

Enlargement of the thyroid gland is known as goiter. A benign diffuse enlargement not caused by inflammation or tumour is called *simple goiter* or *nontoxic diffuse goiter* (NTDG).

TABLE 98.3

Frequency (%) of the presence of antibodies in various thyroid disorders

	TSH receptor antibodies	(Thyroglobulin) antibodies	(Thyroid peroxidase) antibodies
Normal	0	5-20	8-27
Graves' disease	80-95	50-70	50-80
Autoimmune thyroiditis	10-20	80-90	90-100
Thyroid cancer	0	20-40%	+
Pregnancy	0	14	14
Type 1 diabetes mellitus	0	40	40
hTgAb : human thyroglobulin antibodies			
hTPOAb: human thyroid peroxidase antibodies. The figures denote the percentage frequency.			

* Serum thyroglobulin (Tg) estimation is done as a follow up in patients with well differentiated thyroid follicular carcinoma. However, serum Tg can also be elevated in goiter, hyperthyroidism and inflammatory conditions of the thyroid.

Causes of goiter

1. *Simple (non toxic) goiters* may occur due to different causes:
 - i. *Physiological goiter*— This is simple enlargement of the thyroid in puberty and pregnancy. It generally subsides when the physiological stress is over, or it may persist. The term physiological goiter is being questioned.
 - ii. *Parenchymatous goiter or colloid goiter*: — Iodine deficiency, iodine excess, dyshormonogenesis, and intake of goitrogens cause thyroid enlargement, the acini being filled with colloid. In some, the cause may not be evident.
2. Goiter due to thyroiditis—acute, subacute or chronic.
3. *Nodular goiter*—single or multiple nodules.
4. *Toxic goiter*—primary (Graves' disease) or secondary (Plummer's disease).

SIMPLE GOITER

This may be endemic or sporadic. Puberty goiter, colloid goiter and parenchymatous goiter are included in this group. The thyroid gland is diffusely enlarged, painless and non-tender. It may be soft or firm in consistency. The term physiological goiter is being discarded since it is doubtful whether the thyroid enlarges due to physiological reasons. Many of these show occult or overt iodine deficiency. Similarly many of the previously labelled puberty goiters were actually due to autoimmune thyroiditis.

Etiology: Simple goiter is the result of relative iodine deficiency which occurs during periods of increased

demand for thyroid hormones, such as menarche and pregnancy. Diffuse colloid goiters are common in younger subjects and are unusual above the age of 40 years. By the age of 35-40 years, the diffuse goiter becomes multinodular. Retrosternal extension may be present, occluding the thoracic inlet.

The gland enlarges due to hyperplasia and hypertrophy. When the stress is over or it is corrected, the cells undergo hyperinvolution and this leads to the formation of colloid goiter. These subjects are clinically euthyroid. Thyroid function is preserved by the preferential production of excess T3 instead of T4. In many cases the thyroid gland reaches large sizes.

It is possible that repeated cycles of hyperplasia and hyperinvolution may lead to the formation of multinodular goiter later.

Treatment

Administration of thyroxine (up to 0.3 mg/day) brings about a favourable response in 60% of subjects. The gland shrinks within 3 months of starting treatment. Treatment has to be continued for 1-2 years or more. Complete regression of the goiter is rare. Abrupt withdrawal of the drug causes rapid enlargement of the gland.

ENDEMIC GOITER

This is a major public health problem all over the world, especially in India. Iodine deficiency manifests in various ways and goiter is the most easily recognized form. Endemic cretinism, which is also common, leads to severe morbidity in these zones. About 54 million people in India have goiter and the number at risk is estimated to be above 167 million.

It is also estimated that there are 2.2 million cretins and 6.6 million children with mild neurological defects in India attributable to iodine deficiency. The spectrum of abnormalities due to iodine deficiency is now grouped under the title '**iodine deficiency disorders' (IDD)**.

An area is termed endemic for goiter when 10% or more of the population is affected. Important among the well recognized goiter belts of the world are the high mountain regions of Andes, Alps and Himalayas, region of the Great lakes of USA, and several pockets in Africa (Zaire). The broad belt covering the mountain ranges of Afghanistan to the sub-Himalayan regions of India, Pakistan, Nepal, Bangladesh and Myanmar extends up to Malayasian archipelago and Indonesian islands. Apart from these well recognized regions, many other states in India, such as Haryana, Rajasthan, Uttar Pradesh, Orissa, Madhya Pradesh, Tamil Nadu and Kerala also show areas of iodine deficiency. In these endemic belts the daily iodine intake is generally less than 50 µg. The drinking water is very low in iodine content. Normal daily requirement of iodine is 150- 200 µg for adults.

Dietary sources of iodine such as sea fish, milk, and eggs may be absent in the diet of the people in these areas.

Pathology

The thyroid gland is enlarged with hypertrophy and hyperplasia of the cells. The euthyroid state is maintained in many subjects because of the increased production of T3. The plasma inorganic iodide levels are low. The absolute iodine uptake by the thyroid is maintained normal by increasing the plasma clearance rate of iodide. PBI is also normal. Urinary iodide excretion is low. Plasma T4 is normal but T3 may be high. Correction of iodine deficiency leads to resolution of the goiter. Alternatively, the cells may undergo hyperinvolution. In this case the acini become filled with colloid and diffuse colloid goiter may develop. With repeated episodes of iodine depletion and repletion, multinodular goiter may develop.

Iodine deficiency during pregnancy leads to abnormalities in the mother and baby. Neonatal and infantile iodine deficiency leads to a spectrum of clinical abnormalities ranging from latent to overt thyroid disorders. Cretinism occurring as a result of iodine deficiency is widespread, and this is one of the correctable causes of abnormality in growth and development in the endemic areas.

Preventive Measures

Several strategies have been tried on a national and international basis for correcting widespread iodine deficiency.

Fortification of common salt with iodide (1 part to 100,000 parts) and distribution in endemic areas has been partially successful in many regions. Table salt fortified with iodine is freely available in India at present. In remote areas where access to medical help is not easy, one of the strategies to prevent iodine deficiency states is the injection of iodized oil. Intramuscular injection of oil containing about 500 mg of iodine once in three years offers effective personal protection.

Provision of iodide promptly reduces the goiter rate and incidence of cretinism in endemic areas. An adverse effect of iodine supplementation is the development of acute hyperthyroidism (**Jod Basedow phenomenon**) very rarely. This is due to the proliferation of thyroid cells during the iodine deprivation period and also the formation of hyperfunctioning nodules leading to hyperthyroidism on supplementing iodine.

Excessive supplementation of iodine in regions with only marginal iodine deficiency may lead to subclinical hypothyroidism and autoimmune thyroiditis rarely (see also chapter 32).

SPORADIC GOITER

The etiology of sporadic goiter is not fully clear. The possible causes include increased iodine demand during

pregnancy or puberty, presence of goitrogens in the diet and genetic factors.

Exogenous goitrogens include common drugs such as thiocarbamides (antithyroid drugs), chlorpropamide, PAS, amiodarone, glutethimide, iodine on a long-term basis, reserpine, phenylbutazone and lithium carbonate. Items of food like cabbage, turnips, soyabean flour, and cassava may act as goitrogens. Cabbage contains thiocyanates which inhibit iodine uptake by the thyroid. Cassava (tapioca) contains cyanogenic glycosides such as linamarin and lotaustralin, which liberate hydrocyanic acid on acid hydrolysis in the stomach.

Goiter may be the result of defective hormone synthesis. Such defects may involve pathways like oxidation, organification, coupling of iodine or proteolysis. The condition manifests as large goiters which show increased iodine uptake. Features of hypothyroidism or cretinism may be evident in some cases. Clinically retrosternal extension of the goiter can be demonstrated by asking the patient to raise both arms above the head for 30 seconds, when the neck veins will engorge with plethoric appearance of face (*Pemberton's sign*).

In cases of dyshormonogenesis, monoiodotyrosines or diiodotyrosines may be elevated in blood depending upon the enzymopathy. In many cases the goiter is familial.

Management: It is essential to detect the cause and tackle the same. Mild iodine deficiency and drug induced goiters respond to medical therapy. Established goiters which do not respond to medication have to be treated by surgical excision. Since thyroid carcinomas are not rare, all goiters should be investigated, including needle aspiration biopsy. Indications for surgery include cosmetic disability, pressure effects, retrosternal extension, suspicion of malignancy and progressive enlargement.

Hyperthyroidism

Persistent, elevation of the synthesis and release of thyroid hormones T4 and/or T3 leads to hyperthyroidism. It may be due to several causes. Hyperthyroidism affects approximately 2% of women and 0.2% of men.

Causes of Hyperthyroidism

Common Causes

- i. Toxic diffuse goiter (*Graves' disease*) -80%
- ii. Toxic multinodular goiter (*Plummer's disease*) -5%
- iii. Toxic adenoma (*autonomous hot nodule*)

Rare Causes

- i. Neonatal hyperthyroidism due to transplacental transfer of long acting thyroid stimulator (LATS), now designated as thyroid stimulating immunoglobulins (Tslg)
- ii. Thyrotoxicosis factitia caused by the self administration of thyroid hormones.
- iii. Iodine induced hyperthyroidism (*Jod Basedow phenomenon*), rarely seen in regions where iodised salt is

distributed, or also with the use of drugs like amiodarone and radiopaque contrast dyes.

- iv. Hashimoto's thyroiditis may be associated with thyrotoxicosis (**Hashitoxicosis**).
- v. Ectopic secretion of TSH like substances by trophoblastic tumours, e.g. hydatidiform mole or chorio-carcinoma or hyperemesis gravidarum in which chorionic gonadotropins are elevated.
- vi. TSH secreting tumours of the pituitary.
- vii. Tumours such as ovarian teratomas containing thyroid tissue (*struma ovarii*) and metastases from follicular carcinoma of thyroid.
- viii. Acute or subacute thyroiditis may give rise to transient hyperthyroidism. Postpartum thyroiditis occurring as painful enlargement of the thyroid within 6 months of delivery may also be accompanied by hyperthyroidism
- ix. Pituitary resistance to thyroid hormone.

DIFFUSE TOXIC GOITER

Syn: Graves' disease, Parry's disease, Basedow's disease

The disease is quite common in general practice, but the severity may vary. Females are affected more with a peak incidence between 20 and 40 years. Though neonates of thyrotoxic mothers may suffer from hyperthyroidism, usually the condition subsides within 3-6 weeks of birth.

Etiology

The exact etiology is not fully understood. The consensus is that Graves' disease is an autoimmune disorder. Several genetic susceptibility loci and environmental factors are likely to contribute to the development of the disease for e.g. HLA 138, HLA DR3, HLA DR2, CTLA-4 (cytotoxic T lymphocyte associated- 4) gene regions. There is a 50% concordance in monozygotic twins and 5% in dizygotic twins. There is also strong association with other autoimmune diseases like pernicious anemia, type 1 DM, myasthenia gravis, Addison's disease, systemic lupus erythematosus (SLE), idiopathic thrombocytopenic purpura (ITP) and rheumatoid arthritis. Various immunoglobulin antibodies are found directed against antigens in the thyroid cells, orbital tissues and dermis. In some cases thyroid stimulating immunoglobulins (autoantibodies) are demonstrable. These are immunoglobulins of IgG class and have TSH-like action. They cross the placenta and lead to hyperthyroidism in the fetus and neonates as well.

Thyroid stimulating immunoglobulins (TSI) are of two types

- a. (TSH receptor antibodies) TSH RAb compete with TSH at the TSH receptor sites in the thyroid cell membrane and behaves like TSH. The serum levels of TSI correlate with the severity of hyperthyroidism, the more the level of TSI, more severe is the disease.
- b. Inhibiting or blocking antibodies such as TSH R IAB which may block the ligand binding site and act as

TSH agonists. TSH receptor is an autoantigen, and its gene structure and chromosomal location is identified now as (14q 31). TSH R IAb is seen in 15% of patients with myxedema.

Pathology

Thyroid is diffusely enlarged due to hyperplasia of acinar cells and increased vascularity. Histologically the acinar cells are hyperplastic, with accumulation of the colloid. Varying degree of lymphocytic infiltration is also seen. Microsomal and antithyroglobulin antibodies are also found in many patients with Graves’ disease, but in lower levels than in Hashimoto’s disease.

Thyroid associated eye disease is a frequent manifestation of thyroid disorders, particularly hyperthyroidism. Extraocular muscles are the target of autoimmune response. There is evidence of retro-orbital inflammation characterised by focal edema, glycosaminoglycan protein deposition, followed by fibrosis. Retro-orbital tissue may act as an autoantigen which has immune reactivity similar to the TSH receptor. Glycosaminoglycans are secreted by the fibroblasts under the influence of cytokines from local lymphocytes.

The present consensus is that the immune system in the body recognizes an antigen common to the thyroid gland, retro-orbital tissues and skin and this is likely to be TSHR Ab and the level of TSH R Ab correlates with the severity of ophthalmopathy and dermopathy. The interstitium shows diffuse mononuclear infiltration, primarily by activated T-cells with some B-cells and occasional macrophages. The retrobulbar fibroblasts and skin fibroblasts are affected by the autoimmune processes. Graves’ ophthalmopathy and dermopathy are strongly associated (Table 98.4).

Clinical Features

Graves’ disease is more frequent in young women. The effect of thyroid hormone is to increase metabolism and sensitise the tissues to catecholamines. The condition is florid and easily detectable in many cases. The symptoms may be less obvious in others. The general symptoms

attributable to hypermetabolic state include loss of weight, intolerance to heat, increased sweating, excessive appetite, palpitation, tachycardia, exertional dyspnea, nervousness, tremor, diarrhea, easy fatigability, apprehension, and insomnia. Rarely mental changes like severe agitation and frank psychosis may be the presenting features.

Examination of the neck shows the thyroid to be diffusely enlarged, but sometimes it may be asymmetrical. It is soft, warm, pulsatile, and tender. Arterial thrills and bruit may be detectable. These phenomena indicate increased vascularity.

Several organs show abnormality. Though in most cases, many of them are detectable, the severity of involvement may not be uniform.

Thyroid associated eye disease may present in several ways, 90% have overt hyperthyroidism. 10% have no obvious thyroid dysfunction. Those with no signs of thyrotoxicosis are known as *ophthalmic or euthyroid Graves’ disease*. Among them 50% have autoimmune hypothyroidism, the remaining 50% have no detectable clinical or biochemical dysfunction of the thyroid. Main clinical features include diplopia with vertical separation of visual images, asymmetry of palpebral fissures, disorders of movement of the eyes and lids, and compression of the optic nerve (Fig. 98.1).

- 1. Sympathetic overactivity leads to lid lag, stare, increased watering, and infrequent blinking. These subside with correction of thyroid function.
- 2. There is abnormal protrusion of the eyeball (*exophthalmos*) and *partial or complete ophthalmoplegia*. Exophthalmos is generally bilateral, but can be unilateral or asymmetrical. It may precede overt hyperthyroidism. Exophthalmos is assessed by measuring

TABLE 98.4

Binding of thyroid hormones to various protein fractions in blood-%			
	TBG	TBA	TTH
T4	68	20	11
T3	69	11	9
TBG – Thyroid binding globulin TBA – Thyroid binding albumin TTH – Transthyretin 3-6% of plasma T3/T4 are bound to lipoproteins. TBG affinity for T4 is 20 times more than that for T3.			

Fig. 98.1: Bilateral exophthalmosma in a male thyrotoxic patient

the distance between the lateral angle of the bony orbit and the anterior part of cornea by **Hertel exophthalmometer**.

3. Papilledema may develop in advanced cases. Some cases may show optic atrophy.

Skin changes: The skin is soft and moist. The hair is soft. Sweating is excessive. The nails show thinning (*onycholysis*) and may get separated from the nailbed (*Plummer's nails*).

Sometimes localized myxedematous deposits may occur. The common site is the front of the leg (**hence called pretibial myxedema**). Over this site the skin is raised, nodular, indurated, and reddish brown in colour. The lesions may be pruritic. Examination reveals *peau de orange* (orange peel-like) appearance. In addition to the pretibial regions, thighs, genitalia, and lower abdomen may be affected. Pretibial myxedema is attributed to local nonresponsiveness of tissues to the thyroid hormones.

Some cases show clubbing of fingers and toes and hypertrophic osteoarthropathy (**thyroid acropachy**).

Changes in skeletal muscles: There is excessive fatigue and weakness. The proximal muscles of pelvic and pectoral girdles show myopathy characterized by selective weakness and atrophy and this may incapacitate the patient. The condition recovers completely when thyrotoxicosis is controlled. This is an example of reversible endocrine myopathy. Myasthenia gravis may coexist with Graves' disease and the relationship is more of a see-saw phenomenon — myasthenia *abating when thyrotoxicosis* is active and vice versa. Both conditions demand management on their own merits. Hypokalemic periodic paralysis may occur more frequently in thyrotoxic subjects.

Cardiovascular system: Cardiac output increases out of proportion to the rise in basal metabolic rate. Thyroxine has a direct chronotropic effect on cardiac tissues. Increase in workload leads to cardiac hypertrophy. Combination of excessive demand in the presence of reduction of reserve capacity of the myocardium leads to high output cardiac failure. Atrial fibrillation occurs in up to 25% of cases and this is resistant to drug therapy and cardioversion, till the thyrotoxicosis is also controlled.

Other arrhythmias such as paroxysmal tachycardia and atrial flutter are also common. Some patients develop effort angina.

Alimentary system: Abdominal cramps, diarrhea and vomiting are common features. The diarrhea is due to intestinal hurry. In many cases it takes the form of increased frequency of bowel movements, especially after food.

Reproductive system: In women the periods become scanty and fertility is reduced. In men libido and potency

may be altered variably. Gynecomastia may develop. Oligospermia may occur.

Bones: Osteoporosis may develop as a result of increased resorption of bones. Hypercalcemia and hypercalciuria may be demonstrable.

The general clinical picture produced by toxic diffuse goiter and toxic nodular goiter is similar in many respects. However, eye changes and pretibial myxedema are more common in toxic diffuse goiter. Association with other autoimmune diseases is more characteristic of Graves' disease, which is the more frequent form in younger age groups. Toxic adenomas occur usually at later age groups. In them cardiovascular manifestations are more prominent and sometimes may be the only clinical presentation. In toxic adenoma, local examination of the thyroid may not reveal generalized hypervascularity and bruit, but the condition can be easily diagnosed by palpating the nodules.

Sometimes the thyroid gland may produce excessive quantities of only tri-iodothyronine (T₃). Such a condition is called T₃ toxicosis, mostly seen in autonomous hot nodules or in iodine deficient areas.

Diagnosis

In florid cases clinical diagnosis is easy. Subclinical cases may be missed if thyrotoxicosis is not kept in mind. In all cases it is advisable to confirm the diagnosis and establish its severity by investigations.

Differential Diagnosis

When the symptoms are mild, hyperthyroidism may be mistaken for anxiety state, tuberculosis, diabetes or primary muscle disease. In anxiety state the palms are cold and moist, whereas in hyperthyroidism they are warm and moist.

Euthyroid Graves' disease: This is a condition in which exophthalmos is present with or without thyroid enlargement. There may not be signs of overt hyperthyroidism. ¹³¹I uptake is increased or normal, but the uptake is not inhibited by administration of T₃. Moreover, administration of TRH does not lead to elevation of TSH. T₃ and T₄ levels will be normal.

Laboratory Investigations

¹³¹I-uptake by the thyroid gland, levels of T₄ and T₃, are all increased. TSH is low and there is no increase in TSH levels when TRH is administered.

TREATMENT

Thyrotoxicosis may be treated with antithyroid drugs, irradiation by radioactive iodine or surgery.

Drug therapy: Drugs form the first line of management in the ordinary case. Antithyroid drugs block the synthesis of thyroid hormones by inhibiting thyroid peroxidase enzyme, thus blocking iodination of tyrosine. The drugs are started in a small dose and worked up to optimum response, and maintained for a period of 18-24 months. With improvement in the condition the dose can be tapered and maintained at a lower level. In 50% of cases remission is obtained during drug therapy. Many cases may relapse on withdrawal of therapy. Thiocarbamides, potassium perchlorate, and Lugol's iodine are also employed as antithyroid drugs.

Thiocarbamides: *Carbimazole, methylthiouracil and propylthiouracil* are the drugs in this class, of which methylthiouracil is seldom used at present. Carbimazole (Neomercazole) is most widely used on account of its effectiveness, relative safety and free availability. It is started in a dose of 10-15 mg 6 hourly as tablets. Carbimazole has mild immuno-suppressive effects while PTU in addition blocks the conversion of T₄ to T₃. As the desired effect is obtained, the dose is reduced and continued at a lower level to maintain euthyroid state.

Propylthiouracil is used at times when carbimazole is not tolerated. The daily dose is 150 mg 6 hourly as tablets. Both these drugs promptly block the formation of thyroxine and tri-iodothyronine, but do not prevent the release of hormone stored in the colloid. Therefore, it takes 2-3 weeks for the effect to be fully established. If found effective, the therapy should be continued for 12-18 months before reducing the dose and withdrawing it. Early withdrawal may lead to relapse. Even after the full course some cases may still relapse.

Adverse Side Effects

Thiocarbamides are toxic drugs and, therefore, close watch should be instituted when administering them. Adverse effects include fever, lymphadenopathy, splenomegaly, jaundice, leukopenia, thrombocytopenia, and **agranulocytosis**. Generally, adverse effects manifest during the early part of treatment. Reversible enlargement of the thyroid may occur during therapy and this subsides on stopping the drug. Enlargement of the thyroid may be troublesome at times. Another untoward side effect is the worsening of exophthalmos. Concurrent use of thyroxine sodium in a dose of 0.05 to 0.1 mg daily helps to reduce these side effects and continue anti-thyroid medication more smoothly.

Potassium perchlorate: It is an ion inhibitor which inhibits the transport of iodine to the thyroid. In an initial dose of 800 mg daily, the drug is very effective. As the condition improves, the dose is reduced. The action is rapid. Potassium thiocyanate is another drug in this category.

Iodine (inorganic or organic) given in pharmacological doses promptly blocks iodine uptake by the thyroid, formation of thyroxine and also release of preformed hormone from colloid. Iodine blocks the peripheral conversion of T₄ to T₃. For immediate effect iodine or iodides are preferable. Since the vascularity of the thyroid also comes down, it becomes less friable during surgery. Therefore, iodine is given as a preoperative drug for thyroidectomy, and also for the management of thyroid storm.

Dose: *Lugol's iodine* (iodine dissolved in potassium iodide solution containing 10 mg iodine in each drop) or saturated solution of potassium iodide which contains 50 mg iodine per drop is given in a total dose of 500 mg/day. Effect of iodine on the thyroid is not permanent. With continued use exceeding 2-3 weeks, the antithyroid activity wanes. Therefore, iodine or iodides are used only for short-term treatment. Sodium iodide can be given IV-1g/day.

Inorganic iodine is not routinely used because of toxicity and high incidence of recurrence. Organic iodine such as oral cholecystography dye can be used on a short-term basis. Iodine blocks the peripheral conversion of T₄ to T₃. Because of the rapid action iodides are most useful in the management of thyroid crisis. Since the entero-hepatic circulation of T₃ and T₄ is higher in thyrotoxicosis, it may be beneficial to use bile salt sequestrants like cholestipol hydrochloride along with carbimazole in the initial phase of treatment of resistant cases of thyrotoxicosis.

Steroids like dexamethasone which suppresses the peripheral conversion of T₄ to T₃ and secretion of T₄/T₃ are also found to be useful.

Pretibial myxedema responds to the local application of triamcinolone cream under occlusive dressing.

T₄ has a half-life of about 5 days in the body. Therefore, the effect of antithyroid drugs is not immediately evident. There is a latent period of 7-10 days before the symptoms are controlled. In order to reduce the distressing symptoms immediately, beta-adrenergic blockers like propranolol (up to 120 mg/day) may also be used. This promptly controls the tachycardia, palpitation, diarrhea, tremor, and exertional dyspnea. Excitement and insomnia are indications for drugs like phenothiazines (100 mg/day) or diazepam (20-30 mg/day).

Spontaneous development of hypothyroidism after antithyroid drug therapy for autoimmune thyroiditis denotes the presence of TSH blocking antibodies.

Surgery

Subtotal thyroidectomy is the operation of choice.

Indications for surgery are:

- i. Large goiter with pressure effects.
- ii. Nodular toxic goiter.

- iii. Failure of drug therapy or serious toxicity of drugs and
- iv. Poor drug compliance, socioeconomic factors, cosmetic reasons and desire for quick response.

The patient is given drug therapy before surgery to make him euthyroid. This is necessary to prevent *thyrotoxic crisis*. Two weeks prior to surgery carbimazole is replaced by potassium iodide 60 to 100 mg per day in order to reduce the size and vascularity of the gland. Surgery is effective in reducing toxic symptoms in almost all cases. Recurrence after surgery occurs in 10% cases. The immediate complications include recurrent laryngeal nerve palsy and damage to the parathyroid glands (2%). 40-45% of cases may develop hypothyroidism in 10 years, requiring thyroid supplementation.

Radio-iodine treatment: Currently ^{131}I treatment has practically replaced thyroidectomy in the treatment of Graves' disease in adults in many countries. Data from major centers shows that 50% of patients are treated with ^{131}I , 35% with surgery and only 15% with antithyroid drugs alone. In India radio-iodine treatment is available in many centers for routine use. ^{131}I is the commonly used preparation. ^{125}I can also be used for this purpose. ^{131}I has a half-life of 8 days while ^{125}I has a half-life of 60 days.

Indications for Radio-iodine Treatment

- i. Thyrotoxicosis with small or moderate sized gland.
- ii. Recurrent thyrotoxicosis.
- iii. Masked hyperthyroidism.
- iv. Thyrotoxic heart failure.
- v. Poor surgical risk.

Contraindications

- i. Pregnancy is an absolute contraindication since the isotope may reach the fetus and destroy its thyroid as well.
- ii. In severe thyrotoxic patients ^{131}I treatment may precipitate thyroid storm. Hence treatment has to be undertaken with caution.

^{131}I dose: The thyroid will be effectively irradiated with 7000 rads. For this dose, each gram of thyroid tissue should receive 150 microcuries of ^{131}I . The average total dose is 8-10 millicuries (300-400MBq-Mega Bequerel). However this dose leads to hypothyroidism in 30-70% of cases within 2-10 years. Hence lower doses are preferred in many centers. After an initial dose of 4-5 millicuries (150-200 MBq), the dose is repeated after three to six months. Even among those who were given the lower dose hypothyroidism may develop in 50% within 25 years. ^{131}I can be administered orally as a solution on an outpatient basis, but the urine and feces which contain high amounts of radioactivity have to be disposed safely. Antithyroid medication should be withdrawn four days before administering ^{131}I and this can be continued thereafter till

the patient becomes euthyroid. Women of child bearing age should be given ^{131}I within 10 days of onset of menstrual bleeding. In those with irregular menstrual periods pregnancy should be excluded by urine test before drug administration. They should avoid pregnancy for four months thereafter.

THYROTOXIC CRISIS

Syn: Thyroid storm

This is caused by sudden release of thyroid hormones from the gland, spontaneously or immediately after surgery. Thyroid crisis is more frequent if surgery is undertaken during active thyrotoxicosis. Thyroid storm can be precipitated by ^{131}I treatment also. This is a medical emergency.

Thyroid crisis should be suspected if the patient develops high fever, severe tachycardia, restlessness, heart failure, peripheral vascular collapse or psychotic behaviour.

Treatment

This is a medical emergency demanding urgent specific treatment.

1. Diazepam is given in doses of 5-10 mg IV to allay the agitation and quieten the patient. Tepid sponging helps to keep the temperature down from rising to hyperpyrexia levels.
2. I.V glucose saline drip is started and hydrocortisone 100 mg is given at 4-6 hour intervals to combat shock.
3. Sodium iodide is given IV in a dose of 300-600 mg 8 hourly till the metabolic crisis is controlled.
4. Beta-adrenergic blockers are very effective in reducing tachycardia and adrenergic symptoms. Propranolol given IV in doses of 1-4 mg stat over a period of 5 minutes is very effective and the effect lasts for 3-4 hours, after which it is to be repeated. In less severe cases propranolol can be given orally, in doses ranging from 120-240 mg in 24 hours upto 600-1200 mg.
5. If IV sodium iodide is not available, an effective anti-thyroid regimen is to give propyl thiouracil 100 mg 6 hourly along with potassium iodide 50-100 mg orally, rectally or through a Ryle's tube as the case may be. Iodine containing radio-contrast dyes such as *sodium iopodate* 500 mg orally daily will restore the serum T3 to normal in 2-3 days. Propranolol and sodium iopodate can be withdrawn after 14 days. Carbimazole can also be given 15-20 mg 6 h through a Ryle's tube.

HYPERTHYROIDISM DURING PREGNANCY

Both propyl thiouracil and carbimazole are effective. These drugs cross the placenta and appear in breast milk. Propyl thiouracil is preferred in pregnancy since the fetus receives only 0.025% of the administered dose whereas with carbimazole it receives 0.2%. Aplasia cutis of scalp

can develop in neonates with carbimazole. The minimum dose of these drugs required to keep the mother's thyroxine level at the upper limit of normal should be continued. After delivery baby should be fully investigated for thyroid function and appropriate management instituted. In general, hyperthyroidism naturally remits during pregnancy and relapses after delivery.

Toxic adenomas: These are usually autonomous and thyrotoxicosis due to this cause tends to be permanent and prolonged, without any natural remission. Specific anti-thyroid drugs are less effective. Beta-adrenergic blocking drugs may control the adrenergic symptoms. ^{131}I is the more effective therapy, but larger doses up to 10-50 millicuries may be required at times. Surgical removal is the better alternative.

Hyperthyroidism due to thyroiditis: Usually this is a transient phenomenon occurring in subacute thyroiditis or Hashimoto's thyroiditis. The condition is self-limiting, but some cases may go on to hypothyroidism, later becoming euthyroid. Specific antithyroid drugs may not be needed in many. Often beta-adrenergic blocking drugs are sufficient to control the symptoms.

Exophthalmos: There is no specific treatment for exophthalmos. During treatment of Graves' disease, the exophthalmos subsides in some, but in others it remains unchanged or worsens. The treatment of exophthalmos is only empirical since the pathogenesis is not fully understood. Radio-iodine treatment aggravates ophthalmopathy.

Irritation and watering of the eyes are benefited by the use of eyedrops containing corticosteroids, methyl cellulose or 5% guanethidine. Use of sun glasses with side shields and adoption of semi-upright position help to give further relief. Use of prismatic glasses helps to overcome diplopia. Injection of botulinum toxin to paralyse selected extraocular muscles has been tried as a measure to avoid diplopia. Diuretics are also beneficial in some cases.

MALIGNANT EXOPHTHALMOS

When exophthalmos is associated with reddening, edema and bulging of conjunctiva from under the lids and around the corneal limbus it is called malignant exophthalmos. If left untreated, this may lead on to corneal ulceration and blindness. This is also treated on the same line as for exophthalmos but prednisolone orally 90-120 mg daily is found to be beneficial. The eyes are protected from exposure keratitis by performing lateral tarsorrhaphy. Surgical decompression of the retro-orbital space (orbital decompression) is undertaken when the vision is threatened or papilledema develops. Irradiation of retro-orbital tissues may arrest the progression of exophthalmos and this is tried in severe cases where vision is in danger.

Fig. 98.2: Female thyrotoxicosis with exophthalmic ophthalmopathy

The dose required may be up to 2000 cGy given in 10-12 sittings. Plasmapheresis has been used as a temporary measure, with limited success (Fig. 98.2).

Long-term use of octreotide in a dose of 100-200µg daily by subcutaneous injection is beneficial in the management of troublesome exophthalmos.

Graves' ophthalmopathy is self-limiting. Once the active disease is controlled the orbital tissues undergo fibrosis, but full recovery may not occur.

Subclinical hyperthyroidism: This is defined as the condition in which the serum level of TSH is undetectable but with normal serum T4/T3. Subtle signs and symptoms of thyrotoxicosis may be present. Some patients may have atrial fibrillation. Even if asymptomatic, some authors advocate anti-thyroid medication to prevent future atrial fibrillation and osteoporosis, in addition to correcting the thyroid status, especially if the TSH levels are below 0.1µ unit/mL.

Hypothyroidism

Insufficient synthesis and release of thyroid hormones give rise to hypothyroidism. This may be congenital or acquired later in life. Congenital hypothyroidism leads to developmental abnormalities resulting in cretinism. When hypothyroidism occurs in juveniles or adults, a characteristic clinical picture develops in which there is accumulation of hydrophilic mucopolysaccharides in the ground substance of the dermis and several other tissues resulting in induration and coarsening of the skin and enlargement of organs like the tongue. This is called myxedema. Women are affected more with a 10% prevalence in adult women and 3% in adult men. Myxedema is associated with other autoimmune disorders like

diabetes mellitus, rheumatoid arthritis, and pernicious anemia.

There is another entity called subclinical hypothyroidism which is defined as mild TSH elevation with normal T3 and T4. They also may be symptomatic as florid hypothyroidism and they require treatment.

Causes of Hypothyroidism

Primary hypothyroidism—the thyroid gland is primarily at fault.

Non-goitrous

- Spontaneous atrophy (autoimmune)- Myxedema
- Congenital metabolic or other defects.
- Surgical removal or ^{131}I treatment.

Goitrous

- Dyshormonogenesis.
- Dietary iodine deficiency.
- Antithyroid drugs given to the mother during pregnancy.
- Drug induced: PAS, iodides, phenylbutazone, lithium carbonate, amiodarone and others and
- Hashimoto's disease.

Secondary hypothyroidism — In this condition the thyroid is normal but the regulating system is abnormal.

- Hypopituitarism
- Isolated TSH deficiency
- Abnormalities of the hypothalamus (neoplasm, sarcoidosis, encephalitis).

CLINICAL FEATURES

Clinical features of hypothyroidism depend on the age of onset of the disorder and the types.

Cretinism

The incidence of neonatal hypothyroidism in India is nearly 1 in 2500, whereas it has a worldwide incidence of 1 in 4000 on neonatal screening.

This results from hypofunction of the thyroid from birth. This may result from iodine deficiency occurring in endemic goiter belts. Babies born to hypothyroid women or those taking antithyroid drugs during pregnancy may develop cretinism. Though the abnormality is present at birth in many babies, symptoms manifest only after several months and, therefore, the condition may remain undetected in the newborn. The infant is dull and lethargic. Growth is retarded. Other features include large protruding tongue, broad flat nose, widely set eyes, sparse hair, dry skin, protuberant abdomen, and umbilical hernia. Abnormal persistence of physiological jaundice, croaky voice, constipation, somnolence and problems in feeding should raise the possibility of cretinism in the newborn. As the baby becomes older, retardation of growth and milestones become evident (Fig. 98.3).

Neurological abnormalities are prominent in some cases. These include deafness, spastic limbs, and at times,

Fig. 98.3: Cretin. Note: The retardation of growth and dull facies—normal of the same age for comparison on the right

coma. Mental development is severely retarded. If replacement thyroxine treatment is not given within the first 6-12 months, the newborn will lose 3-5 intelligence quotient (IQ) points every month from birth.

The appearance and ossification of several epiphyseal centers are delayed. Delay in the appearance of epiphyseal centers for carpal bones and delay in the eruption of teeth are useful diagnostic features to diagnose florid cretinism but for best results the diagnosis should be made much earlier with biochemical tests as early as possible in the child's life: Delay in diagnosis of even mild hypothyroidism in infancy leads to permanent impairment of the cognitive faculties in the child even though other functions may recover to varying degrees.

Treatment of Cretinism

The development of normal mental function in cretinism depends almost solely on the institution of treatment early in the neonatal period. Any delay in starting thyroid hormone replacement will lead to permanent disability. Therefore, the need to make an early diagnosis cannot be overemphasized. The dose for infants is 10-15 $\mu\text{g}/\text{kg}$ daily—the average infant may require 50 $\mu\text{g}/\text{day}$ and this may go up to even 0.1-0.2 mg/day as the child grows. The child's growth and bone development should be monitored by regular clinical and radiological examination. Undetected congenital hypothyroidism is one of the most frequent causes of remediable mental retardation in later life.

Routine estimation of TSH T4, and T3 in neonates is undertaken in many centers to exclude neonatal hypothyroidism. As a screening test, estimation of TSH

alone is carried out at times. The prospect for normal mental development is poor if treatment is not started before the first few months of life.

Myxedema

Primary hypothyroidism occurring in juveniles and adults leads to myxedema. Hypothyroidism is one of the common endocrine disorders seen in India.

CLINICAL FEATURES

Clinical features depend upon the degree of impairment of thyroid function and its duration. The onset is insidious and often unnoticed by the patient or relatives. Early manifestations include slowing of activities, lethargy, somnolence, constipation and generalized disinterestedness. Due to lowering of metabolism and accumulation of fluid and adipose tissue, considerable weight gain occurs. The patient becomes intolerant to cold and patient prefers to sit in the sun or near the fire. The hair is coarse, dry, and sparse. The scalp and eyebrows may become bald. The skin is lusterless, thick, and dry with scanty hair. Puffiness, coarseness and skin thickening are due to deposition of glucosaminoglycan. This is a diagnostic feature in a well developed case. The voice is croaky due to thickening of the vocal cords. Generalized non-pitting edema is common. Many show periorbital edema and macroglossia (Fig. 98.4).

Neurological features predominate in many cases.

Common presentations are slowness of mental and physical activity, slowed speech, muscle cramps, muscle hypertrophy, paresthesia and entrapment neuropathies.

Carpal tunnel syndrome is common. The tendon reflexes are altered. The relaxation phase is delayed. This abnormality is best seen in the ankle jerk. Nerve conduction velocity is reduced. Psychiatric disturbances (**myxedema madness**) are common. Unless treated early, severe cases go into somnolence, stupor, and coma.

Fig. 98.4: Myxedema: Male aged 50

Myxedema coma is precipitated by exposure to cold, infections, trauma or sedatives. Hypothermia and respiratory depression may develop. Sleep apnea may occur at times. **Myxedema coma** carries a high mortality rate.

Cerebellar dysfunction may develop, manifesting as truncal or limb ataxia and intention tremor. Unless hypothyroidism is kept in mind, these cases may be missed.

Cardiovascular manifestations include cardiomegaly, pericardial effusion, angina pectoris, mild or moderate hypertension, and predisposition to ischemic heart disease due to dyslipidemia. Cardiac failure is not uncommon.

Abnormalities of sexual function: Impotence occurs in men. Women may develop menorrhagia and girls may attain precocious puberty.

Hoffmann's syndrome: Muscle dysfunction is common in hypothyroidism. Hypertrophy of muscles associated with pseudomyotonia (slowness of contraction and relaxation) are features diagnostic of Hoffman's syndrome. Calf muscles are affected very frequently.

Pendred's syndrome: In this congenital condition, there is permanent deafness or deaf-mutism in addition to goitrous hypothyroidism. The defect is a block in the synthesis of thyroid hormone.

Laboratory Investigations

1. Both total and free serum T₃, and T₄, levels are low.
2. The TSH level is very high in primary hypothyroidism. Raised TSH level is the most readily available indicator for primary hypothyroidism. Levels of TSH above 20 mU/L and lowered levels of T₄ are virtually diagnostic. T₃ levels may be unreliable. TSH is low in pituitary or hypothalamic hypothyroidism. In hypothalamic hypothyroidism administration of TRH leads to the production of TSH and increase in T₄ and T₃ levels. Normal serum TSH is 0.4 to 4.0 μ U/L. TSH may be elevated in adrenal cortical (glucocorticoid) deficiency, renal failure and exposure to cold without hypothyroidism.
3. ¹³¹I uptake by the thyroid is low
4. Immunological markers: Titers of antithyroglobulin and antimicrosomal antibodies (TPO) are high, especially if the disease is of autoimmune origin. Antithyroid peroxidase antibodies are more consistently elevated.
5. Serum cholesterol level is raised above 300 mg/dL in many cases of myxedema. In pituitary hypothyroidism the cholesterol level is normal.
6. Creatine phosphokinase level is increased.
7. ECG shows slow rate, low voltage and ST and T wave changes.

The basal metabolic rate (BMR) is low. Since low BMR occurs in many other conditions, this finding is not specific and hence not used as a diagnostic test at present.

Diagnosis

Hypothyroidism should be suspected in all cases of rapid increase in weight without obvious edema, slowing of activity, tendency to fall asleep often, hoarseness of voice, recent onset of constipation and psychiatric disturbances, especially depression. Uncommon presentations include vague aches and pains, non-articular rheumatism, neurological phenomena such as carpal tunnel syndrome and cerebellar disturbances.

The clinical suspicion of hypothyroidism should be strong in all infants and children who fail to thrive and in whom milestones of development are delayed. Since hypothyroidism is a common cause of growth retardation in many communities in India, even a therapeutic trial with 0.05 mg thyroxine will not be out of place in areas where access to specialized endocrinology services are not available.

Differential Diagnosis

Myxedema has to be distinguished from other causes of edema such as nephrotic syndrome and chronic congestive cardiac failure.

Obesity due to any cause may mimic hypothyroidism. In many cases of obesity sub-clinical thyroid dysfunction may co-exist.

Secondary hypothyroidism which is caused by hypopituitarism is to be distinguished from primary hypothyroidism. In the former there is no myxedema, the skin is fine and hair is silky. There is no cardiomegaly. Evidence of hypo-adrenalcorticism and hypogonadism may be present in varying degrees. Diagnosis is established by estimating the level of TSH in serum, which is low in secondary hypothyroidism, and typically high in primary hypothyroidism. T3 and T4 are low. Functions of the adrenal cortex and gonads may also be affected frequently.

Course and Prognosis

The course of hypothyroidism is slowly progressive with fluctuations in thyroid function. Myxedema coma, ischemic heart disease or cardiac failure may prove fatal in some. Myxedema promptly responds to replacement therapy, but the condition recurs on cessation of medication. *Delay in instituting treatment in children results in permanent retardation of mental faculties, even though the physical and sexual characteristics may recover to variable extent with medication.*

Treatment

The principle of therapy is life-long replacement of thyroid hormone so as to produce full clinical remission and

achieve normal biochemical parameters as far as possible. Replacement therapy is started with synthetic **levothyroxine sodium (T4)**, available as 0.05 and 0.1 mg tablets given orally once or twice a day as required. The drug is freely available, cheap and free from serious side effects and very satisfactory for prolonged use. **Tri-iodothyronine (T3)** is available as tablets containing 25 µg. It is more rapid in action and, therefore, employed in emergency situations like myxedema coma.

Dosage Thyroxine is given in a dose of 1.6 µg/kg in adults orally as single daily doses. Average daily dose for adults is 0.1-0.2 mg of L- thyroxine sodium. T4 should be preferred for treatment of an ordinary case. T4 and T3 are available both for oral and parenteral use. In complicated myxedema, monitoring of treatment can be done by clinical assessment and TSH levels which should be kept at the lower levels of normal. When treating children, biochemical monitoring is necessary to achieve full success, whereas in the case of adults clinical assessment is adequate in most cases. But in those with co-existing lipid abnormalities, more meticulous correction of the hypothyroid state is beneficial. Failure to achieve full improvement with thyroxine supplementation should raise suspicion about concomitant diseases such as hypoadrenal corticism.

Since myxedema tends to be permanent, thyroid supplementation has to be life-long. With effective treatment the clinical abnormalities subside within 4-6 weeks, but they promptly return within weeks to months on stopping therapy. During periods of other intercurrent illness and other forms of stress thyroxine supplementation should not be interrupted.

In elderly subjects, due to the presence of co-existent ischemic heart disease, overdose of thyroxine may precipitate angina. It is essential to exclude ischemic heart disease by ECG before starting therapy. In the presence of ischemic heart disease the initial dose of thyroxine should be smaller and the optimum dosage has to be worked up. Hypothyroid subjects are very sensitive to exogenously administered thyroxine. Concurrent administration of beta blockers in doses which reduce the heart rate helps to avoid angina. The optimum dosage has to be worked out.

Overdose may lead to hyperthyroid symptoms.

Treatment of myxedema coma: Treatment of myxedema coma is a medical emergency. Coma is the result of a combination of factors such as heart failure, cerebral ischemia, hypothermia, and hypothyroidism.

The patient should be hospitalized. The drug of choice is tri-iodothyronine (T3) given IV in a dose of 20 µg stat and repeated 4 hours later. At present parenteral preparation of levothyroxine sodium is also available for use. The dose is 500 µg IV stat and thereafter, 100 µg/day. Hydrocortisone should be given along with thyroxine

replacement, in order to prevent hypoadrenal crisis and to help recovery from shock. The dose is 100 mg IV, 3-4 times a day. Dexamethasone 2 mg IV 6 h is a suitable alternative.

Supportive measures include gradual warm up of the patient, intravenous glucose drips, maintenance of proper ventilation and treatment of coexisting infections. Myxedema coma is a condition associated with high mortality and therefore best results are obtained if treatment is undertaken in well-equipped centers. If parenteral preparations of thyroxine are not available, administration of thyroxine through a nasogastric tube in doses of 0.1 mg three or four times a day is advised till the coma clears, and thereafter the dose is modified suitably.

Thyroid Hormone Resistance Syndrome (THRS)

This was first described in 1967. It is defined as an impaired response of the target tissues to thyroid hormone despite increased levels of T3 and T4, with normal TSH levels usually. These patients often present with symptoms of hypothyroidism. About 90% of THRS result from mutations in the gene encoding TR-B and mutant receptors have reduced affinity for T3 and are functionally deficient. Pattern of inheritance is autosomal dominant.

Three types have been described.

1. Generalised resistance to thyroid hormone by all tissues including the pituitary
2. Pituitary resistance to inhibition by thyroid hormone. TSH may be normal or increased in this type. Such patients may show thyrotoxic symptoms.
3. Selective peripheral tissue resistance to circulating thyroid hormone. They are clinically hypothyroid but T3, T4 and TSH levels are normal.

Treatment is difficult because thyroid hormone analogues designed to suppress TSH and relieve the hypothyroid symptoms lead to worsening of the cardiovascular manifestations.

All these patients may respond better to analogues of thyroxine. Patients with selective pituitary resistance may respond to dextrothyroxine or 3,5,3 tri-iodothyroacetic acid (TRIAC). It may be that a higher circulating concentration may initiate some degree of receptor binding to T4. Analogues of thyroid hormone with TR-B may eventually prove useful in treatment.

Ocreotide and bromocriptine are also used to suppress TSH secretion in patients with high TSH.

Thyroiditis

Acute Suppurative Thyroiditis

(Syn: Acute bacterial or pyogenic thyroiditis)

In general, the thyroid gland is resistant to suppuration on account of (1) its capsule (2) rich blood supply,

(3) rich lymphatic supply and (4) high iodine content. Pre-existing thyroid disease may predispose to suppuration.

Acute suppurative thyroiditis is caused by direct invasion by *pneumococcus*, *Staph. aureus* or *Str. hemolyticus*. Local symptoms include painful enlargement of the thyroid with other signs of acute inflammation. Clinical examination and ultrasonography will confirm the diagnosis. Systemic manifestations include fever and leucocytosis. Treatment is with appropriate antibiotics, sometimes requiring incision and drainage.

Subacute Thyroiditis

Mainly three forms are known:

1. Granulomatous thyroiditis
2. Lymphocytic thyroiditis, and
3. Postpartum thyroiditis

Chronic Thyroiditis

- a. Hashimoto's diseases, syn: Struma lymphomatosa
- b. Riedel's thyroiditis also known as Riedel's struma.

Subacute Granulomatous Thyroiditis

Syn: Giant cell thyroiditis, de Quervain's thyroiditis

It may follow an episode of upper respiratory infection. **Subacute granulomatous thyroiditis** is most probably viral in origin caused by Coxsackie, mumps or adenoviruses.

This is painful and the pain radiates to the mandible, neck or the ears. Low grade fever, myalgia and dysphagia may be present. 50% of patients show hyperthyroid features. The thyroid is tender, firm and asymmetrically enlarged. The ESR is elevated.

T4 and T3 levels are elevated, but radioactive iodine uptake is low. Antiviral antibodies may be demonstrable. Mainstay of treatment is to use analgesics and corticosteroids.

Initial dose of prednisolone is 10-20 mg tid for a few days, soon tapered off as a maintenance dose.

In the present AIDS era, *Pneumocystis carinii* thyroiditis which may occur in association with pneumocystis pneumonia has to be borne in mind.

Subacute Lymphocytic Thyroiditis or Painless Thyroiditis

Subacute lymphocytic thyroiditis is also known as silent or painless thyroiditis. This is characterised by an abrupt onset of hyperthyroidism, elevated T3 and T4 levels, low radioactive iodine uptake and a painless non-tender goiter. Autoimmunity is considered to be the cause and there is a high prevalence of thyroid autoantibodies in these patients. Viral antibodies are absent.

Since the hyperthyroidism is transient in both of these types, only beta-blockers are required to control hyperthyroid symptoms. Antithyroid drugs are not given.

Postpartum Thyroiditis

Thyroid dysfunction occurring within the first 6 months postpartum is called *postpartum thyroiditis* (PPT). The prevalence varies from 5-7%. PPT develops in 30-50% of women who have TPO antibodies. Most of the patients go into complete remission. PPT is twice as common in patients with type 1 diabetes mellitus and other autoimmune disorders compared to normals. Thyroid gland is enlarged and painless in the majority of cases, with elevated levels of T3/T4. Histology shows lymphocytic infiltration. Sometimes overt thyrotoxic symptoms develop. More than 80% of patients recover thyroid function within an year. Recurrence in subsequent pregnancies is common.

Unlike as in postpartum Graves' disease ^{131}I uptake is low in this condition.

Management

Thyrotoxic symptoms may have to be treated with beta adrenergic blockers. Later if hypothyroid symptoms develop, thyroxine has to be supplemented.

CHRONIC THYROIDITIS

Chronic Lymphocytic Thyroiditis

Syn: Hashimoto's disease-Autoimmune thyroiditis

Hashimoto's disease is an autoimmune disorder which has close relationship with Graves' disease. Autoimmune diseases like Sjögren's syndrome, pernicious anemia, myasthenia gravis and rheumatoid arthritis may co-exist. Other associations include MEN type II, POEMS syndrome, Turner's syndrome, Down's syndrome and Addison's disease. The peak incidence occurs in the fourth and fifth decades of life. Females are affected more than males.

The thyroid is diffusely enlarged, lobulated, firm or hard in consistency, and painless. More commonly it is associated with hypothyroidism. Rarely thyrotoxicosis may occur in Hashimoto's disease (**Hashitoxicosis**). The thyroid is infiltrated with lymphocytes. Large hyperplastic lymphoid follicles with germinal centers may be present. The thyroid cells tend to be slightly larger and have an acidophilic staining character (Hurthle or Askanazy cells).

The follicles contain very little colloid. Varying degrees of fibrosis may occur.

Most characteristic laboratory feature is the presence of high titers of circulating antibodies which include *anti-thyroglobulin antibodies* and *anti-microsomal antibodies*. Asymptomatic relatives of the patients may show low titers of the antibodies. Erythrocyte sedimentation rate is markedly elevated and serum gamma globulin is high.

Course: The condition may persist as such for many years. As a sequel, hypothyroidism may develop in many cases.

Treatment

Long-term suppressive medication with T4 in a dose of 0.1 - 0.2 mg daily leads to rapid resolution of the goiter.

Riedel's Thyroiditis

Syn: Fibrous thyroiditis; Woody Thyroiditis

This is extremely rare. The patients present with pressure symptoms due to the enlarged thyroid gland which is hard and immobile. 25% of patients may have hypothyroidism. Treatment is surgical removal.

Sick Euthyroid Syndrome

Trauma, stress and severe illness may induce alterations in the production, transport and metabolism of thyroid hormones especially the peripheral conversion of T4 to T3. The regulation of TSH secretion also becomes altered. These manifest as abnormalities of the serum levels of both bound and free T4, T3 and TSH. This condition is known as sick-euthyroid syndrome. The most consistent features are the low levels of T3 in the serum, with decreased, normal or elevated T4.

Different functional abnormalities may be encountered. Correction of the primary disorder helps to correct the thyroid dysfunction as well. The importance of recognizing this condition is to differentiate it from primary thyroid disorders.

Solitary Thyroid Nodule

Many patients may present with solitary thyroid nodule which demands investigation and appropriate management. Thyroid nodules may be solid or cystic. True solitary nodules may occur in 4 to 7% of the adult population.

Generally, functioning adenomas tend to be benign, whereas the chance of malignancy is more in the case of non-functioning nodules, often referred to as *cold nodules*, by isotope scanning. The problem is to distinguish benign lesions from malignant ones and to assess the functional status of the nodule. Clinical examination should include careful local examination of the thyroid, cervical lymph nodes, evidence for pressure effects on cervical structures, and mediastinal obstruction. Thyroid nodules occurring after irradiation of the neck may be papillary adenocarcinomas. Physical findings suggestive of malignancy include a firm or hard non-tender nodule, a recent history of mild or moderate enlargement, fixation to adjacent tissues and the presence of regional lymphadenopathy. Rapid painful enlargement occurring within days or weeks is suggestive more of hemorrhage into a nodule rather than malignancy.

Investigations should include ultrasonography, ^{131}I scintiscanning and fine-needle aspiration cytology (FNAC).

Solid nodules detected by ultrasonography are more likely to be malignant than cystic lesions. FNAC gives histological diagnosis in most of the cases. In case of doubt open biopsy of the nodule is required.

In order to distinguish whether a hyperfunctioning nodule is autonomous or thyrotropin dependent, tri-iodothyronine in a dose of 25 µg t.d.s is administered for five days and scintiscanning is repeated. Autonomous nodules are not suppressed.

Thyroid peroxidase cyto-immunochemistry with a monoclonal antibody (MOAb47) significantly increases the accuracy of FNAC in follicular lesions.

Treatment

The management of a solitary nodule is still a matter of controversy. Early surgery is recommended for solitary cold nodules and hard rapidly growing nodules. For normally functioning and non-autonomous nodules, a course of thyroid hormone 0.3 mg/day is given and in many cases the nodule may reduce in size. Thyroid hormone is of no use in the treatment of autonomous hyperfunctioning nodules. Such nodules can be irradiated with ¹³¹I given preferably after a course of T3 / T4 for 5 days. T3 suppresses iodine uptake by the normal tissue and thus ¹³¹I gets concentrated only in the autonomous nodule.

Autonomous thyroid adenomas may respond to local repeated injection of ethanol (0.4-2 mL) under ultrasonic guidance. Repeated injections may be necessary. Cystic nodular lesions require repeated aspiration followed by injection of sclerosing agents like tetracycline diluted in normal saline (100 mg/mL). Subcutaneous leakage may produce pain. Surgical removal is necessary if other measures fail.

Tumours of the Thyroid

Thyroid may be the seat of benign or malignant neoplasms. Most of the malignant tumours are primary, rarely metastases from the kidneys, breasts, and lungs may occur. Benign tumours are adenomas. Carcinomas are less common. They may be differentiated or undifferentiated. Irradiation to the tonsils, thymus, lungs or cervical lymph nodes during childhood may predispose to carcinoma of thyroid after a latent period of 10-20 years. Therapy with ¹³¹I has not been associated with increase in thyroid carcinoma, but follow-up of children in Marshall's islands where atomic bombs were tested and in the vicinity of the Chernobyl accident, external irradiation has been found to increase the incidence of papillary adenocarcinoma of the thyroid. Rarely thyroid may be the seat of lymphoma or sarcoma. The frequency of thyroid cancer is higher in females. It varies from 0.92-1.99% of cases in males and 0.9 to 5.71% in females. The highest

frequency in India is observed in Kerala State as compared to other states according to a publication of the National Cancer Registry Programme instituted by the ICMR (Tables 98.5 and 98.6).

85% of thyroid cancers in children are papillary type. The peak incidence of anaplastic carcinoma is in the 7th decade and it is characterized by rapid growth of tumour. Lymphomas of the thyroid gland can also occur, and almost always associated with Hashimoto's disease.

Treatment is by total thyroidectomy followed by ¹³¹I. This isotope has no role in the treatment of anaplastic carcinoma. In cases of thyroid cancer the five year survival rate is above 80%. Although the incidence of some forms of thyroid cancer is related to radiation, studies in Kerala did not show any relationship of thyroid cancer to the higher background irradiation from the monazite sands of Kerala sea shores.

Medullary carcinoma of thyroid: Around 10-15% of malignant lesions of the thyroid are medullary carcinomas. The disease may be familial. Relatives of patients may show elevation of serum calcitonin levels, if they are harbouring latent tumours. Medullary carcinoma arises from the 'C' cells or parafollicular cells. Metastasis is common. Elevation of serum calcitonin level is diagnostic in the presence of a palpable thyroid nodule. Medullary carcinoma may secrete serotonin, prostaglandins and even ACTH. Such cases are associated with flushing and diarrhea.

Medullary carcinoma may co-exist with other endocrine tumours multiple endocrine neoplasia (MEN) such as bilateral pheochromocytoma and hyperparathyroidism (MEN IIa and IIb).

Treatment consists of surgical removal of the carcinoma. Medullary carcinoma does not respond to ¹³¹I therapy.

99

Parathyroids and their Disorders

K.P. Poulse, B. Jayakumar

Chapter Summary

General Considerations 642
 Primary Hyperparathyroidism 644
 Secondary and Tertiary Hyperparathyroidism 647
 Hypoparathyroidism 648
 Pseudohypoparathyroidism (PSHP) 649

General Considerations

Collip identified the active principle of the parathyroid glands in 1924. There are two superior and two inferior parathyroids together weighing 120 mg. The superior parathyroids develop along with the thyroid and the inferior parathyroids develop along with the thymus. Twigs from the superior and inferior thyroid arteries supply the parathyroids. Aberrant parathyroids may be seen at the tracheoesophageal groove, substance of the thyroid gland or thymus, retroesophageal space, anterior mediastinum, surface of the pericardium, carotid bifurcation, jugular foramen or pharyngeal mucosa. The parenchyma consists of chief cells arranged in trabecular, alveolar or acinar patterns with mature fat cells interspersed. Parathyroid hormone (PTH) is secreted by chief cells. In addition the glands contain large polyhedral oxyphil cells with bright eosinophilic cytoplasm which appear after puberty. Pre and pro-parathyroid hormones are precursors formed during the synthesis of PTH.

Parathyroid hormone (parathormone): This is a single chain polypeptide having 84 amino acids. Parathyroid hormone is secreted as a pre-pro-hormone with 115 amino acid residues in the endoplasmic reticulum. It is converted into a prohormone containing 90 amino acid residues. The active hormone contains 84 amino acid residues. In circulation PTH is metabolised to biologically inactive fragments. The circulating PTH is a mixture of polypeptide chains of different biological activity. Therefore the biological activity does not correlate strictly

with the total levels of PTH. The secretion of PTH is controlled by several factors. Circulating ionised calcium exerts the major control on PTH secretion and release. Fall in ionised serum calcium stimulates, and rise inhibits PTH secretion. This reciprocal relationship is maintained as long as the serum calcium level ranges between 7 and 15 mg/dL (1.74 to 3.75 mmol/L; 1 mmol/L Ca = 4 mg/dL). Rise in serum phosphate stimulates PTH secretion indirectly by decreasing calcium levels. Extracellular magnesium concentration can also influence secretion of PTH. The half-life of PTH is less than 2 minutes.

Ninety-nine percent of total body calcium remains as hydroxyapatite in bones. In the plasma 50% of the circulating calcium is in ionised form (i.e. free calcium), 40% is protein bound and 10% is complexed with citrate and phosphate ions. Calcium and phosphorus constitute 65% of the weight of bones. Hypoalbuminemia is the commonest cause of hypocalcemia. Therefore it is necessary to estimate the levels of serum albumin along with serum calcium levels before a diagnosis of hypocalcemia is made.

Calcium homeostasis: Normal calcium concentration is essential for bone formation, blood coagulation, cardiac contractility, neural function and secretory activities. Calcium stabilizes biological membranes and serves as a co-factor in cellular reactions. The plasma calcium level is maintained within a narrow range of 9-11 mg/dL.

Actions of PTH: The ultimate effect of this hormone is to conserve body calcium and increase its level in extracellular fluid. It exerts its influence in several ways. The action is receptor mediated.

1. Parathyroid hormone increases calcium resorption from bone, and raises serum calcium.
2. It increases tubular reabsorption of calcium.
3. It increases absorption of calcium from the intestine.
4. It increases the renal excretion of phosphate and hydroxyproline, resulting in decreased plasma phosphate.
5. It enhances the formation of 1,25 (OH)₂D₃ (calcitriol) in the kidneys.

- 6. It increases the secretion of acid and pepsin in the stomach.
- 7. It activates the cyclic AMP-adenyl cyclase system in its target cells (PTH receptors in kidney, osteoblasts and intestines).

PTH acts on bones to modulate both osteoblastic and osteoclastic activity, thereby controlling both formation and resorption. PTH acts on bone to modulate osteoblastic activity directly, and osteoclastic activity indirectly. Only the osteoblasts have receptors for PTH. Indirect activity on the osteoclasts is brought about by releasing cytokines which activate the osteoclasts to increase bone resorption. PTH does not have any direct effect on the intestine. With excess of PTH levels as in hyperparathyroidism bone remodelling is increased and there is increased release of calcium resulting in hypercalcemia. Enhanced absorption of calcium and phosphate is due to increase in the levels of 1,25 (OH)₂ D₃ caused by increased formation of 1,25 (OH)₂ D₃ by the renal tubules under the action of PTH.

The net effect on bones depends on factors such as the bone involved, the dose of PTH and the duration of exposure. In small doses osteoblastic activity is promoted. Higher levels of parathyroid hormone result in increased osteoclastic activity in bone, inhibition of collagen formation by osteoblasts, and accelerated osteolysis. The net result is the resorption of bone with release of calcium, products of collagen breakdown and alkaline phosphatase into bloodstream. Kidney tubules possess PTH receptors. Parathyroid hormone acts on the kidneys to conserve calcium and eliminate phosphate, bicarbonate, and sodium. The net effect on bone depends on the complex interplay of PTH, vitamin D and renal function (Tables 99.1 and 99.2).

Tests of Parathyroid Function

Biochemical Studies

Serum calcium: In normal adults the total serum calcium level is maintained between 9 and 11 mg/dL, regardless of the intake. As age advances, serum calcium level

TABLE 99.1	
Showing the main actions of PTH	
1.	Increases bone resorption - Serum calcium increased
2.	Increases calcium reabsorption from distal nephrons—urinary calcium decreased
3.	Inhibits phosphate reabsorption from proximal tubules—urinary phosphate increased
4.	Increases calcium absorption from gut indirectly by stimulating the production of 1,25 Vit D ₃ from kidneys
5.	Osteoblastic activity—increased in smaller dose and shorter duration
6.	Osteoclastic activity—increased in larger doses on prolonged exposure

TABLE 99.2		
The actions of PTH, Vitamin D and calcitonin		
	Serum Ca	Serum PO ₄
PTH	↑	↓
Vitamin D	↑	↑
Calcitonin	↓	↓
Calcium absorption		Not under PTH influence

20-30%	Henle's loop	Under PTH influence
15-20%	Cortical distal nephrons	

gradually falls in men but it increases in women. Several factors affect serum calcium level. These are serum protein concentration, pH of blood, postural variations, and the actions of PTH and vitamin D. While interpreting serum calcium values, all these factors have to be taken into account. Ionized calcium levels in plasma usually range from 4-5 mg/dL. When serum albumin levels rise above normal, serum calcium levels also rise at the rate of 0.8 mg/dL for every 1 g of albumin/dL. While collecting blood for calcium estimation venous stasis should be avoided (i.e.) blood should be collected from a free-flowing vein.

Serum phosphorus: In adults, the level of serum phosphate ranges from 2.5-4.8 mg/dL. The levels are higher in children (5.0 ± 1.6 mg/dL). Serum phosphate level shows marked diurnal variation. Several factors such as serum protein levels, calcium, renal function, age, sex, and diets rich in carbohydrates influence serum phosphate level. Blood has to be collected in the fasting state for phosphorus estimation. In hyperparathyroidism, serum phosphorus is low. 85% of body phosphate is in bones and 15% either in the inorganic or organic form is distributed in the intra- and extracellular compartments. Phosphate is an integral part of nucleic acids, ATP, phospholipids and creatinine phosphokinase.

Serum alkaline phosphatase: Total serum alkaline phosphatase, especially bone alkaline phosphatase reflects bone turnover in metabolic bone diseases. The normal adult value is 30-110 international units/litre (3-13 KA units/dL). The isoenzyme bone alkaline phosphatase is elevated in osteoclast overactivity.

Parathyroid hormone (PTH) levels in serum can be estimated by RIA. In hyperparathyroidism PTH is elevated and in hypoparathyroidism it is reduced. Parathyroid hormone levels estimated by RIA may not reflect true biological activity since a part of the estimated hormone may not be biologically active. It is more advantageous to estimate PTH and ionised calcium simultaneously. Presence of high levels of PTH along with high calcium levels suggests abnormality of control mechanisms. Elevated PTH levels in the presence of low calcium levels

suggest pseudohypoparathyroidism. In magnesium deficiency also PTH levels are low.

Serum vitamin D: In healthy subjects, total vitamin D level is 35.0 ± 3.4 ng/mL, 25 OHD₃ is 28.5 ± 2.0 ng/mL and 1,25 (OH)₂D₃ is 35.0 ± 3 pg/mL. In hypoparathyroidism and chronic renal failure, circulating levels of 1,25 OHD₃ are low. Dietary intake of calcium and phosphate also influences serum vitamin D levels.

Serum electrolytes: Since PTH inhibits the tubular absorption of bicarbonate it may lead to renal tubular acidosis. Hypercalcemia of primary hyperparathyroidism is often associated with hyperchloremic acidosis. This feature helps to distinguish primary hyperparathyroidism from hypercalcemia occurring in bony metastases or hypervitaminosis D in which there is mild alkalosis.

Urinary calcium: In health more than 95.0% of filtered calcium is reabsorbed by the tubules. If the intake of calcium is steady, urinary loss of calcium is less than 3-4 mg/kg of ideal body weight in 24 hours. In hyperparathyroidism, with sustained hypercalcemia, the daily urinary loss of calcium exceeds 300 mg. This gives a positive *Sulkowitch test*.

Urinary phosphate: Parathyroid hormone facilitates the excretion of phosphates in urine. 88% of the filtered phosphate is reabsorbed in the proximal and distal tubules and only 12% is excreted. When the dietary intake of phosphates is 1-1.5 g/day, the daily urinary loss is less than 1 g. Dietary phosphate is mostly absorbed and it tends to raise serum phosphate level. The urinary excretion therefore varies directly with dietary intake. Normal phosphate clearance, determined by simultaneous measurement of urinary and serum phosphate is 10.8 ± 2.7 mL/minute. The tubular reabsorption of phosphates exceeds 75-85% of the filtered load. Tubular reabsorption is reduced in hyperparathyroidism and thereby phosphate clearance is increased at least by 50%.

Urinary hydroxyproline: Normal adults eliminate 15-42 mg of hydroxyproline in 24 hours. This is increased in hyperparathyroidism and osteomalacia. Other conditions in which urinary hydroxyproline is altered include growth spurt and bone resorption.

Urinary cyclic-AMP: Measurement of urinary c-AMP levels gives useful clues regarding parathyroid function. Normal adults excrete 10 micromoles of c-AMP in 24 h (1.8 to 4.5 nanomoles/dL of glomerular filtrate). In primary hyperparathyroidism, urinary c-AMP levels are high. Administration of PTH raises urinary c-AMP levels in normals. This response is absent in pseudohypoparathyroidism. Urinary c-AMP levels are elevated in hypercalcemia secondary to bony metastases.

Suppression tests: Tests to determine the suppressibility of PTH are employed to differentiate various hypercalcemic states from hyperparathyroidism.

Calcium infusion test: Calcium infusion suppresses normal parathyroid, but not autonomous parathyroid glands. Normally PTH level falls at the end of calcium infusion, 15 mg/kg body weight given over 4 hours and it remains low for 12 hours. Urinary phosphate excretion falls by more than 30% during the infusion.

Cortisone test: Oral administration of prednisolone in a dose of 30 mg/day for ten days suppresses serum calcium levels in non-parathyroid causes of hypercalcemia, but not in primary hyperparathyroidism. With the advent of newer imaging techniques, these suppression tests are seldom done.

Stimulation tests of parathyroid function: These tests are employed to distinguish hypoparathyroidism from pseudohypoparathyroidism.

Ellsworth-Howard test: Normal subjects respond to the administration of 200-400 USP units or 50-80 BPC units of PTH by increasing the urinary levels of phosphate and c-AMP by about 100%. Subjects with hypoparathyroidism show exaggerated increase in these parameters. In patients with pseudohypoparathyroidism, this response is blunted.

Indirect tests of parathyroid function include estimation of bone mineral density and isotopic bone scans.

1. **Estimation of bone mineral density** by radiography and dual energy X-ray absorptiometry (DEXA)
2. **Isotopic bone scans** using ^{99m}Technetium phosphate compounds.

Imaging the parathyroids: This can be done by subtraction techniques using ²⁰⁷Thallium chloride and ^{99m}Technetium pertechnetate radionuclides or imaging with ^{99m}Technetium sestamibi. Initial scan with Technetium delineates the thyroid. Thallium is taken up both by thyroid and parathyroids. Computerised subtraction techniques allow localization of parathyroids.

CT/MRI is also helpful. Selective venous blood sampling for PTH is also useful for localizing the source of abnormal function. Ultrasound neck is also helpful with a sensitivity of 80%.

Primary Hyperparathyroidism

When pathological hypersecretion of PTH occurs persistently, it results in hyperparathyroidism. It is characterized by hypercalcemia, hypophosphatemia, metabolic bone disease, recurrent nephrolithiasis, renal damage, peptic ulceration and other complications. Adult women are more affected than men. Peak incidence is in the sixth decade 2-3 times more in women. Rarely primary hyperparathyroidism may occur in neonates. A wide spectrum of severity ranging from an asymptomatic illness to fatal hypercalcemic crisis may be seen. Though hyperparathyroidism is one of the common endocrine disorders, many patients may remain asymptomatic.

Causes: The main causes are:

1. Benign adenoma of one parathyroid gland seen in 85% of cases.
2. Hyperplasia of all the parathyroid glands (15%) or
3. Carcinoma of one of the glands (1%).

In 85% of cases the lesion is an *adenoma* which may vary in weight from 0.5 to 5 g. Histologically, the adenoma is composed of chief cells in the vast majority, but at times oxyphil cells or mixed cells may predominate. Adenomas remain well-encapsulated within a rim of normal tissue. Ectopic foci for parathyroid adenomas include thymus, thyroid, pericardium or retroesophageal space.

About 15% of cases are due to diffuse or nodular hyperplasia affecting all or most of the parathyroid glands. *Carcinoma* is rare forming only about 1%. When present, it affects only one gland. The degree of malignancy is low. Adenoma or carcinoma may be part of the multiple endocrine neoplasia syndromes. MEN-1 (pituitary and pancreas) and MEN-11 (medullary carcinoma of thyroid and pheochromocytomas) are genetically mediated autosomal dominant disorders.

CLINICAL MANIFESTATIONS

Classic description of hyperparathyroidism is that it is a disease of bones, stones, abdominal groans and psychic moans. The presenting symptoms may vary depending on hypercalcemia, renal involvement, bone involvement or other complications. Sometimes a tumour may be palpable in the neck or visualized radiologically in the mediastinum.

Hypercalcemia: Hypercalcemia manifests in several ways. Common symptoms include lethargy, polyuria, polydipsia, drowsiness, confusion, weight loss, generalized muscle weakness, hypertension and autonomic dysfunction such as anorexia, uncontrolled vomiting and constipation. Proximal muscle weakness may be prominent. Severe cases go into stupor and coma. Long-standing hypercalcemia leads to metastatic calcification in the lungs, cornea, kidneys, blood vessels and other organs. The corneal lesion is *band keratopathy* in which calcium deposition is best demonstrated by slit lamp examination. Cardiac dysfunction occurs. Ventricular systole is shortened. Electrocardiogram shows shortened QT interval and other non-specific changes.

Skeletal manifestations: Osteitis fibrosa cystica or diffuse loss of bone tissue such as osteoporosis or osteomalacia may occur. Osteitis fibrosa cystica is accompanied by severe localized bone pain, marked deformities, and pathological fractures. In osteitis fibrosa, the bone trabeculae are reduced. There is increase in multinucleated osteoclasts and fibrovascular tissue. Radiological abnormalities of bone include subperiosteal erosion of cortical bone, demineralization, local destructive lesions such as cystic changes—(*bone cysts and brown tumours*) and calcification of fibrocartilage. The phalanges show

loss of bone tuft and subperiosteal erosions, and these are diagnostic. Acromioclavicular joints, symphysis pubis and sacroiliac joints also show similar changes. Osteopenia is seen characteristically as punched out and mottled areas in the skull (*pepper pot skull*). The lamina dura of the teeth is lost. Joints may show chondrocalcinosis and degenerative changes. With successful treatment of hyperparathyroidism all the radiological abnormalities clear up.

Renal manifestations: Nephrolithiasis, nephrocalcinosis, and disorders of glomerulotubular function are common in longstanding cases. Renal calculi are made up of a mixture of calcium oxalate and calcium phosphate. Renal stones tend to be recurrent. Hypercalcemia predisposes to urinary infection. Nephrocalcinosis is usually associated with bony changes such as osteitis fibrosa cystica. Glomerular filtration rate is reduced. Blood urea and serum creatinine are elevated. Tubular dysfunction also occurs. Correction of hypercalcemia reverses the functional defects in the kidneys.

Alimentary manifestations: Hypercalcemia increases gastric acid production and thus predisposes to peptic ulceration. Zollinger-Ellison syndrome may co-exist (multiple endocrine neoplasia type I). Hypercalcemia leads to chronic pancreatitis, pancreatic calcification or acute hemorrhagic pancreatitis.

Diagnosis

Primary hyperparathyroidism should be suspected in all cases of hypercalcemia, recurrent urinary calculi, osteitis fibrosa, peptic ulcer, pancreatitis, myopathy, chondrocalcinosis and vague constitutional symptoms. All cases presenting with dehydration, polydipsia, nocturia, anorexia, confusion, joint stiffness and hypertension, in which other causes are not evident, should also be investigated for primary hyperparathyroidism.

Biochemical tests: The diagnosis is confirmed by the presence of hypercalcemia and hypophosphatemia. Serum alkaline phosphatase and urinary hydroxyproline excretion are elevated. Urinary c-AMP excretion is elevated. Parathyroid hormone levels are elevated. Higher levels of 1.25 Vitamin D are also present.

Demonstration of tumour or hyperplasia: Large parathyroid tumours may produce indentation on the barium-filled esophagus, demonstrable by barium swallow examination. Ultrasonography, CT scan with contrast imaging and MRI demonstrate the lesion in most cases. Radioactive thallium technetium subtraction scanning may be employed to locate the tumour. Selective venous blood sampling from the neck and mediastinum to detect a gradient in PTH levels helps to assess the functional status of the lesion as well.

TABLE 99.3

Changes in blood levels of parathormone (PTH), serum calcium, phosphorus and creatinine in various parathyroid disorders

Diagnosis	PTH	Calcium	Phosphorus	Creatinine	Congenital abnormalities
Primary hyperparathyroidism	H	H	L	N	Nil
Secondary hyperparathyroidism	H	L/N	H	H	Nil
Tertiary hyperparathyroidism	H	H	H	H	Nil
Hypoparathyroidism	L	L	H	N	Nil
Pseudohypoparathyroidism	N/H	L	H	N	Present
Pseudopseudohypoparathyroidism	N	N	N	N	Present

Key: H: high, N: normal, L: low

Differential diagnosis: Primary hyperparathyroidism has to be distinguished from secondary hyperparathyroidism and all other causes of hypercalcemia. In secondary hyperparathyroidism, though PTH levels are high, serum calcium values are not elevated, but phosphate is elevated e.g. renal rickets.

Common causes of hypercalcemia are disseminated malignancy involving bone, hypervitaminosis D, thyrotoxicosis, Addison's disease and prolonged immobilisation. Rarely hypervitaminosis A, sarcoidosis, multiple myeloma and thiazide drugs may be the cause of hypercalcemia. Sometimes hypercalcemia runs in families (familial hypocalciuric hypercalcemia). This is due to an autosomal dominant mutation of calcium sensor that results in inappropriate secretion of PTH and enhanced renal calcium reabsorption. Idiopathic hypercalcemia is a rare disorder of infancy, often associated with congenital cardiovascular defects. Hypercalcemia of malignancy seen in bony metastasis and multiple myeloma is either due to local osteolytic lesions releasing cytokines like (IL6, and TNF β) which enhance bone reabsorption or due to release of PTH related polypeptide PTHrP which is a PTH like humoral factor (Table 99.3).

Prognosis

The course of hyperparathyroidism tends to be progressive. If detected and treated early, the condition subsides. Skeletal changes revert to normal but advanced renal lesions fail to clear up and, therefore, it is essential to start treatment before renal damage is established.

Treatment

Surgical removal of the adenoma is the treatment of choice. In the case of hyperplasia, all the glands are removed except for a portion of one gland which is left behind. All cases should be investigated for multiple endocrine

neoplasia and appropriate treatment is indicated if this is detected. Serum calcium level above 11 mg/dL, evidence of bone disease, recurrent renal stones, reduction of glomerular filtration rate below 60 mL/min and uncontrollable peptic ulcer are indications for early surgery.

After successful parathyroidectomy, the serum PTH falls by 50% within 10 minutes and the serum calcium falls to normal within 24-36 hours. This does not happen if surgical removal is inadequate. Some cases develop postoperative tetany due to hypocalcemia. This is managed by giving intravenous infusions of calcium gluconate or calcium chloride (1 mg/mL of fluid), the total dose and duration of therapy being decided by clinical progress. One ampoule of calcium gluconate contains 10 mL, each mL containing 137.5 mg of the drug. If hypocalcemia tends to persist, it is managed on the lines indicated for hypoparathyroidism.

At times magnesium deficiency may be the cause of postoperative tetany. Serum magnesium levels are low (normal values 0.7-1.2 mmol/L or 2-3 mg/dL). Mild cases respond to oral supplementation with magnesium chloride. In severe cases magnesium sulfate can be given intramuscularly repeatedly or as intravenous infusion lasting for 8-12 hours. The total dose is decided by the serum magnesium levels. A severe case may require 2 mmol/kg body weight. Magnesium sulphate is available as 20% solution or 50% solution. Parenteral magnesium therapy should be closely monitored, since serum levels above 4 mmol/litre lead to neuromuscular paralysis.

Medical treatment: Mild cases with moderate hypercalcemia, elderly patients, and those who are poor surgical risks have to be managed medically. In such cases the intake of calcium should be restricted to 200 mg or less by avoiding dairy products. Serum calcium can be lowered by the regular administration of potassium phosphate 1-2 g daily. The patient should be carefully followed up for

detecting metastatic calcification. Peptic ulceration should be managed on its own merits. Liberal intake of fluids (3.5-4.5 litres per day) and calcitonin injections at intervals help to reduce the risk of urinary calculi.

Acute Hypercalcemia and its Management

Normal serum calcium levels range around 2.6 mmol/L (10.4 mg/dL) when the serum albumin levels are normal, i.e. 4g/dL. Acute hypercalcemia usually results from hyperparathyroidism or disseminated secondaries in bones. Serum calcium levels above 3.5 mmol/L (14 mg/dL) lead to life-threatening situations demanding emergency management.

In hyperparathyroidism PTH is elevated. In bony secondaries PTH-related protein secreted by the tumour is elevated whereas PTH values are normal or reduced. Both PTH and PTH-related protein lead to resorption of bone by osteoclasts, increase in the renal tubular absorption of calcium and decrease in the reabsorption of sodium and water. As a result polyuria and dehydration develop. Clinical abnormalities are referable to gastrointestinal, cardiovascular, renal and central nervous systems.

Gastrointestinal symptoms	: Anorexia, nausea, vomiting, constipation and at times acute pancreatitis.
Cardiovascular system	: ECG abnormalities such as Q-T prolongation and increased sensitivity to digoxin.
Excretory system	: Polyuria, polydipsia, nephrocalcinosis and renal failure.
Central nervous system	: Apathy, drowsiness, confusion, coma.

Treatment

- 1. The patient is rehydrated by IV infusion of normal saline. Often 2.5-4 litres may be needed.
- 2. Frusemide given in a dose of 20-40 mg IV helps to increase urinary excretion of calcium. Thiazide diuretics are contraindicated since they enhance distal tubular absorption of calcium.

Drugs which Inhibit Osteoclast Activity

Calcitonin: Both salmon calcitonin and human calcitonin are available for use. Calcitonin is given in a dose of 4 MRC units/kg SC or I.M every 12 hours. It is rapid in action but weaker compared to bisphosphonates. If the response is inadequate the dose may be increased to 8 units/kg. Preparations for nasal spray IV and rectal use are also available.

Bisphosphonates: Etidronate, pamidronate and alendronate are available for use as oral or IV preparations.

Dosage:

Etidronate	7.5 mg/kg daily orally × 6 months
Pamidronate	15-45 mg I.V daily for 6 days
Alendronate	40 mg/day orally before food—10 mg tablets are available.

Other analogues such as ibandronate oral and zoledronate (IV) are also available at present. They also lower serum calcium levels. On a long-term basis they also suppress osteoclastic activity.

Mithramycin (Plicamycin) is given as IV infusion in a dose of 25 µg/kg over 4-6 hours. The serum calcium level starts falling within 12 hours of start of therapy and it continues to fall for 2-3 days. The effect of a single dose lasts for several days. Toxic side effects include nausea, thrombocytopenia and nephrotoxicity.

Sodium phosphate: This is given as IV infusion. Solution containing 11.5 g NaH₂PO₄ and 2.58 g KH₂PO₄/L is given IV as infusion in a volume of 500 mL over 4 hours. It reduces serum calcium level rapidly. Phosphate promotes the deposition of calcium in bones. Though it may be used in a life-threatening emergency, it is associated with adverse side effects.

Disodium acetate: Rapid IV infusion in a dose of 200 mg/kg over 30-60 minutes lowers serum calcium rapidly. Excessive dose should be avoided since it leads to hypocalcemia, tetany and coagulopathies.

Glucocorticoids: Hypercalcemia caused by lesions other than hyperparathyroidism temporarily responds to corticosteroids.

In life-threatening emergencies, calcium can be removed from the system by dialysis procedures using calcium free dialysing fluids.

Secondary and Tertiary Hyperparathyroidism

These are seen in conditions where there is resistance to the action of PTH. Increased levels of PTH are seen in the presence of persistent hypocalcemia. Increased secretion of PTH is the result of chronic stimulation by hypocalcemia.

Secondary hyperparathyroidism is seen in rickets, osteomalacia, malabsorption syndrome, chronic renal failure, and skeletal fluorosis. Removal of the primary cause early in the disease may correct the parathyroid dysfunction also but this is not invariably so. Though, in the initial stages the parathyroids are stimulated by hypocalcemia, later on, the glands become autonomous because of the development of adenomas. This condition is known as **tertiary hyperparathyroidism**.

Biochemical profile includes normal or low serum calcium with elevated serum phosphate. In tertiary hyperparathyroidism, serum calcium may rise. Bone changes are the result of excessive parathyroid activity and calcium deficiency. Serum alkaline phosphatase is high.

Therapy is intended to correct hypocalcemia which is the chronic stimulus for stimulation of the parathyroids. Surgical removal of the adenoma may be indicated in tertiary hyperparathyroidism.

Humoral Hypercalcemia of Malignancy

This refers to the condition in which PTH like substances (peptides or prostaglandins) are secreted by other tumours like carcinomas of the breast, kidneys, lungs and uterine cervix, lymphomas, and also leukemias. Often this leads to severe and fulminant hypercalcemia. Malignancies may also cause hypercalcemia by local bone destruction (e.g. myeloma, breast cancer) or by release of PTH related proteins (e.g. lung, kidneys, squamous cell cancers) or by activating lymphocytes to release interleukin 1 and tumour necrosis factor.

Hypoparathyroidism

Definition

Deficiency in the secretion of parathyroid hormone (PTH) leads to hypoparathyroidism. This is characterized by hypocalcemia, hyperphosphatemia and low levels of circulating PTH. The hyperphosphatemia leads to calcification of the basal ganglia in 50% of cases. Soft tissue calcification may also occur.

Etiology

1. Accidental surgical removal of parathyroids or interference with their blood supply during surgery in the neck.
2. Idiopathic atrophy of the parathyroids.
3. Destruction of the parathyroid by carcinomatous secondaries, infarction, radioiodine therapy or irradiation of the neck.
4. Neonatal hypoparathyroidism may occur as a transient phenomenon in premature infants and infants of mothers with hyperparathyroidism or diabetes mellitus.
5. Autoimmune hypoparathyroidism.
6. Developmental defects as in DiGeorge syndrome.
7. Rare causes- hemochromatosis, Wilson's disease with copper deposition in the parathyroids.
8. Hypomagnesemia.

Postoperative hypoparathyroidism may be transient or permanent. Idiopathic hypoparathyroidism may run in families. It may be associated with other congenital abnormalities involving maldevelopment of the third and fourth pharyngeal pouches such as **DiGeorge syndrome**

in which the thymus and parathyroids are absent. Other immune-mediated endocrinopathies such as Addison's disease, hypothyroidism, hypofunction of ovaries, and pernicious anemia may coexist. Antibodies against parathyroids and other organ specific antibodies may be present.

Clinical Manifestations

Clinical features depend upon the onset, duration and the severity of hypocalcemia. Prominent features include tetany, dental abnormalities, subcapsular cataracts, myocardial dysfunction and neurological abnormalities.

Tetany is due to hypocalcemia. It manifests as muscle cramps, paresthesia of the hands, feet and mouth, *spasmophilia* (*carpopedal spasm*, *bronchospasm* and *laryngospasm*) and severe neuromuscular irritability. Physical exertion, emotional stress, hyperventilation, vomiting, and ischemia to the limb may precipitate *tetany*. In less severe and chronic forms of hypocalcemia tetany may remain latent.

Latent tetany can be identified by eliciting the *Chvostek's sign*, *Trousseau's sign*, and also by *electromyography*. Hyperexcitability of the facial muscles manifesting as contraction of the facial muscles on gentle tapping over the facial nerve in front of the tragus of the ear is the *Chvostek's sign*. *Trousseau's sign* is elicited by making the forearm ischemic by applying a sphygmomanometer cuff to the arm and keeping the pressure above systolic blood pressure for five minutes. The hand goes into painful carpopedal spasm and assumes the *accoucheur's hand position*. Laryngeal spasm gives rise to inspiratory dyspnea or stridor (*laryngismus stridulus*).

Hypocalcemic tetany has to be differentiated from tetany occurring in alkalosis, hypokalemia and hypomagnesemia. When serum magnesium falls below 0.8 mmol/L PTH secretion is depressed and this leads to secondary hypoparathyroidism. Parenteral replacement of magnesium restores parathyroid function.

Common neurological manifestations of hypocalcemia include convulsions which are unresponsive to conventional anticonvulsant therapy, paresthesia and psychiatric behaviour. Other manifestations such as papilledema and extrapyramidal disturbances like chorea, parkinsonism, and athetosis may develop. Soft tissue and basal ganglia calcification can occur.

The skin is dry and scaly. The hair is brittle and coarse. Deformity and moniliasis of the nails are common. The enamel of the teeth is pitted, dental roots are short and blunt, and early loss of teeth is common. Subcapsular posterior or anterior zonular cataracts develop.

Cardiac abnormalities may occur. Chronic hypocalcemia may lead to cardiac failure and tetany. Diuretics further aggravate the hypocalcemia. The electrocardiogram shows prolonged QT interval. The acute manifestations of hypo-

parathyroidism are corrected dramatically by the intravenous administration of calcium. Intravenous administration of 10% calcium gluconate, calcitriol and oral maintenance doses of calcium gluconate restore cardiac function.

Diagnosis

Presence of hypocalcemia with hyperphosphatemia should arouse suspicion of hypoparathyroidism, if renal disease can be excluded. Other causes of hypocalcemia are rickets, malabsorption states, hypoproteinemia, acute pancreatitis, and extreme dietary deficiency of calcium. The total serum calcium is low in hypoproteinemia since the fraction bound to albumin is reduced, even though the ionized calcium is kept normal. Tetany does not occur in this condition. In acute pancreatitis transient hypocalcemia develops which is self-limiting. In rickets and osteomalacia both calcium and phosphorus are low. Diagnosis of hypoparathyroidism can be confirmed by demonstrating low levels or absence of PTH. The response to therapeutic administration of PTH is dramatic.

Pseudohypoparathyroidism (PSHP)

Syn: PTH resistance syndrome

The term *pseudohypoparathyroidism* refers to the condition in which the target tissues become resistant to the action of PTH. As a result, there is overactivity and hyperplasia of the parathyroids with excessive secretion of PTH. In spite of the raised blood levels of PTH, the clinical and biochemical features are those of hypoparathyroidism. In most cases it is an inherited disorder associated with short stature, brachydactyly, round face, obesity and webbing of the neck. Vitamin D deficiency, hypomagnesemia, chronic renal failure, and other renal tubular defects give rise to PTH resistance.

This is characterised by biochemical features of genuine hypoparathyroidism with elevated PTH levels. In the two major forms of this (Type 1 and Type II) disorder, correction of hypocalcemia results in alteration of symptoms and suppression of PTH levels, however the resistance continues. The common disorder PSHP type Ia is characterised by short stature, brachydactyly, round facies, obesity, short fourth metacarpal bone, webbing of the neck, mental retardation, and subcutaneous calcification. The term *Albright's hereditary osteodystrophy (AHO)* has been used to describe the somatic features of Type Ia. This is due to defective functioning of guanine nucleoside coupling protein (GS protein). These patients may also have resistance to other hormones like TSH, glucagons, LH and ADH. Diagnosis is made by estimation of GS protein in red cells. In Type Ib PSHP the somatic features of Type Ia are absent. Several other types of PSHP like Type II have been described.

Pseudopseudohypoparathyroidism Some of the relatives of subjects with pseudohypoparathyroidism show skeletal changes, but none of the biochemical abnormalities of hypoparathyroidism. This condition is called pseudopseudohypoparathyroidism.

Treatment of hypoparathyroidism Aim of treatment is to normalize serum calcium levels without increasing urinary loss. Though correction of hypocalcemia is easy, in the absence of PTH, considerably large amounts of calcium are lost in urine. Therefore, even with low-normal levels of serum calcium, nephrolithiasis may develop. Intestinal absorption of calcium can be enhanced by the administration of vitamin D. This corrects hypocalcemia, but not other metabolic abnormalities. It is desirable to keep serum calcium levels between 8.5 and 9 mg/dL by adjusting the dose of vitamin D. Several preparations are available. Vitamin D₂ 50,000 to 100,000 U/day or the metabolically active product 1-25(OH)₂ cholecalciferol (calcitriol) in doses of 0.25-0.5 µg given orally daily helps to improve serum calcium level. Result of vitamin D₃ therapy is not always predictable, since individual variations are common. Vitamin D preparations take a few weeks to exert their full effect. Loss of control may develop even after long periods of satisfactory control. Along with vitamin D₃, approximately 1.0 g of elemental calcium should be provided in the diet. This will be provided by 2.5 g calcium carbonate, 3g calcium chloride, 8 g calcium lactate or 11 g of calcium gluconate. Hypomagnesemia confers resistance to vitamin D which clears up on supplementation of magnesium orally or parenterally.

Treatment of tetany: Slow intravenous injection of 20 mL of 10% calcium gluconate solution promptly relieves tetany. The relief is maintained by giving an intravenous drip containing calcium gluconate 15 mg/kg body weight. Intravenous calcium injection is quite safe even though it may cause a feeling of heat over the body, which could be disturbing to the patient, unless informed beforehand. In subjects receiving digitalis therapy it may precipitate fatal arrhythmias like ventricular fibrillation. Supplementation of oral calcium carbonate or gluconate along with alpha calcidol serves to increase serum calcium on long term basis.

Alkalotic Tetany

In hysterical subjects who hyperventilate, alkalotic tetany may develop. Alkalosis enhances neuromuscular excitability. This can be prevented by the inhalation of 5% carbon dioxide or re-breathing into the same bag. For tetany due to metabolic alkalosis infusion of isotonic saline is the most effective measure. In alkalosis produced by the excessive administration of alkalis, relief is obtained by giving ammonium chloride orally in a dose of 2 g 6 h.

Introduction

The adrenal glands are two paired glands, which produce hormones necessary for metabolism as well as hemodynamic stability. Several disorders of the adrenals exist, and these range from autoimmune adrenal damage to neoplastic transformations of the glands.

Basic Considerations

Anatomy: The adrenals are paired glands each weighing about 4.7 g. Section of the gland shows an outer cortex and inner medulla. Histologically, three zones are visible in the cortex; the zona glomerulosa, zona fasciculata and zona reticularis from without inwards (Fig. 100.1). The arterial supply is derived from several branches of the phrenic, renal, ovarian or spermatic arteries and aorta. Venous drainage on the left is into the left renal vein and on the right to the inferior vena cava.

Embryology: The fetal adrenal cortex is formed during the fourth to sixth week of gestation from the celomic mesoderm of the posterior abdominal wall. The permanent adrenal cortex is formed from the small basophilic cells, which appear five weeks later. The adrenal medulla develops in the seventh week from sympathogonia that

migrate from the neural crest into the fetal adrenal cortex. The adrenals are relatively bigger at birth, but with the passage of time the size reduces since the inner zone of acidophilic cells undergo involution.

Physiology: Several hormones are produced by the adrenal cortex. The cortex synthesizes cholesterol and also takes cholesterol from the circulation for the production of its hormones. Synthesis of hormones takes place in several steps. The trophic hormone produced by the anterior pituitary-adrenocorticotrophic hormone (ACTH) stimulates the adrenal cortex to secrete hormones. Adrenal medulla secretes adrenaline and noradrenaline.

Adrenocorticotrophic hormone (ACTH) secreted by the anterior pituitary stimulates secretion of adrenal cortical hormones (glucocorticoids and sex hormones) by acting on specific receptors present on the adrenal cortex through the mechanism of c-AMP (Fig. 100.2).

Steroid hormone secretion, role of ACTH, transport and metabolism: The secretion of cortisol (the most physiologically important steroid hormone) occurs only in response to stimulation by ACTH. In health the levels of cortisol are highest in the morning. Plasma cortisol reciprocally influences adrenocorticotrophic hormone, i.e. higher cortisol levels inhibit and lower levels stimulate production of ACTH and also stimulate the melanocytes and activates tissue lipase. Within 2-3 hours of falling asleep the ACTH levels progressively rise and reach the highest level about an hour or so before waking up. During waking hours ACTH levels progressively fall to reach the minimum before falling asleep. The secretion of ACTH and cortisol is increased in response to different stress factors such as trauma, fever, surgery, hypoglycemia, severe anxiety, and several others. The circadian rhythm disappears during periods of stress and in adrenal tumors.

About 75% of cortisol circulates in blood bound to transcortin, which is a glycoprotein. 15% is loosely bound to albumin and 10% circulate in the free state unbound and the latter accounts for the metabolic activities of the hormone. When plasma cortisol level is high (e.g. Cushing's syndrome), plasma transcortin is saturated and

Fig. 100.1: A diagrammatic representation of the layers of the adrenal gland

Fig. 100.2: Diagram showing the hypothalamic-pituitary axis controlling the adrenal gland. Note the feedback loops that exist; CRH-corticotrophin-releasing hormone, ACTH-adrenocorticotrophic hormone. Broken lines indicate negative feedback loops

the level of unbound cortisol increases. This appears in excessive amounts in urine. Steroid hormones are inactivated mainly in the liver. Other tissues such as muscles, skin, fibroblasts, intestine and lymphocytes also metabolize them.

ADRENAL CORTICAL HORMONES

Based on their main functional activity, cortical hormones can be grouped as glucocorticoids, mineralocorticoids, and sex hormones (androgens and estrogens). Glucocorticoids are secreted by zona fasciculata, mineralocorticoids by zona glomerulosa and sex hormones by zona reticularis

TABLE 100.1

Secretory rates of adrenal cortical hormones

Adrenal cortical hormones	Secretory rate in mg/24 h
Cortisol (hydrocortisone)	12-30
Corticosterone	1-4
Aldosterone	0.05-0.15
Deoxycorticosterone	0.05-0.2
Dehydroepiandrosterone	15-50

(Table 100.1 and Fig. 100.2). The adrenal medulla produces the catecholamines, adrenaline and noradrenaline.

Glucocorticoids: The important members of this group are cortisol (hydrocortisone), corticosterone and 11-dehydrocorticosterone. Normal cortisol level at 8 AM is 140-700 nmol/L (5-25 mcg/dL) and it falls to 0.8 mcg/dL at midnight, highest concentration is around 4 AM.

Glucocorticoids promote gluconeogenesis and lead to hyperglycemia. Other major effects include increase of protein catabolism, suppression of ACTH, anti-inflammatory and anti-allergic action, immunosuppressant effects and reduction in the size of circulating lymphocyte pool and lymphatic organs (lympholysis). In addition, glucocorticoids exert minor effects such as induction of several enzymes, stimulation of hematopoiesis, fat deposition over the trunk, uricosuria, elimination of water load, production of a feeling of well being, reduction in circulating eosinophils and maintenance of the capacity

for muscular work. Glucocorticoids are used therapeutically for replacement therapy and in many other conditions. Several synthetic analogues are available for therapeutic use.

Mineralocorticoids: Aldosterone is the most important member in this group, the other being deoxycorticosterone (DOC). These exert their main action on epithelial membranes of the skin, gastrointestinal tract and kidney. The main action is conservation of sodium and chloride and elimination of potassium. Excessive activity of these hormones causes retention of sodium and chloride, edema and potassium loss. Aldosterone secretion is stimulated by angiotensin II which is the final product of the renin angiotensin system initiated by the afferent arterioles of the renal glomeruli. ACTH does not exert any appreciable effect on the secretion of aldosterone.

Details of the rennin-angiotensin system are given in chapter 168.

All available preparations of adrenocortical hormones are synthetic products. Comparison of the potency of natural and synthetic corticosteroids (for equivalent dose) is given in Table 100.2. Betamethasone and dexamethasone differ structurally by a single methyl group and hence their pharmacological effects are also slightly different. Both have the same bioavailability. Betamethasone has a longer half-life and larger volume distribution.

Sex hormones: Adrenal cortex secretes sex steroids (both androgens and estrogens), which are small in amount compared to the secretion of gonads. Under normal conditions they play only a minor role in the development of secondary sex characters. When the secretion is increased under pathological conditions, they may produce virilization and less commonly feminization, which is more evident in the male. Adrenal estrogen-secreting tumours can lead to gynecomastia in males and precocious puberty in girls. In adult women, excessive secretion of adrenal androgens leads to amenorrhea, hirsutism and infertility.

TABLE 100.2

The relative potency of the different corticosteroid for mutations

Steroid preparation	Glucocorticoid activity	Mineralocorticoid activity
Cortisol (Hydrocortisone)	1	1
Cortisone	0.7	0.7
Aldosterone	0.3	300
Fludrocortisone	-	125
Prednisolone	4	0.25
Dexamethasone	25	< 0.1
Betamethasone	25	< 0.1
Triamcinolone/methyl prednisolone	5	< 0.1

Investigation of Adrenal Cortical Disorders

Serum Cortisol: This is the simplest examination, and can be carried out by radioimmunoassay (RIA). The test results depend on the time of sampling. Normally, serum cortisol levels are highest early in the day, and then decline over a period of time to reach a nadir in the late night. If measured at 8.00 am, the normal cortisol levels in the serum range from 5 to 25 µg/dL. However, if measured at 4.00 pm, the normal values would range from 2 to 8 µg/dL. At midnight, for instance, the serum cortisol levels are expected to be below 5 µg/dL. This circadian variability of normal cortisol values is useful in the diagnosis of states of cortisol excess, i.e. endogenous Cushing's syndrome. In this situation, there is a continuous, non-circadian production of cortisol from the adrenal glands and thus the evening cortisol value could be above normal, sometimes even higher than the morning cortisol value.

Urinary cortisol: Level of free cortisol excreted in urine depends on the plasma level of unbound cortisol. Normal range is 55-193 nmol (20-70 µg) in 24 h. This is a very sensitive test for the diagnosis of Cushing's syndrome in which the urinary cortisol is increased.

Aldosterone and its derivatives: Normal plasma concentration estimated by RIA is 10 ng/dL, and the urinary excretion is 5-19 µg/day.

Secretory activity of the adrenal cortex: Cortisol secretory rate can be determined isotopically. Normal value is 250-840 µmol/24 h (i.e.) 150-30 mg cortisol in 24 hours.

Other hormones: Dehydroepiandrosterone sulphate (DHEAS) can be estimated by RIA. The values of DHEAS are extremely high if there is a DHEAS-producing adrenal tumour. DHEAS estimation helps to differentiate androgen secretory tumour of adrenal from that of an ovarian tumour.

ACTH Testing: This is a useful test to detect the adrenal reserve. While a simple serum cortisol level might suffice to pick up adrenal insufficiency, if the value is less than 3 µg/dL at 8 am, many a time the serum cortisol level could be normal, but the adrenal may be damaged, and might therefore lack the capacity to augment the adrenal secretion in response to stress or conditions of increased hormone requirement. In order to pick up these cases, where the adrenal reserve capacity is compromised, ACTH testing is useful. The estimation of plasma and/or urinary steroids before and after ACTH administration reveals the responsiveness of the adrenal cortex to ACTH. A simple method is to administer 250 µg of synthetic ACTH (Synacthen) intramuscularly and to sample serum cortisol at 30 minutes and 60 minutes. Levels greater than 20 µg/dL exclude impairment of adrenal reserve (double the base line value).

TABLE 100.3

Interpretation of diagnostic tests in hyperadrenocortical states

Test	Normal subjects	Pituitary cause (Cushing's disease)	Adrenal tumour and hyperplasia	Ectopic ACTH production
Urinary 17 KGS	Normal	H	H	H
Plasma ACTH	Normal	H	L	H
Suppression by Dexamethasone 1 mg screening test	Suppression of plasma cortisol	No suppression	No suppression	Nil
2 mg/day × 3 days	Suppression	No suppression	Nil	Nil
8 mg/day × 2 days	Suppression	Suppression	No suppression (tumour) Suppression (hyperplasia)	No suppression

Dexamethasone suppression test (DST): Exogenous or endogenous glucocorticoids normally suppress ACTH secretion. This feedback inhibition is lost in Cushing's syndrome. Dexamethasone is given in a dose of 0.5 mg 6h for 2 days. Urinary 17-OHCS comes down below 2.5 mg/day in normals and plasma cortisol falls below 2 mg/dL on the second day of the test. In the overnight version of the dexamethasone suppression test (*o-DST*) plasma cortisol is estimated at 8 am after taking 1 mg of dexamethasone during the previous night at 11 pm. If plasma cortisol is less than 5 µg/L Cushing's syndrome can be excluded. Several other modifications of this test are available at present. Normal subjects show prompt suppression even when small doses of dexamethasone (single dose of 1 mg) are administered. In adrenal hyperplasia, suppression can be achieved only with higher doses (8 mg/day for 2 days) while in the case of adrenal adenoma, carcinoma and ectopic sources of ACTH, cortisol production is not suppressed even by higher dose of dexamethasone. After the estimation of basal cortisol values, in the high dose, DST 2 mg dexamethasone is given every 6 hours for 2 days and cortisol estimations are repeated and in the overnight high dose DST, 8 mg of dexamethasone is given at 11 pm and serum cortisol measured at 8.00 am on the next day: Values more than 50% of the basal value indicate non-suppression (Table 100.3).

Demonstration of the lesion: Adrenals can be visualized radiologically especially if they are calcified. In many cases the tumors are 4 to 6 cm in diameter by the time they show endocrine abnormalities. Adrenals can be well visualized by CT scanning and MRI and these should be done to demonstrate the anatomy of the gland. Even much small tumours can be visualized. Isotope scanning after administration of ^{123}I or ^{131}I metaiodobenzyl guanidine (MIBG) helps to show up the adrenals. Sampling of blood from the adrenal veins helps to identify the abnormal gland in cases where there is a difficulty in localizing

which adrenal (right or left) is the source of excess hormone production.

Diseases of the Adrenal Cortex

CUSHING'S SYNDROME

Syn: Hypercortisolism

Hypercortisolism may develop either due to primary disease of the adrenal cortex such as adenoma, carcinoma or hyperplasia or due to stimulation of the gland by ACTH secreted by the pituitary or ectopic ACTH-like substances produced as paraneoplastic processes. The term **Cushing's disease** refers specifically to the pituitary dependent hyperadrenal corticism. In addition corticosteroids administered therapeutically can give rise to iatrogenic Cushing's syndrome.

Cushing's syndrome is caused by persistent over secretion of glucocorticoids. In addition to increased levels of cortisol in blood, loss of the normal diurnal rhythm is also a prominent feature.

Causes of Cushing's Syndrome

- Pituitary Cushing _ ACTH dependent
- Adrenal Cushing – non-ACTH dependent
- Ectopic Cushing – ACTH or ACTH like substances dependent
- Iatrogenic Cushing – Externally administered glucocorticoids (Table 100.4).

Clinical Features

The symptoms are mainly due to excessive production of glucocorticoids. Almost all features can be attributed to gluconeogenesis, excessive protein catabolism and androgenic effects of cortisol.

General features: The affected subject is plethoric with rounded appearance of the face (moon face). There is a characteristic obesity with deposition of fat over the neck, shoulders, abdomen, and hips. Often, this results in a

TABLE 100.4

The etiology of Cushing's syndrome

ACTH-dependent causes:

Bilateral adrenal hyperplasia: 70% of these are secondary to a small adenoma involving the basophils (Cushing's disease) or chromophobes in the pituitary. Sometimes the abnormality is in the production and release of CRF from the hypothalamus.

Ectopic ACTH secretion: This is seen as a paraneoplastic syndrome in bronchogenic carcinoma, medullary carcinoma of thyroid, carcinoids, pancreatic carcinoma, ovarian carcinoma, neuroblastoma and ganglioma.

ACTH –independent causes:

1. **Adenomas or carcinomas** of the adrenal cortex and micronodular hyperplasia.
2. **Iatrogenic:** Use of physiological or pharmacological doses of glucocorticoids over prolonged periods.

Cushing's syndrome is not uncommon in India. It has been reported from all parts of the country. Pituitary-dependant adrenal hyperplasia and adrenal tumours are more frequent in women in the fourth and fifth decades.

typical crest of fat on the nape of the neck, and this is referred to as “**buffalo hump**” (Fig. 100.3).

The integument: Hirsutism develops in many cases and it is particularly disturbing in women. Face, chest, and other regions are affected most. Acne may develop. The hairline may recede over the temporal regions (temporal baldness) or even general baldness may result. Skin shows painless striae, which develop as reddish streaks over the thighs, gluteal regions, abdomen, axillae, and outer aspect of the arms. Striae are formed as a result of rupture of subcutaneous collagenous tissue. In severe cases the overlying skin may be stretched and thinned out and it tends to rupture and ulcerate. Repair of wounds is considerably delayed. Wound dehiscence is common after surgery. Scar formation is poor. Bruising, purpura, and melanotic pigmentation are seen in some cases. Some cases show secondary polycythemia (Fig. 100.4).

Other features: Hypertension and its complications are common. Muscles are easily fatigable, flabby and atrophic. Proximal muscles show myopathic changes. Psychiatric symptoms like depression and melancholia may be the presenting features in some. Amenorrhea and clitoromegaly develop in women. In women with over-production of androgen hormones infertility may occur. Males show loss of libido and impotence. Bones show osteoporosis, which is more prominent in the axial skeleton. Fractures are common (Fig. 100.5).

Biochemical abnormalities: Secondary diabetes develops in many of these patients. Hypokalemia, and fluid retention may develop.

Pituitary Cushing's Syndrome (Cushing's Disease):

This is the common variety of Cushing's syndrome, next

Fig. 100.3: Cushing's syndrome. Note: truncal obesity and buffalo hump (arrow)

Fig. 100.4: Cushing's syndrome: striae on abdominal wall (arrow)

Fig. 100.5: Cushing's syndrome osteoporosis: Compression fracture of vertebra (arrow)

only to iatrogenic Cushing's syndrome. Usually it is caused by pituitary microadenoma. Insidiously developing diabetes, hypertension and cushingoid habitus, with mild hyperpigmentation are characteristic. Rarely pituitary macroadenoma (>1 cm in size) may occur and in this situation, features of tumour enlargement like visual field defects and headache may be present.

Carcinoma of the adrenal cortex: These tumours are rapidly progressive with local invasion and distant

metastases early in their course. Some tumours do not produce hormones whereas others produce both cortisol and sex hormones. Over 80% of estrogen-producing tumours are malignant.

Iatrogenic Cushing's syndrome: This may occur at all ages in both sexes but it is more prominent in young adults. Daily administration of 5-10 mg or more of prednisolone or its equivalent for a period of more than 3-6 months can give rise to Cushing's syndrome. Though it was considered that only moderate or high doses of glucocorticoids led to hypercortisolism now it is known that even small doses given as aerosols or surface applications can, at times lead to the condition, on prolonged use. The full-fledged case resembles classic Cushing's syndrome. The clinical features are variable in many cases. Regression of symptoms occurs within months of withdrawal of the drug, but established diabetes may not clear up promptly, especially so if there is a family history of diabetes.

Ectopic ACTH secretion: Carcinomas of the bronchus, neural tissue, ovaries and gastrointestinal tract may give rise to ACTH like substances. This syndrome is seen more in older age groups. It is characterized by rapidly developing pigmentation, hypokalemia, and marked alkalosis. In many the complete picture of Cushing's syndrome may not develop. Cushing's syndrome may be the presenting condition in many neoplasms. The primary lesion may not be evident at the beginning but in some cases clinical features produced by the primary lesion may also occur simultaneously. Presence of digital clubbing and osteoarthropathy in any case of Cushing's syndrome, should suggest pulmonary malignancy as the underlying cause.

Important clinical features of Cushing's syndrome

- Truncal obesity
- Moon facies
- Hypertension
- Osteoporosis
- Protein depletion
- Glucose intolerance
- Purple striae
- Muscle wasting and weakness

Diagnosis

Clinical diagnosis is easy in florid cases. It has to be supported by biochemical investigations. Cushing's syndrome has to be differentiated from simple obesity, hirsutism, functional ovarian tumours, diabetes mellitus, and hypertension. In borderline cases, continued observation and repetition of tests might be required to establish the diagnosis.

Work up of Cushing's syndrome is shown in Figure 100.6. Radiological studies, ultrasonography, CT

Fig. 100.6: Flow chart for the diagnosis of Cushing's syndrome

scan, MRI and estimation of cortisol levels in the adrenal veins identify the site of tumour or hyperplasia.

Course and prognosis: Cushing's syndrome due to primary adrenal disease or pituitary lesions is fatal if left untreated, though rarely spontaneous remissions may occur. Death is due to diabetic complications, hypertension, hypokalemia, infections or the physical effects of the underlying neoplasm.

TREATMENT

Surgical removal of the adrenal tumour is the treatment of choice. Since the normal portions of the glands may be atrophic, substitution therapy is needed in the postoperative period to prevent adrenal crisis. Cushing's syndrome due to pituitary adenoma resolves after surgical removal of the microadenomas. Initial results are good. Transphenoidal surgery is preferred in pituitary adenomas. Ten percent develop post-surgical complications. These include CSF rhinorrhea, diabetes insipidus and infection. Recurrence occurs in 15-25% of cases. They may require irradiation. An alternative is to do bilateral adrenalectomy and life-long hormone replacement.

Medical management: Symptomatic management of diabetes, hypertension and electrolyte disturbances is indicated as the conditions warrant. Specific drugs are rarely used. Metyrapone in a dose of 250-750 mg thrice daily blocks the synthesis of cortisol and abolishes the effects of hypercortisolism. Medical therapy is indicated if the primary cause is not correctable surgically.

Aminoglutethimide given orally in a total daily dose of 0.5-2 g daily, blocks the synthesis of aldosterone, cortisol, and other adrenal hormones. It may cause side effects such as ataxia, rashes, fever and drowsiness. **O, P'DDD [2,2-bis- (2-chlorophenyl-4 chlorophenyl-1, 1-dichloroethane – mitotane)]** given orally in divided doses to a total of 10-15 g/day causes atrophy and necrosis of the adrenal cortex and adrenal metastases. This drug may prolong life by a few months to years. **Ketoconazole** in a dose of 800-1000 mg/day inhibits cortisol secretion. Given on a long-term basis it controls the symptoms.

Irradiation: Pituitary tumour may respond to local irradiation with 40-50 Gy using a cobalt- 60 source or 90/Yttrium implantation. However the features of Cushing's syndrome take about one year to resolve even after successful therapy. Cushing's syndrome seen as a paraneoplastic manifestation of advanced malignancy does not generally respond to surgery. The improvements in pituitary surgery have resulted in far fewer patients being treated by irradiation, and hence irradiation is not recommended as the primary treatment.

Nelson's syndrome: Some patients who undergo bilateral adrenalectomy develop enlargement of the pituitary, pressure effects on the optic chiasma and raised intracranial tension. They also show increased pigmentation due to hypersecretion of melanocyte stimulating hormone (MSH). This syndrome follows after a few years of bilateral adrenalectomy.

Abnormalities of Sex Hormones Caused by Adrenocortical Lesions

Adrenal cortex may be the source of excessive androgen production if the lesion is a tumour or congenital enzyme defect interfering with the synthesis of cortisol. Excessive androgens influence the secondary sexual characters. The final clinical picture is determined by the sex of the patient, age of onset of the disorder, and its severity. The condition may remain unnoticed in adult males. Women develop virilization. Boys show precocious puberty. Girls develop clitoromegaly and other signs of hyperandrogenism. The classic example of this situation is congenital adrenal hyperplasia.

CONGENITAL ADRENAL HYPERPLASIA

This rare disorder is characterized by virilization in female and precocious puberty in male children (Fig. 100.7). The underlying defect is congenital deficiency of enzymes leading to metabolic block in hormone synthesis. This

Fig. 100.7: Virilizing adrenal hyperplasia. Note: Enlarged clitoris in the girl on the left. Normal girl of same age—right (Fig. 100.8)

Fig. 100.8: Close up view of enlarged clitoris

results in the accumulation of intermediary metabolites with androgenic activity. Deficient synthesis of glucocorticoids and mineralocorticoids results in functional adrenocortical deficiency.

Etiology

The enzyme defect is transmitted as an autosomal recessive disorder, with clinical expression in the homozygous state. Females are affected more than males. The severity of enzyme defect determines the age of manifestation. Severe defects manifest earlier in life. At least six different enzyme defects are known, but five of these are more frequent. These are, C-21 hydroxylase defect, C-11,C-17 and C-18 hydroxylase defects and 3-beta dehydrogenase defect. Though the clinical effects are grossly similar, minor differences exist between them. C-21 hydroxylase defect accounts for 95% of the cases.

CLINICAL FEATURES

In some cases the newborn female infant shows pseudo-hermaphroditism due to androgen effect on the genitalia. Male infants show precocious sexual development after birth. Manifestations of adrenal insufficiency are failure to thrive, vomiting, hyponatremia, and hypotension. Death may occur due to adrenal insufficiency unless the condition is recognized and treated. Milder cases manifest as virilization in girls and sexual precocity in boys (Fig. 100.8). Due to the premature fusion of epiphyses, growth is retarded. Hyperandrogenism causes testicular atrophy and infertility in adult males.

Diagnosis

This disease should be considered in the differential diagnosis of all cases of hermaphroditism or ambiguous sexual development. Diagnosis is confirmed by estimation of the androgens in urine.

Treatment

Deficiency of glucocorticoids and mineralocorticoids should be corrected by supplementation. Liberal intake

of salt helps in mild cases. Fludrocortisone in a daily dose of 0.05-0.1 mg orally is given to correct mineralocorticoids deficiency. Prednisolone in a dose of 5 mg/day serves to overcome glucocorticoid deficiency. Surgery may be required for cosmetic correction of the genitalia. In those cases in which adrenal tumours or hyperplastic glands are demonstrable, surgical removal is indicated.

Adrenocortical Insufficiency

Hypofunction of the adrenal cortex may be due to a primary disorder of the gland or secondary to hyposecretion of the tropic hormone. The causes are listed in Table 100.5.

Majority of the cases are due to autoimmune adrenal atrophy. The classic features include hypotension, increased skin pigmentation, low levels of serum Na^+ and Chloride, high levels of HCO_3^- and K^+ and lower levels of plasma glucose.

TABLE 100.5

Causes of adrenal insufficiency

Primary adrenocortical insufficiency—Lesions in the adrenal cortex

1. Atrophy of the adrenal cortex due to autoimmune adrenalitis.
2. Tuberculosis, fungal infection, CMV infection, sarcoidosis and other granulomas
3. Infiltration by metastatic carcinoma
4. Hemochromatosis.
5. Amyloidosis
6. Post-surgical (total or subtotal adrenalectomy)

Secondary adrenocortical insufficiency

Hypothalamic causes: Tumours of the third ventricle, meningitis, encephalitis, injury to the base of the brain, corticosteroid therapy, sarcoidosis and histiocytosis

Pituitary causes: All causes of panhypopituitarism, especially tumours, basal meningitis, viperine snake bite, hypophysectomy or irradiation and empty sella syndrome.

Addison's Disease

Syn: Primary adrenocortical insufficiency

Thomas Addison described this condition first in 1855. It was due to tuberculosis of adrenal glands.

Among the diseases of the adrenal cortex this is the most treatable one. Autoimmune adrenal destruction (previously called idiopathic or primary atrophy) is more common in women. Antibodies against adrenal tissue may be demonstrable. Other autoimmune disorders like myxedema, type 1 diabetes, Hashimoto's disease, thyrotoxicosis, pernicious anemia, vitiligo, idiopathic ovarian failure and hypoparathyroidism may be associated.

There is association between Addison's disease and HLA-B38 and HLA-DR3 (Table 100.5).

Pathology

The adrenal glands show total cortical atrophy involving all three zones. The medulla is normal. In the primary form, histology shows lymphocytic infiltration and increase in fibrous tissue. In the other types, evidence of underlying disease may be demonstrable. In tuberculosis of the adrenals evidence of tuberculosis elsewhere in the body may or may not be present. Though tuberculosis used to be a major cause during the early part of the 20th century, primary adrenal atrophy, most commonly due to autoimmune adrenal damage, is more common at present. The major functional defect is marked reduction of glucocorticoids and mineralocorticoids. The main problem is inability to combat stress and the clinical features are determined by the severity of the stress and its nature. Sex hormones are also reduced, but the clinical presentation is less severe. Stress may include infections, injury, physical factors, mental stress and drugs which lead to hypoglycemia or hypotension and opioid narcotics.

Clinical Features

Generally, the onset is slow and may be unnoticed but many patients present for the first time in acute adrenal failure precipitated by stress. Initial symptoms may be vague such as weakness, tiredness, lethargy, weight loss, and gastrointestinal upset, especially vomiting. Sooner or later dark pigmentation develops. When fully developed, the pigmentation is characteristic and in most cases (Figs 100.9 and 100.10), diagnostic of primary adrenal failure.

Fig. 100.9: Male Addison's disease. Note: Dark pigmentation of the whole body—particularly palms, soles and face

Fig. 100.10: Female Addison's disease. Note pigmentation

Face, palms, soles extensor aspects of limbs, flexures, and mucous membranes of the mouth, tongue and genitalia show pigmentation. In severe cases the complexion becomes dark (Figs 100.9 and 100.10). Pigmentation is mediated by the melanocyte stimulating effect of ACTH and also secretion of melanocyte stimulating hormone (MSH). Unlike primary hypoadrenalism, in the secondary type, there is no hyperpigmentation. On the other hand, these subjects are pale and light coloured. Vitiligo is seen in some cases of Addison's disease. Premature graying of hair may occur which reverts to normal with treatment. Women develop amenorrhea and men develop impotence. Addison's disease confers abnormal sensitivity to drugs like morphine or pethidine. Hypoglycemia leads to extreme fatigue, sweating and coma.

Cardiovascular abnormalities include low blood pressure especially postural hypotension, and diminution of heart size.

Laboratory Investigations

1. Hypoglycemia is common. Blood glucose falls further during periods of stress.
2. Hyponatremia and hyperkalemia may occur.
3. Plasma cortisol levels are low and the diurnal rhythm is lost.
4. Stimulation test – There is no response to ACTH stimulation in primary adrenal insufficiency. In secondary types, prompt response occurs.
5. In Addison's disease plasma ACTH levels are high. In secondary hypoadrenocorticism ACTH levels are low.

6. Adrenal antibodies may be demonstrable in autoimmune adrenal damage.
7. X-ray of abdomen may show adrenal calcification. More often calcification is the sequel of tuberculosis of the gland.
8. CT/MRI of abdomen visualizes the anatomy quite clearly. Radionuclide imaging of adrenals gives information of morphology and function.

Diagnosis

Addison's disease should be suspected clinically and confirmed by investigations. Chronic malnutrition, malabsorption states, megaloblastic anemia, tuberculosis, disseminated malignancy, and psychiatric disorders should be considered in the differential diagnosis.

Diagnosis is established by estimating plasma cortisol level before and after ACTH injection.

The normal levels of plasma cortisol at 8 am is 5-25 µg/dL and ACTH is less than 80 pg/mL.

Secondary hypoadrenocorticism is a part of hypopituitarism.

Course and Prognosis

Severe Addison's disease is fatal if untreated. Adrenal crisis occurring during periods of stress causes death. Severe hyponatremia, shock, hypoglycemia or toxic reactions to drugs like morphine are common in them and these may prove fatal.

The prognosis has been completely changed with modern therapy. Apparent clinical and biochemical normalcy can be restored with adequate hormonal supplementation and fairly normal life with normal life span can be ensured. In many of them diabetes mellitus may develop on prolonged follow-up.

MANAGEMENT

The aim of therapy is to replace **glucocorticoids** and **mineralocorticoids** for life, with increase in dosage during periods of stress. Initially hydrocortisone is given in a dose of 100-200 mg/day intravenously in a crisis-like situation, the exact requirement is determined based on clinical and biochemical parameters. The optimum dosage required to keep the patient symptom-free with normal blood glucose and electrolyte levels is determined by trial and error. The treatment is started with 2.5 mg of prednisolone once or twice a day and the dose is increased till the patient becomes clinically normal and biochemical results also become normal.

Once a state of equilibrium is reached, long-term maintenance is by giving any one of the more potent preparations such as prednisolone, betamethasone or dexamethasone. Timing of the dosage is adjusted to

coincide with the normal diurnal variations, i.e. the equivalent of 20 mg cortisol at breakfast and 10 mg at about 6 pm. Peak serum levels are obtained 30-50 minutes after oral administration and the action lasts for 6-8 hours. In general the dose required for replacement therapy is much lower than that required for immunosuppression. Though glucocorticoids bring about considerable benefit, full health will be restored only with the replacement of mineralocorticoid preparations as well.

Mineralocorticoids: In all cases with moderate or severe adrenal deficiency mineralocorticoids have to be supplemented. Fludrocortisone is the most potent preparation in this class and it is given in a dose of 0.05-0.15 mg orally as a morning dose. Adequacy of therapy is assessed by the restoration of blood pressure to normal and corrected serum aldosterone levels. Side effects of overdose include hypertension, edema and hypokalemic alkalosis.

The importance of stress dosing: *During periods of stress and other medical or surgical emergencies the dose of corticosteroids should be stepped up to avoid the development of adrenal crisis. All subjects with hypoadrenocorticism should carry identity cards giving details of the disease, the treatment schedule and the doctor who treats him.*

ADRENAL CRISIS

Syn: Acute adrenal insufficiency (adrenal apoplexy)

Sudden development of adrenal cortical failure leads to adrenal crisis. It is a medical emergency, which is fatal if undiagnosed. Prompt recognition and replacement of glucocorticoids and mineralocorticoids, with other supportive measures gives prompt relief and saves life. Adrenal crisis may complicate chronic adrenal insufficiency or it may occur acutely in subjects who develop fulminant infections.

Causes

1. Sudden withdrawal of ACTH or glucocorticoid therapy.
2. Infections, trauma, surgery, drugs like morphine, diarrhea, vomiting, physical or psychological stress, and obstetric accidents precipitate acute adrenal failure in patients with chronic adrenal cortical insufficiency.
3. During meningococcal septicemia occurring in otherwise normal subjects, hemorrhagic necrosis of the adrenal may develop (Waterhouse-Friderichsen syndrome) leading to shock. Infarction of the adrenal, accidental destruction of the adrenal by trauma or surgery, and neonatal adrenogenital syndrome are rare causes.

Clinical Features

Severe vomiting, diarrhea, and profound shock are the prominent symptoms. Blotchy purpura develops in septicemia. If untreated, coma supervenes and death follows within hours.

Diagnosis

It is based mainly on clinical features. Estimation of serum sodium, potassium, chloride and bicarbonate give the electrolyte status. Estimation of plasma cortisol and aldosterone will help to assess the severity.

Management

Normal saline with 10% glucose should be started immediately. The rate is adjusted to maintain normal blood pressure, serum electrolytes and blood glucose level. Intravenous infusion may have to be continued for days. Drug of choice in an emergency is hydrocortisone hemisuccinate sodium in a dose of 100 mg given intravenously initially and repeated every 4-6 h. Parenteral medication is continued till the patient is fit for oral therapy. If the blood pressure does not come up promptly, or it tends to drop, fludrocortisone 0.1 mg oral is given in addition. After tiding over the crisis, long-term management for adrenal failure is instituted. When the condition is secondary to sepsis or other causes these should receive prompt attention.

Primary Hyperaldosteronism

Syn: Conn's syndrome

This is a rare disorder caused by a primary increase in the production of aldosterone. The condition is characterized by hypertension, unprovoked hypokalemia and low plasma renin activity. Only less than 2% of cases of hypertensive patients show hyperaldosteronism. Around 60-75% of cases are due to aldosterone producing adenoma of the adrenal cortex. In women aldosteronomas are more common. The second type called *idiopathic hyperaldosteronism* is probably due to bilateral adrenal hyperplasia. Idiopathic hyperaldosteronism is more common in men. There is a rare subgroup of idiopathic hyperaldosteronism that is suppressible by glucocorticoids. In normal subjects and hyperaldosteronism glucocorticoid administration does not suppress aldosterone levels.

The combination of low serum potassium, low plasma renin activity, alkalosis and a high non-suppressible plasma aldosterone confirms the diagnosis. *Conn's syndrome patients do not have edema. This phenomenon is called "mineralo corticoid escape".* It is probably due to increase in GFR and by the activity of both atrial and brain natriuretic peptides.

Demonstration of raised aldosterone levels in the adrenal venous blood obtained by selective catheterization helps to identify the side of lesion. CT scanning, MRI and isotopic imaging help to demonstrate the lesion.

Differential diagnosis includes malignant hypertension uni/or bilateral renal ischemia and potassium losing nephropathies.

Treatment

Adenomas have to be treated by surgery. Those with idiopathic hyperaldosteronism have to be treated medically with spironolactone 50-100 mg thrice daily. In intractable cases bilateral adrenalectomy can be done. The blood pressure returns to normal after several months in aldosteronomas, in the other types results are variable.

Secondary hyperaldosteronism can occur due to high renin production occurring in renal artery stenosis, congestive heart failure, prolonged use of diuretics and others.

Disorders of the Adrenal Medulla

PHEOCHROMOCYTOMA

Tumours arising from chromaffin tissue produce excess of catecholamines and give rise to hypertension and other effects. Tumours may occur at several sites. Common locations are the adrenal medulla (90%), Zuckerkandl's bodies adjacent to the abdominal aorta (8%), paraganglionic cells of the sympathetic nervous system, urinary bladder, aortic and carotid bodies, and the mediastinum. It is seen that 0.1-0.3% hypertensive patients may have a pheochromocytoma. The disease may be familial in 10% of cases and show autosomal dominant inheritance. The familial form may occur in association with the syndromes of multiple endocrine neoplasms (MEN) particularly MEN-2 in which primary hyperparathyroidism and medullary carcinoma of the thyroid may also occur. Pheochromocytomas secrete large amounts of adrenaline and noradrenaline. In pheochromocytomas at non-adrenal sites, noradrenaline is the major component constituting up to 80% of the total. Some tumours produce only one of these products. Of the pheochromocytomas, 90% are benign. 10% are malignant and these may metastasize. The secondary sites also produce catecholamines.

Clinical Features

The most prominent feature is hypertension, which is paroxysmal in the initial stages, but later becomes persistent. Headache, flushing, excessive sweating, tachycardia, fever, glycosuria, and postural hypotension accompany hypertensive paroxysms. Abdominal palpation, minor surgery, and parturition may precipitate

hypertensive attacks. The common hypotensive drugs like guanethidine, hydralazine, beta-adrenergic blockers, and methyl dopa lead to paradoxical elevation of blood pressure. Many develop malignant hypertension that may prove fatal. Hypertensive attacks triggered by micturition should suggest pheochromocytoma of urinary bladder.

For practical purposes the '*rule of tens*' is relevant in pheochromocytoma

- 10% extra adrenal
- 10% bilateral
- 10% malignant
- 10% familial
- 10% children

Diagnosis

Pheochromocytoma has to be clinically suspected in subjects developing paroxysmal hypertension associated with other manifestation of sympathetic over activity.

Investigations

Plasma free catecholamines as well as plasma metanephrines are the tests that offer the best diagnostic value, and a high value of either, strongly suggests the diagnosis. As these tests are not available routinely in India, the diagnosis may be established by demonstrating raised levels of **vanillylmandelic acid (VMA)** that is the excretory product of catecholamines present in urine or total or free urinary metanephrines. Normal value of VMA is up to 6 mg/day. Quantitative determinations are done in 24 hour collection of urine. Spot tests are also available for screening. Several drugs and articles of food such as bananas, chocolate, coffee, nuts and vanilla produce false-positive tests when urinary VMA or catecholamine determination are done and, therefore, these have to be avoided preferably for 5 days before doing the test. Plasma levels of catecholamines should be measured for diagnosis and follow-up.

Phentolamine, which blocks alpha-adrenergic system, causes a prompt drop in blood pressure. The basal blood pressure is recorded and 5 mg of phentolamine is given intravenously. Blood pressure is recorded at 30 sec. Intervals for 3 min and 60 sec intervals for 7 minutes. Fall in blood pressure above 35 mmHg systolic and 25 mmHg diastolic is suggestive. Adverse reaction include severe hypotensive crisis. False-positive results may occur. The test is positive only during the hypertensive phase.

Localization of the tumour is achieved by CT scanning, MRI, ultrasonography or radionuclide imaging using metaiodobenzyl guanidine (MIBG) and adrenal angiography. MRI is especially useful: a bright signal on T2-weighted image is highly suggestive of a neuroendocrine tumour like pheochromocytoma. Selective sampling of adrenal venous blood for estimating

catecholamines is a very useful confirmatory test. All these tests should be undertaken only in well-equipped centers since there is the risk of sudden hypertensive crisis.

Treatment

Once the diagnosis is established, treatment is to remove the tumour surgically. Rapid fluctuations in blood pressure occur during premedication, anesthesia, surgical manipulation, and postoperative period.

Preoperatively the blood pressure should be controlled by giving phenoxybenzamine or other alpha blockers like prazosin or doxazosin in doses of 1-4 mg/day. It is important to give adequate fluid intake during this preoperative phase. Beta blockers may be added a few days prior to surgery, especially if there is tachycardia. Intravenous diazoxide, sodium nitroprusside or phentolamine can control hypertensive episodes if judiciously administered IV.

THE ADRENAL INCIDENTALOMA: AN EMERGING DISEASE

There is an increasing trend to do abdominal imaging for diverse purposes, ranging from evaluation of abdominal pain to searches for occult or evident masses. This has resulted in the “incidental” detection of adrenal masses, aptly called adrenal “incidentalomas”. A patient with an incidentaloma needs careful evaluation to rule out a malignancy. A tumour size more than 4-6 cm and a heterogeneous consistency strongly suggests malignancy. However benign adenomas of this size can also occur as incidentalomas without hormonal abnormalities. In addition, in every case, hormonal abnormalities must be ruled out by biochemical tests. This should include tests to look for medullary tumours such as pheochromocytomas as well as cortical tumours that produce excess cortisol or androgens.

Delayed Puberty 667

Sexual Precocity 667

Infertility 668

Hermaphroditism 669

Gonadal Disorders in the Female 669

Ovarian Hormonal Disorders 670

Medical Problems of Menopause 672

General Considerations

Sexual reproduction requires three types of differentiation:

1. **Gonadal**- for production of gametes

2. **Genital**-for transfer of gametes to the site of fertilization and

3. **Behavioral**, for the urge to behave sexually.

The most important gene for gonadal differentiation is SRY gene situated in the short arm of the Y chromosome. This gene induces the gonad to differentiate into a testis.

The gonads and genital ducts intended for reproduction develop under the influence of genetic and hormonal factors. The sex chromosomes X or Y determine the genetic sex or gonadal sex of the offspring. Phenotypic sex (also called somatic sex) comprises the external genitalia and the secondary sex characters. The translation of gonadal sex into phenotypic sex is the direct consequence of the type of gonad formed and the endocrine secretion of the fetal gonads resulting in the formation of male or female urogenital tract. The development of the genitalia, breasts, body build, voice, facial and pubic hair, and other pubertal changes constitute secondary sexual development. The term ‘psychological

sex’ and the ‘gender role’ refers to the behavioural and psychosocial aspects of two sexes.

Gonadogenesis

The genetic composition XX or XY determines the morphological development of the gonads and other structures. The germ cells present in the intermediate mesoderm of the developing embryo transforms into the bipotential gonad, which can differentiate into testes and ovary under the control of sex hormones. In the presence of “Y” chromosome (SRY gene), the gonad differentiates into testes and starts secreting testosterone and mullerian inhibitory factor. Testosterone secreted by the testes directs the Wolffian ducts to differentiate into the male internal reproductive tract. The epididymis, vas deferens, and seminal vesicles develop from the Wolffian ducts. The Mullerian ducts degenerate under the influence of Mullerian duct inhibitor produced by the Sertoli cells of the testes (Fig. 101.1).

In the absence of the “Y” chromosome (SRY gene) the gonad differentiates into an ovary. In the female, the mullerian ducts give rise to the fallopian tube and the uterus. Figure 101.1 shows the schema of sex development. The development of external genitalia is controlled to a great extent by the hormonal profile in the individual. Sexual differentiation should be considered anomalous in any patient with ambiguous genitalia, cryptorchidism, inguinal masses in apparent females, inguinal hernia, clitoromegaly, or gynecomastia.

Pubertal changes: Puberty is the period of rapid physical and sexual development during which a sexually immature child is transformed into a mature adult. Pubertal development is preceded by adrenarche, which is characterized by the enhanced secretion of adrenal androgens- *dehydroepiandrosterone (DHEAS)* and *androstenedione*. The factors that determine the onset of puberty are poorly understood, but the sequence of events is well characterized. The earliest sign of puberty is the sleep-related pulses of LH secretion and episodic FSH secretion. Later on, a persistent and sustained secretion of gonadotropins ensues throughout the day resulting in elevated plasma levels of sex hormones that result in sexual maturation.

Sexual maturation in males and females occurs in stages and this has been divided into five grades. Changes in male include increase in testicular volume, growth of penis and glans, appearance of scrotal rugosity, and scrotal pigmentation. The pubic hair appears and spreads to the medial surface of the thighs and the linea Alba as an inverted triangle (pubarche). In girls, the breasts and areola enlarge and papillae project on the areola. The pubic hair appears and spreads. Mean age for menarche in girls is 12 years, and this is 1-2 years earlier than the age of puberty for boys. The gonadal hormones are essential for the maintenance of fertility, sexual behaviour and systemic effects in both sexes. In addition, in the female, ovulation, menstruation and nidation of ovum are maintained by gonadal steroids. Later axillary hair develops (adrenarche).

Fig. 101.1: The schema of sex differentiation

WT-1 Wilms' tumour gene
SF 1 steroidogenic factor
SRY Sex determining gene region of Y chromosome
DAY-1 Dosage sensitive adrenal hypoplastic gene 1 in X chromosome

Pubarche and adrenarche are under the influence of androgens.

Ovulation: The ovary increases in size after birth. In the years preceding menarche the medullary stroma hypertrophies. When puberty develops, cyclic gonadotropin rhythm is established and under the influence of gonadotrophins, a group of primary follicles are recruited and after the 6th to 8th day of menses one follicle becomes mature and dominant with accelerated growth of granulosa cells, and this results in ovulation. With the approach of menopause the ovary becomes less sensitive to gonadotropin stimulation. Maturation of follicles and ovulation stops. The levels of pituitary gonadotropin increase considerably and remain so for life.

REPRODUCTION IN MALES

The male reproductive system comprises testes, vas deferens, and accessory sex glands. The bulk of the testes is made up of seminiferous tubules embedded in a connective tissue matrix which also contains Leydig cells, blood vessels, and lymphatics. Spermatogenesis takes place in the epithelium of the seminiferous tubules and it takes about 74 days. Spermatozoa are stored in the epididymis. Sertoli cells present in the seminiferous epithelium secrete an androgen-binding protein under FSH control. Interstitial tissue of the testes contains the Leydig cells, which secrete the principal testicular hormone- testosterone.

Androgens are steroid hormones, which are responsible for conferring male characteristics. They are responsible for the development of male reproductive organs, secondary sexual characters and masculine behaviour. The testicular androgens include testosterone,

androstenedione and dehydropiandrosterone (DHE). Androgens are secreted by the testes under the influence of the luteinising hormone (LH) of the pituitary. Testosterone is converted into its active metabolite dihydrotestosterone (DHT) enzymically by 5-alfa reductase (Fig. 101.1). This conversion takes place both in blood and the target tissues.

The testicular hormones show variation with age. About 4-7 months after birth male infants show a substantial increase of circulating testosterone and LH levels. The levels of testosterone fall to low range by one year, so also FSH and LH. Puberty occur by the age of 10-15 years. The FSH reaches adults levels by the age of 15 years and LH reaches adult levels by the age 17 years. During puberty gonadotropin output occurs in spurts related to sleep. After completion of puberty, the gonadotropin levels become steady. After the age of 40 years marked changes in gonadal function occur in women but only to a lesser extent in men. Plasma levels of testosterone gradually decline in men. There is a gradual decline in libido and reduction in size of the testes.

Testicular function is essentially under a dual gonadotropin control. The LH stimulates the Leydig cells and FSH stimulates seminiferous tubules (Fig. 101.2).

Functions of Androgens

Androgens regulate gonadotropins secretion by the hypothalamo-pituitary axis, initiate and maintain spermatogenesis and are also responsible for the development of secondary sexual characters during puberty, and control of libido. Testosterone is necessary for linear growth and muscular development. It enlarges the larynx, including vocal cords, and is responsible for

Fig. 101.2: Shows overview of testicular function. The gonadotropins, FSH and LH are secreted from the pituitary, and they control the Sertoli and Leydig cells respectively, which carry out testicular functions. Note that dotted arrows represent inhibitory pathways, while straight lines represent stimulatory pathways

change of voice in the male. Testosterone is converted to an active metabolite dihydrotestosterone (DHT) in target tissues by the action of 5- α reductase and DHT is responsible for the terminal hair growth of the beard, trunk, limbs, nostrils and external ears (Fig. 101.2).

Gonadal Disorders in Males

HYPOGONADISM

Testicular hypofunction at any age leads to functional and morphological abnormalities depending upon the age of onset and duration of the disorder. This may be primary or secondary depending upon whether the defect is in the gonads or it is in the endocrine glands controlling gonadal function (See below):

I. Causes of primary hypogonadism in males:

A. Disorders involving male sexual differentiation.

1. Chromosomal sex disorders:
 - a. Klinefelter's syndrome (XXY).
 - b. XX male.
 - c. Mixed gonadal dysgenesis (X/XY)
 - d. True hermaphroditism (XX/XY)
 - e. Ullrich-Turner syndrome (XO/XY) and
 - f. Heredofamilial disorders (e.g. Noonan's syndrome).
2. Developmental disorders occurring in normal genotypic males (46 XY):
 - a. Anorchism
 - b. Hypospadias
 - c. Cryptorchidism.
 - e. Germinal cell aplasia and
 - f. Abnormalities in the outflow tract for sperms.
3. Male pseudohermaphroditism:
 - a. Dyshormonogenesis (androgen biosynthetic defects).
 - b. Androgen insensitivity disorders, and
 - c. Persistent mullerian duct syndrome.

B. Adult testicular failure (acquired)

1. Idiopathic type.
2. Primary testicular disease.
3. Orchitis occurring in mumps, lepromatous leprosy and other infections.
4. Neurological diseases, e.g. paraplegia, dystrophia myotonica.
5. Acquired disorders like varicocele.
6. Drugs. e.g. cyclophosphamide, spironolactone, cyproterone, frusemide, cimetidine, heroin, medroxyprogesterone, phenothiazines, estrogens.
7. Hepatic and renal failure
8. Autoimmune disorders and
9. Accidental or surgical trauma, and irradiation.

II. Secondary hypogonadism

- A. Hypothalamic causes: tumour, trauma, radiation
- B. Pituitary causes: tumour, trauma, isolated gonadotropin deficiency.

III. Post-surgical, post-radiation

Testicular atrophy: The seminiferous tubules account for the size and volume of the testes. Normally the adult testes measures 15 to 25 mL in volume. In the prepubertal period, its volume is only 2-3 mL. Testicular size in adults does not depend upon age. Prepubertal damage to the testes manifests as small and firm testes. Damage in the post-pubertal period renders them small and soft. Testicular atrophy in adult may be due to hypopituitarism or due to primary testicular damage. In testicular atrophy, both spermatogenesis and testosterone production are affected to varying degrees.

Testicular atrophy with sterility may be part of liver failure, renal failure, spinal cord lesions, and dystrophia myotonica. Thermal or physical trauma and irradiation of the abdomen and scrotum may lead to testicular atrophy. In lepromatous leprosy direct invasion by the organisms results in panhypogonadism. Testicular atrophy may follow orchitis due to mumps, echovirus or group B arboviruses.

Anti cancer drugs like cyclophosphamide, chlorambucil and vincristine can damage testes especially in the prepubertal period.

The prominent clinical manifestations include small size of the penis, soft small testes, sparseness of facial and body hair, loss of libido and impotence. Testicular atrophy or mal-development occurring in childhood leads to the development of eunuchoidism.

Hypogonadotropic hypogonadism: Though secondary hypogonadism is usually secondary to panhypopituitarism, less commonly, isolated hypogonadotropic hypogonadism may occur. The main features are eunuchoidism, infertility, and impotence. **Kallmann's syndrome** is the combination of testicular failure, eunuchoidism, cryptorchidism and anosmia. Normally neurons secreting LHRH originate in the olfactory placode and migrate to the hypothalamus. When there is a defect in the KAL gene, this migration is affected, resulting in anosmia and hypogonadism of Kallmann's syndrome. When spermatogenesis is present in the absence of Leydig cell activity with under androgenisation, it is called **fertile-eunuch syndrome**.

Treatment of Hypogonadism

Removable causes if any, should be attended to. If this is not possible, symptomatic management should be instituted. The aim of therapy in such cases is to restore secondary sexual characters and the capacity to perform sexual intercourse. This is achieved by androgen

replacement therapy. Restoration of fertility is achieved in some cases by gonadotropin therapy. Gonadotropins have to be given by injection.

Androgen therapy: Orally administered testosterone is rapidly degraded in the liver, so that only a fraction of the administered dose reaches the systemic circulation. Similarly, injected testosterone is rapidly absorbed and metabolized. So for effective androgen therapy, the testosterone must be administered in a slowly absorbable form as e.g. transdermal or slow-release oral preparations or by injection of chemically modified testosterone preparations.

Oral preparations of testosterone include mesterolone acetate in doses of 25 mg/day and testosterone undecanoate. Of these the latter is absorbed through lymphatic systems into the circulation and physiological blood levels may be attained by a dose of 120 mg/day, given in divided doses. Transdermal preparations are also effective; a scrotal patch of testosterone is able to deliver 4-6 mg of testosterone over 24 hours. Of the injectable forms, testosterone propionate is short acting. It is given in doses of 20 mg IM injection. Testosterone caproate (60 mg IM) and enanthate are long acting. They have to be given once every 2-3 weeks. Troublesome side effects of androgens are the development of precocious puberty, premature fusion of the epiphyses in children, dyspepsia, polycythemia, suppression of endogenous androgens, and temporary cessation of spermatogenesis. Prostatic carcinomas may spread under the influence of androgens. Rarely androgens produce hepatic adenoma on prolonged therapy. Androgen withdrawal leads to tiredness, loss of libido, impotence, and hot flushes.

Gonadotropin therapy: This restores fertility in subjects with hypopituitarism. Since prolonged therapy can cause antibody production, this is reserved for inducing spermatogenesis. The commonly available preparations include human menopausal gonadotropins (HMG) which has 75 international units each of LH and FSH activity. Human chorionic gonadotropin (HCG) has got mainly LH activity and only slight FSH activity. HCG is supplied in vials containing 2000 to 10000 units. Usually, treatment is begun with HCG and later HMG is added on to stimulate the FSH-dependent phases of spermatogenesis. Human pituitary gonadotropin (HPG) has strong FSH and weak LH activity. 1mg is equivalent to 500-750 IU. It can also be used with HCG to promote spermatogenesis.

GnRH therapy: Usually GnRH stimulates gonadotropin release, and when given in a pulsatile manner every 90-120 minutes it is the ideal treatment for purely hypothalamic GnRH deficiency. Even though this condition is rare, some of the cases of isolated gonadotropin deficiency may be due to GnRH deficiency. Interestingly, if given continuously, GnRH can produce the opposite effect and suppress gonadotropin release.

The Sexual Act

The capacity for erection, emission, ejaculation of semen and orgasm are all together implied in the term sexual potency. The neural center for erection is situated in S2-S4 segments of the spinal cord. Tactile stimulation of erotogenic zone in the body activates this center. Penile erection is brought about by parasympathetic stimulation. Emission consists of ampullar emptying of semen into the posterior urethra. This is under control of the ejaculatory center of the spinal cord located in L2 and L3 segments. Ejaculation is under sympathetic control. During ejaculation jets of semen are expelled through the urethra. The total somatic and psychological experience accompanying ejaculation is called *orgasm*.

IMPOTENCE

Syn: Impotency

This condition constitutes inability to attain or maintain an erection of sufficient firmness to permit coitus to be initiated and completed.

1. Primary impotence- in this form the subjects have never been potent.
2. Secondary impotence- in this form the subjects experience impotence after a period of normal potency.

The term *apareunia* indicates inability to perform the sexual act.

Even in normal individuals transient episodes of impotence may occur as a result of fatigue, distraction, acute illnesses, or anxiety. These recover spontaneously.

Etiology

85-90% of cases are due to organic causes. In 10-15% cases the condition is psychogenic. In all types of impotence, it is common for psychological or behavioural abnormalities to supervene.

Organic Causes

1. All cases of primary and secondary hypogonadism.
2. Other endocrine disorders-acromegaly, hyper-and hypothyroidism, Cushing's syndrome, Addison's disease.
3. Neurological disorders involving the lumbosacral segments of the spinal cord, nervi erigentes and autonomic neuropathy occurring in diabetes mellitus.
4. Chronic systemic illnesses-diabetes mellitus, hepatic cirrhosis, chronic renal failure, obesity, starvation, disabling arthritis, connective tissue diseases, chronic obstructive airway disease, systemic malignancy.
5. Iatrogenic- antihypertensive drugs, estrogens, H2 receptor blockers, tranquillizers, sedatives, alcohol, psychedelic drugs and anticancer drugs.

TABLE 101.1

Differences between organic psychogenic impotence

Organic	Psychogenic
1. Impotence is always present.	Conditional and situational.
2. Begins insidiously and slowly progressive.	Usually sudden onset.
3. The onset of impotence coincides with any significant illness like myocardial infarction	There may be a temporal association to a stressful event as the death of a parent or child.
4. There is no reflex penile erection in the early hours of the morning	Morning erections are present (nocturnal tumescence).

Psychogenic Causes

1. Affective disorders like depression, mania, schizophrenia, hysteria, and antisocial personality.
2. Alcoholism and other drug addictions.
3. Organic brain syndromes.
4. Personality disorders.
5. Trans-sexualism (a strong desire to change to the opposite sex) (Table 101.1).

Diagnosis

It should be determined whether the impotence is primarily psychogenic or organic. The essential differences between the two are given below:

Treatment

Organic impotence must be managed according to its cause. In many cases the patient or his sexual partner may benefit from counseling or by psychotherapy. Drugs like androgens and replacement hormones are indicated only if the condition is secondary to an endocrine disorder.

Sildenafil

This is a selective inhibitor of cyclic guanosine monophosphate (cyclic GMP)- specific phosphodiesterase type 5, which is present in the cavernosa tissue. By selectively inhibiting this enzyme the catabolism of cyclic GMP is arrested and the normal erectile response of sexual stimulation is restored. Relaxation of smooth muscle allows inflow of blood into the corpora cavernosa and gives rise to penile erection, in response to sexual stimulation.

Sildenafil citrate is rapidly absorbed when given orally, blood levels peak at one hour and the mean half-life is 3-5 hours. Dose varies from 25-100 mg to be taken one hour before the desired sexual activity. The drug should not be used concurrently with nitrates or nitric – oxide donor drugs. Adverse effects include headache, flushing, dyspepsia, nasal congestion, diarrhea and impairment of platelet function.

Tadalafil is a newer drug with marginally better benefit and risk profile as compared with sildenafil.

Contraindications include advanced cardiac, hepatic and renal disease. In the Indian context since a good proportion of elderly women desire to avoid sexual intercourse, the drug should be given to elderly patients only after proper counseling of the sexual partners.

Sexual medicine has attained a high degree of specialization and several methods of treatments are in vogue to achieve penile erection and the sexual act. These include penile stimulation using stimulators, injection of papaverine into the corpora cavernosa and implantation of inflatable penile prosthesis which can be operated from outside.

Cryptorchism (syn: Cryptorchidism)

In male infants the testes are in the scrotum at birth. Descent of the testes into scrotum from the abdominal cavity occurs during the last month of pregnancy. Incomplete decent of testes in the scrotum is known as cryptorchism (**undescended testes**). Cryptorchism can be graded depending upon the extent of descent. Sometimes the testes may descend into the scrotum intermittently (**retractile testes**) or they may be retained at the upper part of the scrotum, groin or within the abdomen. Hereditary defects of testicular development may lead to cryptorchism. Even unilateral cryptorchism may be accompanied by infertility. Complications of cryptorchism include defective spermatogenesis and the development of testicular tumours.

Treatment

Success of therapy depends upon the initial position of testes and early institution of therapy. Treatment should be started before the age of 2 years. Human chorionic gonadotropin (hCG) and synthetic luteinizing hormone releasing hormone (LHRH) are used for this purpose. The hCG is given in a dose of 1500 units twice a week for 3-6 weeks. If the testes have descended into the inguinal canal, the prognosis is good. If there is no response to medical therapy, surgical correction has to be carried out.

Azoospermia

Absence of sperms from semen is called azoospermia. This is common in primary testicular disorders, which are developmental or endocrine in nature. In addition, several structural abnormalities also lead to this condition. These include congenital absence of vas deferens, acquired occlusion of the epididymis and vas deferens, and absence of seminal vesicles. Varicosity of the pampiniform plexus may lead to oligo/azoospermia in about 15% of cases.

Gonadal Disorders Affecting Both Sexes

DELAYED PUBERTY

When sexual maturation is delayed beyond 14 years in boys and 13 years in girls the condition should be fully investigated. Delayed puberty may be constitutional (idiopathic), or secondary to systemic diseases or hormonal disorders.

Causes of delay in puberty

1. Idiopathic delay of growth and development.
2. Neuroendocrine disorders.
 - Tumours of the central nervous system- craniopharyngioma, pinealoma.
 - Congenital malformations of the CNS
 - Hypopituitarism
 - Kallmann's syndrome
 - Laurence-Moon-Biedl syndrome
 - Prader-Willi syndrome
 - Functional gonadotropin deficiency.
3. Chronic systemic diseases
 - Malnutrition
 - Anorexia nervosa
 - Hypothyroidism
 - Debilitating illnesses like uncontrolled diabetes, renal failure, hepatic cirrhosis, thalassemia, malignancies and others.
4. Primary gonadal failure.
 - Chromosomal disorders-Klinefelter's and Turner's syndromes and their variants (Fig. 101.5).
 - Developmental agenesis- anorchia, cryptorchism
 - Other causes of primary gonadal failure.

Kallmann's syndrome: Isolated gonadotropin deficiency associated with partial or total loss of smell is known as Kallmann's syndrome. The olfactory bulb is not developed. There is failure of release of GnRH from the hypothalamus. Menstruation and fertility can be restored by treatment with GnRH or FSH and hCG.

Laurence-Moon-Biedl syndrome: In this rare congenital disorder which is characterized by obesity, dwarfism, hypogonadism, mental retardation, retinitis pigmentosa and polydactyly, a strong familial tendency is noticeable. It is inherited as autosomal recessive.

Prader-Willi syndrome: In this rare anomaly, intrauterine and postnatal hypotonia, obesity, mental deficiency, and hypogonadism are seen. The hands and feet are small. There may be mild retardation of growth. There will be feeding difficulty in the first few years of life followed by severe hyperphagia and uncontrolled obesity later on in life.

Sexual Precocity

The appearance of secondary sexual characters before 9 years of age in boys and 8 years in girls constitutes sexual

precocity. True precocious puberty is due to premature maturation of pituitary gonadal axis. Disorders of puberty may also result from increased secretion of testosterone or estrogen, independent of pituitary control. This leads to incomplete isosexual precocity.

Causes of sexual precocity

1. True precocious puberty (both sexes).
 - a. Idiopathic type
 - b. CNS tumours in the region of the hypothalamus.
 - c. Other CNS disorders, e.g. encephalitis, trauma, tuberculoma, hydrocephalus, neurofibromatosis.
 - d. Severe primary hypothyroidism.
2. Incomplete isosexual precocity in boys:
 - Ectopic hormone secretion, e.g. hepatomas, chorionepitheliomas, congenital adrenal hyperplasia (21 or 11 hydroxylase defects).
 - Adrenal carcinoma, Leydig cell adenoma, and drugs such as androgens, anabolic steroids.
3. Incomplete isosexual precocity in girls:
 - Ovarian diseases, e.g. follicular cysts, granulosa or theca cell tumours, gonadoblastoma, Albright's syndrome
 - Gonadotropin-producing tumours, e.g. teratoma, hepatoma, and drugs such as estrogens, gonadotropins.

Diagnosis

Cardinal feature is the appearance of secondary sexual characters and puberty before 9 years of age in boys and

Fig. 101.3: Sexual precocity girl aged 7 years

Fig. 101.4: Sexual precocity boy aged 8 years

Fig. 101.5: Girl of 18 with Turner's syndrome

8 years in girls. Precocious puberty also leads to increase in somatic growth and premature fusion of epiphysis before full growth is reached. This may result in shortness of stature. In contrast to somatic and sexual abnormalities the psychosexual and intellectual development corresponds only to the chronological age (Figs 101.3 and 101.4).

Differential diagnosis: Familial incidence of sexual precocity should suggest the possibility of true idiopathic precocious puberty, congenital adrenogenital syndrome or neurofibromatosis. Endocrine tumours lead to rapid development of sexual maturation.

Albright's syndrome (polyostotic fibrous dysplasia of bone): This is a rare disorder, which may be associated with precocious puberty due to inappropriate activation of the gonadotropins receptor. Other abnormalities include irregular pigmentation and dysplasia of several bones.

Treatment

Drugs inhibiting gonadotropins are partly successful in avoiding premature fusion of epiphyses and arresting sexual precocity. Drugs like medroxyprogesterone acetate 100 mg given IM once a week or 200-300 mg as depot injections, suppress gonadotropin secretion. For central or true precocity, GnRH agonists given continuously can delay puberty.

INFERTILITY

Definition: Infertility is defined as inability to achieve pregnancy after one year of normal married life. In primary infertility the woman fails to conceive, whereas in secondary infertility there is evidence of fertility occurring in the past such as abortion, ectopic gestation or successful childbirth. In general, the male partner is at fault in 40% and the female partner in 40%. The cause is obscure in 20% cases.

Ovum Transport

Normally the ovum with attached follicular cells passes through the fallopian tubes by ciliary action and reaches

the uterus in 60-70 hours after ovulation. Fertilization takes place in the ampulla of the tube. After fertilization and extrusion of the second polar body, the ovum becomes impervious to penetration by other sperms.

Sperm Transport

In normal adult men seminal ejaculate measures 3-7 mL and the sperm count is greater than 60 million/mL. More than 60% of sperms show progressive motility at 2 hours after ejaculation and more than 60% of the sperms have normal morphology. The ejaculated semen rapidly forms a gel and then liquefies. In the female genital tract the sperms acquire the capacity to penetrate the ovum (capacitation). About 200 sperms rapidly pass into the uterine cavity and the capacitated sperm penetrates the ovum and fertilizes it.

Causes of Male Infertility

To be fertile, a man has to have normal spermatogenesis, successful sperm maturation and storage, normal epididymal transport, proper functioning of the accessory glands and optimal timing of intercourse. Common causes of infertility include sperm counts below 20 million/mL; ejaculate volume below 1.0 mL, infections, failure of liquefaction, and sperm agglutination. Temporarily sperm counts may be suppressed by factors like fever, systemic illnesses, drug therapy and endocrine disorders.

Clinical evaluation comprises of a detailed history, physical examination of the genitalia and systemic examination, semen analysis, hormonal profiles, tests for sperm antibodies in the couple, testicular biopsy, karyotyping and other tests (Table 101.2).

TABLE 101.2

Causes of male infertility

<i>Pre-testicular causes:</i> 1. Hypothalamopituitary diseases Panhypopituitarism or selective FSH deficiency Hyperprolactinemia Drugs like phenytoin, androgens and estrogens Deletion of the long arm of Y chromosome and other subtle defects in the Y chromosome. 2. Testicular diseases: Testicular atrophy Cryptorchism Varicocele Spermatogenesis arrest Drugs like cyclophosphamide and other antimitotic drugs Autoimmune disorders giving rise to antibodies against testicular basement membrane and sperms. 3. Post testicular causes Infection of the genitourinary tract with bacteriospermia, congenital or acquired ductal obstruction, varicocele Disorders of ejaculation, e.g. retrograde ejaculation Anatomical defects such as hypospadias.

Treatment

The management of infertility in men involves effective correction of all treatable disorders like varicocele, endocrinopathies and ductal obstruction. Often specialized surgical interventions and prolonged management are necessary to ensure success. Though many cases respond favourably to therapeutic interventions, some remain intractable.

In vitro fertilization techniques especially intracytoplasmic sperm insertion (ICSI) are highly successful.

Causes of Female Infertility

Investigation and management of female infertility is generally done by the gynecologist. Women show maximal fertility from 24 to 35 years. The investigations include tests to detect defects in ovulation, transport of the ovum and sperms to the uterus, morphological abnormalities of the female genital tract, defects of facilitation of the sperms in the vagina, hormonal abnormalities and immunological causes. About 30-40% of cases have pelvic abnormalities like tubal occlusions, adhesions and endometriosis. Abnormalities of cervical secretions occur in 10-30%. Uterine abnormalities commonly cause recurrent abortions and are diagnosed by a full gynecological examination. Sometimes immunological abnormalities may develop leading to infertility. These are (1) ABO blood group incompatibility (2) circulating sperm agglutinating and sperm immobilization antibodies in women or (3) autoimmune disorders in men.

HERMAPHRODITISM

Syn: intersex

Intersex refers to the condition when the external genitalia are ambiguous; that is neither truly female nor truly male. It could be a male child whose genitalia are not adequately masculinised or a female child whose genitalia are virilised. Intersex is classified into the following categories.

True hermaphroditism: True hermaphroditism is characterized by the presence of both ovarian and testicular tissues in one or both gonads. Variable differentiation of the internal and external genitalia is seen. The external genitalia sometimes resembles that of a male or female, but mostly they are ambiguous. Chromosomal analysis reveals the common karyotypes as 46 XX.

Pseudohermaphroditism

In pseudohermaphroditism, the gonadal sex is at variance with the gender sex. The terms male or female denote the corresponding gonadal sex. Thus, in **male pseudohermaphroditism**, the gonads are exclusively testes with XY karyotype, but phenotypic characteristics are to varying

degrees female (failure of virilization). Causes include: defective testicular stimulation due to gonadotropin resistance or deficiency, sub-optimal testosterone and/or antimüllerian hormone secretion and failure of tissue response to androgens and/or antimüllerian hormone.

In female pseudohermaphroditism, the gonad is an ovary and the karyotype is XX. Varying degrees of virilization of external organs may be present. Ambiguity of external genitalia is usually caused by androgenic influences. Often there is no abnormality of internal genital development or functional capacity of the ovaries. The uterus, tubes and ovaries may be normally present and reproductive function may become possible after suitable correction of the external genitalia, which are masculine. Several causes may lead to female pseudohermaphroditism. The most common cause is congenital adrenal hyperplasia due to 21-hydroxylase deficiency. Patients have impaired cortisol synthesis, high ACTH levels, and adrenal androgen hypersecretion. Steroid therapy can inhibit the ACTH drive and correct androgen excess.

It is preferable to investigate these cases in the first year of life so that the sex of the child can be assigned before the second year. Therapy is based on thorough clinical, psychological, and genetic analysis. In female pseudohermaphroditism the external genitalia should be surgically corrected during the first year of life. In male pseudohermaphroditism and intersexual genitalia, sex is assigned according to the state of external genitalia. Prolonged therapy may be necessary to achieve reasonably satisfactory results. Therapy includes hormone supplementation, surgical correction, and psychological rehabilitation.

Gonadal Disorders in the Female

Ovarian hormones: Estrogens stimulate sexual heat (estrus) in female animals. Major estrogens produced by the ovary are estradiol and estrone. The former is the main and more powerful hormone. Estrogens are inactivated by the liver and several metabolites are excreted in urine and bile as the conjugated products (Fig. 101.6).

Actions of Estrogens

Estrogens bring about pubertal changes occurring in females. They are responsible for the development of the breasts, formation of the feminine body contour, proliferation of uterine endometrium, vaginal keratinization and epiphyseal closure.

Progesterogens and their Action

These hormones prepare the uterus for reception and development of the fertilized ovum. The corpus luteum does this function normally and its main secretion is

Fig. 101.6: Diagrammatic representation of ovarian function. This figure shows the GnRH Pulse generator in the hypothalamus that controls the pulsatile secretion of FSH and LH, which act on the ovarian cells to produce the sex hormones

progesterone which is under the control of LH of the pituitary. Synthetic progesterone with high potency is available for therapeutic uses. Progesterone makes the endometrial glands coiled and secretory (secretory phase). They are prepared for nidation of the ovum. The rise of temperature at ovulation is mediated by progesterone. Withdrawal of progesterone results in menstrual bleeding.

Assessment of ovarian function: Clinically, ovarian function can be assessed from the development and maintenance of the breasts and the internal and external genitalia. Hypofunction of the ovaries manifests as delay in sexual development, menstrual irregularities and disorders of ovulation. Several conditions give rise to such a clinical picture. These include primary ovarian disease, hypothalamopituitary abnormalities, unresponsiveness of the target organs, systemic diseases and gonadal dysfunction occurring in other endocrine diseases.

Investigations

These include: (1) Determination of levels of FSH/LH and ovarian hormones (2) Studies of the effect of ovarian hormones on vaginal epithelium such as cornification, cervical mucus and changes in the endometrium and (3) tests of ovulation such as measurement of basal body temperature which goes up at the time of ovulation, and serial ultrasound measurements of follicle maturation.

OVARIAN HORMONAL DISORDERS

Ovarian dysfunction manifests clinically as amenorrhea, infantilism or sexual precocity. In primary ovarian failure, the levels of pituitary gonadotropins are high. Ovarian failure may be due to primary disease of the ovaries in

60% and extra-ovarian causes in 40% of cases. For proper development and functioning of the ovaries, the essential requirements are:

1. Presence of two genetically active X-chromosomes.
2. Absence of Y- Chromosome.
3. Proper endowment of germ cells (oogonia).
4. Development of germ cells into primary oocytes and
5. Adequate gonadotropin stimulation in fetal life.

Abnormalities of any or all of these factors lead to ovarian failure.

OVARIAN FAILURE

Causes of ovarian failure are shown in the box below. When it occurs due to a disease of the ovary, it is called **primary ovarian failure** when it is secondary to gonadotropin deficiency is called **secondary ovarian failure**.

Primary Ovarian Failure

Causes

1. Dysgenesis or agenesis of the ovaries.
2. Resistant ovary syndrome- the ovaries are resistant to the action of pituitary gonadotropin even though they are morphologically and genetically normal.
3. Polycystic ovaries.
4. Prepubertal infections like tuberculosis and mumps, which give rise to oophoritis.
5. Systemic diseases like thalassemia, mucopolysaccharidoses, dystrophia myotonica, and autoimmune disorders such as primary Addison's disease
6. Female pseudohermaphroditism.
7. Isolated enzyme deficiencies such as 17 –alpha hydroxylase deficiency and 21- hydroxylase deficiency.
8. Genetic disorders, e.g. Turner's syndrome.

Secondary Ovarian Failure

1. Panhypopituitarism.
2. Prolactinomas- prolactin reduces ovarian response to FSH and LH and pituitary response to LHRH.
3. Acromegaly.
4. Isolated gonadotropin deficiency.

AMENORRHEA

Primary amenorrhea is delay of menarche beyond 18 years of age and secondary amenorrhea denotes cessation of menstruation for 6 months or more in normally menstruating women.

Gynecological causes:

1. Diseases of the endometrium
2. Obstruction to the outflow tract of the uterus
3. Imperforate hymen.

Endocrine causes:

1. Primary or secondary ovarian hypofunction and
2. Other endocrine disorders like Cushing's syndrome, adrenogenital syndrome, Addisons disease and thyrotoxicosis

Systemic disease

1. Disorders such as chronic liver disease, renal disease, diabetes mellitus and malnutrition

Drugs:

Several drugs which include hormonal and non-hormonal preparations are capable of producing amenorrhea, e.g. corticosteroids, androgens, estrogens, contraceptive pills, psychotropic drugs, anti-hypertension drugs and others

Hypothalamic causes

Anorexia nervosa, psychiatric disorders, hypothalamic tumours and developmental neurologic defects such as Kallmann's syndrome

Diagnosis

The most common physiological cause of secondary amenorrhea in the young is pregnancy. This should be excluded in all cases. Other common causes include menopause, drug therapy, systemic illnesses and psychiatric disturbances. Signs and symptoms of estrogen deficiency such as vasomotor instability and drying up of vaginal secretions should suggest the possibility of primary ovarian failure or menopause. The investigations and management of amenorrhea are the realm of the gynecologist.

Polycystic Ovary Syndrome (PCOS)

Syn: Stein-Leventhal syndrome,
Cystic disease of the ovary

This is a heterogeneous disorder, clinically characterized by ovulatory failure, hirsutism, obesity, glucose intolerance, resistance to insulin, dyslipidemia and infertility.

The ovaries are enlarged, multicystic, and show hyperplastic theca cells around the cysts. Only very small amounts of estradiol are produced by the immature follicles. Excessive amounts of androgens are produced by the hyperplastic theca cells and stromal cells. The enlarged cystic ovaries on both sides can be made out by bimanual examination, by ultrasonography or by diagnostic laparoscopy. Therapeutic measures are designed to restore fertility, normalize menstruation and reverse hirsutism. Signs of insulin resistance like acanthosis nigricans may be looked for in these patients.

The three key features of PCOS are

- a. oligomenorrhea
- b. hyperandrogenesis (clinical and laboratory parameters) and
- c. absence of other endocrinological disorders such as congenital adrenal hyperplasia, hyperprolactinemia, thyroid dysfunction and androgen secreting tumours.

The exact etiology is not known but the main biochemical abnormality in PCOS is hyperinsulinemia secondary to insulin resistance. This leads to ovarian overproduction of testosterone, and adrenal overproduction of DHEAS and androstenedione. Increased testosterone affects the pituitary ovarian axis leading to decrease in production of estrogen, abnormal production of progesterone, and overproduction of testosterone, LH and FSH.

Those with PCOS are at higher risk of diabetes and cardiovascular disease later in life. The diagnosis of PCOS is by demonstration of the cystic ovaries, exclusion of other hyper-androgenic disorders in women with chronic anovulation and androgen excess. PCOS is considered as a part of the metabolic syndrome.

Treatment of this condition depends on the patient's main concerns. Bilateral wedge section of ovaries were done previously to induce ovulation. Metformin is commonly used to reverse the endocrine abnormalities in PCOS by reducing the resistance to insulin, and correcting the other endocrine abnormalities. Dose of metformin is 500-750 mg bid. Metformin can be continued during pregnancy also especially the first two trimesters. Other treatment modalities include anti-androgens like spironolactone and finasteride for controlling virilizing signs, and cyclical estrogen and progesterone for regularizing the menstrual cycles. For inducing ovulation and fertility, clomiphene citrate can be used in doses of 50 mg daily for 5 days, preferably from the fifth to the ninth day of the menstrual cycle. Clomiphene increases the output of gonadotrophins from the pituitary. Cyproterone acetate which is an androgen antagonist relieves hirsutism. Application of hair removing preparations improves cosmetic results.

Dysfunctional Uterine Bleeding

Excessive or more frequent menstrual bleeding resulting from functional disturbances, but without other obvious pathological causes is called dysfunctional uterine bleeding. Hormonal imbalance and nutritional, psychological and hematologic factors play contributory roles. This is a common gynecological problem in women in the fourth and fifth decades of life, often requiring hysterectomy.

Medical Problems of Menopause

Women attain menopause usually between 40 and 47 years. Menopause is considered to be complete when a woman has not had periods for one year in the absence of any pathological condition or obvious features of ovarian deficiency.

Physiological changes: Menopause represents a form of primary ovarian failure. The number of ovarian follicles steadily decline with age and these follicles become less and less sensitive to the action of FSH as age advances. As women reach menopause the FSH/LH reach high levels and the estrogen levels fall. Because of diminishing number of follicles in the ovary production of estrogen is reduced. In many subjects the development of menopause may be quite uneventful and asymptomatic.

The following four groups of symptoms may develop in those who become symptomatic:

1. **General symptoms:** These include insomnia, nervousness, anxiety, depression, irritability, headache, dizziness, and joint pains. These affect the quality of life considerably.
2. **Vasomotor symptoms:** These consist of hot flushes, inappropriate perspiration, and palpitation, occurring frequently as sudden burning feeling all over the body followed by sweating, faintness, and palpitation. In 10-20% of women these symptoms are very frequent and disabling. Low body weight, sedentary habits and smoking increase the risk of developing these symptoms.
3. **Atrophic changes in the genitals:** The main symptoms are urinary stress incontinence, vaginal atrophy, vaginal discharge and irritation, dryness, dyspareunia, pruritus, and burning.
4. **Cosmetic effects:** Characteristics changes include the development of fine folds and marks radiating from the mouth, sagging of the infraorbital fold of skin on

the face, sagging and atrophy of the breasts, and generalized wasting of adipose tissue. Osteoporosis is common and this may lead to fractures of the vertebrae and limbs.

Management: Till five years ago hormonal replacement therapy (HRT) was widely used to counteract the failure of production of ovarian hormones —estrogen and progesterone. It was symptomatically very effective, but long term studies (Women's Health Initiative Study) revealed that the adverse effects included increase in cardiovascular events, venous thromboembolism, and a small, but significant increase in the incidence of endometrial and breast cancers. These findings have led to the avoidance of HRT as a routine. However, in troublesome symptomatic menopausal syndromes, estrogen supplementation is instituted for a short duration in the small doses. Short term indications for estrogen therapy are: a) hot flushes (b) dyspareunia (c) cosmetic disability. Estrogens are given orally in cycle of three weeks followed by a free interval for one week. In those cases with intact uterus, progestogens are employed in the third week. Estrogen therapy is absolutely contraindicated in those with cerebrovascular accidents, recent myocardial infarction, and carcinoma of breast, pancreatitis, cholecystitis, endometrial carcinoma, and recurrent venous thromboembolism. Designer estrogens (selective estrogen receptor modulators) have beneficial effects of estrogen without the disadvantages. An example is raloxifene in a dose of 60 mg once daily. These are emerging drugs for hormone replacement. Relative contraindications include cystic disease of the breasts, heavy smoking, hypertension, family history of carcinoma of the breast, liver diseases, cholelithiasis, diabetes mellitus, endometrial hyperplasia, gross obesity, and a single episode of thrombophlebitis. There has been an increasing focus on calcium and vitamin D supplementation to preserve bone health, and the judicious use of anti-resorptive agents acting on bone such as alendronate wherever appropriate for the management of osteoporosis. Clonidine in doses of 50 µg twice daily orally has been found useful in women who cannot tolerate estrogen. Clonidine may cause unacceptable side effects like sedation, dizziness and nocturnal restlessness. Drugs used in other systems of medicines such as plant products have been tried.

General measures include nutritional supplements and selective serotonin uptake inhibitors (SSRI) such as fluoxetine and sertraline which improve the mental state and reduce hot flushes.

Endocrine Disorders of the Breast

K.V. Krishna Das

GENERAL CONSIDERATIONS

The breasts develop from the mammary crest of the ectoderm called the milk line. Though the mammary gland is rudimentary at birth, sometimes the high prolactin levels derived from the mother may induce transient milk secretion in the newborn (*witch's milk*). The breasts grow and areolae enlarge with puberty depending on the influence of estrogens and progesterone.

The mammary glands develop fully with the formation of alveoli and they start functioning only during pregnancy. During early pregnancy the breasts enlarge and become nodular. The areolae become pigmented with the development of Montgomery's tubercles. Later, colostrum is secreted.

Hormonal interactions: Estradiol stimulates growth of mammary ducts and nipples and the formation of progesterone receptors. Cortisol and growth hormone potentiate the effects of estrogens. Further development of lobules and alveoli are mediated by four hormones—estradiol, progesterone, growth hormone, and prolactin. Progesterone inhibits the formation of estrogen receptors. Lactation is initiated by increase in prolactin and the sudden reduction in progesterone level on delivery of the placenta. Oxytocin facilitates ejection of milk by

contraction of myoepithelial cells of the alveoli. Regular suckling stimulates prolactin secretion by a neuro-endocrine reflex and this is responsible for maintenance of lactation. Other hormones like growth hormone, ACTH, thyroxine, human placental lactogen, and insulin also play their role in the maintenance of optimal milk secretion.

In health the size of the breasts varies. The two sides are not symmetrical. During menstrual cycles premenstrual pain and tenderness may develop even in normal women. Though generally mild, sometimes the pain and discomfort may be severe. These symptoms are promptly relieved by diuretics, progesterone or bromocriptine. Lactation can be suppressed by high doses of estrogens or bromocriptine.

ATROPHY OF BREASTS

This commonly occurs when the estrogen levels fall as in hypogonadism or menopause. Disorders occurring before puberty lead to abnormal breast development. Lesions occurring thereafter result in regression of the size of the breasts. Breast atrophy is also common in hyper-androgenism due to any cause—adrenal, ovarian or iatrogenic.

HYPERTROPHY OF BREASTS

Hyperprolactinemia may give rise to bilateral hypertrophy of breasts with galactorrhea. This may be idiopathic in some rare cases. Unilateral breast enlargement is usually due to juvenile fibroadenoma, malignant tumours, infections like tuberculosis or infiltrations as in acute leukemia. Bilateral fibroadenosis is associated with premenstrual pain and it commonly develops after puberty.

GYNECOMASTIA

The increase of glandular and stromal tissue of male breast is termed gynecomastia. True glandular enlargement has to be differentiated from adipose tissue deposition (pseudogynecomastia), carcinoma or neurofibromatosis by careful examination. Increased levels of estrogens with or without reduction of androgens lead to gynecomastia. If prolactin is also increased, galactorrhea follows.

Causes of Gynecomastia

1. About 50-70% of normal boys develop transient gynecomastia during puberty.
2. Primary testicular failure as in Klinefelter's syndrome, cryptorchism, leprosy.
3. Testicular tumours—seminoma or teratoma.
4. Hepatic cirrhosis.
5. Endocrine disorders like hyperthyroidism, hypothyroidism, adrenal cortical overactivity.
6. Paraneoplastic syndromes, e.g. bronchogenic carcinoma, renal carcinoma, Hodgkin's disease.
7. Drugs, e.g. estrogens, digitalis, spironolactone, reserpine, marijuana, metoclopramide, methyldopa, H₂-receptor antagonists, phenothiazines and others.
8. Trauma to chest wall.
9. Idiopathic.

The serum levels of testosterone, 17 estriol and gonadotropins are normal in idiopathic gynecomastia. High serum LH levels indicate primary testicular failure or HGH secreting choriocarcinoma of the testes. A very high level of serum 17 = estradiol should suggest a feminising adrenal carcinoma.

Treatment

Pubertal gynecomastia is often self-limiting and this may be left alone after assuring the individual of its benign nature. In others, the cause should be detected and treated. In some cases surgical excision is done for cosmetic reasons and to prevent neoplasia later.

GALACTORRHEA

Nonphysiological secretion of milk from the breast is known as galactorrhea. It is seen in both sexes, and the amount of milk may vary from a few drops to large volumes. Amenorrhea accompanying galactorrhea suggests a hypothalamo pituitary disorder.

Causes

1. Hypothalamo pituitary diseases.
 - a. Hypothalamic lesions, e.g. tumours, granulomas, histiocytosis X, postencephalitic sequelae, trauma, pituitary stalk section.
 - b. Pituitary disease, e.g. prolactinoma, acromegaly, empty sella syndrome, Cushing's syndrome.
2. Functional hyperprolactinemia
 - a. Drugs, e.g. oral contraceptives, digoxin, chlorpromazine, reserpine, methyldopa and several others.
 - b. Chest wall lesions, surgery, herpes zoster, burns.
3. Other endocrine disorders, e.g. myxedema, adrenal cortical disorders.
4. Ectopic prolactin secretion and paraneoplastic syndromes, e.g. bronchogenic carcinoma, hypernephroma, Hodgkin's disease.
5. Chronic renal failure.
6. Idiopathic.

Diagnosis

Galactorrhea may be an isolated symptom or this may be part of other endocrine manifestations. Many patients do not volunteer this symptom and, therefore, it is likely to be missed if not carefully looked for.

Management

Therapy depends upon the cause. Endocrine disorders should be treated appropriately. Drug induced galactorrhea responds promptly to drug withdrawal. When the cause is obscure, bromocriptine in a dose of 5 mg/day may be tried. It stops galactorrhea within a few weeks. Adverse side effects of bromocriptine include nausea, vomiting, and hypotension.

Prostaglandins

R. V. Jayakumar, A.G. Unnikrishnan

Introduction

Von Euler of Sweden first discovered and isolated prostaglandins from human semen in the 1930s. Attributing their origin from the prostate gland, he termed them prostaglandins. Now it is known that prostaglandins are present and are synthesized in all tissues in the body. Prostaglandins are biologically synthesized from arachidonic acid. Essentially they are unsaturated carboxylic acids. They have a 20-carbon skeleton with a five-member ring. Like classic hormones, they act as chemical messengers, but with the difference that they act within the cells which produce them, without being transported to distant sites for their action. As per very rigid nomenclature systems, only the compounds produced by the cyclo-oxygenase pathway and prefixed as "PG" are termed prostaglandins, but all the other molecular derivatives of arachidonic acid which are called eicosanoids, belong to the prostaglandin family and they will be discussed together (Fig. 102.1).

Note : LT stands for Leukotrienes

Fig. 102.1: The eicosanoid family PG—prostaglandins
LT—Leukotrienes

Physiological Role

The most important role is in the modulation of the immune response. Leukocytes flock to areas of tissue destruction and release local prostaglandins that cause fever and even pain. In addition, prostaglandins have effects on vascular function. For instance thromboxane A₂, a potent prostaglandin, causes vascular constriction and aggregation of platelets. Another prostaglandin, PGI₂ has the opposite effect. Some prostaglandins stimulate smooth muscles contraction. For instance, leukotrienes cause bronchoconstriction and PGE₂ stimulates uterine contractions.

Clinical Applications

PGE₂, as mentioned earlier, can stimulate uterine contractions and it is used for inducing labour. Aspirin inhibits the action of cyclooxygenases COX₋₁ and COX₋₂ which can convert arachidonic acid to prostaglandins. By this effect aspirin suppresses prostaglandin-induced inflammation and pain. This is the main mechanism by which aspirin and non-steroidal anti-inflammatory agents (NSAIDs) act as anti-inflammatory and analgesic agents. Some prostaglandins that have beneficial effects on blood flow, like PGE₁ have been used to improve the microcirculation. Administration of PGE₁ helps to occlude a patent ductus arteriosus if administered to be baby in the perinatal and neonatal periods. In addition, leukotriene antagonists like monteleucast have been used in the therapy of bronchial asthma. Prostacyclin (PGI₂) reduces pulmonary artery pressure and therefore it is used in the treatment of pulmonary hypertension. Glucocorticoids exert their anti-inflammatory effects, by inhibiting the enzyme

phospholipase A, which converts phospholipids into arachidonic acid, thereby reducing prostaglandin and leukotriene production.

Aspirin exerts its anti-platelet effect by irreversibly inhibiting action of thromboxane which favours platelet aggregation and promotes thrombosis.

Endocrine Syndromes Produced by Cancer

R.V. Jayakumar, A.G. Unnikrishnan, K.P. Poulse

Introduction

Wherever a hormone is abnormally produced from a source that is different from the tissue of its usual origin, the production is called ectopic. Since most of the conditions are malignant, these are called *paraneoplastic syndromes*. An example of this is small cell lung cancer, which can produce ACTH in excess quantities. Usually ectopic hormones produce clinical syndromes because the hormones are produced in excess and in an unregulated manner. Some of the ectopic hormone producing states and the clinical conditions they produce are listed in Table 102.1. The common syndromes amongst them are discussed below. The appropriate therapy is to treat the hormonal abnormality and attend to the tumours which produce the hormones.

Ectopic Cushing's Syndrome

Ectopic ACTH production can stimulate the adrenal glands to produce excess cortisol and this results in

TABLE 102.1	
Common paraneoplastic hormonal abnormalities	
Hormone excess	Clinical syndrome
Chorionic gonadotropin	Gynecomastia
Vasopressin (ADH)	Syndrome of inappropriate ADH
Parathormone	Hypercalcemia
Growth hormone	Acromegaly
Growth hormone-releasing hormone	Acromegaly
Parathyroid hormone related protein	Hypercalcemia
Calcitonin	No known clinical effect
Somatostatin	Hyperglycemia, diarrhea
IGF-1	Hypoglycemia
ACTH,	Cushing Syndrome
Gastrin	Peptic Ulcer Disease
Erythropoietin	Polycythemia
Activated Vitamin D	
Hypercalcemia	

Cushing's syndrome. The most common neoplasms that result in ectopic Cushing's syndrome are carcinomas of the lung, thymus and pancreas. Rarely pheochromocytomas, medullary carcinoma thyroid, bronchial carcinoids and adenomas can cause this syndrome. The diagnosis should be suspected clinically if features which suggest underlying malignancy such as weight loss, severe pigmentation, muscle weakness, hypokalemia, alkalosis, lack of cortisol suppressibility to the high dose (8 mg) dexamethasone, and ACTH levels more than 1000 pg/mL occur. Recent studies have yielded an insight into the molecular basis of this syndrome. Usually ACTH is part of a larger precursor molecule called proopiomelanocortin (POMC). POMC gene is stimulated by 3 promoter genes: P1, P2 and P3. In the pituitary P2 is the promoter gene, while in all peripheral tissues, usually P3 (which results in a weak activity of the POMC gene) is the dominant one. In tumours resulting in ectopic ACTH syndromes, it has been shown that P1 replaces P3. P2 is a promoter that results in a large transcript with identical product as P2 of the normal pituitary. Thus while normal peripheral tissues have P3, a weak promoter, the ectopic peripheral tissue has P1, which is a strong promoter resulting in Cushing's syndrome.

The treatment of this syndrome is the excision of the tumour. Ketoconazole or adrenalectomy may be needed symptomatically if Cushing's syndrome is very severe.

Hypercalcemia

Hypercalcemia of malignancy may be either parathyroid hormone (PTH) dependent or independent. Usually there is release of PTH or PTH-like protein. PTH or PTH-like protein dependent syndromes result in hypercalcemia with hypophosphatemia, as this is the classic action of PTH. PTH-independent syndromes in malignancies can cause severe hypercalcemia and hyperphosphatemia through different mechanisms like extensive bony metastases, tumour lysis syndrome or overexpression of 1-alpha hydroxylase enzyme, which activates vitamin D at the 1-alpha position in an unregulated manner, resulting in extreme hypercalcemia with hyperphosphatemia.

Hematological malignancies like lymphoma and solid tumours like bronchogenic carcinoma may be associated with hypercalcemia.

Syndrome of Inappropriate ADH Production

ADH or vasopressin or anti-diuretic hormone decreases free water excretion and retains free water, resulting in a dilutional hyponatremia. Unregulated and excess production of ADH is called SIADH. Lung carcinoma, predominantly small or oat cell carcinoma is the most important cause of SIADH. Usually the patient appears euolemic, and hyponatremic. Plasma osmolality low and urine osmolality is high.

Rare Endocrine Syndromes due to Tumours

Growth hormone: There have been a few reported cases of acromegaly due to excess growth hormone or growth hormone releasing hormones from islet carcinoids.

Erythropoietin: Production of excessive quantity of erythropoietin by tumours can result in secondary polycythemia, as erythropoietin stimulates erythropoiesis.

RBC synthesis. Tumours of the kidney, liver, cerebellum and others organs may rarely produces erythropoietin - like substances.

Insulin like growth factors: Some carcinoids can produce insulin-like growth factors or even insulin, causing hypoglycemia. Rarely, large retroperitoneal tumours, especially sarcomas cause excess utilization of glucose resulting in hypoglycemia. Certain tumours like hemangiopericytomas can lead to phosphate depletion due to the elaboration of phosphaturic factors called "**phosphatonins**". In these situations, metabolic activation of vitamin D into its active form is also inhibited. This syndrome is rare. It results in a particular variety of osteomalacia known as "oncogenic osteomalacia".

Human chorionic gonadotropin (hCG): Production of hCG in dysgerminomas can lead to stimulation of the testes by hCG which, in turn produces estrogens and cause breast enlargement in boys.

Principles and Practice of Geriatric Medicine

B. Krishna Swamy, K.V. Krishna Das

Chapter Summary

General Considerations	677
Disease Pattern in Elderly	679
Management Approach to Elderly Patients	680
Common Geriatric Symptoms and their Management	681
Social Problems in the Elderly	682
Development of Geriatric Health Services in India	683

General Considerations

Changing demographic pattern worldwide, resulted in steep rise in elderly population both in developed and developing countries. The elderly population in India has risen from 12 million in 1901 to 70 million in 1999 (7% of the total population). India has the second largest elderly population, next only to China in the world. This phenomenal growth of geriatric population is the result of improved life expectancy, better socioeconomic environment, advances in the medical field and prevention and control of communicable diseases.

Along with this there is an exponential increase in disability, mental and physical morbidity of the elderly population, needing special health and social services. The manner in which persons age and the capacity to ward off disease are linked to socioeconomic factors the mental and physical activity patterns and the degree of fitness during life. Heredity and life-style patterns govern fitness and physiological reserve.

Regulated physical activity protects against obesity, type 2 diabetes mellitus, ischemic heart disease, hypertension, strokes and orthopedic disabilities. Regular employment protects against depressive illness.

Geriatric medicine is that branch of medicine concerned with preventive, curative and rehabilitative methods of management of medical, psychological and social problems of the aged. The term "Geriatrics" is

derived from the Greek word *Gerios* meaning old age and was coined by Ignatz L. Nascher in 1909.

Elderly people behave differently from others in respect to predisposition to disease, general resistance against infections, and response to drugs. The discipline of geriatrics deals with the diagnosis and treatment of persons aged 65 years and above. The age of 65 as the commencement of senescence has been accepted arbitrarily. During senescence all illnesses are accompanied by a higher mortality than when occurring in younger age groups. A better functional definition of senescence will be as the period when there is commencement of loss of vigor, skin changes of old age, slowed activity of the musculoskeletal system and onset of deterioration of mental functions. The life-span of man is increasing all over the world. In India over 7% of the population is above the age of 60 years. The maximum life-span has not changed despite increase in the average life-span.

Definition of aging: The changes in structure and function occurring in persons after the attainment of sexual maturity constitute aging. With advancing age the adaptability to overcome environmental or internal challenges decreases and the probability of death increases. Tissues differ in their behaviour during aging. Visual and auditory functions start deteriorating even in the third decade of life. The rate of deterioration in other organ systems depends to a great deal upon other factors like coexistent diseases, diet, physical exercise, and to a great deal on hereditary factors. The present explanations for aging process are not fully satisfactory though many have been put forward.

In dealing with problems in the elderly, it is essential to bear in mind that they may have (1) multiple problems, (2) atypical presentation of diseases, and (3) the response to drugs and other therapeutic measures may be unpredictable. Irrespective of the symptom, a full physical examination is absolutely necessary to make a complete diagnosis. Since the aged are very susceptible to adverse drug reactions, close monitoring is essential. As yet no drug is available to combat senescence. The aim of therapy is not just to prolong life but to make it useful and

enjoyable. General principles of therapeutics in the elderly are given in Chapter 4.

1. The term old is used to denote persons aged 75 years and above.
2. The term advanced age is used for persons aged above 85 years.

In older persons compensatory mechanisms are impaired either due to aging or due to disease. Therefore, even minor ailments tip the metabolic equilibrium. From a physiological stand point aging may be considered as a progressive diminution of function of each organ system so as to be unable to maintain homeostasis in the presence of a challenge. This graded decline of physiological reserve (homeostenosis) begins in the third decade and occurs in all organs systems independent of each other. This decline may be modified by heredity, environment, diet and personal habits.

Morphological Changes

Cellular changes: The total number of cells comes down in parenchymal organs such as brain, liver, and heart. Cell sizes and staining properties become irregular and many binucleate cells appear. The water content of collagen comes down and cross-linkages increase, rendering it increasingly rigid and inflexible. This affects mobility adversely. Elastin also shows degenerative changes. The proportion of body fat in males rises from 19% at 25 years to 35% at 70. In females, the change is from 33 to 49%. Serum albumin falls from 4g/dL in youth to 3.5g/dL in persons >80 years.

Alterations in Organs

Skin: The skin becomes hyperkeratotic, atrophic, and wrinkled. *Sweat glands* and sebaceous glands diminish.

Greying of hair occurs because of the progressively smaller amounts of dopa-oxidase and tyrosinase in hair follicles, both of which are required for the synthesis of melanin. Greying of the hair shows a strong genetic predisposition (autosomal dominant) and in the majority of people 50% of the hairs are grey above the age of 50 irrespective of the sex and hair colour.

Heart and Blood vessels: Ischemic and hypertensive diseases often supervene as age advances and, therefore, it is difficult to separate these changes from purely aging process. Above the age of 75 years, interstitial fibrosis and fatty infiltration of myocardium develop, even in the absence of any concomitant disease. Lipofuscin accumulates in the myocardium. Endocardium and valves are thickened. Amyloidosis may develop. Loss of elasticity leads to widening and tortuosity of the aorta. Atherosclerosis accelerates these changes.

Lymphatic organs: The spleen undergoes atrophy. There is increase in the number of plasma cells. Above the age of 70 years serum globulins are increased and amyloidosis may develop. This form of amyloidosis may affect the heart, islets of Langerhans, peripheral and autonomic nerves, and brain. There is generalized impairment of immune processes and, therefore, infections take a fatal turn.

Cancer: The risk of cancer increases with age and neoplasia accounts for 20% of the total deaths. Atherosclerosis, hypertension, and cancer together cause the majority of deaths. Invariably multiple diseases coexist in the elderly patients and diagnosis is often difficult. The symptomatology is atypical.

HEALTH PROBLEMS IN THE ELDERLY

Nutrition: The body weight tends to come down above the age of 70. Social neglect, loss of earning capacity, and intercurrent illnesses tend to precipitate malnutrition.

Infections: The general resistance against microbes is lowered by malnutrition and impairment of immune mechanisms. The local defence mechanisms of the respiratory, urinary, and alimentary tracts, mouth, skin, genitalia, and eyes are impaired and, therefore, bacterial infections are common. A common symptom occurring in the elderly subject is alteration in the level of consciousness, delirium, and coma, and these must raise suspicion of generalized infection. Fever may not be a prominent symptom in the early stages. Dehydration and electrolyte disturbances are common because of chronic renal impairment and endocrine deficiencies.

Cardiovascular changes: Ischemic heart disease is common. Above the age of 80 years presbycardia results in cardiac failure and arrhythmias. Recurrent thromboembolism leads to cerebrovascular occlusion, ischemia of limbs, and infarction of other vital organs. Varicosity of veins may develop. Dependent edema occurs as a result of exudation of fluid due to loss of elasticity of the skin and fall in tissue tension. Hypoproteinemia, cardiac failure, venous stasis, and immobility tend to perpetuate edema.

Respiratory system: Atrophic emphysema, chronic respiratory infection, and aspiration pneumonia are disabling problems of old age. Staphylococcal bronchopneumonia may follow influenza and it is a fatal complication. Acute respiratory infection is a common complication of severe illness and this causes death in many cases.

Neurological disorders: Atherosclerosis leads to gradual deterioration of higher functions ending up in dementia.

Cerebrovascular accidents accelerate this process. Subdural hematomas may develop following minor trauma, or even spontaneously. Cervical spondylosis, lumbodorsal osteoarthritis, and ischemia of the spinal cord contribute to pain and dysfunction of the extremities. Peripheral neuropathy occurs frequently. The sensory loss accounts for unsteadiness of gait and clumsiness of movements. Tremor occurring in them aggravates the disability and, therefore, feeding, writing, and other activities become difficult or impossible. Parkinsonism is common. This impairs speech and movements further. Cerebellar dysfunction may develop. Herpes zoster is more common in the elderly and post-herpetic neuralgia tends to be troublesome.

Autonomic dysfunction: Elderly individuals lose control over the bladder and bowel. There is incontinence of urine and feces. This gives rise to problems of nursing. Postural hypotension may contribute to syncope and falls are common in the elderly. The heat-regulating mechanisms are labile. Accidental hypothermia and hyperthermia may occur due to exposure to external environment.

Special senses: Loss of vision due to cataract, retinal degenerations or chronic iridocyclitis, and glaucoma is common. Diabetes and hypertension aggravate the disability. Loss of vision incapacitates them considerably and pastimes like reading, writing, and watching television become problematic.

Loss of hearing is common after the age of 50 years and it is a serious handicap. The diminution in hearing may be universal affecting all tones, or the higher frequencies may be selectively affected. Deafness impairs their ability to communicate with others and thus makes them isolated. Tinnitus and vertigo may be troublesome. Ageusia or parageusia may occur and these may aggravate their feeding problem.

Alimentary disorders: Loss of teeth makes ingestion of several articles of food difficult. Atrophy of the salivary glands, atrophic gastritis, peptic ulcers, colonic polyps, diverticulosis, and cholecystitis are common in the elderly. The poor food intake and immobility lead to constipation. If unattended, this may develop into inspissated feces syndrome in which constipation, alternating spurious diarrhea and fecal incontinence are seen. Malignant lesions in the hepatobiliary system, gall stones and drug-induced hepatotoxicity are more common.

Excretory system: Renal impairment occurs as a result of chronic pyelonephritis and benign nephrosclerosis. Obstructive uropathy due to enlargement of the prostate is an almost invariable accompaniment above the age of 80 years. The severity of symptoms vary. Several precipitating causes such as urinary infection, prolonged

recumbency, instrumentation or sympathomimetic drugs lead to acute obstruction. Elderly women develop senile vaginitis, rectocele, cystocele, and uterine prolapse, all predispose to recurrent urinary infections.

Bones and joints: Many weight-bearing joints such as knees, hips and spine, and small joints of the hands and feet develop osteoarthritis. This tends to make the patient immobile. *Phlebothrombosis and embolism* are common. Accidents and falls are frequent and these initiate the downhill course. Fracture neck of the femur, Colles' fracture, and vertebral compression fractures are brought about by osteoporosis. Movements of the shoulder may be restricted by shoulder-hand syndrome.

Muscles: There is generalized atrophy of muscles, myotonia, and loss of power. In many areas contractures, cramps or tetany, and claudication may develop.

Hematological disorders: Anemia may develop due to poor intake of proteins, iron and vitamins. This is further worsened by loss of blood from hemorrhoids, gastrointestinal blood losses, diverticulitis and malignancies. Incidence of lymphoma shows a peak in the elderly. Minor trauma in areas such as the dorsum of the hands, wrists, and lower parts of the legs and feet show senile purpura.

Endocrine system: The gonads, thyroid and adrenal cortex show generalized hypofunction. Myxedema is not uncommon. Since the presentation may be atypical, they may be initially mistaken for primary psychiatric disorders.

Skin: Atrophy of the skin makes it thin and inelastic. There is reduction in subcutaneous fat. These factors make the skin vulnerable to chronic decubitus ulcers. Paresthesiae and pruritus are common. The latter may become extremely distressing and intractable, leading to severe distress.

Psychological changes: The elderly become irritable and less adaptable to surroundings. Change in social behaviour, emotional instability, loss of self-confidence, mental depression, hallucinations and paranoid and persecutory fears result in social isolation.

Disease Pattern in Elderly

AGING CHANGES AND DISEASE STATES

There is often no clear distinction between changes due to aging and age-associated diseases. Often, medical problems are erroneously considered as aging changes and neglected. Many of the earlier cross-sectional studies on the aging population have created a wrong notion, that aging is always associated with declining function. However recent longitudinal studies in elderly have clearly

shown that physiological functions can be maintained or even improved in the absence of diseases.

The major physiological change associated with aging is the decline in reserve, resulting in a state of “homeostenosis” of every organ system. This decline is gradual and often progressive but variable in individuals. However, this decline in function causes no symptoms and possesses few restrictions in the activities of daily living. Loss of adaptability to an acute stress is the key problem in elderly, due to this functional decline.

Unlike in younger age group, multiple diseases are common in elderly. Numerous studies have shown that mean number of diseases per person, for those above the age of 70 years, is around 5. Chronic diseases like hypertension, coronary artery disease, diabetes mellitus, chronic obstructive pulmonary disease, degenerative joint diseases, cognitive decline, depressive illness, falls, incontinence and visual and hearing impairment may appear in varying combinations. Multiple symptoms and signs in elderly may be due to different diseases rather than a single disease and unitary disease model approach will lead to wrong diagnosis.

Clinical presentation of diseases also varies in elderly. Some diseases are silent and asymptomatic and many present with atypical symptoms. A disease affecting one organ system can precipitate decompensation in another due to age-related decline in reserve. For example, a respiratory infection can present as acute confusional state, mimicking a CNS problem. Whatever the underlying acute disease, the weakest areas like cardiovascular, CNS and musculoskeletal systems are often affected and symptoms pertaining to these systems dominate.

A classical presentation of a disease may totally be absent. For example pneumonia may present often without fever, cough, pleuritic pain and hemoptysis. Myocardial infarction and intra-abdominal emergency can present as shock or acute confusion.

Because of the decreased reserve, elderly persons develop symptoms at an early stage of the disease and if treated actively, the outcome is much better. Unfortunately, this advantage is set-off by the patients’ indifferent attitude toward these early symptoms. The elderly patients seek medical attention at a later stage, when the treatment becomes difficult and the outcome is poor.

At times a coexisting disease may alter the symptoms of another disease, leading to a delay in diagnosis, e.g. disabling old stroke may restrict physical activity, thereby masking an anginal pain of ischemic heart disease at an early stage. Secondary complications of an acute illness are common in elderly, especially if there is a delay in treatment. For instance, a simple gastroenteritis can lead to dehydration and acute renal failure. However, early diagnosis and prompt therapy result in good outcome.

TABLE 103.1

Morbidity pattern in Indian elderly—rural

Vision problems	88%	Skin problems	13.5%
Locomotor problems	40%	Nutrition problems	11.5%
CVS problems	18.7%	Abdominal problems	9.5%
CNS problems	17%	Psychiatric problems	8.5%
Respiratory problems	16%	Hearing problems	8%

Though there are no diseases peculiar to elderly, some ailments are more commonly seen in older persons. Sensory deprivation, degenerative joint disease, cardiovascular disorders, vascular and degenerative neurological diseases, diabetes mellitus malignancies and depression are the most common illnesses affecting the elderly. Immobility, instability (falls), incontinence and intellectual impairment (dementia) constitute the “geriatric giants”, posing management problems.

Tables 103.1 and 103.2 show the diseases pattern in Indian elderly.

MANAGEMENT APPROACH TO ELDERLY PATIENTS

Multidimensional Geriatric Assessment

Assessment of an elderly patient is always multidimensional and interdisciplinary. It is essential to determine the frail elderly person’s medical, psychosocial problems and functional capabilities, with the aim of immediate management, rehabilitation and long-term follow-up. The comprehensive geriatric assessment should include assessment of medical problems and cognitive functions by a physician, assessment of ADL and IADL by a physiatrist and social problems by a social worker. The aim of initial assessment is to set the realistic goal of improvement and to achieve maximum independence.

The term ADL denotes activities of daily living which includes self care activities such as eating, bathing, dressing, transferring and toilet, IADL denotes instrumental activities of daily living such as cooking, managing finance, using telephone, driving a car, etc. which demand better functional competence.

Barthel's index of activities of daily 'living' is a scoring system which helps to assess the functional capacity of the elderly, especially after a disabling illness.

Investigations in the Elderly

Since a coherent history is rarely possible and clinical presentation is often varied and atypical, investigations become essential to arrive at a clinical diagnosis. When an elderly person presents with an acute illness, basic biochemical and radiological tests should be done at the earliest. In asymptomatic patients safety and usefulness of the test should be considered. In general, non-invasive tests are preferred in elderly although age is not a bar for invasive procedures.

Drug Therapy in the Elderly

The problems associated with drug therapy include alteration in drug metabolism due to changes in body mass and composition, polypharmacy, drug interaction, self-medication, adverse drug reactions, compliance and cost of therapy. Worldwide data suggest that elderly are the major consumers of the drugs and adverse drug reactions (ADR) are more frequent in them. Sedatives, NSAIDs, diuretics, anticholinergics and antimicrobial drugs lead to adverse side effects frequently. The principle of "start slow and go low" is the practical method of preventing ADR, and one has to consider the age-related changes in absorption, distribution and metabolism of a drug before prescribing.

Pharmacotherapy in old age: Adverse drug reactions (ADRs) are more common. Most of them are dose related. Drug distribution changes with the changes in the proportion of fat in the body. Lipid and water soluble drugs show corresponding changes in distribution. Drugs such as cimetidine, digoxin and morphine have a smaller volume distribution, hence they show higher blood levels. Fall in the plasma albumin levels results in greater proportion of drugs to be in the free form and this leads to higher side effects e.g. warfarin, oral anti-diabetes drugs, NSAIDs and others. Drugs which depend upon hepatic metabolism may show vagaries in their concentration and actions. Glomerular filtration falls by 35% in the elderly, so too the renal tubular function. Drug dosage has to be adjusted depending upon the creatinine clearance.

Formula for calculating creatinine clearance (CrCl) in the elderly is given below

$$\text{CrCl (mL/minutes)} = \frac{(140 - \text{age}) \times \text{weight in kg}}{72 \times \text{serum creatinine mg/dL}}$$

Changes in hepatic functional impairment, autonomic nervous function and neuromuscular activity influence the actions of drugs. The best method is to individualize the dose on a trial and error basis. A simple prescription with clear instruction of dosage and duration of therapy is mandatory. Periodic review of medication and compliance will be beneficial. In addition to a definitive diagnosis and analysis of risk benefit of therapy, one has to consider the concomitant diseases before choosing a drug.

Common Geriatric Symptoms and their Management

There are a few symptoms which are more prevalent in elderly, requiring different approach and management. Pain, dizziness, constipation, dyspepsia, pruritis, memory disturbances, multiple somatic complaints falls and delirium are some of the common symptoms seen in geriatric clinics. A brief review of these symptoms will be useful. Many physicians adopt a syndromic approach while treating geriatric patients. This takes into consideration the functional disabilities such as restriction of movement, diminution of vision, falls and so on, irrespective of the exact pathology. Reduction of the ill effects of age-related phenomena and diseases is the main goal of geriatric medicine.

Constipation

Constipation is defined as less than three bowel movements per week and its prevalence varies from 40-60% in elderly. Dietary inadequacy, multiple medications, anorectal problems, reduced GI motility are often contributing factors for constipation. Acute constipation associated with acute medical problems often produce distressing symptoms like abdominal distension, confusion and urinary retention. Laxatives in the form of rectal suppositories and enema are useful and often digital evacuation has to be done. Dietary adjustments in the form of increased fluid and fiber in the diet, regular exercise, a fixed time of bowel evacuation are simple measures of preventing chronic constipation. Bulk and osmotic laxatives are the preferred form of therapy and reassurance that chronic constipation is age-related and benign, is quite useful.

Dyspepsia

Sedentary habits and reduced GI motility often leads to dyspeptic symptoms. Acid peptic disease, reflux esophagitis and upper GI malignancy and drugs are the common causes of dyspepsia. Upper GI endoscopy and barium studies are useful and safe in evaluation. Drugs that improve motility like domperidone and H₂ receptor blockers are widely used.

Memory Disturbances

Many elderly patients complain of declining memory function but often perform well during mental status examination. History obtained from the care-giver of declining memory is more reliable and needs evaluation. Age associated memory impairment (AAMI) has to be differentiated from early Alzheimer's disease. A thorough neurological examination and a regular follow-up can differentiate benign AAMI from progressive dementia. While memory loss is the lone disturbance of the higher function in AAMI, there is a diffuse and progressive alteration of mental functions in dementia. A treatable dementia is always to be considered in any dementing illness and a thorough evaluation is mandatory.

Pain

More than 50% of the elderly patients attending a geriatric clinic will present with pain as the primary complaint. Degenerative joint diseases, osteoporosis, muscular pain, neuritic pain, malignant and somatoform disorders are some of the underlying diseases producing pain. Nondrug method of physical therapy is the first line of management. When medication is required, paracetamol is safe and widely used. NSAIDs should be used with caution in elderly, but should not be withheld when required. Adjuvant pain therapy in the form of antidepressants and anticonvulsants is often useful in chronic and neuritic pain. Opioids should be reserved for intractable pain associated with malignancies. Referral to "pain clinics", where multimodal approach is provided, will be beneficial in chronic pain associated with malignancy and depressive illness.

Dizziness and Vertigo

Prevalence of these symptoms vary from 30-40% in elderly. Benign positional vertigo, vestibular dysfunction, age-related changes in the sensory system and drugs are some of the common causes of vertigo in the elderly. A thorough ENT and neurological evaluation is mandatory but often does not contribute in diagnosis or management. The major complication of dizziness includes a fall and fracture in a frail elderly, which should be prevented. Vestibular rehabilitative exercises are the main form of therapy, and vestibular sedatives should be used with caution. Walking aids in the form of walking sticks and walking frames are often useful in preventing a fall.

Multiple Somatic Complaints

Often multiple complaints are the presenting problems in elderly. A depressive illness is usually the cause of multiple somatic complaints and psychiatric counseling will be useful. A thorough clinical and diagnostic evaluation has to be performed in every case to rule out an organic basis and periodic re-evaluation is ideal.

Falls

Instability and frequent falling may be the presenting symptom in the frail elderly, the prevalence varying from 20-30% in the community. Multiple medical illnesses are often the cause for a fall rather than simple aging. Environmental hazards like poor lighting, uneven floor, slippery toilets, stairs without hand rails can lead to falls. Age-related changes in the nervous system, parkinsonism, cognitive decline, polypharmacy and cardiac arrhythmias are the intrinsic causes of recurrent falls. Physical injuries, fractures and psychological trauma and fear of fall can lead to invalidism. Identifying the basic disease and measures to improve the muscle strength and balance, especially of the lower limbs and physical training can prevent falls.

Delirium

Many a time elderly patients are brought in a state of acute confusion. Delirium involves altered consciousness with impaired attention and diminished arousability. Infection, dehydration, electrolyte disturbances, hypoxia, hypotension and drugs are the frequent causes of acute confusion in elderly. Since delirium is often a clinical manifestation of the underlying serious systemic disease, it has to be identified, evaluated and actively managed. Many times outcome of an acute confusional state is rewarding, provided it is treated early.

SOCIAL PROBLEMS IN THE ELDERLY

Elderly persons have several problems which cause hardship. These include health problems, financial problems, social alienation and possibly others. The elderly person tends to become uncooperative, withdrawn and cynical in behaviour. They are not accepted by the younger folk. Many of them are left alone due to death of the near relations or desertion by them. Helplessness is a real medical problem for those above the age of 65 years. Mortality among elderly persons living alone is 3.2% per annum. Mortality is higher in the months of extreme cold and heat. Social rehabilitation measures including living places, hostels, provision of the help at home and device such as emergency alarm for summoning help are available in developed countries. Ideal situation is one in which no elderly person has to live alone and to face death alone.

Socioeconomic problems add and aggravate medical, physical and psychological disabilities in the elderly. The changing demographic pattern has resulted in more number of elderly in the 'dependent population'. Psychosocial problems are the resultant of retirement, loss of occupation and income, housing problems and bereavement in the family. The joint family system which is the basic social support in the community, is unfortunately disintegrating because of the migration of children

for better opportunities. Neglect, loss of respect for elders and elder abuse are increasing in the community. It is vital to promote and protect joint family system to provide basic social and emotional support to the elders. Though old age homes are increasing in number in our country, they can never be a substitute for family care. Developing day care centers, senior citizen clubs and friendly visiting services would help to provide recreation, group activity and emotional outlet for the elders.

Development of Geriatric Health Services in India

At present, there are not many geriatric health units available in India. The few available are mostly placed in larger cities. Since most of elderly population lives in the rural area, geriatric health care should be included in the primary health care system. Multipurpose health workers can be trained to identify health problems of the elderly and to provide simple remedies and referral system whenever required. Taluk and headquarters hospitals should provide outpatient and inpatient geriatric services. Teaching hospitals should develop full-fledged geriatric units and provide geriatric training programs for primary care physicians. It is also vital to develop nursing homes or long stay hospitals with nursing and rehabilitative services for the elderly with chronic physical disabilities.

Appendix

Several indices have been designed to assess the pathological conditions in the elderly. Hachinski score distinguishes between dementia caused by ischaemic brain lesions and non-ischemic lesions. The *Barthel's index* is an assessment of functional capacity. It helps to assess the progress in the medical condition of elderly subjects objectively on follow-up:

Hachinski score-for ischemic versus non-ischemic dementia	
<i>Feature</i>	<i>Score</i>
Abrupt onset	2
Stepwise course	1
Somatic features	1
Emotional incontinence	1
Systemic hypertension	1
History of strokes	2
Focal neurological symptoms	2
Focal neurological signs	2

Interpretation

More than 4-Multi-infarct dementia
Less than 4-Non-vascular dementia

Barthel's Index of Activities of Daily Living	
<i>Feature</i>	<i>Score</i>
<i>Bowels</i>	
Continent	2
Occasional incontinence	1
Constant incontinence	0
<i>Bladder</i>	
Continent	2
Occasional incontinence	1
Incontinent	0
<i>Feeding</i>	
Independent	2
Needs some help	1
Dependent	0
<i>Combing hair, washing face, cleaning teeth and shaving</i>	
Independent	1
Needs help	0
<i>Dressing</i>	
Independent	2
Can do half	1
Dependent	0
<i>Transfer (mobility)</i>	
Independent	3
Minor help needed	2
Major help needed	1
Total inability	0
<i>Using the toilet</i>	
Independent	2
Needs some help	1
Dependent	0
<i>Walking</i>	
Independent	3
Walks with one stick	2
Wheel chair	1
Total inability	0
<i>Climbing stairs</i>	
Independent	2
Needs some help	1
Dependent	-
<i>Bathing</i>	
Independent	2
Needs some help	1
Dependent	0

The total score is ascertained immediately after the onset of illness. The total scores are recorded periodically during treatment. Improvement or deterioration can be assessed objectively thereby.

Rheumatology

104. Disease of Locomotor System	686	109. Polymyositis and Dermatomyositis	718
105. Rheumatoid Arthritis and its Variants	691	110. Miscellaneous Rheumatic Syndromes	719
106. Systemic Lupus Erythematosus, Antiphospholipid Antibody Syndrome	703	111. Seronegative Spondyloarthropathies	721
107. Progressive Systemic Sclerosis (PSS)	709	112. Metabolic Arthropathies	726
108. Systemic Vasculitis	713	113. Osteoarthritis	732
		114. Other Bone Diseases	736

Chapter Summary

General Considerations 686

Symptomatology 687

Disease Pattern in India 688

Investigations 688

General Considerations

The term rheumatology denotes the branch of medicine which deals with the medical disorders of the musculoskeletal or locomotor system. The common disorders include:

1. Inflammatory lesions of joints, periarticular tissue, muscles, tendons, and fascia
2. Degenerative diseases produced by 'wear and tear'
3. Problems of the vertebral column produced by local pathological lesions, postural abnormalities and trauma
4. Generalised vasculitides and
5. Several others.

Rheumatic disorders are probably the most common ailments affecting mankind. In India at any period of time 8-9% of adults suffer from one or other of the rheumatic disorders. It is possible that about 50 million people suffer from these disorders at any one time. Among the rheumatic disorders 47% is constituted by inflammatory arthropathies, mainly rheumatoid disease, 18% by connective tissue disorders, 8.5% by seronegative spondyloarthritis, and 4% by crystal induced arthropathies. All other joint lesions make up the total.

Bones: The human body contains about 206 bones. Structurally, they can be divided into spongy and compact bones. In spongy bone the lamellae are stacked one above the other as trabeculae. In compact bone the lamellae are arranged closely in concentric circles around a central canal containing the osteocyte. Spongy bones house the bone marrow whereas compact bones do not. During bone formation and repair different cells such as osteocytes, osteoblasts and osteoclasts act in a coordinated and orderly

manner under the influence of several humoral factors. Periosteum covers bones. It has an outer fibrous layer and an inner cellular layer capable of producing bone—the osteogenic layer.

Trabecular bone has a greater turnover than cortical bone. Bone matrix consists of type I collagen which is laid down in lamellae. These give tensile strength to bones. Mineralisation of the bone matrix with deposition of hydroxy apatite ($\text{Ca}_{10}(\text{PO}_4)_6 \text{OH}_2$) between the collagen fibrils bestows rigidity to the bones.

Bone remodelling occurs throughout life and it replaces worn-out bone by new bone. About 10% of the skeleton participate in this process at any one time. It starts with the arrival to the site of osteoclasts which are derived from the monocyte macrophages system. These contain the enzyme tartrate resistant alkaline phosphatase. They reabsorb bone matrix and the minerals. At the end of this process osteoclasts undergo apoptosis. Then osteoblasts which are derived from marrow stromal cells arrive to lay down bone matrix which is subsequently mineralised. Osteoblasts are small cuboidal cells which actively lay down bone matrix. They are stimulated by parathormone, platelet derived growth factor and prostaglandins. They are inhibited by corticosteroids. Some osteoblasts remain embedded within bone matrix. They differentiate into osteocytes. They act as sensors of mechanical strain. They also secrete prostaglandins and nitric oxide which are signalling molecules concerned with the functions of neighbouring bone cells. **Osteoprotegerin** is a key regulator of osteoclast activity by inhibiting its action. The receptor activator of nuclear factor KB (RANK), its ligand RANKL and osteoprotegerin constitute a critical mechanism for signalling between osteoblasts and osteoclasts.

Cytokines participate in the process of bone remodelling. Parathormone, activated vitamin D ($1,25(\text{OH})_2 \text{D}_3$) thyroid hormone and growth hormone increase bone remodelling whereas it is suppressed by calcitonin, estrogens and androgens. In conditions like Paget's disease of bone where bone remodelling is very rapid, lamellae formation may be distorted and the resultant bone, though larger, may be brittle.

Long bones transmit body weight and act as levers for movement. The middle part of the tubular shaft is the diaphysis which is flanked on either end by the metaphyseal regions. The ends are expanded to form the articular areas, the epiphyses. Long bones derive their blood supply from diaphyseal, metaphyseal, epiphyseal and periosteal nutrient arteries. Short bones like the carpal bones function as points of absorption of pressure and distribution of shearing forces. They are made of compact bone.

Joints: Joints may be classified as fibrous, cartilaginous or synovial.

Type of joint	Range of movement	Examples
Fibrous	Nil	Cranial sutures, tibiofibular joint
Cartilagenous	Limited	Intervertebral joint, symphysis pubis
Synovial	Wide	Hip, knee, elbow

In a synovial joint the bone ends are capped by hyaline cartilage. At the osseochondrous junction, synovium is attached to bone and reflected from it to line the joint cavity. Outside the synovium is the tough fibrous capsule which is thickened in some areas to form ligaments. The capsule and ligaments prevent excess movement at the joint. In joints like the knee there are fibrocartilaginous pads or menisci which serve to appose the articulating surfaces properly. The synovial fluid and synovium reduce friction during movement. Bursae prevent friction between tissues around a moving joint. These are similar to synovium in structure, function and disease susceptibility. Synovium is highly vascular. Structurally, the synovium presents an ideal stage for humoral and cellular immune reactions. Synovium has only very few nerve endings, while cartilage has none. Articular cartilage is avascular. It derives its nutrition from materials passing into it from bone or synovial fluid. Articular branches of blood vessels enter at the joint margin.

The articular cartilage consists of chondrocytes, embedded in a matrix and it is provided with a framework of type II collagen which imparts its tensile strength. It does not contain nerves. It provides a low friction surface to the articular ends of bones.

Synovial membrane lines the inner surface of joint capsules. It consists of fibroblasts which secrete synovial fluid and macrophage-like cells with phagocytic activity. The synovial fluid is an ultrafiltrate of plasma, to which materials which increase its viscosity such as hyaluronan and lubricin are locally added. Hyaluronan is responsible for lubrication of the joint surface during movement, whereas lubricin acts as the lubricant during static stress.

In addition to its lubricating function synovial fluid provides nutrition to the avascular articular cartilage and helps to perform other metabolic functions. The synovium is supplied by unmyelinated nerve fibers which transmit pain.

The capsules, ligaments and periosteum around the joints are supplied with myelinated nerves for proprioception and unmyelinated nerves for conducting pain.

The points of attachment of tendons and ligaments to bone are called entheses. The joint capsule, entheses, ligaments and tendons are rich in nerve endings that perceive pain and proprioception. When a joint is inflamed, reflexogenic nerve endings cause reflex contractions of neighbouring muscles leading to painful stiffness.

The main function of all synovial joints is to allow stable, controlled movements. Muscles of the locomotor system are all striated muscles. They are all under voluntary control.

Symptomatology

Rheumatology is still a pre-eminently clinical discipline depending heavily on laboratory and other types of investigations. Since the joints and bones respond in a stereotyped clinical manner to different and multiple diseases processes, clinical distinction between the various rheumatological syndromes may not be perfect. So also the laboratory parameters usually undertaken in these diseases are of a more general character rather than being absolutely specific, so that considerable overlap occurs between health and disease. Many of the laboratory investigations such as ASO titre, rheumatoid factor, ESR and almost all others show prevalence in low titers even in apparently normal population, so that the interpretation of an equivocal laboratory value has to be made in the context of the clinical features and the characteristics in the general population.

Main symptoms pertaining to the locomotor system include pain in and around joints or other parts of the axial or appendicular skeleton, deformities of bones and joints, loss of functions of the joints and systemic manifestations such as fever, loss of weight, anemia and involvement of several organ systems. There may be considerable overlap in the clinical manifestations between the different rheumatic diseases. Therefore, it is very necessary to do investigations to pinpoint the diagnosis and follow-up the case.

The main clinical presentation of musculoskeletal disorders is with joint pains, stiffness of muscles, swelling, bone pains and muscle weakness. The source of the symptom can be clinically assessed by examination.

Symptomatology in articular and extra-articular lesions	
Joint tissues	Lesions around the joint or unconnected with the joint
Pain occurs during active and passive movements	Pain occurs during active movement, but not on passive movement
Swelling and tenderness limited to the anatomy of the joint	Not confined to the joint
Crepitus, instability and locking of joint in particular positions present	Not present

The distribution of joint lesions gives some clue. Predominant affection of the joints of the lower segment of the body occur in various spondyloarthropathies such as ankylosing spondylitis, Reiter’s syndrome, psoriatic arthropathy and early stages of polyarticular gout. In rheumatoid arthritis and systemic lupus the upper segment is more often affected. Morning stiffness is a frequent finding in many joint diseases. This term refers to pain on waking up from sleep or prolonged recumbency, felt especially in the lower limbs and spine, which takes 30-60 minutes to get maximum relief. This is a usual feature of inflammatory joint disease.

Disease Pattern Affecting the Locomotor System in India

Numerically, traumatic fractures, dislocations and other lesions head the list. These fall into the realm of orthopedics.

Rheumatological disorders contribute to the rest of the diseases of the musculoskeletal system and connective tissue. Among the connective tissue diseases rheumatoid arthritis tops the list. About a fifth of the rheumatological disorders may be related to allergic processes, e.g. *reactive arthritis*, *serum sickness like reactions*, *allergy to drugs* and so on. *Osteoarthritis* accounts for another fifth of the morbidity. *Osteoporosis*, *osteomalacia nonarticular rheumatism*, *low backache*, *sciatica* and problems related to defective posture and lack of exercise are common. In India, rheumatic fever merits a special mention since it is common in children and adolescents and it leads to life-long crippling cardiac sequelae. Osteoarticular tuberculosis is also common in children and adults, the osseous focus being in the metaphysis in children and in the epiphysis in adults. Tuberculosis can also cause an allergic reactive arthritis resembling rheumatoid arthritis. Arthritis associated with gut lesions such as *ulcerative colitis* and arthritis associated with *ankylosing spondylitis*, *psoriasis* and the *Reiter’s syndrome* are again common enough. Many systemic diseases may present with arthritis; these include *hypothyroidism*, *diabetes mellitus*, *acromegaly*, *bleeding disorders*, *myeloproliferative disorders*, *AIDS*

and other conditions. Finally we come to the diffuse connective tissue diseases (DCTD) under which umbrella come *systemic lupus erythematosus*, *scleroderma*, *inflammatory disease of muscle* and *rheumatoid arthritis*. Each of these may be associated with *Sjögren’s syndrome*. The DCTD’s can overlap with each other as in mixed connective tissue disease and progress on to other forms.

The pattern of rheumatological disorders differ in different age groups. In children the common problems seen are growing pains, hypermobility, hip pain due to several causes, traumatic lesions of knees, rheumatic fever, postviral arthritides, osteomyelitis, pyoarthrosis, juvenile rheumatoid arthritis (JRA), rickets and others. In the young adult male, seronegative spondyloarthritides are common. During the sexually active periods of life, arthritic complication of sexually transmitted diseases are more common. In pregnancy and the puerperium low back pain is nearly universal and sciatica is common enough. The postmenopausal age is associated with bone and joint symptoms. Osteoporosis proceeds rapidly after menopause. Hypothyroidism, depressive illness and osteoarthritis are common causes of rheumatic symptoms in this group. Degenerative joint diseases such as osteoarthritis of several joints, cervical spondylosis, sciatica and lumbar canal stenosis are more common in elderly. Those exposed to repeated occupational trauma during work develop osteoarthritic changes of particular joints early.

Occupation and environment can modify joint diseases, particularly osteoarthritis, e.g. *goal-keeper’s fingers*, *bass player’s thumb*, *Zulu dancer’s hip*, etc. Tenosynovitis like the Achilles tendonitis of long distance runners and prepatellar bursitis in housemaid’s knee are other examples of occupation-related rheumatism. Enthesopathies like lateral and medial epicondylitis of elbow (syn: tennis elbow and golfer’s elbow) are common in Indian housewives who do clothes washing, grain grinding, pounding, etc. Factory workers inhaling metal or polymer fumes can get fever associated with arthralgias. The WHO has categorized rheumatological disorders into four major categories

- 1. Back pain (48%)
- 2. Osteoarthritis (31%)
- 3. Soft tissue rheumatism (12%) and
- 4. Inflammatory rheumatic diseases (9%).

Immunological principles dominate the practice of present day rheumatologists. A sound understanding of immunology will go a long way in interpreting the evolution, course and management of rheumatological diseases (Table 104.1).

Investigations of Rheumatological Diseases

Laboratory Investigations

A. **Erythrocyte sedimentation rate (ESR):** It is common to find very high ESR, often exceeding 100 mm/hour in

TABLE 104.1

Shows the spectrum of cases seen in India

- A. Diffuse connective tissue diseases—rheumatoid arthritis and its variants, systemic lupus erythematosus, systemic sclerosis, polymyositis, dermatomyositis, Sjögren's syndrome, mixed connective tissue disease and various forms of generalised vasculitis
- B. Degenerative joint disease—osteoarthritis
- C. Spondyloarthropathies
- D. Infective arthropathies—by direct infection, e.g. tuberculosis or syphilis or indirectly by immunological mechanisms, e.g. rheumatic fever, Reiter's syndrome
- E. Crystal induced arthropathies gout, pseudogout, chondrocalcinosis
- F. Non-articular rheumatism, tendonitis, enthesitis, fibromyalgia and others
- G. Bone and joint manifestations associated with systemic diseases, e.g. osteomalacia, osteoporosis, Marfan's syndrome, endocrine disorders, psoriasis, fluorosis and others

Note: Almost all the varieties of bone and joint diseases are seen in India, in varying proportions in all age groups and in different geographical regions

active rheumatoid disease (RA), systemic lupus erythematosus (SLE) and infective arthritis. The ESR is generally normal or only mildly elevated in osteoarthritis and allergic arthropathies.

B. C-reactive protein (CRP): This is a beta globulin which is absent in normal plasma but appears in the presence of different types of inflammatory arthritis. CRP is an acute phase serum protein that is synthesized by hepatocytes. This protein is capable of reacting with the capsule of pneumococci, and hence this name. The CRP levels rise by up to 100 folds during infection, tissue injury and inflammation. Though the physiological role of CRP is not known, it may contribute to innate immunity and suppression of autoimmune processes. Estimation of CRP level is a reliable investigation to identify inflammatory processes and follow up their progress. The test can be quantitated. CRP is more expensive than ESR.

The advantages of CRP over ESR

- 1. More rapid procedure; only a few minutes.
- 2. CRP is positive even before ESR starts rising.
- 3. CRP can be quantified by serial dilution.
- 4. It helps to distinguish between rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). In RA it is elevated, whereas in uncomplicated SLE it is not.

Sjögren's syndrome, polymyositis, dermatomyositis, liver cirrhosis, sarcoidosis and several chronic infections including tuberculosis, leprosy, kala-azar and filariasis may lead to elevation of CRP. Tobacco smoking, obesity, diabetes mellitus and hypertension lead to mild elevation of CRP baseline. Higher levels of CRP have been associated with increased risk of myocardial infarction.

In experimental animals high levels of CRP have been associated with myocardial damage. The interpretation of borderline values of the test should be correlated with the clinical picture.

Both ESR and CRP are non-specific markers of joint inflammation and connective tissue diseases. In a case where diagnosis has been made, changes in ESR can be estimated for treatment and follow-up.

C. Serological markers

- 1. **Rheumatoid factor (RF):** This consists of different types of immunoglobulins and it is seen most frequently in rheumatoid arthritis. Their presence is detected by several tests such as sheep red cell agglutination test (Rose Waaler), latex fixation test and other slide agglutination tests. RF is present in a smaller proportion of patients with systemic lupus erythematosus (SLE), progressive systemic sclerosis (PSS), mixed connective tissue (MCT) disease and others. Based on the demonstrable presence of RF, arthritis can be broadly classified into seropositive and seronegative types.
- 2. **Antistreptolysin-O titer (ASO titer):** ASO is the antibody produced against streptolysin produced by *Streptococcus hemolyticus*. Presence of ASO titer in excess of 400 Todd units should suggest active or recent infection by *Streptococcus*.
- 3. **Antinuclear factors (ANF):** These are also known as antinuclear antibodies (ANA). Several components of the nucleus elicit antibody response in the host and detection of these components help to diagnose different rheumatic diseases.

ANAs are immunoglobulins, directed against nuclear components such as DNA, RNA, histones centromere and others. Identification and estimation of levels of ANA are of great diagnostic help. Only in a few diseases their detection is of absolute diagnostic help since several diseases are associated with their presence, at least in low-titers. Methods employed to detect them include radioimmunoassay, ELISA and immunofluorescence microscopy. The pattern of immunofluorescence gives additional information. Some of the antinuclear antibodies are listed below.

Anti DNA antibodies

High levels of anti-double-strand DNA antibodies (anti-dsDNA) are suggestive of active SLE. They are also present in low levels in RA. Anti-single-stranded DNA (anti-ss DNA) is non-specific, seen in SLE, drug induced lupus, chronic active hepatitis, infectious mononucleosis and others.

Antiribonucleoprotein (anti-RNP) is elevated in mixed connective tissue diseases.

Antibodies to histones are elevated in SLE, Felty's syndrome, Juvenile rheumatoid arthritis and primary biliary

cirrhosis. Several other antibodies against various nuclear components have been identified. For example, anti-Smith, and U₃ (fibrillarin) JO-1, Mi, SS-A, SS-B, anti-RO, anti-Ka, Sn RNP, PM sal, Scl 70 and others. Their detection is of help in the specific diagnosis of some of the connective tissue diseases. All these tests are highly expensive for routine use.

Antibody	Diseases association
Anti-dsDNA	SLE
Anti-RNP	MCTD, SLE
Anti-sm	SLE
Anti-histones	
H1, H2, H3	SLE
Anti-histone	
H2A, H2B	Drug induced lupus
Anti-SSA (anti-RO)	Sjögren's syndrome (SS)
	SLE, neonatal lupus
Anti-SSB (anti-La)	SS, SLE
Anti-centromere	Limited systemic sclerosis (CREST syndrome)
Anti-JO-1	Polymyositis-dermatomyositis with lung involvement

4. **Serum complement levels:** Components of the complement system such as C3 and C4 are consumed during antigen-antibody reaction and so levels of C3 and C4 may be reduced generally or selectively.
5. **Lupus erythematosus (LE) cell phenomenon:** This is a test to detect phagocytosis of nuclear material by neutrophils seen in active SLE. Rarely the test is positive in RA and allergic states.
6. **Antineutrophil cytoplasmic antibodies (ANCA's)**
These are antibodies directed against the granules present in the cytoplasm of neutrophils and monocytes. Based upon their pattern and immunofluorescence they have been classified into three types.
1. Cytoplasmic—cANCA—directed against proteinase 3
 2. Perinuclear—pANCA—directed against myeloperoxidase
 3. Atypical—xANCA—antigen specificity not clear

Frequency of ANCA positivity

cANCA- 90% in active diffuse Wegener's granulomatosis (WG) and 70% in limited WG
pANCA- typical of microscopic polyangiitis 50-60%, Churg-Strauss syndrome-25-30%

False positive tests for ANCA are very common. Presence of low levels of ANCA are relevant only if supported by clinical and other investigational parameters.

7. **Anti-phospholipid antibodies (APLA):** These are acquired antibodies which are heterogeneous, directed against plasma proteins bound to phospholipids. APLAs are a family of about 20 antibodies that are directed against phospholipid binding plasma proteins. The target proteins include beta-2 glycoprotein, prothrombin, annexin which is a phospholipid binding

protein with anticoagulant activity, protein C, protein S and others. APLA may belong to IgG or IgM classes. These include circulating anticardiolipin antibodies and circulating lupus anticoagulant. The latter is directed against coagulation factors X and V and platelet phospholipids. The presence of these antibodies is seen in the syndrome known as antiphospholipid antibody syndrome. Lupus anticoagulant is detectable only in 30% of cases of SLE and this name is a misnomer. Lupus anticoagulant is detected by performing rapid Russel viper venom time or kaolin clotting time. Though in the laboratory it behaves like an anticoagulant, in the clinical situation presence of these antibodies leads to thrombo-occlusive phenomena. Anticardiolipin antibodies are demonstrable by ELISA test. Presence of these antibodies also gives rise to false-positive VDRL test.

8. **Serological test for syphilis:** False-positive VDRL may be obtained in SLE, especially in those cases showing the presence of anticardiolipin antibody.

D. **Biochemical tests:** Serum uric acid is elevated in gout. **Blood glucose examination:** It is important to exclude diabetes mellitus since it is a very common cause of nonarticular rheumatism.

E. **Synovial fluid examination:** Synovial fluid should be examined for its mucus content, cells, crystals and viscosity. Diagnostic findings are obtained in different types of arthritis.

F. **Arthroscopy and synovial biopsy:** Several joints can be inspected by direct arthroscopy. Diagnostic findings are present in many cases. Biopsy and several surgical procedures can be done through the arthroscope.

G. **Determination of HLA status:** Several rheumatological disorders show strong HLA associations, e.g. ankylosing spondylitis (AS) and other seronegative spondyloarthropathies show high prevalence of HLA B27. Except HLAB27, which is present in over 75% of cases of AS no other laboratory test is diagnostic of the condition.

Rheumatoid arthritis shows association with HLA DR4.

In addition to the specific investigations in rheumatic diseases, investigations for systemic diseases presenting predominantly with rheumatological symptoms are also to be done when indicated e.g. brucellosis, Lyme borreliosis, rickets, osteomalacia and others.

H. **Imaging procedures:** X-ray examination of the bones and joints gives very important diagnostic information in most of the rheumatological disorders. In conditions like ankylosing spondylitis and gout, the skiagram is pathognomonic.

Other imaging procedures which are available include:
Scintigraphy — Using isotopes the presence of inflammatory and neoplastic lesions

can be delineated and their progress can be assessed periodically. Depending upon the nature of the lesion the appropriate isotope and technique have to be chosen.

Arthrography — Imaging after instilling a radiopaque contrast into the joint.

Tenography — Imaging tendons.

High frequency ultrasound (20MHZ) can be employed to detect muscle inflammation and fascial involvement **Doppler studies** can reveal increased blood flow to inflamed muscles. Calcinosis can be picked up much earlier before radiological evidence develops.

CT Scanning and MRI

CT scanning and MRI have become very specific investigations in rheumatological disorders. CT scan can reveal the anatomical details particularly in the vertebral column, skull bones and in joints. MRI is very useful to bring out the details of cartilage inside joints, especially the semilunar cartilages inside the knees. MRI also brings out details of bone marrow and intraosseous structures. MRI of muscle can be very useful to demonstrate the severity, distribution and extent of muscle inflammation, atrophy, fibrosis and fat infiltration. Involvement of nerves and other soft tissues by bony lesions will be brought out vividly. With the advent of CT and MRI other invasive investigations have gone out of vogue.

Bone densitometry: This imaging procedure aims to measure the bone mass or bone mineral density (BMD) which is the most reliable parameter to diagnose osteoporosis and predict the chances of fragility fractures in future. The two types of bone mineral densitometers available in India are the ultrasound densitometers and dual energy **X-ray absorption (DEXA) densitometers**. This is a very reliable investigation to detect bone mass and the changes in osteoporosis and osteomalacia.

Metastases in bones The skeletal system is a common site for metastases from malignant tumours. The axial skeleton such as vertebrae, skull bones, pelvis, ribs and the long bones of the limbs are commonly affected.

These may be *osteolytic* or *osteoblastic (osteosclerotic)*.

Factors favouring bone as a common site for metastases.

1. High blood flow in areas of red marrow
2. Tumour cells produce adhesive molecules which bind them to marrow stromal cells and bone matrix. These adhesive molecules stimulate the production of angiogenic factors and bone resorbing factors that further enhance tumour growth in bone. The tumour cells establish a parasitic relation on the bone leading to progressive growth.

In osteolytic metastases, the bone destruction is effected by increasing osteoclastic activity. In myeloma, the bone response is purely lytic. Tumour cells stimulate the proliferation of osteoclasts.

Rheumatoid Arthritis: General Considerations

This is perhaps the most common form of inflammatory arthropathy seen in India. Among adult population below the age of 50 years this is the most common form of arthritis. There are several reports on the frequency of rheumatoid arthritis (RA) in different population groups. A study from West Bengal (1997) gave the prevalence rate as 4.48 to 4.63 per 1000 population. Seropositive disease occurred in two-thirds among them. The country wide general prevalence of RA is 0.5% of the population. In the rural parts it is 0.7%. Among the connective tissue diseases, RA is by far the commonest.

In western countries rheumatoid arthritis occur in 1% of the population. Above the age of 50 years osteoarthritis exceeds in number. Often it presents as symmetrical polyarthritis affecting the distal joints more commonly. In the majority it presents as a chronic fluctuating disorder, but less commonly it may have an acute presentation. The disease process may also involve several other tissues such as the skin, lungs, liver, heart, nerves and eyes during the course. Hence, many authors refer to this disease as rheumatoid state.

The exact cause and triggering factor are not fully known. Several evidences point to autoimmune mechanisms as the basic pathological processes and viral infections as triggering factors. There is increased frequency of HLA DRW4, DR4 and DR1 in these subjects. HLA DR4 is also correlated with the severity of the disease. Genetically predisposed individuals produce IgM or IgG antibodies on microbial or other forms of challenge. These antiglobulin antibodies which are known as rheumatoid factor (RF), combine with native IgG and activate complement to release lysosomal enzymes from synovial leukocytes. These elicit a type III immune response. Presence of RF is associated with higher morbidity and amplification of the rheumatoid process.

Pathology

Articular lesions: Most marked changes are seen in the joints. The earliest change is in the synovial membrane which shows congestion, infiltration by mainly CD4+ lymphocytes, plasma cells and macrophages. Synovial effusion occurs. Muscles around the joint also show mononuclear cell infiltration. Synovium shows fibrinoid degeneration surrounded by infiltration with fibroblasts and mononuclear cells. The synovial membrane is thickened, hyperemic, and edematous. It proliferates to form villi which fill the joint. Later, vascular proliferation invades the articular cartilage to form a pannus. Irreversible destruction of cartilage occurs in the later stages of the disease. The proliferated synovial membrane which invades cartilage, ligaments and subchondral bone centripetally liberates proteolytic enzymes which aggravate the destructive process.

Several cytokines participate in the inflammatory process. Among these TNF- α plays the major part. Antigen activated CD4+T cells lead to the production of several cytokines such as 1L-1, 1L-6, and TNF α . TNF α is a soluble 17 kd protein with three identical subunits. It is a potent cytokine involved in normal inflammatory and immune responses. It is an autocrine and paracrine inducer of several other cytokines, such as 1L-1, 1L-6, 1L-8, PDG F- β , eicosanoids, platelet activating factors, and granulocyte monocyte colony-stimulating factor (GM-CSF). TNF α is present in high levels in the synovial fluid and it plays an important role in inflammation and joint destruction which are the hallmarks of RA. Modern biological therapeutic agents target TNF α to block its action in causing inflammation.

The articular cartilage is eventually destroyed with loss of joint space. Fibrosis develops across the joint space to produce ankylosis. The joint is deformed and secondary degenerative changes develop. Infection may supervene in these joints to convert them into pyoarthroses.

Extra-articular lesions: Other tissues are affected to varying degrees. Basic pathology is the same as in the synovium. Lesions are seen in the skin, lungs, heart, liver, nervous system, and eyes. The small blood vessels may be affected. They show intimal hyperplasia, perivascular round cell infiltration, and occasionally necrotizing panarteritis. Subcutaneous nodules consist of a central areas of fibrinoid necrosis surrounded by mononuclear cells arranged in a palisade manner.

Clinical Features

Females are affected more than males in a ratio of 4:1. The disease is more common in the fourth and fifth decades. The disease passes through different stages (Fig. 105.1):

1. Onset to 6 months -early disease
2. 6 months to 3 years -established disease
3. Above 3 years -advanced disease.

Fig. 105.1: Typical rheumatoid arthritis hands, moderately advanced. Note: (1) swelling of finger joints, (2) deformity of fingers, (3) wasting of small muscles of the hands (arrow head)

Early symptoms are non-specific and they include undue fatigability, weight loss, poor appetite, transient myalgias, and paresthesia.

Articular involvement: The onset is generally insidious and the disease presents as a chronic symmetrical poly-arthritis. Less common presentations include: (1) acute polyarthritis, (2) oligoarthritis, (3) acute monoarticular arthritis, (4) chronic monoarticular arthritis, and (5) systemic disease with fever, sweating, leukocytosis and pleural effusion in addition to arthritis.

Any diarthrodial joint may be inflamed. Arthralgia, arthritis, muscle wasting, tendonitis, tendon rupture, and deformities constitute the main lesions. The affected joints are warm, painful, and swollen. Movements are restricted, especially in the morning after sleep (morning stiffness) and after periods of resting. Classic lesions are in the joints of the hands and feet. Metacarpophalangeal, metatarsophalangeal, and proximal interphalangeal joints are inflamed most frequently. Wasting of the small muscles of hand may develop due to disuse and direct muscle involvement (Figs 105.2 to 105.5).

In the hands, there is the typical ulnar deviation of the metacarpophalangeal joints. Sometimes, there is anterior subluxation of metacarpal heads and medial dislocation of the extensor tendons. Swan neck deformity of the fingers consists of hyperextension of the proximal interphalangeal joints and flexion of the distal interphalangeal joints. This deformity impairs effective hand grip. Sometimes, the extensor expansion overlying the proximal interphalangeal joint ruptures resulting in the dorsal protrusion of the head of the proximal phalanx. This leads to flexion of the proximal interphalangeal joint and hyperextension of the distal interphalangeal joint (*boutonnière or button hole*) deformity.

The extensor tendons may undergo attrition, these result in loss of extension of the *fingers (dropped fingers)*. The thumb may show a 'Z'-shaped deformity (*Hitch-hiker's thumb*). Large joints like the knees, wrists, ankles, elbows, and shoulders may also be involved. Tense synovial effusions may develop in the knees. **Baker's cysts** are tense cysts developing in the popliteal fossae as a result of collection of synovial fluid. These may occasionally rupture giving rise to a painful and tender swelling on the calf. Lateral subluxation of the knee joint is also very common. Chronic arthritis develops which leads to permanent deformities. Deformities are also common in the feet. **Hammer toe** is flexion at the proximal interphalangeal joint and hyperextension at the metatarsophalangeal joint. **Hallux valgus** (lateral deviation of the big toe) may develop. The arches of the feet may be lost due to affection of the joints and ligaments. Callosities develop over prominent bony points.

Less commonly, the cervical spine and temporomandibular joints are affected, but when they occur, the lesions

Fig. 105.2: Rheumatoid hand

Fig. 105.3: Rheumatoid hand: swan-neck deformity left index finger

Fig. 105.4: Hitch-hiker's thumb

Fig. 105.5: Dropped fingers

are characteristic. At the atlantoaxial joint the transverse ligament of the atlas may be weakened leading to **atlantoaxial subluxation**. This leads to pain in the neck and pain referred to the temporal and retro-orbital regions. There may also be a “clunking sound” in the neck on flexion. It is dangerous to manipulate the neck to elicit this sign. Atlantoaxial subluxation produces a host of neurological manifestations. The risk of sudden compression of the spinal cord is high in such subjects. Hence, tracheal intubation and similar procedures which require manipulation of the neck should be done only with caution. **Temporomandibular arthritis** leads to pain on mastication. Other portions of the spine such as the dorsolumbar regions and sacroiliac joints are usually not affected.

Tissue Involvement in Rheumatoid Arthritis

<i>Number of joints affected</i>		
Monoarticular (Only one joint affected)	-	3%
Oligoarticular, pauciarticular (less than 4 joints affected)	-	34%
Polyarticular	-	63%
<i>Joints affected</i>		
Proximal interphalangeal joints (PIP)	-	85%
Metacarpophalangeal joints (MCP)	-	70%
Wrists	-	70%
Elbows	-	50%
Knees	-	80%
Ankles	-	65%
Metatarsophalangeal joints (MTP)	-	30%
<i>Nonarticular involvement</i>		
Pulmonary interstitial fibrosis	-	3%
Episcleritis	-	1%
Sjögren’s syndrome	-	2%
Pleural effusion	-	1%
(As reported from Chennai, India)		

Systemic Involvement

Extra-articular Manifestations

Skin: Painless and nontender subcutaneous nodules ranging in size from a few millimeters to a few centimeters develop around the extensor aspects of the elbow and other subcutaneous bony surfaces and over tendons in 20-30 percent of cases. They are almost always associated with a positive serology. They persist for considerable periods (Fig. 105.6). Involvement of blood vessels gives rise to Raynaud’s phenomenon, vasculitis of the nailbeds and finger pulps, nonhealing ulcers of the finger, palmar erythema, and hyperhydrosis of the extremities (Fig. 105.7).

Eyes: Ocular lesions develop in a few cases and these may become disabling. Scleritis is common. In some cases

Fig. 105.6: Rheumatoid nodules elbow

Fig. 105.7: Rheumatoid disease with chronic ulcer ankle vasculitis

it becomes nodular. In necrotizing scleritis the nodules degenerate and the underlying dark uvea imparts a blue colour. Sometimes the sclera may be thickened due to granuloma formation. Perforation of the sclera leads to prolapse of the uvea and eventual rupture of the globe (**scleromalacia perforans**).

In the cornea, band keratopathy may develop. This is more frequent in Still’s disease. Though the sclera is affected, it is rare to involve the iris. Lesions of the iris are more frequent in seronegative arthropathies.

Respiratory system: **Cricoarytenoid** arthritis manifests as dysphonia, stridor, or dyspnea. Recurrent pleural effusion may occur which is usually unilateral. Rheumatoid nodules may develop in the lungs and these may cavitate. Interstitial fibrosis may develop and this may be indistinguishable from the idiopathic type.

Caplan’s syndrome is a special phenomenon occurring in subjects with rheumatoid disease who develop pneumoconiosis. Large coalescing nodules develop in the lungs. These are demonstrable by X-rays (Fig. 105.8).

Fig. 105.8: X-ray of lung—Caplan's syndrome

Cardiovascular system: It is only rarely involved. Lesions include pericarditis, aortic regurgitation, and conduction defects.

Nervous system: Neurological involvement is not uncommon in chronic cases.

1. **Entrapment neuropathy** such as carpal tunnel syndrome and tarsal tunnel syndrome may be the presenting lesions or they may develop during the course.
2. **Symmetrical polyneuropathy** develops which improves with treatment. *Mononeuritis multiplex* develops in some cases.
3. In severe cases of rheumatoid disease (**malignant rheumatoid arthritis**) foot drop and wrist drop may develop. These are generally resistant to treatment.

Cervical cord compression due to atlanto-axial subluxation is a less common complication in long-standing RA. Mild cases present with transient neck pain radiating to the back of the head. It can rarely lead to subluxation of the odontoid process with compression of the cord which may end fatally.

Progressive clinical *myelopathy* at a lower level may develop insidiously. This is characterized by gradual onset of limb weakness, inability to hold the head erect and quadriparesis. The lesion is due to subluxation at lower levels of the cervical cord.

Renal Lesions

Type 1 renal tubular acidosis, drug induced renal lesions.

Secondary amyloidosis is a late complication in some cases of generalized rheumatoid disease (see also Chapter 174).

Laboratory Investigations

Erythrocyte sedimentation rate is markedly raised in the active disease and may exceed 100 mm/hour in the

majority. Normochromic normocytic anemia, iron deficiency anemia or rarely hemolytic anemia may be present in the acute phase. Serum protein electrophoresis may show elevation of alpha-2 gammaglobulins.

Serology: Markers of disease activity

Rheumatoid factor: Antibodies in rheumatoid disease, especially the IgM, can be demonstrated by the *Rose Waaler test*, *latex fixation test* or *bentonite flocculation*. Rheumatoid factor is positive in 80% of adults with rheumatoid arthritis. A differential agglutination titer of 16 and above is diagnostic. In 20% of cases LE cells and antinuclear antibodies may be demonstrable. To establish seropositivity the test should be positive at least on two occasions separated by 3-6 months. If negative, it should be repeated at least once more after 6-12 months. During DMARD treatment quantitative estimation of rheumatoid factor can be used as a marker of disease activity and progression. 5-10% of normal individuals may show RF positivity in low titers.

Synovial fluid aspiration: This reveals a turbid fluid with low viscosity and poor mucin clot. The white cell count in the fluid exceeds 1500/cmm. The cells are mostly neutrophils even though the synovial membrane is not infiltrated by them. Complement levels are low. The protein content is high and the electrophoretic pattern approaches that of serum.

Radiology: Characteristic lesions which have been graded from I to IV are seen on radiological study.

Grade I: Soft tissue swelling which indicates synovitis with or without juxta-articular osteoporosis which indicates active inflammation.

Grade II: Narrowing of joint space due to cartilage destruction.

Grade III: Erosions which may be of 2 types:
i. Surface erosion at joint margins,
ii. Cystic erosion of the bone shaft.

Grade IV: Marked irregularity of articular surfaces with subluxation and secondary degenerative changes. Bony ankylosis occurs only very rarely. (Figs 105.9 to 105.11).

Diagnosis

The diagnosis is to be made on clinical examination and laboratory criteria. Since, clinically several conditions resemble rheumatoid arthritis, diagnostic criteria have been laid down.

Differential diagnosis: Rheumatoid arthritis has to be distinguished from **rheumatic arthritis** in which children are more affected, the joint lesions are migratory, large joints are affected, effusion is prominent and ASO titer is high (more than 1/200).

Fig. 105.9: X-ray wrist-early rheumatoid arthritis. Note: loss of clear margins, haziness of inter carpal joints and juxta articular osteoporosis more so on the right side

Fig. 105.10: Advanced lesion—elbow. Note loss of joint space ankylosis

Fig. 105.11: X-ray of rheumatoid hand. Note the juxta-articular rarefaction of bone

Diagnostic criteria for rheumatoid arthritis (RA)

1. Morning stiffness extending for 1 hour or more.
 2. Arthritis of three or more joints.
 3. Arthritis of hand joints.
 4. Symmetrical arthritis.
 5. Rheumatoid nodules.
 6. Positive rheumatoid factor test: significant titer in India is $>20 \mu\text{U/mL}$
 7. Radiological abnormalities.
- Four or more of these criteria occurring for more than six weeks should make the diagnosis probable.

In **psoriatic arthritis** there is invariably evidence of psoriasis of the skin or nails and the arthritis involves the small joints of the hands (especially distal interphalangeal joints) and feet more. The hand may be severely mutilated (**arthritis mutilans**). Involvement of the sacroiliac joints and spine is not uncommon.

Gout Several joints may be affected in gout. The metatarsophalangeal joint of the big toe is characteristically affected more frequently, though any joint may be involved. In chronic tophaceous gout tophi may be seen as nodules around the joints, especially the elbow.

Osteoarthritis affects elderly subjects. Most common joints affected are the spine, hips, knees, and distal interphalangeal joints. **Heberden's nodes** may be seen at the base of the distal phalanges. The condition is progressive. The ESR is generally normal or only moderately elevated. In many cases rheumatoid and osteoarthritis may coexist in different joints.

Allergic arthritis manifests as arthralgia and arthritis involving several joints, both proximal and distal. Permanent deformity does not occur. Other manifestations of allergy may be evident. The ESR is only moderately elevated and not to the high levels seen in rheumatoid disease.

Other conditions which may mimic rheumatoid arthritis are **syphilitic arthritis**, **gonococcal arthritis**, **Reiter's syndrome** and **ankylosing spondylitis**. In ankylosing spondylitis the sacroiliac joints and spine are maximally affected. Peripheral joint involvement is less common.

In India several other conditions should be considered when the clinical presentation and investigation are not helpful straight away. These include allergy to tuberculosis (**Poncet's syndrome**), serum sickness-like reactions, reactions in leprosy, drug induced arthralgias, infections such as brucellosis and borreliosis, joint tuberculosis, AIDS and others.

PROGNOSIS

In general the disease tends to become recurrent and chronic and in many cases it leads to considerable disability and deformity. Severe rheumatoid arthritis shortens life. It leads to severe impairment of the quality

of life. A third of the patients with RA deteriorate clinically by consumption of food articles such as trout, fishes, peas, carrots, bottled mineral water, sea salt, milk, dairy products, wheat, coffee, chocolate, citrous fruits, corn and others. Free amino acids and oligopeptides contained in some of them are weakly antigenic and they may be responsible for this adverse effect.

Favourable criteria are:

1. Acute onset.
2. Male sex.
3. Onset at late age.
4. Asymmetrical or monoarticular involvement.
5. Negative rheumatoid factor.
6. Absence of subcutaneous nodules,
7. Absence of vasculitis, and
8. Prompt response to therapy early in the disease.

Unfavourable prognostic factors:

1. High titers of rheumatoid factor.
2. Insidious onset and failure to achieve remission even after 12 months of treatment.
3. Early development of nodules and bony erosions.
4. Extra-articular lesions.
5. Female gender.
6. HLADR₄ and DR₁ especially if homozygous.

Management

The aims of therapy are:

- a. Relief of pain
- b. Control of disease activity
- c. Prevention of joint damage and disability
- d. Maintenance and recovery of function
- e. Improvement in the quality of life

The modalities employed include:

- a. Patient education
- b. Physiotherapy and occupational therapy
- c. Drug therapy
- d. Surgical measures
- e. Improvement in nutrition and
- f. Supportive measures.

General Measures

Bed rest is essential during the acute phase of the disease. Local rest is ensured by splints which reduce muscle spasm and deformities. In the stage of deformity, splints are used as corrective measures. Physiotherapy to relieve muscle spasm and maintain joint mobility is an essential component of management during all stages of the disease.

Articles of diet such as fish or fish-oils which are rich in eicosapentanoic acid and docosahexaenoic acid are reported to give relief of inflammation and clinical symptoms, when combined with other modalities of

treatment. These polyunsaturated fatty acids suppress the inflammatory response and platelet activation. They may be tried in suitable cases. The dose of fish oils required for the beneficial effects varies from 10-20 g daily.

Drugs: There is no curative drug. Hence several groups of drugs are used symptomatically. Some also suppress inflammation and bring about resolution of the disease process.

1. *Analgesics*, e.g., aspirin, paracetamol, dextropropoxyphene.
2. *Analgesic anti-inflammatory drugs*, e.g. indomethacin, phenylbutazone, naproxen, ibuprofen, ketoprofen, fentiazac, mefenamic acid, flufenamic acid, diclofenac, nimuselide and the newer selective cyclooxygenase inhibitors (COX2 inhibitors) such as celecoxib, valdecoxib, rofecoxib, etoricoxib and others.
3. *Disease modifying drugs* such as gold salts, chloroquine, hydroxyl chloroquine, penicillamine and salazopyrine.
4. *Anti-inflammatory and immunosuppressant drugs*—corticosteroids and *biological agents* such as infliximab, adalimumab and etanercept, anakinra.
5. *Immunosuppressants* like methotrexate cyclosporin, cyclophosphamide, azathioprine and others.

Aspirin: Aspirin being very effective and cheap used to be the drug of first choice in all cases. This is given as calcium aspirin or the other preparations in doses of 3-6 g/day and an antacid is prescribed concurrently to reduce gastric upset. Troublesome side effects include abdominal pain, upper gastrointestinal bleeding, allergic rashes, tinnitus and vertigo. Due to weaker action and availability of more potent drugs, aspirin is rarely used as the drug of first choice at present.

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

These are the most widely used drugs in view of their analgesic and anti-inflammatory action and free availability. The analgesic effect of NSAIDs is prompt within hours, whereas the anti-inflammatory effects manifest only after two weeks of therapy.

1. Indomethacin	25-50 g three times daily
2. Naproxen	200 mg two times daily
3. Ibuprofen	100-800 mg three times daily
4. Ketoprofen	100 mg two or three times daily
5. Fentiazac	200 mg two times daily
6. Mefenamic acid	250 mg four times daily
7. Flufenamic acid	100 mg four times daily
8.. Diclofenac sodium	50 mg thrice daily
	also the potassium salt and several others.
9. Nimesulide	100 mg twice daily

All of them share the same gastrointestinal side effects of aspirin but to a lesser degree and these are indicated when adequate relief is not obtained with rest, splinting and use of disease modifying drugs. They are several times more expensive than aspirin. NSAIDs are effective in relieving pain and acute manifestations. As a maintenance therapy they help to suppress symptoms and make the patient ambulant. They have only little effect in modifying the course of the disease, so that the disease flares up on withdrawing the NSAID. Therefore, they have to be combined with disease-modifying antirheumatic drugs (DMARDs).

Gastrointestinal complications induced by the ingestion of NSAIDs have assumed importance in recent times since hematemesis and melena occurring in day-to-day practice are commonly induced by these drugs. 1-3% of patients consuming NSAIDs develop a major gastrointestinal problem annually. The manifestations include overt or occult gastrointestinal bleeding, acute and chronic gastritis and progressive anemia. *H. pylori* infection is an independent risk factor which also aggravates hematemesis. NSAID related hematemesis has a mortality of 5-10% if not treated promptly, NSAIDs inhibit the synthesis of prostaglandins. Prostaglandins are protective to the mucosa. Even as small a dose as 30 mg of aspirin can inhibit gastric prostaglandin synthesis. The spectrum of lesions includes subepithelial hemorrhage, erosions and ulcers in the stomach and duodenum. NSAIDs should not be taken on an empty stomach since this favours gastrointestinal complications especially pain and bleeding. These can be prevented to some extent by the concurrent use of a H₂ receptor blocker such as ranitidine 150 mg b.d or a proton pump inhibitor such as omeprazole 40 mg o.d or b.d. Antacids and mucosal protective agents like sucralfate and prostaglandins augment the benefit partially.

The different NSAIDs vary in their propensity to cause gastrointestinal bleeding. Aspirin is highly ulcerogenic to the gastroduodenal mucosa. None of the NSAIDs is totally safe. All NSAIDs cause serious impairment of renal function in those with underlying kidney lesion.

COX-2 inhibitor drugs have been introduced with the claim that they do not produce gastrointestinal bleeding, e.g. celecoxib 100 mg b.d., valdecoxib, rofecoxib, etoricoxib and others. The average dose is 100 to 120 mg b.d. They are more expensive. They are effective pain relievers but, long term use has revealed serious adverse effects including the precipitation of cardiac failure and sudden death. Some of the COX-2 inhibitors such as rofecoxib have been withdrawn from the market due to their adverse effects on the cardiovascular system.

Disease-modifying Antirheumatic Drugs (DMARDs)

Even though DMARDs used to be administrated as the second line drugs when the analgesics and NSAIDs proved inadequate, the present trend is to employ them early in the course of the disease in order to modify the disease activity and prevent progression and permanent disability. The drugs included in this class are chloroquine, hydroxychloroquine, sulfasalazine, glucocorticoids, methotrexate and immunosuppressants and biological disease modifiers. DMARDs should be introduced early during therapy. They are effective in >80% of cases.

Chloroquine diphosphate 250 mg twice daily or once at bed time orally is effective in controlling pain, swelling, and stiffness in chronic cases. The drug is to be used over long periods. It helps to suppress the inflammatory process and prevent further deterioration. Serious side effects include retinopathy and deposition of the drug in the cornea. These are indications for stopping the drug.

Hydroxy chloroquine is more effective and it is to be preferred. The dose is 200 mg b.d orally. This is more expensive than chloroquine.

Salazopyrine and its analogues which are used for ulcerative colitis are excellent drugs to bring about relief and modify the progression of the disease. The dose is 0.5 g thrice a day orally. The effect is manifested after a week or two of starting the drug. It may have to be continued for several months or even years. The common adverse side effects include gastrointestinal upsets, allergic manifestations and blood dyscrasias. The drug is expensive, but widely used.

Systemic corticosteroids: These are very helpful in bringing about dramatic relief in acute cases and during exacerbations. Due to their undesirable side-effects, they should be employed only when other drugs fail and that too for short periods if higher doses are employed.

Indications for systemic corticosteroids are:

- Active and progressive vasculitic disease.
- Severe incapacitation—corticosteroids give temporary relief and make the patient suitable for physiotherapy.
- In severe and progressive radiological joint damage, use of corticosteroids helps to arrest the lesion and salvage the joint.
- Special situations like pregnancy and lactation.

When systemic therapy is unsuccessful intra-articular injections of cortisone acetate or triamcinolone hexacetonide or methylprednisolone acetate may be given. In uni-articular disease this may be advantageous. Intra-articular dose is 50-100 mg of cortisone acetate for large joints and

5-10 mg for small joints. After the acute symptoms are controlled, systemic therapy should be resumed in the minimum dose required. Corticosteroids should be withdrawn as early as possible since they do not modify the course of the disease in chronic cases. They induce steroid-dependence and also confer the adverse effects of corticosteroid therapy if given in doses equivalent to 5 mg prednisolone or above. Still a few patients do require small doses of corticosteroids for symptom free relief (steroid dependent cases), in addition to other drugs.

Immunosuppressant drugs: Cyclophosphamide, azathioprine, cyclosporin A, chlorambucil and low dose methotrexate are potent drugs which suppress the immunological injury and help to arrest the disease process. All these drugs have been tried with benefit. At present methotrexate given orally in a dose of 5-15 mg twice weekly is the most widely used drug in this group.

Biological Therapies

Blocking the action of $TNF\alpha$ is highly effective in the treatment of early and advanced RA. The available biologicals are:

1. **Infliximab:** Is a monoclonal antibody that binds $TNF\alpha$ with high affinity. The dose is 3-10 mg/kg b.w IV at 0, 2 and 6 weeks followed by maintenance infusion once in 8 weeks. It predisposes to reactivation of tuberculosis.
2. **Adalimumab:** It is a fully humanized antibody that binds $TNF\alpha$, made by rDNA technology. It is given in doses of 20-80 mg SC weekly. Adverse side effects include severe infections, neurological defects and lymphoid malignancies.
3. **Etanercept:** This is a recombinant fusion protein which binds 2 $TNF\alpha$ molecules. It is given in a dose of 25 mg SC twice a week or 50 mg once in two weeks. Adverse effects include local irritation at injection sites and predisposition to infection. Other drugs in this group are *lanercept*, *atlizumab*, *abatacept*.
4. **Anakinra:** It is a recombinant form of nonglycosylated human interleukin-1 receptor antagonist, expressed in *E.coli*. The dose is 1-2 mg/kg/SC. Adverse side effects include leukopenia, cardiac arrest, flu-like symptoms and infections like tuberculosis.
5. **Leflunomide** is a new drug which is an isoxazole derivative. Leflunomide is a pro-drug which is converted into its active metabolite in the system. It blocks the enzyme dihydro-orotate dehydrogenase which is needed for the synthesis of pyrimidines. It blocks proliferative activity. Its DMARD activity is comparable to that of sulfasalazine and methotrexate. The dose is 100 mg/day/oral for 3 days and adjusted thereafter. It is contraindicated in pregnancy due to

fetotoxicity. Serious side effects include hepatic damage and others.

TNF inhibitors are indicated in patients with active rheumatoid arthritis who have had no response to conventional DMARDs. TNF inhibitors should not be combined due to risk of infections. Vaccination using live vaccines should be avoided during TNF inhibitor therapy. Pregnancy should be avoided during therapy. If TNF inhibitors are found to be ineffective within 3-6 months of therapy or if they produce severe toxic effects they should be withdrawn. TNF inhibitors increase the incidence of lymphomas.

Indian experience on these biologicals is limited, though a few studies are available. Effect on RA is good, but all authors report the risk of exacerbation of tuberculosis. These drugs are very expensive Rs. 33500 for 100 mg of infliximab and Rs. 16500 for 25 mg of etanercept.

Further reading: Mahajan A. Biological therapy in rheumatoid arthritis, current status Indian J Rheim 2006; 1(1):13-9.

Pregnancy and Antirheumatic Drugs

NSAIDs should not be given during the last four weeks of pregnancy since they may give rise to bleeding complications and delay in labour. During lactation, a short acting NSAID such as ibuprofen is preferable, taken just before feeding the baby. The feeding interval should be four hours or more. Prednisolone, sulfasalazine, paracetamol and azathioprine are safe during pregnancy. Chloroquine is contraindicated. Methotrexate is absolutely contraindicated since it causes fetal death.

General Principles of Therapy

It is now established that use of disease modifying agents which will arrest progress of the disease and prevent joint damage should be introduced from the start of therapy. DMARDs can be used singly or in combination determined by trial and error and the experience of the physician. The effects produced by these drugs are slow. Therefore, analgesics and NSAIDs have to be given for immediate symptomatic relief of acute cases and those who are steroid-dependent, corticosteroid preparations have to be given systemically or intra-articularly.

The present approach is as follows:

Step 1. Early cases	Combination therapy with NSAIDs, DMARDs, and physical modalities.
Step 2. Moderately advanced cases	Combination therapy with immunosuppressants or immunomodulators.
Step 3. Disabling deformities	Drug combinations, surgical correction of deformities and rehabilitation.

Physical Modalities of Treatment

These play a major role in the total management of all cases of moderately advanced and advanced rheumatoid disease. The aims of physiotherapy are:

1. To provide comfort, relieve pain and aid in recovery,
2. To prevent deformities and loss of function of joints, and
3. To help in functional and corrective rehabilitation.

Physical modalities of treatment include various forms of superficial and deep heating devices, ultrasound, short-wave, exercises, manipulation of joints, splinting and several others. During the acute and subacute stages of the disease, rest, splinting and various forms of heat give relief. As the pain subsides, exercises are started with a view to maintain normal range of movement in all joints and prevent wasting of muscles. These have to be accepted as a life-style by the patient. Surgical measures and rehabilitatory procedures are to be instituted in crippled patients.

In Ayurveda and several types of herbal medicine prevalent in India there are modalities of treatment which are preferred by many patients. Their role in the management of rheumatoid arthritis has to be evaluated by modern methods.

Surgical correction: When permanent joint deformities develop, surgical measures have to be employed. These help to relieve morbidity and hasten recovery. Occupational therapy, social rehabilitation and re-education constitute the remedial measures necessary in bringing the cripple back to the stream of almost normal day-to-day activities.

Medical synovectomy: Synovial obliteration can be achieved by the instillation of osmic acid, or a variety of radioactive colloids into the synovial cavity.

Surgical measures include surgical decompression of the joint and synovectomy, especially at the wrists and carpal tunnel, reconstructive tendon surgery, osteotomies, excision arthroplasty, arthrodesis and joint replacement.

Further reading: Indian guidelines for the management of rheumatoid arthritis JAPI 2002;50:1201-18.

Variants of Rheumatoid Arthritis

Several arthritic syndromes occur which show some resemblance to rheumatoid arthritis, but also show distinguishing features with overlap into other conditions. These include:

1. *Juvenile idiopathic arthritis (JIA)*
2. *Felty's syndrome.*
3. *Sjögren's syndrome,* and
4. *Palindromic rheumatism.*

Juvenile Idiopathic Arthritis (JIA)

It is the most common cause of chronic arthritis in childhood. This term encompasses all idiopathic arthritis affecting children below 16 years of age and lasting for more than 6 weeks. This may be oligo- or polyarticular. In the oligoarticular types lower limb joints-knees, hips, ankles and tarsal joints are affected asymmetrically. In the polyarticular type both small and large joints are affected, usually in a symmetrical manner. The clinical features may be confined to the skeletal system, but in 10% the onset and course are characterized by systemic manifestations such as high fever ($>38.5^{\circ}\text{C}$) transient erythematous rash, generalized lymphadenopathy, hepatosplenomegaly, anemia and weight loss. Fever is intermittent with periods of normal temperature in between, during which the child appear to be normal. The serious complications include *macrophage activation syndrome* characterized by onset of thrombocytopenia, anemia, liver dysfunction and rapid downhill course which may end fatally.

Treatment

In addition to all general measures required for poly-arthritis, specific medications include methotrexate in relatively high doses, cytotoxic immunosuppressant drugs, IV IG, and biological therapies such as etanercept. Aspirin, NSAIDs and corticosteroids relive symptoms and may even modify the course of the disease.

About 50-60% of children recover by the time they reach adulthood, where as 40% continue to have active disease even after 10 years.

Aggarwal A, Grover S. Juvenile idiopathic arthritis, classification, diagnosis and treatment. In Sukumar Mukherjee (Ed): Recent-Trends in Connective Tissue Disorders. Indian college of physicians publication 2005;209-21.

Macrophage Activation Syndrome (MAS)

This is a complication which can develop in chronic rheumatic disorders, particularly in systemic onset juvenile idiopathic arthritis. It is a hemophagocytic syndrome characterized by excessive activation of well differentiated macrophages, clinically manifesting as fever, hepatosplenomegaly, lymphadenopathy, peripheral blood cytopenias, liver involvement, intravascular coagulation and neurological lesions. This entity has been described from India, mostly associated with other connective tissue diseases or malignancy. Untreated, the mortality is high reaching up to 40%.

Ref: Pinto L, et al. Macrophage activation syndrome: experiences from a tertiary referral centre. JAPI 2007; 55:185-7.

Classification

1. Familial MAS—caused by gene mutations
2. Secondary or acquired—seen in viral infections and malignancy
3. Reactive—it is also secondary to rheumatic diseases

Pathogenesis

Macrophage activation occurs as a result of Th-1, T cell activity. The T cells augment the phagocytic capacity of the macrophages and also recruit the macrophages to the site of inflammation or infection. Bone marrow is stimulated to produce macrophages. Th-2 cells inhibit the processes.

Strong immunological activation may result from infection, malignancy or autoimmune disease. The viruses particularly incriminated include herpes viruses—especially Epstein-Barr virus, cytomegalovirus and adenoviruses.

The pathological findings in infection-associated histiocytosis include

1. Infiltration of all organs by benign-looking lymphocytes and histiocytes and
2. Atrophy of the germinal centres of lymph nodes and spleen.

The immunological abnormalities include hyperstimulation by infective agents, immunosuppression by drugs or HIV or immune dysregulation as in autoimmunity and malignancy.

Clinical features include fever, cutaneous rash, lymphadenopathy, hepatosplenomegaly and a downhill course. Failure of the liver and central nervous system, disseminated intravascular coagulation (DIC) and overwhelming infections may supervene. If untreated, the disease is fatal in about two weeks.

Investigations reveal cytopenias, rise in liver enzymes such as transaminases, at times alkaline phosphatase, LDH and high serum ferritin levels often exceeding 10000 ng/dL. Blood picture is one of normocytic normochromic anemia, low reticulocyte counts and sometimes, atypical lymphocytes. The ESR is characteristically low due to hypofibrinogenemia.

Bone marrow shows varying cellularity, with normo- or at times, megaloblastic erythropoiesis. There is infiltration by histiocytes accounting for > 2% of the cells. Many show hemophagocytosis (i.e.) phagocytosis of erythrocytes.

Treatment

This includes supportive care and attention to the underlying disease. Two lines of treatment are available.

1. Interruption of function of the activated macrophages and histiocytes by drugs such as etoposide, glucocorticoids and IV immunoglobulin (IVIG).
2. Interruption of function of the activated lymphocytes by glucocorticoids, cyclosporine, antithymocyte globulin (ATG) and biological drugs against TNF α .

Further reading: Joshi VR, Kaushik Bhyani. Macrophage. Activation syndrome. In Mukerjee S (Ed): Recent Trends in Connective Tissue Disorders. Indian College of Physicians Publication 2005;161-9.

Still's Disease (Chronic Juvenile Polyarthritis)

This disorder occurs before the age of 16 years. Girls are affected more than boys. It differs from adult rheumatoid disease in that the disease is more often pauciarticular. Rash, fever, lymphadenopathy, and splenomegaly are characteristic. Subcutaneous nodules are rare and rheumatoid factor is negative. Eye involvement with uveitis and keratopathy is more common. The treatment is along the same lines as for adult rheumatoid arthritis.

Felty's Syndrome

This is seen in older age groups. In addition to the classic features of seropositive rheumatoid arthritis, splenomegaly and neutropenia also occur. Splenomegaly may lead to hypersplenism. Splenectomy may have to be considered to correct hypersplenism, in addition to treatment for the rheumatoid state.

SJÖGREN'S SYNDROME (SS)

This is a chronic inflammatory autoimmune disease characterized by mixed cellular infiltration of the exocrine glands, particularly the lachrymal and salivary glands— a form of autoimmune exocrinopathy (autoimmune epithelitis). This results in dryness of the eyes (xerophthalmia), dryness of the mouth (xerostomia) and frequently, dryness of the nose, throat and vagina. This condition predisposes to increased risk of **mucosa-associated lymphoid tissue lymphoma (MALT lymphoma)**.

SS may be primary in which it is the only demonstrable abnormality. Secondary SS, known also as sicca complex may be associated with any of the other autoimmune diseases. Radiation therapy of the head and neck for Hodgkin's disease, sarcoidosis, amyloidosis and tuberculosis may lead on to SS.

Epidemiology: The disease is rare. 2% of cases of rheumatoid arthritis and 0.73% of SLE may have associated S S. Almost all patients are females. They show association with HLA (DW3) (DR3) and DR52.

Immunology: At least one of the following autoantibodies will be present in the serum. These are-antibodies to Ro/SS-A in 40-60% or LA/SS-B, ANAs or rheumatoid factor. Levels of these antibodies correlate with the degree of cellular infiltration of the salivary and other glands. B-cell activation is the consistent immunoregulatory aberration. Viral infections may trigger off the condition.

Clinical features: A wide spectrum of clinical features may be present. These are:

1. Ocular dryness and consequent symptoms
2. Oral dryness with consequent symptoms
3. Arthralgias in 75%, arthritis in 10%
4. Skin manifestations- annular erythema on the face and trunk
5. Vascular involvement- leading to Raynaud's phenomenon in 35-50%
6. Gastrointestinal symptoms -dysphagia, atrophic gastritis
7. Renal tubular acidosis
8. Hypothyroidism in 10-15%
9. MALT lymphoma (Table 105.1)

Diagnosis

Schirmer's test is positive. This test is based on the wetting of a piece of filter paper by tears when applied to the palpebral conjunctiva. It is positive if the length of the wetting is < 5 mm in 5 minutes. Biopsy of the parotid gland, salivary scintigraphy and parotid sialography are helpful in diagnosis.

Course: The disease follows a benign prolonged course over 10-12 years or more.

Treatment: The conjunctival sac and mouth are kept moist. Hydromellose (hydroxy methyl cellulose) helps to moisten the conjunctival sac.

Strict oral hygiene is advised. Bromhexine 40 mg/day oral in divided doses and pilocarpine hydrochloride 5 mg tds helps the dryness of the mucous membranes. Drugs such as hydroxychloroquine 200 mg oral daily, corticosteroids, cyclosporin and interferon have been tried with modest benefit. High dose IVIG and plasma exchange may produce limited benefit.

TABLE 105.1

Showing clinical features in SS

Glandular features	Extra glandular features
Xerostomia dry eyes parotid enlargement	Arthralgia/arthritis Raynaud's affection of organs—lungs, kidneys, liver peripheral nerves, muscles, CNS and vasculitis and lymphoma

Secondary SS occurs as a complication of RA, PSS, SLE, MCD, and primary biliary cirrhosis, (polymyositis/ dermatomyositis, (PM/DM) chronic active hepatitis (CAH) and mixed cryoglobulinemia. The underlying disease generally manifests earlier.

Prognosis: The condition is generally benign. Purpura, glomerulonephritis, decrease in complement levels and mixed monoclonal cryoglobulinemia are adverse prognostic factors.

Treatment: Eye care, sugar free lozenges for xerostomia and lubricating jellies for vaginal dryness give symptomatic relief. Hydroxychloroquine 200 mg is effective to relieve arthralgia and myalgia. Systemic corticosteroids and immunosuppressants may be required for the treatment of systemic manifestations.

Further reading: Lata Bichile. Sjögren's syndrome. In Mukherjee S (Ed): Recent Trends in Connective Tissue Disorders) ICP publication 2005;113-25.

Palindromic Rheumatism

In this condition repeated attacks of joint pains, redness and swelling occur. The attacks occur suddenly within hours and may affect one joint usually. The affected joint shows signs of inflammation. These last for a few days and subside without any residual lesions. The ESR is raised during the attacks and remains high even during the intervals. After varying periods of time, typical rheumatoid arthritis supervenes in many cases, whereas spontaneous remission occurs in some.

Systemic Lupus Erythematosus, Antiphospholipid Antibody Syndrome

K.V. Krishna Das

Chapter Summary

General Considerations	703
Pathology	703
Clinical Features	704
Laboratory Investigations	705
Management	707
Drug-induced SLE	707
Antiphospholipid Antibody Syndrome	707

General Considerations

Definition: It is an inflammatory disease of autoimmune nature involving the connective tissue of several organ systems and associated with a variable course.

SLE is worldwide in distribution. In India it constitutes 1-2% of the major rheumatological problems. Females predominate and the male to female proportion being 1:18. The disease is rare below the age of 5 years, but children account for 20%. More than 60% of cases are between the ages of 30 and 60. SLE results from a gross disturbance of immune mechanisms. Normal body constituents are rendered immunogenic by various damaging factors such as exposure to sunlight, infection, tissue injury, drugs or others. Among these, viral infection and drugs top the list. Several autoantibodies are produced against the host's own tissues. There is suppression of T-lymphocyte function and overactivity of B-lymphocytes, leading to formation of autoantibodies, mainly belonging to IgG and IgM classes. Antigen antibody complexes are formed, with the utilization of complement factors. Deposition of immune complexes on tissues stimulates further inflammatory processes and this accounts for most of the lesions. C3 and C4 components of complement are mainly used up and, therefore, their levels fall.

Genetic factors: These probably play an important role in many. This is evidenced by the simultaneous occurrence of the disease in monozygotic twins, higher incidence of SLE and other connective tissue disorders in the relatives of SLE patients and the presence of several autoantibodies

and low serum complement levels in many of them. HLA types B8 and DR3 and inherited deficiency of C1, C4 and C2 complements are known to be associated with a higher incidence of SLE.

Pathogenesis

Traditionally SLE has been considered to be a disease of hyperactive immune system. Recent work reveals that the disease process is set in motion by insufficiency of immune regulatory cells and factors. Once the process is triggered off, it proceeds stepwise to produce the florid disease. SLE is an autoimmune disease characterized by insufficiency of immune regulation by T cells and regulatory factors which starts the process. Hyperactive and self-reactive T and B cells produce autoantibodies against several self-components. Activated T and B cells infiltrate several tissues and produce auto-antibodies and immune complexes. Immune complex deposition leads to further inflammation and tissue damage. The progression of the disease occurs in distinct stages.

- Stage: 1 Immune insufficiency stage in which there is lack of immune regulation
- Stage: 2 Hyperactivation stage in which self reactive T and B cells are activated.
- Stage: 3 Invasion of tissues by the hyperactive T and B cells, autoantibodies and immune complexes formed locally and systemically.
- Stage: 4 Active disease: SLE with inflammation of tissues.
- Stage: 5 Organ destruction, fibrosis and progress to end stage.

Further reading: Ram Raj Singh. Pathogenesis of SLE: the author's perspective: Review article. Indian J. Rheumatol 2006;14(1):19-29.

Pathology

The lesions of SLE are widespread and all tissues may be affected. Basically four types of histological pictures are seen. These are fibrinoid change, collagen sclerosis, formation of hematoxylin bodies and inflammatory changes in arterioles and capillaries. Tissue damage occurs

in two different ways. These are: (1) *Direct cytotoxicity (type II reaction) caused by antibody and complement*, e.g. brain damage and abortion, and (2) *type III immune reaction caused by immune complexes and complement*, e.g. renal and vascular lesions. Though the full spectrum of autoimmunity in SLE is not clear, several abnormalities have been observed. Among the tissues which become antigenic, nuclear components, especially nucleosomal histone complex are important. Antinuclear antibodies (ANA) are important demonstrable diagnostic markers occurring in over 95% of cases.

Clinical Features

SLE presents a wide spectrum of clinical presentation depending upon the system affected maximally. Data collected from Indian literature gives the following picture.

Presentation of SLE	Frequency (%)
Arthralgia/arthritis	70-90%
Fever	50%
Cutaneous rashes	50-80%
Malar rash	40%
Lymph node involvement	40%
Renal lesions	45-65%
Neuropsychiatric symptoms	35-40%
Cardiac lesions	30%
Pleuropulmonary lesions	20-25%
Hepatosplenomegaly	20-25%
Discoid lupus	10%
Ocular lesions	10%

In many cases the presenting symptom is fever which may take several forms, from mild subacute illness to severe hectic fever.

Arthritis and arthralgia: Joint manifestations occur in 90% of subjects with SLE in the early stages. Large joints are affected more than others. Severity of joint involvement varies widely. Permanent deformities do not occur. Jaccoud’s arthropathy may affect the hand in upto 50% of cases. It is characterized by reducible, non-erosive joint deformities with preservation of hand function. The pathogenesis of this condition is probably extra-articular secondary to inflammation and shortening of the tendons.

Hip pain may suggest the development of avascular necrosis and is usually a complication of corticosteroid therapy. It may be a manifestation of SLE in which case it is associated with the presence of antiphospholipid antibodies.

Skin lesions: These occur in 65 percent of patients at some stage or other. The classic lesion is the erythematous, photosensitive, butterfly rash affecting the cheeks and nose and this is diagnostic (Fig. 106.1). Discoid lupus, maculopapular rashes and purpura may occur in some. Frontal baldness may develop. Alopecia occurs due to breaking up of the hair. Painful ulcers may develop in the mouth and pharynx.

Fig. 106.1: Facial rash in SLE

Discoid lupus is the form in which the only manifestation of the disease is confined to the skin for a few years. The lesions show scaling, atrophy, telangiectasia and keratotic plugging. They heal with considerable scarring. Some patients develop systemic lupus.

Cardiovascular system: Cardiovascular lesions develop in 25-40% of cases. Cardiac lesions include pericarditis, pericardial effusion, myocarditis with cardiac failure, and valvulitis involving the mitral valve. **Libman-Sacks endocarditis** is a nonbacterial verrucous endocarditis affecting the mitral valve which is occasionally seen. It results in mitral incompetence. Cardiac abnormalities in the form of valvular thickening, vegetations and stenosis develop in decreasing order of frequency. Cardiac involvement does correlate with either the duration or the presence of other clinical manifestations, and their presence increases the morbidity. Vasculitis leads to **Raynaud’s phenomenon**, necrotic ulcers of the finger pulp and chronic ulcers. Patients with SLE have increased risk of ischemic heart disease and major cardiac events apart from the risk factors posed by the disease and its treatment. Proper control of SLE brings down the cardiovascular risk as well.

Respiratory system: Thirty percent of cases manifest lesions in the respiratory system. Common lesions are dry pleurisy, pleural effusion, fibrosing alveolitis, and lupus pneumonitis. A **syndrome of shrinking lung** is uncommon but virtually pathognomonic of SLE. It is characterized by progressive reduction in lung volume with evidence of diaphragmatic weakness.

Kidney: This organ is affected in about 60% of cases. Renal involvement used to be the most important lesion deciding the prognosis. Renal involvement may remain asymptomatic with only proteinuria for long intervals or may manifest as nephrotic syndrome, hematuria, acute nephritic syndrome or renal failure. The histological pattern is that of focal glomerulonephritis, diffuse glomerulonephritis or membranous glomerulonephritis. The wire loop lesions which are produced by thickening of the glomerular walls are characteristic on histology. The

Fig. 106.2: 16 years female suffering from SLE with nephritic syndrome

international society of nephrology renal pathology group proposed a new classification of lupus nephritis by revising the WHO classification in 2003. It has classified the renal lesions into six classes 1-VI (Fig. 106.2).

(Ref: Gupta RK. Current classification of lupus nephritis. J Indian Rheumatol Assoc 2005;13:156-61).

Sm antibodies are associated with membranous nephritis. Renal tubular acidosis is occasionally seen, particularly when Sjögren's syndrome coexists with SLE and it is due to tubulointerstitial disease. Antiphospholipid antibodies may be associated with renal vein thrombosis. Treatment instituted early in the disease helps to avert renal involvement. Indian experience is that 66% of adults and 80% of children develop renal lesions. Among them 14.3% had class II lesions, 22.8% had class III, 17.2% had class IV. Compared to the west, the progress of renal lesions appear to be more severe in Indian subjects. 50% of class IV develop renal failure and 25% develop end stage renal disease (ESRD). There was no significant difference in those treated with cyclophosphamide and azathioprine (see also Chapter 174).

(Ref: Jacob George-management of lupus nephritis. JAPI 2003;51:1489-94).

Nervous system is affected in about 40% of cases. Neurological involvement is generally a later manifestation, even though psychiatric symptoms may occur early. Lesions are caused by vasculitis and occlusive vascular phenomena. Patients with antiphospholipid antibodies are more prone to develop stroke. Other manifestations include psychosis, convulsions, cranial nerve palsies, peripheral neuropathy, mononeuritis multiplex, chorea and cerebellar disturbances. Involvement may be the result of primary CNS lupus or the secondary effects of complications, or drugs. Infection, uremia and malignant hypertension are not uncommon.

Muscle involvement manifests as myalgia, rarely polymyositis and muscle wasting. Patients with neurological involvement have a poor prognosis.

Hematology: Most of the cases show normocytic normochromic anemia. Other abnormalities include *Coombs' positive autoimmune hemolytic anemia*, *leukopenia*, and *thrombocytopenia*. *Lupus erythematosus (LE) cells* are demonstrable by suitable techniques. These are polymorphonuclear leukocytes which have phagocytosed nuclear material under the influence of antibodies. Their number increases with the activity of the disease. Their presence and numbers generally correlate with the activity of the disease. In a marginally positive case their diagnostic value is not absolute since a few other conditions such as rheumatoid arthritis, drug allergy, and drug induced lupus may also show this phenomenon.

SLE may be the primary lesion in at least 10% of cases of immune thrombocytopenic purpura (ITP). For considerable periods of time the diagnosis may masquerade as ITP till other features of SLE manifest. *Antiphospholipid antibody syndrome* gives rise to additional features such as strokes, portal vein thrombosis, thrombophlebitis, pulmonary embolism and abortions in the later part of the second trimester or in the third trimester. Recurrent abortions with or without phlebothrombotic episodes should raise the possibility of this syndrome. Antiphospholipid antibodies (APLAB), lupus anticoagulant (LA) and/or anticardiolipin (ACL) antibodies are demonstrable in over 30% of cases of SLE. Those that show ACL also give false-positive VDRL test.

Presence of LA imposes 30% life time risk of venous thromboembolism. Other features of this syndrome include thrombocytopenia and immune hemolytic anemia. 1-2% of young and 2-12% of elderly among the general population show low levels of antiphospholipid antibodies (APLAB) without any other demonstrable disease.

The liver is enlarged in 60%, spleen in 60% and lymph nodes in 25% of cases. Abdominal emergencies may be produced by the development of acute peritonitis, perisplenitis, or pancreatitis.

Eyes: These may be affected in a few cases, lesions include dryness of the conjunctiva and retinal abnormalities such as hemorrhage and exudates known as cytooid bodies.

Laboratory Investigations

SLE gives rise to an array of abnormalities, some being specific and the other non-specific. The non-specific features include, markedly elevated ESR (above 100 mm), moderate anemia, leukopenia, thrombocytopenia, and moderate to severe proteinuria. The specific tests depend upon the immunological abnormalities and they are described as follows.

Serological Abnormalities in SLE

The antinuclear antibodies (ANA): They occur in over 95% of cases. Though the ANA are not specific for SLE, presence of three or more components is almost diagnostic of this disease. The titer is high during exacerbation and

TABLE 106.1

Showing the frequency of antibodies

ANA	95%
Anti ds. DNA	60%
Anti-Sm	35%
False-positive VDRL	15%
Low level of C3	60%
Low level of C4	70%
Anticytoplasmic antibodies	41%

low during remission. Low levels of ANA occur in rheumatoid arthritis (20%), Sjögren's syndrome (60%), scleroderma (40%) dermatomyositis (30%), and drug reactions in a variable number (Table 106.1).

Lupus erythematosus (LE) cell phenomenon: The phenomenon is due to antinuclear antibodies. Since the titer required for LE cell formation is high, the positivity for LE cells is less than that for ANA (Fig. 106.3).

Other immunological markers which are non-specific are anticytoplasmic antibodies, lymphocytotoxins, antibodies against RBC, WBC and platelets, circulating anticoagulants, antithyroid and other organ specific antibodies, rheumatoid factor, false-positive Wassermann reaction and VDRL, cryoglobulins and circulating immune complexes. Levels of complements C3 and C4 are reduced. Cryoglobulins are IgG and IgM proteins which precipitate when cooled and redissolved when warmed. They get deposited on the walls of blood vessels. They may be monoclonal, polyclonal or both.

Presence of antinuclear antibodies and demonstration of LE cells should make the diagnosis reasonably certain.

Diagnosis

The diagnosis of SLE should be suspected if there are febrile episodes with multisystem involvement and high ESR not responding to general lines of treatment. The American Rheumatism Association (ARA) has laid down

criteria for diagnosis of SLE. These help to distinguish SLE from the other rheumatic disorders. The important criteria are malar rash, discoid lupus, Raynaud's phenomenon, alopecia, photosensitivity, oral and nasopharyngeal ulceration, arthritis, neuropsychiatric manifestations, and the laboratory features. Presence of four or more of these features is highly suggestive of the diagnosis.

Course and Prognosis

The course is variable, but in general the prognosis is grave, if untreated. Treatment improves the outlook for morbidity and mortality considerably. At present the majority of cases are detected early and they respond to treatment. More than 60 to 80% survive over 10 years. The main causes of death are renal failure, hypertension secondary to proliferative or membranous glomerulonephritis, cardiovascular events and central nervous system complications leading to strokes, coma or seizures. With modern therapy the renal lesions can be arrested to a great extent, but neurological complications pose a major threat to life.

SLE and Pregnancy

SLE does not affect fertility. SLE may flare up during pregnancy and this may cause deterioration of renal function. During pregnancy there is increased risk of pre-eclampsia (5-38%). Presence of pre-existing hypertension, nephritis and antiphospholipid antibody syndrome (APAS) increases the risk further. It may be difficult to distinguish between the renal-flare of SLE from pre-eclampsia; since both conditions are associated with hypertension, proteinuria, edema and deterioration of renal function. Complement C3 and C4 levels fall in SLE flare up, whereas they remain unchanged in pre-eclampsia. Anti-ds DNA levels increase in SLE, whereas they are unaffected in pre-eclampsia.

Abortion rates are high 6-35% and still births, 0-22%. Active SLE, presence of antiphospholipid antibodies and history of previous fetal deaths are worse prognostic factors. Both lupus anticoagulant and a ACL are associated with higher rates of fetal loss.

Neonatal lupus erythematosus (NLE) may develop in the baby; caused by maternal antibodies to the 52KD SSA/RO, 60KD SSA/RO or 48 KD, SSB/La ribonucleoproteins. The baby may present with skin rash and congenital complete heart block. Except the heart block the other features disappear in a few days.

Aspirin and NSAIDs should be avoided during the last weeks of pregnancy due to risk of hemorrhage.

Hydroxychloroquine, NSAIDs, prednisolone and azathioprine can be continued during pregnancy if the mother's condition warrants. Breast feeding is safe for the baby if the mother is taking prednisolone and hydroxychloroquine. Breast feeding is contraindicated if the mother is on azathioprine, cyclophosphamide, methotrexate or cyclosporine A.

Fig. 106.3: LE cell—a neutrophilic leukocyte engulfing amorphous eosinophilic material—its own nucleus pushed to the periphery—arrow)

The chance of SLE being transmitted to the offspring is low ($\pm 10\%$). Contraceptive pills do not flare up SLE.

Management

Since there are no curative measures, the main aim is to induce remission and prevent relapses. General management consists of avoidance of direct sunlight and offending drugs and prompt attention to complications.

Drug treatment depends upon the stage and severity of the disease. Mild SLE with only cutaneous and joint involvement without constitutional symptoms respond to chloroquine 250 mg o.d or b.d given orally. An alternate drug is dapsone given in doses of 50-100 mg/day oral. In moderately severe SLE in which organ systems are affected, but there is no general constitutional symptoms, steroids are used as the mainstay of treatment with immunosuppressants as add on drugs. In severe SLE there is gross affection of vital organs, particularly the heart, kidneys, lungs and brain. In them immunosuppressants are almost always required.

Specific drugs used are corticosteroids and immunosuppressants. Corticosteroids are indicated as the first line drugs. On an average the dose is 1 mg prednisolone per kg. body weight given orally daily. Once the symptoms are controlled, alternate day regime with 40-100 mg prednisolone given as a single dose is started. This serves to minimize the unwanted side effects without reducing effectiveness.

The dose is gradually reduced and finally withdrawn over a period of months or years. The activity of the disease is assessed clinically and by the fall in ESR. However, many cases will require maintenance dose for several years.

Symptomatic relief can be provided by the use of NSAIDs and analgesics.

Immunosuppressant drugs: The commonly used drugs are cyclophosphamide and azathioprine. They are indicated in severe life-threatening disease, failure to respond to steroids or intolerance to steroids. However, infections, severe anemia, and leukopenia are relative contraindications. The usual daily dose of cyclophosphamide is 2-3 mg/kg and that of azathioprine is 1-4 mg/kg given in divided dosage. Several dosage schedules of cyclophosphamide have been advocated. High doses such as 0.5-1 g/m² given once a month for 6 months, followed by smaller doses at longer intervals for 2 years have been found to be beneficial in severe cases. Some individuals have genetic defects which lead to severe marrow suppression following exposure to azathioprine. Therefore, persons receiving this drug should be monitored by regular blood tests.

General supportive measures include maintenance of nutrition, management of infection, analgesics, and hematinics. Specific clinical symptoms like convulsions, psychosis, pericardial effusion, and cardiac failure require appropriate management,

Vasculitis: Antiplatelet drugs like aspirin 150 mg daily, and anti-sludging agents like low molecular weight dextran are found to be very useful, in addition to corticosteroids and immunosuppressants.

For maintenance therapy in mild cases, especially with localized skin lesions, chloroquine in a dose of 250-500 mg given oral daily is effective. Long-term therapy may lead to ocular complications which should be looked for.

In severe cases with rapid deterioration of renal function or neuropsychiatric manifestations large doses of methyl prednisolone 1 g given IV daily with pulse doses of cyclophosphamide 0.5-1 g daily IV may be required to tide over the crisis. Newer modalities of treatment include cyclosporin, mycophenolate mofetil, cladribine, fludarabine and others. Supportive treatment for advanced renal failure may be necessary as per indications.

Drug-induced SLE

Several drugs like hydralazine, procainamide, dilantin, mesantoin, oral contraceptives, phenothiazines, INH, PAS, methyl dopa, levodopa, penicillin, and sulfa drugs lead to a syndrome of fever, arthritis, skin rashes, and lymphadenopathy which closely resembles SLE. The clinical and biochemical profile are identical with natural SLE but the course is mild and renal and CNS manifestations are rare. Withdrawal of the offending drug leads to resolution. If resolution is delayed, short course of corticosteroids—20-30 mg prednisolone oral daily will accelerate remission. The patient should be informed about drug toxicity in future.

Antiphospholipid Antibody Syndrome (APAS)

Syn: Hughes syndrome

This condition is seen not uncommonly in all parts of India and several case reports and studies are available.

APAS is characterized by the presence of a family of autoantibodies termed anti-phospholipid antibodies (APAs). These are a family of 20 antibodies that are directed against phospholipid binding plasma proteins. These include **anticardiolipin antibodies (aCL)**, **lupus anticoagulant (LAC)** and others. These antibodies are directed against anionic phospholipids participating in the coagulation cascade. These antibodies are detected by RIA and ELISA tests. APAS shows overlap between systemic autoimmune connective tissue diseases and coagulopathies, particularly thrombophilic states.

APAS may be primary or secondary. In primary APAS there is no evidence of underlying connective tissue disease. Secondary APAS occurs in association with other connective tissue diseases, particularly, SLE in which 15-34% have LAC and 12-30% have aCL.

Several surveys done worldwide show the presence of APAs in small quantities in 2-5% of the general population. LAC and aCL may occur together in the same individual or only either of them may be present. Persons with aCL also show the presence of LAC in 20%. On the other hand the presence of aCL in those with LAC is 80%.

Causes of secondary APS

- A. Connective tissue diseases – SLE, MCTD, PSS, primary SS, discoid lupus, RA and AS
- B. Other immunological disorders
Crohn's disease, systemic vasculitis, immune thrombocytopenic purpura, Behcet's syndrome and others
- C. Malignancy: Lymphomas, cancers of kidney, lung and ovary
- D. Drug induced: Oral contraceptives, quinine, quinidine, phenytoin, hydralazine, procainamide, beta adrenergic blockers, biologics like and alpha interferon.

These antibodies predispose to venous and arterial thrombosis and consequent complications. They also lead to fetal loss in pregnancy. The hallmark of APS is the presence of the antibodies aCL and LAC, false positive Venereal Disease Reference Laboratory (VDRL) and Wasserman reaction (WR) and other antibodies against cofactors associated with anionic phospholipids.

Common Presenting Features

- 1. Deep vein thrombosis 32%
- 2. Thrombocytopenia which is mild and subclinical 22%
- 3. Livedo reticularis 20%
- 4. Stroke 13%
- 5. Superficial thrombophlebitis 9%
- 6. Fetal loss 8%
- 7. Transient ischemic attacks (TIA) 7%
- 8. Autoimmune hemolytic anemia 7%
- 9. Arterial thrombosis in limbs and several organs. This may lead to gangrene of the limbs and superficial structures or infarcts in deep organs. Others include osteonecrosis, pulmonary hypertension, renal lesions and catastrophic anti-phospholipid antibody syndrome (CAPS).

APAS and Pregnancy

Fetal loss occurs around the 10th week of pregnancy. Placental venous thrombosis is a contributory factor. Presence of LAC antibodies or IgG class of aCL antibodies confer a risk of 50% for fetal loss. Proper management leads to successful outcome in over 75% of such cases.

Criteria for the Diagnosis of APAS in Pregnancy

- 1. 3 or more consecutive unexplained miscarriages before the 10th week of gestation
- 2. One or more unexplained deaths of a morphologically normal fetus at 10 weeks of gestation or older
- 3. One or more premature births of a morphologically normal fetus at 34 weeks gestation or younger associated with severe pre-eclampsia or placental insufficiency.

Prevalence of APAS in women with recurrent miscarriages is 15%. Women with APAS has 90% chance of recurrent miscarriages in subsequent untreated pregnancies.

Causes of Miscarriage in APAS

- 1. Thrombosis and infarction of the uteroplacental vasculature
- 2. Other possible effects of antiphospholipid antibodies include interference with signal induction mechanisms which control endometrial cell decidualisation, promotion of trophoblast apoptosis, decrease in trophoblast fusion and impairment of trophoblast invasion.

Management

LMW heparin and low dose aspirin improve the fetal survival in 80 to 85% of cases. Heparin should be given when pregnancy is confirmed or when the cardiac activity of the fetus is demonstrable. Heparin dose should be individualized. Heparin, in addition to its anticoagulant effect, can bind to APAS and antagonize the action of Th-1 cytokine interferon gamma, thereby protecting the fetus from injury.

Aspirin is also given to prevent thrombotic events.

Catastrophic Anti-phospholipid Antibody Syndrome (CAPAS)

In APS widespread vascular occlusions in multiple vital organs may develop. Vascular occlusion occurs in 3 or more organs simultaneously within a period of 1 week. Antiphospholipid antibodies are present. Histology of the organs reveals non-inflammatory thrombotic lesions.

Infections, pregnancy or surgery may trigger off this syndrome. If untreated, mortality exceeds 50%, usually due to cardiopulmonary failure. CAPAS has to be distinguished from disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), other forms of systemic vasculitis and severe infections. Haematology helps to distinguish between them

Condition	Diagnostic feature
Systemic vasculitis	Thrombocytosis
DIC	thrombocytopenia and low fibrinogen levels
TTP	Low platelets and presence of schistocytes

Coexistence of APAS with SLE worsens the clinical features of the latter

Management of APAS 1. Elective long-term anti-coagulant therapy with heparin and later on, coumarin drugs to keep INR at 2-3 to 3-4, depending on the severity and frequency of thrombotic episodes is effective in preventing thrombotic complications.

Normalization of LAC or aCL is not an indication for stopping therapy. Treatment has to be continued indefinitely. There is no firm indication for using glucocorticoids or immunosuppressant drugs unless the APS is secondary to immunological diseases.

Thrombocytopenia: Corticosteroids and/or IVIG should be considered.

Management of catastrophic APS: It is a life-threatening emergency. A combination of high intensity anticoagulation, corticosteroids, plasma exchange and IVIG form the therapeutic modality

Treatment of Symptomatic aPL Positivity

There is no consensus of opinion on this matter. Prophylactic low dose aspirin is recommended by some workers.

At times clinical features of APS occur, without demonstrable antibodies. Anticoagulation therapy, given on presumptive grounds has helped such patients.

Progressive Systemic Sclerosis (PSS)

Syn: Scleroderma

K.V. Krishna Das

Chapter Summary

General Considerations	709
Pathology	710
Clinical Features	710
Treatment	712
Mixed Connective Tissue Disease	713

General Considerations

In this generalized disorder of connective tissue, fibrosis and degenerative changes predominate. The skin, synovium, digital arteries, gastrointestinal tract, lungs, heart, kidneys and other organs may be affected. The most conspicuous feature is thickening and hardening of the skin which becomes "hide-bound". The term scleroderma is derived from the Greek word 'scleros', which means 'hard' and 'derma' which means skin. The two major categories are (1) limited cutaneous scleroderma where sclerosis is confined to the extremities distal to the elbows and knees with or without facial involvement and (2) diffuse cutaneous systemic sclerosis.

The extent of skin involvement and presence of lesions in internal organs form the basis of classification into diffuse and limited diseases.

1. **Localized scleroderma (morphea):** The lesion is restricted to a localized area on the skin.
2. **Linear scleroderma:** The skin involvement is linear. It leads to atrophy of underlying tissues. In the face it gives a characteristic appearance.
3. **Disseminated morphea:** There are multiple skin lesions, but systemic involvement is minimal or absent.
4. **CREST syndrome:** This consists of calcification of subcutaneous tissues, Raynaud's phenomenon, esophageal hypomotility, sclerodactyly, and telangiectasia.
5. **Progressive systemic sclerosis:** There is progressive involvement of skin and other internal organs leading to systemic manifestations. This carries the worst prognosis.

Even in the limited cutaneous disease occlusive vascular lesions, gastrointestinal lesions, interstitial pulmonary fibrosis and pulmonary hypertension may

12

occur. Scleroderma occurs all over the world and is occasionally seen in Indian subjects.

Pathology

The three cardinal features are excessive collagen production and deposition, vascular damage and inflammation or autoimmunity. There is suggestion that human parvovirus B19 may trigger the disease process.

The prominent pathological abnormality is overproduction and cross-linking of collagen and vasculitis. HLA DR1, DR2, DR3, DR5 and DRWS2 class II alleles show association and glycosaminoglycans are produced by fibroblasts. The vascular lesion consists of structural damage to small vessels occurring extensively, resulting in proliferative changes and luminal narrowing. The humoral arm also shows abnormalities. The presence of antinuclear antibodies (ANAs), inflammatory lesions in the skin and lung and increased amounts of pro-fibrotic chemokines in circulation and in tissues are the consequences of immune activation. ANA is positive in 50% of cases, antibodies to single stranded RNA develop. Scl-70, also known as anti-topoisomerase is an antibody against an extracellular nuclear antigen. It may be detectable in 20% of cases. Its presence is a predictive marker for pulmonary involvement. There is activation of T lymphocytes and complement. Advanced lesions show atrophy of the dermis, loss of hair follicles and sweat glands, depigmentation and calcinosis.

Skin: The dermal collagen is increased leading to fibrosis. Endarteritis and calcinosis supervene in some cases. Collagen types 1 and 3 are increased, the former being more abundant.

Joints: Synovium shows infiltration with lymphocytes and plasma cells and deposition of fibrin. The changes may resemble those of rheumatoid disease, but pannus formation is unusual.

Kidneys: Changes occur in the interlobular arteries. These comprise intimal hyperplasia, fibrinoid necrosis of afferent arterioles and glomerular tufts, and thickening of glomerular basement membrane. These changes lead to cortical infarctions and glomerulosclerosis. The lesions may resemble those seen in malignant hypertension.

Muscles: The histological lesions resemble those seen in myopathy such as fragmentation and loss of striation of muscle fibers and nuclear changes. Affected muscles are replaced by fibrosis.

Vasculitis: Affection of small arteries leads to intimal thickening and narrowing of lumen. The lesions are particularly demonstrable in the digital arteries of patients showing Raynaud's phenomenon.

Clinical Features

The disease is seen more in the fourth and fifth decades and male to female ratio is 1:4. Onset is insidious. The initial symptoms are variable. These include Raynaud's phenomenon, tightness of the extremities, arthralgia, and vague manifestations.

Cutaneous manifestations: Three stages can be distinguished during the evolution of the disease. These are edematous, indurative, and atrophic stages. Initial manifestations are edema of the hands and feet, which may extend more proximally. The edema is followed by thickening and tightening of the skin. Skin loses its normal pliability and ultimately becomes "hide bound" and non-pinchable. Appendages are lost over the affected areas. Affection of the face gives rise to the "mouse head" appearance with microstomia, beaked nose, mask like expression, and difficulty in opening the mouth (Figs 107.1 and 107.2).

Pigmentary changes develop over the extremities and anterior chest wall. These consist of hyperpigmentation or a combination of spotty hyper- and hypopigmentation (salt and pepper skin), and telangiectasia over the fingers, palms, face, lips, and tongue. The tight atrophic skin is particularly vulnerable to trauma. Painful, nonhealing, chronic, indolent ulcers are common over the fingers and toe tips. When the extremities are predominantly affected, the condition is called acrosclerosis. Over the palmar aspect of the terminal phalanges subcutaneous calcification occurs. These ulcerate and extrude calcareous material. Ischemia aggravates this tendency. Paroxysmal vasospasm of digital blood vessels leads to Raynaud's phenomenon, which is present in 25% of cases, when exposed to cold environment. Raynaud's phenomenon may also occur during emotional disturbances or even spontaneously.

Raynaud's Phenomenon

Raynaud's phenomenon is the term used to describe the episodic events of vasoconstriction of the digital arteries, pre-capillary arterioles and cutaneous arteriovenous shunts. Raynaud's phenomenon may be primary or secondary. Primary Raynaud's phenomenon shows the following features;

- vasospasm is precipitated by cold or emotional stress.
- symmetrical in distribution
- absence of necrosis and gangrene
- normal nail fold capillaries
- normal ESR and negative tests for dyscollagenoses

Secondary Raynaud's phenomenon is characterized by;

- age over 30 years
- presence of tissue necrosis
- evidence of dyscollagenoses
- abnormal nail fold capillaries and presence of auto-antibodies.

Fig. 107.1: Progressive systemic sclerosis. Note: pinched face, difficulty to open the mouth, swelling of finger joints, painful flexion

Fig. 107.2: Progressive systemic sclerosis. Note: depigmentation of arm and tight skin

Systemic manifestations: The pattern of involvement reported in Indian series is acrosclerosis (53%), arthralgia (83%), arthritis (20%), upper GI lesion (66%), lower GI lesion (33%), lungs (20%), and kidneys (25%).

Progressive systemic sclerosis overlaps with other connective tissue disorders such as systemic lupus erythematosus (14%), rheumatoid arthritis (8.4%), and mixed connective tissue disease (2.8%).

Bones and joints: Mobility is restricted due to fibrosis of soft tissue. Primary articular involvement can occur in many. Crepitus can be palpated over major joints and tendons and 50% develop deformities. Long standing cases show erosion and absorption of the terminal phalanges.

Gastrointestinal tract: Affection of the GI tract can be demonstrated by investigations even in the asymptomatic cases. Esophagus and intestines are affected most frequently. Common symptom is dysphagia, which is initially due to esophageal spasm and later fibrosis. Barium swallow reveals dilated esophagus resembling achalasia cardia. The small and large intestines show dilatation, impaired peristalsis, and malabsorption.

Involvement of the lungs results in progressive interstitial fibrosis and alveolocapillary block syndromes. Cystic changes are seen occasionally. Secondary pulmonary hypertension and cor pulmonale develop in long-standing cases.

Cardiovascular system: Heart is enlarged with myocardial dysfunction and rarely conduction defects. Malignant hypertension is more common.

Renal involvement: Secondary hypertension and renal failure may follow. Scleroderma renal crisis is the rapid development of malignant hypertension and oliguric renal failure during the course of systemic sclerosis.

Limited cutaneous forms, often confined to the skin may be seen at times. These include morphea, linear scleroderma and limited cutaneous systemic sclerosis syndrome, also known as **CREST syndrome**. This consists of *calcinosis*, *Raynaud's phenomenon*, *esophageal involvement*, *sclerodactily* and *telangiectasia*. Morphea and linear scleroderma give rise to well demarcated pale, indurated lesions of the skin and subcutaneous connective tissue. Even in the absence of systemic involvement, the serological markers may be present.

In patients with Raynaud's phenomenon, two markers viz abnormal cutaneous capillaries in the nailfold (detectable by an ophthalmoscope) and presence of antinuclear antibodies predict the subsequent development of scleroderma.

Raynaud's phenomenon may be part of systemic sclerosis, without evidence of cutaneous scleroderma (*scleroderma sine scleroderma*) but with only systemic lesions. In this form the humoral markers such as ANF and Scl-70 are detectable and these help in diagnosis.

Nervous system involvement: This manifests as cranial or peripheral neuropathy at times.

Diagnosis

This is mainly clinical; the most important finding is the hard skin, which is not pinchable and is also devoid of hair. Laboratory investigations help to rule out other conditions. Skin biopsy helps to confirm the diagnosis and rule out other conditions like eosinophilic fasciitis and scleredema.

Laboratory Investigations

Erythrocyte sedimentation rate is moderately raised but it may be normal in early cases and in cases where only the skin is affected. During the active phase IgG may be elevated. Muscle enzymes are elevated when myopathy occurs. Rheumatoid factor is positive in 20-25% and antinuclear factor (ANF) in about 40% cases in low titers Scl-70 are detectable and these help in diagnosis.

Differential Diagnosis

Progressive systemic sclerosis must be distinguished from other collagen disorders such as dermatomyositis and mixed connective tissue disease. Thickening and tightness of the skin may occur in other disorders like eosinophilic fasciitis, scleredema adultorum Buschke, myxedema, and acromegaly.

Scleredema adultorum Buschke: This condition is characterized by painless edematous induration with an abrupt onset over a short period of time occurring in young subjects. Face, scalp, trunk, and proximal parts of the extremities are extensively affected. Though the exact cause is not clear, some cases are seen to follow streptococcal infection. There is accumulation of mucopolysaccharides in the dermis and in the underlying muscles. The condition resolves spontaneously over a period of 6-12 months even without specific treatment. Systemic manifestations of PSS are not present.

In eosinophilic fasciitis which starts in the form of painful and tender swellings over the extremities, there is fasciitis, myositis, eosinophilia, and hypergammaglobulinemia. The skin is indurated and tight. Etiology is unknown. Onset is acute or subacute starting as symmetrical swelling and pain of the extremities followed by induration and joint contractures. Forearms, legs, hands and feet are affected. These parts become shiny and erythematous, which later become taut and woody. The skin is restricted by the subcutaneous tissue. Systemic involvement may develop at times. There is no evidence of autoimmunity.

Biopsy reveals perivascular infiltration by eosinophils, histiocytes, lymphocytes, and plasma cells in the skin, fat and even underlying muscles. These lesions are self-

limiting. Raynaud's syndrome does not occur. Carpal tunnel syndrome may develop. Histology shows inflammatory exudate consisting mainly of eosinophils. Fibrosis is prominent. The condition is self-limiting. Excessive consumption of L. tryptophan in health foods has been associated with the development of eosinophilic fasciitis. Corticosteroids bring about remission promptly.

Myxedema and acromegaly are conditions which may show skin changes mistaken for scleroderma. They are associated with other endocrine abnormalities as well.

Course and Prognosis

Progressive systemic sclerosis is a slowly progressive disease. Widespread skin involvement, lesions of the kidneys, lungs and heart, and onset earlier in life are unfavourable factors. More than 70% survive 5 years or more.

Treatment

At present there is no drug which will arrest the progression of the disease. The use of corticosteroids is controversial. The renal lesions may even be aggravated by corticosteroids. Nonsteroidal anti-inflammatory drugs like indomethacin or ibuprofen may help to relieve arthralgia and arthritis. D-penicillamine may help in the early stages on account of its ability to inhibit cross-linking of collagen. Blood flow in the digital arteries can be improved by the infusion of low molecular weight dextran. This may prevent ischemic ulcers and help in their recovery. Early use of ACE inhibitors helps to allay the progress of renal lesions and hypertensive complications. Calcium channel blockers have found use in complications such as pulmonary hypertension, Raynaud's phenomenon and calcinosis. Nifedipine in usual dosage relieves Raynaud's phenomenon. Severe and disabling Raynaud's phenomenon may respond to infusion of prostacyclin. Epoprostanol 0.5-0.6 ng/kg bw is infused IV for 6-24 hours for 2-5 days. The drug is expensive. Intractable Raynaud's syndrome is relieved by cervical sympathectomy.

Since the potential role of cells, cytokines, paracrine signalling and role of immunity have been known; treatment targeted against these processes is possible. Best results are obtained in the case of vascular complications.

ACE inhibitors prevent renal crisis and these drugs are the preferred choice in the treatment of renal crisis.

The following drugs have been approved by the FDA for the treatment of pulmonary artery hypertension (PAH). These include

1. Epoprostanol, treptostinil, iloprost – They supply prostacyclin to the vascular endothelium
2. Sildenafil - It is a vasodilator. In addition it can generate nitric oxide (NO) which leads to vasodilation.
3. Bosentan - This inhibits endothelin.

These drugs reduce vasospasm and increase the walking distance and quality of life. Epoprostenol and bosentan may prolong survival. Nifedipine is given orally, iloprost and epoprostanol are given IV and nitroglycerine is given as an ointment. Bosentan which is given orally is a receptor antagonist for endothelium. It reduces the frequency of new digital ulcers and necrosis.

Drugs targeted against immune activation include fluorouracil, methotrexate and cyclophosphamide. They improve skin lesion and a few other manifestations, but not the visceral lesions. Cyclophosphamide given in doses of 3-5 mg/kg or higher doses IV monthly for 6 months with prednisolone 20 mg on alternate days showed improvement.

Azathioprine is also effective.

Interferon- γ has shown mild benefit in pulmonary fibrosis but not on the skin lesions. Future strategies aim to modulate transforming growth factor (TGF β) and connective tissue growth factor (CTGF) which also promotes fibrosis

Further reading: Christina Charles, et al. Systemic Sclerosis; hypothesis driven treatment strategies. The Lancet 2006; 367:1683-91.

Overlap Syndrome

Multisystem diseases of varied pathogenesis and clinical features are difficult to be compartmentalized precisely.

This is particularly true of the connective tissue diseases (CTD). Some distinct entities include systemic lupus erythematosus (SLE), systemic sclerosis (SSC), polymyositis dermatomyositis (PM-DM), rheumatoid arthritis (RA), giant cell arteritis and others. Some patients show overlapping features of more than one CTD and these are included under the terms overlap CTD (OCTD) or undifferentiated CTD (UCTD).

Mixed Connective Tissue Disease

A set of patients show features combining the manifestations of SLE, SSC, PM-DM and RA. This combination is termed mixed connective tissue disease (MCTD).

Presenting symptoms are given below.

1. Raynaud's phenomenon.
2. Sausage like swellings of fingers.
3. Skin changes of dermatomyositis or scleroderma.
4. Arthralgias.
5. Prolonged fever.
6. Esophageal achalasia.

Symptomatic measures to relieve Raynaud's phenomenon and arthralgia give relief. Chloroquine given in a dose of 250-500 mg oral daily is beneficial in mild and moderate cases. Corticosteroids and immunosuppressants are indicated in severe cases.

Chapter Summary

Polyarteritis Nodosa	714
Giant Cell Arteritis	715
Polymyalgia Rheumatica	716
Takayasu's Arteritis	716
Kawasaki Disease	716
Churg-Strauss Syndrome	716
Behçet's Disease (Behçet's Syndrome)	717
Mixed Essential Cryoglobulinemia	717
Henoch-Schönlein Syndrome	717

General Considerations

Population data on vasculitides is not available in India. They are seen at times, though not very frequently. Primary vasculitis disorders constitute 1% of the material in Rheumatology Clinics.

Necrotising vasculitic disorders include polyarteritis nodosa (PAN) Wegener's granulomatosis (WG), microscopic polyangiitis (MPA) and Churg-Strauss Syndrome (CSS).

Vasculitis which is defined as inflammation of blood vessels (arterioles, veins and capillaries) is a common

TABLE 108.1

Classification of the primary vasculitis

Size of vessel	Sites	Clinical entity
Large vessels	1. Temporal arteritis	Giant cell arteritis syn: temporal arteritis polymyalgia rheumatica
	2. Aorta and main arteries to head and limbs. Occasionally pulmonary arteries	Takayasu's arteritis
Medium size vessel	1. Diffuse lesions in several arteries 2. Coronary arteries	Polyarteritis nodosa Kawasaki disease
Small vessels—arterioles capillaries or venules	Kidneys, lungs	Microscopic polyangiitis, Goodpasture's syndrome
	Upper and lower respiratory tract	Wegener's granulomatosis, Churg-Strauss syndrome
	Skin, mucous membrane, genitalia, joints	Behcet's syndrome
	Skin, joints, abdominal viscera, kidneys	Henoch-Schönlein purpura
Cutaneous vessels	Isolated angiitis without systemic lesion	Isolated cutaneous leucoclastic vasculitis

The frequency distribution of vasculitic disorders in India

Disease	%
Aortoarteritis	20.2
Henoch-Schönlein purpura (HSP)	22
Giant cell arteritis	3.4
Polyarteritis nodosa	8.8
Small vessel vasculitis	5.7
Wegener's granulomatosis	13.8
Behcet's disease (BD)	13.6
Microscopic polyangiitis	3.9
Kawasaki disease miscellaneous conditions	0.5
Churg-Strauss syndrome	1.8
Not properly diagnosed	5.9

Ref: Joshi VR, Gayatri Mittal. Vasculitis. Indian perspective supplement to JAPI, 2006;12:5.

manifestation of several different immunological processes which may occur as primary manifestations, or secondary to other established entities such as the discollagenoses. In many of the primary vasculitis syndromes the exact pathogenesis is not clearly known. They lead to multisystem manifestations as a result of vascular occlusion in addition to the primary pathological processes specific to them. The vessels show infiltration by leucocytes, secondary changes in the vessel walls and occlusion. Since many of them lead to systemic symptoms such as fever, skin manifestations, arthralgias, vague pains and tenderness they can be included under the rheumatological syndrome. The classification takes into account the size of the vessel that is affected (Table 108.1).

General Clinical Features of Small Vessel Vasculitis

1. Constitutional symptoms and signs: Fever, malaise, arthralgia, myalgia.

2. Skin lesions: Localized purpuras, focal necrosis, ulceration—particularly seen in the lower limbs.
 3. Nervous system: Peripheral neuropathy, mononeuritis multiplex.
 4. Intestines: Ischemic ulceration, bleeding, perforation, intussusception.
 5. Respiratory tract: Infections, often hemoptysis
- Vasculitis may be secondary to several other classes of diseases which are given below:
- Infections—immune-complex vasculitis
- Neoplasms— Paraneoplastic syndromes
Lymphomas
Myeloproliferative disorders
Carcinoma.

Polyarteritis Nodosa

General Considerations

Polyarteritis nodosa (PAN) is characterized by the formation of multiple nodules along blood vessels, mainly affecting the smaller arteries, arterioles, and adjacent veins. Capillaries are spared. Pathologically the lesion consists of polymorphonuclear infiltration, necrosis and aneurysmal dilatation of the arterial wall. Thrombotic occlusions may occur. The lesions are widespread and all tissues may be involved. Main impact is on the arteries of the muscles, kidneys, heart, mesentery, and vasa nervorum. The disease is more common in people who are infected with hepatitis B virus. Circulating immune complexes containing hepatitis B surface antigen may be present in them. In view of this finding PAN may be classified as hepatitis-B-related and hepatitis B-unrelated.

Fig. 108.1: Polyarteritis nodosa: gangrene of fingers, discolouration of hands

Clinical Features

Polyarteritis is rare compared to the other connective tissue disorders. Though all ages may be affected, adults suffer more frequently. Males predominate. The onset is variable. The condition may be precipitated by drugs or upper respiratory infections.

The onset is with general symptoms like fever, muscle pains, arthralgia, rash and anorexia. Inflammatory nodules ranging in size from 5-10 mm may be palpable over the superficial arteries. These nodules are tender. Symptoms referable to organ systems develop depending on the lesions. In about 50% cases the kidneys are affected leading to the clinical picture of acute nephritic syndrome or glomerulosclerosis with secondary hypertension and renal failure. Vascular occlusion leads to distal gangrene of extremities. Occlusion of vasa nervorum leads to mononeuritis multiplex. Retina may show hemorrhages and exudates. Pericarditis, pleurisy, myocardial infarction, ulceration, and bleeding from intestines and necrosis of the liver and gallbladder may be encountered at times (Fig. 108.1).

Diagnosis

The condition has to be suspected clinically. There are no specific laboratory tests. The ESR is markedly elevated. Neutrophil leukocytosis is common. Diagnosis is confirmed by demonstrating the lesions on biopsy specimens. Muscle, kidney or liver is selected for biopsy depending on the presentation. Tests for infection by hepatitis B and C are indicated in all cases.

Differential Diagnosis

Polyarteritis nodosa has to be differentiated from allergic vasculitis and Goodpasture’s syndrome and microscopic polyangiitis.

PAN has to be differentiated from microscopic polyangiitis (MPA).

Difference between microscopic polyangiitis and PAN	
PAN	MPA
Lesions: medium arteries and arterioles-necrotizing vasculitis	Small vessels—capillaries, venules and arterioles necrotizing vasculitis
Renal involvement leads to hypertension	Mainly rapidly progressive glomerulonephritis
Pulmonary hemorrhage—rare	Common
Relapse—rare	Frequent
HBV- HCV association—frequent	Indefinite
C-ANCA—Positive	Negative

Prognosis

Polyarteritis nodosa is a serious illness with a mortality ranging from 50-60% in one year. Common causes of death are renal failure, myocardial infarction, infections, congestive heart failure, and gastrointestinal bleeding.

Treatment

Corticosteroids may cause symptomatic improvement. Immunosuppressants are of benefit if used judiciously. With proper treatment mortality and morbidity can be brought down considerably. Patients who show evidence of hepatitis B infection improve better if the infection is also treated simultaneously.

Giant Cell Arteritis

Syn: Temporal arteritis, Cranial arteritis

Definition

This form of systemic connective tissue disease occurs in the elderly, in the sixth and seventh decades.

It is characterized by panarteritis with giant cell infiltration, predominantly affecting the cranial vessels. The etiology is not established.

Pathology

The arterial wall normally contains dendritic cells in the adventitia. The inflammation is T-cell mediated. The activation of the dendritic cells sets in motion a complex cascade consisting of cytokine activation, intimal proliferation supported by neo-angiogenesis, oxidative injury to smooth muscles and effects of systemic inflammation. The larger arteries such as the internal and external carotids, temporal, occipital, and ophthalmic arteries are usually involved, though any other artery may show lesions. The lesions are segmental with intervening

normal areas. The media of the artery is infiltrated by round cells and giant cells. The vessels may be occluded by thrombi which recanalize later.

Clinical Features

Both sexes are equally affected. Onset is with severe, unilateral or bilateral headache in the temporal or less commonly in the occipital regions, associated with vomiting. Diagnostic feature is the palpably thickened, tender and nonpulsatile temporal arteries.

Loss of vision due to occlusion of the ophthalmic artery is a dreaded complication. Rarely patients present as facial neuralgia with jaw claudication on chewing, deafness, necrosis of the tongue, or an associated widespread necrotizing arteritis of small vessels which presents as peripheral neuropathy.

Laboratory Diagnosis

ESR often exceeds 100 mm and all immunoglobulin fractions are elevated. Temporal artery biopsy which reveals the characteristic histology is diagnostic. However, a negative biopsy does not rule out the diagnosis, since the lesions may occur segmentally.

Treatment

Corticosteroids are indicated in high doses. Prednisolone (50-60 mg/day) may be started initially and tapered off slowly to the minimum maintenance dose required to keep the ESR down. This treatment must be continued for at least one year. Once blindness occurs it is irreversible and it has to be prevented by early diagnosis and institution of steroid treatment. Relapse occurs in 20-30% on stopping treatment. This is an indication for restarting treatment with addition of immunosuppressants such as azathioprine or methotrexate. Low dose aspirin is useful in long-term management.

Polymyalgia Rheumatica

This is a syndrome rarely only seen in India, characterised by severe pain and stiffness in the neck, back, shoulder, upper arms and thighs, particularly worse in the morning.

This condition may be associated with giant cell arteritis which may coexist, or in some cases, develop later. The ESR is elevated, muscle enzymes are normal and this finding helps to differentiate this condition from polymyositis. Treatment with corticosteroids gives prompt improvement.

Takayasu's Arteritis

This is described in Section 13 along with diseases of the aorta.

Kawasaki Disease

Syn: Mucocutaneous lymph node syndrome. The disease is mainly described from Japan. This disease has been reported from Chennai and Chandigarh. Probably there is under-reporting of cases from India.

Kawasaki disease- Indian data M:F ratio 83:17

Age group	Total no. of cases	%
< 1 year	5	14
1-5 years	26	72
>5 years	5	14

Affection of organs

Incomplete or atypical 17%, Conjunctiva 81%, Oral mucosa 94%, Lymph nodes 83%, Skin lesions 92%, Arthritis 19%

Ref: Nutan Kamath, et al. Kawasaki disease in India. J Indian Rheumatic Assoc 2005;13:113-20.

This is an acute or subacute exanthema-like disease, often affecting children, characterised by onset of abrupt fever, erythematous rash over the face, mouth, palms and soles, nonsuppurating cervical lymphadenopathy, conjunctival congestion and vasculitis affecting particularly the coronary arteries. The arterial lesion leads to aneurysms in the coronary arteries. The coronary arterial lesion can be demonstrated by 2D echocardiography and the lesion can be quantified. Treatment during the acute febrile phase consists of aspirin given in a dose of 80-100 mg/kg bw/day to be tapered off later and IVIG given as IV infusion in a dose of 2 g/kg bw over 10 hours. 5% of children who develop Kawasaki disease develop coronary aneurysms.

Churg-Strauss Syndrome

This is characterised by vasculitis and granuloma formation. There is previous history of asthma and eosinophilia antedating the vasculitic manifestations by 3-4 years. Pulmonary infiltrates with eosinophilia may be present. Necrotising vasculitis occurs in several organs leading to skin nodules or rashes, mononeuritis multiplex, myocarditis, cardiac infarction, and pericarditis. Cause of Churg-Strauss syndrome is not known.

American College of Rheumatology criteria for diagnosis of Churg Strauss syndrome

- 1. Asthma
- 2. Eosnophilia > 10%
- 3. Neuropathy mono or polyneuropathy
- 4. Pulmonary infiltrates
- 5. Paranasal sinus lesions and
- 6. Extravascular eosinophil infiltration on biopsy.

Note: Four out of six criteria should be present

Antineutrophil cytoplasmic antibodies ANCA are present in high titers in 70-80% of cases. These antibodies act

against neutrophil granules and the lysosomes of monocytes. The antibodies show further specificities. ANCA is positive also in Wegener's granulomatosis and microscopic polyangiitis which all are together grouped as ANCA associated vasculitis.

Treatment is with high doses of corticosteroids. Immunosuppressants are only rarely indicated.

Behçet's Disease (Behçet's Syndrome)

It is an inflammatory disease of unknown cause characterised by recurrent aphthous ulceration in the mouth, genital ulcers, uveitis and skin lesions. The uveitis tends to recur and leads to blindness, whereas the other manifestations are self-limiting.

Pathologically it is a recurrent acute inflammatory disease rather than a chronic inflammatory process. Persons with HLA B1 have a strong predilection to develop Behçet's disease. This disease is present in India rarely and it may masquerade as other multisystem diseases.

The basic pathophysiological process is small vessel vasculitis, autoimmune responses and hyperfunction of neutrophils. The neutrophils are overactive with increased lysosome production and chemotaxis.

Clinically this can be demonstrated by the pathergy tests in which a needle prick area is infiltrated by neutrophils to produce a visible papule or pustule seen at 48 hours. Lymphocyte function is also abnormal. Diagnosis is almost certain if in addition to oral ulceration, any two of the following criteria are present.

Clinical Features

Recurrent genital ulcers, eye lesions, skin lesion especially erythema nodosum, folliculitis, pustules or acneiform lesions.

Skin lesions: Erythema nodosum, pseudofolliculitis, papular pustular or acneiform lesions.

Recurrent ulcers over the scrotum, penis or vulva.

Ocular lesions: Uveitis and retinal vascular occlusions.

Joint lesions: Mono- or polyarthritis—major joints are affected.

Gastrointestinal features include recurrent oral ulcerations. Abdominal pain, hematemesis, melena and perforation of viscera.

Neurological manifestations include meningitis, meningoencephalitis, motor disturbances, brainstem symptoms and psychiatric disturbances.

Treatment

Mainstay of treatment is corticosteroids. Immunosuppressants such as azathioprine and cyclosporine and cytotoxic drugs such as cyclophosphamide and chlorbucil are required in cases resistant to corticosteroids. Ocular lesions are treated with local corticosteroid drops and colchicine 0.5-1.5 mg/day orally. In intractable cases interferon alpha is being used with success.

Arteritis is treated with a combination of corticosteroids and immunosuppressants. Thrombotic complications are treated with anticoagulants and antiplatelet drugs. Hemoptysis is a dangerous symptom occurring in patients with pulmonary vasculitis. Fifty percent of patients die within 3 years of onset of hemoptysis. In spite of recent modalities of treatment, functional recovery is unsatisfactory.

Mixed Essential Cryoglobulinemia

Cryoglobulinemia is a systemic vasculitic disorder secondary to the deposition in small and medium sized blood vessels of circulating immune complexes and complement, which precipitate at reduced temperatures. Serological classification defines type I as isolated monoclonal immunoglobulin without rheumatoid factor (RF), predominantly associated with malignant conditions of the immune system such as multiple myeloma. Types II and III are polyclonal containing IgG and rheumatoid factor. The manifestations include mild vasculitis, arthralgia, mild Raynaud's syndrome and palpable cutaneous purpura. More severe vasculitis involving renal and neurological systems may be seen. Treatment consists of corticosteroids, alkylating agents and in selected cases, interferon.

Henoch-Schönlein Syndrome

General Considerations 718
Pathology 718
Clinical Features 718
Management 719

General Considerations

Idiopathic Inflammatory Myositis (IIM)

Inflammatory muscle diseases, currently referred to as idiopathic inflammatory myositis (IIM) are a group of acquired and potentially treatable muscle disorders.

These can be separated into 3 subsets:

1. Dermatomyositis
2. Polymyositis and
3. Inclusion body myositis

In addition, myositis may occur in association with malignancy and connective tissue diseases. Crucial investigations in IIM include elevated muscle enzymes, typical EMG changes and muscle biopsy findings.

POLYMYOSITIS

Polymyositis is a diffuse immune-mediated connective tissue disease in which predominantly muscles show nonsuppurative inflammatory lesions associated with weakness, atrophy and later calcification. Some are associated with changes in the skin manifesting as rash, pigmentation or others. These are included under the term dermatomyositis. In India this disease may be seen in skin clinics, rheumatology services, neurology clinics or internal medicine departments. Majority of them are primary without any underlying disease. Secondary form occurs in the course of other connective tissue diseases or as a paraneoplastic manifestation of malignancy.

Analysis of 87 patients with inflammatory myositis seen over a 10 year period at the Madras Medical College gave the following break up.

- Adult polymyositis 24,
Adult dermatomyositis 26,

Juvenile myositis 5,
Carcinomatous myositis 1,
Amyopathic dermatomyositis 1
Overlap connective lesions 30
Male to female distribution was 1.2: 3.5

Ref: Porkodi R, et al. Clinical Spectrum of Inflammatory Myositis in South India. JAPI 2002;50:1255-8.

DERMATOMYOSITIS

Dermatomyositis is the least common among the connective tissue disorders. It consists of inflammatory and degenerative lesions involving the striated muscles, skin, and other connective tissues in varying combinations.

The *clinical types* are:

- Type I *Typical polymyositis.*
Type II *Typical dermatomyositis.*
Type III *Dermatomyositis associated with malignancy.*
Type IV *Childhood dermatomyositis.*
Type V *Dermatomyositis or polymyositis associated with other collagen diseases as part of an overlap syndrome.*

Pathology

The muscles show fragmentation, loss of cross-striation, cellular infiltration of interstitial connective tissue, increase in sarcolemmal nuclei, and rarely calcification. Perivascular inflammatory changes are present. Skin shows swelling and edema of dermal collagen, atrophy of epidermis, and flattening of rete pegs.

Clinical Features

Dermatomyositis is more common in the second, fifth, and sixth decades. Women are more affected than men. A wide spectrum of clinical severity ranging from an acute, extensive rapidly fatal paralytic syndrome to a very slowly progressive muscle disease closely resembling a muscular dystrophy may be seen. Proximal muscles are affected more than others in the early stages. Muscle tenderness is prominent in the acute stages. Eventually fibrosis and

contractures occur. The muscles are hyperreflexic. Though in a third, the esophageal and pharyngeal muscles are affected, the ocular muscles are spared. Muscle enzymes are increased. The EMG shows myopathic pattern.

The diagnostic skin lesion is a heliotrope eruption on the face associated with periorbital edema. Skin lesions may precede, coexist, or follow the muscular involvement. Cutaneous lesions may ulcerate and leave behind depressed scars. Subcutaneous and periarticular calcification may be seen. Around 35% of cases show a non-erosive arthritis particularly small joints of the hands.

Diagnosis

The diagnosis is made on clinical grounds, electromyography, raised levels of creatine phosphokinase, aldolase, SGOT and lactic dehydrogenase. *Rheumatoid factor* is present in many cases and antinuclear factor in 30%. Muscle biopsy confirms the diagnosis.

The course is variable. In some it is rapidly progressive and fatal due to cardiac (myocarditis), renal or pulmonary complications (interstitial lung disease). Many follow a slowly progressive course extending over 10-15 years leading to muscle weakness, contractures, and

deformities. Spontaneous remission is seen in some cases. In the course of other connective tissue disorders like rheumatic fever, rheumatoid disease, Sjögren's syndrome, scleroderma or lupus erythematosus, a picture of dermatomyositis may occur. In such cases the occurrence of muscle weakness out of proportion to the primary condition should suggest the possibility of superadded dermatomyositis. Death in dermatomyositis is mainly due to respiratory complications.

Management

Prednisolone in a dosage of 1-2 mg/kg/day to start with and subsequently tapered off is effective in majority of cases. Immunosuppressive agents are indicated when the response to corticosteroids is unsatisfactory. Physiotherapy is indicated to prevent disuse atrophy and contractures.

Since dermatomyositis may occur as a paraneoplastic phenomenon, an underlying malignancy should be excluded in all cases. The usual primaries are the breasts, lungs, ovaries, prostate and stomach. Removal of the tumour brings about remission.

Drugs such as hydroxyurea, NSAIDs, quinidine, penicillamine and others may cause dermatomyositis as side effects.

110

Miscellaneous Rheumatic Syndromes

12

K.V. Krishna Das

Chapter Summary

Lumbago-sciatica Syndrome 719
Frozen Shoulder 720
Shoulder-hand Syndrome 720
Tennis Elbow 720
Golfer's Elbow 720
Fibromyalgia 720

In many musculoskeletal syndromes no definite disorders of bone, cartilage or connective tissue may be demonstrable. These present with pain and varying grades

of disability due to local inflammatory changes but follow a self-limiting course. *Precipitating factors* include exposure to inclement weather, unaccustomed exercise, infections, faulty postures, and mild trauma. These disorders are more common in the older age groups. In many cases underlying diseases such as diabetes may be present, which have to be specially looked for.

Lumbago-sciatica Syndrome

Pain is vaguely located in the low back, it may radiate to the lower limbs. Signs of nerve root compression do not occur.

Frozen Shoulder

This is a condition of painful limitation of movement of the shoulder. In the initial stages the shoulder is tender and painful, but later on it becomes painless. It is most probably caused by lesions of the rotator cuff. Myocardial infarction, hemiplegia, herpes zoster or surgery on the chest wall may be followed by the syndrome of “frozen shoulder”.

Shoulder-hand Syndrome

This is a condition in which shoulder movements are restricted and it is associated with pain and swelling of the hand. Conditions which lead to frozen shoulder also may give rise to this syndrome. The incidence is more in epileptics and those on barbiturates and anti-tuberculosis drugs. Treatment consists of judicious administration of analgesics, anti-inflammatory drugs, corticosteroids, local short wave diathermy and manipulation, in some cases sympathetic nerve block may be required. In many cases shoulder-hand syndrome may be the first manifestation of diabetes mellitus or impaired glucose tolerance.

Tennis Elbow

This condition is caused by the traumatic rupture of the common origin of the extensor tendons at the lateral epicondyle.

Golfer's Elbow

This condition is caused by the rupture of the common flexor tendon from the medial epicondyle.

Other Painful Conditions Around the Shoulder

These include *supraspinatus tendinitis*, *subacromial bursitis*, *bicipital tendinitis* and *periarthritis* of the shoulder joint. These result from over-use of the joints or faulty positions. They are more common in diabetics and elderly persons.

Management

Though these various rheumatic syndromes are not serious, they can lead to painful limitation of movement, prolonged morbidity and atrophy of shoulder muscles. Treatment consists of nonsteroidal anti-inflammatory drugs, local physiotherapy and manipulation of the joint to restore mobility. Local injection of cortisone acetate into the affected tissue gives immediate relief.

Fibromyalgia

Pain and stiffness arising in muscles or other soft tissues may occur in the absence of any definable musculoskeletal pathology. It is a syndrome of widespread chronic muscular pain and tender points. Widespread pain is defined as pain on the axial spine together with pain at least in two contralateral quadrants of the body; ‘chronic’ is defined as more than three months of pain; high tender count was defined as 11 or more tender points out of a specified set of 18 points to be examined. These tender points may have physical humps of all sizes ranging from the size of wheat grain to that of an apple. Associated symptoms such as fatigue, poor sleep and stiffness are also recognized as common. They were also more likely to report depressive symptoms, anxiety and difficulty with sleep. There are other associations with diseases such as irritable bowel syndrome and chronic fatigue.

The etiology of this condition is unclear. The relationship with psychological factors suggest an abnormal sensitivity to pain. Analgesic therapy is of questionable benefit. Cognitive therapies are being assessed.

Whether we label patients as having fibromyalgia or not, there is no doubt that many patients have diffuse pain, sleep disturbances, fatigue and tender points. There is no specific treatment and the prognosis is poor, but individual patients may be helped by an adequate explanation of the condition, to learn to live with it and avoid further unnecessary investigations and drug treatment.

111

Seronegative Spondyloarthropathies

K.V. Krishna Das

Chapter Summary

- Ankylosing Spondylitis 721
- Enteropathic Arthritis 723
- Psoriatic Arthropathy 724
- Reiter's Syndrome 724
- Whipple's Disease 725
- Joint Involvement in Sarcoidosis 725

The term seronegative inflammatory arthropathy includes ankylosing spondylitis, enteropathic arthritis, psoriatic arthropathy and Reiter's syndrome. These diseases are characterized by chronic inflammatory arthritis, major affection of the axial skeleton, strong HLA association, varying grades of multisystem involvement and absence of the serological markers characteristic of the connective tissue diseases. The common factor is HLA B27. In the general population HLA B27 positivity is below 5%.

The positivity rates for HLA B27 in the different forms of arthritis.

- Ankylosing spondylitis—above 90%
- Reiter's syndrome—75%
- Psoriatic arthropathy—50-75%
- Enteropathic arthritis—30-70%

Association with HLA B27 is one of predispositions to the disease. The genetic markers for these diseases are probably on chromosomes 2,6 and 10. The HLA B27 group consists of at least 14 subtypes which differ in their amino acid substitutions-B 2701 to B 2714. The subtype 2704 is probably more common in Indians.

HLA B27 shows weaker association with anterior uveitis, reactive arthritis, sacroiliitis, late onset juvenile chronic arthritis in boys and inflammatory bowel disease with axial joint involvement.

Ankylosing Spondylitis

Syn: Marie-Strümpell disease, Bamboo spine, Poker back

This is an inflammatory arthropathy predominantly involving the axial skeleton, and in the advanced stages

the entire vertebral column undergoes bony ankylosis. This disease entity belongs to the group of seronegative spondyloarthritides (SSA).

Prevalence and epidemiology: This disease is rare compared to rheumatoid arthritis. It is not an uncommon disease in India. Male to female ratio is 7:3.

Genetic factors: The histocompatibility antigen type HLA B27 is positive in over 90% of patients and 53% of their first degree relatives. The presence of the HLA B27 antigen predisposes such individuals to develop arthritis in response to several environmental factors. The triggering event is probably an infection. In many cases the organism is *Klebsiella pneumoniae*. Maximal lesions are in the entheses which show edema and infiltration by lymphocytes, plasma cells and polymorphonuclear leucocytes. The adjacent bone marrow also shows edema and inflammation.

Pathology

The sacroiliac joints and vertebral joints are maximally affected, but the manubriosternal joints, symphysis pubis, costovertebral and sternocostal joints, shoulders, hips, and rarely the joints of the hands and feet may also be affected. The joints show mild synovitis. Periarticular fibrous tissue, ligaments, and articular cartilage also show inflammation. Extra-articular lesions develop in various ligaments, tenoperiosteal junctions (entheses), the ascending aorta, uveal tract and the upper lobes of the lungs. Ankylosis develops in the joints on account of the tendency for calcification and ossification. The new bones formed are known as syndesmophytes which form the characteristic feature of the disease. Calcification and ossification of the annulus fibrosus and proliferative bony outgrowths from the vertebral borders result in ankylosis of the spine. The spinal column becomes a rigid pillar giving the radiological appearance of *bamboo spine*.

CLINICAL FEATURES

The clinical severity ranges from partial forms (formes frustes) to the classic picture of severe ankylosis of the

spine and other joints. The disease is more common in the second, third, and fourth decades. Bouts of low backache, felt mostly in the morning and aggravated by periods of rest are the early manifestations. Later, the pain becomes constant. At this stage the obliteration of lumbar lordosis and generalized limitation of movements of the lumbar spine due to muscular spasm are detectable. Later, ankylosis of spinal joints (*poker back*) occur. The whole spine becomes a single rigid column.

Tenderness over the sacroiliac joints is elicitable by deep palpation. Pain from the sacroiliac joints is elicited by the *pump handle test*, the pelvic compression test and hyperextension test.

Other joints may be involved in 50% of cases, the most common being the root joints, viz. hips and shoulders, and hence the term *rhizomelic spondylitis*. It is rare to get affection of the peripheral small joints. When it occurs, it is asymmetrical and milder compared to rheumatoid arthritis. Later on they also may be ankylosed.

The patient with advanced ankylosing spondylitis develops forward craning of the neck, high dorsal kyphosis, rounding of the shoulders, obliteration of the normal lumbar lordosis, wasting of the glutei, flattening of the chest, and ballooning of the abdomen. Forward vision is impaired due to the stooping posture.

A simple but reliable test to diagnose ankylosing spondylitis is the *modified Shober test*. A 10 cm long line is drawn perpendicularly up from the midpoint of a line joining the posterior superior iliac spines. In normal persons this line stretches to 16 to 22 cm when the patient fully bends forwards. In established ankylosing spondylitis this line does not stretch more than 1 or 2 cm (Fig. 111.1).

Extra-articular Features

These include unilateral iritis (20%), aortic incompetence, heart block, pericarditis and fibrosis of the upper lobes of the lung.

Fig. 111.1: Ankylosing spondylitis. Note: the kyphosis and fixed flexion deformity of the neck and upper thoracic spine in two patients, almost similar

Enthesopathy occurs in many cases. This manifests as plantar fasciitis, costochondritis or Achilles tendonitis.

Complications

Fracture dislocations of the spine and other bones and secondary amyloidosis constitute the main complications.

Though in the majority of cases the picture of ankylosing spondylitis is typical, less commonly the presentation may be atypical. These are: (i) isolated sacroiliitis, (ii) asymmetrical peripheral polyarthritis or (iii) uveitis.

Laboratory Data

The ESR is elevated in the early phases of inflammation, but it returns to normal levels in the later stage when ankylosis is complete.

Radiology

Early abnormality is in the sacroiliac joints which show an appearance of widening (*pseudowidening*) and erosions. As the disease progresses, the adjacent zones become sclerosed and the joint space is obliterated by bony fusion. The vertebrae appear square due to a combination of osteitis of the borders and filling up of the anterior concavity. The fully developed stage gives the typical picture of *bamboo spine* (Figs 111.2 and 111.3).

Diagnosis

Clinical diagnosis has to be confirmed by radiology and the diagnosis is strengthened by the demonstration of HLA

Fig. 111.2: X-ray spine PA view—ankylosing spondylitis
Note: sclerosis of sacro-iliac joints

Fig. 111.3: X-ray spine lateral view—ankylosing spondylitis
Note: calcification of anterior and posterior regiments leads to the appearance of bamboo spine

B27. When the age of onset is below 20 years, other forms of arthritis which involve this age group have to be distinguished. The diagnosis is likely to be delayed in such cases.

The New York criteria for diagnosis include

- Limitation of movements of spine in all planes
- Pain in lumbar spine or dorsolumbar junction
- Chest expansion less than 2.5 cm
- Radiological features of unilateral sacroiliitis grade III-IV or bilateral sacroiliitis grade I-II.

Differential Diagnosis

This includes osteoarthritis, cervical spondylosis, other causes of sacroiliac arthritis, and endemic fluorosis. In endemic fluorosis radiology may show lesions of the spine resembling ankylosing spondylitis but the sacro-iliac joints are normal (Fig. 111.4).

Management

Treatment is aimed at improving spinal mobility, preventing ankylosis and giving symptomatic relief. The modalities of treatment include physical measures and appliances, medications, irradiation or surgery.

Physical Measures and Appliances

Regular spinal exercises help to correct postural abnormalities and strengthen the spinal ligaments and paraspinal muscles. Prolonged immobility tends to accelerate ankylosis and this should be avoided. Spinal braces help to correct postural defects partly. Prismatic spectacles enable the patient with severe kyphosis to see objects in front.

Fig. 111.4: X-ray spine—fluorosis
Note: that SI joints are free

Drugs

Commonly used drugs are indomethacin, aspirin, and the nonsteroidal anti-inflammatory agents. Corticosteroids are not widely used except for limited indications. Salazopyrin in doses of 500 mg 6 h orally, given over prolonged periods help to relieve pain of peripheral arthritis and possibly of the axial lesion too. Anti rheumatic biologicals have been used in the treatment of intractable spondylarthropathies. Infliximab given in a dose of 5 mg/kg IV at weeks 0, 2 and 6 produced remarkable improvement when followed up to 1 year. Reactivation of tuberculosis was seen in 50% of patients. In resistant cases combination of sulfasalazine, weekly subcutaneous injections of 20-25 mg of methotrexate and monthly cycles of 3 injections of 500 mg of IV methyl prednisolone give relief. Pamidronate 60 mg given IV as slow infusion has been tried with encouraging results.

Ref: Grover R, et al. Clinical experience with infliximab on spondylarthropathy: an open label study in fourteen patients. J Ind Rheumatol Assoc 2005;13:78-82.

Malaviya AN, et al. JAPI 2007;55:193-7.

Surgery

Permanent deformities of the spine, hip and other joints can be corrected by orthopedic procedures. The disability has been considerably reduced by total hip replacement which has improved the outlook for patients with ankylosing spondylitis.

ENTEROPATHIC ARTHRITIS

A heterogenous group of arthritic syndromes develop secondary to primary lesions in the gastrointestinal tract.

The primary gastrointestinal disorders leading to arthritis are: (i) Chronic inflammatory bowel diseases such as ulcerative colitis, Crohn's disease (regional ileitis) and Whipple's disease (intestinal lipodystrophy); (ii) acute infective disorders such as salmonellosis, bacterial dysenteries, and *Yersinia enterocolitica* infection; (iii) intestinal bypass surgery; and (iv) gut associated neoplasms which produce arthritis as paraneoplastic manifestations.

Arthritis associated with chronic inflammatory disease of bowel: Even though ulcerative colitis, Crohn's disease, and Whipple's disease are separate entities, arthritis produced by all the three are similar clinically. Two types are seen: (i) A *peripheral polyarthritis*, and (ii) *ankylosing spondylitis* with sacroiliitis.

The peripheral arthropathy manifests as asymmetric affection of the major joints of the lower limbs. Distal interphalangeal joints may be affected. The arthritis is self-limiting and residual damage is unusual. With subsidence of the intestinal lesion, the arthritis also subsides.

A clinical picture identical with idiopathic ankylosing spondylitis may develop in some cases but there is no male preponderance. Unlike the peripheral arthritic syndrome, the spondylitic variety does not bear any relation to the severity or extent of the bowel disease.

Investigations

Neither the synovial fluid nor the synovial biopsy shows diagnostic features. Radiology of the joints remains essentially normal except for the soft tissue swelling and minimal osteoporosis. The diagnosis is based on the clinical picture, temporal relation with bowel disease and exclusion of other forms of arthritis.

Management

Since the peripheral type of arthritis is self-limiting only symptomatic and supportive measures are required for the joint disease. Treatment is directed toward the bowel disorder.

In the spondylitic type, line of management is similar to that of idiopathic ankylosing spondylitis.

Arthritis Associated with Other Forms of Intestinal Disease

Infective disorders of the intestines: A migratory polyarthritis may develop up to three weeks after the occurrence of bacillary dysentery, *Salmonella* infections and *Yersinia enterocolitica* infection. This is an immunologically-mediated reactive arthropathy.

Gastrointestinal bypass surgery: Jejunocolic or jejunoleal anastomosis done as a therapeutic measure for severe obesity may be followed by a polyarthritic syndrome 2-3 months later. Restoration of normal bowel anatomy clears the arthropathy.

Arthritis associated with malignancies of the gastrointestinal tract may precede or accompany the neoplasm. Removal of the tumour clears the joint lesions also.

Psoriatic Arthropathy

Joints may be affected in psoriasis in one of the following four ways:

1. Predominantly distal arthritis involving the interphalangeal joints.
2. Classic arthritis mutilans with digital telescoping and sacroiliac involvement.
3. Arthritis closely resembling rheumatoid arthritis but with asymmetrical involvement and negative serology, and
4. Spondylitis with or without peripheral arthritis.

Clinical Features

Pain and disability are less severe than in rheumatoid arthritis. Psoriatic lesions may be demonstrable in the skin or nails along with the arthritis. Rarely the joint lesion may precede or follow the skin lesion and in such cases diagnosis may be presumptive for long periods. Involvement of the distal interphalangeal joint has to be distinguished from rheumatoid arthritis, osteoarthritis, hypertrophic osteoarthropathy and enteropathic arthropathy.

Management

Psoriatic arthropathy is managed on the same lines as rheumatoid arthritis. Chloroquine and gold are seldom used due to risk of exacerbating the skin lesion. Corticosteroids bring about dramatic relief in an acute case. For long-term use, NSAIDs, salazopyrin and methotrexate are all useful. The retinoid—*etretinate*-20 mg daily is an effective adjuvant to treat the joint as well as the skin condition. A newer analogue is *acitretin* which is cleared faster from the system the dose is 25 to 50 mg/day, to be given for several months. It should be avoided in young women due to risk of teratogenicity.

The primary treatment for psoriasis, i.e. photochemotherapy with methoxy psoralen and long wave ultraviolet light (PUVA), while relieving the skin condition may benefit the arthritis as well. Biological antirheumatic drugs such as infliximab are being used in intractable cases.

For further details see Section 18, Chapter 196 Psoriasis.

Reiter's Syndrome

This is one among the reactive arthritis.

The triad of symptoms—non-specific urethritis, conjunctivitis, and arthritis—which follows an attack of dysentery or urethritis is termed Reiter's syndrome. The etiology is unknown. Reiter's syndrome develops as a complication of nongonococcal or postgonococcal

urethritis and dysenteries. Over 80% of subjects have HLA B27.

Age and Sex

Young adult males are considerably more affected in Reiter's syndrome following nongonococcal urethritis but this phenomenon is less striking in the post-dysenteric group.

Clinical Features

The clinical spectrum may vary from the fully developed picture of urethritis, arthritis, and conjunctivitis to less complete forms with only urethritis and arthritis. The clinical spectrum includes recurrent episodes of tenosynovitis, plantar fasciitis, enthesopathies and frank arthritis. 20% may develop lesions of the sacroiliac joints and secondary spondylitis. Other common features include stomatitis, circinate balanitis, and *keratoderma blennorrhagica* (hyperkeratotic lesions of the palms, soles, and other regions) which may proceed to pustulation and scaling. The oral and cutaneous lesions are painless. The ESR is elevated upto 100 mm and this is a common finding. Uveitis may develop which may lead to blindness. Cardiac lesions similar to those that occur in ankylosing spondylitis may develop. In many cases the disease tends to become chronic and progressive leading to considerable disability.

Diagnosis

Clinical features and the presence of the precipitating cause should suggest the diagnosis. Rheumatoid factor is negative. X-ray changes are unusual except in chronic or recurrent cases. Presence of primary infection supports the diagnosis.

Management

Management is symptomatic since there is no specific curative treatment. Tetracycline is employed to treat the urethritis. Nonsteroidal anti-inflammatory drugs give symptomatic relief. Immunosuppressive therapy is indicated for severe progressive arthritis and keratoderma blennorrhagia. Intra-articular corticosteroids have been tried with temporary benefit.

Whipple's Disease

This is a rare disorder affecting several systems characterized predominantly by diarrhea, steatorrhea, malabsorption, fever, anemia, pigmentary disturbances and joint lesions.

The causative agent is most probably a gram-positive bacillus belonging to the *Actinobacter* group and designated *Tropheryma whipelli*. Histologically the small intestine shows characteristic lesions. Large macrophages containing glycoprotein-rich lysosomes are seen to

infiltrate the lamina propria and submucosa. The bacilli are seen within the macrophages. The mucosal and submucosal lymphatics are dilated and obstructed. Other tissues may be involved. These include mesenteric and peripheral lymph nodes, liver, spleen, heart, lung and central nervous system.

Clinical features are protean, depending upon the predominant pathological process. Joint symptoms occur in about 60% of cases. These may pre-date the intestinal symptoms, or coexist with them. Joint symptoms include episodic inflammatory arthritis of abrupt onset involving large joints mainly, but also the joints of the hands at times. Diagnosis is established by demonstrating the intestinal lesion by mucosal biopsy. The joint fluid shows only signs of non-specific inflammation.

Treatment

Whipple's disease responds to antibiotics such as cotrimoxazole, chloramphenicol or tetracyclines. Symptomatic measures are instituted for joint symptoms.

Joint Involvement in Sarcoidosis

Joint manifestations develop in 25% of cases with systemic sarcoidosis, especially in the pulmonary form. Two types of joint manifestations may occur.

1. An acute transient polyarthropathy, associated with erythema nodosum. Usually this affects the large joints.
2. A chronic persistent polyarthropathy, usually affecting the small joints of the fingers. Larger joints may be affected less commonly. The synovium shows granulomatous changes. Joint destruction may follow. Treatment is symptomatic with NSAIDs. Improvement may result from chloroquine, other DMARDs, colchicine and corticosteroids. Immunosuppressant drugs act as adjuvants to glucocorticoids. (Refer Section 14 chapter 143).

Joint Symptoms in Infective Conditions

Several infections give rise to joint symptoms either as allergic manifestations or due to direct involvement. Polyarthritis occurring in systemic tuberculosis (**Poncet's syndrome**) and reactions in leprosy fall in the former group. Joints may be directly involved by pyogenic organisms, *M. tuberculosis*, *T. pallidum*, gonococci, meningococci, *S. typhi*, *brucella*, *Lyme borreliosis*, rubella, hepatitis B virus, mumps, chickenpox, smallpox, AIDS and several others.

Several drugs give rise to arthralgia and possibly arthritis as adverse side effects. These include immune sera and vaccines, penicillin and other antibiotics, antihypertensive drugs, parenteral iron, iron chelators, interferons and others. Detailed drug history is important to diagnose these conditions.

Metabolic Arthropathies

Osteoporosis, Gout and Other Forms of Crystal Induced Arthropathies

K.V. Krishna Das

Chapter Summary

Osteoporosis 726
Gout 729
Other forms of Crystal Induced Arthropathy 731

Osteoporosis

Osteoporosis is defined at a consensus conference, as a systemic skeletal disease characterised by lowered bone mass and microarchitectural deterioration of bone tissue with consequent increase in fragility and susceptibility to fractures. The WHO has defined osteoporosis based on bone mineral content (BMC) and bone mineral density (BMD). In simple terms osteoporosis can be described as a reduction in bone mass without gross alteration in its chemical composition. Osteopenia is reduction in bone mass or disruption of bone architecture leading to increased risk of fractures. Osteoporosis can also be defined in terms of bone mineral density (BMD) studies as a dual energy X-ray absorptiometry (DEXA) score of – 2.5 or less at the spine, hip and forearms. BMD studies of the hips are the most reliable parameters to predict fracture risk.

The bone matrix itself is deficient but osteoid that is present is normally mineralised. Bone formation and resorption are in equilibrium in adults upto the age of 50 years and, therefore, upto this age the bone mass is fairly constant. The bone mass declines steadily but slightly after the age of 50. Osteoporosis results from excessive resorption compared to formation. The precise mechanism leading to osteoporosis is not clear. In the majority an etiological factor is demonstrable while in a few this is not so. Genetic factors play a role. Several potential candidate genes have been described especially the one for vitamin D receptor.

Pathogenesis

The resorption rate is high in osteoporosis, even though bone formation proceeds normally. Particular areas of the

Common Causes

Generalised Osteoporosis

- A. *Idiopathic osteoporosis*: Two types of idiopathic osteoporosis are seen—the adult type and the juvenile type (8-12 years).
- B. *Secondary osteoporosis*:
 1. Senile osteoporosis.
 2. Prolonged bed rest, especially in the elderly subjects.
 3. Endocrine abnormalities:
Postmenopausal osteoporosis,
Diabetes mellitus,
Cushing's syndrome and corticosteroid therapy
Hypogonadism,
Hypopituitarism,
Thyrotoxicosis, and
Hyperparathyroidism.
 4. *Nutritional causes*:
Protein malnutrition,
Malabsorption syndrome,
Scurvy, and
Alcoholism.
 5. *Hereditary connective tissue diseases*:
Ehlers-Danlos syndrome,
Marfan's syndrome,
Homocystinuria, and
Osteogenesis imperfecta.

Localised Osteoporosis

- i. Localized immobilization following fractures.
- ii. Inflammatory arthropathy, e.g. rheumatoid arthritis.
- iii. Reflex bone dystrophy, e.g. shoulder-hand syndrome, and
- iv. Secondary to irradiation therapy.

skeleton such as the metacarpals, femoral neck and vertebral bodies show higher rates of resorption. Maximum impact is on the axial skeleton. The peripheral bones are affected to a varying extent.

Two types of bone loss are seen

Type I and type II which are due to different mechanisms occurring after menopause.

Type I is seen mainly in women in the age group 51-75. It is due to accelerated bone loss with fracture sites mainly in the vertebrae and distal part of the radius. In type II trabecular bone is not affected. Cortical loss of

Fig. 112.1: X-ray osteoporosis spine. Note: 1. Kyphosis, 2. Loss of density of vertebrae compression fracture—arrow, cod fish vertebrae—arrow head

bone occurs above the age of 70 years. It presents with multiple wedge fractures of the vertebrae and fracture of hip.

CLINICAL FEATURES

Osteoporosis remains asymptomatic for considerable periods till bone loss has become advanced. The vertebral bodies become soft and compressed. The intervertebral discs herniate into the vertebral bodies and this results in shortening of the vertebral column. The terms *dowager’s hump* or *widow’s hump* are used to denote the dorsal kyphosis with exaggerated cervical lordosis brought about by vertebral compression. When symptoms occur, they include vague muscular aches and pains, loss of height of the spine, and kyphoscoliosis. Vertebral collapse, fracture neck of the femur, and Colles’ fracture (fracture distal end of the radius) develop as a result of trivial trauma or even spontaneously. In general the fractures heal within 4-6 weeks with simple treatment (Figs 112.1 and 112.2).

These sites may become painful and even tender for varying periods before demonstrable fractures develop. Early institution of treatment of this stage may relieve this symptom.

Skiagram reveals reduction in density of the vertebral bodies in the early stages, and the vertical trabeculations appear more prominent. The vertebra becomes biconcave and this is referred to as *cod fish vertebra*. The inter-vertebral discs herniate into the vertebral bodies. Vertebral

Fig. 112.2: Osteoporosis wrists. Note: haziness and translucency of carpal bones

collapse in the late stages results in anterior wedging of the vertebral bodies. The medullary cavities of long bones are expanded with thinning of the cortex. Sometimes differentiation from osteomalacia can be extremely difficult but pseudofractures are not seen in osteoporosis.

The most reliable investigation is to measure bone mineral density by DEXA. Quantitative values of BMD are given, expressed in two forms—T score and Z score. T score compares the BMD of the patient with the mean peak BMD of the normal young adult population and expressed in terms of standard deviation (SD). Z score compares the BMD of the patients of the same age.

WHO criteria for osteoporosis in adult women using T-scores by DEXA	
Normal	: BMD is within 1.0 SD of the young adult reference mean
Osteopenia	: BMD 1 to 2.5 SD below the young adult mean
Osteoporosis	: BMD more than 2.5 SD below the young adult mean
Severe osteoporosis	: Osteoporosis with the presence of one or two fragility fractures.
BMD values of 0.72 suggests fracture threshold in South Indian elderly person	

The sites commonly measured are the lumbar spine (L1-L4) including the intervertebral discs, hips and forearms. BMD of any other part of the skeleton or that of the whole skeleton can also be determined.

Workers at the KJ Hospital, Chennai have evolved a formula for diagnosing post-menopausal osteoporosis. The KJ Hospital Amburajan’s *empirical formula* is based on the radiographic features of the clavicle in plain radiographs of the chest.

Ref: Amburajan MM 1999. Evaluation of osteoporosis using conventional radiographic methods and dual energy X-ray absorptiometry PhD thesis, Anna University, Chennai.

Before accepting the diagnosis as osteoporosis a careful search for primary bone malignancies such as

multiple myeloma and malignant secondaries from the female genital organs, breasts and other sites should be excluded by appropriate investigations.

Laboratory Findings

The serum calcium, phosphorus, and alkaline phosphatase are normal and this distinguishes osteoporosis from osteomalacia in which calcium and phosphorus are low and alkaline phosphatase is elevated. As a result of excessive resorption of bone, urinary hydroxyproline is elevated above normal range (6.42 mg/g of creatinine up to 55 years of age), during the active phase of the disease.

Treatment

Acute episodes of fracture should be managed in the usual orthopedic lines.

General measures: Adequate nutrition should be ensured, especially with supplements of calcium, vitamin D and proteins. Calcium supplementation given as calcium gluconate, lactate or carbonate 500-1000 mg/oral/day helps to improve bone mineralization. Active vitamin D₃ analogues such as calcitriol and alfa calcidol stimulate the formation and action of osteoblasts. A small but definite risk of urolithiasis occurs. Supplementation of vitamin D 800 units/day reduces the risk of fracture. Calcitonin, given intranasally in a dose of 200 IU/day reduces the risk of fracture. This drug is available in India, but is expensive. Vertebral collapse usually heals satisfactorily with bed rest and analgesics. Early ambulation and exercise help to improve muscle tone. Provision of weight-bearing appliances or corsets helps to relieve pain and prevent further damage in the acute phase.

Bisphosphonates: Bisphosphonates are synthetic analogues of inorganic pyrophosphate. They are deposited on bone surfaces. When ingested by osteoclasts during bone turnover their main action is anti-resorptive.

These are excellent drugs which help to restore bone mineral density in both sexes, relieve bone pains and possibly reduce the progression of osteoporosis. They are indicated for the treatment of the established cases with demonstrable X-ray or DEXA criteria, on a short-term (a few months) or a long-term basis depending on the individual case. Though several preparations available, one acceptable drug is **alendronate sodium** which is an aminophosphate. It inhibits osteoclastic activity. Given over periods up to three years in daily doses of 10 mg, it relieves the symptoms of postmenopausal osteoporosis and restores bone density. An alternative is to give 75 mg orally on an empty stomach once a week. Since the drug causes esophageal ulceration by local contact, the patient should maintain the erect posture for 15-30 minutes after taking the tablet. Side effects include heartburn, nausea,

abdominal pain and vomiting. The drug is freely available in India. Other drugs in this class include etidronate, pamidronate, clodronate, tiludronate and others. These can be employed under special indications. Follow-up studies exceeding 10 years in osteoporosis have shown continued benefit. On stopping bisphosphonates the bone density falls gradually. In a trial of glucocorticoid induced osteoporosis alendronate in a dose of 10 mg/oral daily was more effective than alpha calcidol.

Other than for osteoporosis bisphosphonates have been used for the treatment of hypercalcemia, malignant secondaries in bones and multiple myeloma.

Calcitonin: Though it is an excellent drug to relieve osteoporosis, it is seldom used due to its high cost.

Parathyroid hormone (PTH) given intermittently over short courses in doses of 100 µg/day by injection increases bone strength primarily by stimulating bone formation, especially of trabecular bone like the vertebrae and other sites. Both intact PTH as well as the 34- aminoacid peptide, known as *teriparatide* are effective in reducing fracture risk, as long as the drugs are continued. The risk for fracture in postmenopausal women is also reduced. Continued elevation of parathyroid hormones, as is seen in hyperparathyroidism gives rise to bone demineralization and bone loss.

Hormone replacement therapy (HRT): This is an accepted regimen for prevention of osteoporosis and fragility fractures in postmenopausal women. Menopause before the age of 45 years, surgical menopause, lean body mass, presence of nutritional inadequacy, lack of aerobic exercise and concurrent use of drugs such as corticosteroids (for asthma) aggravate the tendency and prepone the onset of osteoporosis. Benefits of HRT are several including the feeling of well-being, reduction in progression of ischemic heart disease and cosmetic effects. In postmenopausal osteoporosis administration of 0.625-1.25 mg of conjugated estrogen daily for 3 weeks every month helps to arrest the progression of bone loss. Since estrogens may increase the tendency to develop endometrial cancer, it is advisable to give intermittent therapy with estrogens and progesterone. A popular regimen is 0.625 mg conjugated estrogen and 2.5-5 mg medroxy progesterone daily. Withdrawal bleeding may be a troublesome side-effect in some.

The possible adverse effects include slight, but statistically significant increase in cancer of the breast and endometrium, increase in venous thrombosis, especially in these with thrombophilia. Persons on HRT should have regular gynecological check-up once a year and also self palpation of the breasts. In males the situation is less clear.

With the availability of evidence that female hormones will increase the risk of cancers of the endometrium and

breasts and venous thrombosis, their use has come down markedly.

Androgens or anabolic steroids may be tried in particular situations. Stanozolol in a dose of 2.5-5 mg oral o.d, or nandrolone in a dose of 50 mg I.M once a week are available for use. Attention to the primary cause is necessary to relieve secondary osteoporosis.

Newer Anti-osteoporotic Drugs

These include (1) strontium ranelate and (2) biological agents such as monoclonal antibody with high affinity to RANKL, thereby preventing its action in promoting osteoclast differentiation and survival. These drugs are under trial.

Ref: Philip Sambrook, Cyrus Cooper. Osteoporosis. The Lancet 2006;2010-8.

Prevention

Incidence of generalised osteoporosis can be reduced by ensuring regular exercises and proper intake of proteins, vitamins, and calcium in persons above the age of 65 years.

Pharmacological interventions for osteoporosis			
Intervention	Dosing regimen	Route of administration	Licensed indication
Alendronate	70 mg once weekly, or 5 mg or 10 mg once daily	Oral	Postmenopausal osteoporosis; glucocorticoid-induced osteoporosis; osteoporosis in men
Etidronate	400 mg daily for 2 weeks every 3 months	Oral	Postmenopausal osteoporosis; glucocorticoid-induced osteoporosis
Ibandronate	150 mg once monthly	Oral	Postmenopausal osteoporosis
	3 mg once every 3 months	Inter-venous injection	Postmenopausal osteoporosis
Risedronate	35 mg once weekly, or 5 mg once daily	Oral	Postmenopausal osteoporosis; glucocorticoid-induced osteoporosis
Raloxifene	60 mg once daily	Oral	Postmenopausal osteoporosis
Strontium ranelate	2 g once daily	Oral	Postmenopausal osteoporosis

Teriparatide	20 µg once daily	Subcutaneous injection	Postmenopausal osteoporosis
Parathyroid hormone 1-84	100 µg daily	Subcutaneous injection	Postmenopausal osteoporosis

Gout

Gout is a metabolic disorder of purine metabolism clinically characterized by recurrent attacks of acute arthritis progressing to chronic deforming arthropathy, formation of tophi and development of systemic complications like renal failure. Gout causes elevation of uric acid levels in blood and leads to deposition of urate crystals in tissues. Hyperuricemia is the cardinal abnormality leading to gout. Chronic hyperuricemia caused by any lesion, whether primary or secondary, may lead to gout. Gout is present in India, though primary gout is less common.

The term “gout” includes a heterogenous group of diseases characterized by hyperuricemia. This can be the result of several metabolic errors operating singly or in combination. Plasma levels of uric acid vary from 2 to 7 mg/dL (0.12-0.42 mmol/L) in health. The term hyperuricemia denotes values above 7 mg/dL (0.42 mmol/L) in men and 6 mg/dL (0.36 mmol/L) in women.

Uric acid metabolism follows different pathways. Uric acid is the end product of purine metabolism. Purines are derived partly from the diet and partly from endogenous metabolism. In the liver nucleic acids and purine nucleotides are degraded to form the purine bases xanthine and hypoxanthine. These are oxidised to form uric acid by the enzyme xanthine oxidase. The urates circulate in the plasma to be excreted mainly by the kidneys. A smaller amount is secreted into the gut.

Precursors of uric acid can be utilised by endogenous metabolism to synthesize purine nucleotides, through pathways involving several enzymes, including 5 phosphoribosyl-l pyrophosphate (PRPP) synthetase and hypoxanthine-guanine phosphoribosyl transferase (HGPRT).

In normal men taking purine-free diets the daily urinary excretion of uric acid is 350-500 mg. Increased production of uric acid, reduced urinary elimination or a combination of both these processes lead to hyperuricemia.

Causes

1. **Primary or genetic gout:** This accounts for 95% of the total cases and is either due to primary overproduction or underexcretion of uric acid. The underlying metabolic error is complex.

2. **Secondary gout (5%):** Hyperuricemia results from a demonstrable disorder, leading either to overproduction or defective excretion of uric acid.

Causes of Overproduction of Uric Acid

1. **Increased breakdown of cellular nuclei** occurs in malignant disease, especially when treated by anticancer drugs, e.g. chronic and acute leukemias, myeloma, polycythemia and others.
2. **Several inborn errors of metabolism lead to overproduction of uric acid:**
 - i. **Lesch-Nyhan syndrome** where there is congenital deficiency of hypoxanthine-guanine phosphoribosyl transferase (HGPRT). This syndrome is characterised by spasticity, choreoathetosis, mental retardation and compulsive self-mutilation.
 - ii. **Type I glycogen storage disease** where there is glucose 6-phosphatase deficiency, and
 - iii. **Phosphoribosyl pyrophosphate synthetase overactivity.**

Impairment of excretion of uric acid: The excretion of uric acid is impaired (i) in chronic renal failure; (ii) during intake of drugs like thiazides and other diuretics, low doses of aspirin and salicylates, pyrazinamide, sulfonamides, alcohol, in lead poisoning (*saturnine gout*); (iii) in lactic acidosis; and (iv) in miscellaneous conditions like hypertension, hyperparathyroidism, myxedema, Down's syndrome, toxemia of pregnancy, starvation and exercise.

Pathogenesis

12

Hyperuricemia is the central abnormality in gout but this may not lead to gout in all cases.

Arthritis is caused by the deposition of monosodium urate crystals in the synovium. Polymorphonuclear leucocytes ingest the crystals. They release lysosomal enzymes which cause inflammation. Kinins and related cytokines lead to increased vascular permeability. Crystals are demonstrable in the synovium and articular cartilage in the stage of acute arthritis. In the chronic stage, erosion of articular cartilage, proliferation of synovial membrane, pannus formation, cystic erosions of bones and secondary osteoarthritic changes develop. **Tophi** are nodular urate deposits found in and around the joints and in the articular cartilage. Histologically these consist of monosodium urate crystals surrounded by mononuclear cell infiltration and foreign-body giant cells. These lead to osteoarthritic changes, ankylosis of joints and tissue destruction.

Urate deposition and inflammatory reaction in the parenchyma of the kidneys lead to hyalinization or fibrosis of glomeruli. Multiple urate calculi, chronic pyelonephritis, and arteriolosclerosis are other changes seen in long-standing gout.

Clinical Features

Gout passes through three clinical stages, namely, asymptomatic hyperuricemia, acute gouty arthritis and chronic tophaceous gout. Gout is seen predominantly in men during middle life. The M: F ratio is 7:1 to 9:1. Onset of gout in the second or third decade of life should raise the possibility of other metabolic disorders of purine metabolism such as *hypoxanthine guanine phosphoribosyl transferase* deficiency.

Acute gout: Classically intensely painful monoarticular arthritis of the metatarsophalangeal joint of the big toe develops within minutes to hours. The joint is red and swollen and this may be mistaken for septic arthritis. The term **podagra** denotes painful affection of the foot occurring as a result of metatarsophalangeal arthritis. Later other joints are involved. This may be associated with fever and other constitutional disturbances.

The initial attack subsides with treatment or spontaneously to recur periodically, due to precipitating factors like dietary excess, alcoholic bouts, infections, trauma, undue physical exercise, surgery or withdrawal of drugs.

Chronic tophaceous gout: The acute attacks do not remit completely and the joints become constantly painful and swollen. Tophi develop as subcutaneous nodular masses around the joints and on tendons. They are soft and small initially but later on become hard and may reach up to 7 cm in diameter. They may ulcerate discharging chalky material. Most common sites for tophi are around the olecranon, ankles, tendo-Achilles, helix of the ear, and over other joints. Osteoarthritis and ankylosis supervene.

Atypical forms may develop in addition to the typical gouty arthritis. Subacute polyarthritis similar to rheumatoid disease or isolated joint lesions may occur. Sometimes the initial presentation may be with soft tissue involvement such as Achilles tendonitis or olecranon bursitis. Tophi may be seen in organs such as the cornea, heart, tongue, bronchi, and pleura.

Complications

1. **Renal damage:** This may occur in two forms. Acute hyperuricemic nephropathy is due to obstruction of renal tubules by urate crystals or uric acid calculi. Chronic hyperuricemic nephropathy is due to urate deposition in the renal parenchyma. It presents as chronic renal disease. Renal failure is the major cause of death in gout.
2. **Cardiovascular system:** There is higher incidence of hypertension and ischemic heart disease in gouty subjects (see Section 13, Chapter 124).
3. Gout is associated with insulin resistance.

Diagnosis

Strong clinical suspicion is essential to make prompt diagnosis. Gout should be considered in all cases of obscure

mono- or polyarticular disease. Presence of positive family history, tophi, and radiological findings strengthen the diagnosis. Serum uric acid levels above 7 mg/dL are diagnostic. Often serum uric acid may be normal in acute gout. Urate crystals can be demonstrated in synovial fluid by their birefringence under polarized light.

Radiological changes: Radiological changes occur in chronic recurrent gout. In well developed chronic gout periarticular bone shows small punched out erosions due to urate deposits, with superadded osteoarthritic changes.

Treatment

Emergency management of the acute attack: The affected part is immobilized in a splint. Indomethacin 25 mg twice daily initially and then reduced to a maintenance dose is very effective in relieving pain and arthritis. Other NSAIDs are also effective. Colchicine in a dose of 1 mg initially followed by 0.5 mg 2 h is specific in relieving the acute attack but sometimes the response may be delayed. Colchicine is given orally. Troublesome diarrhea limits its use. The mechanism of action of this drug is not clear. This drug is not freely available in India. In resistant monoarticular involvement intra-articular hydrocortisone is highly useful. All precipitating factors should be meticulously avoided.

Interval Therapy

1. **Diet:** Acute attacks can be avoided by omitting purine-rich diets like red meat, liver, pancreas, testes, peas, and alcohol. Though vegetable articles of diet such as lentils, peas, beans, spinach, mushrooms, cauliflower and oatmeal are rich in purines they generally do not provoke acute attacks. Obese individuals should lose weight gradually.
2. **Uric acid lowering agents:** When the attacks are frequent, or serum uric acid level is high and in the presence of tophi, drugs are indicated to lower serum uric acid. **Allopurinol** inhibits xanthine oxidase which is required for the conversion of xanthine and hypoxanthine to uric acid and is a very effective drug to lower serum uric acid. In addition, allopurinol also helps in elimination of urates. The advantages of this drug are its low toxicity and sustained therapeutic effect even in the presence of renal disease or diuretic therapy. The starting dose is 100 mg thrice daily, to be increased upto 500 mg/day if required, to achieve the effect. Later the dose is reduced to a maintenance level. Diarrhea, dyspepsia, and skin rashes are untoward side effects. Dose dependent toxic effects consisting of hypersensitivity reactions such as fever, eosinophilia, dermatitis, hepatic dysfunction, renal failure and vasculitis may develop in persons taking more than 400 mg/day. If allowed to proceed, the condition can be fatal. Treatment is to desensitize the patient and use lower doses of the drug.

Febuxostat is a newer non-purine selective inhibitor of xanthine oxidase, effective in gout, in a dose of 80-120mg/day. It reduces serum urate levels. Adverse side effects include hepatic and renal toxicity. The drug is still under trial.

Uricosuric agents such as probenecid 0.5-1 g twice daily and sulphinpyrazone 100 mg thrice daily help to eliminate uric acid in urine and lead to reduction of attacks and disappearance of tophi. They are indicated in conditions where production of uric acid is normal but elimination is impaired. They are contraindicated in conditions with overproduction of uric acid, renal failure, and urate calculi.

Asymptomatic hyperuricemia: This warrants treatment if there is:

- i. previous history of gout,
- ii. presence of tophi,
- iii. family history of gout,
- iv. presence of uric acid stones,
- v. presence of renal damage, and
- vi. serum uric acid greater than 9 mg/dL.

Other Forms of Crystal Induced Arthropathy

Calcium pyrophosphate dihydrate crystals may be deposited in joint tissues and this leads to acute gout like attacks. This is known as **pseudogout**. Basic calcium phosphates (hydroxy apatite and octacalcium phosphate) may be deposited in joint tissues mainly affecting shoulders and knees. Calcium oxalate crystals may be deposited in cartilage, synovium, bone and other tissues in renal failure patients treated with dialysis regimen and those with primary oxalosis.

Calcium Pyrophosphate Crystal Deposition Disease (CPPD)

Syn: Pseudogout

CPP crystals are seen in synovial fluid and these are derived from articular cartilage. Processes that lower solubility of the CPP crystals lead to their precipitation. The condition may be familial, sporadic or caused by metabolic disorders such as hyperparathyroidism, hemochromatosis, hypothyroidism, hypomagnesemia, hypophosphatasia and others. CPP crystals deposit in hyaline cartilage and fibrocartilage, the latter is affected more. The menisci of the knees, articular discs of distal radioulnar joints, acetabulum, symphysis pubis and annulus fibrosus of lumbar and dorsal intervertebral discs are sites of predilection. Men above 50 years are more affected though both sexes are susceptible. The patients may fall into one of three categories.

1. Familial,
2. Those associated with metabolic disease, trauma or joint surgery, and
3. Sporadic.

Though many cases may be silent, some present with recurrent attacks of subacute inflammation and progressive degeneration of joints. Once the degenerative process starts, it proceeds relentlessly, despite treatment.

The presentation may resemble gout, rheumatoid arthritis, osteoarthritis or neuropathic joints.

Differential diagnosis includes all other types of mono- or polyarthritis, depending upon the presentation. X-ray of the joints reveals calcification in distinctive locations and this is diagnostic. Microscopy of the synovial fluid is confirmatory.

Management

During acute attacks NSAIDs may be tried. Colchicine given IV in a dose of 1 mg is very effective. Aspiration of synovial fluid and injection of microcrystalline cortisone (cortisone acetate) gives rapid relief.

Basic Calcium Phosphate (BCP)

Crystal Arthropathy

Syn: Milwaukee shoulder/knee syndrome

This condition affects elderly persons, mostly women. The shoulder or knee may be affected. Many cases may be asymptomatic despite the deposition of crystals. Symptoms include pain in the shoulders or knees after exertion and at night. Progressive destruction of joints occurs. Treatment is symptomatic.

Calcium Oxalate Arthropathy

This is a complication occurring in renal failure when the serum creatinine levels exceed 8 mg/dL, especially so in patients undergoing dialysis regimen. Crystals of calcium oxalate may be deposited in joints, skin, blood vessels and other tissues. Joint manifestations include subacute, chronic or acute painful episodes. Several other substances may get deposited in joints and lead to crystal-induced arthropathy. These include xanthine, cholesterol, cystine, aluminium phosphate, Charcot-Leyden crystals and possibly others

Osteoarthritis

K.V. Krishna Das

Chapter Summary

General Considerations 732
Clinical Features 733
Management 735

General Considerations

Syn: Osteoarthritis, Degenerative joint disease

Osteoarthritis (OA) is predominantly a disease of the elderly but no age is exempt. It is caused mainly by wear and tear of the joints. It may be primary or secondary. Presence or absence of Heberden's nodes on the distal interphalangeal joints helps to distinguish two forms of primary osteoarthritis—the nodal and non-nodal types.

The former indicates the presence of generalized disease. Osteoarthritis forms about 25-35% of the joint lesions seen in clinical practice.

Etiology

The most regular association of osteoarthritis is with aging. Beyond the age of 50 years osteoarthritis is demonstrable in one or more joints invariably, but it may be asymptomatic. Several factors predispose to the disease and accelerate its progression. These include pre-existing joint disease, obesity, hypermobility, orthopedic deformities, endocrine disorders like diabetes mellitus, acromegaly and hyperparathyroidism, and sensory neuropathies which impair joint sensations. Overuse of any joint and adoption of unusual postures for long

Fig. 113.1: X-ray spine PA view—osteoarthritis vertebrae

Fig. 113.2: X-ray spine lateral view—osteoarthritis vertebrae

periods predispose to the condition e.g. OA of the knees of obese subjects and long distance walkers and OA of the neck in computer professionals.

Pathogenesis and Pathology (Fig. 113.3)

The basic pathology can be defined as a loss of focal areas of hyaline cartilage with increased activity in marginal and subchondral bones in synovial joints. Primary lesion starts in the articular cartilage. Due to mechanical stress the collagen fiber network of the articular cartilage is disrupted. This leads to alteration in the composition of the ground substance with resultant loss of resilience. The chondrocyte function and number change. Bone turnover is less in OA, but cartilage turnover is more. Crystals may be present in synovial fluid, especially in the knee. These include hydroxyapatite, octacalcium phosphate and

Fig. 113.3: Pathogenesis of osteoarthritis knee—diagram

5. Bony sclerosis and cysts
6. Femur
7. Fibula
8. Tibia

tricalcium phosphate (BCP) and calcium pyrophosphate dihydrate (CPPD). Presence of crystals in synovial fluid is strongly associated with cartilage degeneration.

Wear and tear leads to further disruption of collagen fibers. The lubricating mechanism of the joint is impaired. The normal surface matrix is lost, resulting in exposure and fibrillation of the cartilage fibers and later cleft formation. Synovial fluid gains access to the deeper layers of the cartilage. This leads to further destruction of load-bearing cartilage. The cartilage undergoes calcification. The exposed weight-bearing bones undergo eburnation. Osteophytes grow at the margins of articular bones. Still later subchondral bone may fracture to form cysts. Crystals are liberated into the synovial cavity. These add to the inflammatory process. Though synovial inflammation and effusion occur, these processes are generally mild compared to the primary inflammatory arthropathies.

Clinical Features

Many cases are asymptomatic though abnormalities are detectable radiologically. Knees, cervical spine, lumbar spine, hips, shoulder, and distal interphalangeal joints are affected most frequently. Figures 113.1, 113.2, 113.4A and

Fig. 113.4A: X-ray knees—osteoarthritis
Note: osteophytes—arrow

Fig. 113.4B: Osteoarthritis knees lateral view
Note: reduction of joint space and osteophytes

Fig. 113.5: Osteoarthritis hand—Heberden's nodes

Fig. 113.6: Osteoarthritis knees

Fig. 113.7: Osteoarthritis cervical spine. Note: the osteophytes in front and back of the vertebral bodies, narrowing of disks spaces and loss of cervical lordosis

sideways causes pain. Vague pain and stiffness in the knee especially after getting up from the sitting posture are the early symptoms. Cartilage is aneural and therefore it does not contribute to pain. The tissues from which pain arises are (1). osteophyte growths (2). localized areas of increased intra-osseous pressure (3). synovitis and (4). periarticular structures. Subchondral bone and synovium may be responsible for nociceptive stimuli. Sensitization of peripheral neuronal elements aggravates the pain response. The processes of attempted joint repair lead to osteophyte growth as well as subchondral bone changes

B, 113.5 and 113.7 weight bearing joints such as the knees develop deformities (Fig. 113.6).

Osteophyte formation at the distal interphalangeal joints leads to the formation of **Heberden's nodes** which may become painful. In the knees movement of the patella

which are nociceptive. Production of secondary particles and chemical mediators from the cartilage give rise to secondary synovitis. In addition altered mechanics of the joints give rise to periarticular phenomena such as strain on muscles and ligaments, and inflammation of bursae which are all painful. These lesions which cause pain lower the pain threshold centrally either at the spinal cord level or cortical level, or both.

The patients experience disability while walking down the stairs or slopes. The quadriceps undergoes atrophy. Transient effusions may occur even in asymptomatic cases. Osteophytes may be palpated around the joints. Crepitus may be elicited on movement. Deformities develop. Later osteoarthritis of the cervical spine leads to a group of clinical manifestations. These are described along with cervical spondylosis (section 17 chapter 199). Affection of the lumbar spine leads to low backache and sciatica.

Radiology

The bones show subchondral sclerosis, narrowing of joint spaces, osteophyte formation, joint destruction, cyst formation in the cortical bone, and loose bodies (joint mice) within the joints.

Laboratory Investigations

These are not diagnostic. They help to exclude other forms of inflammatory arthropathies. The acute phase reactants are not elevated. The leucocyte pattern is not altered. Synovial fluid shows normal viscosity, normal mucus content and cell count below 2000/cmm. Fragments of cartilage or bone and crystals of hydroxyapatite and calcium pyrophosphate dihydrate may be seen.

Arthroscopy

Using appropriate arthroscopes the interior of many of the peripheral joints can be directly inspected and this helps to confirm the diagnosis. Arthroscopic surgery is also practiced widely. Arthroscopy is available in many centers in India.

Course and Prognosis

Osteoarthritis is a slowly progressive disease which leads to considerable morbidity with passage of time, if allowed to proceed unchecked. The rate of progress and morbidity

can be considerably retarded by lifestyle changes such as weight reduction, use of appropriate footwear on walking and regular exercises for 1) strengthening the weight bearing muscles in and around the joints and 2) for preserving the range of movements. Any postural or orthopedic deformity should be corrected to prevent progress of the arthritis.

Management

The principles of management include prevention of overuse of the affected joint, limitation of activity to reduce pain, and physiotherapy to strengthen the muscles. Application of heat and graded movements help to reduce pain.

Medical treatment is symptomatic. Nonsteroidal anti-inflammatory drugs relieve pain and inflammation. Reduction of weight and management of metabolic and endocrine disorders may serve to arrest the progress of the joint lesions.

Intra-articular cortisone acetate or triamcinolone may be given as temporary measures to relieve acute pain and disability. Intra-articular corticosteroids may accelerate degenerative changes in the joint if given repeatedly.

Drugs have been introduced with the claim that they protect cartilage from degeneration. These include glycosaminoglycan polysulfate ester (arteperon), glycosaminoglycan peptide complex—rumalon pentosan polysulfate and hyaluron. Their role in prevention and treatment of degenerative joint disease is to be evaluated, even though they give relief of pain.

Joint replacement should be considered for osteoarthritis of the hip and knee if medical measures fail to relieve pain and disability and to restore mobility. The mechanical impairment caused by OA lesions in the knees can be properly assessed by simple tools such as pedometers and the 'GAIT rite' gait analysis system. The results of knee and hip replacement are excellent in most of the cases. Therefore replacement surgery should be advised without undue delay. In good centers the success rate is high. The average life for a prosthetic knee is more than 10 years and that for a hip is 10-15 years. Second operations can be undertaken. The cost for surgery varies between Rs. 40-50 thousands.

HYPERTROPHIC OSTEOARTHROPATHY

Syn: Hypertrophic pulmonary osteoarthropathy, Marie-Bamberger's syndrome

This is an acquired disorder characterized by clubbing of the fingers and toes, painful thickening of the ends of long bones such as the tibia and radius, and varying degrees of arthritis. In most cases it is secondary to other underlying disorders, rarely it may be idiopathic and at times it runs in families. The exact mechanism of development of the lesions is not clear.

Causes

Pulmonary lesions: Chronic suppuration such as bronchiectasis, lung abscess and empyema, carcinoma lung, pleural mesothelioma, alveolocapillary block syndromes, fungal infections, and chronic fibroid tuberculosis.

Cardiovascular lesions: Cyanotic congenital heart disease, infective endocarditis, aneurysm of the aorta or its branches.

Other conditions: Chronic malabsorption states, ulcerative colitis, Crohn's disease, cirrhosis liver, hepatic abscess, and thyrotoxicosis.

Clinical Features

Onset is very insidious in the vast majority of cases, but it is rapid in malignancy of the lung or pleura and infective

endocarditis. It is usually bilateral but unilateral clubbing may develop in aneurysm of the subclavian artery.

The manifestations include clubbing of the fingers and toes, symmetrical painful enlargement of distal ends of bones at the wrist and ankle and intermittent swelling and painful limitation of joint movements. In a few cases true arthritis, fibrous ankylosis, and deformity may result (Figs 114.1A and B).

When hypertrophic osteoarthropathy is associated with marked thickening of the skin of the limbs and face, this is called *pachydermoperiostosis*.

Management

In all secondary cases the primary cause should be detected and corrected. This leads to resolution of the bone changes. Nonsteroidal anti-inflammatory drugs relieve pain.

PAGET'S DISEASE OF BONE

Syn: Osteitis deformans

This is a rare disease of unknown etiology, characterized by enlargement, softening, and deformity of several bones, seen after the age of 40 years, more commonly in men. Though this disease is common in the west, it is seen only rarely in Indians. The involvement is localized in the majority of cases but may be widespread, involving several bones.

Pathology

There is increased and disorderly formation and destruction of bone. This results in a high rate of bone turnover. There is increase in the number and activity of osteoclasts. The osteoblasts try to compensate by adding more bone, but osteoclastic activity preponderates. The bone is highly vascular and functional arteriovenous shunts develop, resulting in a high cardiac output state. The marrow is replaced by highly vascular fibrous tissue. Pelvis, femur, skull, tibia, and vertebrae are affected in the order of frequency.

Figs 114.1A and B: (A) Hypertrophic pulmonary osteoarthropathy male 52 years. Note: Clubbing of fingers. (B) X-ray chest of the same patient showing cancer left lung arrow

CLINICAL FEATURES

Many cases are asymptomatic and detected on routine radiological examination. Symptoms include pain on weight-bearing, progressive enlargement of the skull, deformities of the affected bones, pressure on the nerves which pass through bony canals (cranial nerves, spinal nerves and spinal cord) and rarely the development of high output cardiac failure state. Though the bones are thickened, they are weaker than normal. The femur and tibia undergo bowing and other deformities due to weight-bearing. The overlying skin is warm due to increased vascularity. Deafness, optic atrophy, and paraplegia are rare neurological complications. **Serum alkaline phosphatase is grossly elevated. Bone specific alkaline phosphatase is the iso-enzyme that is diagnostic.** Serum calcium and phosphorus are normal. Urinary hydroxyproline is increased during the active phase of the disease.

Complications

These include fractures, progressive deformity, cranial nerve palsies (especially deafness), spinal cord compression, degenerative joint disease, high output cardiac failure if the disease is extensive and in long-standing cases, osteogenic sarcoma (Figs 114.2 and 114.3).

Diagnosis

The diagnosis is based on clinical features and is confirmed by radiography. The bone appears larger, chalky white and nonhomogenous in the skiagram. Localised enlargement and hyperdensity of bones is suggestive. This feature helps to differentiate from multiple osteosclerotic secondaries and other osteosclerotic conditions such as myelosclerosis and endemic fluorosis.

Fig. 114.2: X-ray Paget's disease of bone Skull. Note: Non-homogenous moth eaten appearance arrow head

Fig. 114.3: X-ray Paget's disease of bone Note: Dense enlarged deformed lower end of femur normal tibia

Treatment

Asymptomatic localised lesions have to be left alone. Symptomatic relief of pain is achieved by aspirin, indomethacin or corticosteroids. Human calcitonin in a daily dose of 0.5 mg subcutaneously for six months (or salmon calcitonin 100 MRC units/day) promptly relieves bone pains and helps to reduce the turnover of bone with improvement in the condition, the serum level of alkaline phosphatase also comes down. Mithramycin (Now called plicamycin) in a dose of 25-50 µg/ kg given intravenously for 10-14 days is effective. This drug inhibits bone resorption. It produces myelosuppression and a hemorrhagic tendency. Bisphosphonates (disodium etidronate) in a dose of 5-10 mg/kg/day also reduce bone turnover and bring about clinical relief in some cases. Bisphosphonates correct the chaotic bone formation by inhibiting the osteoclasts and inducing the formation of lamellar bone. Alendronate, 10 mg may be given orally daily on a long term basis. Pamidronate may be given by slow IV infusion. Newer bisphosphonates include zoledronic acid 5 mg given IV as infusion over 15 minutes or at longer intervals. The effect may last even as long as 6 months.

Schedule of pamidronate dose

- < 2 years of age : 0.5 mg/kg bw/day for 3 days every 2 months
- 2-3 years : 0.75 mg/kg bw/day for 3 days every 3 months
- > 3 years : 1mg/kg bw/day (maximum 60 mg) for 3 days every 4 months

The rate of infusion is 0.1 mg/minute. Total time for infusion is 3-4 hours.

Treatment improves bone strength and reduces fracture risk. In severe cases not amenable to medications bone marrow transplantation is curative. However, they are less effective than calcitonin. Calcitonin and etidronate can be combined. Other bisphosphonates that are available include alendronate, pamidronate, clodronate, tiludronate and others. The bone formed during the therapy with these drugs is usually normal.

Immobilization should be avoided since it leads to hypercalcemia and hypercalciuria. The onset of osteogenic sarcoma should be looked for in long-standing cases.

Juvenile Paget's Disease of Bone

Syn: Hyperostosis corticalis deformans

This is a rare autosomal recessive disorder causing bony deformities. Nerve deafness may occur due to compression of the 8th nerve in the petrous temporal bone. It usually starts in infancy or early childhood. It is characterized by painful debilitating fractures and deformities. Accelerated bone remodeling occurs throughout the skeleton. Juvenile Paget's disease is different from the adult form of the disease.

Treatment

Recombinant osteoprotegerin is effective in treating Juvenile Paget's disease.

Achondroplasia

This is the most common inherited disorder of bone and cartilage. It is transmitted as autosomal dominant. Some cases arise as mutations. It presents as disproportionate dwarfism characterized by normal trunk and short limbs (*circus dwarfs*). Face appears small, the skull vault is normal but the base is shortened. Other features are lordosis, waddling gait, large and flat feet, and diverging fingers of equal length (trident hands). In general, the muscles are well developed and some of the joints appear stiff, but are not painful. Complications include premature osteoarthritis involving the weight-bearing joints, spinal stenosis and hydrocephalus. Apart from the cosmetic disabilities they lead normal lives, enjoy family life and rear children. The condition does not warrant any treatment unless complications develop.

Osteogenesis Imperfecta

Syn: Fragilitas ossium, Brittle bone disease

This is a generalised connective tissue abnormality inherited as an autosomal dominant, manifesting as a peculiar brittleness of the bones, making them vulnerable to recurrent pathological fractures. This disease is occasionally seen in India. There is either reduction in the production of type I collagen or formation of abnormal collagen due to mutations in the type I collagen genes. There is defective formation of osteoid with associated osteoporosis but the process of calcification is essentially normal. Two groups have been recognized.

In some cases the disease manifests *in utero* with the birth of a severely affected baby with multiple fractures. The baby may die *in utero* or soon after birth. The other group manifests later in life—*osteogenesis imperfecta*

Fig. 114.4: Osteogenesis imperfecta: bowing of leg bones

tarda. Severe skeletal deformities result from the softening and bending of bones under stress or following repeated fractures with excessive callus formation. Bowing of long bones, kyphoscoliosis, pectus excavatum, and bulging of the calvarium are some of the common deformities (Fig. 114.4). Fractures may remain without union and give rise to pseudojoints. The sclerae show a characteristic blue colour due to thinning. Bruising of the skin and laxity of ligaments and joints are common. Wound healing and scar formation are imperfect.

The clinical severity varies widely. Severity can be graded as follows.

- Type I Mild form—occasional fracture before puberty. The stature is normal.
- Type II Most severe form—fractures *in-utero*, pulmonary insufficiency and perinatal death.
- Type III High frequency of fractures in postnatal life leading to severe deformities and short stature.
- Type IV Less severe form—deformities and fractures occur.

Types I and IV are autosomal dominant, the others are autosomal recessive. Bisphosphonates, especially pamidronate given intravenously in short courses with intervals in between, may produce clinical improvement and also reduce the frequency of fractures.

Bone and Joint Tuberculosis

This is common in India. Bone tuberculosis is generally secondary to established tuberculosis in other parts such as lungs, lymph nodes or kidneys. The organisms reach the synovium or subchondral bone by hematogenous or lymphatic spread. In the vast majority of cases a single large joint like the hip or knee is affected. Involvement of the vertebrae is common. In addition to the general symptoms of tuberculosis, severe local pain and restriction of movement of the affected region occur. If left untreated, the joint may be destroyed. Tuberculosis of the vertebrae leads to cold abscess formation and compression of the spinal cord. This used to be frequent cause of paraplegia in India.

Diagnosis

Strong clinical suspicion is necessary for making early diagnosis. X-rays show periarticular osteoporosis and soft tissue swelling in the early stages. Later, there is narrowing and irregularity of joint space and erosion of the cartilage and subchondral bone. Cold abscess may be seen (Figs 114.5 and 114.6).

The Mantoux test is often strongly positive. X-ray of the affected joint and synovial biopsy help in confirming the diagnosis.

Treatment

Standard systemic anti-tuberculous therapy is indicated for durations ranging from 9-12 months. Local measures

Fig. 114.5: X-ray-PA view—tuberculosis spine
(See cold abscess: arrow)

Fig. 114.6: X-ray lateral view—tuberculosis spine
Note: Compression of vertebra: arrow

include immobilization of the spine to reduce pain and spinal compression. Surgery may be indicated to relieve spinal cord compression.

Bone and Joint Involvement in Hematological Disorders

Several hematological disorders may present with bone and joint symptoms. Unless these are borne in mind, the primary condition may be missed.

Leukemias: In acute lymphatic leukemia, arthralgia, arthritis, and bone pains are common. These may be mistaken for rheumatic fever or rheumatoid arthritis.

Secondary gout is common in all forms of leukemias either in the florid stage or this may be precipitated by treatment.

Allergic purpura: Joint manifestations are characteristically seen in Henoch-Schönlein purpura. Large or small joints may be affected.

Sickle cell anemia: Involvement of finger joints and other periarticular tissues and severe bone pains are common during crises.

Hemophilia and other coagulation defects: Bleeding into weight-bearing joints is common. The knees, ankles and elbows are frequently affected. In the early stages a primary joint disease may be suspected. Later, due to recurrent bleeding the joint is damaged and ankylosis results.

Multiple myeloma: This disorder commonly presents with bone pain, and fractures, especially in the axial skeleton. It may also lead to secondary gout.

Malignant lymphoma: This disorder may involve bones directly or indirectly by giving rise to secondary gout.

Sports Injuries

In modern times several children take to sporting activities which expose them to repeated injuries. These include growth plate fractures, epiphyseal fractures, osteochondrosis dessicans and traction apophysitis. Sports injuries are becoming increasingly common. Most of them are soft tissue lesions and are often managed inadequately. Many of them are preventable. There are two major mechanisms of injury—trauma and overuse. Overuse may be due to intrinsic factors like malalignment of joints or limbs. Extrinsic factors are related to equipment and environment.

Excessively strenuous training, especially for competitive sports leads to injuries associated with overuse and growth problems. Negligence on the part of the children, such as failure to wear protective equipment like helmet, knee guards face shields predispose to injury. They may also not care to follow proper techniques which will minimize injuries to themselves and others. Evidence based preventive measures are available which have to be followed by those in training.

Principles of General Management

Prevention is by addressing the contributory factors like malalignment of joints which should be corrected and the equipment used should be reviewed. Management of acute

phase involves treatment of inflammation, the NICER approach.

NSAID is used to reduce pain and inflammation.

ICE is an analgesic and it limits excessive inflammation.

Compression and

Elevation of the injured area reduces swelling.

Rest for 24 hours and supportive protective strapping may be helpful to relieve muscle spasm and pain.

This may be followed by exercise which is the corner stone of the rehabilitation of soft tissue injury. This prevents muscle weakness and wasting. It includes strength training and flexibility training. Local steroids have no role in acute soft tissue injury even though they may be useful and needed in chronic tendon insertion injury unresponsive to conservative management. Arthroscopic surgery procedures may have to be performed with minimal invasiveness for faster rehabilitation.

Specific structural injuries to tendon, ligament, muscle and bone may require special management. Commonly affected tendons are the Achilles tendon and supraspinatus. The most common ligament injury in sport is the sprained lateral ligament of the ankle. Muscle injury results from trauma or overstretching. Rupture is uncommon and hematoma may be complicated by myositis ossificans. Stress fracture of bone may be missed unless a high degree of suspicion is maintained.

In many countries athletes in training for major sports events are subjected to appropriate investigations to rule out the known causative factors.

SUDDEN DEATH IN YOUNG ATHLETES

The frequency is 1/100000 annually. The male to female ratio is 10:1. Probably this is due to the higher prevalence of cardiological abnormalities in males.

Causes

Cardiac lesions account for the majority of sports related sudden death

Atherosclerotic heart disease in athletes aged > 35 and congenital and inherited disorders – in those who are younger

Hypertrophic cardiomyopathy – This accounts for over 30% of deaths

Congenital coronary anomalies

Other causes include arrhythmogenic right ventricular cardiomyopathy, myocaditis, mitral valve prolapse, conduction defects, W PW syndrome, aortic rupture in Marfan's syndrome, bronchial asthma, subarachnoid hemorrhage and non penetrating strike to the chest wall.

Sudden death in sports may be the only evidence of underlying heart disease. There may be no previous history or any familial predisposition.

Diagnosis can be made by making a careful history and physical examination. Plain radiography, bone scanning, CT or MRI all have a role in selected cases.

Cardiology: General Considerations

C.G. Bahuleyan

Chapter Summary

Cardiac Physiology 742

Symptomatology in Cardiovascular Diseases 743

Physical Examination 744

Special Investigations 747

Cardiac Physiology

The normal adult human heart weighs 250-350 g. The left ventricle is two to three times the thickness of the right ventricle. The former constitutes 60% of the total weight. Histologically the cardiac muscle forms a syncytium though the myocardial cells are electrically isolated by high resistance membranes. Cardiac muscle possesses intrinsic properties such as excitability, contractility, rhythmicity, conductivity, and distensibility. As the cardiac muscle is stretched within physiological limits the force of contraction increases (*Starling's law*). Though the sinoatrial node (S-A node), atrioventricular node (A-V node), the conducting tissues and cardiac muscle are all capable of impulse production, in health, the heart beat is initiated by impulses from the S-A node. Vagal impulses depress the rate of the S-A node and increase the refractory period of the cardiac muscle. Sympathetic fibers arising from the cervical and upper thoracic ganglia supply the heart and they accelerate the S-A node and decrease the refractory period of the myocardium. Atrial contraction is followed by ventricular contraction. Atrial contraction helps in pumping blood remaining in the atria towards the end of diastole and this helps to augment ventricular filling, thus preparing the ventricles for more effective contraction. Atrial contraction gives rise to the a-wave in the jugular veins. With the onset of ventricular systole, A-V valves close and the A-V valve apparatus bulges towards the atria giving rise to the c-wave in the jugular veins. As the ventricular pressure increases rapidly, the semilunar valves open and blood is ejected into the aorta and the pulmonary artery. The ventricles eject 60-70% of their contents during each systole. Initial phase is one of rapid ejection. This is

followed by the period of slowed ejection. During each contraction the ventricles eject 70 mL of blood which is the stroke volume. The atrial filling continues during ventricular systole and the rise of pressure in the right atria gives rise to the v-wave of the jugular venous tracing. At the end of ejection the semilunar valves close and the isometric relaxation follows. Though, in a broad sense, the ventricular contraction occurs synchronously on the right and left sides of the heart, closer examination will reveal that the right ventricular ejection starts earlier and is completed slightly later than left ventricular ejection. Atrioventricular valves (A-V valves) open when the ventricular pressure falls below that of the atria during diastole. Atrial blood flows into the ventricle rapidly in the early part of diastole and this may give rise to the third heart sound (S_3).

Heart sounds: These are produced by deceleration of blood impinging on elastic structures in the heart, giving rise to vibration. More rapid deceleration gives rise to louder sounds and *vice versa*. The pitch of the sound (frequency) is determined by the relative contribution of the mass of blood and the elastic properties of the structures which are responsible for producing the sounds.

First heart sound (S_1) occurs at the commencement of systole and coincides with the closure of the A-V valves. **Second heart sound (S_2)** marks the onset of diastole and indicates closure of the semilunar valves. **The third heart sound (S_3)** occurs in the earlier part of diastole and it coincides with rapid ventricular filling. **The fourth heart sound (S_4)** is produced by atrial contraction and this is a late diastolic sound. When S_3 or S_4 becomes pathologically accentuated giving rise to a characteristic cadence resembling the canter of a horse, it is termed "*gallop rhythm*". The terms "*protodiastolic gallop*" and "*presystolic gallop*" were used to denote S_3 or S_4 respectively. When both these are audible, and the diastolic interval is shortened due to rapid heart rate, these may merge (summate) and such a phenomenon is called *summation gallop*.

Cardiac output: This is the volume of blood pumped by the left ventricle in one minute. Normal average is 5-6

liters in healthy adults. It is also expressed as the cardiac index, when related to the surface area of the individual. *Normal cardiac index* is 2.8-4.2 (mean 3.4) liters/min/m². Cardiac output is controlled by several factors such as heart rate, effective filling pressures of the ventricles, compliance of the chambers, contractile force of the ventricles and the blood pressure. Generally, the increase in cardiac output is achieved by increasing the heart rate and stroke volume. Exercise and emotion normally increase the cardiac output, whereas extreme tachycardia, extreme bradycardia, atrial fibrillation, myocardial dysfunction and anatomical or functional obstruction to the outflow of blood reduce it.

Heart receives its oxygen supply and nutrition from the coronary arterial blood flow which is 72-85 mL/100 g of cardiac muscle/min in the resting phase. The heart utilises 8-10 mL of oxygen/100 g every minute. The oxygen demand during systole is thrice that during diastole. Diastole is also an active energy-consuming process. Proper diastolic function is essential to accommodate the optimum quantity of blood before the onset of systole.

Right ventricular physiology: Right ventricle has the same output as the left. It has only 1/6 the muscle mass and performs only 1/4 the stroke work as the left ventricle. This is due to the fact that the pulmonary vascular resistance is only 1/10 that of systemic resistance. The two ventricles differ in shape but their function is made interdependent through the mechanism of action of the interventricular septum and surrounding pericardium. The systolic pressure wave caused by LV septal contraction augments the systolic force of the RV and promotes pulmonary perfusion.

Arterial blood pressure: The arterial blood pressure is influenced by several factors such as the cardiac output, peripheral resistance in the arterial system, blood volume in the arterial system, viscosity of blood, and elasticity of the arteries. The control of blood pressure is achieved mainly by alteration in the cardiac output and peripheral resistance. Normally, arterial blood pressure fluctuates widely depending on exercise and emotional stress, time of the day and posture. The systolic blood pressure falls by 15-30 mm Hg during sleep. In the erect posture diastolic blood pressure is greater than during recumbency.

Average systolic blood pressure readings are:

1. Neonates—40 mm Hg,
2. Infants aged 2 weeks—70 mm Hg,
3. Children upto 12 years—105 mm Hg, and
4. Above 17 years—120 mm Hg.

In adults, for a considerable period of life (up to the sixth or seventh decade) the blood pressure remains more or less steady, but with old age, due to reduction in elasticity of the arterial wall, the systolic pressure may tend to rise.

Symptomatology in Cardiovascular Diseases

Dyspnea is the most common symptom which brings the patient to the doctor in most instances. This is the uncomfortable awareness of breathing. Several factors may contribute to dyspnea. Dyspnea has been quantitated for assessing the severity and for helping in follow-up.

Grade I (slight)—symptoms are provoked by more than ordinary activity like running, climbing uphill.

Grade II (moderate)—symptoms occur in ordinary activity like walking briskly, going two flights of stairs.

Grade III (considerable)—symptoms develop with less than ordinary activity like walking on level ground, light household work.

Grade IV (gross)—total incapacity and dyspnea at rest and recumbency.

Orthopnea (dyspnea on recumbency) is common in left-sided heart failure. **Paroxysmal nocturnal dyspnea** is the occurrence of sudden onset of dyspnea which abruptly wakes the patient up in the early hours of sleep. The patient jumps up for breath with cough and frothy sputum. Assuming the erect attitude relieves the distress in many cases. Paroxysmal nocturnal dyspnea (also known as *cardiac asthma*) is an early symptom of left-sided heart failure. Pulmonary congestion and edema account for this phenomenon. Cheyne-Stokes respiration is the periodic alteration in the rate and depth of breathing. The respiratory rate waxes and wanes alternately with apneic pause in between. Cheyne-Stokes respiration occurs in several conditions, left-sided heart failure being a common cause.

In the presence of other evidences of heart disease, dyspnea is a strong pointer of cardiac failure.

Edema: Subcutaneous edema is demonstrated by the phenomenon of pitting on pressure. Considerable amount of fluid (more than 2 liters) should accumulate in the body before manifesting as generalized edema. Abnormal increase in weight (0.5-1 kg/day) associated with oliguria occurs early. When edema is manifest, the skin is stretched and shiny and pitting can be demonstrated.

The factors which help in retaining sodium and fluid are:

1. Reduction in the cardiac output
2. Increased venous pressure, transudation of fluid into the interstitium, and
3. Overactivity of aldosterone and antidiuretic hormone.

These hormones acting together reduce the renal output of sodium and water. The edema is '*dependent*', i.e. it is more prominent in the most dependent parts of the body. In those who are ambulant the edema is maximal

on the feet, and that too in the evening. In bed ridden patients, the edema is localized to the back and sacral region.

Precordial pain: Among the several causes of precordial pain, cardiac disease is the most important. Pain sensitive structures in the heart are the pericardium which gives rise to pain due to inflammation (pericarditis) or stretching as in pericardial effusion, and the myocardium in which severe pain may occur as a result of ischemia. Pain arising from the pericardium and myocardium are distinguishable in many cases, but sometimes they are identical.

Ischemic pain is vague, felt over the precordium or retrosternal region and may be described as crushing, bursting, lancinating, burning or otherwise. Anginal pain comes on with exertion or emotional stress and is relieved with rest. In myocardial infarction the pain is of longer duration and is experienced usually at rest. The pain shows characteristic radiation. The classical sites of radiation are: (1) along the inner aspect of the left arm to the little finger, (2) left or both sides of neck and jaw, (3) left scapular region, (4) right shoulder and arm, (5) epigastrium and at times, to any other part of the body. Patients with cardiac neurosis and hypochondriasis may complain of chest pain. This pain is localized to the cardiac apex and may be described as catching or pricking. Such pain may not have an organic basis.

Palpitation: This is awareness of the heart beat. Though normal individuals can experience the heart beat during exercise or emotional stress, under pathological states this symptom may be troublesome. Palpitation may be due to tachycardia, extreme bradycardia, irregularity of rhythm or increase in stroke volume. In anxious individuals this is a common symptom.

Syncope (Faint): Loss of consciousness occurs when the cardiac output is not sufficient to maintain cerebral blood flow. The patient loses consciousness rapidly over seconds, unlike epilepsy in which the loss of consciousness is more abrupt. As the patient sinks into the flat position, consciousness is regained. If cerebral ischemia continues the patient may develop convulsions (*Stokes-Adams attacks*). Syncope is common in Fallot's tetralogy, aortic, pulmonary and mitral stenosis, intermittent heart block and at the onset of acute myocardial infarction.

Other causes of syncope include pooling of blood in the lower limbs as seen in persons standing still for a long time (e.g. parade or drill), sudden rise in intrathoracic pressure resulting in diminution of venous return to the heart (e.g. cough syncope), or hyperreactivity of the carotid sinus in which sudden neck movements or pressure over the carotid sinus leads to severe bradycardia and syncope.

Apart from these specific symptoms, general symptoms such as extreme fatigue may be the result of

low cardiac output states. Anemia and fever occur in infective endocarditis. Clubbing of fingers is a common symptom of cyanotic congenital heart disease and infective endocarditis.

Physical Examination

Before proceeding to the examination of the cardiovascular system, a full general examination should be performed. Findings that may point to disease of the cardiovascular system are cyanosis, digital clubbing and dependent edema. Other general findings like anemia, skin rashes, pyrexia, and obesity may have relevance in the final analysis.

Cyanosis: Congenital heart disease gives rise to central cyanosis due to mixing of arterial and venous blood within the heart or outside it. In central cyanosis due to cardiac cause the extremities and tongue are all cyanosed, the periphery is warm and the cyanosis is not abolished by breathing 100% oxygen (Fig. 115.1).

Low cardiac output states may give rise to peripheral cyanosis in which there is stagnation of blood in the capillaries and overextraction of oxygen by tissues resulting in cyanosis. The limbs are cold to feel and only the periphery is affected, the central parts like tongue are not cyanosed.

Edema: Careful search for edema and its distribution is essential in all cases.

Temperature of the limbs: This depends on the state of arterial circulation. In low cardiac output states peripheral vasoconstriction gives rise to coldness of the palms and feet.

In high cardiac output states (e.g. thyrotoxicosis), the limbs are warm and the arterial pulsations may become prominent.

Fig. 115.1: Central cyanosis

Arterial pulse: The radial artery is generally taken up for examining the pulse. The rate, rhythm, volume and character of the pulse and nature of the arterial wall are noted. Pulse is of large volume in high cardiac output states such as thyrotoxicosis and anemia and in conditions where the stroke volume is high as in aortic incompetence. Small volume pulse (*pulsus parvus*) occurs in low cardiac output states such as mitral stenosis. When there is anatomical obstruction to the outward flow of blood as in aortic stenosis, the pulse is small in volume and slow rising (*slow rising pulse* or *pulsus parvus et tardus*). The pulse is jerky in hypertrophic subaortic stenosis. When the stroke volume is large and there is vasodilatation. The pulse is of high volume and low tension, such a pulse is called “*collapsing pulse*” or “*Corrigan’s pulse*”. This occurs classically in aortic incompetence and some cases of patent ductus arteriosus. The term “*bisferiens pulse*” is used, when the pulse wave shows two upstrokes. This is seen when there is a combination of aortic stenosis and incompetence or sometimes even in pure aortic incompetence. Pulsus bisferiens may be more clearly identified over the carotid artery.

In normal subjects, during inspiration the pulse volume falls slightly, but this is often not noticeable. Marked fall of pulse volume and pulse pressure during inspiration is called “*pulsus paradoxus*”. This is seen in pericardial effusion and constrictive pericarditis. “*Pulsus alternans*” is the condition in which alternate beats are weak. This difference may be palpable in most cases. When in doubt, this abnormality can be brought out using the sphygmomanometer. The difference between the stronger and weaker beats may be up to 40 mm Hg. Presence of pulsus alternans signifies gross impairment of left ventricular function.

Examination of the arterial wall for thickening, nodularity, and calcification reveals several abnormalities. When the medium-sized arteries like the radials are nodular and thickened, it suggests medial sclerosis (*Mönckeberg’s sclerosis*), which is generally seen with advancing age.

All the major arteries should be palpated to assess whether they are patent or occluded. Generally the carotid, axillary, brachial, radial, femoral, popliteal, dorsalis pedis, and posterior tibial are examined. Simultaneous palpation of the radial and ipsilateral femoral artery helps to detect occlusion of the aorta. Normally the femoral pulse precedes the radial pulse by 0.005 sec. The femoral pulse is delayed in coarctation of the aorta and aortoarteritis. Auscultation over the arteries may reveal bruit. Bruit may be the result of narrowing of the lumen (e.g. carotid stenosis and renal artery stenosis) or may arise from increased blood flow through the artery (e.g. carotid artery opposite to the side of carotid occlusion, thyroid arteries in Graves’ disease).

Jugular venous pulse: It is ideal to examine the internal jugular vein with the patient resting comfortably at an angle of 45°. The jugular vein closely reflects the pressure changes within the right atrium. In health, at 45° incline the upper limit of the venous column lies just behind the right sternoclavicular joint, which is at the same horizontal level as the sternal angle. When right atrial pressure is increased as in right-sided heart failure, the venous column is seen above the right sternoclavicular joint and the vertical height of this column is measured to express the increase in venous pressure. The waves a, c and v and the troughs x and y are studied. The jugular vein is a low pressure system and, therefore, the waves are occluded easily by palpation.

‘a’—wave is caused by atrial contraction and is presystolic. It is more prominent when the right atrium is contracting against increased resistance. It disappears in atrial fibrillation.

‘c’—wave is recordable but not usually visible as a separate wave. It reflects the bulging motion of the closed tricuspid valve during isovolumic systole.

‘v’—wave is systolic and is due to passive filling of RV during systole when tricuspid valve is closed.

‘x’—wave is the trough caused by atrial relaxation.

‘y’—wave is caused by opening of the tricuspid valve and rapid inflow of blood into the right ventricle (Fig. 115.2).

In the ordinary case it is easy to distinguish carotid artery pulse from jugular venous pulse, but sometimes

Fig. 115.2: Jugular venous tracing and arterial pulse: (A) Jugular venous pulse (B) Carotid arterial pulse (1) Systole (2) Diastole

TABLE 115.1

Differences between the jugular venous pulse and carotid artery pulse

Jugular vein	Carotid artery
1. Better seen than felt	Seen and felt well
2. Wavy column with 2-3 waves	Jerky, only one wave
3. During inspiration the vein becomes empty	Not much change with the phase of respiration
4. Vein becomes more prominent when the patient lies flat	No change
5. Hepatojugular reflux present	No change

when the former is very prominent or when both coexist, difficulty may arise (Table 115.1).

The hepatojugular reflux: While observing the jugular vein, the abdominal wall is pressed. Rise in intra-abdominal pressure drives blood from the liver to the inferior vena cava, thus increasing the venous return to the heart. This results in rise of the jugular venous pressure. Release of abdominal pressure promptly brings back jugular venous pressure also to the normal level. In early right-sided heart failure, abdominal pressure raises the jugular venous pressure, but release of the pressure is not followed by prompt fall of the jugular venous column.

Proper examination of the jugular venous pulse is a simple and very reliable bedside method to assess the hemodynamic events in the right atrium and it is absolutely essential that the clinical student spends time to learn this technique fully.

JVP is increased in right-sided heart failure, in which this is the earliest sign. Hypervolemic states (over-hydration) lead to engorgement of the jugular (e.g., acute nephritic syndrome). Study of the wave pattern helps in diagnosing arrhythmias such as atrial fibrillation and A-V dissociation. *Cannon waves* are jugular venous waves occurring in conditions such as complete heart block or extrasystoles when the atrium contracts against a closed tricuspid valve. Regular cannon waves may occur in junctional rhythm and in ventricular rhythms with 1:1 retrograde conduction. Irregular cannon waves are more common and occur in complete heart block and ectopic beats (ventricular or junctional) and ventricular tachycardia without retrograde atrial activation.

Examination of the Chest

Inspection: Cardiomegaly occurring in early life gives rise to precordial bulge. This is true of congenital heart disease and juvenile rheumatic heart disease. In the majority of these cases right ventricle is enlarged. Displacement of the apex beat and abnormal pulsations occurring in ventricular aneurysm or aortic aneurysm can be made out.

The epigastrium pulsates in right ventricular hypertrophy. Liver pulsates in tricuspid incompetence.

Palpation: This is the method to locate the apical impulse. Other valuable informations obtained by palpation are the presence of ventricular hypertrophy, expansile pulsation of aneurysms, abnormally loud heart sounds, and thrills produced by loud murmurs.

Normal apex beat is palpable in thin and moderately built individuals. It just lifts the palpating finger. Normally the apex beat is felt in the fifth left intercostal space 1 cm inside the midclavicular line. It may be impalpable if the chest wall is thick or if it is behind a rib. Pathological causes include emphysema and pericardial effusion. When the apex beat is not located in the normal position, the right side should be palpated, so as not to miss dextrocardia. *When there is volume overload of a ventricle, the impulse is more forcible (also called hyperdynamic), but not sustained. Forcible and sustained impulse (heave) is suggestive of pressure overload.* Left ventricular hypertrophy is manifested by heaving apex beat, whereas right ventricular hypertrophy manifests as left parasternal heave. Normal pulmonary artery pulsation may be visible in the second and third left intercostal spaces in thin individuals. If this is prominent, it suggests abnormal pulsation and pulmonary hypertension.

Thrills are caused by vibrations imparted to the palpating hand by turbulent blood flow.

Percussion: The precordial dullness is increased in cardiomegaly due to various causes and in pericardial effusion. The cardiac dullness is obliterated in emphysema, and left sided pneumothorax. Enlargement of the pulmonary artery, occurring in atrial septal defect or gross pulmonary hypertension can be detected by extension of the dullness outside the normal in the left second intercostal space. Normal pulmonary artery does not extend beyond 1 cm outside the left sternal edge. Since assessment by percussion can at best be only approximate, more accurate estimation by radiography or ultrasonography has to be resorted to in all cases when facilities permit (Fig. 115.3).

Auscultation: Rene Theophile Hyacinthe Laennec (1781-1826 French Physician) invented the stethoscope between 1816 and 1819 AD and introduced auscultation in cardiology. The original instrument was made of cedar wood or ebony. It was 30 cm long, 3.7 cm thick and with a central lumen of 0.6 cm in diameter. He named it stethoscope ('stethos' – chest, scopein- to observe (GK)). The modern stethoscope has undergone many changes.

The chest piece of many stethoscopes has the bell and the diaphragm. The former picks up low-pitched sounds better, whereas the latter is more useful to receive high-pitched sounds. Newer stethoscopes have only one chest piece. The sensitivity of the diaphragm to different pitches of the sound can be altered by the pressure exerted with

Fig. 115.3: Skiagram of normal chest

Note: Lungs are translucent and bronchial and vascular markings are traceable to the chest wall. The cardiothoracic ratio is less than 50%. The blood vessels at the hilum and major bronchi are visible.

the chest piece. The mitral, tricuspid, pulmonary and aortic areas are auscultated in sequence and then the third left intercostal space (second aortic area) is auscultated. Several additional areas of the chest or body have also to be auscultated, when there are indications. These include the interscapular area, neck, first and second left intercostal spaces, apices of lungs, abdomen, spine, and head. Normal heart sounds, additional sounds such as (third and fourth heart sounds), clicks and murmurs, and pericardial rub are specially looked for. In general, the events occurring at the different valves are heard best over the corresponding areas.

The second sound in the pulmonary area shows two components—the aortic and the pulmonary (A_2 and P_2). Normally, during inspiration the pulmonary component becomes delayed whereas the aortic component occurs slightly earlier and S_2 becomes split. In expiration, both the components merge and S_2 becomes single. Splitting of the second sound is called “fixed”, if it does not show a variation between inspiration and expiration. This happens in atrial septal defect and right ventricular failure. In atrial septal defect the phasic changes in venous return during respiration are associated with reciprocal changes in the volume of left to right shunt. Inability to vary its stroke volume by the failing right ventricle accounts for the fixed splitting of S_2 in right ventricular failure. If the splitting of the second sound becomes narrow during inspiration, it is called *reversed split (paradoxical split)*. This occurs in aortic stenosis and left ventricular failure.

Gallops are diastolic events and appear to be related to filling of the ventricles. The ventricular diastolic gallop also known as third heart sound occur during the rapid filling phase. This is an early sign of ventricular

dysfunction, although it can occur physiologically in normal children and young adults. The atrial gallop also known as fourth heart sound occurs during the presystolic filling phase due to atrial systole. It is abolished in atrial fibrillation.

Murmurs: These are produced by turbulence of blood flow at or near the valves or through abnormal communications. If a murmur occurs as a result of abnormally large amount of blood flowing through a normal valve or artery, this is termed flow *murmur* (previously known as functional murmurs). This disappears when the hemodynamic abnormality is corrected. On the other hand organic murmurs are produced by structural abnormality in the heart or blood vessels and these murmurs tend to persist. In addition, murmurs may occur without intrinsic structural or functional abnormalities in the heart valves and blood vessels. These are generally benign, without any hemodynamic abnormality. In addition to the location of the murmur several other characteristics help to identify its source. These are: (1) the timing, (2) duration, (3) character (high-pitched or low-pitched), (4) change with respiration and position of the patient (5) conduction, and (6) response to maneuvers like hand grip, Valsalva and squatting.

Extra-cardiac adventitious sounds are venous hum, bruit over arteries, pericardial rub and pleuropericardial rub.

Recording the blood pressure: The appropriate sized cuff for adults and children has to be used, otherwise the values will be altered. It is ideal to use mercury sphygmomanometers. If aneroid instruments are used, their accuracy should be verified periodically. Generally the blood pressure is recorded in one of the arms. If there is any abnormality in the blood pressure or if arterial occlusion in the arm is suspected, the blood pressure should be recorded in both arms and legs. Normally the systolic blood pressure recorded in both the arms does not vary more than 10-15 mm Hg. The systolic pressure in the lower limb is 20-30 mm higher than in the upper limb. Though the point of muffling of *Korotkoff's sounds* denotes the diastolic blood pressure, to achieve consistency in recording, the point of disappearance of these sounds can be accepted to represent the diastolic blood pressure for clinical purposes.

Special Investigations

Radiology: The size and shape of the heart can be assessed from chest radiographs. Posteroanterior views, lateral views and oblique views are used to assess abnormalities of the different chambers. Normally the cardiothoracic ratio is less than 50%. Enlargement of different chambers gives characteristic configuration in the X-ray. The contraction of the chambers can be seen

Fig. 115.4: Line drawing of chest X-ray
Note: Transverse diameter of the heart is 1 + 2
Cardiothoracic ratio (CTR) $\frac{1 + 2}{3}$

by fluoroscopy. Pulsation of the aorta and pulmonary artery can be observed. Pulmonary congestion, pulmonary oligemia and pulmonary edema can be diagnosed. Serially taken chest radiographs also help in assessing the progress of cardiac disease (Figs 115.3 to 115.5C). Chest radiographs taken in different views bring out the different chambers clearly.

Electrocardiography: The electrical changes that take place in the heart during different phases of the cardiac cycle are recorded in the electrocardiogram (ECG). The standard 12 lead ECG consists of three standard bipolar limb leads (L_1 , L_2 and L_3), three augmented unipolar limb leads (aVR, aVL and aVF) and six precordial unipolar leads (V_1 - V_6) (Fig. 115.6). When required, further additional leads such as right-sided chest leads, high anterior chest leads or left posterior leads are also taken. Normal ECG shows the P-wave which is caused by electrical activation of the atria, QRS which represents ventricular depolarization, and T-wave which is caused by ventricular repolarization. The amplitude of these waves, their configuration, their duration, and the time interval between various deflections (P-R, QRS and QT, P-P and R-R intervals) are all studied to derive diagnostic information (Fig. 115.7).

Clinical applications: Following are the clinical applications of electrocardiography:

1. determining the heart rate and rhythm;
2. to detect atrial or ventricular enlargement;
3. diagnosis of all arrhythmias and disorders of impulse production and conduction;
4. detection, localization, and semiquantitation of myocardial ischemia (reversible and irreversible);
5. diagnosis of myocardial diseases (myocarditis or cardiomyopathy);
6. diagnosis of pericardial diseases (pericarditis, effusion);

The ECG has been employed in several varied clinical situations so that recording the ECG is a routine basal investigation to look for evidence of heart disease.

The following modifications have been made over the conventional ECG.

1. **Stress test:** Treadmill test is the most commonly used type of stress test. This can be used to assess the likelihood and extent of coronary artery disease, prognosis of coronary artery disease, functional capacity and effects of therapy. Stress test is positive for inducible ischemia when ECG shows ≥ 0.1 mV horizontal or down sloping ST depression or ≥ 0.15 mV slow upsloping ST depression or a ST segment elevation of ≥ 0.1 mV in a noninfarct territory. This is a highly reliable test.
2. **Holter monitoring:** ECG is recorded continuously for long periods on audio tapes in ambulant subjects. This is very useful for evaluation of arrhythmias and silent ischemia.
3. **His bundle electrography:** Electrical activity of the bundle of His may be recorded by an electrode catheter placed near the tricuspid valve under fluoroscopy. This technique known as His Bundle electrography permits division of the P-R interval into two subintervals, namely, the A-H interval (an approximation of A-V nodal conduction time) and H-V interval (representing conduction time within the His Purkinje system). Thus, more precise localisation

of the site of atrioventricular block and distinction between supraventricular and ventricular beats become possible.

Signal Averaged ECG (or) High Resolution Electrocardiography

This technique is used to identify the different frequencies and voltage components that constitute the QRS complex. Late potentials (delayed low-voltage signals) detected by this technique serve as predictors for the development of ventricular arrhythmias especially in ischemic heart disease.

Echocardiography

In principle this method records the reflection of pulsed ultrasound from various parts of the heart studied in different directions. Ultrasound of 1-7 megahertz frequency is generally used. The earlier machines used time-motion mode display, but later versions permitted two-dimensional imaging. Color coding has also been introduced for specialised investigations. The echocardiogram can be visualized on a fluorescent screen, photographed or recorded on tapes to be examined on a video screen for future use. In the echocardiogram the anterior right ventricular wall, both sides of the interventricular septum, mitral valve, posterior left ventricular wall, pericardium, walls of the aorta, aortic valve, pulmonary artery and valve, pulmonary veins, posterior left atrial wall, both atria, and the tricuspid valve can be identified distinctly. Incorporation of Doppler echography in echocardiography helps to assess abnormal flow of blood as occurring in septal defects and valvular incompetence. Being a simple easily available and non-invasive procedure the use of echocardiography has become an integral part of cardiological studies. With its use, invasive investigations such as catheterization and angiocardiology can be avoided in many cases (Figs 115.8 to 115.9B).

One of the drawbacks of conventional transthoracic echocardiography has been the difficulty to get proper images of the posterior aspect of the heart and finer details such as valvular vegetations and intra-atrial thrombi. This has been overcome by the introduction of *trans-esophageal echocardiography* in which the probe is introduced into the esophagus and images are recorded. Better visualization of the intracardiac structures is possible. Coupling this method with *Doppler imaging and colour-coding* of the images helps to assess the dynamics of blood flow and its abnormalities. Another application is the intraoperative use of this method to get continuous recording of cardiac events during procedures such as mitral valve reconstructive surgery.

Stress echocardiography is a very useful technique in the evaluation of coronary artery disease and valvular heart disease. This is done by evaluating the cardiac chambers by echocardiography at rest and during and

Fig. 115.8: Schematic drawing showing a sagittal section of the heart through the long axis of the left ventricle. The path of the ultrasound beam emitted by the transducer (T) placed over the chest wall, as it is swept through an arc of 82° is illustrated. This diagram serves as a reference for the normal cardiac anatomy as visualized by ultrasound in the time motion mode display (M-mode) schematically illustrated in Figure 115.9B along with simultaneous ECG record.

immediately after applying some forms of stress. Commonly used modalities of stress are exercise, atrial pacing and pharmacologic methods (dobutamine, adenosine).

Intravascular ultrasound uses crystals mounted on arterial catheter. This probe can be passed through small arteries like the coronary arteries. This technique is employed in the assessment of arterial lesions such as atherosclerosis and thrombus and utilized in the treatment of coronary artery disease (CAD) by angioplasty and stenting.

Uses of Echocardiography

- Assessment of cardiac function
- Diagnosis of valvular heart disease
- Diagnosis of congenital heart disease
- Evaluation of coronary artery disease
- Diagnosis of pericardial disease, cardiomyopathy and tumours.
- Demonstration of the vegetations of infective endocarditis.

From its original introduction, the ultrasound scanners and the techniques have undergone steady improvement in machine design, probe specifications and probe positioning. Whereas the early studies are conducted with the

EKG—Electrocardiogram

1. At papillary muscle level,
2. At the level of chordae tendinae, 3 and 4-further up. The ventricular internal dimensions and ventricular and septal thickness are measured at this level. Slight superior angulation of the transducer brings into view the anterior and posterior leaflets of the mitral valve. The normal leaflet motion pattern has a characteristic appearance of M and W for the anterior and posterior leaflets respectively. The normal aortic valve (AV) echogram has a box like configuration in systole. The left atrium is immediately posterior to the aorta.

Fig. 115.9B: Normal echocardiogram

Note the pattern of motion of the anterior and posterior mitral leaflets. Anterior leaflet motion pattern resembles the letter 'M' (DEFAC) point D marks the beginning of mitral valve opening it is completed at E. F denotes mid-diastolic closure. A denotes valvular opening at the beginning of atrial systole. Point C marks the beginning of systole. Motion pattern of posterior leaflet resembles the letter 'W' (mirror image of M).

transducer probe positioned outside the body, at present probes which can be attached to endoscopes and arterial or venous percutaneous catheters are available. These permit real time events inside the chambers and vascular lumen.

In many conditions such as valvular lesions, congenital heart disease, cardiac failure, ischemic heart disease, cardiomyopathy, pericardial disease and others accurate measurement of the structural and hemodynamic abnormalities is possible. Being non-invasive and repeatable, the echocardiogram has established its place in preoperative and postoperative assessment. In the follow up of patients with diseases of the cardiac muscle, this investigation is invaluable.

Isotopic investigations: Availability of radionuclides such as ^{99m}Tc (half-life 6 h) and ^{201}Tl (half-life 73 h) and sestamibi has enabled isotopic studies to assess blood flow and myocardial perfusion. Isotopic studies are also non-invasive.

Flow studies: ^{99m}Tc compounds are used for dynamic flow studies. These include: (i) delineation of the various cardiac chambers during systole and diastole (*nuclear angiocardigraphy*); (ii) calculation of ejection fraction; (iii) evaluation of congenital cyanotic heart disease; (iv) demonstration of akinetic segments of the ventricular wall following myocardial infarction; and (v) quantitation of intracardiac shunts.

Myocardial scanning: For this purpose ^{201}Tl which is concentrated in the myocardium is employed. This isotope behaves similar to potassium and its concentration in the myocardium depends on the myocardial blood flow. Areas of diminished perfusion can be detected as "cold" areas in ischemic heart disease. Appearance of cold areas during exercise is an indication of stress induced ischemia. Sestamibi is another isotope used for myocardial imaging. It is not taken up by necrotic myocardium. Isotope studies are employed for the following conditions.

- i. for assessing myocardial perfusion during rest and exercise;
- ii. studying the configuration of the myocardium, especially hypertrophy;
- iii. to detect the presence of myocardial infarct, its extent, and viability of the ischemic myocardium
- iv. for the evaluation of post-bypass surgery patients.
- v. for the identification of hibernating myocardium.
- vi. for the assessment of the prognosis in myocardial infarction.

MRI in Clinical Cardiology

Magnetic resonance imaging (MRI) has established its place in cardiology, over the past ten years. It is a useful investigation in various situations for the assessment of (1) cardiac structure (2) function (3) perfusion and

(4) myocardial viability. MRI is accurate and reproducible. Images of cardiac chambers and the great vessels help to assess morphological and functional changes in these locations. MRI is being increasingly used for imaging the coronary circulation, myocardial perfusion, study of intravascular plaques and for the delineation of heart valves. Hypertrophic cardiomyopathy and cardiac tumours are well demonstrated. Next to skiagram of the chest, MRI is the investigation of choice in the study of pericardial lesions. More sophisticated and dedicated machines are being introduced into this branch of investigative cardiology. Cardiac MRI studies show promise as non-invasive investigative tools to assess coronary artery occlusions. Unlike the contrast agents used in conventional angiocardiology, gadolinium used in MRI is not nephrotoxic.

Single photon emission computed tomography (SPECT) and positron emission tomography (PET) can be employed to study the myocardium in greater detail. These studies are available in India only in a few centers, since the equipment is expensive. Studies employing these methods help to identify potentially salvageable myocardium in ischemic heart disease. Using appropriate radiolabelled isotopes the metabolic activity of the myocardium can be assessed.

Cardiac catheterization: The right and left sides of the heart can be catheterized, using special catheters. Pressures in the different chambers can be recorded during catheterization and this helps in identifying anatomical abnormalities.

Blood can be sampled from different locations for estimation of oxygen (*oximetry*) and this helps to quantitate left-to-right or right-to-left shunts. Cardiac output and cardiac index can be calculated by oximetric studies in the aortic and pulmonary arterial blood. Normal cardiac index is 2.8-4.2 liters/min/m². Reduction below 2.4 indicates abnormality. Pressure tracing of the ventricles enables detection of obstruction to ventricular filling, outflow obstruction, intactness of interventricular septum, and the presence of large septal defects, and also permits the calculation of the *systolic ejection time*. Systolic ejection time is the interval between the end of isometric contraction and the end of ejection.

A suitable catheter can be passed into the right side of the heart and manipulated into the pulmonary artery and advanced till it gets impacted in a small branch. Measurement of the pressure at this site (*pulmonary wedge pressure*) reflects the left atrial pressure.

Upper limit of normal pulmonary artery pressure is 30/14 mm Hg. Rise in right ventricular end diastolic pressure above 8 mm Hg and left ventricular end diastolic pressure above 12 mm Hg is indicative of ventricular failure or restriction to ventricular filling due to pericardial disease or myocardial fibrosis.

Fig. 115.10: Normal coronary angiogram showing the various branches filling normally

Selective angiocardiology is the imaging of the different cardiac chambers after injecting contrast material into them. This method helps to visualize the cardiac chambers and sequential flow of the dye during the different phases of the cardiac cycle. Angiocardiology clearly demonstrates the anatomical and functional abnormalities in the heart. Mitral incompetence, mitral stenosis, aortic stenosis, aortic incompetence, tricuspid and pulmonary valve lesions, cardiac aneurysms, and complex congenital malformations can be fully visualized.

Coronary angiography is the method of demonstrating the right and left coronary arteries after selective catheterization using special catheters (Fig. 115.10).

Angiocardigraphic studies provide invaluable information in several disorders where other non-invasive methods fail. Therefore, angiocardiology has to be resorted to particularly in the preoperative assessment of some of the cardiac lesions.

Interventional Cardiology—Catheter Laboratory (CATH lab) Procedures

This term is used for the therapeutic procedures done by an interventional cardiologist in a catheter laboratory. This specialty has expanded rapidly during the last two decades. The procedures include primary angioplasty for acute myocardial infarction, coronary angioplasty and stent for CAD, renal angioplasties, peripheral angioplasties, closure of PDA by coil or device, device closure of ASD and VSD and balloon valvuloplasties for mitral stenosis, pulmonary valve stenosis and aortic stenosis.

Coronary angioplasty is widely used for management of single vessel disease and 2 vessel disease. For three vessel disease with normal LV function and suitable lesions for angioplasty the results are comparable to bypass surgery except for the greater need for repeat revascularization. However complex 3 vessel disease,

especially in diabetics is preferably managed by bypass surgery.

Balloon valvuloplasty is employed for definitive treatment of mitral stenosis and pulmonary valve stenosis. Balloon pulmonary valvuloplasty is the treatment of choice for pulmonary valve stenosis. Mitral stenosis with suitable valve morphology treated by balloon mitral valvuloplasty has excellent short-term and long-term outcome which is comparable to open surgical commissurotomy. Balloon aortic valvuloplasty still remains largely as a palliative measure.

Routine stenting during angioplasty helps to keep vascular patency over long period.

Conventional stents have given place to drug eluting stents. These stents are coated with drugs such as

tacrolimus, paclitaxel and others. The initial studies over a few years have shown that the rate of re-occlusion of the coronary arteries is lower and the patency of the lumen is maintained for longer periods. Drug eluting stents are considerably more expensive than the plain stents.

Digital subtraction angiography: In this technique the bony cage and soft tissue shadows are eliminated by computer-aided subtraction which makes the vascular anatomy stand out prominently. Enhancement of vascular image obtained by elimination of other shadows enables one to visualize lesions in the major arteries (cerebral, thoracic, visceral or peripheral) by venous injection of small doses of contrast media, thereby avoiding arterial puncture.

Heart Failure (Syn: Cardiac Failure)

C.G. Bahuleyan

Chapter Summary

General Considerations 753
Clinical Features 756
Investigations 758
Management 759

General Considerations

Definition: Heart failure is a pathophysiological state in which the heart is unable to pump at a rate commensurate with the requirement of the metabolizing tissues (systolic failure) or can do so only with elevated filling pressures (diastolic failure).

Heart failure manifests as a complex clinical syndrome characterized by circulatory congestion, impaired systolic function, impaired diastolic function or both, and progressive activation of the neuroendocrine system. ***In all forms of cardiac disease, if the abnormality is allowed to progress without treatment, heart failure sets in, invariably after varying periods of time.***

Though there have been significant advances in the treatment and prevention of heart failure, it is still

increasing in incidence and prevalence. Approximately 1.5-2% of the population has some form of cardiac failure and the prevalence increases to 6-10% in patients >65 years old.

Heart failure should be distinguished from circulatory failure, in which an abnormality of any of the components of circulation—the heart, the blood volume, concentration of oxygenated hemoglobin in the arterial blood or vascular bed is responsible for the deficiency in cardiac output.

PATHOPHYSIOLOGY

During the past 4 decades there has been a progressive evolution in the concept and understanding of heart failure (Table 116.1).

In 1940-60s, heart failure was considered as a 'cardio-renal' disorder where it was thought that impaired ventricular function led to reduced cardiac output, and renal perfusion leading on to salt and water retention. Later on in 1960-80s, heart failure was considered as 'cardio-circulatory' disorders where the 'hemodynamic abnormality' was given more emphasis. Now it is known that heart failure cannot be simply defined in

TABLE 116.1

Pathophysiology of CHF

a. Hemodynamic alterations
1. Increased EDP; EDV
2. Reduced cardiac output
b. Neurohumoral alterations
1. Alterations in autonomic nervous system
a. Increased norepinephrine
b. Altered baroreceptor control
2. Alterations in beta adrenergic receptors
a. Down regulation of beta receptors
b. Increased beta-adrenergic receptor kinase
3. Alterations in renin-angiotensin system
a. Increased renin
b. Increased angiotensin II
c. Increased aldosterone
d. Down regulation of angiotensin I and II receptors
4. Others
a. Elevated atrial and brain natriuretic peptide (ANP)
b. Elevated endothelin
c. Role of cytokines
c. Cellular and molecular alterations
1. Calcium kinetics
a. Reduced Ca++ cycling
b. Reduced SERCA 2 enzyme level
c. Reduction in calcium release channels
2. Changes in contractile apparatus
a. Re-expression of genes
3. Free radicals and apoptosis

hemodynamic terms and the role of neurohumoral, cellular and molecular mechanisms are all important.

A. Hemodynamic Alterations

In the early stages of heart failure (HF), the hemodynamic abnormalities occur only during exercise. As the HF progresses they occur at rest as well. Reduction in cardiac output is associated with a rise in end-diastolic pressures (EDP) in the ventricle and increased venous pressure. Increase in end-diastolic pressure is accompanied by increase in end-diastolic volume (EDV) generally. The end-diastolic pressure and volume determine the extent to which myocardial fibers are stretched prior to acute active contraction, this is termed **preload**. The load the ventricle has to move once it starts contracting is called **afterload**. As the preload and afterload increase venous congestion develops behind the failing chamber to manifest as pulmonary or systemic venous congestion in left sided and right sided heart failure respectively. Reduction in cardiac output leads to reduction in tissue perfusion. Blood flow to the vital organs like brain and heart is maintained by diverting the flow from less vital organs.

B. Neurohumoral Alterations

Consequent to the two principal hemodynamic alterations viz reduced cardiac output and atrial hypertension—a complex series of neurohumoral alterations occurs. In

early stages, these alterations act as compensatory mechanisms, but later on they lead to undesirable effects and injury.

1. Alterations in Autonomic Nervous System

These include increased sympathetic activity and elevation of plasma norepinephrine (NE) levels. Extent of elevation of plasma NE correlates directly with the severity of heart failure. Augmented, sympathetic activity and elevated NE causes vasoconstriction and arrhythmias and may cause sudden cardiac heart death. The increase in adrenergic activity is mainly due to altered control of adrenergic outflow from the CNS.

2. Alterations in the Beta-adrenergic Receptor Pathway

Increased levels of local NE concentration cause down regulation of beta-I adrenergic receptors in the ventricles. In addition there is increase in beta-adrenergic receptor kinase (BARK) enzyme level, which leads to uncoupling of beta receptors. Down regulation of beta-receptors can be reversed by beta blockers.

3. Alteration in Renin Angiotensin System (RAS)

Increased adrenergic activity stimulates the $\beta 1$ receptor in juxtaglomerular apparatus of the kidneys. Also, decreased blood flow to kidney activates the baro-receptors. Both these lead to release of renin. Renin acts on *angiotensinogen* to form *Angiotensin I* which is acted upon by angiotensin converting enzyme (ACE) to form *angiotensin II*. Angiotensin II is a potent vasoconstrictor and leads to elevated systemic vascular resistance, which in turn leads to a vicious cycle. Angiotensin II also stimulates production of aldosterone and NE.

Only 1-10% of ACE is found in circulation. 90-99% is present in tissues such as vasculature, heart and kidneys. Angiotensin has 2 receptor subtypes AT1 and AT2. In patients with severe heart failure there occurs a down regulation of these receptors. Angiotensin acts on these receptors and causes cell growth and altered gene expression.

4. Role of Arginine Vasopressin (AVP)

In CHF, circulating AVP is elevated. This leads to salt and water retention and systemic vasoconstriction.

5. Role of Natriuretic Peptides

3 Natriuretic peptides—atrial natriuretic peptide (ANP); brain natriuretic peptide (BNP) and C-natriuretic peptide (CNP) have been identified. ANP is stored mainly in the right atrium. BNP is stored mainly in the ventricles. They cause vasodilatation and natriuresis and diuresis and counteracts the effects of adrenergic, RAS and AVP

systems. CNP is located primarily in the vasculature and it is produced by vascular endothelium as a response to shear stress, primarily in the vasculature. In addition, these peptides inhibit myocytes and vascular smooth muscle hypertrophy. They improve functions of the failing myocardium. Circulating levels of ANP and BNP are increased in heart failure and they confer beneficial effects. Levels of BNP and ANP have been utilized as diagnostic test in ventricular failure. Normal level is < 100 pg/mL. In CHF the levels go above 675 ± 450 pg/mL. This estimation supports the diagnosis of CHF in doubtful cases.

6. Role of Endothelin

It is a potent vasoconstrictor released by endothelial cells. 3 types of endothelins 1, 2 and 3; and 2 subtypes of receptors, A and B have been recognized in CHF. Circulating endothelin levels are increased.

7. Role of Cytokines

Cytokines implicated in the pathogenesis of CHF include tumour necrosis factor α , transforming growth factor β , peptide growth factors and interleukin-1 beta. They have crucial roles in mediating the changes in myocardial structure and function in CHF.

C. Cellular and Molecular Mechanisms

1. Role of Calcium

Calcium plays a central role in myocardial contraction and relaxation. In CHF, there is prolonged elevation of intracellular calcium during relaxation and calcium cycling is reduced by 50%. Calcium reuptake by sarcoplasmic reticulum is mediated by ATP-dependent enzyme Ca^{++} -ATPase (SERCA-2). SERCA 2 activity is inhibited by phospholamban. In CHF, SERCA 2 activity is reduced.

Calcium release channel (CRC) located on the sarcoplasmic reticulum (SR) mediates release of Ca^{++} from the SR into the myoplasm during systole. In CHF, MRNA level for CRC is decreased.

2. Changes in the Contractile Apparatus

There occurs a qualitative and quantitative change of the contractile proteins. Myosin ATPase activity is reduced in CHF. Also there occurs a re-expression of genes coding for fetal and neonatal isoforms of myosin, rather than adult isoforms. In addition, there is alteration in the regulatory protein-expression of troponin T. In normal myocardium 98% of the regulatory protein is troponin T. In CHF, there is a change to troponin T-2.

3. Role of Free Radicals and Apoptosis

In CHF, altered mitochondrial oxygen metabolism results in formation of free radicals, i.e. molecules with unpaired electrons. These molecules cause cell damage.

Apoptosis is programmed cell death. Free radicals produced by various mechanisms have been shown to result in apoptosis of cardiac myocytes in CHF.

4. Diastolic Heart Dysfunction and Failure (DHF)

Nearly 50% of patients with congestive heart failure have diastolic dysfunction – often referred to as diastolic heart failure. The LV function and ejection fraction may be normal. DHF is more common in older age groups, more in women. Hypertension is more common and IHD less common in them. Some show impairment of active ventricular relaxation and compliance of the ventricles. Ventricular diastolic pressures rise. This results in increase of pulmonary venous pressure. Stroke volume does not increase with exercise. When effort intolerance, dyspnea, venous congestion and pulmonary edema develop, it is termed diastolic heart failure.

Ref: A. Radfield MM. Understanding diastolic heart failure. N Eng J Med 2004;350:1930-1.

Forms of Heart Failure (HF) (Table 116.2)

1. Forward vs Backward HF

In backward failure hypothesis, when the ventricles fail to discharge the content, blood accumulates and pressure rises in the atria and venous systems emptying to it.

In forward failure hypothesis, manifestations of CHF are due to reduction in cardiac output. In most cases, both these mechanisms operate simultaneously.

2. Right Sided vs Left Sided Failure

In right sided failure, systolic output of right ventricle and/or right atrium falls. Common causes include pulmonary artery hypertension (PAH) in mitral stenosis, ASD and cor pulmonale; pericardial diseases, pulmonary stenosis, right sided cardiomyopathy, massive pulmonary embolism and tricuspid stenosis. This manifests as elevated right atrial pressure, elevated JVP, and systemic venous congestion leading to edema and hepatomegaly.

Left sided failure is caused by dysfunction of left ventricle and left atrium, chronic ischemic heart disease, systemic hypertension, and aortic and mitral valve disease. This manifests as dyspnea, orthopnea and paroxysmal nocturnal dyspnea. Persistent left heart failure gives rise to pulmonary hypertension which results in right heart failure as well.

3. Low Output vs High Output Failure

In the former, the cardiac output is reduced resulting in inadequate tissue perfusion, e.g. mitral stenosis, ischemic heart disease and hypertensive heart disease.

In the latter, cardiac output is above the normal range, but it falls from the original levels as heart failure sets in, e.g. thyrotoxicosis, anemia, beriberi.

TABLE 116.2

Causes of cardiac failure

1. Myocardial causes which reduce the contractile force of the myocardium	
a. Myocarditis	Infective (e.g. rheumatism, typhoid, Coxsackie infection) Toxins-diphtheria, scorpion stings, drugs like emetine, adriamycin Nutritional causes—beri beri Dyscollagenosis—lupus erythematosus Other miscellaneous causes—alcohol, diabetes myxedema
b. Coronary artery disease	Acute myocardial infarction Chronic ischemic myocardial damage
c. Cardiomyopathy	Primary and secondary
d. Infiltrations	Amyloidosis, hemochromatosis, leukemia, malignant deposits, iron
2. Structural abnormalities in the heart or great vessels arteriosclerotic which reduce the cardiac output	Valvular heart disease (rheumatic, syphilitic, and congenital) Infective endocarditis, traumatic lesions (injury or post-surgical) congenital heart diseases
3. Pericardial disease which leads to interference with diastolic filling of the ventricles especially the right ventricle	Pericardial effusion, constrictive pericarditis
4. Arrhythmias	
Tachycardias which lead to reduction in the diastolic interval, thereby reducing the end diastolic volume	Paroxysmal tachycardias, atrial flutter and fibrillation
Extreme bradycardia	Heart block in which the ventricular rate goes below 30/min.
5. Increased demand on cardiac output. Normal heart is able to cope up with even extremes of demand within physiological limits, since the reserve capacity is great. In the majority of pathological states increased demand is associated with impairment of cardiac function as well	Pregnancy, fever, thyrotoxicosis, severe exercise, arteriovenous fistula, chronic respiratory failure, hepatic failure
6. Cor pulmonale	Acute cor pulmonale as in pulmonary embolism or chronic cor pulmonale as in obstructive airway disease
7. Increased resistance to ventricular emptying	Systemic arterial hypertension leads to left ventricular failure, and pulmonary hypertension leads to right ventricular failure

4. Acute vs Chronic Heart Failure

In acute heart failure, there is insufficient time for compensatory mechanisms to become operative and hence clinical manifestations are marked, e.g. acute myocardial infarctions, tachyarrhythmias, acute pulmonary embolism.

In chronic heart failure, there is time for adaptive mechanisms to develop and hence patients are able to tolerate the reduction in cardiac output better.

5. Systolic vs Diastolic Heart Failure

When the abnormality is in systolic function leading to defect in ejection of blood, it is systolic heart failure whereas if the abnormality is in diastolic function leading to defect in ventricular filling, it is diastolic heart failure. More often both coexist, but in a third of the cases of heart failure, it may be purely diastolic.

Pathology: At autopsy the heart may be dilated in cases of chronic congestive cardiac failure. The underlying cardiac lesions may be evident. The lungs are heavy, congested, and edematous. In chronic cases the pulmonary

vessels show medial hypertrophy and intimal hyperplasia. Liver is enlarged, firm, and edematous. The central hepatic veins and sinusoids are congested. Cardiac cirrhosis is histologically characterised by centrilobular necrosis, atrophy, and extensive fibrosis.

The spleen may be enlarged and congested. Pancreas may show venous congestion. Intestines may reveal infarction and hemorrhagic necrosis. Kidneys and brain show chronic venous congestion.

Clinical Features

Symptoms: Most common symptom is dyspnea, which is more marked in left-sided heart disease. Orthopnea, paroxysmal nocturnal dyspnea and Cheyne-Stokes respiration are seen in left-sided heart failure.

Weakness, fatigue, and apathy are suggestive of low cardiac output states. Oliguria and nocturia may develop even before dependent edema manifests. Nocturia occurs in the early stages of heart failure. During daytime when the patient is ambulant cardiac function is impaired and fluid accumulates. At night, with recumbency edema fluid

Fig. 116.1: Cardiac cachexia

Note: Feature of cardiac failure and emaciation

is reabsorbed into the circulation, cardiac function improves with rest, and the excess fluid is eliminated.

Edema is the most prominent symptom in right-sided heart failure. Initially the edema is dependent, later it becomes generalized. In the early stages the edema readily pits on pressure but in long-standing cases the part becomes indurated and pigmented. Hepatic congestion manifests with upper abdominal pain and tender hepatomegaly. In long-standing congestive heart failure, weight loss and emaciation develop as a result of inadequate intake of food and wasting of tissues. This picture is termed “**cardiac cachexia**”. Alterations in the cytokine system, especially increase in levels of tumour necrosis factor, interferon gamma and interleukin III also play a part in the production of cardiac cachexia (Fig. 116.1).

Physical Examination

Pulse and blood pressure: The pulse becomes rapid as a result of compensatory adrenergic activity. *Pulsus alternans* is suggestive of left ventricular failure. The blood pressure is not generally affected in mild and moderately severe cases. But in severe heart failure the systolic pressure may fall due to reduction in cardiac output. The diastolic pressure is maintained by increase in the peripheral resistance.

Engorgement of the jugular vein: This is seen characteristically in right-sided and combined heart failure. Abnormality of the hepatojugular reflux can be demonstrated even before the jugular venous pressure is elevated.

Examination of the precordium: In the majority of cases the heart is dilated, though in many cases (e.g. mitral

stenosis, acute myocardial infarction, myocarditis, and constrictive pericarditis) it may not be so. Evidence of the underlying heart disease may be found. In left ventricular failure a protodiastolic gallop (S_3) may be heard over the apex beat, and it is better heard during expiration. In right ventricular failure S_3 gallop is heard over the lower left sternal border and it is better heard during inspiration. Rise in pulmonary arterial pressure gives rise to accentuation of the pulmonary second sound. Dilatation of the ventricle gives rise to valvular incompetence. Functional pansystolic murmurs arising from the mitral or tricuspid valves may be audible, which disappear when the heart size returns to normal.

Abdomen: The liver is enlarged, soft and tender and this may be evident even before overt edema manifests. Hepatic enlargement persists for varying periods after edema clears up with treatment, but with intensive therapy it recedes completely. Mild jaundice and impairment of hepatic function may occur. In long-standing right-sided heart failure with **cardiac cirrhosis**, the liver is firm and nontender. It does not recede with treatment at this stage. Mild to moderate splenomegaly occurs in some cases initially due to passive venous congestion, later the organ may become fibrotic. Significant splenomegaly should suggest the possibility of infective endocarditis. Ascites may develop as a result of passive venous congestion. Prominent ascites occurs in organic tricuspid valve disease, constrictive pericarditis, and right ventricular endomyocardial fibrosis (Fig. 116.2).

Lungs: Physical signs in the lungs are more pronounced in left-sided heart failure. These are the presence of rales over the infrascapular regions, bronchospasm, uni- or

Fig. 116.2: Female 35 cardiac cirrhosis

Note: Cachexia and prominent abdomen—arrow

bilateral hydrothorax, frequent respiratory infections (pneumonia, bronchopneumonia or bronchitis) and pulmonary infarcts.

DIAGNOSIS (TABLE 116.3)

TABLE 116.3
Framingham criteria for diagnosis of congestive heart failure (CHF)
Major criteria
1. Paroxysmal nocturnal dyspnea
2. Neck veins distension
3. Rales (crackles) over the lower portions of the lung
4. Cardiomegaly
5. Acute pulmonary edema
6. S3 gallop
7. Increased venous pressure > 16 mm Hg
8. Circulation time >25 sec
9. Hepatojugular reflux
Minor criteria
1. Ankle edema
2. Night cough
3. Dyspnea on exertion
4. Hepatomegaly
5. Pleural effusion
6. Decrease of vital capacity exceeding 1/3
7. Tachycardia > 120/mt
Major or minor criteria
1. Weight loss > 4.5 kg in 5 days in response to treatment.
2. Major +2 minor criteria if present concurrently establishes the diagnosis of CHF

Note: Framingham is a township in the USA where a cohort of persons have been followed up meticulously over a long period of time and several biological parameters have been recorded continuously. This study has become a classic prospective study, for several disorders, especially for cardiovascular disorders. The follow up and observation are still continuing.

Investigations

Based on the American College of Cardiology/American Heart Association Task Force Guidelines.

Class I: Investigations (usually indicated and always acceptable)

- 1. Blood counts—helpful to exclude infections
- 2. Urinalysis—proteinuria may occur due to renal congestion
- 3. Blood biochemistry:
 - i. Serum Na⁺, K⁺. In severe CHF, dilutional hyponatremia occurs. Diuretics may cause hypokalemia.
 - ii. Blood urea nitrogen and creatinine are moderately elevated. Severe elevation indicates reduction in renal blood flow.

Fig. 116.3: Acute aortic regurgitation with pulmonary edema
Note: Cardiomegaly with left ventricular contour, filled up pulmonary artery segment, enlarged left atrium and “bat-wing” type of pulmonary opacity

- iii. Blood glucose, phosphorus, magnesium, calcium and albumin levels are helpful in etiological diagnosis.
- iv. TSH levels help to point to thyroid function.
- 4. ECG: Though not directly diagnostic of CHF, underlying diseases like ischemia, ventricular hypertrophy, arrhythmias and conduction defects can be diagnosed.
- 5. X-ray chest: This may show cardiomegaly, and features of pulmonary venous or arterial hypertension. Acute pulmonary edema gives characteristic butterfly-shaped opacity extending on both sides from the hilum. A normal chest radiograph does not rule out systolic or diastolic dysfunction (Fig. 116.3).
- 6. Echo-Doppler evaluation: This is very useful in evaluating both RV and LV functions and identifying causes like ischemic heart disease, valvular abnormalities, ventricular hypertrophy, congenital heart disease, infiltrative myocardial and pericardial diseases and thrombi. Quantitative measurement of systolic function like ejection fraction, fractional shortening, stroke volume, cardiac output and rate of changes of ventricular pressure (dp/dt) can be obtained with accuracy.

Doppler echocardiography is the corner stone for evaluation of diastolic heart failure. Measurements like isovolumic relaxation time (IVRT), mitral inflow pattern, deceleration time; and pulmonary and hepatic venous flow patterns are very helpful in the diagnosis and quantification of diastolic dysfunction.
- 7. Non-invasive stress testing (treadmill test; stress echocardiography and nuclear perfusion studies): These tests can detect ischemia in patients with and without angina, but with a high probability of coronary artery

disease who could be candidates for revascularization and in patients with previous coronary artery disease.

8. **Assessment of myocardial viability:** In patients with ischemic heart disease it is necessary to determine the amount of viable myocardium which is the important determinant for assessing prognosis and formulating therapy. This can be done using dobutamine or dipyridamole stress echocardiography, myocardial contrast echocardiography, nuclear imaging using thallium or sestamibi and positron emission tomography.
9. **Cardiac catheterization and coronary angiography:** This is indicated in patients with angina or large areas of ischemic viable myocardium and those at risk of coronary artery disease who require surgical coronary revascularization and those who have to undergo surgery for noncardiac conditions.

Right and left heart catheterization can determine the cardiac output, filling pressures, pulmonary artery pressure, pulmonary and systemic vascular resistance, shunts and parameters of diastolic function.

Class II: Investigation (acceptable but of uncertain efficacy)

These include:

1. **Serum iron and ferritin** to exclude iron overload states.
2. **Endomyocardial biopsy:** This is indicated in patients with clinical indication of myocarditis and systemic disease with possible cardiac involvement such as hemochromatosis, amyloidosis, sarcoidosis, subendocardial fibroelastosis and those who have received adriamycin chemotherapy.

Complications of Cardiac Failure

Cardiac failure on its own can produce many complications. These include:

1. Arrhythmias and sudden death
2. Venous thrombosis and pulmonary embolism
3. Intracardiac thrombi and related problems
4. Pulmonary infections due to venous congestion
5. Cardiac cirrhosis in long-standing cases
6. Renal failure.

Course and prognosis: The prognosis depends upon the type of heart failure and the nature of underlying disease. In the majority of cardiac disorders, cardiac failure is a major cause of death. Acute pulmonary edema occurring in myocardial infarction, systemic hypertension, mitral stenosis, and myocarditis may prove fatal, if emergency treatment is not instituted. In systemic hypertension, ischemic heart disease, aortic valvular disease and chronic cor pulmonale, onset of cardiac failure marks a steady downhill course and the majority die within two years, if not properly managed. On the other hand, in mitral stenosis, tricuspid valve disease, pericardial diseases and right ventricular endomyocardial fibrosis, chronic right-

sided heart failure may become established and these cases progress to cardiac cirrhosis with ascites, or **cardiac cachexia**. They show waxing and waning of cardiac function from time to time (Fig. 116.1).

In the Framingham heart study, the median survival was 3.2 years. The risk for death in mild CHF is 5-10% annually which increases to levels as high as 30-40% annually in patients with advanced CHF (NYHA class II and IV). Many factors affect the prognosis adversely (Table 116.4).

TABLE 116.4

Poor prognosticators in CHF
1. Diabetes mellitus
2. Hypertension
3. Tobacco use
4. ECG abnormalities—left ventricular conduction abnormalities
5. Ejection fraction < 25%
6. Peak exercise capacity < 14 mL/kg/mt of oxygen consumption
7. Pulmonary capillary wedge pressure >18 mm Hg
8. Poor socioeconomic factors
9. Age > 65 yrs
10. Male sex
11. Serum sodium < 135 mmol/L
12. Arrhythmias—esp. ventricular
13. Plasma norepinephrine levels >400 microgram/dL

Management

The principles of management include: (1) *restoration of cardiac function*; (2) *removal of the precipitating factors*, and (3) *elective correction of all remediable lesions after controlling the heart failure*.

Based on these guidelines, the broad components of management may be considered as under (Table 116.5):

Principles of management of HF

- A. General measures
- B. Pharmacologic therapy
- C. Devices
- D. Surgery
- E. Newer evolving therapies

TABLE 116.5

Management outline
1. Establish that patient has heart failure
2. Ascertain presenting features—acute pulmonary edema, exertional breathlessness/fatigue, edema
3. Determine etiology
4. Identify relevant concomitant disease
5. Assess severity
6. Estimate prognosis
7. Anticipate complications
8. Counsel patients and relatives
9. Choose appropriate management strategy
10. Monitor progress and manage accordingly

General Measures

1. **Rest:** During periods of acute decompensation bed rest is recommended. Since restriction of activity promotes physical deconditioning on prolonged immobilization, bed rest should not be prolonged indefinitely. Activities leading to exhaustion should not be undertaken. Aerobic training may improve symptoms and exercise capacity. Ambulation reduces the incidence of venous thrombosis and pulmonary embolism.
2. Tobacco smoking should be stopped forthwith and alcohol discontinued. There are reports that tobacco produces systemic effects also when chewed. Therefore, it is better to stop this form of tobacco as well.
3. Co-morbidities like hypertension, dyslipidemia and diabetes should be controlled.
4. Weight reduction is advised in obese patients.
5. Factors aggravating or precipitating CHF such as anemia and systemic infections should be corrected.
6. Salt restriction—sodium intake should be limited to < 2 g/day.
7. Fluid restriction—to 1-2 L/day is advisable in patients with dilutional hyponatremia.
8. Daily weight measurement helps to detect early occurrence of fluid retention.
9. Regular follow-up to monitor progress.
10. The patient and his family members should be informed regarding the disease, treatment and prognosis in order to enlist their cooperation.
11. Specific interventions for treatable causes, e.g. revascularization in patients with ischemic heart disease.

Pharmacologic Therapy (Table 116.6)

TABLE 116.6

Drugs used in treatment of CHF

Indicated and acceptable drugs

1. ACE inhibitors
2. Digoxin
3. Diuretics
4. Beta blockers
5. Anticoagulants
6. Hydralazine and isosorbide dinitrate

Acceptable; as alternate drugs or add- on drugs

1. Angiotensin receptor blockers
2. Aldosterone antagonists
3. Calcium antagonists
4. Antiarrhythmics
5. Positive inotropes

1. ACE INHIBITORS (ACEI)

ACEI have shown definite benefit in all classes of CHF, due to their actions on the heart as well as vasodilatory effect on blood vessels.

Indication

All patients with heart failure and systolic dysfunction benefit from ACEI; and these are indicated, unless otherwise contraindicated.

Mechanism of Action

ACE inhibitors act by reducing the formation of angiotensin II. In addition they block kininase II, which is responsible for degradation of kinin, thereby augmenting effects of kinins. By these actions ACEI suppress the neurohumoral mechanisms, reduce the afterload and improve the hemodynamic parameters such as cardiac output.

Drugs: The ACE inhibitors (ACEI) approved for the CHF treatment include captopril, enalapril, lisinopril, quinapril, fosinopril and ramipril.

Adverse Effects

- i. **Hypotension:** Patients with hyponatremia or on diuretics experience hypotension more frequently. This can be avoided by correcting hyponatremia, decreasing the dose and frequency of diuretics, and by initiating ACEI therapy with smaller doses.
- ii. **Renal failure:** This is seen more in patients with concurrent use of diuretics, hyponatremia and in NYHA class 4 patients. Renal failure has been reported in 5-15% of patients.
- iii. **Hyperkalemia:** This can be severe enough to cause cardiac arrhythmias. Patients at risk include those taking potassium supplements, potassium sparing diuretics or those having renal failure.
- iv. **Cough:** This is characteristically a non-productive and irritating cough which can be very distressing. It is seen in 5-15% of patients and this is the most common reason for withdrawing ACEI.
- v. **Angioedema:** This is seen in 1% of patients and this can be life-threatening at times.

Contraindications to ACEI

1. Hypotension; SBP < 80 mm Hg
2. Serum creatinine > 3 mg/dL
3. Bilateral renal artery stenosis
4. Hyperkalemia (K^+ > 5.5 mmol/L)
5. History of angioedema

Benefits of ACEI

Alleviation of symptoms

1. Improves ejection fraction
2. Improves NYHA class
3. Decreases need for hospitalisation
4. Reduces mortality

2. ANGIOTENSIN RECEPTOR BLOCKERS (ARBs)

These drugs include losartan, valsartan, irbesartan, candesartan and eprosartan. These are as effective as and others. They are not substitutes for ACEI in patients who are tolerating ACEI. They are useful in patients who are intolerant to ACEI, due to disturbing cough or angioedema. Like ACEI they can also cause hypotension, worsen renal failure and cause hyperkalemia. At present there is no indication to replace ACEI with these drugs in patients well controlled by the former. ACEIs and ARBs can be combined for better results in resistant cases.

3. DIURETICS

Diuretics inhibit the reabsorption of sodium and chloride at specific sites in the renal tubules and thereby prevent sodium retention. Commonly used agents include furosemide, torsemide and bumetanide which act at the loop of Henle (loop diuretics) and thiazides, metolazone and potassium sparing agents which act at the distal tubule. Loop diuretics are more powerful. They increase sodium excretion by 20-25% whereas thiazides increase sodium excretion only by 5-10% in moderately impaired renal function.

Indications

Diuretics should be prescribed for all patients with symptoms of CHF who have fluid retention. Goal of diuretic therapy is to eliminate symptoms and signs of fluid retention. Diuretics produce symptomatic benefit more rapidly than any other drug. Appropriate use of diuretics is complementary for the successes of other drugs. Under-dosing of diuretics may lead to fluid retention, and decrease the efficacy of ACEI. Overdosing can lead on to volume depletion, and increase the risk of hypotension and renal failure with ACEI.

Risks of Diuretic Therapy

1. **Electrolyte depletion:** Hypokalemia and hypomagnesemia can occur which may cause serious arrhythmias particularly those caused by digitalis therapy. Concomitant administration of ACEI or combination with potassium sparing agents such as spironolactone can prevent potassium depletion.
2. **Neurohumoral activation:** Diuretics increase the activation of endogenous neurohumoral systems particularly renin angiotensin system. In the long-term this can increase the risk of disease progression. Hence, neurohumoral antagonists are combined.
3. **Hypotension and azotemia:** Excessive use of diuretics can cause hypotension and azotemia. Other problems include allergic rashes and damage to the auditory nerves.

Dose: Therapy is initiated with low doses such as 20-40 mg furosemide/day. The dose is increased till the symptoms or signs of fluid retention are abolished. The dose is 20-120 mg per day. Wherever possible the drug is given orally. The action starts within 2 hours and lasts for 6-8 hours or more. In emergencies such as acute pulmonary edema furosemide is given IV as slow injection not exceeding 4 mg/minute, to a dose of 40 mg, increased if necessary upto 120 mg. Action starts within 15-30 minutes. Other diuretics such as thiazides and potassium sparing diuretics such as spironolactone or amiloride can be given as per indications, once the emergency is tided over. Some patients develop diuretic resistance, which can be overcome by use of diuretic combinations or by using IV diuretics.

NSAIDs can inhibit the therapeutic effect of diuretics and may precipitate the development of azotemia.

Benefits of Diuretics

1. Alleviate symptoms and signs of CHF
2. Improve cardiac function and NYHA class
3. Improves effort tolerance

4. BETA ADRENERGIC BLOCKERS

Beta adrenergic blockers have shown definite beneficial role in the management of CHF, since adrenergic overactivity plays a role in the pathogenesis of CHF.

Indications

1. All patients with class II or III, CHF unless otherwise contraindicated benefit by beta blockers.
2. Recent data has shown definite benefit in class IV patients also.

Mechanism of Action

The effects on sympathetic nervous system helps to prevent progression of CHF. Risk of fatal arrhythmia is reduced. Ventricular volumes and peripheral vasoconstriction are reduced. Cardiac hypertrophy and apoptosis of cardiac muscle are reduced.

Initiation and Maintenance

Beta blockers that have been found most beneficial in CHF include carvedilol, metoprolol, bisoprolol and bucindolol. Treatment is initiated with small doses such as carvedilol 3.125 mg twice daily; bisoprolol 1.25 mg once daily or metoprolol sustained release tablet 12.5 mg once daily. The dose is increased every 2-4 weeks till the target dose is achieved. In clinical trials optimal dose of carvedilol was 50-100 mg/day and that of metoprolol was up to 200 mg/day.

Contraindications include

- Bronchospasm, asthma
- Symptomatic bradycardia with heart rate below 60/minute.
- Higher grades of blocks in patients who have no implanted pacemakers.
- Patients on IV inotropic support
- Acutely ill patients

Benefits of Beta Blockers

1. Reduction in mortality, especially by retarding progression of CHF and abolition of fatal arrhythmias.
 2. Reduces symptoms
 3. Retards progression of CHF
 4. Improves NYHA class
 5. Reduces the risks of hospitalization
 6. Improves ejection fraction.
- Beta blockers produce additive effects with ACEI.

Risks of treatment with beta blockers include

- Hypotension
- Fluid retention and worsening of CHF
- Bradycardia and heart blocks

5. DIGOXIN

This is the most commonly used digitalis glycoside and the most time-honoured drug used in treatment of CHF. William Withering (British) published his treatise on the use of foxglove (*digitalis purpurea*) in 1785.

Indications

It is indicated in patients with congestive heart failure and atrial fibrillation with fast ventricular rate. It is also indicated in patients who continue to be symptomatic despite treatment with ACEI or beta blockers.

Mechanism of Action

It inhibits Na^+ , K^+ -ATPase enzyme in the myocytes and increases the contractility. Digoxin also decreases the sympathetic outflow from CNS. Thus, it acts both as a positive inotropic agent and neurohumoral attenuator.

Clinical Effects

It reduces the heart rate, relieves symptoms, enhances diuresis and brings about overall symptom benefit even though it does not affect the ultimate fatal outcome.

Adverse Effects

Digoxin is a double – edged weapon since the difference between the therapeutic and toxic levels is narrow.

- i. Arrhythmias—ventricular ectopics and bigeminy, paroxysmal atrial tachycardia with block;

ventricular tachycardia (VT) especially bidirectional VT and ventricular fibrillation. These arrhythmias may be fatal unless proper care is taken. The therapeutic margin of digoxin is narrow and therefore in selected cases estimation of serum digoxin levels should be done to guide therapy.

ii. Different grades of AV blocks

- b. GIT symptoms—anorexia, nausea, vomiting
- c. CNS symptoms—disorientation, visual disturbances

Optimal therapeutic level of digoxin in serum is 1-1.5 ng/mL especially women. Serum levels of > 2.0 ng/mL are toxic. Those at particular risk include elderly patients, with renal failure, hypokalemia, hypothyroidism and on concurrent medication with quinidine, verapamil, amiodarone, spironolactone and flecainide. Estimation of serum digoxin levels are helpful for optimal therapeutic benefit, without the risk of toxicity.

Dosage

Tablets are available in strengths of 0.0625 mg; 0.125 mg and 0.25 mg. Parenteral preparation containing 0.25 mg/mL is available for IV injection. Effect of oral dose of digoxin manifests in 30-45 minutes. **The drug is cumulative on repeated administration. The digitalising dose is the total dose of digoxin required to produce optimum therapeutic effect.** Following the full digitalising dose, maximal action is seen in 3-5 hours and some activity persists for 2-6 days. Rapid digitalisation is done by giving 0.5-0.75 mg initially followed by 0.25-0.5 mg at 48 hrs intervals. In the majority of patients the digitalising dose is 2-2.5 mg. In slow digitalisation 0.25 mg is given once or twice a day and the serum level reaches the desired maximum in 5-7 days. After initial digitalisation, the serum level is kept up by maintenance therapy given in a dose of 0.125-0.25 mg daily for 5-6 days a week.

Intravenous digoxin is only rarely used. Dose is 0.5-1 mg slowly over 3-5 minutes. After a loading dose the clinical effect starts within minutes, and the full effect occurs in 2-3 hours. A lower maintenance dose of digoxin is advised in patients above 70 years and those with impaired renal function. In appropriate situations it is life saving.

Contraindications to Digoxin

1. AV blocks—second degree, complete heart block and unstable AV blocks
2. Pure diastolic dysfunction
3. Wolff-Parkinson-White syndrome
4. Suspected digitoxicity
5. Hypertrophic obstructive cardiomyopathy

Treatment of digitoxicity: The remedial measures depend on the serum levels of the drug. Depending the severity

of toxicity and serum levels, the therapy has to be modified.

Principles of therapy include the following:

1. Withdrawal of digoxin
2. Potassium supplementation—2-4 g orally once or twice a day
3. Phenytoin, beta blockers or lignocaine for ventricular arrhythmias
4. Temporary pacing for AV blocks or symptomatic sinus bradycardia
5. Digoxin antibodies in severe grades of toxicity. These are available for use in critical situations.

Benefits of Digoxin

1. Improves symptoms, quality of life, functional capacity and effort tolerance
2. Improves ejection fraction
3. Withdrawal results in hemodynamic and clinical deterioration
4. No significant reduction in mortality

6. ANTICOAGULANTS

CHF patients are at increased risk for thromboembolic complications. Incidence is 1-3% annually. Current recommendation is that warfarin is justified in patients with heart failure who have experienced a previous embolic episode or who are in atrial fibrillation (see also Section 15).

7. HYDRALAZINE AND ISOSORBIDE DINITRATE

The combination acts as venodilator and arterial dilator agents. They reduce the preload and afterload and improve ejection fraction. This combination is recommended in patients who are intolerant to ACEI, or having renal insufficiency. There is no evidence to support the use of nitrates alone or hydralazine alone.

8. ALDOSTERONE ANTAGONISTS

Aldosterone antagonists exert favourable effects on the neurohumoral system and decrease the risk of progression of CHF. Spironolactone has been shown to reduce mortality, improve symptoms and decrease hospitalization in CHF patients. Use of spironolactone is recommended in patients with recent or current class IV symptoms. Dose recommended is 25 mg/day.

9. ANTIARRHYTHMICS

Patients with CHF have frequent complex arrhythmias and are at high risk for sudden death. Hence there has been considerable interest in the use of antiarrhythmic

intervention. Three groups of antiarrhythmics have been evaluated in patients with heart failure.

Class I agents (quinidine, procainamide, flecainide and encainide)—These drugs have shown increased mortality in clinical trials.

Class II agents—Beta blockers have shown definite benefit.

Class III agents (amiodarone, d-sotalol and dofetilide)—Amiodarone may have benefit in nonischemic CHF patients and in those with supraventricular and ventricular arrhythmias.

10. POSITIVE INOTROPES

Though theoretically these drugs may be expected to produce benefit, in clinical trials their effects are disappointing and hence drugs such as dobutamine, milrinone and vesnarinone are not routinely used in CHF.

Mechanical Devices

I. Ventricular Assist Devices (VADs)

Both left ventricular and dual chamber assist devices are available. These include

- i. Hemopumps—indicated only for a short-term use
- ii. Centrifugal devices (Biomedicus Biopump)
- iii. Pulsatile devices (Abiomed BVS—5000)
- iv. Implantable devices, e.g. Heart mate

These are used in many cases to tide over the waiting period before cardiac transplantation. Newer assist devices are being introduced.

II. Extracorporeal Membrane Oxygenator (ECMO)

This device has a centrifugal pump to drive blood from patient to a membrane for CO₂ and O₂ exchange.

III. Implantable Cardioverter Defibrillator (ICD)

This is a multifunctional multiprogrammable electronic device designed to abort life-threatening arrhythmias. Patients with CHF who had episodes of definite VT/VF are likely to benefit from ICD. These are capable of producing regular impulses for contraction and also defibrillate the heart in case of emergencies.

IV. Pacemakers in CHF

There is growing evidence in support of hemodynamic benefits and long-term improvement in clinical status of patients with CHF after biventricular dual chamber (DDD) pacing. The main mechanism is by resynchronization of LV activity. Clinical trials have established the beneficial role of single chamber and dual chamber pacing.

Surgical Options

1. Dynamic Cardiomyoplasty

In this procedure the latissimus dorsi muscle with its pedicle is wrapped around the cardiac apex and a myostimulator is implanted. Though there is improvement in the cardiac indices, long-term outcome is disappointing.

2. Mitral Annuloplasty and Mitral Valve Repair

Where there is associated secondary MR, these procedures are indicated.

3. Partial Left Ventriculectomy (Batista procedure)

This procedure was introduced in 1994 by the Brazilian surgeon Batista. The principle is that return of the dilated ventricle to a more normal volume/mass/diameter relation reduces the wall stress and improves the function. Basic procedure involves resection of the lateral wall from apex to the atrioventricular groove. The results are good in experienced hands.

4. Aneurysmectomy

LV aneurysm causes paradoxical expansion and loss of effective contraction and it contributes to CHF. Aneurysmectomy improves the cardiac function.

Cardiac Transplantation

When the myocardium is damaged beyond repair life cannot be sustained by the failing heart. Cardiac transplantation is indicated under such circumstances if a donor heart and technical expertise are available.

Indications

1. Persistent cardiogenic shock requiring mechanical assistance
2. Refractory CHF with continuous inotropic infusion
3. NYHA class 3-4 with a poor 12 months prognosis
4. Progressive symptoms despite maximal therapy
5. Severe symptomatic hypertrophic cardiomyopathy (HCM) or restrictive cardiomyopathy
6. Refractory angina with unsuitable anatomy for revascularization
7. Life-threatening ventricular arrhythmias despite aggressive medical and device interventions
8. Cardiac tumours with only low tendency for metastasis
9. Hypoplastic left heart syndrome and complex congenital heart disease.

Pre-requisites for surgery

1. Received maximal medical therapy
2. Been considered for alternative surgical options

3. Been addressed for all reversible causes
4. Peak oxygen consumption ($\text{VO}_2 \text{ max}$) falls below 14 mL/kg/mt or it shows a marked and steady decline.

Gene Therapy

This is an evolving treatment strategy where attempt is made to increase the myocardial contractility at molecular level. This is accomplished by using nanoparticles as potential gene therapy carriers or vectors.

In this method, over expression of β_2 receptors in the myocardium is accomplished using adenovirus vector. Genes expressing SERCA2a are increased by using adenovirus transfection of myocytes. Preliminary studies have shown that this improves contraction and relaxation, but there was increased incidence of arrhythmias.

Refractory Cardiac Failure

Definition: Refractory CHF is defined as NYHA class III or IV CHF, in whom symptoms have not improved or have actually worsened following recent attempts to escalate therapy. Triple therapy with digoxin, diuretics and vasodilators should have been attempted prior to labelling the heart failure as refractory.

Management

- I. Take a fresh look to find out conditions causing recent deterioration in CHF like
 1. Excessive diuretics
 2. Digitoxicity
 3. Electrolyte abnormalities
 4. Renal failure
 5. Untreated medical problems such as infections.
- II. Search for factors causing refractory CHF
 1. Myocardial problems like ongoing or recurrent ischemia, mitral regurgitation, arrhythmia, hypertension
 2. Compounding illnesses like renal failure, infections, pulmonary embolism, uncontrolled diabetes, hypothyroidism.
 3. Patient factors—Dietary indiscretion, non-compliance, alcohol abuse
 4. Iatrogenic problems—NSAIDs, steroids, antiarrhythmics
- III. Optimize the medical therapy
- IV. Consider positive inotropic agents
- V. Consider devices
- VI. Consider surgical options

Intractable Cardiac Failure

If patient fails to respond to the above measures and needs a mechanical assist device, heart failure is considered intractable and they are candidates for transplantation.

Emergency Treatment of Acute Pulmonary Edema

1. *Patient is hospitalized* and put to rest with a back rest or cardiac table, in the position of maximum comfort.
2. *The patient is given oxygen immediately at a flow rate of 7-10L/minute.*
3. *Morphine sulfate* 3-5 mg is given intravenously over three minutes and repeated to a total dose of 15-20 mg, at 15 min. intervals. In less acute cases the drug can be given intramuscularly in doses of 15-20 mg. Morphine abolishes anxiety, depresses the respiratory center, allays dyspnea, and reduces the adrenergic vasoconstrictor stimuli.
4. *Diuretic:* Frusemide 40 mg should be given intravenously. If the effect is not evident in 30 min the dose may be repeated.
5. *Aminophylline* in a dose of 5 mg/kg given intravenously slowly is very effective in increasing the cardiac output and relieving bronchospasm. Aminophylline has different actions such as improvement of cardiac output, stimulation of the respiratory center, bronchodilation and diuresis. Hypotension and anaphylaxis are potential complications. In many cases the effect of aminophylline is dramatic.
6. *Reduction of preload:* Tourniquets are applied to the extremities proximally to reduce venous return and thus reduce preload. The venous return from three limbs is obstructed at a time and the tourniquets are rotated at 15 min. intervals. This method of physiological venesection is very effective. Rarely open venesection to remove 300-500 mL blood rapidly may be required. Venesection should not be done on hypotensive patients.
7. *Digitalisation:* Rapid digitalisation is done by intravenous injection of 0.5-1 mg digoxin when there is clear indication.
8. *Vasodilators* such as nitroprusside given intravenously may be required in intractable cases. Once the emergency is managed successfully, further elective management depends upon the underlying condition.

Hypodynamic
5. Neurogenic
6. Hypoadrenal

General Considerations

Definition: Shock is a clinical syndrome resulting from gross impairment of tissue perfusion and widespread cellular dysfunction caused by diminution in oxygen delivery.

Classification of Shock

1. Hypovolemic
2. Traumatic

Pathophysiology

In shock there is a disparity between the blood volume and the circulatory bed. This may be due to loss of blood volume, diminished cardiac output or loss of vascular tone affecting the circulatory bed. Shock is reversible in the early stages. Compensatory phenomena such as sympathetic overactivity leading to vasoconstriction and reflex tachycardia serve to maintain the blood pressure and systemic perfusion. These vascular responses are maximal

in the vessels of the skin, kidneys, splanchnic areas, and skeletal muscles. These vasomotor phenomena serve to redirect the available blood to the vital organs like brain and heart. If shock persists or becomes severe, the compensatory mechanisms fail and progressive tissue damage occurs. Blood supply to the vital organs also suffers.

When the perfusion of tissues and delivery of oxygen are decreased, anaerobic metabolism supervenes. Hypoxia, hypercapnia, and acidosis (both metabolic and lactic) ensue. Cellular injury created by the inadequate delivery of oxygen and substrates also induces the production and release of inflammatory mediators that further compromise perfusion through functional and structural changes within the microvasculature. Integrity of the capillary wall is lost leading to extravasation of protein-rich fluid into the extravascular space. This leads to a vicious cycle in which impaired perfusion is responsible for cellular injury which causes maldistribution of blood flow, further compromising cellular perfusion leading to multiorgan dysfunction. Intense ischemia damages the intestinal mucosa resulting in the entry of bacteria and toxins into the circulation. This leads to further aggravation of hypotension and shock. Release of histamine and histamine like substances enhances vasodilation and capillary permeability. Disseminated intravascular coagulation results from the release of thromboplastic substances and this further damages the microcirculation of vital organs. This worsens the shock. Irrespective of the primary cause, persistence of shock leads to myocardial dysfunction and further reduction in cardiac output.

CLINICAL FEATURES

13

Clinically shock is usually accompanied by hypotension i.e, a mean arterial pressure < 60 mmHg in a previously normotensive person. The shock syndrome is characterized by rapid thready pulse and cold clammy skin. Alteration in the consciousness such as agitation, somnolence, confusion or coma is a common feature. The urinary output falls below 20 mL/h with the urinary sodium falling below 30 mmol/liter. Metabolic acidosis manifests with tachypnea and Kussmaul's respiration. Several complications develop if shock continues. The majority of cases end up fatally, if left untreated.

Complications

Pulmonary	Adult respiratory distress syndrome (ARDS), characterized by tachypnea, diffuse bilateral rales, and respiratory failure.
Cardiac	Myocardial dysfunction and arrhythmias.

Renal	Acute tubular necrosis and obstruction of tubules by casts
Gastrointestinal	Hepatocellular failure, mesenteric vasoconstriction, hemorrhagic necrosis of bowels.
Hematological	Disseminated intravascular coagulation (DIC).

Cardiogenic Shock

Intrinsic Cardiogenic Shock

This form of shock is caused by failure of the heart to act as an effective pump. The onset is usually sudden. It occurs most commonly as a complication of acute myocardial infarction. It can also occur due to severe brady or tachyarrhythmias, valvular heart disease, or in the terminal stage of chronic heart failure of any cause, including ischemic heart disease and dilated cardiomyopathy. Cardiogenic shock is characterized by a low cardiac output, diminished peripheral perfusion, pulmonary congestion, and elevation of systemic vascular resistance and pulmonary vascular pressures. Acute right heart failure can arise as a result of right ventricular myocardial infarction or may complicate the acute respiratory distress syndrome and severe pulmonary hypertension of any etiology. As a consequence of right ventricular failure, left ventricular preload falls, and this, in turn, reduces systemic perfusion. In contrast to other forms of shock, absolute or relative hypovolemia is usually not present in cardiogenic shock.

Compressive Cardiogenic Shock

This is caused by extrinsic compression of the heart. The heart becomes less compliant and, therefore normal filling pressures are inadequate to achieve proper diastolic filling. Blood or fluid collecting in the pericardial sac may cause tamponade since the pericardium is not distensible. Any cause of increased intrathoracic pressure such as tension pneumothorax, herniation of abdominal viscera through a diaphragmatic hernia, or use of excessive positive pressure ventilation produces compressive cardiogenic shock. Acute right heart failure with sudden decline in cardiac output can be caused by pulmonary embolism obstructing right ventricular outflow tract and this impairs ventricular filling. Although initially this condition responds to increased filling pressures produced therapeutically by volume expansion, as the compression increases, cardiogenic shock ensues.

Treatment

General measures: Shock should be diagnosed early. Survival is inversely related to the duration of the shock

before starting treatment. Prompt institution of specific treatment reduces mortality. The patient is put to bed with foot-end of the bed elevated to increase the venous return to the heart. Patency of the airway is established by removing foreign bodies from the mouth and throat and by keeping the neck extended backwards to prevent the tongue from falling back. If there is pain, morphine 5 mg is given intravenously and repeated, if needed, every 10-15 minutes to reach a total dose of 15-20 mg. Vital signs like pulse, respiration, blood pressure and urine flow are monitored. A venous cannula introduced into the jugular vein helps in monitoring the central venous pressure and also in administering fluids, if prolonged treatment becomes necessary. It is ideal to keep the central venous pressure at 10-14 cm of water. Metabolic acidosis is corrected by administration of 50-100 mmols of sodium bicarbonate given as a 7.5% solution.

Vasopressor drugs: Sympathomimetic drugs are used to improve vascular tone. **Dopamine** is given intravenously at a rate of 3-15 µg/kg/min, depending upon the response of blood pressure and urine output. Other drugs in this group are **isoprenaline** (4-8 µg/min.) and **dobutamine** (3-15 µg/kg/min). These drugs cause improvement in cardiac output and blood pressure, but cardiac arrhythmias may be precipitated.

Vasodilator drugs: Commonly used vasodilator drugs include:

1. **Sodium nitroprusside** given IV at a dose of 10-20 µg/min,
2. **Nitroglycerine** given IV at a dose of 10-20 µg/min, or
3. **Phentolamine** given IV at a dose of 0.5 µg/min.

Vasodilators have the following effects.

1. Reduction of ventricular afterload due to dilation of systemic arterial bed.
2. Decrease in ventricular preload by dilating venous capacitance vessels and reducing pulmonary capillary, arterial and right ventricular pressures.
3. Decrease in myocardial oxygen demand and increase in the subendocardial flow of blood.

Vasodilators should be started in small dosage and the dose should be worked up, depending on the response. Combination of vasodilators with inotropic agents gives better results.

Apart from these general measures each type of shock demands appropriate specific management. For example, thrombolytic therapy and surgical revascularisation for acute myocardial infarction, antibiotics for septic shock and dialysis procedures for poisoning.

Hypovolemic shock: Rapid replacement of the blood volume by administration of the appropriate fluid (depending on the fluid lost) is life-saving and this should be undertaken without delay. Blood, isotonic saline or plasma volume expanders such as 6% w/v dextran or other colloidal solutions should be used. The rate of infusion should match the rate of fluid loss. In severe cases of gastroenteritis up to 3-4 litres of fluid may have to be infused in the first 1-2 hours. Fluid infusion is continued until the systolic blood pressure comes up to 100 mm Hg. Further maintenance depends on rate of fluid loss. If the shock is unresponsive to replacement of conventional fluids, infusion of 7.5% saline (100-400 mL) may help to restore the blood pressure.

Cardiogenic Shock

Inotropic agents to improve cardiac contractility, vasodilators to reduce the afterload on the heart and correction of the cardiac abnormality are the main principles of treatment. If the cardiac output is persistently low, the circulation can be assisted by means of balloon counterpulsation in the aorta if facilities permit. The balloon is positioned in the upper part of descending aorta. It is inflated during diastole and deflated during systole. This helps to reduce afterload in systole and to increase the filling pressure of the ventricles and coronary arteries during diastole. By these mechanisms, balloon counterpulsation improves the cardiac output and coronary circulation. In conditions such as rupture of inter-ventricular septum or acute damage to a valve, emergency surgery may have to be undertaken if the shock remains unresponsive to medical treatment. In shock due to acute myocardial infarction thrombolytic therapy is beneficial, but results are less rewarding than in those without shock. Early revascularization procedures such as percutaneous transluminal coronary angioplasty (PTCA) or coronary artery bypass surgery (CABG) bring about dramatic benefit and improve survival and in many centres early revascularization is the method of choice.

Anaphylactic Shock

It is treated by intramuscular injection of 1 mL of 1/1000 adrenaline, repeated if needed every 5-10 min. Adrenaline corrects the hypotension and bronchospasm. If the bronchospasm is severe, 250 mg of aminophylline is given intravenously slowly. In severe cases hydrocortisone in doses of 100 mg or its analogues (betamethasone or dexamethasone 8 mg) are given intravenously either by repeated injections or through an intravenous drip, until the condition improves. If laryngeal edema obstructs the airways, emergency tracheostomy has to be done to save life.

Chapter Summary

General Considerations	768
Etiology	768
Classification	769
Malpositions of the Heart	770
Congenital Aortic Stenosis	771
Coarctation of Aorta	772
Pulmonary Stenosis	773
Atrial Septal Defect (ASD)	774
Ventricular Septal Defect (VSD)	776
Patent Ductus Arteriosus (PDA)	777
Eisenmenger's Syndrome	778
Congenital Cyanotic Heart Disease	779
Tetralogy of Fallot (TOF)	779
Pulmonary Atresia	780
Tricuspid Atresia	780
Complete Transposition of Great Vessels	781
Anomalous Pulmonary Venous Connection	781

accompany at least 25% of significant cardiac defects and they may aggravate morbidity and mortality. They are often multiple and about a third of them are classified into distinct syndromes.

Congenital heart disease results from abnormal development of particular portions of the heart during embryonic development, e.g. defective development of the interventricular septum results in various types of ventricular septal defects (VSDs). Abnormal development of a single structure can also lead to multiple abnormalities, e.g. abnormal development of the spiral septum results in ventricular septal defect, right ventricular outflow tract obstruction, overriding of aorta, and right ventricular hypertrophy which are all seen in tetralogy of Fallot.

Etiology

The exact etiology of the disease is unknown. It is generally believed that congenital heart disease is multifactorial in origin, mainly an interplay between genetic as well as environmental factors. Some of the congenital heart diseases are found to be familial, e.g. mitral valve prolapse, atrial septal defect, patent ductus arteriosus and pulmonic stenosis. The incidence of congenital heart disease in the offspring or siblings of an index patient is 2-5%.

The genetic mechanisms tend to be different. Atrio-ventricular septal defects seem to be single gene disorders. Tetralogy of Fallot is polygenic in origin. Isolated transposition of great vessels arise from sporadic defects. Identification of 22q11 deletion by fluorescent *in situ* hybridization (FISH) is correlated with a variety of conotruncal abnormalities in relation with Di George's syndrome. Recognition of thymic hypoplasia is important in that they should avoid live vaccinations and may need irradiated blood for transfusion when indicated. Similarly these children should be evaluated for hypocalcemia and neonatal convulsions can be avoided with adequate supplementation.

The environmental factors include maternal age above 35 years, maternal infections like rubella and cytomegalo-

Congenital heart disease (CHD) can be defined as abnormalities in the cardiovascular system occurring at birth. A primary abnormality occurring in one part of the cardiovascular system *in utero* can lead on to functional abnormalities resulting in further anatomical defects. This process gives rise to various complex types of cardiac defects at birth. The frequency of major congenital heart disease has been estimated to be approximately 0.8% of all live births. This does not take into account the common congenital abnormalities like mitral valve prolapse and bicuspid aortic valve. Though the different types of congenital heart disease show no predilection for either sex, in general males are affected more than females. However Atrial septal defects (ASD), persistent ductus arteriosus (PDA) and Ebstein's anomaly of tricuspid valve are more common in females. Extracardiac abnormalities

Extracardiac anomalies in association with congenital heart disease		
Syndrome	Cardiovascular anomaly	Clinical features
1. Holt-Oram syndrome	Secundum ASD	Hypoplastic thumb with three phalanges, absent thumb, hypoplasia of metacarpals extending onto radius
2. Chance association (not a specific syndrome)	Conotruncal anomalies (TOF, truncus arteriosus) aortic arch anomalies (interrupted aortic arch)	Coloboma, heart defect Choanal atresia, growth/mental retardation Genitourinary anomalies, ear anomalies, genital hypoplasia
3. Vater association (vateral syndrome)	VSD	Vertebral defects, anal atresia, cong. heart disease, tracheo-esophageal fistula, renal dysplasia
4. Pierre-Robin syndrome	VSD/PDA	limb anomalies (radial dysplasia) Deafness, cataract, CHD mental deficiency, hepatosplenomegaly, jaundice, thrombocytopenia anemia
5. Cornelia de Lange syndrome	VSD	Prenatal growth retardation, microcephaly, hirsutism, anteverted nares, downturned mouth mental retardation,
6. Fetal alcohol syndrome	VSD, PDA, ASD	Microcephaly, mental deficiency
7. Noonan's syndrome	Pulmonary valve dysplastic	Webbed neck, mental deficiency
8. Ellis-van Creveld syndrome	Common atrium	Malignant hyperthermia
9. Rubinstein-Taybi syndrome	PDA	Multiple frenulae post axial Polydactyly Chondroectodermal dysplasia. Broad thumb and toes mental retardation

CHD in selected chromosomal aberrations	
Condition	Common defects
1. Trisomy 21 (Down's syndrome)	Endocardial cushion defects
2. Turner's syndrome	Coarctation of aorta, AS, ASD
3. Klinefelter's syndrome	PDA
4. Cri Du Chat syndrome	VSD, PDA, ASD
5. Trisomy 13 (Patau's syndrome)	VSD, PDA
6. Trisomy 18 (Edward's syndrome)	VSD, PDA, PS

virus, drugs consumed by the mother during the first trimester of pregnancy, nutritional status of the mother and alcoholism. Maternal rubella results in congenital rubella syndrome (cataract, deafness, microcephaly, patent ductus arteriosus with pulmonary valve stenosis or pulmonary arterial stenosis). Chronic maternal alcohol abuse results in birth of babies with *fetal alcohol syndrome* (microcephaly, micrognathia, microphthalmia, and ventricular septal defect).

Prenatal teratogens	
Agent	Cardiac defect
Ethanol	VSD
Phenytoin	VSD
Lithium	Ebstein's anomaly
Retinoic acid	TGA
Rubella	PDA, PS
Valproic acid	Coarctation of aorta
Vitamin D	Supravalvular PS
Warfarin	PDA, PS

Insulin dependant diabetes mellitus at conception in the mother predisposes to cardiac diseases like TGA, VSD, coarctation of aorta and cardiomyopathy in the offsprings. Macrosomia and benign cardiac hypertrophy mimicking hypertrophic cardiomyopathy is more common with gestational diabetes. SLE is associated with congenital complete AV block in the offspring due to transfer of maternal autoantibodies across the placenta, which produce inflammatory damage to the conduction system of the fetus. Carrier state for phenylketonuria in the mother is associated with a variety of congenital cardiac malformations.

Congenital heart disease can be broadly classified into cyanotic and acyanotic varieties. Cyanotic lesions may be accompanied by reduced as well as increased pulmonary blood flow, the former being the more common.

Classification

Acyanotic

Left to right shunt

1. Atrial septal defect (ASD)
2. Ventricular septal defect (VSD)
3. Patent ductus arteriosus (PDA)

Obstructive lesions

1. Aortic stenosis (AS)
2. Pulmonary stenosis (PS)
3. Coarctation of aorta (CoA)

Cyanotic

Reduced pulmonary blood flow

1. Tetralogy of Fallot (TOF)
2. Transposition of great arteries (TGA), VSD, PS
3. Corrected TGA (c-TGA)-VSD—PS
4. Tricuspid atresia-VSD—PS

- 5. Single ventricle—PS
 - 6. Endocardial cushion defect (ECD)—PS
- Increased pulmonary blood flow
- 1. TGA
 - 2. Truncus arteriosus
 - 3. Tricuspid atresia—VSD with no PS
 - 4. Total anomalous pulmonary venous connection (TAPVC)
 - 5. Endocardial cushion defect
 - 6. Single ventricle—no PS

Malpositions of the Heart

The position of the heart and major blood vessels may be abnormal due to aberrations during embryonic development. Cardiac malpositions can be associated with or without visceral heterotaxy. The term heterotaxy refers to anomalous placement or location of viscera and vascular structures. In patients with visceral heterotaxy the organ and vascular arrangements are not in an orderly concordant manner.

There are three basic cardiac malpositions in patients without visceral heterotaxy—situs inversus with dextrocardia, situs solitus with dextrocardia and situs inversus with levocardia.

Dextrocardia

One of the common anomalies is dextrocardia. This term refers to the condition in which the heart is in the right hemithorax and the left sided chambers are on the right, the left ventricular apex being palpable on the right side. Dextrocardia may be associated with situs inversus in which the other organs such as liver and stomach are also

reversed, i.e. liver is on the left and stomach is on the right. Such dextrocardias are termed mirror-image dextrocardias. This condition is generally asymptomatic and not associated with other serious congenital anomalies.

In dextrocardia with situs solitus the abdominal organs are not reversed. Such dextrocardias are usually associated with several other congenital defects.

Dextroversion is the condition in which the viscera, atria and aortic arch are in the normal position, but the cardiac apex is on the right.

Dextrocardia gives rise to diagnostic findings in the skiagram and ECG (Fig. 118.3). Dextrocardia has to be differentiated from dextroposition of the heart in which the heart is shifted to the right hemithorax due to lesions such as pulmonary fibrosis, pleural effusion or thoracic skeletal abnormalities.

Visceral heterotaxy can occur with right or left isomerism. The term isomerism refers to bilateral similarity, if not equivalence of structures (Figs 118.1 and 118.2).

Right Isomerism—Features

- 1. Right Isomerism
 - a. Bilateral morphologic right bronchi
 - b. Bilateral morphologic right atrial appendages
- 2. Visceral heterotaxy
 - a. Liver: transverse
 - b. Stomach: left sided, right sided or rarely midline
 - c. Lungs: trilobed
- 3. Heart: Dextrocardia (common)
- 4. Asplenia common but not invariable

Left Isomerism—Features

- 1. Left isomerism
 - a. Bilateral morphologic left bronchi
 - b. Bilateral morphologic left atrial appendages

Fig. 118.1: Dextrocardia with situs inversus

Note: The heart is in the right hemithorax with apex to the right. The stomach (G) is under the right hemi-diaphragm which is at the lower level than the left. The liver is on the left side (situs inversus). Associated anomalies are rare

Fig. 118.2: Dextrocardia with situs solitus

Heart is on the right with apex pointing to the right, stomach (G) is on the left, and liver is on the right. This anomaly is associated with complex malformations

Fig. 118.3: ECG — Dextrocardia (1) Standard leads (2) Right precordial leads
Note: (1) Inverted ‘P’ waves in lead I and aVL and upright ‘P’ in the other leads. (2) The pattern of lead I is a mirror image of the normal. The pattern in aVL resembles the normal pattern observed in lead aVR. (3) The precordial leads V₁ to V₆ show only S waves of decreasing amplitude without R waves. The normal transition from right ventricular to left ventricular pattern can be recorded from leads placed further on the right side V₃R to V₆R.

- 2. Visceral heterotaxy
 - a. Liver-transverse
 - b. Stomach right sided, occasionally left sided but not midline
 - c. Lungs bilobed
- 3. Heart
 - a. Levocardia (common)
- 4. Polysplenia

Congenital Aortic Stenosis

Obstruction to the left ventricular outflow tract may be valvular, subvalvular, or supravalvular, the valvular form being the commonest. The stenotic aortic valve is most often bicuspid, although tricuspid aortic valve may also become stenotic in the younger age group.

Morphology of congenital valvular aortic stenosis	
Bicuspid valve	44%
Bicuspid valve with rudimentary commissure on one cusp	23%
Tricuspid valve	30%
Unicuspid valve	3%

Mild cases are asymptomatic and are picked up during routine examination or when complications occur. Moderately severe and severe cases present with exertional syncope, effort angina or cardiac failure. Aortic stenosis predisposes to infective endocarditis. Unicuspid valve is

inherently stenotic even at birth and this is the one presenting with aortic stenosis in the newborn. Bicuspid valves develop degenerative changes early and lead to stenosis on an average by 20-30 years of life.

Critical aortic stenosis produces congestive heart failure in infancy. In moderate and severe cases the pulse is characteristically small in volume with slow-rising ascending limb of the pulse wave and pulse pressure less than 20 mm Hg. The heart may not be enlarged, but the apex beat is heaving in nature. In most of the cases there is a systolic thrill, best felt in the right upper sternal border as well as over the carotids. Auscultation reveals ejection systolic murmur preceded by a constant ejection click, best audible over the right upper sternal border, and conducted to the carotids. In many cases the murmur and click are very well audible over the cardiac apex also. An early diastolic murmur of associated mild aortic regurgitation may also be heard in some cases. In mild cases of aortic stenosis the murmur may be present without any abnormality in the pulse or apex beat.

The presence of a constant ejection click suggests that the stenosis is at valvular level. This is associated with poststenotic dilatation of the ascending aorta. Both these features are absent in subvalvular stenosis.

Congenital subvalvular aortic stenosis may take the form of a discrete membrane or a tunnel type of obstruction.

Supravalvular aortic stenosis may be familial, associated with a characteristic facies, hypercalcemia, and mental retardation (**Williams' syndrome**). In supravalvular aortic stenosis, the jet of blood flow may be directed towards the innominate artery resulting in a higher pulse volume and higher blood pressure in the right arm than on the left.

Treatment: Mild cases have been treated with balloon valvotomy, though the results are less satisfactory when compared to balloon dilation of the pulmonary valve. In more severe cases open valvotomy or valve replacement may be required. Substituting the pulmonary valve for the aortic valve is done in the innovative Ross procedure. Low pressure pulmonary circulation can be supported by either autologous pericardial valve or rarely a homograft valve.

Coarctation of Aorta

This condition is characterized by obstruction of the aorta in the region of the ductus arteriosus or ligamentum arteriosum just distal to the left subclavian artery. Very rarely it may occur at a more proximal site in the arch or in abdominal aorta. In the majority of cases coarctation occurs as a discrete infolding of the dorsal aortic wall. In about 20% of cases coarctation exists as the only abnormality, whereas the rest have associated abnormalities like bicuspid aortic valve, patent ductus arteriosus, ventricular septal defect, atrial septal defect, mitral stenosis, mitral regurgitation, and transposition of great vessels. Bicuspid aortic valve is the commonest associated anomaly, majority of them being hemodynamically insignificant. When coarctation is severe, arterial blood from the proximal part is taken to the distal part through collateral circulation which develops from the intercostal arteries and the subclavian system. **Taussig-Bing anomaly** refers to double outlet right ventricle with sub pulmonic VSD and has a good association with coarctation. **Shone's complex** consist of coarctation with supramitral membrane and subaortic or aortic valve obstruction. In Turner's syndrome, coarctation is a typical manifestation. Coarctation is uncommon with cyanotic congenital heart diseases with large VSD like tetralogy of Fallot and pulmonary atresia since these conditions lead to dilatation of the aortic root and good growth of the isthmus.

Classification

1. Simple — without PDA
— with PDA
2. Complex—associated with
VSD
Valvular aortic stenosis
Combination (VSD + AS)

Clinical features: Approximately 50% of coarctation present in the neonatal period, many of them with varying

degrees of heart failure. Those who present during adolescence and adulthood give history of intermittent claudication of legs, mild fatigue, and dyspnea. In older individuals it may present as congestive heart failure. Disproportionate development of the arms, chest, and shoulder girdle compared to the legs may be noted in some patients. The upper limb pulses, suprasternal pulse, and carotid pulse are prominent and the blood pressure is high in the arms. The femoral pulse is felt feebly and is delayed. The apex beat may be heaving in nature. Usually there is an ejection systolic murmur with a constant ejection click, best heard over the right sternal border. This is caused by the associated bicuspid aortic valve. Sometimes, there may be an early diastolic murmur of aortic incompetence. The collaterals may be visible and palpable over the back of the chest, around the scapula, and sometimes in front of the chest. Continuous murmur may be produced from the site of coarctation or from the collaterals.

Diagnosis: The diagnosis should be suspected by the finding of absence or delay of the femoral pulses, presence of high blood pressure in the upper limbs, low blood pressure in the lower limbs, and the cardiac abnormalities.

Investigations

ECG shows left ventricular hypertrophy.

X-ray shows localized indentation of aorta at coarctation site with dilatation above and below (3 sign). X-ray also shows rib notching (Fig. 118.4). On barium swallow, esophageal indentation due to aortic dilatation occurs (E sign, reverse 3 sign).

Echocardiogram: Suprasternal view shows narrowing of aorta just beyond left subclavian artery. Colour flow localizes the site of narrowing. Continuous wave Doppler can assess gradient across coarctation.

Fig. 118.4: Coarctation of the aorta. Note 3 sign on the aorta—'x', and rib notching (arrows)

Catheterization can be avoided with a good echo study. However, it is indicated for precise definition of anatomy of coarctation site, assessment of ductus and collaterals and for assessment of other intracardiac lesions (Fig. 118.5).

Management

1. Medical management: This includes stabilization of infants with cardiac failure and infective endocarditis prophylaxis. Neonatal coarctation is a surgical emergency. It manifests as a ductus dependent systemic circulation keeping the patent ductus arteriosus open. Prostaglandin infusion helps to stabilize the child for transport to a neonatal cardiac surgical unit.
2. Surgery is the preferred treatment in native coarctation. Surgical methods include resection and end-to-end anastomosis, prosthetic patch aortoplasty and subclavian flap aortoplasty. Ideal time for surgery is between 3 and 5 years. Surgery done less than 3 years of age results in restenosis and beyond 5 years of age chances of residual hypertension are more.
3. Catheter based techniques: Balloon angioplasty is the first choice in postsurgical restenosis. In native coarctation, angioplasty carries a high risk of aneurysm development and rupture. In postsurgical cases due to surrounding fibrosis chances of rupture are less. The balloon size is chosen to equal the diameter of aortic isthmus just distal to left subclavian artery and inflation time is limited to 10 seconds.
4. Stenting of the coarctation is at present the procedure of choice in adolescence and adults. Palmaz-Schatz stents, Jo-Med stents and CP stents are the favourite stents. Presently all these stents are compatible with MRI examination. Postsurgical aneurysm rupture of the aorta during dilatation and simultaneous closure

Fig. 118.5: Descending aortogram showing coarctation

Fig. 118.6: Metallic stent after its deployment at the coarctation using a balloon

of ductus can all be undertaken with the covered CP stents. These stents are usually deployed under fluoroscopic guidance under anesthesia after crossing the coarctation segment using suitable guide catheters. Intermediate term follow-up results are favourable. Rarely self expanding nitinol stents are also used (Fig. 118.6).

Pulmonary Stenosis

Right ventricular outflow obstruction may be valvar, supra-ventricular or sub-ventricular. As an isolated anomaly pulmonary valve stenosis is the commonest type of right ventricular outflow obstruction. This is characterized by a thick valve with fused commissures and central or eccentric opening. The valve demonstrates characteristic doming with varying degrees of restriction of opening during systole. The main pulmonary artery shows post-stenotic dilatation with prominence of the left pulmonary artery. Mild cases may show only an ejection systolic murmur, best audible in the left upper sternal border. This is preceded by phasic (inconstant) ejection click which is more prominent during expiration and less prominent during inspiration. In moderate and severe cases the murmur is harsh and may be associated with thrill. The ejection click becomes closer to the first heart sound and the pulmonary second sound becomes feeble and delayed. There is right ventricular hypertrophy as evidenced by left parasternal heave. The jugular venous pulse shows prominent 'a' wave due to rise of right atrial pressure. In severe cases the right ventricular and right atrial pressures become elevated and a right to left shunt may develop through a stretched patent foramen ovale. In this stage right ventricular failure may develop.

Mild cases usually do not progress further. Moderate and severe cases require valvotomy. Critical pulmonary stenosis is associated with the risk of sudden death in the pediatric age group and, therefore, surgery should not be delayed if the diagnosis is confirmed. Balloon valvuloplasty has replaced surgical therapy as the first approach. Via the femoral vein a balloon catheter is advanced into the right side of heart and then across the pulmonary valve. Two types of balloons are available, Mannsfield and Tyshak. Balloon is inflated to about 20-40% greater size than the measured pulmonary annulus thus ripping the valve. If measured pulmonary annulus is more than 20 mm double balloon technique is used. Inflation time is restricted to 10 seconds. A dysplastic valve as in the case of Noonan's syndrome is not suitable for balloon valvuloplasty. Presence of other cardiac lesions which cannot be tackled by catheter technique, puts the patient into surgical group. Significant reduction of gradient across pulmonary valve is seen immediately and is maintained long term. Major complications reported are less than 0.6%. Predictors of suboptimal results include dysplastic valve, complex valve morphology, age of child at dilatation less than 2 years and use of balloon:annulus ratio less than one.

Left to Right Shunt Lesions

ATRIAL SEPTAL DEFECT (ASD)

This is the most common congenital heart disease found in the adults. This is characterized by the presence of one or more defects in the interatrial septum. Based on the developmental defect there are mainly three types.

1. Ostium secundum
2. Ostium primum
3. Sinus venosus

Ostium secundum defect occurs in the region of the fossa ovalis and this is the most common. This results from the maldevelopment of the septum secundum. The only abnormality is the presence of the atrial septal defect.

Ostium primum defect is the result of abnormal development of the endocardial cushion. The defect is in the lower portion of the interatrial septum. This may be associated with cleft mitral or tricuspid valve resulting in their incompetence.

Sinus venosus type of defect occurs in the upper portion of the interatrial septum. It is due to the abnormality of development of the upper part of the interatrial septum and it is associated with anomalous connection of one or more pulmonary veins to the superior vena cava or right atrium.

Hemodynamics

In ASD the blood is shunted from left atrium to right atrium and then to the right ventricle. The right ventricular

output and the pulmonary blood flow are considerably increased. This leads to progressive enlargement of the right atrium, right ventricle, and pulmonary arteries. Even though pressures are equal, shunt occurs from left atrium to right atrium as right ventricle is more compliant than left ventricle. As there is no pressure difference shunt *per se* does not produce a murmur.

Atrial septal defect is found more in females. This may occur as an isolated anomaly or in association with other intracardiac anomalies like pulmonic stenosis or ventricular septal defect. Rheumatic mitral stenosis may coexist with ASD (Lutembacher's syndrome).

CLINICAL FEATURES

Palpitation and recurrent respiratory infection are the usual symptoms. Effort intolerance usually develops in the third and fourth decades and thereafter features of congestive heart failure develop. Clinically there is cardiac enlargement with hyperactive precordium as a result of right ventricular enlargement. Pulmonary artery pulsation is felt in the left second intercostal space. In some cases a systolic thrill may be felt over the upper part of the sternum on the left. A pulmonic systolic murmur may be heard. The murmur and the thrill are produced by increased blood flow through the pulmonary valve. The second sound in the pulmonary area is widely split since the pulmonic valve closure is delayed by the larger volume of blood to be ejected by the right ventricle. During inspiration more venacaval blood flows into the right side of the heart and during expiration more of left atrial blood flows through the shunt. These phenomena account for the ejection of the same quantity of blood across the pulmonary valve during inspiration and expiration. Therefore, the split of the pulmonary second sound remains fixed. The **auscultatory hallmark is wide fixed split of second heart sound**.

Increased flow across the tricuspid valve during diastole may produce a tricuspid mid-diastolic murmur, best heard along the left lower sternal border. This is usually preceded by a right ventricular third heart sound.

Severity of shunt is assessed by cardiomegaly, presence of RVS₃, and tricuspid mid-diastolic murmur. A thrill palpable in pulmonary area can occur in large shunt or with associated mitral stenosis or associated pulmonary stenosis.

Course and prognosis: Small atrial septal defect may remain asymptomatic. Small atrial septal defects below 2 mms are common in infants upto one year. They are known to close spontaneously or remain as persistent foramen ovale. Persistent foramen ovale, can be identified in about 25% of normal hearts in various autopsy studies. Recently they have been implicated in variety of problems like migraine, paradoxical embolism causing **stroke, decompression sickness** and **orthodeoxia** (development of desaturation on lying down). Attempts

to close these defects with **amplatzer PFO devices** to prevent stroke and TIAs are under trial.

Defects more than 4 mm in infancy have been noted to become larger in natural history studies. When the shunt is large, the right-sided chambers progressively enlarge. Pulmonary hypertension develops in course of time. The pulmonary pressure may be elevated to high levels and the same is reflected in the right ventricle and right atrium. When right atrial pressure exceeds that of the left atrium, the blood flow is reversed and this leads to the development of central cyanosis. This phenomenon is called **Eisenmenger's syndrome**. Pulmonary hypertension and reversal of shunt occurs in less than 10% patients. Primum type of ASD carries a poorer prognosis than the secundum type.

Other complications include paradoxical embolism, arrhythmias like atrial fibrillation and very rarely infective endocarditis.

Investigations

ECG: Shows rsR' pattern in lead V1, right ventricular hypertrophy and right axis deviation. Left axis deviation is seen in Ostium Primum ASD. PR interval prolongation is seen in familial types of ASD and in ostium primum defects.

Chest X-ray: Shows cardiomegaly, enlargement of right atrium without the engorgement of the superior vena cava, increased pulmonary vascularity as evidenced by multiple end on vessels and enlargement of main pulmonary artery, right pulmonary artery and left pulmonary artery if the shunt is large (Fig. 118.7).

Echo with colour Doppler: Can diagnose the type of ASD, measure the size of ASD, note the direction of shunt and quantify the shunt. The suitability for device closure can also be assessed by echo. Pulmonary venous drainage

can also be visualised and anomalous pulmonary venous drainage can be made out. Doppler with colour mapping is comparable with angiographic visualization of intracardiac shunting.

Cardiac catheterization: Generally this is not required for preoperative diagnosis. It is indicated for the following reasons (i) in adults, to assess pulmonary vascular resistance and hence to decide on surgery, (ii) to assess coronary arteries above the age of 40, when corrective surgery is contemplated, (iii) if any disparity between clinical and echo quantification of shunt exists. Catheterization will show increase in oxygen saturation from superior vena cava to right atrium. Left atrium can be entered from right atrium through the ASD and the pressures in the two chambers are equal can be measured.

Management

Medical: ASD by itself has very low risk for infective endocarditis. If associated mitral regurgitation is present, infective endocarditis prophylaxis is advised. In late stages as the patient goes in for cardiac failure, digoxin and diuretics are to be used.

Surgical: Any shunt more than 1.5:1 should be closed. In adults surgery is advised only if pulmonary vascular resistance is low. Median sternotomy, right thoracotomy or atrial wall approach can be used. ASD closure is done by suturing the edges of ASD directly or by using pericardial patch or prosthetic material.

Catheter based techniques: Various devices have been used. Previously used devices include double umbrella device by King and Mills, Rashkind single umbrella device (first generation); Lock clamshell device, ASDOS, Das Angel Wings (second generation).

Presently used devices are of the third generation and include Amplatzer device and Cardioseal. Advantages of new devices are smaller size of the delivery system. Amplatzer device is made of Nitinol which after extrusion from its sheath, forms into a double button with a connecting waist, the left atrial button being larger than the right. Careful sizing of the defect using a balloon catheter by pulling it from left atrium to right atrium is to be done before the procedure. Prerequisites for device closure include (i) ostium secundum location, (ii) small and moderate sized defects (iii) margins of at least 5 mm all around the defect, and (iv) distinctly away from A-V valves. Success of Amplatzer device is more than 90% and residual shunt is reported only in 1.2-6% cases. Presence of atrial septal aneurysm, if it can not be contained inside the device is a contraindication to its use.

The approximate cost of Amplatzer device will come to Rs. 1,200,00 in India. More than 25,000 devices have been successfully deployed all over the world since 1995. In the Amplatzer registry about 50 life-threatening complications have been documented including complete

13

heartblock, device thrombus, air embolisation, erosion of device to adjacent structures, and infective endocarditis (Figs 118.8 and 118.9).

Ventricular Septal Defect (VSD)

This is the most common congenital heart disease in the pediatric age group. This is characterized by one or more defects in the ventricular septum.

Types

1. 80% perimembranous with variable extension into the inlet, trabecular or outlet sections of muscular septum.
2. 5-7% subarterial defects.
3. 5-8% inlet defects.
4. Muscular septum defects.

Crista is considered to be a part of the right ventricle, which demarcates the outflow tract from the body.

Infracristal type of defects is the commonest. Ventricular septal defect may occur as an isolated anomaly in the majority, or in association with other cardiac anomalies such as ASD, right ventricular outflow obstruction, coarctation of aorta and transposition of great vessels. The blood flows from left ventricle to the right and then to the pulmonary circulation. This leads on to enlargement of left and right ventricles, pulmonary artery, and the left atrium.

Large VSDs can lead to congestive cardiac failure in infancy. Recurrent respiratory infection and failure to thrive may also be noticed. Those who survive develop varying degrees of pulmonary hypertension. Small VSDs are asymptomatic and they are detected on routine examination. Moderate VSDs present with palpitation and recurrent respiratory infections.

CLINICAL FEATURES

Small VSDs are characterized by a harsh pansystolic murmur associated with thrill, best heard in the left third and fourth intercostal spaces. Moderate and large VSDs produce pansystolic murmur and cardiac enlargement. The apex beat is forcible with hyperactive precordium. Pulmonary artery pulsation may be felt. There may be left ventricular third heart sound and mid-diastolic murmur heard over the cardiac apex suggestive of increased blood flow across the mitral valve.

Severity: Left ventricular third heart sound, mid-diastolic murmur over mitral area and cardiomegaly indicate a large shunt.

Complications may occur. These include congestive cardiac failure, Eisenmenger's syndrome, infective endocarditis and aortic incompetence due to prolapse of the aortic valve cusp through the defect.

Investigations

ECG: Can be normal with small defects or show biventricular involvement with large defects.

X-ray: With small defects, heart size and pulmonary blood flow are normal. With large defects, moderate to marked enlargement of heart, prominent main pulmonary artery and pulmonary plethora are seen. There is no right atrial enlargement unlike ASD and unlike PDA, the aorta is not prominent.

Echocardiogram: Visualization of the site of VSD and size measurement are possible with 2D-Echo. Colour flow mapping can identify small muscular defects. Continuous wave Doppler can detect the pressure gradient between the two ventricles and from this RV systolic pressure can be derived.

Catheterisation: Shows increase in oxygen saturation at the right ventricular level. With large defects right ventricular and pulmonary artery pressures are elevated.

Left ventricular angiogram delineates the number of defects and the exact site and size of the defect.

MANAGEMENT

Medical: This includes infective endocarditis (IE) prophylaxis and treatment of cardiac failure.

Surgical: Surgery is to be done between 2-5 years of age if shunt is more than 1.5:1. Earlier surgery in infancy is indicated if the child remains symptomatic despite medications or the pulmonary artery pressure shows elevation on follow up. Transatrial and transventricular approaches are utilized for VSD closure.

Catheter based techniques: VSD closure has been attempted with double umbrella device. The catheter has to be passed across interatrial septum and mitral valve into left ventricle and from there across the ventricular septal defect into right ventricle. This procedure is yet to achieve wide popularity. The more popular method at present is to access the VSD by an arterio venous loop. This loop is created by passing a balloon catheter through the aorta into left ventricle. This balloon floats along with the flow through the VSD into the pulmonary artery. Then a guide wire is passed through the balloon and is snared from the venous side. This continuous guide wire from the venous to the arterial end allows smooth passage of variety of large sheaths across the VSD from the venous end through which the VSD closure devices can be positioned. The difficulty in positioning a device in the subaortic position without touching the aortic valve is being overcome by eccentric VSD devices. Larger VSDs in children pose a challenge to both the surgeon as well as the interventional cardiologist. Hence hybrid procedures are adopted where, in the surgical theatre, the surgeon exposes the heart and under transesophageal echo guidance large devices can be positioned to achieve good closure. The surgeon helps the interventionist in putting an appropriate large sheath into the heart in between purse string sutures, which is otherwise impossible in small children either by venous or arterial access. The procedure time is shortened and cardiopulmonary bypass is avoided for the surgeon.

Patent Ductus Arteriosus (PDA)

Embryologically the ductus arteriosus is the posterior part of the persistent left sixth aortic arch. In the fetus it allows the egress of blood pumped from the right ventricle into the pulmonary trunk to the descending aorta bypassing the lungs which are non-functional. Normally, as the lungs get aerated after birth, functional closure of the ductus occurs in 24 h and anatomical closure within 1-2 weeks after delivery. Patency of the ductus after birth results in the flow of blood from the aorta to the pulmonary artery since the pulmonary artery pressure is lower. The aortic end of the ductus lies beyond the origin of the left

subclavian artery and the pulmonary end is located immediately to the left of the bifurcation of the pulmonary trunk. In the early stages of the disease blood from the aorta flows to the pulmonary artery throughout systole and diastole. When pulmonary hypertension develops this blood flow diminishes, initially the diastolic flow. The blood flow may be reversed when **Eisenmenger's syndrome** develops. Patent ductus arteriosus is more common in females and in premature infants. It may occur as an isolated lesion or as part of a complex anomaly with other congenital heart diseases. Maternal rubella is associated with increased incidence of PDA in the child. Clinical features depend upon the amount of left to right shunt through the ductus.

CLINICAL FEATURES

Many cases remain asymptomatic, even though the mother would have detected the murmur and thrill in the child. Palpitation and exertional dyspnea set in if the ductus is large and pulmonary hypertension develops. Later, congestive heart failure supervenes. The pulse may be collapsing in character. There is left ventricular type of cardiac enlargement. Cases with pulmonary hypertension may reveal left parasternal heave. In the vast majority of cases a continuous thrill may be felt over the left second intercostal space outside the sternal border. The most characteristic auscultatory finding is the presence of a continuous machinery type of murmur, audible most loudly over the left upper sternal border. The murmur is louder during systole and less so during diastole. The systolic phase is interrupted by multiple systolic clicks. Less commonly, large shunts may be accompanied by left ventricular third heart sound followed by a decrescendo mid-diastolic murmur best heard over the apex beat. This indicates large blood flow across the mitral valve. The second heart sound is usually immersed in the murmur. In cases with pulmonary hypertension the pulmonic component becomes louder and well-heard.

Course and prognosis: Mild cases do not impair cardiac function and they may remain asymptomatic. Large ductus may present with congestive heart failure in infancy. Those cases which recover from heart failure may develop pulmonary hypertension later in life. Large left to right shunt leads to enlargement of left atrium, left ventricle, aorta and pulmonary artery.

Complications: Cardiac failure, infective endocarditis, paradoxical embolism and Eisenmenger's syndrome may complicate PDA.

Investigations

ECG: Left ventricular hypertrophy is noted with large shunts.

X-ray chest: It shows cardiomegaly, pulmonary plethora, prominent aortic arch and sometimes ductal calcification.

Echocardiogram: Colour flow mapping shows shunt flow into left pulmonary artery. Using Doppler the gradients in systole and diastole between aorta and pulmonary artery can be calculated and this gives an idea regarding pulmonary artery pressures.

Catheterization: This is mostly done as a pre-device-closure procedure. Catheterization shows oxygen step up in pulmonary artery and sometimes catheter passes from pulmonary artery, through ductus to the aorta. Aortic angiograms demonstrate the length, diameter and any tortuosity of the ductus and help to plan device closure (Fig. 118.10).

MANAGEMENT

Closure of PDA is advised in all cases due to high risk of infective endocarditis.

Medical: Indomethacin 0.1 mg/kg body weight, can be given in the neonatal period for ductus closure. It acts by inhibiting prostaglandin. Other medical measures include correction of cardiac failure and infective endocarditis prophylaxis.

Surgical closure: Is resorted to if the type of PDA precludes device closure.

Catheter based techniques: A ductus, which is less than 10 mm wide and, has a roomy ampulla and is not very tortuous can be occluded by *Gianturco coil*. Ductus is crossed from aortic to pulmonary artery side or vice versa and the spring coil is deployed with the intent to leave at least one loop on pulmonary artery side and at least three loops on aortic side. Complete closure is reported in 93% cases. Amplatzer ductal occluder is a conical device, that is self-expanding at aortic end and useful for large ductus.

Eisenmenger's Syndrome

Pulmonary hypertension may develop at variable periods of time in congenital heart disease with initial left to right shunt. When severe pulmonary hypertension develops the volume of left to right shunt diminishes. As the pulmonary artery pressure increases, the shunt becomes bidirectional and finally the flow is only from right to left. When the right to left shunt produces cyanosis, the condition is designated as Eisenmenger's syndrome. The common congenital anomalies which cause Eisenmenger's syndrome are ventricular septal defect, patent ductus arteriosus, and atrial septal defect. The VSD and PDA give rise to Eisenmenger's syndrome in childhood itself whereas ASD gives rise to this picture usually after the third decade of life.

Clinical features: The clinical hallmark of Eisenmenger's syndrome is the combination of central cyanosis, digital clubbing, and pulmonary hypertension. In some cases the central cyanosis may be mild and not obvious at rest. Exercise unmasks the cyanosis in such cases. In PDA with Eisenmenger's syndrome, the cyanosis and clubbing are present only in the lower limbs (*called differential cyanosis and clubbing*) because the patent ductus joins the aorta after the origin of the left subclavian artery so that the desaturated blood goes only to the lower limbs.

The second heart sound is the key to diagnosis of the underlying shunt lesion in Eisenmenger's syndrome. ASD-Eisenmenger is characterized by persistence of wide and fixed splitting. PDA is characterized by normally split S2 and VSD by single S2 when they develop Eisenmenger's syndrome.

Course and prognosis: Once Eisenmenger's syndrome develops, the symptoms related to left to right shunt

Fig. 118.10: Aortogram showing the ductus and the positioning of coils using a bioprobe inserted via the femoral vein right ventricle and pulmonary artery to occlude the ductus

disappear. At this stage easy fatigability and tiredness dominate the clinical picture. Once congestive heart failure sets in, steady deterioration occurs culminating in death within 3-5 years. Heart lung transplantation or single lung transplant with appropriate surgical correction of the cardiac lesion are the treatment options available at advanced centres.

Congenital Cyanotic Heart Disease

These are all characterized by cyanosis from birth. The common congenital cyanotic heart diseases are associated with reduced pulmonary flow, the commonest being tetralogy of Fallot (TOF).

Tetralogy of Fallot (TOF)

In this condition there is pulmonary stenosis, ventricular septal defect, overriding of the aorta, and right ventricular hypertrophy. The essential abnormality in TOF is obstruction to the right ventricular outflow associated with ventricular septal defect (VSD). The perimembranous VSD is responsible for the aortic override. Right ventricular outflow obstruction leads to right ventricular hypertrophy. In two-thirds of the cases the right ventricular obstruction is caused by infundibular stenosis and in one-third it is caused by pulmonary valvar stenosis. Annular or supra-valvular stenosis may coexist in some.

The right ventricular outflow tract (RVOT) obstruction causes reduction in pulmonary blood flow. Arterial desaturation occurs because of right to left shunt across the VSD. Both right and left ventricular blood enter the aorta.

CLINICAL FEATURES

The main symptoms are cyanotic spells, squatting, and exertional dyspnea. The age at which the symptoms appear depends upon the severity of right ventricular outflow obstruction. However, tetralogy of Fallot seldom presents with cyanosis at birth. Cyanotic spells usually occur after the age of three to six months when the child becomes increasingly active. It is characterized by sudden onset of dyspnea, restlessness and increasing cyanosis. Irritability, incessant crying and hyperventilation are common in younger infants. Sometimes, such attacks may be fatal. Grown up children adopt the squatting position when they become breathless since they obtain relief in this posture.

Varying grades of central cyanosis and clubbing are detectable early. Palpation reveals normal-sized heart without left parasternal heave or pulmonary artery pulsation. This is often referred to as the “*silent precordium*”. In some cases a systolic thrill may be felt in the left upper sternal border. Auscultatory findings are the presence of an ejection systolic murmur over the pulmonary area and left sternal border. The second sound is mostly single and is loud. This is the aortic component. In milder cases the pulmonic component may also be

heard as a feeble sound. The murmur is caused by the right ventricular outflow tract obstruction. The length of the murmur bears an inverse relationship with the degree of RVOT obstruction. In some cases an aortic ejection click may be audible. In cases with severe RVOT obstruction, bronchopulmonary collaterals may develop in an attempt to increase the pulmonary blood flow. These give rise to the presence of continuous murmurs over the chest as well as along the paraspinal region.

Assessment of severity

1. Early onset of symptoms
2. Severe cyanosis
3. Squatting
4. Growth retardation
5. Short murmur
6. Soft murmur

Course and prognosis: This is the commonest cyanotic congenital heart disease which often survives into adolescence and adulthood. In severe cases frequent cyanotic spells occur in infancy and these may be fatal in some cases. TOF predisposes to infective endocarditis. Some cases may develop aortic regurgitation due to prolapse of the aortic cusp into the VSD. In adults with TOF, congestive heart failure may occur. Anemia, infective endocarditis, severe aortic regurgitation and hypertension are the associated conditions which tip these patients into heart failure.

Investigations

ECG: It shows right atrial overload, right ventricular hypertrophy (RVH), right axis deviation and early transition of R waves from lead V₁ to V₂.

X-ray: In classic cases the cardiac size is normal, pulmonary artery is not prominent, there is reduced pulmonary vascularity and the heart is boot shaped (Figs 118.11A and B).

Echocardiogram shows ventricular septal defect with aortic override, right ventricular outflow tract narrowing, pulmonary valve stenosis and also the size of the pulmonary arteries. Doppler evaluation can assess the gradient across right ventricular outflow tract.

Cardiac catheterization: It is useful to rule out coronary artery anomalies, assess the pulmonary artery size and presence of additional VSD if any.

MANAGEMENT

Medical: It includes prophylactic beta-blockers such as atenolol to prevent cyanotic spells and infective endocarditis prophylaxis. The dose of atenolol is 12.5 mg bd or tid.

Surgical: It includes palliative surgeries like **Blalock-Taussig (B-T) shunt** wherein subclavian artery is

Fig. 118.11A: Tetralogy of Fallot

Note: Normal heart size with upturned apex. Concavity at the site of the pulmonary artery. Lung vascularity is reduced. Aorta is left sided in the majority

Fig. 118.11B: Tetralogy of Fallot with right sided aortic arch
Note: Concave pulmonary artery segment, decreased lung vascularity and right sided aortic arch. This occurs in 20% of subjects

anastomosed to pulmonary artery. Modified B-T shunt using Goretex tube to connect subclavian artery to pulmonary artery and corrective surgery, i.e. intracardiac repair during which the RVOT obstruction is corrected by resection, VSD is closed and a trans-annular patch is placed across the pulmonary valve in selected cases.

If there are repeated cyanotic spells or failure to thrive, surgery may have to be undertaken in severely affected children even within the first six months of birth. The procedure of choice is total correction.

Catheter based techniques: Dilatation of pulmonary valve, and dilatation of pulmonary artery stenosis are tried using catheters. Closure of aortopulmonary collaterals using coils is also tried following intracardiac repair.

Pulmonary Atresia

This is characterized by total discontinuity between the right ventricle and the pulmonary artery. The obstruction may take different anatomical forms. These childrens present with cyanosis and reduced pulmonary flow early in infancy. Two types are recognized depending upon the presence or absence of VSD. Pulmonary atresia with VSD is essentially like the tetralogy of Fallot, but the RVOT obstruction is complete. Pulmonary atresia with intact ventricular septum has been divided into two types on the basis of right ventricular (RV) size. In the majority of cases the RV is of diminutive size and in a small percentage RV is of normal size. Blood flows into the pulmonary artery from the aorta though the ductus if it is patent, otherwise, through the bronchopulmonary collaterals. They usually present with progressive neonatal cyanosis, respiratory distress, and early death.

Untreated cases of pulmonary atresia die before the first year of life due to congestive heart failure. In severely cyanotic children, pulmonary blood flow can be increased by doing a *Blalock-Taussig shunt*, which is a palliative procedure. Definitive surgery is undertaken in those with good right ventricular function. The principle of surgical correction is to perform pulmonary valvotomy with a systemic-pulmonary shunt procedure. Trans-catheter perforation of the atretic pulmonary valve using laser and radiofrequency wires, followed by graded dilatation using balloons have achieved impressive results. Till good antegrade flow is achieved the ductus can be kept patent using either prostaglandin E₂ infusion or ductal stenting.

Tricuspid Atresia

Tricuspid atresia is a complex of several separate anatomic abnormalities. These are: (1) Atresia of the tricuspid valve; (2) defect in the inter-atrial septum; (3) hypoplasia of the sinus portion of right ventricle, and (4) usually a ventricular septal defect. The great vessels may be normally connected or transposed. The tricuspid valve is atretic and its location is marked by a dimple. The major clinical finding is moderate generalized cyanosis, often present from the first day of life. In cases with large pulmonary blood flow the left atrium and left ventricle will be dilated and infants present with congestive heart failure.

Severe cases of tricuspid atresia die in infancy due to congestive heart failure. In cyanotic children with small inter-atrial communication a balloon septostomy (creating a large orifice in the septum by using a suitable balloon catheter introduced percutaneously) can be done to allow more free mixing of blood in the atria and this improves the cyanosis. Definitive surgery is **Fontan's procedure** in which the right atrium is connected to the pulmonary artery by a conduit which increases pulmonary blood flow.

Another procedure introduced recently is total cavopulmonary connection in which the superior and inferior vena cavae are anastomosed to the pulmonary artery. The results are better than that of atriopulmonary anastomosis.

Complete Transposition of Great Vessels

Complete transposition of great vessels is the most common cardiac anomaly producing cyanosis in the newborn. The venous connections of the heart are normal, the ventricles occupy normal position, but the right ventricle is connected to aorta which is anterior and the left ventricle is connected to pulmonary artery which is posterior. The two circulations are parallel, and independent of each other. Right ventricle pumps blood into the aorta and this blood is returned by the systemic veins and the vena cavae into the right atrium. Left ventricle pumps blood into the pulmonary artery, which is returned by the pulmonary veins into the left atrium. Life is sustained by the mixing of blood returning from the pulmonary and the systemic veins through VSD, ASD, or PDA.

Clinical features: The condition presents with cyanosis and increased pulmonary blood flow and such cases lead on to congestive heart failure in infancy. Those who survive may develop pulmonary vascular disease. Unless emergency surgery is done, infants presenting with congestive cardiac failure invariably die. Patients with reduced pulmonary blood flow have better prognosis than those with increased blood flow (Fig. 118.12).

Surgical procedures commonly employed to save life	
Corrective surgery	Time
Anatomic repair (arterial switch) (Jatene)	Less than 2 weeks of age
Physiologic repair (atrial switch) (Mustard or Senning)	Neonatal period to 1 year of age
Palliative	
Balloon atrial septostomy	Less than 2 months of age
Blade atrial septostomy	More than 2 months of age
Palliative atrial switch	Other children

Treatment: As soon as the diagnosis is established, an emergency balloon septostomy is made in the inter-atrial septum. This permits flow of at least some oxygenated blood from the left atrium to the right sided chambers and aorta, thereby improving the oxygen saturation in systemic circulation. Keeping the ductus open using prostaglandins can stabilize the baby till it can be transported to a tertiary centre where septostomy is possible.

Later, depending upon the child's condition and availability of surgical expertise more radical procedures can be attempted.

Fig. 118.12: Chest X-ray—Transposition of great arteries
Note: (1) 'Egg on side' appearance of the heart, (2) Relatively narrow vascular pedicle, and (3) Increased pulmonary vascularity

- 1. An arterial switch operation is done in which the aorta is connected to the left ventricle and the pulmonary artery is connected to the right ventricle.
- 2. An alternate procedure which can be undertaken at the age of 6-12 months is to re-route the venous return intra-atrially so that blood from the pulmonary veins is redirected to reach the right ventricle and aorta, and the venacaval blood is redirected to reach the left ventricle and pulmonary artery.

Anomalous Pulmonary Venous Connection

This is also known as total anomalous pulmonary venous drainage. It is the condition in which all the four pulmonary veins enter the right atrium, or vena cava or other systemic veins. In the partial variety, one or more of these veins enter the right atrium (Fig. 118.13).

Fig. 118.13: Chest X-ray—Total anomalous pulmonary venous drainage (supra cardiac type)
Note: Figure of '8' configuration. Right border formed by SVC and left by the vertical vein — slight cardiomegaly and pulmonary plethora.

Often there is associated atrial septal defect. In total anomalous pulmonary venous drainage the site of entry of the pulmonary veins may be supradiaphragmatic (left superior vena cava, vertical vein, coronary sinus, right superior vena cava or right atrium) or infradiaphragmatic (portal vein, hepatic veins or inferior vena

cava). Varying degrees of pulmonary venous obstruction may exist.

The clinical picture is variable. Some may be cyanotic, others present with congestive heart failure from early life, yet others present a picture similar to atrial septal defect. Correction of the defects is by surgery.

Chronic Valvular Heart Disease

C.G. Bahuleyan

Chapter Summary

General Considerations 782
Mitral Stenosis (MS) 783
Mitral Regurgitation (MR) 788
Mitral Valve Prolapse (MVP) 790
Acquired Aortic Stenosis (AS) 791
Aortic Regurgitation (AR) 793
Tricuspid Valve Lesions 796
Acquired Lesions of the Pulmonary Valve 797

over four months or longer lead to cardiac valvular insufficiency, especially mild AR and MR.

Chronic valvular heart disease—etiology

- Rheumatic fever
- Congenital
- Ischemic heart disease
- Degenerative changes
- Infiltrative and storage diseases
- Heritable disorders of connective tissue, e.g.: Marfan's syndrome
- Collagen vascular diseases
- Rheumatoid disease
- Tumours of heart
- Infective causes
 - Infective endocarditis
 - Syphilis
 - Coxsackie B virus
- Miscellaneous causes
 - Trauma
 - Anticardiolipin antibody
 - Hypereosinophilic syndrome

13

GENERAL CONSIDERATIONS

At present in India rheumatic fever is the most common cause for chronic valvular heart disease. In several other countries the incidence is falling. The heart valves are inflamed in the rheumatic process. Approximately 40% of patients with acute rheumatic carditis develop chronic valvular lesions as sequelae. The incidence of rheumatic heart disease varies from 1.8-11.0/1000 school children in the school surveys conducted by Indian Council of Medical Research in different parts of India. Currently there is a decrease in the incidence of rheumatic fever in India. The mitral, aortic, tricuspid and pulmonary valves are affected in the order of frequency. In many cases valvular lesions are multiple. Very rarely all the four valves may be involved.

It has been recognized that appetite suppressant drugs such as fenfluramine, phenteramine and dexfenfluramine when taken alone or in combination for weight reduction

Recent evidence suggests that Coxsackie group B virus which causes carditis may also be involved in the genesis of chronic valvular heart disease. Other causes are syphilis, myxomatous degeneration occurring in Marfan's syndrome, congenital abnormalities of valves, direct infection by bacteria or other pathogens in infective endocarditis, sclerosis affecting the valves, and connective tissue disorders. All valvular heart diseases lead to hemodynamic disturbances in one or both the ventricles and often the atria as well. This is initially overcome by compensatory mechanism but ultimately they lead to

muscle dysfunction, congestive heart failure and sometimes, sudden death.

Mitral Stenosis (MS)

Rheumatic Fever

About 50% of patients with mitral stenosis give history suggestive of antecedent rheumatic fever or other rheumatic manifestations. Others may have subclinical episodes. In the developed countries MS was found to develop 7-10 years after the episode of rheumatic fever. In India, this interval is shorter (2-3 years). This may be a manifestation of the severe nature of the disease in Indian subjects. It is not uncommon to find fullfledged mitral stenosis in children (juvenile MS) (Refer also Section: 6 Chapter 37).

Pathology and pathophysiology: Stenosis results from the involvement of the cusps, commissures and the chordae of the mitral valve apparatus. The cusps become thickened and fibrosed, the commissures fuse and the chordae are thickened, shortened and fused. Anterior leaflet is deformed and there occurs restricted mobility of leaflets. These pathological processes cause distortion and narrowing of the mitral valve orifice. In long-standing cases calcification develops. Normal mitral valve orifice is 4-6 cm² in area. When it is reduced to 2.5 cm² auscultatory findings suggestive of mitral stenosis develop. Aperture size of 2.5-1.6 cm² is mild mitral stenosis and further reduction to 1.5-1.1 cm² leads to moderate stenosis. Valve area below 1 cm² is called severe mitral stenosis. A valve area of < 0.6 cm² is called pinhole MS.

In MS obstruction to left atrial blood entering the left ventricle leads to elevation of intra-atrial pressure. In severe cases, left atrial pressure is often 25-30 mm Hg. The left atrial pressure is reflected back in the pulmonary veins leading to pulmonary venous hypertension. Subsequently pulmonary arterial hypertension sets in. The symptoms and signs of pulmonary venous hypertension decreases when pulmonary arterial hypertension supervenes. Pulmonary arterial hypertension is the result of the following factors:

1. *Passive transmission of pulmonary venous pressure to the arteries (passive pulmonary hypertension);*
2. *Reflex spasm of the arterioles in response to the rise in left atrial and pulmonary venous pressure (reactive pulmonary hypertension);*
3. *Structural changes in the pulmonary vascular bed (obliterative pulmonary hypertension).*

Generally pulmonary artery hypertension correlates with severity of MS. But disproportionate elevation of PA pressure reaching up to systemic or suprasystemic pulmonary pressures may be seen, especially in Indian population.

Chronic pulmonary hypertension leads to right ventricular hypertrophy and eventually right ventricular failure and tricuspid regurgitation.

Clinical Features

Symptoms: Mild to moderate MS may remain asymptomatic and be picked up on routine examination. Severe MS is mostly symptomatic. However, patients may reduce their activities and remain asymptomatic. Commonest symptom is exertional dyspnea and its severity depends upon the degree of stenosis. Exertion leads to tachycardia and increased venous return. These may cause sudden rise in left atrial pressure on account of the narrowed mitral orifice. This in turn causes pulmonary venous engorgement and reduced compliance of the lung which manifests as *dyspnea*, *paroxysmal nocturnal dyspnea* and *orthopnea*. Occasionally this may lead on to *acute pulmonary edema*. Patients with severe pulmonary arterial hypertension and congestive heart failure may experience fatigue, loss of appetite, and occasionally chest pain.

Other common symptoms are *palpitations*, *cough*, and *hemoptysis*. **Hemoptysis is an early symptom** in significant MS. This may result from the following causes:

1. Rupture of dilated intrapulmonary bronchial veins due to rise in pulmonary venous pressure;
2. Recurrent bronchitis;
3. Acute pulmonary edema; and
4. Pulmonary infarction.

Hemoptysis tends to subside as pulmonary arterial hypertension develops.

In long-standing cases of mitral stenosis with gross enlargement of the left atrium, *atrial fibrillation* (AF) develops as a frequent complication. AF occurs in 40% of patients with MS. Incidence is related to duration as well as severity of MS. As age increases, incidence increases. In patients more than 50 years age, 80% are in AF. Atrial fibrillation predisposes to the formation of thrombi in the atria and further embolization. In the younger age groups MS is the commonest cause of atrial fibrillation. The symptoms are aggravated during pregnancy.

Physical signs: In tight MS the pulse is of low volume. Totally irregular pulse should suggest the presence of atrial fibrillation. Jugular venous pulse shows prominent 'a' wave in cases with pulmonary arterial hypertension and prominent 'v' wave in cases with tricuspid regurgitation. In patients with congestive heart failure the mean jugular venous pressure (JVP) is elevated. Signs of right ventricular hypertrophy may be evident. Pulmonic component of S2 may be palpable. The apex beat is characteristically tapping and it is usually felt in the normal position. A diastolic thrill may be palpable over the apex beat. This can be made more prominent by

palpating in the left lateral position with the breath held in expiration. Exercise accentuates the thrill and murmur. The *characteristic auscultatory features of MS are*: (1) Loud first heart sound; (2) mid-diastolic murmur with presystolic accentuation; and (3) the opening snap. The murmur is low-pitched, rough and rumbling in character, and it is preceded by the opening snap. The opening snap is a sharp sound (high-pitched) which is best heard over the apex beat, but conducted widely over the precordium, especially towards the sternum. The duration of the murmur and the interval between the second heart sound and opening snap (A2-OS) correlate with the severity of MS. A short A2-OS interval of < 0.08 sec. indicates severe MS, but converse need not be true. A loud and sharp S1 and OS indicate a pliable valve and hence suitability for balloon mitral valvotomy (BMV). When atrial fibrillation sets in, the presystolic accentuation of the murmur is generally lost in most cases. The pulmonary second sound is accentuated due to pulmonary arterial hypertension. Tricuspid regurgitation gives rise to systolic murmur best audible in left lower sternal border. Its hallmark is the accentuation with inspiration.

Radiology: Plain X-ray film shows features, generally referred to as “mitralization”. These include

- Straightening of the left border of the heart, which is often due to left atrial enlargement
- Prominent main pulmonary artery segment
- Enlargement of the left atrium, may be seen as elevation of left bronchus with widened carinal angle; enlarged left atrial appendages; a shadow with increased density having a convex border medial to right atrial border (shadow through shadow); or as a shadow extending outside the right atrial border (Figs 119.1 and 119.2).

Fig. 119.1: X-ray chest advanced mitral stenosis. Note: 1. Prominence of pulmonary artery segment (+) (previously referred to as pulmonary conus) 2. left atrial shadow within the right atrial border—arrowhead 3. cardiomegaly

Fig. 119.2: X-ray chest gross pulmonary hypertension etc. Note: (1) right ventricular pattern of cardiac enlargement (2) prominent pulmonary artery segment (3) moderate cardiomegaly

When the left atrium enlarges it bulges posteriorly leading to pressure on the esophagus. The indentation caused by the enlarged left atrium can be demonstrated by a barium swallow picture taken in the right anterior oblique (RAO) view (Fig. 119.3).

Calcification of the mitral valve, may be seen on X-ray by careful examination. Fluoroscopy using image intensifiers brings out calcification better. In a small number of cases the chest X-ray may even appear normal. Acute or chronic pulmonary edema can be seen in the

Fig. 119.3: X-ray chest with barium swallow – mitral stenosis. Note: The indentation caused by the left atrium on the barium filled esophagus—arrow

skigram as fluffy shadows radiating laterally from the hilum.

One of the early features of pulmonary venous hypertension is redistribution of blood flow. Blood vessels of the upper lobes dilate, the lower lobe vessel calibre remaining normal. Later all veins are affected.

Chronic venous congestion leads to collection of fluid in interlobar fissures and interlobar septa. The latter appears as **Kerley-B lines** which are dense, short straight, horizontal lines in the costophrenic angles (Fig. 119.4).

Since echocardiography is a much more reliable method to visualize the abnormal anatomy and the presence of atrial thrombi, the importance of radiological methods has come down.

Fig. 119.4: X-ray chest mitral stenosis: Kerley's B lines indicating chronic pulmonary venous hypertension (arrow)

Electrocardiogram (ECG): The ECG reveals left atrial enlargement in patient with sinus rhythm.

Features of left atrial enlargement includes.

- Longer duration of P wave (> 0.10 sec) with notching, the summit of the notches separated by > 0.03 sec.
- Biphasic P in V1 with P terminal force ≥ 0.04 mm sec.
- Leftward shift of P wave axis.
- Duration of P wave (Macruz index) > 1.6 of the PR segment

Right axis deviation and right ventricular hypertrophy are demonstrable in cases with pulmonary arterial hypertension. QRS axis correlates with severity of MS. When QRS axis is $0 \pm 60^\circ$ the mitral valve area (MVA) is $> 1.3 \text{ cm}^2$ and if $> +60^\circ$, MVA is $< 1.3 \text{ cm}^2$. Axis $> +150^\circ$ indicates PA pressures at systemic levels. Atrial fibrillation is a common complication in long-standing mitral stenosis (Fig. 119.5A).

Echocardiography: This is the most useful and reliable non-invasive method for evaluation of MS. Echocardiography can detect the structural details. Hemodynamic abnormality can be assessed by Doppler's echocardiography. Structural details of the mitral valve including calcification, thickening, mobility and subvalvular pathology can be assessed and presence of clot can be found. Mitral valve area can be measured and severity can be graded. Information on LA, RV and LV size and function can be obtained. A scoring system by Abascal *et al* has been found useful in assessing the suitability of mitral valve for balloon mitral valvotomy (BMV). This score evaluates 4 factors—leaflet mobility; leaflet thickening; calcification and degree of subvalvular fusion. A score of 8 or less indicates excellent results with BMV and score more than 10 indicates suboptimal results.

Transesophageal echocardiography provides better images of the left atrium and mitral valve and this is more sensitive in detecting LA thrombi (Figs 119.6 and 119.7).

Cardiac Catheterization

This is done only in the following indications:

- To assess coronary artery disease when mitral valve replacement is planned in persons > 40 years of age.
- To assess the hemodynamic changes due to associated mitral or aortic regurgitation (Fig. 119.8).
- To assess the extent of pulmonary vascular abnormality in cases where the clinical and echocardiographic findings are contradictory.

Course and prognosis: This depends on the severity of the stenosis. Though mild cases are generally asymptomatic, heavy exertion may lead to acute pulmonary edema. In moderate and severe cases the disability progressively increases. Pulmonary hypertension becomes established and progresses over many years leading to right ventricular hypertrophy and subsequently failure.

ATRIAL FIBRILLATION

Atrial fibrillation is a very frequent complication. AF is seen in 40% of patients. AF increases risk for embolism and incidence of embolism may be as high as 20%. It also increases mortality and morbidity.

The frequency of atrial fibrillation increases with the duration of the disease and with the enlargement of the left atrium. Onset of atrial fibrillation marks a downhill course in mitral stenosis. Clots form in the atria and, therefore, the risk of systemic and pulmonary embolism is high. **Systemic embolism** manifests as hemiplegia, other neurological deficits, embolism in the arteries of the limbs, mesenteric embolism, renal infarcts and embolism in other parts of the circulation. Clots arising from the right atrium give rise to multiple pulmonary emboli (see also Section 14 chapter 140).

Fig. 119.8: Mitral stenosis: cardiac catheterization; LV and LA pressures are superimposed, showing the gradient in diastole between LA and LV indicating high pressure in the atrium in mitral stenosis

Onset of atrial fibrillation further reduces cardiac output in cases of critical mitral stenosis and, therefore, precipitates cardiac failure. In mitral stenosis all forms of cardiac failure may develop. These include acute pulmonary edema, congestive heart failure and right sided heart failure.

Acute pulmonary edema may occur in unexpected circumstances and this may prove fatal, if emergency treatment is not given. The most common type of cardiac failure is **congestive heart failure** involving both sides of the circulation. Events such as pregnancy, parturition, systemic infection or unaccustomed exercise precipitate cardiac failure and this may be the mode of presentation in at least a few cases.

Infective endocarditis may complicate pure mitral stenosis, but the incidence is low. Combined lesions such as mitral stenosis and regurgitation are more prone to develop secondary infection. Ten years mortality in class III patients is 85% while none of class IV patients survive beyond 10 years. Majority of deaths are due to CHF (around 60%) and systemic embolism (around 20%).

TREATMENT

General measures: As such, mitral stenosis does not resolve through medical treatment. In a considerable proportion of cases, however, several coexistent remediable factors aggravate the disability. These include anemia, pulmonary eosinophilia, systemic and respiratory infections, obesity, thyrotoxicosis, and pregnancy. Proper management of these conditions may give considerable symptomatic relief.

Medical therapy includes:

1. Long-term anticoagulation in patients with AF with previous history of embolism and/or in those > 35 years with AF
2. Infective endocarditis prophylaxis
3. Rheumatic fever prophylaxis
4. To reduce heart rate using negative chronotropic drugs. In patients with AF, A-V blocking drugs like beta blockers, diltiazem, and verapamil or digoxin can reduce ventricular rate and reduce symptoms. Even in patients with sinus tachycardia, reducing the heart rate with beta blockers can reduce the pulmonary venous pressure and reduce the symptoms.
5. Diuretics are used if symptoms of pulmonary or systemic venous congestion develop.

Dose of drugs

Diltiazem—30-90 mg oral b.d or t.i.d

Verapamil—40-80 mg oral b.d or t.i.d

Digoxin—0.125-0.25 mg daily oral for 5 days a week continuously

Diuretics-frusemide—40 mg oral o.d in the morning

Ethacrynic acid—50-100 mg oral o.d

Triamterene—150-250 mg oral o.d

Catheter Interventions

Balloon Mitral Valvotomy (BMV): Inflatable balloon (Inoue, Accura) are introduced through the femoral vein and manipulated to enter LA by puncturing interatrial septum and positioned across the mitral valve and dilated.

This has now become the treatment of choice in patients with pliable valve. BMV should be considered in patients with $MVA \leq 1.5 \text{ cm}^2$ who are symptomatic class II and above or in asymptomatic patients if pulmonary artery systolic pressure is $> 50 \text{ mm Hg}$. BMV is now done in many centers in India, the approximate cost of which is Rs. 25,000. 5-7 year survival without mortality, repeat valvotomy or MVR is 80-90%. Most frequent complication is development of mitral regurgitation (MR).

Though initially only ideal pliable valves were taken-up for BMV, with technical improvements and expertise, especially with newer devices like **Cribier Commissurotome**, patients with calcification and mild to moderate MR are also being taken for BMV with good results.

Randomised clinical trials comparing BMV and surgical techniques like open mitral valvotomy and closed mitral valvotomy have shown no significant differences in terms of acute results, complication rates, clinical improvement and exercise time at 1 year and 3 years.

Surgical Treatment

1. **Closed mitral valvotomy (CMV):** In this technique, closed surgical commissurotomy is performed without cardiopulmonary bypass, using either transatrial or transventricular approach. Pliable noncalcified valves without subvalvular fusion achieve best results. CMV remains the surgical treatment of choice in many centers in India. In expert hands the mortality is less than 2% and the immediate results are excellent. Success of the procedure depends on the degree and quality of split of the valve achieved. Complications include improper split, tear of the valve with production of significant MR, and dislodgement of atrial clots with thromboembolism. Reported 5 years reoperation rate is 5-7%.
2. **Open mitral valvotomy (OMV):** In developed countries OMV is the surgical procedure of choice. OMV allows direct inspection of the valve under cardiopulmonary bypass so that commissures can be split under direct vision and other repair procedures can be undertaken. Mortality in different centers varies from 1-3%.
3. **Mitral valve replacement (MVR):** MVR is an accepted procedure for patients who are not candidates for surgical commissurotomy or BMV. Mortality is less than 5%. However postoperative complications of prosthetic valve like risk of anticoagulation, infective endocarditis, valve malfunction and embolic events may occur. The cost of open heart surgery varies from Rs 60,000 to 100,000.

Actuarial analysis done on Indian series has shown that 94%, 89.4%, 85% and 78.3% survived without need for second procedure after mitral valvotomy at 6, 12, 18 and 24 years follow-up. The restenosis rate ranged from

4.2-11.2 per 1000 patient years annually, on 5 and 15 years follow-up.

Pregnancy and Mitral Stenosis

MS is the most common rheumatic valvular lesion complicating pregnancy. Previously asymptomatic patients may present with symptoms. Pregnancy has to be avoided in patients with tight mitral stenosis, till the latter is corrected. If MS is diagnosed during middle or late pregnancy, and if symptoms persist despite medical management, surgical intervention may be necessary. If patient develops acute pulmonary edema refractory to medical therapy, emergency intervention is indicated. Risk to mother and fetus is quite acceptable, and hence intervention should not be delayed. BMV is very safe, the fetal and maternal mortality has been virtually nil.

MITRAL REGURGITATION (MR)

Syn: Mitral incompetence

The mitral valve apparatus consists of six components:

1. Valve cusps,
2. Mitral annulus,
3. Chordae tendinae,
4. Papillary muscles,
5. Portion of the left ventricle where the papillary muscles are implanted, and
6. Portion of the left atrium adjacent to the mitral annulus.

Defective function of one or more of these components may lead to inadequate coaptation of the mitral leaflets in systole giving rise to various degrees of mitral regurgitation. The common *etiological factors* of isolated mitral regurgitation are:

Mitral Regurgitation—Etiology
• Rheumatic • Congenital • Myxomatous degeneration • Ischemic heart disease • Cardiomyopathies • Infective endocarditis • Mitral annulus calcification • Trauma • Post-surgical/intervention • Collagen vascular disease • Abnormalities of collagen, e.g. Marfan's syndrome

At present, in many countries severe grades of mitral valve prolapse syndrome (MVP) is the commonest cause for mitral incompetence. In India also this is probably so, though rheumatic mitral incompetence is also quite common. On account of the wide prevalence of MVP among Indian subjects, it is described separately.

In rheumatic mitral regurgitation the valve leaflets are thickened, fibrosed and contracted. The chordae are also

shortened and fused. This process causes inadequate closure of the mitral leaflets in systole and hence MR results.

Ischemic heart disease leading to MR is commonly seen in males after the age of 40 years. Transient or permanent dysfunction of the papillary muscles leads to MR. Posterior papillary muscle is more commonly involved. Occasionally rupture of the papillary muscles may complicate myocardial infarction and this results in severe acute mitral regurgitation. Ischemia of the myocardium can result in transient dyskinesia of the portion of left ventricle where the papillary muscles are implanted and this may result in MR. Chronic ischemic heart disease with ventricular aneurysm may also be associated with MR.

Cardiomyopathy involving the left ventricle results in MR. It may be seen in all the three main types of cardiomyopathy (endomyocardial fibrosis, dilated cardiomyopathy and hypertrophic cardiomyopathy). Severity of mitral regurgitation varies widely in these cases. In infective endocarditis, rupture of chordae may occur and this gives rise to acute mitral regurgitation.

Hemodynamic changes: Left ventricular blood regurgitates into the left atrium during systole. The blood returning from the left atrium is larger in volume, leading to diastolic overfilling of the left ventricle. Since part of the blood flowing into the left ventricle shuttles between the left atrium and ventricle without participating in cardiac output the left ventricular work load is increased. The output into the aorta is maintained normal or near normal for considerable periods, but the systolic ejection time is shortened and this gives the characteristic rapid upstroke for the pulse. In mild cases the cardiac function is well compensated, but in severe cases gross left ventricular dilatation and hypertrophy develop. Ultimately left ventricular failure supervenes resulting in pulmonary hypertension and right ventricular failure as well. Fall in the ejection fraction below 60% and rise in the end systolic volume of left ventricle worsen the prognosis.

CLINICAL FEATURES

This depends on the severity of MR. Symptoms include palpitation, exertional dyspnea, weakness, and fatigue. The only abnormality in mild cases is the presence of a pansystolic murmur over the cardiac apex. In moderate and severe cases other features develop. The pulse of severe MR is described as pseudocollapsing with the pulse pressure above 40 mm Hg, it is normal in volume, but short in duration. Left ventricular enlargement is evidenced by the forcible apex beat which is shifted down and out. The characteristic murmur of MR is medium to high-pitched pansystolic murmur heard best over the apex beat. In cases where the anterior mitral leaflet is damaged,

the murmur is conducted to the axilla because the direction of the regurgitant stream from the left ventricle is towards the body of the left atrium. In cases with posterior leaflet involvement the murmur is conducted to the anterior chest and to the right upper sternal border because the regurgitant stream is directed towards the interatrial septum. In moderate and severe cases the murmur occupies the whole of systole and is moderately loud in intensity. Such cases show evidence of left ventricular enlargement. A left ventricular third heart sound is common. A mid-diastolic murmur which is decrescendo in character may be heard over the apex beat following the third heart sound. The third heart sound and the diastolic murmur indicate increased flow across the mitral valve. In severe cases evidence of pulmonary arterial hypertension may be evident.

Electrocardiogram is normal in mild cases. In moderate and severe cases left ventricular hypertrophy and left atrial enlargement are seen. The ECG may also help in determining the etiology of MR as in the case of ischemic heart disease, or cardiomyopathy (Fig. 119.5B).

Chest X-ray: Moderate and severe cases show left ventricular type of cardiac enlargement. The left atrium is also enlarged. Very large left atrium (giant left atrium) occurs in some of the severe cases. Evidence of pulmonary venous and arterial hypertension may be seen (Fig. 119.9).

Echocardiography—is useful in the assessment of etiology and severity of MR. It is also useful to decide the timing of surgery and suitability for surgical repair. With widespread use of Doppler and colour Doppler echocardiography, severity of MR can be assessed accurately, even though the quantitation remains only approximate. Information on ventricular function and

Fig. 119.9: X-ray chest showing cardiac enlargement of left ventricular type. Note: The convex left border with the apex reaching down. Note also left atrial enlargement

Fig. 119.10: 1. Upper panel showing colour Doppler echo with mitral regurgitation 2. lower panel showing continuous wave Doppler of mitral incompetence

pulmonary hemodynamics are obtainable from echo studies obviating the need for invasive investigations (Fig. 119.10).

Cardiac catheterization may be indicated in situations where associated coronary artery disease is to be assessed or coexisting valvular lesions are to be quantified.

Complications: These include congestive heart failure, atrial fibrillation and infective endocarditis. It should be remembered that MR is one of the best tolerated lesions and, therefore, may remain asymptomatic for several years.

Course and prognosis: Mild MR may remain asymptomatic. Unless complicated by infective endocarditis, it may not progress further. Moderate and severe cases become symptomatic. Development of pulmonary hypertension is relatively slow in MR and the pulmonary pressure tends to be lower than that seen in mitral stenosis. In India where rheumatic heart disease is still rampant, severe grades of pulmonary arterial hypertension are seen in MR. Severe MR usually progresses and results in congestive heart failure. Atrial fibrillation may develop as a complication, but embolic episodes are less frequent compared to mitral stenosis.

Acute severe MR is almost always a medical emergency and even with emergency treatment, the mortality is high. Common causes of acute severe MR are acute myocardial infarction with papillary muscle rupture, infective endocarditis, trauma and acute rheumatic fever.

TREATMENT

Medical: Treatment includes:

- Infective endocarditis prophylaxis
- Rheumatic fever prophylaxis
- Diuretics if pulmonary or systemic venous congestion occurs
- Treatment of congestive heart failure if present

e. Afterload reduction—In acute MR, IV nitroprusside to reduce afterload may be life-saving. In chronic MR, ACE inhibitors or oral hydralazine may be used which can reduce the severity of symptoms.

Surgical management: Mitral valve repair and valve replacement are the available options. Valve repair is indicated for less damaged valves. Valve replacement is needed for more grossly damaged and calcified valves. Both are open heart surgical procedures with surgical mortality of 1-2%. Valve replacement also necessitates long-term anticoagulation.

Optimal timing of surgery is important. Patients with asymptomatic MR should be followed up periodically to decide the progression of MR as well as detect onset of LV dysfunction. Aim is to give the corrective treatment before onset of LV dysfunction. Recently the mortality of MVR has declined in good centers to 1-2% so that surgical corrective treatment can be advised more liberally.

Indications for surgery in chronic MR

- Symptomatic severe MR
- Moderate MR with class III/IV symptoms
- Asymptomatic severe MR if
 - LVEF < 60%
 - LV end systolic diameter ≥ 4.5 cm
 - LV dp/dt ≤ 90 mmHg/s

COMBINATION OF MITRAL STENOSIS AND INCOMPETENCE

In a large number of cases of rheumatic affection of the mitral valve there is a combination of mitral stenosis and incompetence. Either may predominate. The clinical findings are modified depending upon the severity of each lesion. In such cases mitral valve replacement is the treatment of choice.

Mitral Valve Prolapse (MVP)

Syn: Midsystolic click syndrome, floppy valve syndrome, Barlow's syndrome

Prolapse of the mitral valve into the left atrial cavity during systole may develop in 5-10% of apparently healthy young adults. MVPS is a heterogenous condition. Strict echocardiographic criteria have been formulated for diagnosis. When these are applied, the frequency of this disorder is 3% in the general population. Most of the cases are sporadic, but autosomal dominant familial incidence is noted in a few. In most of them the abnormality remains asymptomatic till detected by routine medical examination or investigative procedures. In some the valve cusps show myxomatous degeneration which makes them redundant. Prolapse resulting from myxomatous degeneration of the valves and unaccompanied by other defects is called *primary mitral valve prolapse*. In classic MVP, the valves

are more thickened and the prolapse is more. In non-classic prolapse, thickening and the extent of prolapse are less. MVP may also be associated with other defects like atrial septal defect, tetralogy of Fallot, Marfan's syndrome, straight back syndrome, acute rheumatic fever, ischemic heart disease, pectus excavatum, Ebstein's anomaly, and hyperthyroidism. This type is called *secondary mitral valve prolapse*. MVP may exist with or without mitral regurgitation. The mechanism of myxomatous degeneration of the valve leaflets is not clear. The middle spongiosa layer of the valve cusps is thickened due to accumulation of proteoglycans. The leaflets and chordae become abnormal. There are abnormalities in the distribution and architecture of fibrillin, elastin and collagen I and II. Chordal rupture may develop which can result in severe mitral regurgitation.

CLINICAL FEATURES

Symptoms occur only in a small proportion of patients with MVP. These include palpitation, vague chest pain, dyspnea, and non-cardiac symptoms such as vascular headache and anxiety state. In most cases chest pain is non-cardiac. In a few there may be associated spasm of the coronary artery. Undue stretch on the papillary muscles may also impair the blood flow in the branches of the coronary artery adjacent to them. These factors may lead to anginal pain. Palpitation may result from anxiety or arrhythmias such as ectopic beats and paroxysmal tachycardias (both supraventricular and ventricular). Diagnosis is made on the presence of a non-ejection systolic click with or without late systolic murmur, best made out over the apex on auscultation. The click moves towards the first sound and the murmur becomes louder and prolonged when the patient stands. These changes are reversed when the patient squats. The degree of MVP correlates inversely with the size of left ventricular cavity, and this accounts for the change in auscultatory phenomena with the position of the patient. ECG may show non-specific ST-T changes in II, III, aVF and sometimes in anterior chest leads and this can mimic ischemic heart disease especially if patients present with atypical chest pain. Diagnosis can be confirmed by echocardiography which is the investigation of choice. *Often there is an overdiagnosis of MVP with echocardiography and this may lead to anxiety neurosis. More than 2 mm displacement of one or both leaflets in parasternal long axis view as well as apical 4 chamber view is diagnostic.* In the vast majority of patients the prognosis is excellent for life and health.

Complications: All cases of MVP have increased risk of developing infective endocarditis. 90% are hemodynamically normal. Ten percent develop significant mitral regurgitation, in whom some may progress and become severe. Acute mitral regurgitation may result from chordal rupture. Sudden cardiac death due to ventricular arrhythmias and thromboembolism are rare complications.

Treatment: Those presenting with symptoms of anxiety and chest pain may be benefited by the use of tranquilizers like chlordiazepoxide 10 mg. Propranolol 20-40 mg/day may alleviate chest pain and palpitation. Cardiac arrhythmias should be treated with antiarrhythmic drugs. Cases developing severe mitral incompetence may require valve repair or replacement. All subjects with mitral valve prolapse should be informed about the condition so as to avoid undue anxiety, and invasive investigations. All of them should have prophylaxis against infective endocarditis, when indicated. MVP patients with thromboembolic phenomenon in whom no other cause is found may be started on aspirin. Operative risk of mitral valve repair in MVP is <1%.

Acquired Aortic Stenosis (AS)

Etiology: Current evidence is that stenosis developing in congenital bicuspid aortic valve is the most common cause below the age of 30 years. Between 30-70 years bicuspid aortic valves, rheumatic valvulitis and calcification account for the majority of cases. Above the age of 70 years degenerative calcification, bicuspid valves, and rheumatic valvulitis are the frequent causes.

Rheumatic aortic stenosis: Active rheumatic endocarditis of the aortic valve leads on to thickening of the valve cusps with fusion of all commissures or fusion of a single commissure. This results in varying degrees of narrowing of the aortic valve orifice. Subsequently, hemodynamic stress on this abnormal valve produces further degenerative changes and consequent calcification. However, calcification occurs much later than in the case of congenital bicuspid aortic valve. Pure aortic stenosis is rare to develop in rheumatic heart disease. In most cases it is associated with aortic incompetence and mitral valve disease. In the series reported from CMC Vellore mitral stenosis was present in 11.8% of cases with aortic valve disease. 91.7% has a combination of aortic regurgitation and stenosis.

Degenerative calcification of aortic valve: This results from the degeneration and calcification of the tricuspid aortic valve. The calcification is more towards the base of the aortic leaflets and the commissures are free. Hypertension and hypercholesterolemia accentuate the process.

Hemodynamic changes: The aperture of the normal valve is 2.5 cm². Narrowing of the aperture to 0.75 cm² or less produces severe obstruction to left ventricular ejection and a pressure gradient across the aortic valve develops which may reach 50 mm to even 200 mm Hg. In critical AS the valve area is < 0.5 cm². The left ventricle undergoes

concentric hypertrophy which clinically manifests as heaving apex beat. The hypertrophy is both adaptive – to increase the force of contraction and maladaptive in that the hypertrophied myocardium is less perfused even in the presence of normal coronary arteries. Finally, the left ventricle dilates and fails. Heart failure may be the result of diastolic dysfunction, systolic dysfunction or both. The former is due to increased thickness of the left ventricle. Systolic dysfunction results from excessive afterload, decreased ventricular contractility or both. When the force of contraction of the ventricle reduces, the intensity of the murmur diminishes. Due to the fixed cardiac output, syncope results when the subject exerts. Angina is caused by increased oxygen demand resulting from left ventricular hypertrophy and reduction of coronary blood flow due to increased intraventricular pressure.

CLINICAL FEATURES

The symptoms are not very reliable in assessing the severity of aortic stenosis, since even significant aortic stenosis may remain asymptomatic for long periods. Sudden death may occur as a result of fatal arrhythmias even in asymptomatic subjects. **The three most important presentations of significant aortic stenosis are angina pectoris, syncope, and left ventricular failure.** Fifty percent of patients with angina are found to have associated significant coronary artery disease on coronary angiogram. Other symptoms include palpitation, exertional fatigue and visual field defects probably secondary to minute calcific emboli from the aortic valves.

The characteristic physical findings develop in significant aortic stenosis. The pulse is described as *anacrotic*. This is a small volume and slow rising pulse. The decrease in amplitude and delay in time is referred to as *pulsus parvus et tardus*. The pulse pressure is usually less than 30 mm of mercury because of depression of the systolic pressure. In the elderly subjects even with significant aortic stenosis the systolic pressure may occasionally reach 160 mm Hg more due to inelasticity of the aorta. Consequently, in such patients the severity of aortic stenosis cannot be predicted from the amplitude of pulse pressure. Apex beat is characteristically forcible and sustained (*heaving*). There may be a systolic thrill, best felt in the second right intercostal space, or along the left sternal border and very rarely over the apical impulse also. Auscultation reveals a harsh grunting ejection systolic murmur which is conducted to the carotids and well heard over the apical impulse as well. The ejection systolic murmur corresponds to the period of ejection, i.e. it starts with the opening of the aortic valves and is over before the second sound is heard. The murmur becomes louder with the phase of maximal

ejection and towards the latter part of systole the murmur comes down. In severe stenosis the murmur is longer, louder, and its peak is reached later in systole. The aortic component of the second heart sound is delayed and soft. The second heart sound may be split paradoxically. P2 is accentuated when PAH develops and S4 may be audible. If valve cusps are mobile ejection click may be present and this disappears when the valve gets calcified or infective endocarditis occurs. In patients with calcified valves, high frequency components of the murmur may be selectively radiated to the apex, a phenomenon called **Gallavardin phenomenon**. When LV fails, cardiac output falls and the murmur becomes soft and may disappear.

Electrocardiogram is normal in mild cases. In significant aortic stenosis, ECG shows left ventricular hypertrophy as well as left atrial overload pattern. The ECG pattern of left ventricular hypertrophy generally correlates with the severity and prognosis of aortic stenosis (Fig. 119.11).

Radiological findings: In aortic stenosis the heart is not usually enlarged. The ascending aorta is dilated. Post-stenotic dilation of the aorta may be seen. This post-stenotic dilation does not have any relation with the severity of aortic stenosis. Calcification of the valve may be seen (Fig. 119.12).

Echocardiography: It is helpful in visualizing the nature of the aortic valve and the severity of the stenosis. Doppler studies can estimate the gradient across the valve, and the valve area, and assess the severity.

Cardiac catheterization and angiography help in the accurate determination of the severity of aortic stenosis. Intracardiac pressure studies reveal the gradient between left ventricular pressure and aortic pressure. Coronary angiography should be performed to exclude coronary artery disease (Fig. 119.13).

Course and prognosis: Mild cases do not progress and may remain asymptomatic. However, the course of aortic stenosis cannot be predicted with confidence because of the variability in its progression due to the deposition of calcium. Rapid progression may be seen in elderly.

Grave symptoms may develop abruptly in an asymptomatic patient. In patients with significant AS, 5-year survival is 64%. Once they become symptomatic with angina, syncope or LVF, the average survival is only 5, 3 and 2 years respectively. Sudden cardiac death usually occurs in symptomatic patients. In asymptomatic patients it is rare (2%).

Aortic stenosis due to any cause detected clinically or echocardiographically is associated with increased mortality as an independent factor even in the absence of hemodynamic abnormalities.

Fig. 119.11: ECG showing left ventricular hypertrophy in aortic stenosis. Note: 1. Deep S waves in V1 and V2 and tall broad R waves in V5, V6. ST depression in leads V5, V6. The amplitude of SV2 + RV5 or V6 is above 35 mm

Fig. 119.12: X-ray chest – Aortic stenosis
Note: Left ventricular type cardiac contour. Muscle hypertrophy is more prominent than dilatation

Fig. 119.13: Cardiac catheterization in aortic stenosis (AS): LV and aortic pressures are superimposed. This shows gradient in systole between LV and aorta indicating aortic stenosis. In severe AS the peak systolic pressure gradient exceeds 75 mm Hg and the mean gradient is more than 50 mm Hg

13

Management

Medical: Management includes

- Infective endocarditis prophylaxis
- Rheumatic fever prophylaxis
- Evaluation and treatment of coronary risk factors
- Treatment of congestive heart failure

Surgical interventions include

- AVR (aortic valve replacement)
- Aortic valvotomy—surgical or balloon
- AVR along with CABG if associated coronary artery disease is present.

Indications for surgery

- Symptomatic patients
- Asymptomatic severe AS

Aortic valve replacement (AVR) is the surgical intervention of choice. Balloon or surgical valvotomy is

effective in children with congenital AS, but is much less successful in adults.

Aortic Regurgitation (AR)

Syn: Aortic Incompetence

Aortic regurgitation results when the aortic valve cusps are not able to close the aortic orifice completely during diastole. This may be caused by abnormalities of the valve or dilation of the aortic root. Aortic valve cusps are inflamed in acute rheumatic carditis giving rise to mild aortic regurgitation. Moderate to severe aortic regurgi-

tation may *develop* later. Generally, aortic valve and the mitral valve are affected simultaneously in rheumatic fever.

Causes of aortic regurgitation

- Congenital—bicuspid, tricuspid, quadricuspid valves
- Rheumatic valvulitis
- VSD—Ventricular septal defect
- Infective endocarditis
- Syphilis
- Ankylosing spondylitis
- Marfan's syndrome
- Aortoarteritis
- Rheumatoid arthritis
- Aortic aneurysm
- Aortic dissection
- Annulo-aortic ectasia
- SLE—Systemic lupus erythematosus
- Hypertension—severe and acute
- Myxomatous degeneration
- Ehlers-Danlos syndrome
- Trauma
- Reiter's syndrome
- Behcet's syndrome
- Osteogenesis imperfecta
- Mucopolysaccharidoses

The most common cause of isolated aortic regurgitation is congenital bicuspid aortic valve. Such valves may be primarily incompetent or further damage by infective endocarditis may make them so. In subaortic stenosis also varying degree of AR may be present. Ventricular septal defect may be associated with AR. Diseases such as syphilis, ankylosing spondylitis, Reiter's disease, rheumatoid arthritis, annuloaortic ectasia, aneurysm of the aorta and aortic dissection which affect the root of the aorta can all produce abnormality in valve closure resulting in varying degrees of aortic regurgitation.

Infective endocarditis produces and worsens aortic regurgitation. Acute rupture of the valve cusps in infective endocarditis leads to acute AR. Blunt trauma to chest and acute elevation of systemic blood pressure also account for a few of the cases. In Marfan's syndrome aortic regurgitation is not uncommon.

Hemodynamic disturbances: In AR part of the blood pumped out into the aorta leaks back into the left ventricle during diastole. The proportion of the cardiac output regurgitating may vary widely. The left ventricle receives blood from the left atrium and the aorta during diastole and this leads to diastolic overfilling. The ventricle undergoes dilatation and hypertrophy. Stroke volume is increased. The systolic blood pressure may go up. Peripheral vasodilatation develops in moderate to severe cases and the peripheral resistance falls. Regurgitation of aortic blood and fall in peripheral resistance result in considerable lowering of the diastolic pressure. The pulse

pressure is markedly increased. The heart compensates and maintains the cardiac output for considerable periods by dilatation and hypertrophy, but ultimately left ventricular failure develops. **AR is an example of combined volume overload (distended ventricle) and pressure overload (increased systolic BP of left ventricle).**

CLINICAL FEATURES

Mild and moderate cases may remain asymptomatic. Chronic severe AR is associated with symptoms like palpitation, exertional dyspnea, and chest pain. The symptoms are gradually progressive and when the compensatory mechanisms become inadequate, congestive heart failure ensues. Angina especially at night also may occur in chronic severe AR. Acute severe AR presents as a medical emergency because it results in congestive heart failure.

Mild cases may have only an early diastolic murmur as evidence of AR. This murmur is high-pitched and is best heard along the left sternal border. The murmur is best appreciated when the patient leans forward and holds the breath in expiration. The murmur of AR resulting from aortic root dilatation may be best heard along the right sternal border (Fig. 119.14).

In moderate and severe cases the peripheral signs are present. These are high volume collapsing pulse (**Corrigan's pulse**), wide pulse pressure (high systolic and low diastolic), prominent carotid pulsation and prominent capillary pulsation demonstrable in the nail bed as well as in the retina. Pistol shot sounds can be heard over the femoral arteries. While auscultating over the femoral artery proximal compression gives rise to systolic murmur and distal compression gives rise to diastolic murmur (**Duroziez Murmur**). The systolic blood pressure recorded in the lower limb is 60 mm above that recorded in the upper limb (**Hill's sign**).

Peripheral signs of AR are shown below. They are of value in diagnosis only in the absence of conditions like fever, anemia, thyrotoxicosis, beriberi and other high output states.

Fig. 119.14: The timing of murmur of AR: The diastolic murmur starts with the aortic component of the second sound and extends for variable duration in to diastole

Peripheral signs of AR

Alfred de Musset's sign	Head nodding with heart beat
Landolfi's sign	Change in pupil size with heart beat
Muller's sign	Uvula pulsation
Rosenbach's sign	Liver pulsations
Gerhardt's sign	Spleen pulsations
Quincke's sign	Digital capillary pulsations
Pistol shot sound	Systolic booming sound over femoral artery
Traube's sign	Systolic and diastolic booming sound over femoral artery
Duroziez's sign	Systolic sounds on proximal compression and diastolic sounds on distal compression over femoral arteries
Hill's sign	Lower limb systolic BP exceeding Upper limb systolic BP by ≥ 60 mmHg
Corrigan's pulse	High volume collapsing pulse
Becker's sign	Retinal artery pulsations
Corrigan's sign	Prominent carotid pulsation

Precordium is hyperactive. Apex beat is characteristically shifted down and out and it is forcible. A mid-diastolic, or presystolic murmur or a combination of both may be heard well over the apex beat (Austin-Flint murmur). This is produced because of the premature closure of the mitral valve caused by the regurgitant stream of blood. There may be an ejection systolic murmur heard along the left sternal border as well as over the aortic area, and this murmur is conducted to the carotids. This is caused by the increased flow across the aortic valve in systole. The aortic component of the second sound is usually soft in severe AR. In cases with pulmonary arterial hypertension, the pulmonary second sound is loud. Acute severe AR is conspicuous by the absence of peripheral signs and left ventricular enlargement. LV gallop may be present if patient develops LV dysfunction.

Electrocardiogram shows left ventricular hypertrophy.

Chest radiograph shows left ventricular enlargement. The aorta in most of the cases appears dilated and on fluoroscopy it is hyperdynamic (Fig. 119.15).

Echocardiography: 2D echo along with Doppler and colour flow can provide anatomical information on the aortic valve, aortic root, etiology of AR, measurements of ventricular function, and estimates of severity of AR. Echo also helps in assessing the pulmonary artery pressures and deciding the timing and type of surgery (Fig. 119.16).

Cardiac catheterization and angiography can provide accurate assessment of the hemodynamic abnormality.

Fig. 119.15: X-ray chest AR showing cardiac dilatation (LV type) and dilated aorta

Fig. 119.16: Colour Doppler echocardiograph showing aortic regurgitation

Course and prognosis: Mild cases usually do not progress. However, infective endocarditis may complicate even mild cases. Moderate and severe cases progress with time at varying rates leading to progressive left ventricular enlargement and left ventricular failure. Once cardiac failure occurs, the course is rapidly downhill and majority of patients die within 2 years. Patients with CHF, angina and those in NYHA class III and IV are at high risk of mortality of 25% per year, if untreated. Marked ventricular enlargement is associated with increased risk of sudden death. Risk of aortic dissection is increased in those with annuloaortic ectasia and those with wider aorta. Doppler echography is the mainstay of conservative assessment of severity of AR. *If the regurgitant valve orifice is $>0.3\text{cm}^2$ and the regurgitant volume is $> 60\text{ mL/beat}$ it is severe AR.*

TREATMENT

Medical

- Infective endocarditis prophylaxis
- Rheumatic fever prophylaxis

- c. Treatment of CHF
- d. Afterload reducing agents: These are beneficial in asymptomatic patients with severe AR and normal LV function. Nifedipine and ACE inhibitors have been tried with benefit. Sustained release nifedipine has been shown to postpone the need for aortic valve replacement (AVR)
- Dose: Nifedipine 5-10 mg b.d or t.i.d oral
- Enalapril 5 mg b.i.d or t.i.d oral.

Surgical techniques include aortic valve and root repair, aortic homograft and pulmonary autograft. Associated coronary artery disease may need CABG if indicated.

Indications for surgery

Symptomatic patients with severe AR
Asymptomatic patients with severe AR and depressed LV function
LV EF $\leq$ 50%
End diastolic dimension > 75 mm
End systolic dimension > 55 mm
AR due to aortic root dilatation > 50 mm
Acute AR

Early surgery is less risky and more effective. Asymptomatic patients with ejection fraction between 50-53% should also be considered for surgery. The surgical mortality ranges from 4-6.8%.

Tricuspid Valve Lesions

TRICUSPID STENOSIS (TS)

Normal tricuspid orifice is larger than the mitral orifice (7cm²). The tricuspid leaflets differ from the mitral leaflets in being thinner, more translucent and less clearly separated into well defined leaflets. The three major leaflets are anterior, septal, and posterior. The tricuspid valve may be stenotic, regurgitant or both. Tricuspid stenosis is clinically detectable in 3-5% of cases with multivalvular involvement, but tricuspid lesion can be demonstrated in a much higher proportion (up to 30%) during autopsy. Rheumatic TS is almost always associated with MS.

Etiology

1. Rheumatic valvulitis,
2. Congenital tricuspid stenosis,
3. Carcinoid syndrome,
4. Endocardial fibroelastosis,
5. Endomyocardial fibrosis,
6. Systemic lupus erythematosus.

Rheumatic valvulitis causes fusion of the adjacent free edges of the leaflets. The valve cusps are also moderately

thickened. The involvement of the subvalvular apparatus is less marked compared to the distortion in mitral stenosis. When the valve area falls below 1 cm² it leads to severe tricuspid stenosis. If the valve area is between 1 and 1.5 cm², it is designated as moderate stenosis. In tricuspid stenosis the flow of blood from the right atrium to the right ventricle is hampered. This results in reduction in cardiac output and elevation of the right atrial pressure. Ultimately this leads to systemic venous hypertension.

CLINICAL FEATURES

Rheumatic tricuspid stenosis is almost always associated with mitral stenosis. Presence of tricuspid stenosis leads to reduction in pulmonary venous congestion and, therefore, the symptoms of mitral stenosis such as paroxysmal nocturnal dyspnea, pulmonary edema and hemoptysis are considerably less. The most common symptoms attributable to tricuspid stenosis are effort intolerance and easy fatigability produced as a result of the low cardiac output. Physical examination reveals small volume pulse. The jugular venous pulse shows elevation of mean pressure, prominent 'a' waves with slow 'y' descent. In the presence of atrial fibrillation the characteristic 'a'-wave is lost, but the slow 'y' descent persists. The left parasternal heave seen in mitral stenosis is usually absent. The characteristic auscultatory feature is the presence of a mid-diastolic or pre-systolic murmur which is best heard at the lower left sternal border. Though the murmur is also rumbling in character, its pitch is higher than the murmur of mitral stenosis. It increases in intensity with inspiration (*Carvallo's sign*). The first sound is often split as a result of delay in tricuspid valve closure.

The ECG shows evidence of right atrial enlargement. Chest X-ray shows right atrial dilatation without significant enlargement of the pulmonary arteries. Echocardiography clearly demonstrates the lesion in the valve. Cardiac catheterization is seldom required for tricuspid valve disease.

Course and prognosis: Though the symptoms of pulmonary venous hypertension in patients with mitral stenosis are ameliorated by the coexistence of tricuspid stenosis, the cardiac output is considerably reduced and systemic venous hypertension develops. In such cases, failure to identify tricuspid stenosis preoperatively, and correct it during surgery of the mitral and aortic valves, leads to poor postoperative results.

Treatment: Moderate or severe tricuspid stenosis should be corrected by commissurotomy at the time of surgery for the mitral lesion. Balloon valvotomy has also been found feasible in TS.

TRICUSPID REGURGITATION (TR)

Tricuspid regurgitation (TR) results from inadequate closure of the tricuspid orifice by the valve leaflets. Right ventricular blood regurgitates into the right atrium during systole. The most frequent cause of TR is functional incompetence secondary to pulmonary hypertension which may be primary or secondary. As the right ventricle dilates secondary to the effect of pulmonary hypertension, the valve becomes incompetent. Secondary tricuspid incompetence may be seen in cases of severe mitral stenosis.

In primary tricuspid regurgitation, which is relatively rare, the valve is abnormal.

Causes of primary TR

1. Rheumatic valvulitis,
2. Congenital anomalies (Ebstein's malformation, atrioventricular cushion defects),
3. Carcinoid syndrome,
4. Infective endocarditis, and
5. Trauma.

With the onset of TR, the pressure in the right atrium increases during systole. The elevated mean right atrial pressure is reflected back as elevation of the systemic venous pressure. Ultimately the right atrium and right ventricle dilate with clinical features of systemic venous hypertension.

CLINICAL FEATURES

The usual symptoms are easy fatigability and effort intolerance resulting from reduction of cardiac output. In severe cases there is usually peripheral edema and in some cases there may be ascites. The liver is enlarged and tender and shows systolic pulsation. The most conspicuous finding is elevation of jugular venous pressure with prominent 'v' wave and exaggerated 'y' collapse. When the jugular veins are overdistended, pulsations may not be prominent. In such cases the ear lobes may reveal pulsations. Atrial fibrillation is present in 80-96% of patients with TR. When atrial fibrillation is present, the pulsation in the jugular vein is monophasic with only prominent 'v'-wave. *The characteristic murmur of TR is a high pitched pansystolic murmur best heard in the lower left sternal border. This murmur increases in intensity with inspiration. Inspiratory augmentation of the murmur may not be very conspicuous in cases with severe congestive cardiac failure.* In primary TR, the murmur is medium-pitched and short. The inspiratory augmentation is less conspicuous. When TR is severe, there is usually a third heart sound as well as a mid-diastolic flow murmur heard along the lower left sternal border. The ECG and X-ray chest may show evidence of right atrial enlargement.

Echocardiogram delineates the lesion well. Using Doppler echocardiogram, pulmonary pressures can be assessed and this may help in differentiating primary and secondary TR. Cardiac catheterization and angiography may be required in selected cases.

Course and prognosis: With treatment of congestive heart failure the features of secondary TR come down, and the duration of the murmur comes down. If the damage to the right ventricle is irreversible such cases follow a downhill course.

Treatment: Medical treatment is given for those cases with functional tricuspid regurgitation. Valvuloplasty or valve replacement may be necessary in cases with primary TR. Even in functional TR surgical correction may have to be done if the lesion is severe.

Acquired Lesions of the Pulmonary Valve

Etiology: The pulmonary valve is only rarely involved by acquired heart disease. In carcinoid syndrome, the pulmonary valve shows fibrous scarring with retraction leading to pulmonary stenosis and regurgitation. In severe forms of rheumatic heart disease the pulmonary valve also may be involved as part of the quadrivalvular affection. Bacterial endocarditis may affect congenitally abnormal or even normal pulmonary valve. The pulmonary valve may be the seat of tumours such as myxoma or fibroma in rare cases. In Marfan's syndrome the valve shows myxomatous degeneration. The valve may be damaged during surgery for tetralogy of Fallot or pulmonary stenosis. Severe pulmonary hypertension resulting from any cause may produce functional pulmonary regurgitation with pulmonary diastolic murmurs (*Graham-Steell murmur*). Very rarely pulmonary valve may be involved by tuberculosis and syphilis.

CLINICAL FEATURES

Clinical manifestations depend upon the severity of valve involvement and its cause. In quadrivalvular involvement identification of the pulmonary lesion is difficult because the clinical features are influenced by the lesion of the more proximal valve. In isolated involvement the murmur of *pulmonary stenosis* is easily recognized as an ejection systolic murmur often associated with a thrill, most prominent over the left upper sternal border.

Pulmonary regurgitation (PR) produces an early diastolic murmur along the left sternal border, and this murmur may closely resemble that of aortic regurgitation (AR) in timing and quality. Careful examination can distinguish them in most cases.

Differentiation of AR and PR diastolic murmurs		
Features	AR	PR
Inspiratory increase	–	+
Murmur begins with A2	+	–
Murmur begins with P2	–	+
Murmur increases with phenylephrine and hand grip	+	–
Murmur decreases with amyl nitrate	+	–

Course and prognosis: In quadrivalvular disease, the hemodynamic abnormalities are largely determined by the lesions of the proximal valves. Pulmonary valve disease may not alter the natural history significantly. However, recognition of pulmonary valve disease is important to

decide the line of management. When pulmonary regurgitation is mild or moderate, right ventricle accommodates the increased diastolic blood volume without considerable hemodynamic disturbance, but severe pulmonary regurgitation may lead on to progressive right ventricular failure.

Treatment: Management largely depends on the severity and etiology of pulmonary valve disease. Pulmonary valve replacement may have to be considered under the following indications.

1. Severe and progressive pulmonary regurgitation following surgical correction of tetralogy of Fallot or pulmonary stenosis;
2. Tumours involving the pulmonary valve; and
3. Infective endocarditis, when medical treatment fails.

120

Syphilitic Affection of Cardiovascular System

C.G. Bahuleyan

Chapter Summary

Aortitis	798
Aortic Insufficiency	799
Aneurysm of Aorta	800

Introduction

Cardiovascular involvement is one of the important manifestation of syphilis in its tertiary stage. About 10% of patients with syphilis develop clinical evidence of cardiovascular disease. These include aortitis, aortic insufficiency, aneurysm of aorta, coronary ostial stenosis, gumma of the myocardium, and syphilitic endarteritis. Cardiovascular syphilis occurs more common and earlier in men than in women.

AORTITIS

This may occur in 70-80% of the untreated cases, if allowed to progress. The causative organism, *Treponema*

pallidum, invades the adventitial layer of the aorta soon after the primary infection, spreading later to the media through the lymphatics surrounding the vasa vasorum after several years. Endarteritis of vasa vasorum results in necrosis of the elastic and connective tissues of the media. At first the intima overlying the areas of medial necrosis becomes thickened. Later it becomes pitted and scarred to resemble the bark of a tree. *Treponema pallidum* may survive in the aortic wall for 20 to 30 years (Fig. 120.1).

Inflammatory changes are most frequent and severe in the ascending aorta and arch and they are least in the distal parts. Damage to the media causes ectasia of proximal part of the aorta, which increases to as much as twice its normal diameter. If left untreated, 10% of subjects with syphilis may develop aortic regurgitation or coronary ostial narrowing due to involvement of the proximal aorta. Longer the delay in treatment, greater is the likelihood of lethal complications. Damage to the media increases the severity of atherosclerosis in the proximal aorta.

Fig. 120.1: Rough pitted intimal surface (tree bark appearance) characteristic of syphilitic aortitis

Fig. 120.2: Dilated ascending aorta with calcification in a patient with syphilitic aortic aneurysm

Clinical features: The patient may complain of a burning type of retrosternal pain or true anginal pain felt over the retrosternal region.

Diagnosis

1. Prominent parasternal heave suggestive of dilatation of the ascending aorta,
2. A ringing loud aortic component of second heart sound (tambour like second heart sound) in a normotensive subject without evidence of atherosclerosis, and
3. A systolic murmur in the aortic area.

Calcification of the anterolateral wall of aorta may be seen on fluoroscopy (calcification due to atherosclerosis is more frequently along the medial border of the ascending aorta and arch). Dilatation of aorta is detectable by echocardiography and angiography (Fig. 120.2).

AORTIC INSUFFICIENCY

Aortic valvular regurgitation, the most frequent complication of syphilitic aortitis, results from dilatation of aortic valve ring and improper apposition of the leaflets due to mesoaortitis of proximal aorta. The aortic valve cusps may be thickened and rolled up at the edges without calcification or stenosis. Left ventricular dilatation and hypertrophy may occur. In addition, coronary ostial narrowing and aneurysm of aorta may coexist.

CLINICAL FEATURES

Males are affected four times more frequently than females. Around 10-25 years may elapse between the primary lesion and the onset of AR. When the AR is significant, cardiac signs and all the peripheral signs of free aortic regurgitation may be detectable. The high-pitched decrescendo early diastolic murmur of aortic

regurgitation is best appreciated with the diaphragm of the stethoscope firmly applied in the second right intercostal space with the patient leaning forward and holding his breath in expiration. As the AR is the result of dilatation of the aortic root the murmur is often better heard in the right sternal border than the left. A hyperdynamic apical impulse, soft first heart sound, a ventricular diastolic gallop and mid-diastolic rumble at the apex (**Austin Flint murmur**) constitute the other physical signs. *Austin Flint murmur* can be distinguished from the mid-diastolic murmur of mitral stenosis by the absence of loud first heart sound.

Echocardiography demonstrates the lesions in the valve, aorta and the cardiac chambers. Doppler studies help to quantify the hemodynamic abnormality. Angiography and cardiac catheterisation are required only in a few cases.

History of syphilitic infection, evidence of syphilis elsewhere in the body, positive serological tests for syphilis and the presence of murmur of AR are pointers to the diagnosis. Since syphilis may coexist with other conditions such as bicuspid aortic valve or degenerative disease which can lead on to aortic regurgitation, the etiological diagnosis during life is mostly presumptive.

Prognosis: Syphilitic lesion of the valve tends to progress with time if it is not treated. Some cases develop **Jarisch-Herxheimer reaction** and edema of the coronary ostial lesion leading to acute myocardial ischemia when instituting penicillin therapy. This should be borne in mind when giving antisyphilitic therapy.

Once syphilitic damage has happened the valvular lesion does not recover even with full antisyphilitic therapy. Presence of heart failure and angina worsen the prognosis, and if left untreated, end up fatally within three years.

Treatment: If the lesion is detected before the valve is grossly damaged, antisyphilitic treatment arrests the progress of the disease and may prevent deterioration.

In such cases moderate restriction of heavy physical exertion and prophylaxis for infective endocarditis may be the only treatment needed. If the valve lesion has progressed so as to produce major hemodynamic disturbance, surgery has to be done after clearing syphilitic activity. Surgical treatment consists of replacement of aortic valve to correct AR and coronary artery bypass grafting when there is coronary ostial stenosis.

ANEURYSM OF AORTA

This is a late complication of syphilis which occurs from 15-30 years after primary infection. Aortitis may lead to a generalized dilatation and fusiform aneurysm or a localized dilatation to form saccular aneurysm. As aortitis most frequently involves the ascending aorta, more than 50% of aneurysms also occur in this location (see pp 690).

Clinical features: Symptoms and signs of aneurysm arise from compression of adjacent structures. Ascending aortic aneurysms compress the pulmonary artery, superior vena cava or right main bronchus. Aneurysms of the arch compress the oesophagus, trachea, bronchus, recurrent laryngeal nerve, sympathetic nerves, and vertebrae. These lead to dysphagia, dyspnea, stridor, cough, hoarseness of

voice, Horner's syndrome and pain over the vertebra. An interesting physical sign in aneurysm of the arch is the **tracheal tug**, which is a tugging sensation felt when the neck is extended and larynx is held up. Aneurysms of the descending aorta compress the lungs, erode vertebrae or ribs, and impinge on nerve roots. Descending thoracic or abdominal aortic aneurysms may present as pulsatile or non-pulsatile masses. Aneurysms may rupture into bronchus, pulmonary artery, pleura, pericardium or esophagus leading to fatal hemorrhage. Once symptomatic, the life expectancy for a patient with syphilitic aneurysm is only a few months. Antisyphilitic therapy should be followed up by surgery to resect the aneurysms without delay.

Coronary ostial stenosis: In syphilitic aortitis occlusion of the coronary opening is a slow process and, therefore, acute myocardial infarction is rare. Ostial stenosis is often associated with AR. Diagnosis is made by aortic root angiography and coronary arteriography. Angina and sudden death due to arrhythmia may occur. Coronary artery bypass graft may be required after antisyphilitic therapy.

Myocardial gummata: They may produce bundle branch block or A-V block or electrocardiographic pattern of myocardial infarct. Antemortem diagnosis is extremely difficult.

Chapter Summary

- Etiology 801
- Clinical Features 802
- Diagnosis 802
- Treatment 803

Definition: Infective endocarditis is defined as microbial infection of the endothelial surfaces of heart and great

vessels (Infective endarteritis). Endocarditis may be acute or subacute.

Acute infective endocarditis: The heart valves and endocardium may be the seat of direct invasion by microbes. Virulent organisms such as *Staphylococcus aureus*, *Streptococcus hemolyticus*, and pneumococci produce acute ulcerative endocarditis during the course of a septicemia and these affect normal valves. Fortunately, this complication is rare.

TABLE 121.1

Showing the primary cardiac lesion and the most common precipitating event

Pre-existing heart disease	Precipitating factors
Congenital heart disease	Dental procedures, abortion, procedures on lower urinary tract, intravenous drug use
Rheumatic valvular disease	Dental procedures, minor surgery, systemic infections.
Atherosclerotic valve lesions and degenerative lesions	Urinary endoscopy and other manipulations
Prosthetic heart valves	Bacteremias
Cardiac surgery	Intravenous cannulae and shunts, foreign materials
Normal valves in immuno-compromised individuals	Emergency room procedures including IV catheter and injections
Drug addicts: Normal valves	Intravenous drug injection, needle-sharing

Acute infective endocarditis and subacute bacterial endocarditis differ in their etiology, microbial flora, pathology, clinical features and management. Whereas acute endocarditis presents as part of a more fulminant generalized infection, the subacute form often takes the picture of a stealthy superinfection on an already existing cardiovascular lesion by organisms which are of low virulence in normal individuals (Table 121.1).

Etiology—Subacute Bacterial Endocarditis (SBE)

Predisposing causes: Infection is predisposed to by congenital heart disease or rheumatic heart disease. Organisms may colonize on the endocardium, valves or arteries that are already damaged or subjected to hemodynamic abnormalities. Combined valvular lesions are more often the seat of vegetations than pure stenosis or incompetence. Among the congenital lesions, ventricular septal defect, patent ductus arteriosus, pulmonary stenosis, Fallot’s tetralogy and coarctation of the aorta may be complicated by infective endocarditis. This risk is less in the case of secundum type of atrial septal defect. Open heart surgery and surgical introduction of prosthetic heart valves, grafts and pacemakers are associated with increased risk of bacterial colonisation. Atherosclerotic lesions may form nidus for infective endocarditis.

In immunodeficient individuals and intravenous drug users, even normal valves may become colonized by pathogens.

Microbial flora: Common organisms are *Streptococcus viridans*, *Streptococcus fecalis* and other streptococci. Less common organisms include *staphylococci*, *pneumococci*, *H. influenzae*, *gonococci*, *meningococci*, *salmonellae*, *E. coli*. *Bacterium anitratum*, *Candida* sp.,

aspergillus sp., *anaerobes* and *Coxiella burneti*. Most of these organisms are commensals in the human body, particularly abundant in sites such as the mouth, upper respiratory tract, genitalia, and urinary tract. Any infective illness or minor surgical procedures such as dental surgery, tonsillectomy, urinary instrumentation, parturition, abortion or medical termination of pregnancy causes transient bacteremia which conveys the organisms to the abnormal cardiac tissues, where they settle and multiply.

PATHOLOGY

On the endocardial surface the organisms multiply and proliferate. Fibrin is deposited over the organisms and this gives a protective coat against the defences of the host. Further growth of the organisms and fibrin deposition result in the formation of friable vegetations which show three layers—the inner layer made up of erythrocytes, leukocytes and platelets; the middle layer containing a heavy growth of the organisms; and an outer layer made up of fibrin. As fibrin gets deposited further, the vegetations grow and they get embolized from time to time. Organisms which reach the cardiac tissues adhere to the damaged valves and other parts within minutes. After adhesion to tissues they multiply and envelope themselves in fibrin and lead to the development of vegetations. Monocytes which adhere to these sites do not engulf the organisms. On the other hand they produce procoagulant factors which favour the development of further fibrin and vegetations. Normally adhesion of platelets tends to inhibit organisms, but in infective endocarditis, this does not happen; but further growth of vegetations occur. Tissue invasion and abscess formation follow (Fig. 121.3B).

The vegetations are located differently on the different valves. Generally vegetations are located at the downstream portions of a communication between high and low pressure areas.

- Mitral valve — Atrial surface and line of apposition
- Aortic valve — Ventricular surface
- Ventricular septal defect — On the right ventricular endocardium where the abnormal jet impinges, and around the defect.
- Patent ductus arteriosus — Pulmonary artery and the ductus

The chordae tendineae and papillary muscles may be affected. These may rupture leading to acute valvular incompetence or they undergo fibrosis when they heal.

Embotic episodes form an integral clinical feature of infective endocarditis. The emboli may be septic or sterile. Embolism leads to infarction of organs. Septic emboli reaching the vasa vasorum lead to weakness of the arterial wall and the formation of mycotic aneurysms especially in the intracranial vessels.

Repeated release of organisms into the circulation starts off immunological processes. Large amounts of

antibodies are formed which give rise to the formation of immune complexes. Complement activation occurs. As a result, immunological lesions like glomerulonephritis, perisplenitis and vasculitis develop. Septic emboli also lead to focal glomerulonephritis. Spleen enlarges due to reticuloendothelial hyperplasia and formation of microabscesses.

Untreated cases end fatally. Death is caused by massive embolism to vital organs (brain or heart), cardiac failure or renal failure.

CLINICAL FEATURES

Symptomatology can be described under four groups:

1. **Features of subacute infection:** This manifests as low-grade or high-grade intermittent or continuous fever, often associated with chills and rigor. Digital clubbing may develop within weeks and this may be painful. In some cases the symptoms may be non-specific. Even unexplained fatigue, anemia or resistant cardiac failure should draw attention to endocarditis. Splenomegaly develops and the organ is well palpable by the second week. A brownish pigmentation develops over the face and limbs—*cafe-au-lait pigmentation* (meaning, coffee with milk) (Fig. 121.1).

2. **Hemodynamic changes:** Destruction of a valve may result in valve rupture leading to the development of fresh murmurs, aggravation of existing murmurs and sudden cardiac failure. In some cases the vegetations obstruct the valves. The papillary muscles and the chordae tendineae may rupture giving rise to incompetence of the atrioventricular valves.

3. **Embolic phenomena:** The emboli are generally small though large fatal emboli may develop at times. Emboli produce several manifestations.

Cutaneous embolism: This leads to painless, erythematous or hemorrhagic lesions on palms and soles called *Janeway lesions*.

Nails: *Splinter hemorrhages* occur as longitudinal streaks under the nails.

Spleen: Painful splenomegaly and splenic infarcts may develop.

Peripheral arteries: Occlusion of the arteries to the extremities gives rise to absence of peripheral pulses, claudication and distal gangrene.

Central nervous system: The carotid or vertebral system may be involved giving rise to paralysis, convulsions, visual loss, aphasia, and cerebellar disturbances.

Renal infarction: This condition causes hematuria and renal failure.

Pulmonary embolism gives rise to pulmonary infarction, pleurisy, and pleural effusion.

Fig. 121.1: Male 25 mitral valve disease with infective endocarditis. Note: Pallor, splenomegaly, cardiomegaly

4. **Immunological disturbances:** These lead to vasculitis which manifests as **Osler's nodes** (raised tender nodules on the pulps of the fingers), **Roth's spots** (circular hemorrhages with central white spots) seen on the retina, and **glomerulonephritis**.

Diagnosis

A high index of clinical suspicion is very essential for early diagnosis. In persons with congenital or acquired heart disease, fever, anemia, clubbing, refractory cardiac failure, changing murmurs, development of emboli or even vague ill health should suggest the possibility of infective endocarditis. Infective endocarditis should be differentiated from activation of rheumatic fever, disseminated lupus erythematosus, drug toxicity, and other prolonged fevers. Development of normocytic normochromic anemia, mild leukocytosis, elevation of ESR, proteinuria, and microscopic or frank hematuria should strengthen the clinical diagnosis.

Criteria for diagnosis evolved from Duke university (Duke criteria) in 1994. These criteria offer improved sensitivity and specificity for diagnosis of endocarditis.

Duke's Criteria for Diagnosis of Infective Endocarditis

Definite Infective Endocarditis

Pathologic criteria: Pathologic lesions: vegetation or intracardiac abscess present, confirmed by histology showing active endocarditis.

Microorganisms: demonstrated by culture or histology in a vegetation, or in a vegetation that has embolised, or in an intracardiac abscess or

Clinical criteria, using specific definitions listed below:

Two major criteria or

One major and three minor criteria, or five minor criteria

Possible Infective Endocarditis

Findings consistent with infective endocarditis that fall short of “definite” but not “rejected”.

Rejected Firm alternate diagnosis for manifestations of endocarditis.

Or

Resolution of manifestations of endocarditis, with antibiotic therapy for 4 days or less or

No pathologic evidence of infective endocarditis at surgery or autopsy after antibiotic therapy for 4 days or less.

Definitions of Clinical Criteria

Major Criteria

Positive blood culture for infective endocarditis

Typical microorganism for infective endocarditis from two separate blood cultures, or persistently positive blood culture, defined as recovery of a microorganism consistent with infective endocarditis from:

1. Blood cultures drawn more than 12 hours apart or
2. All of three or a majority of four or more separate blood cultures, with first and last drawn at least 1 hour apart

Evidence of Endocardial Involvement

Positive echocardiogram for infective endocarditis

1. Oscillating intracardiac mass on valve or supporting structure, or in the path of regurgitant jet or on implanted material in the absence of an alternative anatomic explanation, or
2. Abscess, or
3. New partial dehiscence of prosthetic valve, or New valvular regurgitation (increase or change in pre-existing murmur not sufficient).

Minor Criteria

- **Predisposition:** Predisposing heart condition or intravenous drug use
- **Fever** $\geq 38.0^{\circ}\text{C}$ (100.4°F)
- **Vascular phenomena:** Major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhage, Janeway lesions.
- **Immunologic phenomena:** Glomerulonephritis, Osler’s nodes, Roth’s spots, rheumatoid factor.

Fig. 121.2: Transthoracic echocardiogram shows vegetation attached to anterior mitral leaflet—arrow

- **Microbiologic evidence:** Positive blood culture but not meeting major criterion as previously defined or serologic evidence of active infection with organism consistent with infective endocarditis.
- **Echocardiogram:** Consistent with infective endocarditis but not meeting major criteria as previously defined.

Echocardiogram: Vegetations above 0.5 cm can be detected easily. Smaller vegetations may escape detection and, therefore, a negative result should not be a reason for ruling out the diagnosis. In practice demonstration of vegetations by echocardiogram is the most rapid and definite method to establish the diagnosis. Since demonstrable vegetations take days to weeks to develop, repetition of echocardiography is indicated if clinical suspicion is strong. Echocardiogram also helps to assess progress with treatment (Figs 121.2 and 121.3).

Organisms can be cultured from blood and this should be attempted in all cases. Blood is collected before starting antimicrobial drugs. Three separate sets of blood culture; each from separate venupuncture, obtained over 24 hours are recommended to evaluate patients with suspected endocarditis. Each sample should be inoculated in aerobic medium and anaerobic medium. The organisms are slow growers and, therefore, the cultures should be continued for 2-3 weeks. In doubtful cases they should be subcultured. In many cases mixed flora may be seen, or with treatment, the microbial flora may change. Hence repeat cultures should be done when treatment is prolonged or the progress is not fully satisfactory. Drug sensitivity of the organisms should be determined to assess the choice of antibiotics. The organisms vary considerably in their drug sensitivity and, therefore, prior assessment of the antibiotic sensitivity is of great value in ensuring successful therapy.

TREATMENT

Treatment use of bactericidal antibiotics is the corner stone of successful therapy.

Fig. 121.3: Transesophageal echocardiogram picture of a (A). Vegetation attached to mitral valve (B) Aortic root abscess on right side - arrow

Empirical Therapy

When the causative organism is not known, the choice of empirical therapy should depend on whether the patient has acute or subacute disease. Acute bacterial endocarditis (ABE) requires broad-spectrum therapy that covers *Staph. aureus* as well as many species of streptococci and gram-negative bacilli. Subacute bacterial endocarditis (SBE) requires a regimen that eradicates most streptococci, including *E. fecalis*.

- For acute bacterial endocarditis (ABE): Nafcillin 2.0 g IV q 4 h + ampicillin 2.0 g IV q 4 h + gentamicin 1.5 mg/kg IV q 8 h. If methicillin-resistant *Staph. aureus* is a possibility, for example, in a hospital-acquired case, vancomycin, 1.0 g IV q 12 h should be substituted for nafcillin
- For SBE: Ampicillin 2.0 g IV q 4 h + gentamicin 1.5 mg/kg IV q 8 h.

Treatment should be appropriately modified when the etiologic organism is identified and antibiotic sensitivity established.

The standard treatment for endocarditis due to penicillin susceptible viridans streptococci is aqueous penicillin G 12-18 million unit/24 hours either continuous or every 4 hours in six equally divided doses for 4 weeks and gentamicin 1 mg/kg IM/IV 8 hourly for first 2 weeks. Vancomycin is recommended for patients allergic to penicillin.

Surgery: When medical treatment fails to clear the infection, the underlying abnormality may have to be corrected surgically and this has to be done as a life-saving procedure. Other indications for surgery include acute valvular incompetence leading to cardiac failure, large friable vegetations which are likely to embolize, unstable prosthesis, and perivalvular extension of infection.

Prognosis: With the help of echocardiography and microbiological studies the diagnosis can be confirmed in most cases if clinical suspicion is high. Prognosis depends on

the timely institution and prolonged administration of appropriate antibiotic combination. *Prognosis is best when the specific organism and its antibiotic sensitivity are known. Therefore, it is of utmost importance, that blood should be taken for microbiological studies before starting antibiotics empirically, even if treatment may be delayed slightly.*

It is important to prevent the onset of infective endocarditis in all patients with anatomical lesions in the cardiovascular system.

Recommendation for Endocarditis Prophylaxis

Indication

High risk category

- Prosthetic heart valves, including bioprosthetic homograft and allograft valves
- Previous bacterial endocarditis
- Complex cyanotic congenital heart disease (e.g. single ventricle states, transposition of the great arteries, tetralogy of Fallot)
- Surgically constructed systemic pulmonary shunts or conduits

Moderate risk category

- Most other congenital cardiac malformations (other than that listed above or below)
- Acquired valvular dysfunction (e.g. rheumatic heart disease)
- Hypertrophic cardiomyopathy
- MVP with auscultatory evidence of valvular regurgitation
- MVP with auscultatory evidence of valvular regurgitation and or thickened leaflets

Low or negligible risk category

- Isolated secundum atrial septal defect

TABLE 121.2		
Endocarditis prophylaxis regimens for dental, oral, respiratory tract or esophageal procedures		
Situation	Agent	Regimen*
Standard general prophylaxis	Amoxycillin	Adults: 2.0 g; children 50 mg/kg PO 1 h before procedure
Unable to take oral medication	Amoxycillin	Adults: 2.0 g IM or IV; children: 50 mg/kg im or IV within 30 min before procedure
Penicillin-allergic	Clindamycin or	Adults: 600 mg; children: 20 mg/kg PO 1 h before procedure
	Cephalexin† or cephadroxi† or	Adults: 2.0 g; children 50 mg/kg PO 1 h before procedure
	Azithromycin or clarithromycin	Adults: 500 mg; children 15 mg/kg PO 1 h before procedure
Penicillin-allergic and unable to take oral medications	Clindamycin or Cefazolin†	Adults: 600 mg; children 20 mg/kg IV within 30 min before procedure
		Adults: 1.0 g; children 25 mg/kg IM or IV within 30 min before procedure
* Total children's dose should not exceed adult dose		
† Cephalosporins should not be used in individuals with immediate type hypersensitivity reaction (urticaria, angioedema, or anaphylaxis) to penicillin. From Dajani <i>et al</i> (with permission)		

TABLE 121.3 Endocarditis prophylaxis regimens for genitourinary/gastrointestinal (excluding esophageal) procedures		
Situation	Agent(s)*	Regimen†
High-risk patients	Ampicillin plus gentamicin	Adults: ampicillin 2.0 g I.M/IV plus gentamicin 1.5 mg/kg (not to exceed 120 mg) within 30 min of starting the procedure. Six hours later, ampicillin 1 g IM/IV or amoxcillin 1 g PO Children: ampicillin 50 mg/kg IM or IV (not to exceed 2.0 g) plus gentamicin 1.5 mg/kg within 30 min of starting the procedure. Six hours later, ampicillin 25 mg/kg IM/IV or amoxicillin 25 mg/kg PO
High-risk patients allergic to	Vancomycin plus gentamicin	Adults: vancomycin 1.0 g IV over 1-2 h plus gentamicin 1.5 mg/kg IV/IM (not ampicillin/amoxicillin to exceed 120 mg). Complete injection/infusion within 30 min of starting the procedure Children:vancomycin 20 mg/kg IV over 1-2 h plus gentamicin 1.5 mg/kg IV/IM. Complete injection/infusion within 30 min of starting the procedure
*A second dose of vancomycin or gentamicin is not recommended.		
† Total children's dose should not exceed adult dose. From Dajani <i>et al</i> (with permission)		

- Surgical repair of atrial septal defect, ventricular septal defect or patent ductus arteriosus (without residual lesion > 6 mo)
 - Previous coronary artery bypass graft surgery
 - MVP without valvular regurgitation
 - Physiological functional or innocent heart murmurs
 - Previous Kawasaki disease without valvular dysfunction
- Cardiac pacemakers and implanted defibrillators.

Infective endocarditis prophylaxis is indicated in all high risk and and moderate risk categories (Tables 121.2 and 121.3).

Since oral sepsis is a very common cause for transient and recurrent bacteremia proper dental hygiene is the most effective and definite prophylactic measure.

Cardiac Arrhythmias

K. Suresh

Chapter Summary

Sinus Arrhythmia	807
Sinus Bradycardia	807
Sinus Tachycardia	807
Ectopic Beats	807
Paroxysmal Tachycardias	816
Wolff-Parkinson-White Syndrome	817
Ventricular Tachycardias (VT)	818
Torsade-De-pointes	820
Atrial Flutter	820
Atrial Fibrillation	820
Ventricular Fibrillation	822
Heart Blocks	822
Ventricular Standstill	824
Management of Cardiac Arrest	825
Sick Sinus Syndrome (SSS)	825

General Considerations

13

The myocardial cells have the property of spontaneous excitability (automaticity). This is responsible for the pacemaking function of the heart. The sino-atrial (SA) node which has the fastest rate of excitability controls the heart rate. The SA node contains specialized electrically active cells known as P cells which are most excitable. The rate of impulse production and conduction are controlled by various physiological, pharmacological and pathological processes. In normal adults the heart rate varies between 60 and 100/min.

The action potential: The cardiac action potential is generated by movement of charged ions across the cell membrane through various channels. The action potential has five phases [phase 0,1,2,3 and 4]. However the two major phases involved in depolarization are - the spike [phase 0] and the plateau [phase 2]. A large fast inward movement of Na^+ through the fast sodium channel is responsible for the early spike. A slower steady influx of Ca^{++} through a separate set of slow channels accounts for

the plateau phase. The SA node and the atrio-ventricular node [AV node] contain cells whose action potential is dominantly mediated by the slow calcium channels. In contrast, the Purkinje cells and the working myocardial cells have both fast and slow channels.

The calcium channel: The exact structural details of the calcium channels in the sarcolemmal membrane are not known. It is believed that each ionic channel is a specific protein that floats in a lipid bilayer matrix with a water filled central pore for ion movement. These channels have a selective filter which determines the nature of ions passing through them. In addition, the channels are also influenced by intracellular voltage variations, and hence they are also called “voltage-dependent channels.”

The slow response type of action potential seen mainly in the SA node and AV node, is mediated by the slow channels. Although there are various types of slow channels, the calcium-mediated slow channel is most widely recognized. Compared to the fast channels, these channels are not only kinetically slower, but they also operate at a less negative to a more depolarized voltage range. A variety of agents block the slow channels. Local anesthetics, volatile general anesthetics and others produce a non-specific blockade of both fast and slow channels. In contrast, drugs like verapamil, nifedipine and diltiazem produce a selective direct blocking action on the slow channels. The result is blockade of calcium entry into the cell. Calcium channel blockers are extensively used in the treatment of arrhythmias and hypertension.

The conduction system: From the SA node, the impulse travels through the atria to the A-V node. There are three functionally specialized pathways in the atria which conduct impulses from the sinus node to the A-V node. These are the anterior, middle and posterior internodal tracts. A branch of the anterior tract – the Bachmann’s bundle connects the two atria also. From the A-V node the impulse travels through the bundle of His, bundle branches and the Purkinje system to reach the ventricular musculature.

In general, arrhythmias may be of two types- disorders of impulse production or disorders of impulse conduction

and may be caused by abnormalities of automaticity, and/or abnormalities of conduction. When the main pacemaker is suppressed, the lower centres become active and take up the pacemaking function. This gives rise to escape rhythms such as junctional escape or ventricular escape. Enhanced automaticity of ectopic foci may occur and this leads to the development of ectopic rhythms and ectopic tachycardias (junctional ectopics and junctional tachycardia).

Abnormality in the conduction of impulses may give rise to “re-entry phenomenon” which is considered as one of the common mechanisms of tachyarrhythmias. When the normal conducting pathway becomes refractory, an incoming impulse may take a different course and pass down. By the time it reaches lower down, the refractoriness of the distal end of the normal pathway, would have passed off and it may become capable of conduction. Hence, the abnormal impulse gets into it and it is conducted in a retrograde direction. This is designated as re-entry phenomenon and is responsible for genesis and perpetuation of ectopic tachycardias. In order for re-entry to occur three conditions must be met (1) two functionally distinct conducting pathways (2) Unidirectional conduction block in one of the pathways (3) A differential in the conduction rates in the pathways, with slow conduction via one pathway and return of conduction via the second.

In some individuals, accessory pathways for conduction exist. These accessory pathways are anomalous extranodal connections which connect the epicardial surfaces of the atrium and ventricles along the A-V groove. Accessory pathways may conduct impulses in both antegrade and retrograde directions – the former mostly silent. The accessory and normal pathways conduct impulses from the atria to the ventricles in various combinations resulting in the production of re-entrant tachyarrhythmias, e.g. WPW syndrome.

Sinus Arrhythmia

Even in normal subjects with sinus rhythm, slight beat to beat variation in time-interval occurs. When the difference between the longest and the shortest cycles exceeds 0.12 sec., it is termed sinus arrhythmia. This is seen more often in children and young adults. In the vast majority of cases, this is a benign condition with no detectable underlying disorder of the heart.

Sinus arrhythmia may occur in 2 forms (1) phasic and (2) nonphasic. In the phasic form, which is more common, there is characteristic acceleration of the heart rate with inspiration and slowing with expiration. This is caused by the respiratory fluctuations in the vagal tone mediated through the ‘Bainbridge’s reflex’. The nonphasic form does not show any relation to the phases of respiration.

The electrocardiogram shows a difference of at least 0.12 sec between the longest and the shortest P-P intervals. The configuration of the P-wave and the P-Q intervals remain constant (Figs 122.1A and B).

Sinus Bradycardia

Sinus bradycardia implies a sinus rate below 60/min. Often this is seen normally in athletes and heavy manual labourers. Disease states such as hypothyroidism, obstructive jaundice, raised intracranial tension and acute inferior wall myocardial infarction may be associated with bradycardia. Drugs like digoxin, verapamil and propranolol may produce sinus bradycardia. Pathological processes affecting the S-A node give rise to sick sinus syndrome in which the patients may present with extreme sinus bradycardia, sinus arrest, sinus blocks and escape rhythms.

Sinus Tachycardia

Sinus tachycardia implies a sinus rate of more than 100/min. It is seen normally during exercise and anxiety. Fever, thyrotoxicosis, infections, hypoxia, anemia, hemorrhage, hypotension, heart failure and shock are the common pathological causes. Drugs like atropine, adrenaline and ephedrine cause sinus tachycardia. Usually the heart rate does not exceed 150/min (Fig. 122.2).

Ectopic Beats

Heart beat produced prematurely as a result of impulse originating in areas other than the sinus node is designated as ectopic beat. It may be early or late in diastole. Following a premature beat the normal impulse reaching the A-V node finds the ventricle refractory and so the subsequent normal beat is missed. This is the “compensatory pause”. If the R-R interval in the ECG encompassing the ectopic is twice the normal it is called fully compensated, otherwise it is partial. Premature beat may be atrial, junctional or ventricular.

Atrial premature beats (APB): These are premature beats arising from ectopic foci in the atria. Ectopic foci may be single or multiple. All age groups may be affected and in many cases, there is no detectable organic disease of the heart. Common causes include anxiety, excessive intake of coffee or tea and heavy tobacco smoking. However, in the presence of organic heart disease it can predispose to atrial tachyarrhythmias such as atrial tachycardia, flutter and fibrillation. Clinically, premature beats are appreciated as dropped beat. The compensatory pause is not full in atrial premature beat. The normal beat coming after the compensatory pause is more forceful on account of the longer diastolic filling and this may be felt as a thud by

Fig. 122.1A: Normal ECG with sinus bradycardia. Note: The QRS rate is around 60/minute. The rhythm is regular with normal P and other complexes. QRS duration is less than 0.12 seconds

Fig. 122.1B: Sinus arrhythmia: Note the change in heart rate with inspiration and expiration – increase during inspiration with shorter R-R intervals and decrease during expiration. This is a normal phenomenon

13

Fig. 122.2: ECG sinus tachycardia: Note: 1. Rate 150/minute 2. P waves precede all QRS complexes

Fig. 122.3: Atrial premature beats: Note: 1. The 3rd and 7th beat of the rhythm are premature beats. 2. The QRS morphology of premature beat is same as the normal beat 3. The premature beat is preceded by abnormal P wave (arrow)

Fig. 122.4: Premature ventricular beat (PVC) Note the bizarre ventricular ectopic beat. Note the compensatory pause—arrow

Fig. 122.5: Paroxysmal atrial tachycardia (PAT): Note: The first half of the rhythm strip shows rate of nearly 190/minute. The run of tachycardia terminates and is replaced by sinus rhythm in the latter part (arrow)

Fig. 122.6: Paroxysmal atrial tachycardia with block

Fig. 122.7: Multifocal atrial tachycardia (MAT) Note: 1. The varying morphology of the P waves indicated by arrows 2. Tachycardia with a rate of nearly 150/min

Fig. 122.8: AVNRT (A V nodal re-entrant tachycardia): Note: 1. AVNRT is a re-entrant tachycardia which utilizes the fast and slow pathways in the AV node for its circuit. The uniform and narrow QRS complexes at a rate of nearly 180/min 2. Short RP intervals and long PR intervals (marked by arrows in aVR) is a hall mark of AVNRT

Fig. 122.9: Wolff-Parkinson-White (WPW) syndrome: Note: The classic triad of WPW syndrome include: 1. short PR interval 2. delta wave (arrows) and 3. QRS widening. The delta wave represents the conduction through the aberrant bypass tract

Fig. 122.10: Ventricular tachycardia (VT). Note: The non-uniform QRS complexes 1. Broad QRS complexes at rate of 150 per minute. 2. Mild irregularity in RR intervals. 3. Mild variation in morphology of QRS complexes. 4. Evidence of AV dissociation. Marked by arrow in V1

Fig. 122.11: Torsade de pointes: Note: 1. Torsade is a form of malignant ventricular tachycardia 2. The QRS is polymorphic 3. The axis of the QRS shifts across the baseline around a point 4. Often this occurs in the setting of prolonged QT interval

Fig. 122.12: Atrial flutter without A-V block: Note 1. Ventricular rate above 180/minutes 2. Large and negative P waves in leads II, III and aVF. Comment: Generally when the atrial rate increases functional A-V block develops

Fig. 122.13: Atrial flutter: Lead V_1 to show the flutter waves 1. The rapid flutter waves (marked by arrow) which are usually inverted in leads II, III and avF 2. The QRS rate is much slower due to associated AV block (arrow head)

Fig. 122.14: Atrial fibrillation: Note: 1. Totally irregular RR intervals 2. Absence of $-P$ waves 3. Fibrillatory waves marked by arrows. Usually the QRS rate is fast in untreated atrial fibrillation. This record is made after starting treatment and showing of the heart rate
(1) Upper tracing lead 2
(2) Lower tracing shows the fibrillatory waves best brought out in lead V_1

Fig. 122.15: Ventricular fibrillation: Note: 1. Totally irregular QRS activity with undulating base line.
2. Absence of normal QRS and T waves

Fig. 122.17: Sinus arrest: Note the absence of all complexes with long pause

Fig. 122.18: SA block: The PR interval is normal. The sinus fails to produce impulse as is seen by the absence of P wave and the QRS (arrow)

Fig. 122.19: First degree A-V block: Note the prolonged PR interval beyond 0.2 second (i.e.) > 5 small divisions

Fig. 122.20: Second degree heart block Mobitz type 1: Note: 1. progressive prolongation of PR interval 2. The fourth P wave is blocked and is not followed by a QRS (arrow) Wenckebach's phenomenon

Fig. 122.21: Second degree heart block Mobitz type 2: High grade AV block: Note: the 4th, 5th and 6th P waves (marked by arrows) are not conducted to the ventricles indicating high grade A-V block 2. All the conducted beats show PR interval which remain constant

Fig. 122.22: Third degree A-V block. 1. P waves are regular and normal in rate 2. QRS are also regular but much slower in rate and wider 3. No relation between P and QRS

Fig. 122.23: ECG left bundle branch block (LBBB Note 1). duration of QRS exceeds 0.12 seconds 2) widened, slurred and bizarre R waves in lead 1 aVL, V5 and V6 slurred S waves in V1 and V2

Fig. 122.24A: RBBB: complete right bundle branch block Note: 1. Prolongation of QRS duration above 0.12 seconds 2. Slurred R’waves in V1 and V2 3. Wide S waves in L1, aVL and V5 and V6

Fig. 122.24B: LAHB Note: 1. QRS axis is abnormally shifted to the left (left axis deviation) 2. Small Q, tall R morphology in aVL 3. Persistent S waves in V5 and V6

Fig. 122.25: Asystole: Note complete electrical silence (ventricular standstill)

Fig. 122.26: Sick sinus syndrome: note the tachy and bradyarrhythmias. 1. The first half shows atrial fibrillation with fast heart rate 2. The latter half shows a long pause

the patient. Electrocardiogram shows the abnormally shaped ectopic P-wave preceding the normal QRS complex. The compensatory pause is not full. The PQ interval is usually short though sometimes it may be prolonged (Fig. 122.3).

Junctional premature beats: These beats arise from the A-V junction. These are less common than atrial and ventricular premature beats. The physical findings resemble those of atrial premature beats. Sometimes cannon waves may be observed in the neck veins, if the atria contract while the A.V valves remain closed. The conduction of impulse in the atrium is retrograde and so the P-wave appears inverted in L_{II}, L_{III} and aVF, but it is upright in lead aVR. They may precede the QRS with a shortened P-Q interval, be immersed in the QRS, or follow the QRS. The QRS of the junctional premature beat is usually normal. The compensatory pause is not full.

Ventricular premature beats (VPB): An ectopic focus in any part of the ventricle can give rise to ventricular premature beats (VPBs). This is the commonest arrhythmia seen both in health and in disease. Continuous monitoring has shown that even apparently healthy individuals may show this arrhythmia. Ventricular premature beats occurring in a healthy heart usually disappear on exercise. The ventricular premature beats are seen pathologically in ischemic heart disease, acute myocardial infarction, cardiomyopathy, myocarditis, hypertension and digitalis toxicity. VPB occurring after every normal beat leads to pulsus bigeminus in which after two beats a pause occurs regularly. This is the characteristic arrhythmia seen in digitalis toxicity.

Clinically, VPB manifests as irregularity in the pulse. The premature beat may be felt as an early feeble pulse or the strong post ectopic beat may give rise to a pounding sensation in the chest. Jugular venous pulse may show irregular cannon waves. In the electrocardiogram the ventricular premature beat appears as a widened QRS which is often bizarre in shape. The ST segment and T wave is in a direction opposite to the direction of the QRS. The QRS is not preceded by the P-wave. The compensatory pause is often complete. Sometimes a ventricular premature beat may be seen sandwiched in between two sinus beats. They are known as *interpolated ventricular premature beats*. The R-R interval encompassing the VPB is equal to one cardiac cycle. The interval between the sinus beat and the VPB is known as coupling interval. Coupling interval is constant in case of unifocal VPB, but it is variable in multifocal VPBs (Fig. 122.4).

Paroxysmal Tachycardias

These are tachycardias produced as a result of enhanced impulse production from ectopic foci (in contrast to sinus tachycardia in which the normal pacemaker produces

impulses) or as a result of re-entry phenomenon. All the paroxysmal tachycardias are characterized by abrupt onset. Paroxysmal tachycardias depending on the focus of impulse production may be divided into:

1. **Supraventricular** – Atrial or A-V junctional
2. **Ventricular** – Right or left ventricular

Irrespective of the type of tachycardia, symptoms tend to be similar. Paroxysmal tachycardias usher in abruptly with a feeling of rapid thumping cardiac contractions in the chest. This may make the patient extremely uneasy and anxious. Autonomic phenomena such as sweating, syncopal feeling and tachypnea may develop. In patients with coronary artery disease, angina may be precipitated. If the arrhythmia tends to be prolonged beyond a few hours, signs of cardiac failure may develop especially if there are underlying abnormalities. Termination of the attack is also felt as an abrupt cessation of the tachycardia. This may be accompanied by diuresis, usually in supraventricular tachyarrhythmias.

In predisposed individuals, tachyarrhythmias are triggering factors to induce cardiac failure. In all forms of these arrhythmias, ECG is absolutely essential to arrive at the diagnosis.

Paroxysmal atrial tachycardia (PAT): Impulses arise in the atrium and the arrhythmia is usually produced as result of reentry phenomenon. The heart rate varies from 140-230/min and the rhythm is regular. The ECG shows normal QRS with a rate of 140-230/min. In some cases the P-waves may be identifiable preceding the QRS. Vagal stimulation (carotid pressure, dipping the face in or swallowing ice-cold water or pressure over eyeball) generally slows the rate and abolishes an attack. In the majority there is no underlying cardiac disease. Common causes are excess of caffeine or tobacco, alcohol, anxiety or thyrotoxicosis (Fig. 122.5).

Paroxysmal atrial tachycardia with block (PATB): This is a special form of PAT in which some of the atrial impulses are not conducted down to the ventricles. This gives rise to varying grades of atrioventricular block. Electrocardiographically P waves occur at a rate of 140-230/min, with an isoelectric shelf separating the P waves, and a slower QRS rate. This abnormality is characteristically seen in digitalis toxicity. It is an indication for withdrawing digitalis (Fig. 122.6).

Multifocal atrial tachycardia: This is characterized by an irregular rhythm and P waves with different morphology. It is seen in conditions such as bronchitis emphysema syndrome, cor pulmonale, hypoxia from any cause, ischemic heart disease, diabetes mellitus and after cardiac surgery. It indicates a poor prognosis. Diagnosis of multifocal atrial tachycardia can be made only with ECG. The ECG criteria include (Fig. 122.7):

1. Rate above 100/min.

2. At least three different forms of P waves in the same lead and
3. Variability of P-P, P-R and R-R intervals.

Management

1. Carotid sinus massage in the recumbent posture may serve to abolish PAT. Only one side should be massaged at a time;
2. Intravenous administration of verapamil or propranolol in small doses of 5 -10 mg at a time may terminate the episode;
3. Other antiarrhythmics that may be tried include amiodarone, or the Class I antiarrhythmics.

In resistant cases DC shock may be required. Investigation for the underlying condition and specific measures should be instituted to prevent recurrence.

A-V junctional tachycardia: Both paroxysmal (ventricular rate 130-240/min) and non-paroxysmal (ventricular rate 70-140 min) forms exist. The ECG shows normal QRS complexes, but the P-wave usually follows the QRS.

AV Nodal Re-entrant Tachycardia (AVNRT)

AVNRT is a tachycardia with a narrow QRS complex and a ventricular rate typically in the range of 150-250 beats/min. The mechanism in AVNRT appears to be a re-entrant circuit composed of separate slow and fast pathways involving the AV node. It is generally seen in subjects without underlying heart disease. Palpitations and dyspnea are common presenting complaints. Angina, CHF and rarely shock may be seen in those with a history of underlying heart disease. Syncope occurs rarely. ECG shows narrow QRS regular tachycardia with a rate of 150-250/min. P waves are generally not seen as they are hidden within the QRS complex (Fig. 122.8).

AV Re-entrant Tachycardia (AVRT)

AVRT is another narrow QRS tachycardia with ventricular rates often greater than 200/min.

The clinical features are very similar to those of AVNRT but are distinct on an electrophysiological basis. The mechanism in AVRT relies on the presence of re-entrant circuit comprising of an accessory pathway as one portion of the circuit and the AV node as the other portion. Accessory pathways may be “concealed” (inapparent by ECG) due to having only retrograde conduction properties (V to A) or “manifest” (apparent on ECG as delta waves) due to variable degrees of antegrade conduction [e.g. Wolff-Parkinson-White pattern as described below].

AVRT may be orthodromic or antidromic. Orthodromic AVRT is a narrow-complex tachycardia that uses the AV node as the antegrade limb and the accessory pathway as the retrograde limb of the circuit. Antidromic

AVRT is a wide QRS complex tachycardia that is the opposite such that the accessory pathway serves as the antegrade limb and the AV node as the retrograde limb of the circuit.

Orthodromic AVRT is the most common re-entrant AVRT accounting for 95% of cases. It is a narrow QRS complex regular tachycardia and the P wave will be seen just after the QRS complex inscribed on the ST segment (unlike AVNRT where the P waves are hidden in the QRS).

Wolff-Parkinson-White Syndrome (WPW syndrome) (Pre-excitation Syndrome)

WPW syndrome is not an uncommon cause of tachyarrhythmia seen in both sexes. In this condition an abnormal band of atrial tissue connects the atria and ventricles. In sinus rhythm this tissue conducts impulses faster bypassing the AV node. Conduction of impulse from atrium to ventricle occurs partly through the AV node and partly through the faster bypass tract. The ECG shows shortening of the PR interval and slurring of the ascending limb of the QRS complex, termed the delta wave, in addition to widening of the QRS complex (Fig. 122.9).

Since the AV node and the abnormal conducting tract have different conduction velocities, re-entrant tachycardias occur frequently resulting in paroxysmal tachycardias. Depending upon the direction of passage of the impulse through the AV node and the abnormal conducting tissue, the re-entry mechanisms vary giving rise to ECG patterns either resembling supraventricular tachycardia or with broader QRS complexes resembling ventricular tachycardias. Atrial fibrillation and ventricular fibrillation may occur at times. The condition is disabling since it affects the quality of life of the patient.

Management of SVT

This includes pharmacological therapy, radio-frequency ablation of the abnormal conduction pathway or surgical treatment. At present, catheter ablation is done for life-threatening arrhythmias [e.g. WPW syndrome, VT, incessant SVT, AF, atrial flutter etc] where accessory pathways are demonstrable and medical treatment fails.

i. Pharmacological therapy

Mainly 3 types of drugs are employed.

Those that prolong the conduction time or refractoriness in the AV node, e.g. Adenosine, propranolol and digoxin.

ii. Those that prolong the conduction or refractoriness of the accessory pathway, e.g. Class 1A and Class 1C drugs.

iii. Prolongation of conduction time and refractoriness of both pathways. Class III drugs, e.g. Amiodarone, sotalol.

Digoxin, IV verapamil and lignocaine can be used, but with caution, and not if the patient presents with atrial fibrillation. In patients with anterograde conduction through the accessory pathway, use of digoxin, adenosine, Calcium blockers, beta blockers etc may be contraindicated since these drugs increase accessory pathway conduction and predispose to fast ventricular rates.

Amiodarone: This is a potent antiarrhythmic drug which is effective both in supraventricular and ventricular arrhythmias. It may be given both parenterally as well as orally. Peak levels occur within 4-5 hours after an oral loading dose. It has a long half-life in the body (more than eight days). It is concentrated in the myocardium. Initial dose is 100-200 mg, 6- 8 hourly orally for 5-7 days and then the dose is reduced gradually to reach a maintenance dose of 100-200 mg/day. Adverse side effects include antagonism to vitamin K dependent coagulation factors and photosensitivity. This drug is useful in the treatment of resistant supraventricular and ventricular arrhythmias and WPW syndrome. This drug can also be given IV as a bolus injection in a dose of 150 mg, followed by a continuous infusion of 1.0 -1.2 gm over 18 to 24 hrs.

Calcium channel blockers: Verapamil and diltiazem have pronounced antiarrhythmic properties. They reduce the SA node activity and AV nodal conduction. Verapamil is very effective in the treatment of supraventricular tachycardias when given intravenously in a dose of 5 mg to be repeated ten minutes later, if necessary. Diltiazem is also effective particularly when given parenterally and also in the more conventional mode orally. Both these drugs are contraindicated in the presence of left ventricular failure, shock and conduction defects. They are not effective in the treatment of ventricular tachycardias.

When drug therapy fails and the condition of the patient demands rapid termination of the arrhythmia, more aggressive methods have to be used. These include DC shock and catheter ablation of the abnormal conduction pathways. In the latter, radio-frequency energy is used to ablate the abnormal pathways.

Termination of an Acute Episode

If there is no hemodynamic compromise, vagal pressure can be applied initially to reduce the rate. This is followed up with IV adenosine (6-12 mg IV rapid bolus) and later intravenous verapamil or diltiazem. Atrial fibrillation with fast heart rate may occur after drug administration, particularly adenosine. This should be treated with electrical cardioversion.

In those with very rapid ventricular rates or signs of hemodynamic impairment, electrical cardioversion is the treatment of choice.

For atrial flutter or fibrillation, drugs that prolong refractoriness in the accessory pathway often coupled with

drugs prolonging AV nodal refractoriness such as procainamide and propranolol are used (Fig. 122.16).

Prevention of Tachycardia

Drug combinations are usually employed

- Quinidine and propranolol or procainamide and verapamil
- Amiodarone or sotalol can be used singly. Dose of sotalol 80-320 mg/day in divided doses

Radio-frequency catheter ablation of the accessory pathway is advisable for the following groups:

- Symptomatic arrhythmia not fully controlled by drugs.
- Drug intolerance.
- Reluctance to take medication.

In experienced hands for electrical ablation the success rate varies from 95-98%.

Surgical ablation: Rarely surgical interruption of accessory pathway may be necessary.

Ventricular Tachycardia (VT)

When three or more ventricular ectopic beats occur in succession, it is called ventricular tachycardia. The common causes are ischemic heart disease, myocarditis, digitalis toxicity, electrolyte disturbances and cardiomyopathies. Rarely this may occur in an otherwise normal heart. The ventricles beat regularly at the rate of 150-210/min, slight irregularity may occur. VT can be monomorphic or polymorphic. The blood pressure is low and the patient may go into shock. Carotid massage does not bring down the rate as in the case of supraventricular tachycardia.

Ventricular tachycardia may be preceded by the occurrence of ventricular ectopics. Frequency of more than 6 ectopics/min, multifocal ectopics, ectopics occurring in succession and ectopics falling on the T-wave of the preceding beat (R on T phenomenon) are features which are associated with a higher risk of developing VT.

Diagnosis: VT is confirmed by the ECG which shows wide, regular, QRS complexes with evidence of dissociation between P-waves and QRS. Occasional sinus capture beats and fusion beats due to the inherent AV dissociation may be seen. VT needs to be distinguished from other wide QRS complex tachycardias like SVT with aberrant intraventricular conduction, pre-existing bundle branch block, antegrade conduction over an accessory pathway. Presence of AV dissociation (more QRS complexes than P waves) is diagnostic of VT (Fig. 12.10).

Prognosis: Ventricular tachycardia is a grave arrhythmia associated with high mortality, since it usually indicates serious underlying heart disease. Death is due to shock or transition to ventricular fibrillation.

Fig. 122.16: Guidelines for the management of tachyarrhythmias. Acute management of patients with hemodynamically stable and regular tachycardia. *A 12-lead ECG during sinus rhythm must be available for diagnosis. Adenosine should be used with caution in patients with severe coronary artery disease and may produce AF, which may result in rapid ventricular rates for patients with pre-excitation. **Ibutilide is especially effective for patients with atrial flutter but should not be used in patients with EF less than 30% due to increased risk of polymorphic VT. AF indicates atrial fibrillation; AV, atrioventricular; BBB, bundle-branch block; DC, direct current; IV, intravenous; LV, left ventricular; QRS, ventricular activation on ECG; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

Modified from ACC/AHA/ESC guidelines for the management of tachyarrhythmias. Ref: Circulation 2003;108:1871-1909.

Management: Patient presenting with shock and ventricular tachycardia should be given synchronized DC shock of 100-150 joules to convert the rhythm to normal without delay. Antiarrhythmic drugs tend to take time for action and aggravate hypotension. Pressor agents such as dopamine may be required if the blood pressure does not come up.

In uncomplicated cases the drug of choice is lidocaine (lignocaine). It is given as a 2% solution intravenously. Bolus doses of 50-100 mg are repeated (up to a total dose

of 250 mg) till the tachycardia is arrested. Then a maintenance dose of 2-4 mg/min is given continuously as an intravenous drip, 1g added to 500 mL 5% glucose and 1-2 mL given every minute. The drip is tapered off within 48-72 hours. If the VT recurs despite lignocaine, other antiarrhythmic drugs should be tried to control the arrhythmia. Drugs like procainamide, disopyramide, mexilitine, propranolol or amiodarone are given intravenously for immediate control of VT. The dose of amiodarone is 150 mg IV bolus in 15 mts followed by a

infusion of 900 mg in 24 hrs (1 mg/kg for 6 hrs and then 0.5 mg/kg for 18 hrs). Once the VT is controlled oral maintenance therapy can be continued preferably with the same drugs. The following drugs are for oral use.

1. Procainamide 1-3 g daily in divided doses.
2. Quinidine sulphate 0.8-2 g daily in divided doses.
3. Disopyramide 400-600 mg daily in divided doses.
4. Dilantin sodium 100 mg thrice daily.
5. Amiodarone: 100-300 mg/day.
6. Mexiletine 200 mg three times daily to start with and then continued at 100 mg thrice daily.
7. Sotalol dose 80-320 mg/day in divided doses.

In acute myocardial infarction with a slow ventricular rate, transvenous pacing to increase the heart rate prevents the development of ventricular tachycardia. The development of curative catheter based therapies especially in patients with normal heart and implantation of ICD (implantable cardioverter defibrillator) especially in post ischemic VT have reduced the role of antiarrhythmic drugs in the prevention of recurrence.

Torsade-De-pointes

This is an acquired or congenital polymorphic ventricular tachycardia in the range of 180-250/min characterised by QRS complexes of progressively changing amplitude and contour, that seem to revolve around the isoelectric line. Successive bursts of unsustained ventricular tachycardia occur. Sometimes these attacks may be prolonged and lead to syncope. The ECG shows prolonged Q-T interval (Fig. 12.11).

Arrhythmogenic Right Ventricular Dysplasia (ARVD)

ARVD is a cardiomyopathy in which the right ventricular muscle becomes increasingly replaced by adipose and fibrous tissue as the disease progresses. VT arising in the right ventricle is often an early manifestation of this disorder. VT has an LBBB morphology, although in sinus rhythm there is often inversion of T waves in the anterior leads and a slurring of the terminal portion of the QRS complex known as an "epsilon wave".

General points in the management of acute tachycardias: Paroxysmal tachycardias present as medical emergencies demanding acute care management. The ECG gives the clue to the nature of the tachycardia – whether VT or SVT. Wide QRS complex with a duration of > 140 msec is suggestive of VT unless proved otherwise. Based on the ECG, the tachycardias may be classified as regular or irregular and narrow or wide QRS complex. Regular narrow complex tachycardia can be treated with adenosine or drugs that slow the AV conduction. Irregular narrow complex tachycardia is due to AF and warrants treatment with drugs to achieve rate control by AV nodal blocking

action. Monomorphic wide QRS tachycardia should be presumed to be VT unless otherwise proved, and procainamide, amiodarone, or electrical cardioversion should be tried. Polymorphic wide complex irregular tachycardia should be classified into those with wide QT, those with normal QT and those with AF with WPW. Treatment of choice in these situations is magnesium, beta blockers and procainamide or amiodarone respectively.

Atrial Flutter

This is an uncommon arrhythmia in which the atria contract at the rate of 300/min. The mechanism is one of re-entrant tachycardia affecting the atria. Since the A-V node cannot conduct impulses at this rate, a physiological block develops and only half, a third, or a fourth of the atrial impulses are transmitted to the ventricles. The ventricles contract at a lower rate, but regularly. Flutter waves are seen in the jugular vein. Carotid pressure increases the block and reduces the ventricular rate further (Figs 12.12 and 12.13).

Treatment: Generally atrial flutter is resistant to drug treatment, but it responds to DC shock readily, 50 joules may be sufficient. Digoxin either abolishes the arrhythmia or converts it into atrial fibrillation and reduces the ventricular rate. On withdrawing digoxin normal rhythm may be restored. Quinidine is also effective in the treatment of atrial flutter.

Atrial Fibrillation

This is the condition in which the coordinated contraction of the atrium is abolished and the atrial muscle fibrillates. Abnormality of atrial activation is caused by impulses arising from different foci at the rate of 400-600/min. Since coordinated contraction at this rate is not possible, fibrillation sets in. This is the most common sustained arrhythmia in clinical practice. Prevalence increases with age. Above the age of 65 years, AF occurs in 5% of persons and above 75 years it affects 10% or more. 5% of persons with paroxysmal AF and 20% of those with persistent or permanent AF have no other demonstrable pathology.

Etiology: Atrial fibrillation (AF) may be due to different causes. In the order of frequency these are:

1. Rheumatic mitral valvular disease, mixed mitral lesions, mitral stenosis and mitral regurgitation.
2. Ischemic heart disease
3. Hypertensive heart disease
4. Thyrotoxicosis
5. Myocarditis
6. Cardiomyopathies
7. Digoxin toxicity

8. Chronic pericardial disease
9. Pneumonia
10. Congenital heart disease esp atrial septal defect
11. Sick sinus syndrome
12. Lone atrial fibrillation [AF without any predisposing diseases]
13. Familial AF [An abnormality of chromosome 16 occurring as an autosomal dominant disorder]
14. Infections and alcoholic bouts (Holiday heart syndrome).

Classification

- a. *Paroxysmal AF*: transient, reverting to normal sinus rhythm spontaneously.
- b. *Persistent AF*: does not revert spontaneously, but does so with electrical or pharmacological intervention.
- c. *Permanent AF*: cannot be reverted to sinus rhythm by electrical or pharmacological intervention.

Pathophysiology: Ectopic impulses arise in the atria, or pulmonary veins and their ostia at the rate of 400-600/min. They reach the A-V node at irregular intervals. Many of them find the A-V node totally or partially refractory and therefore, conduction to the ventricle is totally irregular. In AF the electrical activity produces multiple wavelets which circle round the atria. Some of these circle back themselves forming re-entry loops. The conduction velocity and refractory periods of portions of the atrial wall vary so that wavelets follow altering courses. A few complete classic re-entrant loops. Atrial enlargement predisposes to AF by accommodating more wavelets.

Rheumatic valvular disease predisposes to AF since it leads to deranged hemodynamics, atrial inflammation, fibrosis and impaired propagation of the impulse.

Ventricular contraction occurs irregularly – both in rhythm as well as in force. The ‘a’-wave in the jugular vein disappears since the atrium fails to contract as a whole. Loss of atrial contraction abolishes the augmented transit of atrial blood into the ventricle during end diastole, thereby abolishing the stretch to the ventricular muscle preceding systole (atrial booster effect). In normal hearts this may not be clinically significant, but in a diseased heart, atrial fibrillation precipitates cardiac failure because of the loss of atrial booster effect. Thrombi form in the atria as a result of stagnation. These embolize periodically resulting in systemic or pulmonary embolism.

Clinical features: The onset of atrial fibrillation may be felt as palpitation, especially so if the heart rate is high. Atrial fibrillation may be acute with duration less than a few days, paroxysmal or chronic and insidious in onset and course.

The pulse is totally irregular in rhythm and volume (irregularly irregular). The irregularity is best felt when the heart rate is rapid. In slow heart rates with ventricular

contraction around 70/min, the arrhythmia may be more difficult to detect clinically at rest. Pulse deficit can be made out by simultaneous palpation of the pulse and auscultation of the heart rate (by two different observers). A difference of more than 10 beats per min is highly suggestive of atrial fibrillation. The irregularity increases with exertion. Auscultation reveals total irregularity and varying intensity of the first heart sound. The ‘a’ wave of the jugular venous pulse is abolished. The presystolic accentuation of the mid-diastolic murmur of mitral stenosis disappears in most cases. If the fourth heart sound was audible prior to the onset of AF, it disappears. Confirmation of the diagnosis is made by ECG which shows absence of P-waves and the presence of fibrillary waves instead. The QRS complexes are irregular in rhythm but may be normal in pattern (Fig. 122.14).

Differential diagnosis: Frequently occurring irregular extra systoles may be mistaken for AF, especially if the heart rate is slow. Exercise abolishes the extrasystoles whereas it aggravates atrial fibrillation. In a few cases where clinical distinction is difficult electrocardiogram is needed for final diagnosis.

Course and prognosis: When the underlying condition is reversible such as myocarditis, pneumonia or thyrotoxicosis, treatment of the primary cause corrects the AF also. In chronic conditions such as valvular or congenital heart disease, cardiomyopathy and ischemic heart disease, the arrhythmia tends to persist even after treatment of the primary disease.

Atrial fibrillation gives rise to thromboembolic episodes, especially so when there is obstruction to atrioventricular flow as in mitral stenosis. Risk of thromboembolism is increased considerably in all cases of atrial fibrillation, compared to sinus rhythm. The risk of thromboembolism occurs in all types of atrial fibrillation. In paroxysmal AF usually embolization occurs on restoring sinus rhythm. Other abnormalities such as LV function impairment, disturbances of hemostatic mechanism and hypercoagulability accentuate the risk. In general 65% of emboli arise from the atrial appendage. Presence of mitral stenosis increases this risk several fold further.

Occurrence of atrial fibrillation leads to deterioration in the cardiac status and a progressive downhill course in chronic rheumatic heart disease, cardiomyopathies and systemic hypertension. Total mortality is doubled by the presence of AF in all forms of serious underlying heart disease.

Management : The aims of treatment are:

To restore sinus rhythm if possible [rhythm control]

1. If not, reduce the ventricular rate so as to improve the cardiac output [rate control]
2. Prevent recurrences and maintain sinus rhythm
3. Prevention of thromboembolism

Direct current (DC) shock helps to convert AF to sinus rhythm in 70-80% of cases. If the AF is less than 2 days duration electrical conversion can be attempted without anticoagulation. Flecainide is given to maintain sinus rhythm if the left ventricular function is good. If it is compromised amiodarone is the drug of choice.

If the AF is more than 2 days duration cardioversion should be attempted only after instituting anticoagulation with warfarin for 3 weeks. Warfarin has to be continued for 4 weeks after the procedure. The INR has to be kept between 2-3.

Ventricular rate control in atrial fibrillation can be done with digoxin, beta-blockers, amiodarone and calcium channel blockers (verapamil or diltiazem). In acute cases these drugs can be given IV, but for long-term use oral route is preferred.

Conversion to sinus rhythm can be achieved with drugs such as flecainide [90% success], propafenone [72%], and amiodarone [64%] also. AF < 48 hours duration responds well. In AF >48 hrs duration, drugs are less effective – dofetilide or amiodarone maybe tried [success rate 25-40%].

Atrial pacing is effective on long-term to prevent recurrences of AF, by preventing bradycardia and suppressing ectopic beats. Ablation of the ectopic foci in the atria or pulmonary vein ostia or isolation of these foci from conducting to the rest of the heart can be done by either catheter based radio-frequency techniques or surgically. The Maze procedure and the corridor procedure are such methods. The re-entrant circuits perpetuating AF are disrupted.

The risk factors for stroke in AF include mitral valve disease, age > 65 yrs, hypertension, LV dysfunction and previous h/o TIA or stroke. In patients less than 65 yrs of age with no risk factors for stroke only aspirin (150 mg/day) is required to prevent thromboembolic episodes, in all other patients with AF anticoagulation with warfarin is required, titrated to maintain INR (2-3) to prevent thromboembolic episodes.

Ventricular Fibrillation (VF)

This is the commonest fatal arrhythmia in ischemic heart disease. The myocardium of the ventricles contract asynchronously and fractionally to produce a fibrillary movement without any sustained synchronous beat. Pumping action of the heart is abolished, circulation comes to a standstill and death ensues if resuscitatory measures are not instituted immediately. The physical signs are exactly those of cardiac asystole. The ECG distinguishes ventricular fibrillation from asystole.

Management: Electrocardiogram is mandatory for diagnosis. Ventricular fibrillation is recognised on the ECG by the absence of QRS complexes and T-waves and

the presence of low amplitude baseline undulations which are quite variable both in amplitude and rhythm. The heart is defibrillated by direct current (DC) shock of 300-400 joules. Management of VF is the same as that of sudden cardiac arrest (Fig. 122.15).

Bretylium tosylate given intravenously in a dose of 5-10 mg/kg body weight is very effective in preventing the recurrence of ventricular fibrillation. Implantable cardioverter defibrillators (ICD) have become available in recent years. These compact devices detect ventricular tachycardia and fibrillation and automatically deliver shocks on to the myocardium, to terminate the arrhythmias.

Shock resistant VF is defined as VF persisting even after 3 attempts of electrical defibrillation.

Life Support Measures

In many developed countries the public has been trained to give emergency cardiac support by external cardiac massage, mouth-to-mouth respiration and external cardiac defibrillation. In many of the public places emergency defibrillators are also provided. If cardiac rhythm is restored within three minutes of onset of ventricular fibrillation or asystole the chance for recovery and brain function are good. Standardized practice guidelines have been laid down to assist physicians in clinical decision making in such emergencies.

Heart Blocks

Delay or interruption of the conduction of impulses from the SA node along the normal pathway to the ventricular myocardium results in heart block. The SA node produces impulses at the rate of 70-80/min. Velocity of conduction in the atria is 1m/Sec. It is 0.2 milliseconds in the A-V nodal tissues and 4 milliseconds in the Purkinje system. The A-V node being less conductive, there is a delay of 80-120 milliseconds, at this level. Heart block can be caused by abnormalities of impulse conduction at the SA node as in sinus blocks or conduction at the A-V node, the bundle of His and its branches.

Sinus arrest: In this condition the sinus node ceases to produce impulses (Fig. 122.17).

Sinoatrial block: impulses arising from the SA node are blocked at the junction of the SA node with the atrial musculature and hence the beat is missed. The ECG shows a pause with total absence of the PQRST complexes, corresponding to the missed impulses. Sometimes escape beats or escape rhythms may occur (Fig. 122.18).

Atrioventricular block (A-V block): This is caused by abnormalities at the A-V junction or along His Purkinje system. Three forms may occur.

1. **First degree A-V block:** Clinical detection of this form may be difficult. The ECG shows prolongation of P-R interval exceeding 0.20 sec (Fig. 122.19).
2. **Second degree A-V block:** This block is of two types. In both the types some of the impulses from the S-A node fail to reach the ventricles resulting in dropped beats.
 - a. **Mobitz type I block (Wenckebach's phenomenon):** The P-R interval increases progressively till a QRS is totally missed. This is clinically evident as a regular irregularity. Almost always this is caused by a block in the A-V node (Fig. 122.20).
 - b. **Mobitz type II block:** This is a more serious arrhythmia than type I block. The P-R interval of the conducted beats is fixed, but some of the P-waves are not conducted to the ventricles and are not followed by QRS. The P-waves outnumber the QRS complexes. Mostly this is due to a block in the His-Purkinje system and often the QRS may show some widening (Fig. 122.21).
3. **Third degree heart block (complete heart block):** In this condition impulses from the SA node are totally interrupted from reaching the ventricular muscle. The ventricles respond to impulses produced by the A-V junction or areas distal to that. When the impulses arise from the ventricles (idioventricular rhythm) the rate is usually less than 40/min. The ECG shows regular P-waves occurring at 70-80/min, and QRS complexes are usually bizarre occurring at a rate of about 30-40 /min. There is total dissociation between the P-waves and QRS complexes. The pulse is regular in established complete heart block because the QRS complexes are produced regularly (Fig. 122.22).

Clinical features: First degree heart block is an abnormality usually detected by ECG. Second degree heart block causes regular missing of heart beats and the pulse. Unlike benign extrasystoles in which the irregularity disappears with exertion, the irregularity in heart block tends to persist. Mobitz type II is associated with more serious disorders such as acute myocardial infarction or degenerative disorders of the conduction system. It may also be seen in digitalis toxicity, rheumatic carditis or cor pulmonale. It is considered a more serious block because often it progresses to complete A-V block.

Etiology of Heart Block

1. Primary degeneration of the conducting tissues. (Lev's disease, Lenegre's disease)
2. Diseases affecting the myocardium: myocardial infarction, chronic coronary artery disease and myocarditis.
3. Drugs and toxins: digoxin, quinidine, procainamide, beta adrenergic blocking drugs, cerbera thevetia and cerbera odollam.
4. Trauma to the conducting tissue during surgery.

5. Congenital abnormality of the conducting tissue (congenital heart block).
6. Infections: Tertiary syphilis, South American trypanosomiasis (Chagas' disease) and cysticercosis.
7. Sick-sinus syndrome.

Complete heart block should be suspected when the heart rate is 30-40/min or less, not increasing with exercise. The patients may complain of palpitation or syncopal attacks on exertion or even at rest. Syncope is transient loss of consciousness as a result of diminution of arterial blood supply to the brain. The patient complains of dimness of vision, a sinking feeling and may become unconscious. In the majority of cases consciousness is regained on falling down due to resumption of cerebral circulation.

If the heart beats are not resumed, the patient develops convulsions – *Stokes Adams- attacks*. These attacks are seen when periods of asystole or transient ventricular tachycardia or ventricular fibrillation occur in complete heart block. This may also be seen when one idioventricular focus changes over to another. If the heart beat is not resumed within minutes, the condition ends fatally. When the lesion is fully established and the rhythm is regular even at a slow rate, compensatory mechanisms develop and the frequency of syncopal attacks diminish.

Physical examination reveals slow, high volume pulse, forceful apex beat (due to diastolic overdilatation), presence of irregular cannon waves in the jugular veins, widened pulse pressure (high systolic and normal or low diastolic), and varying intensity of the first heart sound. Independent atrial sounds may be heard.

The ECG shows the slow ventricular rate and complete dissociation of the P and QRS complexes.

Diagnosis: Complete heart block should be suspected when the heart rate is slow and regular. His-bundle electrography gives further information about the site of lesion (infra-Hisian or supra-Hisian).

Prognosis: First and second degree heart blocks may resolve completely with treatment or proceed to complete heart block when the lesion is progressive. During the stage of evolution the prognosis should be guarded. In the stage of evolution and when the lesion is unstable complete heart block can progress to cardiac arrest or ventricular fibrillation.

Management

First and second degree heart blocks: Apart from close ECG monitoring and observation of the clinical state, no specific treatment may be indicated. Treatment of the primary condition clears the conduction defect as well. Atropine 0.5 mg given intravenously abolishes vagal tone and improves the heart rate in A-V blocks. Isoprenaline

or adrenaline given intravenously increases the heart rate and this is life-saving in an emergency. The heart rate can be maintained at a high level by giving ephedrine 30 mg orally thrice daily. These sympathomimetic drugs have the risk of triggering off serious tachyarrhythmias and hence in acute myocardial infarction these are not recommended.

When a patient with myocardial infarction develops progressive heart block leading to complete heart block, it is an indication for **transvenous pacing** using an external pacemaker and electrode catheter introduced into the right ventricle.

In established complete heart block, long-term prognosis is poor and therefore, **permanent pacemakers** are implanted. Pacemaker consists of two components.

(1) Pulse generator which is made of various type of batteries and (2) The lead which can be connected to the heart. The pulse generator is implanted into the body by making a pocket in the subcutaneous tissue in the infraclavicular area or on the abdominal wall. The generator is connected to one end of the lead and the other end of the lead may be placed in the right ventricle transvenously (endocardial pacemaker) or over the left ventricular apex (epicardial pacemaker). Dual chamber pacemakers are available in which stimulation of the atrium is followed by stimulation of the ventricle so that the normal sequence of contraction is reproduced. These are also known as physiological pacemakers. Modern pacemakers are programmable regarding the rate, voltage output and refractory period by telemetry from outside. Sensors which recognize the level of activity of the patients are incorporated in the pacemakers so that the rate of pacing is automatically adjusted to the requirement.

Since the advantage of pacemakers in giving symptomatic relief and prolonging life has been established it should be the aim to provide pacemakers wherever indicated. The cost ranges from Rs. 40000 to 60000 for the basic models to higher prices for more advanced options. Majority of them have a trouble free life exceeding 15 years. Dual chamber pacemakers probably are more effective with less of complication rate.

It is important that patients with implanted pacemaker should avoid strong magnetic fields such as MRI installations and metal detecting equipments. It is ideal to implant pacemakers early to avoid the development of Stokes- Adams attacks or sudden cardiac death. Once implanted, they require regular follow-up care.

BUNDLE BRANCH BLOCK (BBB)

His bundle divides into right and left branches, the left further divides into the anterosuperior and posteroinferior fascicles. Conduction of impulse below His bundle occurs thorough these three fascicles (trifascicular conduction). Conduction disturbance occurring in the right bundle branch (RBB) is known as right bundle branch block

(RBBB) and left main bundle as left bundle branch block (LBBB). Blocks at the fascicles of the bundle are called fascicular blocks. These may be involving two or three fascicles (bifascicular or trifascicular blocks). *Bundle branch blocks do not produce any arrhythmia by themselves.*

Complete left bundle branch block (LBBB): This involves the main stem of the left bundle. The anterosuperior or posteroinferior fascicle may be selectively affected at times. These are called left anterior hemiblock (LAHB) and left posterior hemiblock (LPHB) respectively. Sometimes the main left bundle may be affected, along with one or both of its branches (Fig. 122.23).

Complete right bundle branch block (RBBB): Interruption of the right bundle may occur as the lone abnormality or along with block of one or both of the branches of the left bundle. The combination of RBBB with LAHB or LPHB is called bifascicular block. In trifascicular block, RBBB exists with alternating LAHB and LPHB. RBBB plus LAHB /LPHB with prolonged PR interval is also a form of trifascicular block .

PARTIAL BUNDLE BRANCH BLOCKS

Left Anterior Hemi Block (LAHB) (Fig. 122.24)

Complete interruption of conduction of impulses in the bundle branch causes the QRS complex to prolong beyond 0.12 sec. When there is only delay without complete block of the impulse (partial bundle branch block) the duration of the QRS is between 0.10 and 0.12 sec. (normal 0.08 sec).

Bifascicular and trifascicular blocks give rise to characteristic ECG patterns. When the bundle branches are blocked, ventricular activation takes place through the remaining bundle or its fascicles.

Bundle branch block may result from ischemic heart disease, sclerodegenerative disorder of the conduction system of the heart, myocarditis, cardiomyopathy, drugs like quinidine and surgical trauma. In addition, RBBB may be seen in atrial septal defect, acute pulmonary embolism, right ventricular dilation and right ventricular failure. Congenital RBBB may occur rarely.

In myocardial infarction, presence of bifascicular or trifascicular block is considered an indication for temporary transvenous pacing of the heart, since complete heart block or the fatal arrhythmias are likely to develop in such patients.

VENTRICULAR STANDSTILL (VENTRICULAR ASYSTOLE) (FIG. 122.25)

When there is total cessation of stimuli reaching the ventricles, ventricular standstill develops. The ECG shows

absence of QRS (Fig. 122.26). Often the P-wave may also be absent. Cardiac asystole may occur in myocardial infarction and other forms of ischemic heart disease or in complete heart block. Treatment involves external cardiac massage and instituting the procedure for cardiac resuscitation.

Cardiac arrest and its management: Cardiac arrest is a most dramatic medical emergency which may happen in all unexpected situations from time-to-time. The picture is one of an apparently healthy or ailing person falling unconscious, with total loss of consciousness and cessation of heart beat and pulse. The most common causes are ventricular fibrillation and ventricular asystole. If cardiac standstill is not corrected within 3-4 minutes, irreversible damage occurs to the brain and vital centers. Resuscitation becomes futile thereafter or even if the cardiac rhythm is restored, full consciousness is not regained. Such a patient may continue to live a vegetative existence without regaining consciousness and other cerebral functions.

Other supportive evidences are:

1. Dilation of the pupils.
2. Cessation of breathing or gasping respiration.
3. Cyanosis or pallor.
4. Loss of consciousness.

The ECG will confirm whether the heart is in asystole or ventricular fibrillation.

A planned line of management is absolutely essential to avoid these catastrophies.

Resuscitative measures should be instituted if the main pulses are not palpable and heart sounds are not heard. Management of cardiac arrest is a team work. One person starts the procedure, the others soon join him for assistance. It is mandatory to distinguish between the ventricular asystole and the ventricular fibrillation for specific management.

Steps to be followed:

1. Put the patient on a firm non-resilient surface and clear the airway. Remove dentures and foreign bodies from the mouth and throat, loosen clothing, pull the chin up so that the tongue does not fall back to obstruct the throat, and remove secretions from the air passages by proper positioning and suction. Introduce an airway, if available.
2. Start external cardiac massage by pressing firmly over the sternum (so as to compress the precordium) and releasing it, at the rate of 50-60/min. If the maneuver is properly done, the carotid pulse will be felt.
3. Start artificial ventilation simultaneously by mouth-to-mouth respiration, or using an Ambu bag. If facilities are available, the trachea is intubated with a cuffed endotracheal tube and positive pressure

respiration given with oxygen-enriched air at the rate of 10-12 L/min, without interference to the external cardiac massage.

4. Start an intravenous line with 5% glucose, to act as a route of medication.
5. If ECG shows ventricular fibrillation, apply the electrodes and give a DC shock of 200 joules (100-400 joules). Often the fibrillation disappears and heart resumes normal beat. The DC shock can be repeated if conversion is not achieved with single shock. If ventricular asystole is detected, adrenaline 0.5 mg is given intravenously or intracardiac (0.5 mL of 1/1000 solution) into the cavity of the right ventricle using a lumbar puncture needle inserted through the third or fourth left intercostal space. Often this converts asystole into ventricular fibrillation and this can be converted by DC shock. In many centres adrenaline is given by the intravenous route. This is adequate if external cardiac massage is performed effectively.
6. Other drugs: Sodium bicarbonate is given I V in a dose of 100 mmol (100 mL of 7.4% solution) for an adult, rapidly to counteract metabolic acidosis.
7. If the heart returns to activity, continue massage till the systolic blood pressure is maintained at 70-80 mm Hg.
8. If the heart is beating, but BP is low, dopamine may be started as an intravenous drip at the rate of 2-3 µg/kg/min.
9. If the heart continues in asystole after adrenaline, and massage, 20 mL of 5% solution of calcium chloride can be given IV, after repeating sodium bicarbonate and adrenaline.

External cardiac massage and resuscitatory measures are stopped if the heart fails to recover within one hour, or the pupils remain dilated and fixed despite adequate massage.

As soon as the emergency team starts to give first aid, steps are taken to transport the patient to the hospital in a suitably equipped ambulance. Emergency first aid management of cardiac arrest is taught to several groups such as ambulance personnel, paramedical staff, porters, scouts and so on. Periodically, guidelines are published to simplify the procedure so that more persons can practice emergency resuscitation. Life saving equipment such as defibrillators, ventilators and oxygen delivery systems are available in public places and in several aircraft. Emergency resuscitation helps to prevent death and permanent morbidity.

Sick Sinus Syndrome (SSS)

Normal sinus node produces impulses at the rate of 60-70 per minute under basal conditions. Depending on physiological demands it may increase the rate upto

180 per/min (exceptionally 200 per min.). During sleep, heart rate may go down to 50-60 per minute (exceptionally as low as 40 per min). Persons with increased vagal tone achieved by physical training or otherwise have lower resting heart rates. In them the rate of rise of heart rate with exercise is also lower. When the sinus node is diseased and consequently the impulse production becomes defective it may give rise to various electrophysiological abnormalities of the heart. The clinical spectrum resulting from these is termed sick sinus syndrome (SSS). In about 30% of cases A-V node (A-V Junction) may also show abnormality.

SSS is relatively common in clinical practice, particularly among the elderly. Although various drugs such as digitalis, propranolol, and quinidine produce dysfunction of the sinus node, these functionally reversible situations are not considered as part of SSS. Ischemic heart disease, idiopathic sclerodegenerative processes, toxic myocarditis, various types of cardiomyopathies, Friedreich's ataxia, infiltrative disorders like amyloidosis, hemochromatosis and metastatic deposits account for the vast majority. In many cases, the etiological factor may not be apparent. The clinical picture may be dominated by bradyarrhythmias such as severe sinus bradycardia, sino-atrial block, intermittent sinus arrest or sinus pause singly or in combination. Because of this, patient may develop dizziness, mental confusion, syncope or near syncope. In patients with underlying heart disease progressive congestive heart failure may result.

The other group of manifestations results from atrial tachyarrhythmias, such as recurrent atrial fibrillation, flutter, or re-entrant tachycardia. Sudden onset atrial fibrillation with relatively slow ventricular response, especially in elderly subjects, should alert the possibility of SSS. Palpitation, confusion, syncope, near-syncope, angina pectoris and congestive heart failure may result from the tachyarrhythmia. SSS may produce extreme bradyarrhythmia associated with sudden change into

tachyarrhythmia in the same patient. This is termed as bradytachyarrhythmia syndrome (BTS).

Diagnosis can be suspected from the clinical manifestations. Routine 12 lead ECG is very useful in the diagnosis. ECG manifestations may include:

1. Persistent, inappropriate and marked sinus bradycardia
2. S-A block
3. Sinus arrest
4. Long pause following an atrial premature contraction
5. Chronic atrial fibrillation or flutter with slow ventricular rate
6. Carotid sinus hypersensitivity
7. Unstable sinus rhythm after cardioversion
8. A-V junctional escape rhythm with or without slow and unstable sinus activity and (Fig. 122.26)
9. Bradytachyarrhythmia syndrome.

Ambulatory electrocardiogram (Holter's monitoring) is particularly useful for diagnosis and prognosis. Those with equivocal findings can be studied by treadmill exercise test, or response to drugs like atropine or isoproterenol. Electrophysiological studies for determining the sinus node recovery time or sino-atrial conduction time and His bundle electrocardiography may be required in selected cases for diagnosis and management.

Prognosis: The abnormality of the sinus node tends to be chronic, progressive and permanent. In those who present with symptoms of recurrent syncope or near syncope, progressive angina and congestive heart failure especially with underlying heart disease, the prognosis is bad. Sudden death may occur in untreated cases.

Management: Once the diagnosis is established, in symptomatic patients, implantation of suitable permanent pacemaker is the treatment of choice, particularly in those with symptomatic bradycardias. It helps to relieve the symptoms and improve the quality of life. Tachyarrhythmias due to SSS may be safely managed with antiarrhythmic drugs, provided a pacemaker is also implanted.

Appendix

Anti Arrhythmic Drugs – Dosage and Indications				
Sl.No.	Anti arrhythmic drugs	Dosage		Indications
		Oral	Parenteral	
1.	Quinidine	200-400 mg 3-4 times a day (up to 600 mg Q 6 H)	IM-600 mg followed by 400 mg every 2 hours or IV-800 mg in 50 mL 5% Dextrose @ 1mL/mt infusion	Atrial flutter, atrial fibrillation AVNRT
2.	Procainamide	2-4 g/day in 3-4 divided doses (max daily dose 6 gm)	IM or IV 25-50 mg over 1 mt to rpt at 5 mts interval till arrhythmia is controlled. Or IV infusion 2-6 mg/mt	Atrial fibrillation SVT (AVNRT, AVRT)
3.	Disopyramide	100-200 mg Q 6H Max 1200 mg/day	IV – 1 -2 mg/kg bolus followed by 1 mg/kg/hr	SVT (AVNRT, AVRT), atrial flutter, atrial fibrillation, VT
4.	Lignocaine	N A	IV 1-2 mg/kg bolus max 5 mg/kg then infusion at 1-4 mg/mt	Rapid termination of VT refractory VT/VF
5.	Mexiletine	200 mg tid	100-250 mg I V bolus followed by 250 mg infusion over 1-2 hrs	Ventricular tachycardia
6.	Phenytoin	1 g loading dose day 1 followed by 500 mg on D2 and D3 and 300-400 mg daily thereafter	IV 100 mg, repeated, up to max 1 g	Digoxin related atrial and ventricular arrhythmias
7.	Flecainide	100 mg every 12 H max 400 mg/day	I V – 2 mg/kg then 100-200 mg Q 12 H	Paroxysmal AF, SVT, VT
8.	Esmolol	N A	I V 500 mcg/kg loading followed by 50-200 mcg/kg/mt	Rapid rate control in SVT
9.	Amiodarone	200 mg tid × 1 week then 200 mg bd for a week, maintenance 100-200 mg/d	150-300 mg I V bolus then 1 mg/kg/mt for 6 hrs and 0.5 mg/kg/mt for 18 hrs	Atrial flutter fibrillation AVNRT refractory VT/VF and VF
10.	Sotalol	80 mg/d in 1-2 divided doses, max of 640 mg/d	I V 100 mg over 1-2 mt	Atrial flutter atrial fibrillation, VT
11.	Bretylum	4 mg/kg/daily	I V 5-10 mg/kg bolus followed by 0.5-2 mg/mt infusion	Refractory VT and VF
12.	Ibutilide	N A	I V 1 mg over 10 mts to repeat if needed	Termination of a/c episode of atrial flutter/ atrial fibrillation
13.	Dofetilide	0.1-0.5 mg BD	IV 2.5 mcg/kg, to repeat if needed	Acute and chronic AF
14.	Verapamil	120-480 mg/day in 3-4 divided doses	I V 5-10 mg over 2-3 mts	SVT
15.	Adenosine	N A	6-12 mg I V as rapid bolus	Termination of PSVT
16.	Digoxin	0.5-1 mg loading followed by 0.125 mg 0.25 mg daily	I V 0.5-1 mg	Atrial flutter fibrillation control of heart rate

Key: SVT – Supraventricular tachycardia
 VT – Ventricular – do –
 AVNRT – AV nodal re-entrant – do –
 VF – Ventricular fibrillation
 AF –Atrial fibrillation
 PSVT – Paroxysmal SVT

GENERAL CONSIDERATIONS

Systemic arterial hypertension is one of the most common maladies of mankind, affecting about 20% of the population globally. Though it was considered to be a disease related to affluence, it is no longer so. All sections of the population in India suffer from the disease, the prevalence in urban population is higher compared to that of the rural population. This is a major public health problem for India along with diabetes, ischemic heart disease and strokes. Diabetes and hypertension coexist in about 30-40% of cases and the combination adversely affects the long-term prognosis mutually. Hypertension leads to damage of the target organs – heart, brain, optic fundi, kidneys and blood vessels both acutely and on a long-term basis.

The damage to the target organs correlates generally with the values of elevated blood pressure (both systolic and diastolic). This is not always so since other factors such as hyperlipidemias and tobacco smoking may also influence the final outcome.

Measurement of Blood Pressure

This is ideally done using a mercury sphygmomanometer. The patient should be seated in a quiet room for 15 minutes before recording BP. BP may also be recorded in

the supine and standing position. At all postures, the arm should be supported at heart level. The BP cuff for adults should have a bladder 13-15 cm wide and 30-35 cm long, which is adequate for most of the average sized persons.

Larger cuffs are required for stout arms and vice versa. Using a cuff of smaller size gives erroneously higher values. The cuff is rapidly inflated to 30-40 mm Hg above the level at which the pulse becomes palpable and then deflated at the rate of 2 mm/sec. Auscultating over the cubital fossa, the onset of Korotkoff's sounds (phase I) and their disappearance (phase V) are recorded. The former denotes the systolic and the latter, the diastolic blood pressure. At least two measurements made three minutes apart are taken and the average values taken as the blood pressure. The unit of BP is expressed as mm Hg or as kilo Pascals (KPa = 7.5 mm Hg). All other instruments used to record blood pressure such as aneroid manometers, electronic devices and others should be periodically calibrated with the mercury instrument. Other modalities of measuring BP are automatic instruments preset to record at regular intervals, direct intra-arterial measurement, instruments that can be fitted to a finger with the patient lying supine and ambulatory recording.

The blood pressure values in a community follow a bimodal pattern lying within a broad range of normalcy. The cut off points separating normal and abnormal BP tend to be arbitrarily based on statistical evidence of adverse consequences of raised pressure – both systolic and diastolic.

The blood pressure recorded in the doctor's clinic or office, are quite reliable for purpose of diagnosis and management. The presence of physician or nurse while measuring blood pressure may cause elevation of BP due to emotional causes. This is known as the "white coat effect". This should not be set aside as non-pathological. On follow-up many white coat hypertensives may show sustained elevation of BP levels. Ambulatory BP recording is a more reliable predictor of cardiovascular risk than a routinely determined BP measured by sphygmomanometer. This can be undertaken in special cases. The test is expensive.

In more than 2/3rd of cases of hypertension both the systolic and diastolic blood pressure levels (SBP and DBP) are elevated. In about a third the SBP is greater than 140 mm Hg while the DBP is 90 mm Hg or less (Isolated systolic hypertension). SBP is also associated with higher risk of vascular occlusions in the coronary and cerebral vasculature. SBP and DBP together and also individually are associated with increased risk of complications. Systolic BP increases with age upto the 8th decade, whereas DBP increases only upto the age of 50 yrs. In the elderly the DBP may actually fall and pulse pressure widens. In the Framingham study, SBP and widening of pulse pressure were found to be important predictors of risk in the elderly.

Factors which Influence Blood Pressure

Age: There is a positive relation between age and BP in most of the population groups.

Sex: Males have slightly higher values than females of the same age.

Ethnic groups: Some communities show higher prevalence of hypertension. In USA the BP in the black races is higher than that in the whites.

Risk factors

Hereditary factors: Family history of hypertension is the strongest predictor for the development of hypertension.

Genetic factors: Several factors and genes have been studied. The inheritance seems to be polygenic.

Birth weight: Low birth weights and adverse environment in early life are associated with higher prevalence of hypertension and diabetes.

Obesity: In adults obesity may confer a two-fold risk to develop hypertension. Central obesity is the stronger predictor of risk.

Dietary sodium and potassium intake: The SBP and DBP are related directly with sodium intake and urinary sodium loss. Reduction of dietary sodium by 100 mmol/day definitely leads to lowering of SBP on long-term follow up. Potassium intake bears an inverse relation to blood pressure. Higher potassium intake lowers blood pressure.

Other factors: Alcohol intake, tobacco smoking, sedentary life style and noise pollution markedly elevate the BP level. Modification of life style helps to lower the BP considerably.

In clinical practice over 97% of hypertension belong to idiopathic or primary variety. 3% may be secondary. Clinical features which should suggest the possibility of secondary hypertension include a positive history of hypertension and renal diseases in the family, history of

TABLE 123.1		
Showing SBP and DBP in different age groups		
Age	Normal	Significant hypertension
< 2 years	104-111 70-73	112-117 74-81
10-12 years	122-125 78-81	126-133 82-89
Note: BP in a one day old infant is ± 70 mm Hg. It rises to ± 85 mm Hg at 1 year. Boys have a slightly higher BP than girls.		

intake of drugs, endocrinological disorders and resistance to the action of common anti-hypertensive drugs.

Systemic Hypertension Systemic hypertension is a major risk factor for coronary artery disease, heart failure, stroke and renal disease. So early detection and effective management of hypertension is important in reducing the morbidity and mortality attributed to it. The risk of cardiovascular diseases in a hypertensive patient is determined also by the other coexisting cardiovascular risk factors in addition to the level of blood pressure.

Definition: Hypertension is defined as systolic blood pressure of 140 mm Hg or greater, and diastolic BP of 90 mm Hg or greater. Isolated systolic hypertension is defined as systolic BP of 140 mm Hg or greater and diastolic BP below 90 mm Hg (Tables 123.1 and 123.2).

When the blood pressure is elevated without an evident organic cause, it is called **essential hypertension**. Hypertension produced by an identifiable cause is called **secondary hypertension**.

Essential hypertension far outnumbers secondary hypertension. It is necessary to detect the primary cause for secondary hypertension since correction of the cause leads to regression of the hypertension. In essential hypertension since no underlying removable cause is detectable, treatment has to be, at best, palliative.

TABLE 123.2			
JNC VII classification of blood pressure for adults (≥18 years) (Joint national committee on prevention, detection, evaluation and treatment of high blood pressure)			
BP classification	SBP (mmHg)		DBP (mmHg)
Normal	< 120	and	< 80
Prehypertension	120-139	or	80-89
Stage 1 Hypertension	140-159	or	90-99
Stage 2 Hypertension	≥ 160	or	≥ 100
When SBP and DBP fall in different categories, higher category should be selected to classify the individual's BP status.			

Causes of Secondary Hypertension

I. Renal

A. Renal parenchymal disease

1. Acute glomerulonephritis
2. Chronic nephritis
3. Polycystic disease of kidney
4. Diabetic nephropathy
5. Hydronephrosis
6. Post-traumatic renal damage

B. Renovascular

1. Renal artery stenosis
2. Intrarenal vasculitis

C. Renin producing tumours

D. Primary sodium retention

II. Endocrine

A. Acromegaly

B. Hypothyroidism and hyperthyroidism

C. Hyperparathyroidism

D. Adrenal

1. Cortical
 - Cushing's syndrome
 - Primary hyperaldosteronism (Conn's syndrome)
 - Congenital adrenal hyperplasia
2. Medullary – pheochromocytoma

E. Exogenous hormones

- Estrogen
- Glucocorticoids
- Mineralocorticoids
- Sympathomimetic drugs
- Tyramine containing foods and mono-amine oxidase inhibitors

III. Vascular causes: Coarctation of aorta

IV. Pregnancy induced hypertension

V. Neurological disorders

- a. Increased intracranial pressure
 - Brain tumours
 - Encephalitis
- b. Guillain-Barré syndrome
- c. Familial dysautonomia

VI. Miscellaneous causes: Sleep apnea, acute stress, postoperative, hypoglycemia, burns, post-resuscitation, alcohol withdrawal, etc.

standardized prevalence was 17%. The body mass index and waist-hip ratio were significantly higher in the hypertensive group. The prevalence of diabetes mellitus, obesity and coronary artery disease were significantly higher in those with hypertension.

Ref: Shanterani, et al. JAPI 2003;51:20-7.

Longitudinal study of the population at Framingham (USA) has revealed that the prevalence of hypertension was 29.7%. The blood pressure showed a rise of 20 mm in SBP and 10 mm DBP when persons were followed up from 30-65 years. Systolic blood pressure continued to rise in women up to 80 years and in men up to 70 years. There was strong genetic and familial predisposition to hypertension. Persons with diabetes mellitus and impaired glucose tolerance have a high prevalence of hypertension (even up to 50%), whereas hypertensives have a 15-18% chance of having associated abnormalities of glucose metabolism.

Contributory factors: Following factors contribute to the occurrence of this condition.

- a. *Genetic factors:* Essential hypertension shows a polygenic pattern of inheritance.
- b. *Psychological stress:* Persons who have to undergo mental stress during the course of their duties and those with tense personality are affected more.
- c. *Salt and water intake:* Communities with high salt intake have a higher prevalence of essential hypertension.
- d. *The renal hormones:* The role of renin- angiotensin aldosterone system has been extensively studied. Renin is produced by the juxtaglomerular apparatus in response to various stimuli. The control of renin release is complex. Several stimuli lead to renin release. These are:
 1. the impulses from pressor receptors in the afferent arterioles of the glomeruli;
 2. chemoreceptors of the macula densa which are stimulated by hyponatremia;
 3. the sympathetic stimuli which lead to renin release on assuming the upright posture;
 4. chemical stimuli such as hypokalemia, etc.

Renin converts angiotensinogen to angiotensin I, which is further converted to angiotensin II, by the converting enzyme. Angiotensin II stimulates the production of aldosterone. Angiotensin II causes vasoconstriction and aldosterone leads to retention of salt and water. Among the hypertensives, 60% have normal, 30% have low, and 10% have high values of plasma renin activity.

- e. *Other factors* such as deficiency of prostaglandins and kinins which normally help in lowering the vascular tone have also been incriminated in the production of essential hypertension.

EPIDEMIOLOGY

Overall prevalence of hypertension in India is about 26.2% in men and 23.6% in women. The prevalence is significantly more in urban subjects (30.9%) than in rural population (21.2%). A prospective study conducted at Chandigarh showed that the prevalence of hypertension rose from 26.9% in 1968 to 44.9 in 1996-97.

Ref: Akhlawat SK, et al. J Ind Med Asso 2002;100-92:547-55.

A report from Chennai showed the crude prevalence rate of hypertension was 21.1% whereas the age

- f. **Atrial natriuretic hormone:** Atrial tissue secretes a group of peptides, at least one of which is secreted as a regulatory hormone. *In vivo* experimental studies show that this peptide produces immediate marked increase in sodium loss, increase in glomerular filtration rate (without altering the total renal blood flow) and fall in arterial blood pressure. The other effects include inhibition of renin secretion, aldosterone secretion and opposing the vasoconstrictor effect of angiotensin II.

PATHOLOGY

Main pathological process occurs in the heart and several parts of the arterial tree.

Cardiac changes: The left ventricle hypertrophies in 20-50% of mild to moderate hypertensives. The muscle fibres hypertrophy and this process is reversible with anti-hypertensive therapy. At autopsy, left ventricular hypertrophy is diagnosed if it weighs above 131 g/m² body surface in men and 100 g/m² body surface in women. Unlike physiological hypertrophy occurring as a result of exercise, in hypertension left ventricular hypertrophy leads to diastolic dysfunction, arrhythmias, acceleration of coronary atherosclerosis and left ventricular failure. Cardiac failure is caused by degeneration and lysis of myofibrils. The extent of hypertrophy and levels of blood pressure do not correlate in all cases but hypertrophy is more pronounced in those with early onset hypertension.

Arterial changes: Arteries and arterioles show thickening (arteriosclerosis). Arteriolar changes are well seen in the kidneys. Renal vessels show medial hypertrophy and intimal fibrosis. Progressive occlusion of arterial lumen leads to scarring of glomeruli and tubular atrophy.

In the coronary arteries there is accelerated progression of atherosclerosis. Cerebral arteries, renal arteries, aorta and its major branches show progressive atheromatous change. Small arteries of the brain show microaneurysms, known as Charcot-Bouchard aneurysms, which may rupture resulting in cerebral hemorrhage. Thrombotic and embolic occlusion of atheromatous arteries gives rise to infarction in the heart, brain and kidneys.

CLINICAL FEATURES

Essential hypertension: The condition is asymptomatic and over 50% of the patients are unaware of the condition. Elevated blood pressure is detected during a routine medical examination in such subjects. A few of them present for the first time with one of the major complications. Many develop symptoms after knowing that they are hypertensives. The symptoms are vague and non-specific in such patients. These symptoms include fatigue, dizziness, palpitation, headache and anxiety.

Though many types of headache have been described, throbbing headache, felt in suboccipital region on waking up after sleep is suggestive of hypertension.

Physical examination may reveal a heaving apex beat and loud aortic second sound in many cases. The pulse may show rise in tension (requiring more pressure to obliterate) in some. Further physical signs develop as the target organs (heart, brain, kidneys and retinae) are involved.

In **secondary hypertension** evidence of the primary disorder may be detectable in many cases. In the others, hypertension may be the only evident abnormality and the diagnosis has to be established by investigation.

Coarctation of the aorta has to be diagnosed by the detection of weak or delayed femoral pulse and the presence of hypertension in the upper limbs with lower pressure in the lower limbs. Renal artery bruit may be auscultated over the abdomen lateral to the umbilicus or over the renal angles and this finding is a clue to renovascular cause for hypertension. Palpability of the kidneys suggests polycystic disease, hydronephrosis or tumour.

COMPLICATIONS OF HYPERTENSION

Hypertensive

- Accelerated – malignant hypertension (grade III and IV retinopathy)
- Encephalopathy
- Cerebral hemorrhage
- Left ventricular hypertrophy
- Congestive heart failure
- Renal insufficiency
- Aortic dissection

Atherosclerotic

- Cerebral thrombosis
- Coronary artery disease
- Peripheral occlusive vascular disease

1. Cardiovascular system:

1. Left ventricular hypertrophy [LVH]: This is the most common cardiac abnormality in hypertension. LVH is a powerful predictor of serious cardiovascular sequelae. Echocardiography is more sensitive and specific than ECG for detection of LVH.
2. Congestive heart failure [CHF]: The various alterations of LV systolic and diastolic function seen with LVH ultimately leads to the development of CHF. Hypertension remains as an important and major preventable factor leading to the development of CHF.
3. Ischemic heart disease is more common in them. This may present as angina pectoris, myocardial infarction or sudden death. Acute myocardial infarction may be unrecognized in 30-32%.

4. Atherosclerosis is accelerated. Atherosclerosis of the coronary, cerebral, renal and peripheral arteries lead to their progressive occlusion.
5. Arrhythmias – both supraventricular and ventricular are more common in hypertensives. Tobacco smoking worsens the cardiovascular complications.

2. Central nervous system: Strokes are among the most common complications in hypertension. The lesion may be an ischemic infarct resulting from thrombosis or a hemorrhage resulting from rupture of an artery. Hypertension is the most important single factor leading to all forms of strokes in the general population.

Hypertensive encephalopathy: It is a specific complication seen in hypertensives when there is a rapid rise of blood pressure. The incidence is higher in acute glomerulonephritis, pheochromocytoma and malignant hypertension. The cerebral arteries go into spasm in response to a rapid rise in blood pressure. Edema and ischemia of the brain develop.

Clinically it is characterized by intense headache, visual disturbances, convulsions, loss of consciousness and varying degrees of focal neurological deficits. Prompt reduction of blood pressure completely reverts the attacks and restores the normal state. This feature distinguishes hypertensive encephalopathy from cerebral infarction or hemorrhage in which the neurological deficit persists.

3. Kidneys: Atheroma of the renal arteries results in reduction of blood supply to the kidney and progressive loss of renal function. In malignant hypertension renal function deteriorates rapidly, ending in renal failure.

4. Retina: The retinal arterioles undergo changes. These have been graded. The retinal changes give an indication of the progress of hypertension and help to determine the prognosis. Grades I and II are seen in the early phases of hypertension. Grade III is suggestive of the accelerated phase and grade IV indicates transition to the malignant phase.

Grade I : Arteriolar narrowing and increase in light reflex over the arterioles.

Grade II : Marked arteriolar narrowing and arterio-venous nicking.

Grade III: Grade II + flame-shaped hemorrhages and fluffy (soft) exudates.

Grade IV: Grade III + papilledema.

5. Malignant hypertension and accelerated hypertension: If hypertension is allowed to progress unchecked, many cases may go into the malignant phase. Its exact mechanism is not still clear. Secondary hypertension occurring in renal disease and pheochromocytoma shows a greater tendency to progress to the malignant phase. It is characterized by further elevation of blood pressure and grade IV retinal changes. At this stage, there is widespread fibrinoid necrosis of arterioles. Retinopathy may lead to visual impairment. The diagnosis of the malignant phase

Fig. 123.1: Hypertensive retinopathy in malignant hypertension. Note: Papilledema, hemorrhages (arrow and soft exudates—arrowhead)

and the accelerated phase depends on the evidence of vascular damage in a patient with severe hypertension. Malignant hypertension is characterized by papilledema whereas accelerated hypertension shows only grade III retinopathy. Once the malignant phase sets in, death occurs within two years as a result of cardiac failure, renal failure, or cerebral hemorrhage. Prompt treatment arrests the malignant phase and its complications. The retinal changes also regress and revert to Grade II (Fig. 123.1).

Prognosis: Hypertension leads to reduction of lifespan, and also considerable morbidity. Death is caused by cardiac failure, cerebrovascular diseases or renal failure. Damage to the target organs worsens the prognosis considerably. Target organ damage should be diagnosed if any one or more of the following abnormalities are detectable. Hypertension is associated with higher incidence of retinal venous and retinal arterial occlusions and visual loss.

1. Cardiac failure,
2. Signs and symptoms of atherosclerotic vascular disease,
3. ECG evidence of myocardial infarction, ischemia or left ventricular hypertrophy,
4. Evidence of previous stroke,
5. Renal insufficiency or proteinuria, and Hypertensive changes on funduscopy.

ECG evidence of left atrial enlargement and presence of late diastolic gallop (S_4 gallop) indicate the presence of diastolic dysfunction. Proper control of blood pressure leads to reduction of the complications.

Reduction of strokes	– 35-40%
Coronary artery events	– 20-30%
Congestive heart failure	– 50-60%
Cardiovascular mortality	– 20%

MANAGEMENT

The goal of management of hypertension is to reduce morbidity and mortality by the least invasive means as possible. This may be accomplished by achieving and maintaining systolic blood pressure below 140 mm Hg and diastolic blood pressure below 90 mm Hg and lower, if tolerated, while controlling other modifiable risk factors for cardiovascular disease. Blood pressure reduction therapy is required particularly to prevent stroke, to preserve renal function and prevent or slow heart failure progression. This goal may be achieved by lifestyle modification alone or with pharmacologic treatment.

Risk stratification: Risk of cardiovascular disease in patients with hypertension is determined not only by the levels of blood pressure but also by the presence or absence of target organ damage or other risk factors. Hypertensive patients can be classified into risk group A, B and C based on the presence or absence of major risk factors, target organ damage and clinical cardiovascular disease.

Major Risk Factors

- Smoking
- Dyslipidemia
- Diabetes mellitus
- Age older than 60 years
- Sex (men and postmenopausal women)
- Family history of cardiovascular disease.

Target Organ Damage (TOD) / Clinical Cardiovascular Disease (CCD)

Heart disease

- Left ventricular hypertrophy
- Angina/prior myocardial infarction
- Prior coronary revascularization
- Heart failure

Stroke or transient ischemic attack

Nephropathy

Peripheral arterial disease

Retinopathy

Risk group A – No risk factors, no TOD/no CCD

Risk group B – At least one risk factor excluding diabetes mellitus, no TOD/CCD

Risk group C – TOD/CCD and/or diabetes mellitus, with or without other risk factors.

This empiric classification stratifies patients with hypertension into risk groups for making therapeutic decisions.

Life Style Modifications

- Lose weight, if overweight

- Moderation of alcohol intake to less than 30 ml spirits per day
- Increase aerobic physical activity (30–45 minutes on most days of the week, at least five sessions)
- Reduce sodium intake to less than 100 mmol per day.
- Maintain adequate intake of dietary potassium (90 mmol/day)
- Maintain adequate intake of dietary calcium and magnesium for general health.
- Stop smoking and reduce intake of dietary saturated fat to below 7% of total calorie intake for overall cardiovascular health.
- Relaxation and biofeedback technique– transcendental medication, yoga exercise such as Savasana.

Lifestyle modification brings down blood pressure and also helps to reduce the dosage of drugs needed (Table 123.3).

Pharmacological Treatment

Reduction of blood pressure with drugs clearly decreases cardiovascular morbidity and mortality. Objective reduction of stroke, coronary events, heart failure, progression of renal disease, progression to more severe hypertension and all cause mortality has been demonstrated in several trials.

GENERAL GUIDELINES

Dosage and Follow-up

Therapy for most patients with uncomplicated hypertension, (stages 1 and 2) should begin with the lowest dosage in order to avoid the adverse effects of abrupt reduction in blood pressure. In hypertensive patients, abrupt lowering of blood pressure produces signs of cerebral hypoperfusion. If blood pressure remains uncontrolled after 1 or 2 weeks of drug therapy the next dosage levels should be tried.

- Optimal formulation should provide 24 hour efficacy with once daily dosage with at least 50% of peak effect remaining at the end of 24 hour.
- For most patients the initial choice of therapy is a diuretic or a beta blocker unless there is a compelling indication for another type of drug. There are numerous randomized controlled trials which have shown a reduction in mortality and morbidity with these agents.

Drug Combinations

Combinations of low doses of two agents from different classes have been shown to provide additional antihypertensive efficacy, thereby minimizing the likelihood of dose dependent adverse effects. Very low dose of diuretics can potentiate the effects of other agents without producing adverse metabolic effects. Low dose combinations with

TABLE 123.3

Lifestyle modifications to manage hypertension (JNC VII)

Modification	Recommendation	Approximate systolic BP reduction, range
Weight reduction	Maintain normal body weight (BMI, 18.5-24.9)	5-20 mmHg/10 Kg weight loss
Adopt DASH eating plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat	8-14 mm Hg
Dietary sodium reduction	Reduce dietary sodium intake to no more than 100 mEq/L (2.4 g sodium or 6 g sodium chloride)	2-8 mm Hg
Physical activity	Engage in regular aerobic physical activity such as brisk walking (at least 30 minutes per day, most day of the week)	4-9 mm Hg
Moderation of alcohol consumption	Limit consumption to no more than 2 drinks per day (1 oz or 30 mL ethanol [e.g. 24 oz beer, 10 oz wine, or 3 oz 80-proof whisky]) in most men and no more than 1 drink per day in women and lighter-weight persons	2-4 mm Hg

Abbreviation: BMI, body mass index calculated as weight in kilogram divided by the square of height in meters; BP, blood pressure; DASH, Dietary Approaches to Stop Hypertension

*For overall cardiovascular risk reduction, stop smoking. The effects of implementing these modifications are dose and time dependent and could be higher for some individuals.

ACE inhibitor and a non-dihydropyridine calcium antagonist may reduce proteinuria more than either drug given singly. Combination of dihydropyridine calcium antagonist and ACE inhibitor reduces the incidence of pedal edema compared to calcium antagonist given alone.

Management of Blood Pressure in Persons Aged 18 yrs or Older (JNC VII guidelines)

The most crucial factor in the selection of drugs is the presence of concomitant conditions like cardiac failure, renal insufficiency, ischemic heart disease and diabetes mellitus (Table 123.4).

Renal insufficiency

ACE inhibitor (caution in renovascular HTN and creatinine > 3 mg/dL)
Alpha blockers

Dyslipidemia

The following drugs may have unfavourable effects on comorbid conditions.

Asthma

Beta blocker

Depression

Beta blocker, reserpine

Diabetes mellitus

Beta blockers, high dose diuretic

Peripheral vascular disease

Beta blocker

Renal insufficiency

Potassium sparing agents

Pregnancy

ACE inhibitors,
Angiotensin II receptor blockers.

Step-down Therapy

An effort to decrease the dosage and number of antihypertensive drugs should be considered after hypertension has been controlled effectively for at least 1 year. Step-down therapy is often successful in patients who are also making lifestyle modifications. This may be possible in approximately 10% of patients.

DRUGS USED IN HYPERTENSION AND THEIR DOSAGES

Diuretics: Diuretics initially lower blood pressure by increasing urinary sodium excretion and by reducing plasma volume, ECF volume and cardiac output. Within 6-8 weeks the lowered plasma volume, ECF volume and cardiac output returns towards normal. On long-term

Compelling indications, unless contraindicated

Diabetes mellitus with proteinuria	ACE inhibitor
Heart failure	ACE inhibitor, diuretics
Isolated systolic hypertension (older patients)	Diuretics preferred Calcium antagonists
Myocardial infarction	Beta blocker (non ISA*), ACE inhibitor (in those with systolic dysfunction)

*Note: ISA: intrinsic sympathomimetic activity.

The following drugs may have favourable effect on comorbid conditions.

Angina	Beta blocker, calcium antagonist
Prostatism	Alpha blocker

Individual Choices of Drug Therapy – JNC VII Guidelines

TABLE 123.4

Scheme of treatment of hypertension						
BP classification	Management					
	Systolic BP, mm Hg*		Diastolic BP, mm Hg*	Lifestyle modification	Initial drug therapy	
					Without compelling indication	With compelling indications†
Normal	< 120	and	< 80	Encourage		
Prehypertension	120-139	or	80-89	Yes	No antihypertensive drug indicated	Drug(s) for the compelling indications‡
Stage 1 hypertension	140-159	or	90-99	Yes	Thiazide-type diuretics for most; may consider ACE inhibitor, ARB, β-blocker, CCB, or combination	Drug(s) for the compelling indications Other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β-blocker, CCB) as needed
Stage 2 hypertension	≥ 160	or	≥ 100	Yes	2-Drug combination for most (usually thiazide-type diuretic and ACE inhibitor or ARB or β-blocker or CCB)§	Drug(s) for the compelling indications Other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β-blocker, CCB) as needed
Abbreviations: ACE angiotension-converting enzyme; ARB, angiotension-receptor blocker; BP, blood pressure; CCB, calcium channel blocker						
Treatment determined by JNC VII guidelines						
‡Treat patients with chronic kidney disease or diabetes to BP goal of less than 130/80 mm Hg						
§Initial combined therapy should be used cautiously in those at risk of orthostatic hypotension						

basis, antihypertensive effect is due to a fall in peripheral vascular resistance – mechanism responsible for lowering peripheral vascular resistance is not clearly known.

Dosage and choice of agent: A thiazide diuretic is the usual initial choice often in combination with a potassium sparing agent. Loop diuretics should be reserved for those patients with renal insufficiency, resistant hypertension or hypertension associated with acute left ventricular failure or congestive cardiac failure.

Hydrochlorothiazide	: 6.25-50 mg/day (OD)
Chlorthalidone	: 12.5-50 mg/day(OD)
Indapamide	: 1.25-5 mg/day(OD)
Furosemide	: 40-240 mg/day (2-3 times)
Amiloride	: 5-10 mg/day (OD)
Spironolactone	: 25-100 mg/day (OD)
Triamterine	: 25-100 mg/day (OD)

Side effects: hypokalemia, hypomagnesemia, hyperuricemia, hyperlipidemia, hyperglycemia and insulin resistance, hypercalcemia, impotence.

Inhibitors of adrenergic system

- I. Peripheral neuronal inhibitors
 - a. Reserpine

- II. Central adrenergic inhibitors
 - a. Methyldopa
 - b. Clonidine
- III. Alpha-receptor blockers
 - a. Alpha 1 and alpha 2 receptors
 - 1. Phenoxybenzamine
 - 2. Phentolamine
 - b. Alpha 1 receptor
 - 1. Prazosin
 - 2. Doxazosin
 - 3. Terazosin
- IV. Beta receptor blockers
 - Nonselective
 - Propranolol
 - Nadolol
 - Timolol
 - Pindolol
 - Cardioselective
 - Atenolol
 - Acebutolol
 - Metoprolol
 - Bisoprolol
- V. Alpha and beta receptor blockers
 - Labetalol

Note: Pindolol, acebutolol and bisoprolol also have intrinsic, sympathomimetic activity (ISA). These do not lower the heart rate like the other beta blockers without ISA activity.

Reserpine: It acts by depleting the levels of norepinephrine in postganglionic adrenergic neurons by inhibiting the uptake of norepinephrine into storage vesicles. It depletes the central catecholamine levels. Daily dose is 0.1 to 5 mg. Adverse side effects include nasal congestion, mental depression and the development of parkinsonism. This drug is seldom used now. Initial studies on reserpine were conducted by Rustom Jal Vakil, the celebrated cardiologist from Bombay, in the 1950's.

Methyldopa: The primary site of action of methyldopa is central nervous system. It stimulates central alpha adrenergic receptors, thereby reducing the sympathetic outflow from the central nervous system. It is effective in a dose of 250 to 500 mg given orally 3-4 times a day. It does not reduce the renal blood flow and therefore can be given safely even in the presence of renal impairment. Adverse side effects include dryness of mouth, sedation, extrapyramidal features, fever, hepatitis and hemolytic anemia. Currently the role of methyl dopa is mainly in the management of resistant hypertension and also in pregnancy induced hypertension.

Clonidine: It acts centrally and is effective in an oral dose of 0.1 to 1 mg a day. Dryness of the mouth and drowsiness are the adverse side effects. Sudden withdrawal of the drug causes rebound hypertension.

Alpha Adrenergic Receptor Blocking Drugs

Nonselective [alpha1 and alpha 2 blockers]

Phenoxybenzamine and phentolamine belong to this class. Mainly they are used to control the excessive rise of blood pressure in pheochromocytomas. The former is slow in action and the effect is sustained. The latter is quicker in action, but the effect is short lived. The dose is 5-30 mg given intravenously in a drip, the rate of flow is adjusted depending upon the response. Phentolamine is used to control the hypertensive crisis occurring in pheochromocytomas. It is also used as a diagnostic test.

Selective Alpha 1 Blockers

Prazosin: Is a selective antagonist of postsynaptic alpha I receptors. It acts by blocking alpha mediated vasoconstriction, thereby reducing peripheral vascular resistance. Total daily dose is 2-30 mg given two or three times a day. It may cause first dose hypotension.

Terazosin and doxazosin: These are also alpha I receptor blockers. Beyond longer duration of action and less propensity for first dose hypotension, they differ little

from prazosin. They can be safely and effectively used in patients with renal failure. Lipid profile is not adversely altered by treatment. Alpha blockers are ideal for older men with benign prostatic hypertrophy. However in the elderly these drugs should be started cautiously to avoid hypotension. Tachyphylaxis on long-term use, and also less impressive reduction in adverse clinical outcomes as compared to the other major antihypertensive drug classes are the major limitations of most alpha blocking drugs.

Beta-adrenergic blocking drugs are the second most widely used antihypertensive drugs after diuretics. They reduce cardiac output, inhibit renin release and reduce sympathetic tone by central mechanisms. In cases with coexistent ischemic heart disease, beta blockers are found to be more useful. Long-term use of beta blockers has been shown to reduce mortality by preventing major cardiac events such as myocardial infarction and fatal arrhythmias.

Although beta blockers were formerly thought to be contraindicated in patients with heart failure, they have now been found to be useful, especially metoprolol, carvedilol and bisoprolol.

Side effects: The most common side effect is fatigue. It may cause worsening of other concomitant problems like bronchospasm and peripheral vascular disease. In diabetics, warning signs of hypoglycemia may be masked. Other problems are insomnia, nightmares, depression, impotence and alteration of lipid metabolism leading to hyperlipidemia.

Cardioselective beta blockers are available for use. These are acebutalol 100-200 mg/day, metoprolol 100-400 mg/day, atenolol 100 mg/day, and pindolol 10-40 mg/day. Of these atenolol and metoprolol have become the most popular drugs due to their effectiveness, ease of administration and freedom from major adverse effects.

Drug with both alpha and beta blocking action: e.g. Labetolol is given orally in doses of 100 mg twice daily orally.

Vasodilators: These drugs cause vasodilation in the various vascular compartments.

Hydralazine: This drug causes predominantly arteriolar dilation. It is effective in a dose of 20-50 mg thrice daily. This drug increases the renal, coronary and hepatic blood flow. Adverse side effects include angina induced by reflex tachycardia and lupus erythematosus, which regresses on withdrawing the drug. Though it is at present rare to start a patient on hydralazine as the first drug, many patients who are on this drug for a long-term, find it acceptable to continue with the same.

Sodium nitroprusside: This is an effective vasodilator which rapidly lowers blood pressure and, therefore, it is used in hypertensive emergencies. It is given only as an

intravenous drip, 50 mg being added to 500 mL 5% glucose and infused at the rate of 1-8 µg/kg/min, the response being monitored continuously. The drug is withdrawn when the emergency is controlled. Adverse side effects include severe hypotension, nausea, psychotic behaviour and muscle spasms.

Diazoxide: This is a potent vasodilator with short action and therefore, it is used in hypertensive emergencies. When given in a dose of 100-300 mg intravenously, it lowers the blood pressure rapidly.

Minoxidil: This is effective when given orally in doses up to 20-40 mg daily. It is effective in patients with severe hypertension associated with renal impairment. Side effects may be troublesome, but uncommon. These include hypertrichosis (increased hair growth), coarsening of facial appearance, salt and water retention, and tachycardia. Minoxidil should always be given along with diuretics.

Angiotensin Converting Enzyme Inhibitors (ACE inhibitors)

These drugs inhibit the enzyme [ACE] which converts angiotensin I to angiotensin II, thereby leading to the reduction in the production of angiotensin II and also aldosterone. In addition, this group of drugs has other beneficial effects in correcting impaired cellular metabolism and improving myocardial function. Drugs in this group are **captopril, enalapril, lisinopril, ramipril, perindopril** and others. The same enzyme, ACE is involved in the breakdown of bradykinin, and therefore ACEI also reduce the breakdown of bradykinin. Bradykinin is responsible for some of the adverse side effects such as cough, angioedema, renal dysfunction and hypotension. ACE inhibitors do not abolish the production of angiotensin II completely, since it may be formed by other pathways also.

Captopril is effective in oral doses of 150-400 mg daily. It is particularly effective in high renin hypertension. Captopril lowers peripheral resistance without altering the cardiac output and heart rate. It is effective in hypertension resistant to other drugs. It can be combined with other drugs. Side effects include fever, rashes, pruritus, distaste in the mouth, orthostatic hypotension, nephropathy, bronchospasm, hyperkalemia and leukopenia.

Enalapril is an analogue similar in action but with a longer half-life of 12-24 hrs. It is given in a total dose of 5-40 mg per day in divided doses. Lisinopril is a lysine derivative of enalapril. It is absorbed and is effective when given orally. The action is prolonged and therefore the whole dose may be given together once a day. The initiating dose is 2.5-5 mg once or twice a day. This may be increased up to 20 mg daily. In patients with renal

impairment the dose should be reduced. Ramipril is effective in a single oral dose of 1.25-10 mg daily. Perindopril is given in doses of 2 to 8 mg daily, starting at 2 mg and working up to 8 mg if needed.

Angiotensin II Receptor Blockers (ARBs)

Drugs in this class, act by displacing angiotensin II from its specific receptor. They are at least as effective as ACE inhibitors. However, since they do not cause accumulation of bradykinin, cough as a side-effect is infrequent. The major advantage is the minimal side effect profile for this class of antihypertensives. Moreover since they act on the final common pathway viz the receptor, alternate pathway production of angiotensin II does not blunt the effectiveness. There is total blockade of angiotensin II effects.

Currently available drugs in this class are **losartan, valsartan, telmisartan, candesartan and irbesartan**. Studies have found that they are at least as effective as ACEI in controlling BP. Dose: losartan –25-100 mg/day, valsartan – 80-320 mg/day, telmisartan –40-80 mg/day, candesartan – 8-16 mg/day and irbesartan –150-300 mg/day.

Calcium Channel Blocking Drugs

Calcium antagonists are commonly used in the treatment of hypertension. Dihydropyridine calcium antagonists (**nifedipine, amlodipine and felodipine**) have the greatest peripheral vasodilator action with little effect on cardiac automaticity, conduction or contractility. Vasodilation leads to dependent edema.

The nondihydropyridine calcium antagonists (diltiazem, verapamil) cause less peripheral vasodilatation compared to dihydropyridines, but they have profound effects on cardiac contractility, automaticity and conduction. So they cause fewer side effects related to vasodilatation. They may aggravate established cardiac failure.

Dosage: Amlodipine 2.5-10 mg/day once a day, felodipine 2.5-20 mg/day once a day, nifedipine extended release 30-120 mg once a day. These drugs may cause dependent edema in some patients due to peripheral vasodilatation. Withdrawal of the drug leads to prompt relief.

Dose of diltiazem is 30-90 mg and that of verapamil is 40-80 mg twice or thrice a day. Parenteral preparations are available for emergency. Verapamil 5-10 mg IV is given over 3 minutes.

GENERAL PRINCIPLES IN ANTIHYPERTENSIVE THERAPY

Optimum benefit is obtained only if the blood pressure is maintained at the desired levels throughout the day and night continuously. Proper adjustment of dosage, frequent consultation, and counselling to ensure drug compliance

Commonly used antihypertensive drugs		
Drugs	Oral.dose/day (frequency/day)	Parenteral dose
<i>Diuretics</i>		
Hydrochlorthiazide	12.5-50 mg (1)	
Amiloride	5-10 mg (1)	
Triamterine	25-100 mg (1)	
Furosemide	40-240 mg (2-3)	
Indapamide	1.25-5 mg (1)	
<i>Central alpha agonists</i>		
Clonidine	0.2-1.2 mg (2-3)	
Methyldopa	500-300 mg (2)	
<i>Alpha-adrenergic blockers</i>		
Doxazosin	1-16 mg (1)	
Prazosin	2-30 mg (2-3)	
Terazosin	1-20 mg (1)	
<i>Beta-adrenergic blockers</i>		
Atenolol	25-100 (1)	
Metoprolol	50-300 (2)	5 mg IV, repeated at 5-10 minutes to a maximum of 15 mg to be used in emergencies
Propranolol	40-480 (2)	
Carvedilol	12.5-50 (2)	
Labetolol	200-1200 (2)	
<i>Direct vasodilators</i>		
Hydralazine	50-300 mg (2)	
<i>Calcium channel blockers</i>		
Nifedipine (SR)	30-120 mg (1)	
Felodipine	2.5-20 mg (1)	
Amlodipine	2.5-10 mg (1)	
Diltiazem	180-240 mg (3)	
Verapamil	160-240 mg (3)	
<i>ACE inhibitors</i>		
Enalapril	5-40 mg (1-2)	
Captopril	25-150 (2-3)	
Lisinopril	5-40 (1)	
Ramipril	1.25-20 (1)	
<i>Angiotensin 2 receptor blockers</i>		
Losartan	25-100 (1-2)	
Valsartan	80-320 mg (1-2)	
Telmisartan	40-80 mg (1-2)	
Candesartan	8-16 mg (1-2)	
Irbesartan	150 mg (1)	
<i>Emergency drugs</i>		
Sodium nitroprusside		0.25-10 micro-gram/kg IV infusion
Nitroglycerine		50-100 micro-gram/mt IV infusion
Diazoxide		50-100 mg IV bolus repeated or 15-30 mg/mt infusion
Enalapril		

are all important to ensure success. Since adverse side effects may lead to loss of morale and discontinuation of therapy, all patients should be fully informed of the side effects.

ACE inhibitors are preferable when there is left ventricular dysfunction with ejection fraction below 40% and in those with diabetes mellitus. In both groups ACE inhibitors reduce mortality. In the latter it also delays the onset of renal failure.

In patients with signs of prostatism alpha-blockers are useful, since these reduce both hypertension and prostatic symptoms.

Failure to comply with therapy is the most frequent cause for failure of control of hypertension. Abrupt withdrawal of therapy may lead to rebound rise of blood pressure and hypertensive complications such as hypertensive encephalopathy or cerebrovascular accidents. Once established, essential hypertension tends to persist and, therefore, life-long therapy may be required in most cases but it may be possible to reduce the dose in many or even withdraw drugs in a few (see Fig. 123.2).

Resistant Hypertension

Resistant hypertension is the failure to reach the goal BP in patients who are adhering to full doses of an appropriate three-drug regimen that includes a diuretic. After excluding potential identifiable causes of hypertension, clinicians should carefully explore reasons why the patient is not at the goal BP. (See Table 123.4). Particular attention should be paid to the type of diuretic and its dose in relation to renal function. Consultation with a hypertension specialist should be considered if goal BP cannot be achieved.

Causes of Resistant Hypertension

1. Improper BP Measurement
2. Volume overload and pseudotolerance
 - Excess sodium intake
 - Volume retention from kidney disease
 - Inadequate diuretic therapy
3. Drug-Induced or other Causes
 - Nonadherence
 - Inadequate doses
 - Inappropriate combinations
 - Nonsteroidal anti-inflammatory drugs esp. cyclo-oxygenase 2 inhibitors
 - Cocaine, amphetamine, other illicit drugs
 - Sympathomimetics (decongestants, anorectics)
 - Oral contraceptives
 - Adrenal steroids
 - Cyclosporine and tacrolimus
 - Erythropoietin
 - Licorice (including some chewing tobacco)

BP indicates blood pressure; ACE, angiotensin-converting enzyme; ARB, angiotensin-receptor blocker; and CCB, calcium channel blocker.

Fig. 123.2: Algorithm for treatment of hypertension (JNC VII)

- Selected over-the-counter dietary supplements and medicines (ephedrine)
- 4. Associated Conditions
 - Obesity
 - Excess alcohol intake, smoking tobacco
- 5. Identifiable Causes of Hypertension (sleep apnea, renal diseases, endocrine causes, etc.)

Hypertensive Urgencies and Emergencies

Patients with marked BP elevations and acute target-organ damage (emergency) (e.g., encephalopathy, myocardial infarction, unstable angina, pulmonary edema, eclampsia, stroke, head trauma, life-threatening arterial bleeding, or aortic dissection) require hospitalization and parenteral drug therapy. Patients with markedly elevated BP but without acute target organ damage (urgency) usually do not require hospitalization, but they should receive immediate combination oral antihypertensive therapy. They should be carefully evaluated and monitored for hypertension-induced heart and kidney damage and for identifiable causes.

Additional Considerations in Antihypertensive Drug Choices

Antihypertensive drugs can have favourable or unfavourable effects on other comorbidities.

Potential Favourable Effects

Thiazide-type diuretics are useful in slowing demineralization in osteoporosis. Beta-adrenergic blockers (BB) can be useful in the treatment of atrial tachyarrhythmias/fibrillation, migraine, thyrotoxicosis (short term), essential tremor, or perioperative hypertension. Calcium channel blockers (CCB) may be useful in Raynaud’s syndrome and certain arrhythmias, and alpha-blockers may be useful in prostatism.

Potential Unfavourable Effects

Thiazide diuretics should be used cautiously in patients who have gout or who have a history of significant hyponatremia. BBs should generally be avoided in individuals who have asthma, reactive airway disease, or

second or third degree heart block. ACEIs and ARBs should not be given to women likely to become pregnant and are contraindicated in those who are. ACEIs should not be used in individuals with a history of angioedema. Aldosterone antagonists and potassium-sparing diuretics can cause hyperkalemia and should generally be avoided in patients who have serum potassium values more than 5.0 mmol/L while not taking medications.

Renal Hypertension

See also chapter 175.

Renal parenchymal hypertension which results from primary glomerular and tubulointerstitial disease of the kidney is both volume dependent and renin-mediated. These account for about 70% of all cases of renal hypertension. In glomerular disease renal symptoms and hypertension set in almost simultaneously, whereas in tubulointerstitial diseases hypertension precedes the renal symptoms by several years. Renovascular hypertension (RVH) constitutes only around 1% of the total cases of hypertension but in children below 15 years without gross urinary abnormalities, RVH constitutes more than 60% of cases.

Hypertension in Children

Blood pressure (BP) in children correlates more with that of their mothers. Elevated BP in children may be a forerunner of essential hypertension in adults. The clinical features of elevated BP in neonates and young infants is failure to thrive, irritability, feeding problems including vomiting, cyanosis, respiratory distress, cardiac failure and seizures. Most common causes include renal artery thrombosis following umbilical artery catheterization, coarctation of the aorta, congenital renal diseases, renal artery stenosis, hypercalcemia, neurofibromatosis and endocrine disorders.

Hypertension in Pregnancy

See also chapter 176

This may fall into three groups:

1. Chronic hypertensive patient becoming pregnant
2. gestational hypertension occurring during pregnancy and remitting after delivery and
3. preeclampsia and eclampsia (hypertension with proteinuria).

Maternal complications include increased risk of preeclamptic toxemia, abruptio placentae.

Fetal complications include intrauterine death, increased perinatal mortality and morbidity.

In the management of hypertension in pregnancy, care should be taken to ensure that the antihypertensive drug does not cause fetal damage and affect materno-fetal

placental circulation. Methyldopa is the drug of choice. Hydralazine and calcium channel blockers can also be used. Atenolol and ACE inhibitors should be avoided.

Mineralocorticoid Hypertension

This is caused mostly by increase in aldosterone production by the adrenal cortex, rarely it may be any other mineralocorticoid such as 11-deoxycorticosterone. Mineralocorticoid induced hypertension is associated with hypokalemia.

Normally aldosterone production is regulated by angiotensin II levels, which in turn is controlled by renin levels. Increased aldosterone levels in turn suppress renin levels, and low renin levels are the hallmark of primary hyperaldosteronism.

Primary hyperaldosteronism may result from aldosterone producing adrenocortical adenoma, bilateral adrenocortical hyperplasia or rarely carcinoma. The first two conditions may form part of familial multiple endocrine neoplasia type I (MEN-1).

Clinical features: In the early stages it may resemble other forms of hypertension, but when hypokalemia and alkalosis develop, additional features such as muscle weakness, tetany and cardiac arrhythmias may develop. Classic diagnostic markers are hypertension resistant to drug therapy and hypokalemia. Diagnosis is established by simultaneously estimating plasma levels of renin, aldosterone and potassium, in a patient who is seated for 5 minutes. The ratio of aldosterone to renin is very high in such cases. Further confirmatory tests are available. The site of overproduction of the hormone can be identified by sampling the adrenal venous blood on either side. CT may reveal the tumour if it is of sufficient size.

Treatment: Dexamethasone given orally with a view to suppress corticotrophin also suppresses aldosterone levels in familial hyperaldosteronism type 1. Familial hyperaldosteronism type II is not suppressible by glucocorticoid.

Adenomas have to be removed surgically. In the case of bilateral adrenal hyperplasia, medical treatment with spironolactone or amiloride is beneficial. Spironolactone may be required in small doses of 12.5-25 mg twice daily given orally. Dose of amiloride is 2.5 mg daily.

Orthostatic Hypotension

See also Chapter 201

Sudden fall of blood pressure may occur on adopting the erect posture leading to symptoms such as giddiness and syncope. Generally this may result from several underlying diseases. The term postural hypotension is used when the systolic blood pressure falls by 20 mm Hg or to below 100 mm Hg on standing for five minutes.

When a person stands, there is a tendency for 10-15% of blood to get sequestered in the splanchnic circulation and the lower limbs. The consequent fall in blood pressure (BP) is counteracted by counter-regulatory mechanisms which include sympathetic activity and discharge of hormones like catecholamines, renin, angiotensin and vasopressin. Peripheral vasoconstriction, increase in heart rate and rise in plasma volume help to maintain the BP steady. When a normal person stands, it takes about a minute for circulatory adaptation. The heart rate and diastolic BP rise by 10%. The systolic BP is not affected. In postural syncope the BP falls immediately after standing. Fainting occurs due to fall in cerebral perfusion.

Orthostatic hypotension may result from two groups of lesions:

- 1. Lesions affecting the afferent pathways from the baro-receptors to the vasomotor center, and
- 2. Lesions affecting the efferent pathways from the vasomotor center to the arterioles.

Various neurological disorders that can lead to orthostatic hypotension	
1. Afferent lesions	Neuropathies
2. Central lesions	Multiple system atrophy, Parkinson's disease
3. Spinal lesions	Lesions of cervical and dorsal regions of the spinal cord
4. Ganglionic lesions	Progressive autonomic failure
5. Post-ganglionic lesions	Neuropathies

Common Causes of Orthostatic Hypotension

- 1. Polyneuropathy in diabetes, beriberi and amyloidosis
- 2. Autonomic neuropathy in syringomyelia, tabes dorsalis and subacute combined degeneration
- 3. Following surgical or medical sympathectomy
- 4. Adverse reaction to drugs, especially antihypertensive drugs
- 5. Idiopathic autonomic neuropathy (Shy-Drager Syndrome)
- 6. Dehydration, blood loss, fever, severe anemia, convalescence from debilitating illnesses, prolonged bed rest and starvation.

Clinical features: Dizziness or fainting on standing is the presenting symptom. Fainting from autonomic failure differs from other causes of fainting by the absence of sweating, pallor and cardiac slowing in the former.

Shy-Drager syndrome: is the condition where postural hypotension is associated with other autonomic phenomena such as sphincter disturbances, anhidrosis and impotency and other neurological disorders such as external ocular palsies, parkinsonism and cerebellar disturbances.

Diagnosis: It is important to diagnose the condition and establish the cause since the outlook varies in the different types. In normal subjects the BP falls during sleep and rises prior to waking up. This circadian rhythm of blood pressure is reversed in patients with autonomic failure.

Management: Immediate management is to put the patient supine and elevate the legs or press the thighs against the abdomen to improve venous return. In many cases the patient recovers. Stimulating drinks such as coffee or lime juice containing 20 g sugar and 6 g salt help to raise the blood pressure within a short time. In more severe cases with syncope or sustained hypertension an intravenous drip of 10% glucose saline should be started. Still, if the condition does not recover pressor agents such as ephedrine 30 mg oral or intravenous infusion of dopamine may be required. Fludrocortisone in doses of 0.01 to 0.02 mg/day is the best treatment on a long-term basis. The underlying causes should be detected and corrected.

Long term management consists of dietary advice to take more salt, avoid hypotensive drugs and exercise programmes to improve muscle tone, and treatment of the cause.

The term orthostatic intolerance is given to a syndrome characterized by adrenergic symptoms that occur when upright posture is assumed. The heart rate increases by at least 30 beats/minute without developing orthostatic hypotension. Most subjects are women between the ages 20-50. These symptoms overlap with the clinical presentation of other functional disorders such as DaCosta's syndrome, Soldier's heart, neurocirculatory asthenia and also mitral valve prolapse.

Unstable Angina Pectoris 860

Prinzmetal's Angina 862

blood from the heart is drained into the right atrium through the coronary sinus, thebesian veins and the anterior cardiac veins.

Around 4-6% of the cardiac output flows into the coronary arteries in health. The coronary arteries run on the epicardial surface and their branches penetrate to supply the myocardium. The outer two-third portion is supplied by the epicardial branches and the inner one-third is supplied by perforating branches which form subendocardial ramifications. The left ventricular myocardium receives blood almost exclusively during diastole whereas the normal right ventricular myocardium receives blood during both phases of the cardiac cycle. In normal persons myocardial blood flow is controlled by constriction and dilation of the microcirculation (vessels < 400 μ m). The large coronary arteries offer no resistance to blood flow. When stenosis occurs the arterial pressure drops distally. In health coronary blood flow can increase 3.5-8 times the resting blood flow. When coronary obstruction occurs the microcirculation dilates and compensates to maintain the blood flow. When arterial stenosis becomes severe, even this vasodilation will fail to maintain adequate blood flow. Such occlusions become functionally important.

Metabolism of cardiac muscle is aerobic. The myocardium extracts 70% of the oxygen supplied to it in arterial blood. If the oxygen supply is interrupted for over two minutes, the myocardium becomes ischemic and the mechanical activity ceases totally. Ischemia may result from organic narrowing of the coronary arteries or spasm or both. In normal subjects blood flow to the myocardium is maintained even when the coronary diameter is reduced to 50%, i.e. the cross-section is reduced by 75%. The resting blood flow is maintained till the arterial lumen is reduced by 90%. Factors which further reduce coronary blood flow are extreme tachycardias (due to reduction of diastolic interval), hypertension, elevation of intraventricular pressure as in aortic and pulmonary stenosis, and cardiomegaly. Ischemia to the myocardium causes the characteristic pain.

General Considerations

13

A wide spectrum of clinical disorders is included under this term. All of these are caused by reduction in arterial blood supply to the myocardium. The lumen of the coronary arteries is narrowed leading to impairment of blood supply and in the vast majority of cases the lesion is atherosclerosis.

The right and left coronary arteries arise from the root of the aorta as its first branches. The left coronary artery divides into two major branches, the left anterior descending and left circumflex. Branches of the left descending branch supply the free wall of the left ventricle and a major portion of the interventricular septum. The left circumflex artery supplies the left atrium and parts of the posterior and lateral walls of the left ventricle. In 45% of cases this artery supplies the S-A node as well. The right coronary artery supplies the right ventricle, a major portion of the diaphragmatic surface of the left ventricle, the A-V node (in 90%) and the S-A node (in 55%). Venous

Etiology of Ischemic Heart Disease

1. **Coronary atherosclerosis:** This is the most common cause for myocardial ischemia.
2. **Non-atheromatous coronary artery disease**
 - a. **Arteritis:** Polyarteritis nodosa, Takayasu's disease, Kawasaki's syndrome, non-specific arteritis, syphilitic aortitis, systemic lupus erythematosus, thromboangiitis obliterans and others.
 - b. **Thickening of coronary arteries:** Mucopolysaccharidoses, amyloidosis.
 - c. **Spasm of coronary arteries:** Generally, spasm supervenes on diseased arteries but sometimes no other pathological lesion may be detectable. Under extreme conditions of stress, even normal arteries may undergo spasm. This can lead to myocardial ischemia and fatal arrhythmias.
 - d. **Dissecting aneurysm of the aorta, dissection of the coronary arteries.**
 - e. **Embolism:** Infective endocarditis, emboli from the left atrium or left ventricle, left atrial myxoma or paradoxical embolism may affect the coronary arteries.
 - f. **Congenital anomalies:** Anomalous origin of the left coronary artery from the pulmonary artery, single coronary artery, coronary arteriovenous fistula, aneurysms of the coronary arteries, myocardial bridges.
 - g. **Trauma to the coronary arteries,** penetrating wounds, injury during pericardiocentesis.
 - h. **Thrombosis without underlying atherosclerotic plaque:** Polycythemia, Thrombocytosis, hypercoagulability states
 - i. **Substance abuse:** Cocaine, amphetamines
 - j. **Imbalance between oxygen demand and blood supply:** Severe aortic stenosis, aortic regurgitation, prolonged hypotension, severe anemia, thyrotoxicosis and other conditions of ventricular hypertrophy

Epidemiology: In all the developed countries where reliable statistics are available ischemic heart disease is one of the most common causes of death and cardiac morbidity in middle and elderly age groups. Till the early part of this decade the incidence was rising, but there is a slight drop recently. Though complete statistics are not available, in India Cardiovascular diseases account for 24% of total deaths of which coronary heart disease appears to be the dominant form. Ischemic heart disease death rates are three times higher than stroke rates. Men suffer 9 times more frequently than premenopausal women, but after menopause the risk of coronary atherosclerosis rapidly increases to catch up with that of men over a period of several years. The disease is more common in the affluent classes of society, but the poor

socioeconomic groups and manual labourers are not totally spared.

ETIOLOGY

Risk factors for atherosclerosis: Several risk factors have been identified as contributing to the development of coronary atherosclerosis. For purposes of management, they have been broadly divided into modifiable and non-modifiable risk factors.

1. Non-modifiable Risk Factors

- a. **Genetic predisposition** to atheroma is revealed by a positive family history of ischemic heart disease (sudden deaths, myocardial infarction, or angina) or cerebrovascular accidents occurring at relatively younger ages among close relatives. The higher prevalence of coronary artery disease in persons having diagonal crease in the ear lobe has been found in many population groups including that in Kerala.
- b. **Personality factors:** High strung aggressive and competitive individuals (type A) are more prone to develop myocardial infarction than the more relaxed type of personality (type B).
- c. **Sex:** The disease is considerably less prevalent in women during their reproductive periods of life. In the Framingham study the male: female ratio in the 35-44 years age group was 6.8:1 but in the age group 75-84, the prevalence equalled in both sexes. Despite the lower prevalence, once the disease manifests, it runs a more aggressive course in women.

2. Modifiable Risk Factors

- a. **Cigarette smoking:** Cigarette consumption is the single most important modifiable risk factor for coronary artery disease. Even among non smokers passive exposure to cigarette smoke increases coronary risk. The offending agents are nicotine and carbon monoxide present in cigarette smoke.
- b. **Hyperlipidemia:** The risk of coronary atherosclerosis is directly related to elevation of serum cholesterol. Increase in levels above 250 mg/dL is associated with increasing risk. Lipids circulate in blood in the form of lipoproteins. Based on electrophoretic pattern and density gradient they can be classified into alpha-lipoproteins (high density HDL), beta lipoproteins (low density LDL) and prebeta lipoproteins (very low density lipoproteins—VLDL). An elevated LDL-cholesterol level appears to be the primary CHD risk factor, and the higher the total and LDL cholesterol levels are, the greater is the risk of an atherosclerotic event. A low level of HDL cholesterol is also a potent individual predictor for IHD. Many types of hyperlipidemias are genetically determined, but by proper dietary modification, exercise, and drug therapy the serum levels can be lowered and this risk

can be brought down to some extent. See also section: 10 Chapter: 93

- c. **Hypertension:** Systemic arterial hypertension is a major independent risk factor for CHD, although it pathogenetically appears to be a cholesterol-dependent accelerator of atherosclerosis. Raised blood pressure increases the rate of progression of atheroma, especially when present along with hyperlipidemia. It has been suggested that associated hormonal changes, including generation of angiotensin II by systemic and/or local renin-angiotensin systems, could also play a pathogenetic role.
- d. **Diabetes mellitus:** Another pathogenetically cholesterol-dependent, but statistically independent, major cardiovascular risk factor is diabetes mellitus. Diabetes and hypercholesterolemia interact strongly in the genesis of IHD. The precursor to type 2 diabetes, insulin resistance with impaired glucose tolerance also carries a strongly increased risk for cardiovascular disease. The risk of developing coronary atherosclerosis is considerably increased.
- e. **Exercise:** Persons with sedentary jobs develop coronary artery disease more often than those having regular physical exercise.
- f. **Novel Risk Factors:** Increased levels of homocysteine, C – reactive protein, plasma fibrinogen and fibrin D - dimer, and lipoprotein (a) have been implicated as independent risk factors for atherosclerosis and IHD.

Work done at Bangalore has shown that in resident Indians of South India, tobacco smoking, hypertension, diabetic state and central obesity were the more important risk factors seen in patients with the first attack of acute myocardial infarction. In western countries the incidence of IHD is coming down in the richer groups due to modification of lifestyles whereas it is increasing in the poorer groups.

Pathology

Atheroma commonly affects the epicardial vessels. This may lead to single or multiple obstructions.

The location of infarct depends upon the vessel occluded

Left anterior descending branch: Anterior and apical portions of left ventricle.

Left circumflex branch: Lateral and inferoposterior walls of the left ventricle.

Right coronary artery: Inferoposterior wall and inferior portion of the interventricular septum.

In atherosclerosis, focal fibrofatty elevations (plaques) develop in the intimal and subintimal regions resulting in progressive narrowing of the lumen. Inflammation is an important component in the development of atheroma. It is associated with activation and proliferation of

macrophages, endothelial cells and smooth muscle cells and generation of cytokines and growth factors. The lipid rich atheromatous material itself is a potent inducer of inflammation. Oxidised LDL is taken up by macrophages to form subintimal foam cells. Oxidised LDL also acts as a chemotactic factor for macrophage accumulation.

The inflammatory changes have been the focus of intense research in recent years. Inflammation within the arterial wall starts with the entry of low density lipid (LDL) through the damaged intima. This attracts cellular components such as monocytes, macrophages which are transformed monocytes and T. lymphocytes. Several cytokines such as IFN γ , TNF, IL-1 and others have been detected and incriminated in the process. Several microbial antigens have been detected. These include *Chlamydia pneumoniae*, herpes viridae, CMV and others. Several markers of inflammation such as C-reactive protein, fibrinogen, IL-7, IL-8 and others have been detected. All these point to a strong possibility of inflammation playing a major role in atherothrombotic coronary artery disease.

Several complications may develop in the atheroma. These include hemorrhage into the atheroma, ulceration of the intimal surface with thrombosis over the atheroma, embolization of the atheromatous material, and calcification. Progressive occlusion of the lumen of the coronary arteries may remain totally asymptomatic till the circulation is considerably diminished. In general the development of complications gives rise to one of the clinically detectable syndromes.

Once a coronary artery is occluded and the myocardium is infarcted, gross changes are noticeable by six hours. The infarct appears pale, blue and edematous. Early histological features are interstitial edema, neutrophilic infiltration and clumping of muscle cells. Granulation tissue appears by the tenth day. The infarcted area is converted into a scar by the sixth week. An infarct may involve the total thickness of the ventricular myocardium (transmural infarcts) or may be confined to the subendocardial region.

Further changes may develop over the area of initial infarction. These are: (1) extension of the infarct leading to further loss of ventricular function; (2) involvement of conducting tissues leading to disruption of impulse conduction; (3) rupture of the infarct resulting in hemopericardium; (4) inflammation of the overlying pericardium giving rise to pericarditis; and (5) formation of ventricular aneurysm. The ischemic myocardium is electrically unstable and heterogenous and this acts as a focus for re-entry, which give rise to several arrhythmias in the immediate postinfarction period.

Clinical Presentations

The following distinct clinical syndromes have been recognised:

1. Acute myocardial infarction; with ST segment elevation (ST elevation myocardial infarction – STEMI) without ST segment elevation (non ST elevation myocardial infarction – NSTEMI)
2. Unstable angina pectoris
3. Stable angina pectoris
4. Sudden cardiac death;
5. Arrhythmias and conduction defects;
6. Ischemic cardiomyopathy, and
7. Asymptomatic coronary artery disease.

Acute Myocardial Infarction

Despite impressive strides in diagnosis and management over the past three decades, acute myocardial infarction (AMI) continues to be a major public health problem. Almost all MIs result from coronary atherosclerosis, generally with superimposed coronary thrombosis. Before the thrombolytic era, clinicians typically divided AMI patients into those suffering a Q-wave or non-Q-wave infarct, based on the evolution of the pattern on the electrocardiogram (ECG) over several days after AMI. In the thrombolytic era, AMI is classified based on the presence or absence of ST segment elevation in the 12-lead ECG – into ST elevation myocardial infarction (STEMI) or non-ST elevation myocardial infarction (NSTEMI) (Figs 124.1 to 124.4).

Pathogenesis: Slowly developing high-grade stenoses of epicardial coronary arteries may progress to complete occlusion, but do not usually precipitate AMI, probably because of the development of a rich collateral network. During the natural evolution of atherosclerotic plaques, especially those that are lipid laden, an abrupt and catastrophic transition may occur, characterized by plaque rupture. After plaque rupture there is exposure of substances that promote platelet activation and aggregation, thrombin generation, and, ultimately, thrombus formation. The resultant thrombus that is formed interrupts blood flow and leads to an imbalance between oxygen supply and demand and, if this imbalance is severe and persistent, to myocardial necrosis.

CLINICAL FEATURES

This is characterized by the occurrence of severe retrosternal pain with the characteristic radiation. The pain is usually severe and excruciating, but at times it may be mild and rarely pain may be absent. The pain is described as crushing, tearing, bursting, burning, lancinating or vague. The pain generally lasts for more than 30 minutes and the attack occurs during rest. Several phenomena are associated with this pain. These are severe anxiety and a feeling of impending death, profuse sweating, dyspnea, shock, cardiac arrhythmias, syncope, nausea, vomiting, and epigastric pain. The attack follows the circadian

rhythm in that a good number of cases occur in the early hours of the morning. In some patients, especially diabetics and elderly there may be no chest pain. They may be totally asymptomatic or present with symptoms like dyspnea, extreme fatigue, syncope, confusion, arrhythmia or peripheral embolism.

Signs: In 20% of cases the symptoms may be trivial and physical examination may be unrewarding. In the majority the findings are diagnostic. Coldness of limbs, sweating and sudden onset of pulmonary edema are suggestive of acute left ventricular failure. In cardiogenic shock the extremities are cold and cyanosed and the blood pressure is low and often unrecordable. Heart rate is variable. In the initial stages, severe bradycardia may occur in some cases as a result of increased vagal tone. Others show tachycardia and arrhythmias such as frequent ventricular ectopics, atrial fibrillation or ventricular fibrillation. The blood pressure drops in most cases, but sometimes it may remain normal or even be elevated as a result of intense vasoconstriction. The jugular venous pressure may be elevated, if there is congestive heart failure or right ventricular infarction. About 24-48 h after the infarct fever may occur as a response to tissue necrosis.

Physical examination of the heart reveals muffling of sounds, presence of gallop suggesting ventricular failure, arrhythmias, and accentuation of the pulmonary second sound (P2), as a result of rise of pulmonary artery pressure. On the second or third day pericardial friction rub may be heard. If complications develop these will be clinically evident.

Diagnosis: Strong clinical suspicion is needed for early diagnosis. It should be remembered that in the middle-aged and elderly, one of the common causes for chest pain is myocardial infarction. Clinical suspicion is strengthened by the presence of the characteristic radiation and the associated phenomena. Even in the absence of pain, myocardial infarction should be suspected if a middle-aged person develops any of the complications suddenly. WHO criteria for diagnosis of acute myocardial infarction requires at least two of the following three elements to be present; (1) a history of ischemic type chest discomfort, (2) evolutionary changes on serially obtained ECG tracings and (3) the typical rise and fall in serum cardiac markers.

Investigations: Electrocardiogram (ECG) taken within a few hours of symptoms show diagnostic changes in over 80% of cases. More than 95% show positive ECG findings if recorded 12-24 h after the onset of symptoms. The changes depend upon the type of infarction, site of infarct, presence of arrhythmias, and conduction defects. Non ST elevation infarction produces depression of the ST segment or T wave inversion in ECG. Presence of ST elevation infarction is recognized by the elevation of ST

Fig. 124.1: ECG of anterior wall MI showing ST elevation in leads V1-V5

Fig. 124.2: ECG: Hyperacute inferior wall myocardial infarction. Note: (1) ST elevation in inferior leads– viz lead II, III, and aVF (2) Reciprocal ST segment depression in V2-V4

Fig. 124.3: ECG showing inferior and lateral MI. Note ST elevation in leads 2, 3, aVF, V5,V6 and ST depression in leads I, aVL, V1,V2

Fig. 124.4: ECG showing inferior and posterior wall MI. Note ST elevation in 2, 3, aVF and ST depression in I, aVL. Also tall R waves with upright T waves in V1 and V2

segment in ECG. Later majority of them will develop Q-waves and inversion of the T-waves. The site of infarct can be determined depending on the leads which show abnormalities.

<i>ECG leads showing changes</i>	<i>Location of infarct</i>
V1 to V3	anteroseptal
V4 to V6, L1 and aVL	anterolateral
aVF, L2 and L3	inferior wall
ST depression in V1 and V2	
Presence of tall R-waves and upright T-waves in lead V1 and V2	True posterior infarct
ST elevation in Rt sided chest leads and Q waves (V3R, V4R)	Right ventricular infarct
Note:	
1. In true posterior infarct. V1 will show upright R and T waves, unlike as in right ventricular hypertrophy in which T is inverted.	
2. Right ventricular infarction has to be suspected when there is jugular venous changes resembling constrictive pericarditis and shock without hypovolemia. In such circumstances right sided leads should be taken to demonstrate RV infarction. Presence of right ventricular infarction calls for special management.	

It should be remembered that in a small proportion of cases ECG may not show any diagnostic change even in the presence of the typical pain and enzyme changes.

Biochemical Markers of Myocardial Infarction

Several enzymes and other components of cardiac muscle are liberated into circulation from injured and necrotic myocardium. Their presence above diagnostic levels, their peak levels in the plasma and the pattern of their rise and fall, have all been studied in detail and their reliability in the diagnosis of myocardial infarction has been established. It is routine practice to estimate these components to establish or exclude the diagnosis of myocardial infarction (Table 124.1).

The transaminases: Serum glutamic oxaloacetic transaminase (SGOT) also known as aspartate transaminase is liberated from the myocardium when it undergoes infarction. The levels start rising in 8-12 hours, peak at 18-36 hours and come down in 3-4 days. Their estimation is cheap and freely available in several laboratories.

Creatine Kinase (CK)

The level rises within 4-8 hours of infarction, reaches its peak in 24 hours and falls to normal levels within 2-3 days. CK shows three isoenzymes—MM, BB and MB which can be identified electrophoretically. MM is more specific to skeletal muscle, BB to brain and kidney, and MB to the heart, though there is some degree of overlap. Thrombolytic therapy, percutaneous revascularization or spontaneous thrombolysis leads to early rise in the enzyme levels. CK is present in several other tissues and therefore non-MI conditions also cause increase in CK levels, e.g. muscle diseases, alcoholic bouts, diabetes mellitus, muscle injury, vigorous exercise, convulsion, intramuscular injections, thoracic outlet syndrome and pulmonary embolism. Estimation of the cardiac specific isoenzyme CKMB is more specific for MI.

CKMB shows two isoforms CKMB1 and CKMB2. Elevation of CK (MB2) is more suggestive of cardiac infarction in the absence of other obvious reasons. Levels of CKMB isoform >1.0 U/L or a ratio of CKMB2/CKMB1 >1.5 is diagnostic of acute MI.

Cardiac Specific Troponins

The troponin complex usually consists of three subunits that regulate the calcium mediated contractile process.

- Troponin C—binds to calcium
- Troponin I—binds to actin and inhibits actin-myosin interactions
- Troponin T (Tn-T)—binds to tropomyosin

TABLE 124.1
Showing the details of common biochemical markers diagnostic of myocardial infarction

Marker and normal level	Time to show rise in serum levels hours after onset	Peak level	Time to return to normal	Time for collection of blood
SGOT 5-40 IU/L	8-12	18-36 hours	3-4 days	Once in 12 hours
LDH 20-220 IU/L	10	24-48 hours	10-14 day	24 hours
CK MB	3-12	24 hours	48-72 hours	Every 12 hours for 3 days
C TnT	3-12	12 hours to 2 days	5-14 days	Once at least every 12 hours
C TnI	3-12	24 hours	5-10 days	Once at least every 12 hours

Myocardial injury leads to a rapid rise in cardiac troponin in plasma. Troponin I and troponin T are released into the plasma so that reliable diagnostic sensitivity is reached by 12 to 16 h and maximal activity is reached by 24 to 36 h. The levels return to normal within 10 to 12 days. Quantitative bedside assay tests for cardiac Tn-I and Tn-T are available for diagnosing acute MI.

In some patients with chest pain C Tn-T may be raised but CKMB is in the normal range. The term 'minor myocardial damage' has been used to denote this condition. Such patients have adverse outcome on follow-up including fatal and nonfatal MI.

Lactate Dehydrogenase (LDH)

This used to be done frequently before the availability of specific markers such as cardiac troponins. LDH is an enzyme found in the heart muscle, along with several other tissues in the body. It consists of five isoenzymes, among which LDH1 is principally seen in the heart. Levels of LDH1 increase following myocardial necrosis. Several other disorders also lead to rise in LDH, e.g. hemolysis, megaloblastic anemia, leukemia, hepatic disorders, renal disease, muscle disorders, pulmonary embolism, shock and others. Estimation of the ratio of LDH1 to LDH2 has been accepted as a more reliable test for diagnosing AMI. Ratios of LDH1/LDH2 >1 are diagnostic. However routine LDH isoenzyme analysis for the diagnosis of AMI is no longer recommended.

Conclusion

At present the diagnosis of AMI can be established within 12 hours of onset by estimation CKMB, C Tn-T or C Tn-I at intervals of 8-12 hours. Several other biochemical markers such as heart fatty acid binding proteins (hFABP), myosin light chains (MLC), myosin heavy chains (MHC) and glycogen phosphorylase isoenzymes are being studied for their promptness and reliability in diagnosis.

Levels of serum lipids such as cholesterol and HDL fall within 24-48 hours after MI and therefore the ideal time to determine the lipoprotein profiles of such patients is 8 weeks after the event.

Imaging Procedures

Chest X-ray film: Since the patient should not be moved, portable X-ray machine may be required. When present, prominent pulmonary vascular markings on the X-ray reflects elevation of pulmonary venous pressure indicating left ventricular failure. The chest film may also assist in excluding other causes of chest pain such as pneumothorax, pulmonary infarction with effusion, aortic dissection and skeletal fractures.

Echocardiography: Echocardiography is particularly valuable in assessing the patient with an equivocal ECG. The presence of a regional wall motion abnormality provides strong supportive evidence of acute coronary ischemia. Echocardiography also provides an assessment of ventricular function. It can provide information on complications like ruptured chordae tendineae with mitral regurgitation and ventricular septal defect. It can help to estimate cardiac hemodynamics by using colour Doppler studies.

Nuclear imaging: Radionuclide imaging, angiography, perfusion imaging, infarct avid scintigraphy and positron emission tomography are all in use to study the nature of the myocardial lesion, its viability and prognosis.

CT scan: It can be used to reveal cavity dimensions, wall thickness, aneurysms, and intracardiac thrombi.

MRI scan: It can be made use of to assess the perfusion of infarcted and non-infarcted tissue as well as the state of reperfused myocardium. It can also identify areas of jeopardised but not infarcted, myocardium.

Both CT scan and MRI are generally reserved for subsequent evaluation after the acute condition is managed.

Differential diagnosis: Acute chest pain may occur in pleurisy, pneumonia, pericarditis, pneumothorax, pre-herpetic neuralgia, dissecting aneurysm of the aorta or lesions on the chest wall. Pericarditis may closely resemble acute myocardial infarction in respect of the pain and its radiation. Fever, leukocytosis, and pericardial rub occur early in pericarditis, whereas these develop only 24 hours after the onset of myocardial infarction. Dissecting aneurysm of the aorta is uncommon. It causes tearing pain, which is abrupt in onset and severe from the beginning. Pain may radiate to the back, epigastrium, flank, and lower extremities. Ventricular dysfunction is less common to develop.

Sometimes the pain of myocardial infarction may be felt mainly under the jaws, shoulder, or epigastrium, and these may be mistaken for primary disease at these sites.

COMPLICATIONS

Several complications can occur following acute myocardial infarction and can lead to morbidity and mortality.

1. **Arrhythmias:** Several arrhythmias develop. These include frequent ventricular ectopics, ventricular tachycardia, ventricular fibrillation, sudden cardiac arrest, atrial fibrillation, and varying grades of heart block. The incidence of arrhythmias is higher in those patients seen earlier after the onset of symptoms. The treatment of tachyarrhythmias

involves not only the use of antiarrhythmic drugs but also correction of abnormalities of plasma electrolyte concentrations, acid-base balance disturbances, hypoxemia, anemia, and digitalis intoxication.

2. **Left ventricular failure:** Left ventricular dysfunction remains the single most important predictor of mortality after acute myocardial infarction. Clinical manifestations of left ventricular failure become more common as the extent of the injury to the left ventricle increases. In addition to infarct size, other important predictors of the development of symptomatic left ventricular dysfunction include advanced age and diabetes. Apart from myocardial necrosis, another condition which can lead to left ventricular failure is myocardial stunning

Myocardial stunning: The term myocardial stunning defines a prolonged but reversible contractile dysfunction observed after transient myocardial ischemia, i.e. even after blood supply to the myocardium is restored. The recovery of contractile function may take hours or days.

The term '**hibernating myocardium**' is used to denote the condition in which cardiac function is depressed due to persisting ischemia and which recovers fully on restoration of blood supply.

3. **Cardiogenic shock:** Cardiogenic shock is a severe form of left ventricular failure. Infarction of 40% or more of the ventricular myocardium leads to cardiogenic shock. Features of cardiogenic shock include systolic blood pressure <80 mm Hg, markedly reduced cardiac index (<1.8 L/min/m²) and an elevated pulmonary capillary wedge pressure. Mortality in cardiogenic shock is >70%.
4. **Pericarditis:** Pericarditis may occur as early as the first day and as late as 6 weeks after MI. This develops in 15-20% of patients. It is seen in full thickness infarcts. The development of pericarditis appears to be correlated with a larger infarct and greater hemodynamic compromise. Treatment of pericarditis pain consists of aspirin. Doses of 650 mg orally every 4 to 6 hours may be needed.
5. **Phlebothrombosis and pulmonary embolism:** These develop as a result of prolonged recumbency, venous stasis, and tendency for venous thrombosis.
6. **Arterial embolism:** Mural thrombi develop on the infarcted endocardium and these may embolize into several arterial trunks. This risk starts a day or two after the infarction and persists for a few weeks.
7. **Papillary muscle dysfunction and rupture:** Ischemia and infarction of the papillary muscles leads to mitral regurgitation. Rupture of the papillary muscles results in the development of

acute mitral incompetence which tips the patient into acute pulmonary edema.

8. **Rupture of the interventricular septum:** This condition leads to acquired ventricular septal defect. A ruptured interventricular septum is characterized by the appearance of a new harsh, loud holosystolic murmur that is heard best at the lower left sternal border and that is usually accompanied by a thrill. Biventricular failure generally ensues within hours to days.
9. **Cardiac rupture:** This may develop by the third to the fifth day. The infarcted area gives way giving rise to hemopericardium, cardiac tamponade, and death in the majority of cases. Rupture of interventricular septum carries a mortality of 24% in the first 24 hours, 46% at 1 week and 67-82% at 2 months. Surgical closure improves the prognosis.
10. **Delayed complications:**
 - a. **Cardiac aneurysm:** Weakening of the scar leads to bulging out of the ventricle and the development of ventricular aneurysm. The common sites are the anterior and apical regions. This leads to persistent congestive failure, recurrent embolism, and ventricular tachycardia. On palpation of the precordium the aneurysm can be felt as a see-saw pulsation in relation to the apex beat. The condition can be confirmed by X-ray examination, echocardiography, and angiocardiology.
 - b. **Dressler's syndrome:** This is probably an immune-mediated reaction in which pericarditis, pleurisy, fever, arthritis, and elevation of ESR develop 1-6 weeks after the infarction.
 - c. **Shoulder hand syndrome** may develop in a few cases weeks to months after the acute event.

PROGNOSIS

Myocardial infarction is a serious disease, with an overall immediate mortality ranging up to 25% if proper management is not instituted. About 50 percent of the deaths associated with AMI occur within 1 hour of the event and are attributable to arrhythmias, most often ventricular fibrillation. For the first six months after infarction, the risk of developing sudden death is still high, but this risk falls after this period. Anterior infarction carries a grave prognosis if accompanied by conduction disturbances. All the major complications worsen the prognosis. Age above 70 years, hypertension, diabetes mellitus, and heavy cigarette smoking worsen the outlook further. Women below the age of 75 years have higher mortality rates after AMI compared to men of similar age.

Several ECG criteria have been employed to predict increased risk of fatal arrhythmias and death in the post-infarct period.

These include:

- Signal averaged late potentials
- Heart rate variability and
- Q-T dispersion

Patients who had sudden cardiac death and required cardiopulmonary resuscitation during the course of the illness run a higher risk of fatal arrhythmias in the first few years after discharge from hospital.

Management

Prehospital care is an important factor in preventing sudden death and immediate complications and also improving long-term outcome. No time should be lost in seeking hospital admission after the initial symptoms manifest. The time elapsed between the onset of chest pain and reaching the appropriate hospital (pain to hospital time) and the time elapsed between the arrival at hospital and receiving the first dose of medication (door to needle time) are the most important factors which reduce immediate and in-hospital mortality and complications. Several attempts have been made from time-to-time to educate the public on the need to get immediate hospitalization. Provision of special trained teams with coronary care ambulances which can reach the patient's home within minutes and administration of thrombolytics in the ambulance with minimum delay have reduced early mortality in many countries.

EMERGENCY ROOM MANAGEMENT

Aspirin is given straight away in a dose of 325 mg to be chewed. A rapid decision as to the need for thrombolysis should be taken depending on the indication.

A 12 lead ECG forms the cornerstone in decision making regarding thrombolysis in acute myocardial infarction. Presence of ST segment elevation of 1mm or more in two or more contiguous leads with a history compatible with AMI are the indications for starting thrombolytic therapy if there are no absolute contraindications. There is no benefit in giving thrombolysis in the absence of ECG showing ST segment elevation. Before giving thrombolytic agents blood is collected for the biochemical parameters.

If the ECG is suggestive of ischemia without infarction (i.e.) S-T depression or T-wave inversion, start on anti-ischemic therapy.

If the ECG is not diagnostic, observe the patient repeating the ECG at 2 hour intervals, estimate the serum markers and if necessary, echocardiography. If there is no evidence of infarction on observation for 24-48 hours, the patient should be subjected to a stress test to provoke ischemia.

DRUG THERAPY

Aspirin

It is the first line drug in the initial management of AMI and all other forms of ischemic heart disease. Initial dose of aspirin should be 162 to 325 mg to be chewed to ensure rapid buccal absorption. Subsequent dose of aspirin is 75 to 162 mg.

Recent studies have shown that addition of clopidogrel to aspirin in AMI is beneficial.

Control of Cardiac Pain

Pain relief has to be achieved as early as possible. Persistent pain perpetuates sympathetic overactivity, especially so in the early phases of AMI. Control of pain is achieved by a combination of narcotic analgesics, nitrates and beta blockers.

Morphine is the analgesic of choice.

Morphine: Its mode of action includes central narcotic action, depression of vasomotor and respiratory centers, reduction of sympathetic tone, and reduction of histamine release from the periphery.

Administration of morphine leads to reduction of pain, anxiety, vasodilation, reduction of the heart rate and effort for breathing, all helping to reduce oxygen demand.

In the ICCU morphine should be given intravenously, initial dose of 4 to 8 mg and subsequently in doses of 2-8 mg repeated at intervals of 5-15 minutes until the pain is relieved or adverse effects appear. The adverse effects include hypotension, respiratory depression, vomiting, urinary retention and constipation. Maximum dose should not exceed 2-3 mg/kg in 24 hours.

Adverse effects of morphine are managed as follows:

Hypotension is counteracted by maintaining the supine position and elevating lower extremities if the systolic blood pressure is less than 100 mm Hg. Administration of atropine 0.5 to 1.5 mg helps to reduce the vagomimetic effects of morphine.

Respiratory depression is treated with naloxone in dose of 0.1-0.2 mg IV, repeated after 15 min if needed.

Nausea and vomiting can be treated with a phenothiazine.

OXYGEN

It was a routine practice to give oxygen to all patients with anginal pain for 24-48 hours based on the empirical assumption of hypoxia. But, augmentation of the fraction of oxygen in the inspired air does not elevate oxygen delivery significantly in patients who are not hypoxemic. Furthermore, it may increase systemic vascular resistance and arterial pressure and thereby lower cardiac output slightly. In view of these considerations, arterial oxygen

saturation may be estimated by pulse oximetry, and oxygen therapy may be given if oxygen saturation is less than 90%.

NITRATES

These are used for immediate relief of anginal pain, as well as prevention of its recurrence. For immediate action nitroglycerine (glyceryl trinitrate) is used IV or sublingually. The vasodilatory effect is immediate and the action is of short duration. For maintenance therapy other preparations are used. Their action is more prolonged.

Actions

Nitrates dilate the epicardial coronary arteries and collaterals, and improve the blood supply. It reduces the preload and also the myocardial oxygen demand. Blood flow of normally perfused areas is redistributed to ischemic areas of the myocardium. Other actions include inhibition of platelet aggregation, limitation of infarct size and improvement in exercise capacity.

Indications

In acute MI with angina, congestive heart failure, persistent angina or hypertension, nitrates are given for the first 24-48 hours. Maintenance dose is continued in patients with recurrence of angina and persistent pulmonary venous congestion.

Glyceryl trinitrate is available in vials of 5 and 25 mg at concentrations of 1 or 5 mg/mL. One vial is diluted in 500 mL normal saline prior to infusion and run at a rate of 5-10 mcg/minute to start with. It is increased by 5-10 mcg/minute until clinical effect is manifest. This includes relief of angina, fall of blood pressure by 10% in normotensive, and up to 30% in hypertensive patients.

Sublingual Dose

Glyceryl trinitrate is available as tablets containing 0.5, 2.6 and 6.4 mg. It is given initially at doses of 0.3-0.6 mg. Additional doses of 0.3 mg may be repeated every 5 minutes to a maximum of 1.2 mg in 15 minutes.

Other preparations are buccal spray containing 400 mcg metered doses, 2% skin ointment and transdermal patches containing 2.5, 5.0 and 15 mg, released over 24 hours.

Side Effects of Glyceryl Trinitrate

These include headache and flushing, hypotension, hypovolemia and ventilation-perfusion imbalance in the lungs. Methemoglobinemia may develop after large doses.

In general, reduction or withdrawal of the dose helps to relieve the side effects. Hypotension and hypovolemia

are managed by elevation of the foot end of the bed and intravenous fluids.

Tolerance to nitrates develops after all forms of nitrate administration if given continuously even within 12-24 hours, but generally it is delayed. The loss of effect is limited to the capacitance and resistance vessels. Large conductance vessels including epicardial coronary arteries and radial arteries are not affected.

Tolerance to nitrates is prevented by giving the drug at eccentric intervals allowing 10-12 hours of nitrate free intervals in between, e.g. 8 am and 2 pm. Transdermal preparation should not be used continuously for more than 12 hours.

Isosorbide Dinitrate

This is available as 5 mg, 10 mg and 20 mg sustained release tablets, or 1.25 mg metered dose buccal spray.

Isosorbide 5 mononitrate tablets of 10 and 20 mg tablets and long acting tablets of 40, 50 and 60 mg are available. These are used for maintenance therapy and prevention of angina after the emergency is tided over.

Beta Adrenergic Blockers

Beta blockers relieve pain and reduce the need for analgesia in many patients and reduce infarct size. When used in the early hours of infarction, they limit infarct size, reduce the incidence of ventricular arrhythmias, atrial fibrillation and cardiac arrest. They reduce the incidence of recurrent ischemia and reinfarction within the first six weeks of initial MI.

In the acute phase, intravenous metoprolol is the drug of choice. If there are no contraindications, metoprolol is given IV in three boluses of 5 mg each at intervals of 2-5 minutes if the heart rate is >60/minute. If hemodynamic stability continues for 15 minutes after the last I.V dose, oral metoprolol 50 mg is given 6 hourly for two days and then changed to 100 mg b.i.d.

Contraindications for beta blockers include cardiac failure evidenced by the presence of rales heard over the lower parts of the chest 10 cm above the level of the diaphragm, hypotension (BP < 90), bradycardia (heart rate < 60/minute), prolonged PR interval > 0.24 second or third degree heart block. Other commonly used beta blockers include atenolol 50-100 mg daily, and bisoprolol 5 mg daily, given orally.

The ultra short acting drug esmolol can be used in an emergency in a dose of 500 mcg/kg/minute for 4 minutes IV.

THROMBOLYTIC THERAPY

Plaque rupture and thrombus formation play a major role in the genesis of acute coronary occlusion leading to acute myocardial infarction. The introduction of thrombolytic (fibrinolytic) therapy was a major advance in the treatment

of acute ST elevation myocardial infarction (STEMI) since over 90 percent of such patients have complete occlusion of the culprit artery. Early reperfusion of the ischemic myocardium has brought down the immediate post-MI mortality from 10-15 to 5-10%. Several randomised trials have upheld its benefit and safety. Whenever possible thrombolytic drugs should be given by the first attending physician; irrespective of the speciality, if the indications are clear.

Classification of Thrombolytic Agents

1. **First generation drugs:** Streptokinase, urokinase: These act on all sites where fibrin is formed. In addition to dissolution of the clots locally, they also produce generalised hemorrhagic state.
2. **Second generation:**
 TPA—tissue plasminogen activator. Single chain—alteplase and double chain—duteplase.
 APSAC—Anisoylated plasminogen streptokinase activator complex
 SCU-PA—Single chain urokinase type plasminogen activator.
 TCU-PA—Two chain urokinase type plasminogen activator.
 These are clot specific agents acting at the site of fibrin formation with very little or no generalized hemorrhagic tendency.
3. **Third generation:**
 - i. Reteplase (rPA)—recombinant TPA
 - ii. Tenecteplase (TNK – PA)
 Though several thrombolytic agents are available, the first generation drugs are the ones widely used in India on account of their free availability, effectiveness, safety and above all, the lowest cost. A course of streptokinase costs Rs. 3000, whereas urokinase costs Rs. 10000. All the others are several times more expensive and also are not freely available. Therefore, they are employed only under exceptional situations.

Indications

1. In those with S-T elevation in the ECG, more than 0.1 mV(1mm) in two or more contiguous leads within 12 hours of onset of symptoms.
2. In those with new onset or presumably new onset left bundle branch block within 12 hours of onset of symptoms.

Best results are obtained if thrombolysis is done within 6 hours of onset, earlier the better. Benefit may occur even up to 12 hours of onset, though in a smaller proportion.

Dosage and Administration

Streptokinase (SK) is available as lyophilised powder in vials containing 2,50,000, 7,50,000 or 15,00,000 units. It has to be stored at 15-25°C. The initial dose is 1.5 million units diluted in 100 mL normal saline and infused over one hour.

Occurrence of thrombolysis and reperfusion of the myocardium is evidenced by the following features.

1. Relief of chest pain
2. Resolution of the S-T segment elevation of >50% by 60-90 minutes.
3. Evidence of reperfusion phenomena such as
 - a. arrhythmias-VPCs, accelerated idioventricular rhythm or bradycardia
 - b. abrupt rise in serum creatine kinase activity
 - c. recanalisation of the coronary artery demonstrable by angiography.

Contraindications

- A. Absolute contraindications
 1. Previous hemorrhagic stroke at any time
 2. Ischemic stroke within 3 months
 3. Known intracranial neoplasm, structural cerebrovascular lesion (AV malformation)
 4. Suspected aortic dissection
 5. Active internal bleeding or bleeding diathesis (other than menstrual bleeding)
 6. Significant closed head or facial trauma within 3 months
- B. Relative contraindications
 1. Hypertension with BP > 180/110 mm Hg
 2. History of prior cerebrovascular accident or known intracerebral pathology
 3. Current use of anticoagulants in therapeutic doses and other known bleeding diatheses
 4. Recent trauma including head trauma or major surgery within 3 weeks
 5. Noncompressible vascular puncture
 6. Occurrence of internal bleeding within 2-4 weeks
 7. For streptokinase and anistreplase, previous history of use of the same drug within 5 days to 2 years, or history of allergic reaction
 8. Pregnancy
 9. Active peptic ulcer

Complications of Streptokinase Therapy

1. Allergic reactions such as angioneurotic edema, hypotension, bronchospasm, urticaria, rashes and fever may develop. Administration of 4 mg betamethasone IV helps to reduce the allergic reactions. Presence of antibodies to streptokinase reduces its therapeutic effects and increases allergic reactions.

2. Bleeding complications: Minor bleeding occurs in 3-4%. Major bleeding 0.4-1%. Intracranial bleed may occur in less than 0.6%.
3. Hemodynamic effects: Transient hypotension and bradycardia.
4. Reperfusion adverse effects: These are the effects of sudden reperfusion into areas of ischemic myocardium. They are caused partially by the effect of free radicals. Adverse effects include arrhythmias such as VPC, accelerated idioventricular rhythm, ventricular tachycardia, ventricular fibrillation and bradyarrhythmias. Cardiac rupture may occur due to further damage to infarcted myocardium and hemorrhage into it.
5. Coronary reocclusion: 15% of recanalised vessels undergo thrombotic occlusion within a few hours to 3 days.

OTHER THROMBOLYTIC AGENTS

Urokinase (UK)

Urokinase is a double chain glycoprotein which acts as a trypsin like protease and occurs in two molecular forms. It was first isolated from human urine and hence its name. It is also obtained by recombinant DNA technology from cultured human renal cells. It is nonantigenic. It is not fibrin specific and therefore it causes generalised bleeding tendency. Its half-life is 10 minutes. It produces less sustained systemic fibrinolysis. Dose for IV use is 3 million units given over 45 to 60 minutes. Different dosages of 1.5, 2 and 3 million units have been used in several trials. Patency at the end of 1 hour is 60%. Infusion is similar to that of streptokinase. Anaphylactic reactions are practically nil. It is more expensive than streptokinase and therefore it may be reserved for patients allergic to SK or who have received SK previously.

Since the other newer class of thrombolytic agents are seldom used in the Indian scene, only passing mention is made about them.

Tissue Plasminogen Activator (tPA)

TPA is a naturally occurring enzyme that binds to fibrin with greater affinity than streptokinase, without increasing generalized bleeding tendency. It has been in use since 1984. rtPA is produced by recombinant DNA technology. Several dosage schedules are in use.

Total dose should not exceed 100 mg. It should be accompanied by IV heparin 5000 units bolus followed by 1000 units/hour with the dose adjusted to keep the partial thromboplastin time (PTT) at 1.5-2 times the normal. This helps to prevent reocclusion of the coronary arteries.

APSAC, Anistreplase

APSAC is a preformed complex of SK and plasminogen, which is spontaneously activated after IV administration. Once activated it behaves identical to SK, except that it has a longer half-life. It has a spectrum of activity and incidence of complications similar to SK. It is easy to administer. Hence it is used for prehospital thrombolysis in AMI patients. Dose is 30 units IV over 2-5 minutes. The half-life is 30-90 minutes and it retains its effect for 4-6 hours.

Comparison of Thrombolytic Therapy

Several international trials (GISSI-2, ISIS-3 GUSTO-1) TIMI-IV have compared different modes of thrombolytic therapy. Based on their evidence, consensus on this form of therapy has been arrived at.

Choice of Agent

In patients presenting within 4 hours of onset of symptoms the speed of reperfusion of the occluded vessels is of paramount importance and a high intensity thrombolytic regimen such as TPA or APASC is the preferred treatment, except in those individuals in whom the risk of death is low.

For those patients presenting between 4 and 12 hours after the onset of chest discomfort, the speed of reperfusion of the occluded vessel is of lesser importance and therefore streptokinase and TPA are equivalent options. Cost is the main factor for choice.

Late Therapy

There is no definite reduction in mortality if thrombolytic drugs are routinely administered to patients presenting after 12 hours of onset. Still we consider it reasonable to give thrombolytic therapy in selected patients with persistent symptoms and ST elevation in ECG beyond 12 hours.

Since elderly patients are at increased risk of cardiac rupture if thrombolytic drugs are given later than 12 hours after the onset of symptoms, it is better to restrict late thrombolysis to patients younger than 65 years with ongoing ischemia, especially those with large anterior infarctions. Older patients with ongoing ischemic symptoms who come in after 12 hours of onset are probably better managed with PTCA than with thrombolytic therapy.

Percutaneous Transluminal Coronary Angioplasty (PTCA)

Several studies (PAMI, GUSTO IIB and others) have confirmed the advantages of this method in cases not amenable to drug therapy or even as a primary therapy.

Advantages include reduction of mortality, preventing re-infarction and a recanalization rate of > 90%.

Indications

1. As an alternative to thrombolytic therapy in patients with S-T segment elevation or new onset LBBB. PTCA can be done within 12 hours of onset of AMI or even later if symptoms persist. Success rate of PTCA depends upon the skill of the operator and facilities in the hospital.
2. Patients below the age of 75 years who present with shock within 36 hours onset of AMI should also be considered for PTCA.
3. In those presenting with severe congestive heart failure and/or pulmonary edema.

Calcium Channel Blockers

They have no role in the primary or secondary prevention of acute MI. Even the possibility of harm has been raised. In patients with first episode of non-Q infarction or first episode of acute inferior wall infarction without LV dysfunction, use of verapamil and diltiazem may reduce the incidence of reinfarction but they have no advantage over beta blockers and aspirin.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS (ACE INHIBITORS)

Indications

1. Patients seen within 24 hours of acute MI with S-T segment elevation, in the absence of contraindications.
2. In those patients with MI and clinical heart failure or left ventricular ejection fraction (LVEF) less than 40% during and after convalescence from AMI.

ACE inhibitors should generally be started within the first 24 hours, ideally after thrombolytic therapy has been completed and the blood pressure has stabilized, if there are no contraindications. Initially low doses such as 6.25 mg captopril or 5 mg lisinopril or equivalent doses of other ACE inhibitor should be started and later stepped up if necessary. They can be stopped if there is no evidence of symptomatic or asymptomatic left ventricular dysfunction by 4-6 weeks.

Lipid Lowering Agents

All patients recovering from AMI should be considered potential candidates for modification of their lipid profile. The target LDL cholesterol in patients with IHD is <100 mg/dl. Initial therapy should consist of dietary modification (<7 percent of total calories as saturated fat and cholesterol <200 mg/d). In patients with an LDL cholesterol level greater than 130 mg/dl on admission, it

is better to start lipid lowering drugs. HMG-CoA reductase inhibitors (statins) are the first line lipid lowering drugs.

Magnesium Salts

The available data suggests that routine use of intravenous magnesium in ST elevation myocardial infarction has no place in current practice. Magnesium is useful only in known or suspected hypomagnesemic states and especially when these are associated with severe ventricular arrhythmias or QT prolongation.

Anticoagulants

Heparin is used in the acute stage in those undergoing PTCA, those who have received tPA or rPA and those at high risk for systemic emboli (large or anterior MI, AF, LV thrombus). The dose is 5000 units given as IV bolus admission and followed by IV infusion at the rate of 800-1000 units/hour.

The indication for routine use of long-term anticoagulation after acute MI is not clear. It may be given for the following conditions:

1. Prevention of recurrence of MI in patients who cannot tolerate aspirin
2. Post MI patients in persistent atrial fibrillation
3. Presence of left ventricular thrombus (see Chapter 165).

General Measures

To reduce risk of vomiting early after infarction and reduce risk of aspiration, during the first 4-12 hours after admission patients should receive a clear liquid diet. Thereafter diet with 50-55% of calories derived from complex carbohydrates and up to 30% from mono and unsaturated fats should be given. The diet should contain fruits and vegetables which are rich in potassium and magnesium. The foods should be small in quantity and given at frequent intervals.

RESUMPTION OF PHYSICAL ACTIVITY

Graded and supervised physical activity is encouraged as early as the patient can tolerate. In the absence of complications such as shock, cardiac failure or serious arrhythmias, mobilization of the patient should be started on the second day itself.

Before allowing the patient to get up and walk, vital signs should be checked and safety of mobilization should be ensured.

Stage 1—First 2 Days

Use bed pan or commode for toilet purposes. The patient is allowed to feed from the food tray with arm and back supported. All joints are given active and passive

movements. The ankle joint is exercised actively. The patient may be allowed to sit in a chair for short periods.

Stage 2—Days 3-4

The patient is allowed to walk out of the room under supervision. The upper part of the body can be bathed with the patient sitting in a chair with back supported. Bed to chair transfer for 20-30 minutes may be allowed daily.

Stage 3—Days 5-7

Patient can walk up to 200 meters two or three times a day. Before the patient is discharged, an exercise tolerance test is performed so that the schedule of exercise at home can be advised.

Early ambulation reduces the risk of deep venous thrombosis, pulmonary embolism and prolonged invalidism, in addition to improving the morale of the patient.

APPENDIX: EVIDENCE BASED MEDICINE

The development of newer methods, newer drugs, surgical methods and newer equipment have necessitated large scale multinational studies to evaluate their advantages and cost effectiveness. The number of well known studies in this field, outnumber all other similar studies done in other branches of medicine. Based on these studies several consensus protocols have evolved. Further studies are in the pipeline. Evolution of the management strategy has drawn heavily from these trials and the present state of the art technology is a classic example of evidence based medicine.

A few of the trials are listed below

SAVE: Survival and ventricular enlargement (CAPTOPRIL)

SMILE: Survival of myocardial infarction long-term evaluation (ZOFENOPRIL)

AIRE: Acute infarction-ramipril efficacy

TIMI: Thrombolysis in myocardial infarction

CONSENSUS II: IV ENALAPRILAT

CHINESE CAPTOPRIL STUDY

ISIS: International study of infarct survival

LIMIT-2—Second Leicester intravenous magnesium intervention trial

MAGIC—Magnesium in coronary disease

GISSI—Gruppo Italiano per lo studio della streptochinasi nell'infarto miocardico

GUSTO I—Global use of strategies to open occluded coronary arteries

GUSTO III—Newer antiplatelet drugs

FTT: Fibrinolytic therapy trialist collaborative study

EMERAS: Studio Multicentrico Estreptoquinase Republican de America de Surcollaborative study

ISAM—Intravenous Streptokinase in acute MI

4S—Scandinavian simvastatin survival study

(S)MASH (Swiss)—Multicentre trial of angioplasty for shock

ASSET—Anglo-Scandinavian study of early thrombosis

Several subsequent trials organized on national and international levels have published their results. Further studies are going on at present and publishing their results from time-to-time.

CORONARY REVASCULARISATION

Percutaneous transluminal coronary angioplasty PTCA is a radiological intervention procedure undertaken by cardiologists in which the stenotic segment of the arteries are dilated by suitable balloons passed through catheters, percutaneously through the femoral artery, retrograde into the aorta and then into the coronary arteries. By inflating the balloon the atheroma is crushed and the arterial lumen is restored. The lumen is maintained patent by the use of different types of stents. The number of stents depend on the number of occlusions. Re-occlusion by thrombus is prevented by using antiplatelet drugs like aspirin and clopidogrel. In addition to aspirin and clopidogrel several newer drugs including glycoprotein IIb-IIIa receptor blocking agents are used. These agents have considerably improved the results of PTCA by maintaining luminal patency in much higher proportion of patients. In well equipped centers the success rate exceeds 90%. Even complicated lesions can be treated by angioplasty by skilled operators (Figs 124.5 and 124.6).

The original stents introduced in 1987 were simple metallic stents. In them the re-occlusion rate was 30% and above within 1 year. Subsequently drug eluting stents were introduced. These elute drugs such as sirolimus, paclitaxel and others which serve to inhibit re-occlusion. Drug eluting stents are considerably more expensive than the plain stents. The cost is Rs. 150000 to 300000 per procedure depending on the number of stents required.

In the early days of angioplasty the percutaneous interventions (PCIs) were done as elective procedures in stabilized and chronic patients. With the accumulation of experience and technology many cases of complex and acute myocardial infarction have been taken up for emergency angioplasty. PCIs are done as life-saving and myocardium-saving procedures. The results of such emergency procedures are often dramatic. The complication of re-stenosis following PCI has been treated by options such as further balloon angioplasty, intracoronary radiation therapy (brachy therapy) and implantation of further drug eluting stents.

Fig. 124.5: Coronary angiogram in a patient with acute inferior wall myocardial infarction showing RCA. First picture: Before primary PTCA, RCA was totally occluded with thrombus.(arrow). Second picture: After primary PTCA, showing RCA with good flow and the branches (arrows)

Fig. 124.6: Coronary angiogram in a patient with acute anterior wall myocardial infarction showing LAD. First picture: Before primary PTCA, LAD was totally occluded from ostium with thrombus and is not seen (arrow). Second picture: After primary PTCA, showing LAD with good flow and the branches (arrows)

13

Coronary Artery Bypass Graft (CABG)

This operation is being done in India for about 30 years and many centers have gained considerable expertise and experience in the procedures. The intra- and perioperative mortality is around 2-3% in good large volume centres. Surgery is indicated for stenosis of left main stem, multivessel disease especially in presence of LV dysfunction, in which the clinical benefit and coronary disease-related mortality are significantly improved. Several grafts (3-5 or even more) are introduced at the same session, which connect the root of the aorta to the coronary artery distal to the occlusion.

Originally saphenous vein was used as the conduit. At present in addition to this vein, internal mammary artery and other arteries are also being employed. The results are better with arterial grafts. Several modifications

of the original technique have been introduced. Including keyhole surgery on the beating active heart.

Both bypass surgery and angioplasty may be complicated later by reocclusion. In case of stents the restenosis is due to smooth muscle proliferation. Several newer techniques are being experimented upon to prevent reocclusion of the stent. These include irradiation of the stented artery by gamma or beta radiations and impregnation of the stents with antiproliferative drugs like sirolimus, actinomycin D and paclitaxel (drug eluting stents) which prevent smooth muscle cell proliferation. All these innovations are being evaluated for their long-term results.

The procedure followed in most of the centers to pick up cases requiring revascularisation is to subject patients who have angina or who have suffered an acute

myocardial infarction (after 2-3 weeks of convalescence) to a stress test on the treadmill. Stress test is taken as positive if it provokes angina or produce ST segment depression in ECG of 1 mm or more from the baseline, which recovers on rest. Such patients with positive stress test are taken up for coronary angiography. Cases with limited number of stenosis are ideal for coronary angioplasty. Those with multiple vessel disease and multiple occlusions require bypass graft surgery.

Transmyocardial laser revascularisation is an operative treatment for refractory angina pectoris when CABG or PTCA are not feasible. This method may prove beneficial in those with no other treatment options.

Right Ventricular Infarction

The right coronary artery is the major source of blood flow, supplying the right atrium, right ventricle, inferior wall and posterior wall of left ventricle and posterior part of the interventricular septum. Right ventricle is supplied by the RV branches of the right coronary artery. The RV has a more favourable oxygen supply-demand ratio compared to the LV. In addition, the collateral circulation in the RV is also better.

RV infarction may occur in nearly half of all inferior myocardial infarctions, although only 10 to 15% of patients show classic hemodynamic abnormalities of clinically significant RV infarction. Right ventricular infarction with hemodynamic abnormalities accompanying inferior STEMI is associated with a significantly higher mortality (25% to 30%) than inferior MI alone.

RV infarction results from occlusion of right coronary artery proximal to the right ventricular branches. Majority of cases of RV infarction occurs in association with inferior wall infarction. Isolated RV infarction accounts for less than 2% of the total.

Physical findings: The diagnostic triad includes hypotension, clear lung fields and elevation of jugular venous pressure in the setting of an inferior wall infarction. Although this combination of findings is specific, it occurs only in less than a third of the cases.

ECG recorded with right precordial leads may show the features of RV infarction. Demonstration of 1 mm or more ST-segment elevation in lead V1 and in the right precordial leads V3R and V4R is the single most predictive ECG finding in patients with RV infarction (Fig. 124.7). The finding may be transient; half of patients show resolution of ST elevation within 10 hours of onset of symptoms. Echocardiography gives diagnostic findings. Right heart catheterization may be helpful in diagnosing RV infarction. Confirmation of the diagnosis can be made by radionuclide ventriculography. Complications include shock, which is uncommon but serious when it occurs, varying degrees of heart block, atrial fibrillation, atrioventricular asynchrony, septal rupture and development of right to left shunt through a patent foramen ovale.

Management: The principles of therapy include:

1. Maintenance of RV preload – maintenance of intravascular volume
2. Reduction of RV afterload – inotropes, and intra aortic balloon counter pulsation
3. Inotropic support to the failing myocardium, and
4. Early reperfusion – primary angioplasty or thrombolysis

Volume loading with IV normal saline helps to maintain RV preload. *Measures usually undertaken to treat LV infarction such as diuretics, nitrates and injection of morphine sulphate can reduce the RV preload and aggravate hypotension and shock.*

Inotropic support is given by infusion of dopamine or dobutamine in usual doses. If atrioventricular asynchrony occurs, it has to be corrected by A-V sequential pacing. Atrial fibrillation demands prompt cardioversion.

If there is concomitant LV failure the RV afterload is increased and this further depresses RV function. In such circumstances measures such as sodium nitroprusside infusion or an intra-aortic balloon counterpulsation which serves to improve LV function should be undertaken. Improvement in LV function automatically leads to fall in afterload as well.

Measures aimed at reperfusing the occluded coronary artery such as fibrinolytic therapy and emergency

Fig. 124.7: ECG showing inferior MI with right ventricular MI. Note ST elevation in 2, 3, aVF, V1 and right chest leads. ST depression in I, aVL

angioplasty have been found to improve RV function early. Emergency revascularization by angioplasty improves survival.

Prognosis: When inferior myocardial infarction is complicated by RV infarction the mortality may go up to 30% compared to 6% in inferior infarction without involvement of the RV. In survivors of RV infarction generally the RV function recovers on follow-up.

**Stable Angina Pectoris
(Chronic Stable Angina)**

The term “angina pectoris” is used to denote the pain or discomfort produced by reversible myocardial ischemia brought on by exertion or emotion and relieved by rest. Coronary atherosclerosis is the most common cause. Other causes include aortic stenosis, aortic incompetence, syphilitic aortitis, polycythemia vera, rapidly developing anemia and others.

CLINICAL FEATURES

Ischemic cardiac pain starts and increases with exertion or emotion and forces the patient to stop activity. With rest the pain completely subsides within a few minutes. The quality of pain, its location and radiation are similar to that described under myocardial infarction, but it is milder. At times the manifestation may be only undue dyspnea or vague chest discomfort rather than clear cut pain.

Physical examination in between the attacks is unrewarding in most cases, but during the attacks of pain, elevation of blood pressure, a third or fourth heart sounds, and evidence of mitral incompetence due to papillary muscle dysfunction may be detectable.

Diagnosis: Angina pectoris should be diagnosed by history. Resting ECG may be normal in approximately half of patients with chronic stable angina. The most common ECG changes are non-specific ST –T wave changes with or without abnormal Q waves. During an episode of angina, ECG becomes abnormal in 50% or more patients with normal ECGs. Exercise ECG is helpful in those patients with chest pain and normal resting ECGs. The depression or elevation of the S-T segment during exercise are diagnostic of angina. The whole procedure has been quantitated by the treadmill test, in which the ECG response to graded exercise can be recorded. The pattern of ECG abnormality has been correlated with the severity of coronary artery occlusion. Myocardial perfusion imaging using radioactive isotopes and stress echocardiography are also useful in diagnosis of myocardial ischemia.

Prognosis: Annual mortality in patients managed by medical therapy is about 4%. The mortality is 3,7 and 11% with affection of one, two or three coronary arteries

respectively. Presence of resting ECG abnormalities and congestive cardiac failure worsen the prognosis.

MANAGEMENT

General measures include control of hypertension and diabetes, treatment of thyrotoxicosis and anemia, weight reduction, and avoidance of smoking and caffeine (coffee and tea in excess of 3 cups a day).

Drugs

Antiplatelet Agents

The use of aspirin is associated with a 33% reduction in the risk of adverse cardiovascular events. In the absence of contraindications, aspirin 75 to 150 mg daily should be used routinely in all patients with acute and chronic ischemic heart disease with or without manifest symptoms.

Lipid Lowering Agents

One percent reduction in total cholesterol would reduce coronary events by 2%. Continued treatment is associated with angiographically demonstrable arrest of progression, more stabilization and even regression of the plaque lesions and decreased incidence of clinical events. Both mortality rate and major coronary events are reduced by 30-35%. Lipid lowering therapy should be recommended even if the elevation of total cholesterol and LDL fraction is moderate. Statins (HMG – CoA reductase inhibitors) are the first choice drugs for the treatment of hyperlipidemia.

Anti-anginal and Anti-ischemia Therapy

Drugs in this group include mainly the beta adrenoreceptor blocking agents (beta blockers), calcium antagonists and nitrates. Other classes of drugs include: ACE inhibitors and metabolic agents.

Beta Blockers

Mechanism of action: Inhibition of beta-receptors cause decrease in heart rate, decrease in myocardial contractility and lowering of arterial pressure thus decreasing myocardial oxygen demand. Reduction in heart rate also increases diastolic interval thereby improving myocardial perfusion.

The beta blockers used commonly are:

Propranolol	20-80 mg twice daily
Metoprolol	50-200 mg twice daily
Atenolol	50-200 mg/day
Bisoprolol	5-20 mg/day

Other drugs such as nadolol, acebutalol, nebivolol are also available.

The goal is to reduce the resting heart rate to 50 to 60 per minute. Beta blockers reduce the rate of cardiac related

TABLE 124.2

Calcium antagonists		
<i>Dihydropyridine group</i>	<i>Dosage</i>	<i>Side effects</i>
1. Amlodipine	2.5-10 mg/d	Headache, edema of the legs and feet
2. Felodipine	2.5-10 mg/d	Headache, edema
3. Nicardipine	20-40 mg t.i.d	Headache, dizziness, flushing, edema
<i>Other groups of drugs</i>		
<i>Diltiazem</i>		
Immediate release	30-90 mg t.i.d	Hypotension
Slow release	60-180 mg b.i.d	Myocardial depression Bradycardia
<i>Verapamil</i>		
Immediate release	80-120 mg t.i.d	Myocardial depression
Slow release	120-480 mg/d	Bradycardia

TABLE 124.3

Commonly used nitrates		
1. Nitroglycerine	Sublingual tablets	0.3 to 0.6 mg upto 1.5 mg
	Buccal spray	400 µg as needed
	Transdermal	15 × 15 cm patch containing 7.5-40 mg
	Oral sustained release	2.5 mg-13 mg
	Buccal	1-3 mg 3 times daily
	Intravenous	5-20 µg/min
2. Isosorbide dinitrate	sublingual	2.5-15 mg
	Oral	5-80 mg, 2-3 times daily
	Buccal spray	1.25 mg metered doses
	Chewable tablets	5 mg
	Oral slow release	40 mg o.d or b.i.d
	Intravenous ointment	1.25-5 mg/h 100 mg/24 h
3. Isosorbide mononitrate	oral	20 mg twice daily 60-240 mg once daily

mortality, non fatal MI, and unstable angina. Beta blockers can be combined with nitrates. The advantages are:

1. Reflex tachycardia seen with nitrates is decreased
2. The increase in LV volume and diastolic pressure and wall tension associated with decreased heart rate caused by beta blockers is counteracted by concomitant use of nitroglycerin.

Side effects include fatigue, inability to perform exercise, lethargy, insomnia, nightmares, worsening of claudication and impotence.

Calcium Antagonists (Table 124.2)

Mechanism of action: Calcium antagonists inhibit calcium ion movement through slow channels in cardiac and smooth muscle membranes by noncompetitive blockade of voltage-sensitive L-type calcium channels. The three major classes of calcium antagonists are the dihydropyridines (nifedipine is the prototype), the phenylalkylamines (verapamil is the prototype), and the modified benzodiazepines (diltiazem is the prototype). All calcium antagonists exert a negative inotropic effect.

The newer second generation agents such as amlodipine, felodipine and others decrease coronary vascular resistance and increase coronary blood flow. They reduce myocardial oxygen demand primarily by reduction of systemic vascular resistance and arterial pressure. The negative inotropic effect of calcium antagonists like verapamil and diltiazem also decreases the myocardial oxygen requirement.

Hypotension, depression of cardiac function and worsening heart failure may occur during long-term treatment with all the calcium antagonists. Dependent edema may occur as a troublesome complication. This resolves on withdrawing the drug.

Nitrates

Clinical effects: In patients with chronic stable angina, nitrates improve exercise tolerance, time to onset of angina and ST segment depression during treadmill exercise test. Combination with beta blockers, or calcium antagonists enhance these beneficial effects (Table 124.3).

Contraindications: Nitroglycerine and nitrates are relatively contraindicated in hypertrophic obstructive cardiomyopathy because in these patients nitrates can increase LV outflow tract obstruction and can precipitate presyncope or syncope. It should also be avoided in cases of critical aortic stenosis.

Other Anti-anginal Agents

Nicorandil: A potassium channel activator, this has pharmacologic properties similar to those of nitrates and is effective in the treatment of stable angina.

Metabolic agents: Such as trimetazidine, ranolazine and carnitine have been observed to produce antianginal effects in some patients. They are still being investigated further.

Bradycardiac agents: Such as alinidine and zatabradin have been used for the treatment of stable angina. Other drugs such as ketanserin and ACE inhibitors have also been tried successfully.

Risk Factor Modification

1. Cessation of cigarette smoking
2. Management of hyperlipidemia
3. Control of hypertension
4. Control of diabetes mellitus

5. Treatment of obesity
6. Physical exercise—graded regimen
7. Relief of anxiety

Revascularisation procedures: Coronary revascularisation procedures like PCI and CABG are indicated when angina is refractory to medical management. They improve the quality of life and prolong survival.

Unstable Angina Pectoris

Introduction

Coronary artery disease presents a spectrum of conditions with acute transmural infarction at one end and non transmural infarction, unstable angina, chronic stable angina and silent ischemia at the other end. Unstable angina (previously also known as preinfarction angina, crescendo angina, acute coronary insufficiency and intermediate coronary syndrome) is at the centre of this spectrum.

Definition

The condition is diagnosed under the following circumstances:

1. Crescendo angina - angina that is more severe, prolonged or more frequent, superimposed on a pre-existing pattern of relatively stable exertion related angina pectoris.
2. Angina pectoris of new onset usually within one month
3. Angina pectoris at rest as well as with minimal exertion.

Classification

Based on the severity, clinical features, and response to treatment Braunwald *et al* have classified unstable angina as follows.

Based on Severity

Class I: New onset severe or accelerated angina

The duration is less than 2 months. Anginal attacks are more severe, more frequent occurring more than thrice a day and the threshold of exertion to cause angina is less. There is no rest angina.

Class II: Angina at rest—subacute

Patients with one or more episodes of angina at rest during the preceding month, but not within the preceding 48 hours.

Class III: Angina at rest—acute

Patients with one or more episodes of angina at rest within the preceding 48 hours.

Based on Clinical Circumstances

Class A: secondary unstable angina

This is a clearly distinct condition caused by extrinsic factors which worsen myocardial ischemia, e.g. anemia, infection, fever, hypotension, tachyarrhythmias, thyrotoxicosis, and hypoxemia secondary to respiratory failure.

Class B: Primary unstable angina

Class C: Post-infarction unstable angina. This occurs within 2 weeks of documented myocardial infarction

Based on Response to Intensity of Treatment

1. Absence of treatment or minimal treatment
2. Occurring in the presence of standard therapy with conventional dose of oral beta blockers, nitrates and calcium antagonists for chronic stable angina.
3. Occurring despite maximally tolerated doses of all three categories of oral therapy and intravenous nitroglycerine.

This classification can be correlated with the underlying disease. For example, class III patients are more likely to have intracoronary thrombus and heparin may be of greater value in such patients than in class I and II. A clinical score based upon this classification is available. It is an important predictor of intracoronary thrombus and complexity of the lesions.

Pathophysiology

The majority of patients with unstable angina have significant obstructive coronary atherosclerosis. Rupture or erosion of an atherosclerotic plaque with superimposed nonocclusive thrombus is by far the most common cause of unstable angina. The type of plaque that ruptures, the so-called vulnerable plaques, are usually lesions with less than 50 percent stenosis. A patient having a small increase in myocardial oxygen demand, in conjunction with a reduction in coronary blood flow due to the plaque rupture can lead to an episode of ischemia. Other important mechanisms contributing to aggravation of ischemia include platelet aggregation, thrombosis and coronary vasoconstriction.

Clinical and Laboratory Findings

Symptoms: The chest discomfort in unstable angina is similar in quality to that of classic effort induced angina, but it is more intense. There is an abrupt and progressive reduction in the threshold of physical activity required to provoke angina and this should be taken as a warning for the onset of unstable angina. Rest angina or nocturnal angina may occur in many cases. Radiation of pain to an additional site and onset of new associated features such as sweating, nausea, vomiting, palpitation and dyspnea should all be taken as suggestive symptoms.

Physical Examination

This may reveal non-specific findings such as transient third and fourth heart sounds, dyskinetic apical impulse suggesting left ventricular dysfunction, and transient murmur of mitral regurgitation during or immediately after an ischemic episode. Features of congestive cardiac failure may occur. There may be hypotension during the episodes of pain. These indicate adverse prognosis.

Electrocardiogram

In unstable angina, ST segment depression (or transient ST segment elevation) and T wave changes occur in up to 50 percent of patients. New ST segment deviation, even of only 0.05 mV, is a specific and important measure of ischemia and prognosis. T wave changes are sensitive but non-specific of acute ischemia. An unusual finding is the presence of transient inverted 'U' waves. Continuous ECG monitoring can be used for two purposes in unstable angina: (1) to detect arrhythmias in association with the acute episode and (2) to monitor the ST segment for evidence of recurrent ischemia.

Laboratory Parameters

- Cardiac troponin T and troponin I:
The degree of increase of troponins has prognostic implication in unstable angina.
- C-reactive protein: This is a sensitive indicator of inflammation and the level of this marker is correlated with adverse prognosis
- Serum amyloid A protein and
- Fibrinogen

Coronary Angiography

Three vessel disease is found in approximately 35%, two vessel disease in 25%, single vessel disease in about 25% and left main coronary artery disease in approximately 5-10%. Critical obstruction may not be demonstrable in any vessel in 15% of patients with unstable angina. Coronary angiogram demonstrating eccentric lesions with scalloped or overhanging edges are more characteristic of unstable angina.

Adverse Prognostic Factors

- Older age
- Continuing rest pain despite medical therapy
- Ischemia detected by Holter's monitoring
- Significant ST-T wave changes on electrocardiogram at initial presentation.
- Troponin -positive cases
- Levels of markers of inflammation such as C-reactive protein, serum amyloid A and fibrinogen
- Multivessel disease, presence of thrombus or complex coronary morphology at coronary angiography

Management

Comprehensive management of unstable angina or non-Q myocardial infarction (MI) include the following:

- Antithrombotic therapy including antiplatelet drug and anticoagulants
- Antianginal drugs
- Revascularization procedures
- Risk factor modification and pharmacologic measures to slow or halt progression of atherosclerosis.

Antiplatelet Agents

Aspirin is the drug of choice. It should be started in a dose of 162-325 mg given orally as early as possible. Maintenance dose of aspirin is 75-162 mg/day. Aspirin reduces the risk of myocardial infarction by 35% at 6 months and 40% at 1 year.

Clopidogrel is a thienopyridine derivative that inhibits platelet aggregation by inhibiting ADP action on platelet receptors. Recent studies have shown that addition of clopidogrel to aspirin in high risk unstable angina decreases the mortality and further cardiovascular events.

Other antiplatelet drugs are abciximab, eptifibatide and tirofiban which are inhibitors of glycoprotein IIb - IIIa receptors on platelets. Their indication is only under very special circumstances. These are highly expensive, and not freely available.

Anticoagulants

Heparin given in doses intended to keep the activated partial thromboplastin time at 1.5-2 times the normal value reduces the incidence of nonfatal MI from 1.9 to 1.2% and refractory angina from 22.9 to 9.6%. In the acute phase heparin is more effective than aspirin but a combination is even better. After the acute phase heparin is withdrawn and aspirin is continued. Low molecular weight heparin is found to be superior and easier to be administered than unfractionated heparin in unstable angina.

Direct thrombin inhibitors such as hirudin, hirulog and argatroban are effective anticoagulants which could be considered when heparin is contraindicated. These drugs are used only in limited situations at present.

Oral anticoagulants are not routinely used on a long-term basis. Thrombolysis is not indicated for patients with uncomplicated unstable angina. Combined prophylaxis with warfarin and antiplatelet drugs is more effective than using single drugs alone (see Chapter 165).

Antianginal Therapy

Nitrates, calcium channel blockers and beta blockers are used for this purpose.

Nitrates

They form the mainstay of therapy. Intravenous nitroglycerine controls the angina and prevents recurrence.

They also improve global and regional left ventricular function. Nitrates may be given sublingually, orally, topically or intravenously. Intravenous nitroglycerine is started in a dose at 5-10 µg/min by continuous infusion and increased by 10 µg /min every 5 to 10 minutes until relief of symptoms is achieved or limiting side effects appear. Headache, fall of systolic blood pressure below 90 mm Hg or more than 30% below the initial mean arterial pressure are indications for stopping the infusion. Patients controlled with intravenous nitroglycerine should be switched on to an oral or topical nitrate preparation when they are symptom-free for 24 hours. Tolerance to continuous intravenous nitroglycerine therapy develops within 24 to 48 hours.

Beta Adrenergic Blockers

These drugs are standard therapy for unstable angina. They reduce the risk of developing MI by 13%. For immediate effect intravenous esmolol or metoprolol can be used. This can be followed by oral drugs, the dose of which can be titrated to keep resting heart rate between 50 and 60/mt.

Calcium Channel Blockers

These drugs are as effective as beta blockers in relieving symptoms. They do not prevent the development of acute myocardial infarction or reduce mortality. Even an increased risk of MI has been reported if short acting nifedipine is used as monotherapy in unstable angina.

Diltiazem has been found to be effective in reducing reinfarction and post-infarction ischemia in non-Q MI. Calcium antagonists should be used as a second line therapy in patients with continued ischemia despite treatment with nitrates and beta blockers. Particular caution should be taken in adding a calcium antagonist to beta blocker in patients with left ventricular dysfunction.

The anti-anginal effects of nitrate, beta blockers and calcium channel blockers are often additive. Triple therapy is recommended in refractory unstable angina. Anti-thrombotic therapy is generally used concurrently.

Percutaneous Coronary Interventions

Patients with suspected unstable coronary syndromes should be assessed for the risk based on clinical history, physical examination and presenting electrocardiogram. Patients considered to be at low risk may be treated with nitrates, aspirin and beta blockers as outpatients. They can undergo stress testing after 48 hours and should undergo coronary angiogram if indicated. Medium and high risk patients should be admitted and treated aggressively with heparin, aspirin, clopidogrel, nitrates and beta blockers. Platelet receptor antagonists (GPIIb-IIIa) should be considered in higher risk groups. Cardiac catheterisation

and revascularisation should be performed early in the high and medium risk patients with elevated troponin levels. The sensitivity and specificity of diagnosis can be improved with addition of thallium imaging, SPECT imaging or stress echocardiography.

Role of Ventricular Assist Devices: Intra-aortic Balloon Pump (IABP)

This increases diastolic flow through the stenotic segment and this may prevent complete occlusion. It also improves ventricular function. IABP is extremely effective in controlling.

1. Recurrent ischemia, and
2. Complications in very high risk patients.

Upto 5% of patients may require IABP to control severe recurrent ischemia and to stabilize ventricular function.

Coronary Artery Bypass Grafting (CABG)

The subsets of patients in whom CABG offers better control of symptoms and survival benefits are those who have:-

1. Left main stem disease, and
2. 3-vessel disease with left ventricular dysfunction.

Risk Factor Modification and Pharmacological Measures

This includes cessation of smoking, control of hypertension and diabetes, lipid lowering, weight reduction and dietary modifications. Long-term treatment with aspirin, beta blockers and lipid lowering agents (statins) should be emphasized.

Measures to lower serum lipids should be undertaken in patients with dyslipidemias. Aim should be to keep LDL levels below 100 mg/dl. Drug therapy should be instituted also in marginally abnormal patients if other measures fail to control the lipid levels.

Statins are used more liberally in this group of patients. Statins have the additional benefit of stabilizing the plaques in the vessels.

Prinzmetal's Angina

(Syn) Variant Angina

In 1959 Prinzmetal *et al* described an unusual syndrome of cardiac pain secondary to myocardial ischemia that occurs almost exclusively at rest, not precipitated by physical exertion or emotional stress and also associated with ST segment elevation in the ECG. This is known as Prinzmetal or variant angina. It may be associated with acute myocardial infarction, severe cardiac arrhythmias including ventricular tachycardia and fibrillation as well as sudden death.

Pathogenesis

Angina is caused by spasm occurring in normal or diseased coronary arteries. Spasm is usually focal and involves a single site usually adjacent to an atheromatous plaque.

The possible mechanisms include

1. Hypercontractility of arterial wall associated with atherosclerotic process itself.
2. Endothelial injury.
3. Myocardial sympathetic dyssynergia.

Cigarette smoking, use of cocaine, hyperinsulinemia and insulin resistance are known risk factors. Anginal episodes show a circadian rhythm, peak attacks occurring during early morning hours between midnight and 8 am.

CLINICAL FEATURES

Patients with variant angina tend to be younger than patients with chronic stable angina or unstable angina and many do not exhibit classic coronary risk factors except that they are often heavy cigarette smokers. The anginal discomfort which is extremely severe may be accompanied by syncope, the latter presumably due to arrhythmias. Occasionally the angina is accompanied by other vasospastic disorders such as migraine and Raynaud's phenomenon.

Electrocardiogram

ECG changes are characteristic. The diagnostic feature is the elevation of ST segment during pain. A pattern of *alternating* ST segment elevation between the precordial and inferior leads is associated with angiographically documented multivessel spasm involving both the left anterior descending and right coronary systems. Conduction disturbances and ventricular arrhythmias may occur during the anginal attacks.

Arteriographic Studies

Spasm of a proximal coronary artery with resultant transmural ischemia and abnormalities in left ventricular function has been convincingly documented arteriographically and is the diagnostic hallmark of Prinzmetal angina. Significant fixed proximal coronary obstruction of at least one major vessel occurs in the majority of patients, and in these patients spasm usually occurs within 1 cm of the obstruction. The remainder has normal coronary arteries in the absence of ischemia.

Several provocative tests for coronary spasm have been developed.

1. Ergonovine test. This test has 100% sensitivity
2. Acetylcholine test, sensitivity 99%
3. Methacholine test

4. Miscellaneous: other provocative agents are exercise, cold pressor test and induction of alkalosis by hyperventilation.

Prognosis

Long-term survival is good. Survival at 5 years is 89-97%. The extent, severity and activity of coronary artery disease have adverse influence on prognosis for long-term survival and freedom from myocardial infarction. Nonfatal myocardial infarction occurs in up to 20% of patients and death in up to 10% during this period. Patients with variant angina are at a higher risk of sudden cardiac death.

Management

Drugs acting in Prinzmetal's angina bring about relief predominantly by the relief of coronary vasospasm

1. In Prinzmetal's angina nitrates are beneficial, the action being exclusively direct vasodilating effect of spastic coronaries.
2. Calcium antagonists are very effective in preventing the coronary artery spasm of variant angina and they should be used in maximally tolerated doses.

Calcium antagonists along with long and short acting nitrates are the mainstay of therapy. Even after surgical revascularisation procedures these drugs should be continued as maintenance therapy.

3. Beta blockers: Response to beta blockers is variable. They may even cause deterioration in Prinzmetal's angina.
4. Prazosin which is a selective alpha adrenoceptor blocker is beneficial in Prinzmetal's angina.
5. Aspirin in dose of 75 mg daily should be given. Larger doses of aspirin inhibit the synthesis of the naturally occurring coronary vasodilator prostacyclin. This may even increase the severity of ischemic episodes.
6. Coronary angioplasty and CABG are helpful in variant angina with discrete proximal fixed obstructive lesions. PTCA and CABG are contraindicated in patients with only isolated coronary artery spasm without accompanying fixed obstructive lesions.

ISCHEMIC CARDIOMYOPATHY

Multiple small infarcts and extensive diffuse fibrosis of the myocardium present a picture of cardiomegaly and congestive cardiomyopathy. There may be accompanying mitral incompetence. End stage ischemic cardiomyopathy is an indication for cardiac transplantation.

Asymptomatic Coronary Artery Disease

This is not uncommon even in apparently normal individuals. Routine stress testing may bring out the abnormality. Such cases may develop acute myocardial infarction or die suddenly as a result of ventricular fibrillation or cardiac arrest. Significant abnormalities in

the treadmill test are indications for coronary arteriography. Occlusion of the left main coronary artery or all the three vessels is an indication for early bypass surgery.

Prevention of coronary artery disease: Primary prevention can be achieved by:

1. proper dietary manipulation to avoid high intake of saturated fats, and overnutrition;
2. avoidance of smoking;
3. regular exercises; and
4. regular medical check-up.

Diseases of the Myocardium

C.G. Bahuleyan, K. Suresh

Chapter Summary

Myocarditis	864
Cardiomyopathy	865
Dilated Cardiomyopathy	865
Hypertrophic Cardiomyopathy	866
Obliterative (Restrictive) Cardiomyopathy	868
Endomyocardial Fibrosis	868

Myocarditis

ACUTE MYOCARDITIS

Myocarditis most commonly results from an infectious process, the most common being viral infection, specifically, Coxsackie B. Myocarditis can also be caused by radiation, chemicals, or hypersensitivity to drugs. In the majority of patients, active myocarditis remains unsuspected because the cardiac dysfunction is subclinical, asymptomatic, and self-limited.

Infection by cardiotropic viruses prompted the initial hypothesis that the viral infection was responsible for myocardial injury. However it was noted that cardiac dysfunction increased after the eradication of the infective agent and speculated that the pathogenesis may be due to the immunologic responses initiated by the virus. Demonstration of T-lymphocyte and macrophage infiltration, and a variety of cytokines known to depress myocardial contractility in endomyocardial biopsies of patients with active carditis strengthened the concept of immune-mediated injury. In addition to chronic inflammatory immune mechanism or persistent viral infection,

apoptotic cell death may be another mechanism by which myocarditis can result in cardiomyopathy. Several different viruses have been reported to be triggers for apoptosis.

Causes

1. Infectious:

Viruses

Coxsackie virus, adenovirus, echo virus, influenza virus, herpes simplex virus, varicella-zoster virus, hepatitis, Epstein-Barr virus, and cytomegalovirus, HIV, hepatitis (A and B), polio virus, mumps, rabies, respiratory syncytial virus, arbovirus.

Bacteria

Corynebacterium diphtheriae, Streptococcal and staphylococcal species, *Haemophilus influenzae*, *Bartonella*, *Brucella*, *Neisseria gonorrhoea*, *Actinomyces*, *Chlamydia spp*, *Treponema pallidum*, *Leptospira*, *Borrelia burgdorferi*.

Fungi

Candida spp, *Aspergillus spp*, Histoplasma, Blastomyces, Cryptococcus, Coccidioidomycetes.

Parasites

Trypanosoma cruzii, toxoplasma, schistosoma, trichinella.

2. Non infectious

Drugs causing hypersensitivity reactions

Antibiotics: sulfonamides, penicillins, chloramphenicol, tetracycline, amphotericin B.

Antituberculous: isoniazid, para-aminosalicylic acid

Anticonvulsants: phenytoin, carbamazepine

Anti-inflammatory: indomethacin, phenylbutazone

Diuretics: acetazolamide, chlorthalidone, hydrochlorothiazide, spironolactone

Others: lithium, doxorubicin, emetine, cocaine, numerous catecholamines, acetaminophen, zidovudine

Wasp, scorpion, spider stings

Radiation

Connective tissue disorders such as systemic lupus erythematosus (SLE), rheumatoid arthritis, dermatomyositis, Kawasaki disease, sarcoidosis, and giant cell arteritis.

Nutritional disorders: Deficiency of thiamine—beriberi.

CLINICAL FEATURES

Clinical manifestations of myocarditis are variable. Most patients have a self-limited disease, whereas others present in profound cardiogenic shock. The most obvious symptom suggesting myocarditis is an antecedent viral syndrome. Flu-like symptoms occur in approximately 60 percent of patients. Unexplained tachycardia, arrhythmias, hypotension, cardiomegaly, and evidence of cardiac failure occurring in the presence of any of the etiological disorders should suggest the possibility of myocardial damage. The disease process affects the impulse producing and conducting tissues and produces arrhythmias and varying grades of conduction defects. Sudden cardiac death can be the initial presentation of myocarditis in some patients, presumably from complete heart block or ventricular tachycardia. The ECG shows sinus tachycardia, non-specific changes in ST and T-waves, conduction defects, low voltage complexes and sometimes myocardial infarction pattern. X-ray may reveal cardiomegaly. Increase in CK-MB is observed in approximately 12 percent of patients. Troponin levels may also increase. Echocardiography can reveal left ventricular systolic dysfunction in patients with a normal-sized left ventricular cavity. Endomyocardial biopsy is the critical test to confirm the diagnosis.

Prognosis: Myocarditis is a serious condition associated with mortality. Death occurs as a result of sudden cardiac failure, heart block or fatal arrhythmias. The prognosis depends upon the extent of cardiac involvement and the underlying cause.

Management: The condition should be anticipated and early treatment instituted. The patient is put to absolute bed rest with cardiac monitoring in an intensive cardiac care facility. Complications such as cardiac failure, heart block, and arrhythmias are managed as they arise. Immunosuppressive therapy is not routinely recommended for infective myocarditis. Standard heart failure treatment remains the mainstay of therapy.

CHRONIC MYOCARDITIS

This condition may follow the acute condition or arise *de novo*. The clinical picture resembles one of cardiomyo-

pathy, but milder. Mainly it presents with cardiomegaly and congestive heart failure.

Cardiomyopathy

Cardiomyopathy is a primary disorder of the heart muscle that causes abnormal myocardial performance and is not the result of disease or dysfunction of other cardiac structures. Thus, the term *cardiomyopathy* excludes cases of myocardial failure due to myocardial infarction, systemic arterial hypertension, valvular stenosis or regurgitation and congenital heart disease.

The currently used clinical classification of cardiomyopathy was developed by the World Health Organization (WHO) and the International Society and Federation of Cardiology.

WHO Classification of Cardiomyopathy

Dilated cardiomyopathy This condition is characterized by dilatation and impaired contraction of the left or both ventricles.

Hypertrophic cardiomyopathy This condition is characterised by left and/or right ventricular hypertrophy, which is usually asymmetric and involves the interventricular septum. Typically, the left ventricular volume is normal or reduced. Mutations in sarcomeric contractile protein genes cause disease.

Restrictive cardiomyopathy This entity is characterised by restrictive filling and reduced diastolic volume of either or both ventricles with normal or near normal systolic function and wall thickness.

Arrhythmogenic right ventricular cardiomyopathy The disorder is characterised by progressive fibrofatty replacement of right ventricular myocytes.

Unclassified cardiomyopathies Unclassified cardiomyopathies include a few cases which do not fit readily with any group. e.g. fibroelastosis, systolic dysfunction with minimal dilatation, mitochondrial involvement, etc.

Specific cardiomyopathies

- Ischemic cardiomyopathy
- Valvular cardiomyopathy
- Hypertensive cardiomyopathy
- Inflammatory cardiomyopathy
- Metabolic cardiomyopathy
- General system disease
- Muscular dystrophies
- Neuromuscular disorders
- Sensitivity and toxic reactions
- Peripartal cardiomyopathy

Dilated Cardiomyopathy

Idiopathic dilated cardiomyopathy (IDC) is diagnosed by excluding significant coronary artery disease, valvular

abnormalities, and other causes. It is a relatively common cause of heart failure, with an estimated prevalence rate of 0.04 percent and incidence rates varying from 0.005 to 0.006 percent. The incidence increases with age, and males are afflicted at a higher rate than females. IDC may be familial in as many as 35 to 50 percent of the patients when first-degree relatives are carefully screened. Majority are autosomal dominant, due to mutations of the cardiac actin or desmin gene, but in the majority of cases the disease gene is still unknown.

CLINICAL FEATURES

Main symptoms are shortness of breath, orthopnea, dyspnea upon exertion, fatigue, palpitation and edema. Atrial fibrillation and ventricular dysrhythmias may be early signs of myocardial disease. Some patients may present with systemic embolism or stroke. On examination there may be tachycardia, narrow pulse pressure and jugular venous distension. There may be cardiomegaly, left ventricular third heart sound and murmurs of mitral and tricuspid regurgitation. ECG demonstrates sinus tachycardia or atrial fibrillation, varying degrees of ST-T wave changes and intraventricular conduction disturbances. Chest X-ray usually demonstrates left ventricular and left atrial enlargement. Echocardiography will show dilatation of left ventricle and left atrium and sometimes of right sided chambers, and left ventricular systolic dysfunction (Figs 125.1 and 125.2).

Management: In general, treatment consists of the use of ACE inhibitors in asymptomatic or symptomatic patients, the use of diuretics in volume-overloaded subjects, and the use of digoxin in subjects who remain symptomatic on the former medications. In mild to moderately symptomatic subjects, β -adrenergic blocking agents improve symptoms and reduce mortality. Adjunctive therapy includes anticoagulation in subjects

Fig. 125.2: 2D echo picture of a patient with dilated cardiomyopathy showing dilated left ventricle and left atrium LV – left ventricle, LA – left atrium, RV – right ventricle

with lower LV ejection fractions to prevent thrombo-embolic complications, amiodarone to treat symptomatic arrhythmias and maintaining potassium levels in the high normal (4.3-5.0 mEq/L) range. Those with malignant ventricular arrhythmias may benefit from implantable cardioverter defibrillator. Those who are resistant to medical therapy are candidates for cardiac transplantation.

Hypertrophic Cardiomyopathy (HCM)

K. Suresh

Known previously as idiopathic hypertrophic subaortic stenosis, HCM has a prevalence of 1/500 in the general population. HCM is genetically heterogeneous caused by mutations in any one of ten genes that encode contractile proteins of the cardiac sarcomere, involving thick filaments (beta-myosin heavy chains, and regulatory myosin light chains), thin filaments (cardiac troponin T, cardiac troponin I, ∞ - tropomyosin, and ∞ - actin), and cardiac myosin-binding protein C. More than 150 mutations involving the 10 genes have been reported. HCM has an autosomal dominant pattern of inheritance.

Location of genetic alterations and their relative frequency of occurrence in familial HCM.

Gene	Chromosome	Frequency (%)
B-Myosin heavy chain	14q1	35-45
Cardiac Troponin T	1q31	15
∞ - tropomyosin	15q2	5
Myosin binding protein C	11p 13-q 13	10

The clinical diagnosis of HCM is based on the most characteristic morphologic feature of the disease, i.e. thickening of the left ventricular wall associated with a

Fig. 125.1: Chest X-ray of a patient with dilated cardiomyopathy showing cardiomegaly, left and right atrial enlargement

non-dilated cavity in the absence of another cardiac or systemic disease capable of producing left ventricular hypertrophy (e.g. systemic hypertension or aortic stenosis). The most important features of HCM are (i) the heterogeneous nature of the left ventricular hypertrophy which predominantly involves the interventricular septum (IVS) and (ii) the dynamic left ventricular outflow tract obstruction caused by the systolic anterior motion of the anterior mitral leaflet.

Left ventricular hypertrophy is the gross anatomic marker of HCM. The distribution of hypertrophy is almost always asymmetric, with wall thickening dominantly involving the anterior interventricular septum (IVS). Dynamic obstruction to left ventricular systolic outflow develops. The main physiologic consequence is caused by the bulge of the asymmetric septal hypertrophy into the left ventricular outflow tract and the systolic anterior motion of the anterior mitral leaflet. In some patients the pattern of hypertrophy is diffuse, involving both septum and substantial portions of the lateral free wall. In some concentric left ventricular hypertrophy can be observed. In the generalized form the left and/or right ventricle show hypertrophy without obstructive features (Fig. 125.3).

The pathophysiological abnormalities determine the clinical outcome. These include:

1. LV diastolic dysfunction
2. LV dynamic outflow tract obstruction
3. Myocardial ischemia
4. Arrhythmias particularly AF, VT and sudden cardiac death.

Fig. 125.3: Pathological specimen of hypertrophic cardiomyopathy showing asymmetric hypertrophy of IVS (ASH) and normal thickness LV free wall.

Septum – interventricular septum, LV–LV free wall, MV–mitral valve

Ref: J.P. Veinot: Cardiomyopathy and Pericardial diseases

Clinical Features

The onset of symptoms is often between 20 and 40 years of age, although they can become evident at any age. They include exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea, fatigue, chest pain (which may be atypical of angina pectoris), and palpitation. Impaired consciousness including dizziness, near syncope, and syncope or sudden death may occasionally be the first manifestation.

Those with left ventricular outflow tract (LVOT) obstruction may have a brisk carotid pulse, double or triple apical impulse, fourth heart sound and the characteristic diamond shaped systolic murmur best heard at the lower left sternal border and apex.

Electrocardiogram shows left ventricular hypertrophy, ST-segment changes and T-wave inversion, left atrial enlargement, abnormally deep Q waves, and diminution or absence of R-waves in the right precordial leads. Chest X-ray may show cardiomegaly and pulmonary venous congestion.

Echocardiogram is the main diagnostic tool in HCM. The asymmetric hypertrophy of the septum (ASH) and the systolic anterior movement (SAM) of the anterior mitral leaflet can be visualized. In addition the dynamic LVOT obstruction can be quantified. Doppler echocardiography can assess the left ventricular outflow tract pressure gradient and values above 30 mm Hg across the aortic outlet are diagnostic.

Features which predict higher risk of major cardiovascular events in patients with HCM include the following:

1. Family history of sudden death
2. Specific mutations in sarcomeric proteins (e.g. Troponin T mutation)
3. History of resuscitation after cardiac arrest, recurrent syncope
4. Presence of ventricular tachycardia on Holter monitoring
5. Extreme left ventricular hypertrophy (>3 cm thick)
6. Rise in hemodynamic outflow pressure gradient >30 mm Hg
7. Fall in BP with exercise
8. Limitation of myocardial reserve and
9. Bridging of the left anterior descending coronary artery in children.

Prognosis

HCM may present with a fatal cardiac event as the first manifestation in an unsuspected case. A frequent cause for unexpected sudden death during competitive sports activities is HCM. In a low risk patient the overall annual mortality is <1%.

Management

Symptomatic patients with HCM may benefit by drugs such as beta-blockers, verapamil, and disopyramide. Judicious addition of diuretic agents in those with severe symptoms of heart failure despite treatment with beta blockers or verapamil leads to symptomatic improvement. Beta-adrenergic blocking agents or verapamil are usually efficacious in controlling heart rate in patients with chronic atrial fibrillation. If atrial fibrillation develops, anticoagulant therapy should be started and continued indefinitely. In those patients who are symptomatic despite medical management, septal ablation is one method which reduces the outflow gradient and the symptoms. This is a method to induce infarction of the hypertrophied septum by injecting alcohol into the septal artery. Surgical septal myomectomy may be required some patients (Morrow's operation). Infective endocarditis prophylaxis should be given to those with LVOT obstruction.

Competitive sports and strenuous, exertion should be avoided since sudden death may occur during these activities. All first degree relatives should be screened by echocardiography. In adolescents aged 12-16 years screening should be done annually. In those above 40 years screening can be done at longer intervals. Prophylactic measures include avoidance of dehydration and drug therapy using beta-adrenergic blockers.

Apical HCM

Hypertrophy confined to the left ventricular apex ("apical HCM") has been reported most commonly by Japanese investigators. It is characterized by isolated apical hypertrophy and is common in Japan where it constitutes 25% of all cases of HCM. Outside Japan it constitutes only 1-2% of cases. Clinical presentation is similar and patients experience chest pain, dyspnea, fatigue, and in rare instances, sudden death. The diagnosis is made by the typical electrocardiographic, echocardiographic and angiographic features. ECG shows giant negative T waves in precordial leads and LV hypertrophy. Echocardiogram shows localized hypertrophy in the distal left ventricle, increase in thickness in the apical region of at least 15mm, or a ratio of maximal apical to *postero basal* thickness greater than 1.5 and absence of outflow tract obstruction. LV angiogram shows spade like configuration of the LV cavity at the end of diastole, obliteration of apical LV cavity at the end of systole. Compared to the other forms of HCM prognosis is favourable. Treatment consists of β -blockers and calcium channel blockers.

Obliterative (Restrictive) Cardiomyopathy

The term *restrictive cardiomyopathy* refers to either an idiopathic or systemic myocardial disorder characterised

by impaired diastolic filling of ventricles, normal or reduced left ventricular (LV) and right ventricular (RV) volumes, and normal or nearly normal systolic (LV and RV) function. The hemodynamic and clinical manifestations may mimic those produced by constrictive pericarditis, which, in contrast to restrictive cardiomyopathy, is a surgically curable disorder.

Classification of Restrictive Cardiomyopathy

- **Idiopathic**
- **Specific heart muscle disease**
 - Endomyocardial fibrosis
 - Eosinophilic endomyocarditis
 - Infiltrative
 - ♦ Amyloidosis - common
 - ♦ Hemochromatosis (dilated left ventricle with restrictive physiology) – rare
 - ♦ Glycogen storage disease - rare
- **Iatrogenic**
 - ♦ Following heart transplantation
 - ♦ Following mediastinal radiation
- **Malignancy**
 - ♦ Metastatic endocardial and myocardial infiltration
 - ♦ Carcinoid heart disease

Endomyocardial Fibrosis

A particularly common form of this disorder is *endomyocardial fibrosis* (EMF), prevalent in Kerala, other states of India, Africa and Brazil. This condition is characterized by fibrosis and obliteration of the ventricular inflow tract and restriction to ventricular filling. Males are affected more, especially children and young adults and more among the poor. The etiological agent is not yet identified for certain, though several factors such as malnutrition, dietary deficiency of trace elements such as selenium, infection, filariasis, eosinophilic infiltration and an imbalance of trace elements (magnesium vs cerium) have been implicated. Pathologically the disease is characterized by fibrosis affecting the inflow tracts and apices of one or both ventricles; the endocardium and subjacent myocardium being affected. Combined right and left ventricular disease occurs in half of the cases, pure left ventricular involvement in 40% and pure right ventricular involvement in 10%.

Clinical Features

The onset is slow, and symptoms may be present for a few months to several years before presentation. Children and adolescents are affected more.

Left Ventricular EMF

Patients with left ventricular involvement present very early with varying grades of dyspnea and palpitation –

clinically they may resemble mitral incompetence. Physical examination reveals cardiomegaly, loud apical third heart sound and pansystolic murmur in the mitral area. Complications include pulmonary hypertension and left heart failure. ECG may reveal left ventricular hypertrophy. Myocardial calcification may develop and this may be detected by imaging studies. Echocardiography is diagnostic. The characteristic plastering of the posterior mitral leaflet to endocardium, the marked endocardial thickening, obliteration of cavity and sparing of outflow regions are typical of endomyocardial disease. Cardiac catheterization may reveal raised left ventricular end diastolic pressure and pulmonary hypertension.

Right Ventricular EMF

These cases develop features of right ventricular inflow tract obstruction resulting in back pressure in the right atrium which dilates to aneurysmal levels. Tricuspid incompetence may develop. The patients present with long duration of fatigue and abdominal distension due to

Fig. 125.4: 18 years old female with endomyocardial fibrosis

Fig. 125.5: X-ray chest in right ventricular EMF showing gross cardiomegaly and enlarged right atrium

hepatomegaly and ascites. Long standing cases may develop cardiac cirrhosis. Ascitic fluid shows high protein content. Physical examination reveals rise in JVP, loud third heart sound and features of tricuspid regurgitation. Atrial fibrillation, thromboembolism, pericardial effusion and cardiac cirrhosis may develop as complications (Fig. 125.4).

ECG may show qR pattern in right precordial leads, indicating right atrial enlargement. X-ray chest reveals gross cardiomegaly, mainly due to the aneurysmal right atrium (Fig. 125.5).

Echocardiography is diagnostic, with the RV cavity obliteration, dimpling of the apex, outflow dilation, and huge right atrial enlargement. Right ventricular end diastolic pressure is increased.

Differential diagnosis includes other forms of cardiomyopathy, pericardial diseases, infiltrative lesions of the myocardium and valvular heart disease. Biopsy studies help to exclude infiltrative diseases.

Treatment is symptomatic. Measures to control congestive heart failure using diuretics and inotropes help to relieve symptoms in early cases. Surgical excision of endocardium, valve replacement, etc. have been tried in selected cases.

Diseases of
the Pericardium

C.G. Bahuleyan

Chapter Summary

Acute Pericarditis 870

Pericardial Effusion and Tamponade 871

Constrictive Pericarditis 872

The pericardium is the serous membrane covering the heart and the root of the great vessels. The visceral layer is closely apposed to the heart and the parietal layer encloses the pericardial space which contains a thin film of fluid which lubricates the surfaces. Function of the pericardium is to keep the heart in position and allow smooth and controlled movements within the thorax.

ACUTE PERICARDITIS

Acute fibrinous or dry pericarditis is a syndrome, resulting from pericardial inflammation of no more than 1 to 2 weeks duration and characterized by typical chest pain, a pathognomonic pericardial friction rub, and specific ECG changes. A variety of conditions are associated with acute pericarditis. However the majority of cases are idiopathic, i.e. no specific etiology could be identified with routine diagnostic testing. Most such cases are due to viral etiology.

Causes

1. **Idiopathic**
2. **Infections:**
 - a. Viral infections, e.g. Coxsackie B.
 - b. Bacterial infections, e.g. rheumatic fever, tuberculosis, pneumococci, staphylococci, streptococci, salmonellae, actinomyces, nocardia.
 - c. Protozoal, e.g. *E. histolytica*, toxoplasma. In tropical countries amebic liver abscess may give rise to pericarditis and effusion.
 - d. Fungal, e.g. histoplasmosis.
3. **Connective tissue disorders:**
 - a. Disseminated lupus erythematosus.
 - b. Rheumatoid disease.

- c. Scleroderma.
- d. Polyarteritis nodosa

4. **Myocardial infarction**
5. **Immune-mediated disorders:** Post-myocardial infarction and post-cardiotomy syndromes.
6. **Traumatic:** Blunt injury to chest, penetrating injuries, following paracentesis of pericardium.
7. **Metabolic disorders:** Uremia, myxedema.
8. **Malignancy:** Leukemias, lymphomas, secondary deposits from the primary tumours.
9. **Other causes:** Rupture of aortic aneurysm, dissecting aneurysm of the aorta, irradiation, cardiomyopathy.

CLINICAL FEATURES

Acute pericarditis typically produces sharp retrosternal pain that radiates to the trapezius ridge and is aggravated by lying down and relieved by sitting up; its onset frequently is heralded by a prodrome of fever, malaise, and myalgia. The pain of pericarditis is often worse with inspiration and is difficult to distinguish from pleurisy. The hallmark of acute pericarditis is the pericardial friction rub. It has a superficial, creaky, or scratchy character. It is usually heard between the lower left sternal edge and the cardiac apex with patient leaning forward. Pericardial rub usually has three components - during ventricular systole, during ventricular diastolic filling and during atrial systole, resulting in a triphasic rub. Sometimes it may be monophasic, with only the systolic component or it may be biphasic.

ECG is the most important diagnostic test in acute pericarditis. The ST-T wave changes in acute pericarditis are diffuse and have characteristic evolutionary changes. In the first stage, ST-segment elevations typically occur within a few hours of the onset of chest pain and persist for hours or days. In the second stage, the ST segments return to baseline and the T waves may appear normal or exhibit a loss of amplitude. In the third stage, tracings show inversion of T waves. The ECG normalizes in the fourth stage. In uncomplicated acute pericarditis, the chest radiograph is generally normal. An enlarged cardiac silhouette may occur because of a moderate or large

pericardial effusion. Echocardiographic identification of pericardial effusion confirms the clinical diagnosis of acute pericarditis, but a patient with purely fibrinous acute pericarditis often has a normal echocardiogram.

Treatment: Acute idiopathic pericarditis is a self-limiting disease in 70 to 90% of individuals. Symptomatic patients should be treated with NSAIDs. Aspirin 650 mg q3–4h or ibuprofen 600 to 800 mg q6h are the commonly used drugs. Narcotic analgesics may be required for severe pain. Those who do not respond to NSAIDs may require steroid therapy (prednisolone 60 to 80 mg/day) for a week to control pain, with the dose tapered rapidly thereafter. Patients in whom pericarditis is a manifestation of systemic illness, such as sepsis, uremia, connective tissue disease, or neoplasia, in addition to symptomatic treatment, therapy directed towards the primary disorder is required. If symptoms of pericardial tamponade develop, aspiration will be required.

PERICARDIAL EFFUSION AND TAMPONADE

Accumulation of transudate, exudate, or blood in the pericardial sac is a common complication of pericardial disease and should be sought in all patients with acute pericarditis. Idiopathic pericarditis and any infection, neoplasm, autoimmune diseases and radiation, which can cause acute pericarditis, can cause pericardial effusion. Effusions are common after cardiac surgery. Hydropericardium can occur in severe cardiac failure. Bleeding into the pericardial sac (hemopericardium) can occur following blunt or penetrating chest trauma and due to cardiac rupture in post – MI patients. Those effusions with high chance of progression to tamponade are caused by bacterial, fungal and HIV associated infections.

Clinical manifestations of pericardial effusion are highly dependent upon the rate of accumulation of fluid in the pericardial sac. Rapid accumulation of pericardial fluid may cause elevated intrapericardial pressures with as little as 80 cc of fluid, while slowly progressing effusions can grow to 2 liters without symptoms.

When sufficient amount of pericardial fluid accumulates, it can increase the intrapericardial pressure, cause obstruction to inflow of blood into the ventricles, fall in cardiac output and result in cardiac tamponade. In cases of trauma rapid accumulation of small quantity of blood can cause tamponade, while in cases of chronic effusions large quantity of fluid accumulates before tamponade develops.

Clinical Features

Many patients with pericardial effusion also have pericardial pain. However effusions do not by themselves cause symptoms unless tamponade is present. Patients with tamponade may develop dyspnea. They also have

chest tightness and dizziness. In the most severe cases, consciousness may be impaired, and except for the raised venous pressure, such patients appear to be in hypovolemic shock.

A careful general examination in case of pericardial effusion may give clue to the etiology. In effusions without tamponade CVS examination is normal, except in very large effusions where the cardiac impulse is difficult to palpate and heart sounds are muffled. If tamponade is present patient will be uncomfortable with dyspnea, tachypnea, diaphoresis, cold extremities, peripheral cyanosis and depressed sensorium, due to low cardiac output. Tachycardia is the rule. Hypotension is usually present. A paradoxical pulse is present in most cases. Paradoxical pulse is the exaggerated inspiratory fall in systolic blood pressure, often exceeding 10 mm Hg. Jugular venous pressure is markedly elevated and Y descent is absent. Normal decrease in venous pressure on inspiration is maintained. Physical examination reveals reduced force or absence of the apical impulse, enlargement of the area of cardiac dullness, muffled heart sounds and pericardial rub (Fig. 126.1).

ECG usually shows sinus tachycardia, reduced voltage and sometimes, electrical alternans of the QRS complex. In chest X-ray cardiac silhouette assumes a flask like appearance in moderate to large effusions. Echocardiography is the procedure of choice for the diagnosis of pericardial effusion. Pericardial effusion appears as an “echo-free” space between the visceral and parietal pericardium. Early diastolic collapse of right atrium and right ventricle seen in echo indicate presence of tamponade (Figs 126.2 and 126.3).

Management

In pericardial effusions without tamponade aim is to establish the etiology by a careful history including

Fig. 126.1: 14 years female with chronic pericardial effusion. The cotton seal is over the site of aspiration

Fig. 126.2: Chest X- ray in pericardial effusion showing flask shaped enlargement of heart and stenciled appearance of cardiac borders

Fig. 126.3: 2D –Echocardiographic picture of pericardial effusion which is seen as echo free space behind the left ventricle. LV – left ventricle, PE – pericardial effusion

13

medication review and radiation therapy, general physical examination and investigations. Depending on the circumstances, the investigations should include, skin testing for tuberculosis, screening for neoplastic and autoimmune diseases, infections and hypothyroidism. Drainage of the pericardial effusion is usually unnecessary unless purulent pericarditis is suspected or cardiac tamponade supervenes. If a definite etiology is not evident by non-invasive testing, pericardiocentesis is required.

Pericardial Aspiration

Those patients with tamponade should be considered as having a medical emergency. Volume expansion should be done with blood, plasma, dextran, or isotonic sodium chloride solution, as necessary to maintain adequate intravascular volume. Removal of pericardial fluid is the definitive therapy for tamponade. Removal of small amounts of pericardial fluid (~50 mL) produces consi-

derable symptomatic and hemodynamic improvement. Most commonly employed method for closed pericardiocentesis is the sub xiphoid approach. A 16- or 18-gauge needle is inserted at an angle of 30-45° to the skin, near the left xiphocostal angle, aiming towards the left shoulder. Surgical creation of a pericardial window, which involves the surgical opening of a communication between the pericardial space and the intrapleural space is sometimes required in recurrent effusions.

CONSTRUCTIVE PERICARDITIS

Constrictive pericarditis is a condition in which a thickened, scarred, and often, calcified pericardium forms a tough cover around the heart limiting diastolic filling of the ventricles. Although acute pericarditis from most causes may eventuate in constrictive pericarditis, the most common causes are idiopathic conditions, cardiac trauma and surgery, tuberculosis and other infectious diseases, neoplasms (particularly lung and breast), radiation therapy, renal failure, and connective tissue diseases. Rare causes include Dressler's syndrome, sarcoidosis, Whipple's disease, amyloidosis, methysergide therapy and dermatomyositis.

Patients generally complain of fatigue, dyspnea, weight gain, abdominal discomfort, nausea, increased abdominal girth, and edema. Physical findings include ascites, hepatosplenomegaly, edema, and, in long-standing cases, severe wasting. This general appearance often leads to an erroneous diagnosis of hepatic cirrhosis. Misdiagnosis is avoided through a careful examination of the neck veins. In constrictive pericarditis, the venous pressure is elevated and displays deep Y and often deep X descents. Kussmaul's sign is usually present. Often the heart is normal-sized. Infrequently a pericardial knock can be detected on auscultation infrequently.

Fig. 126.4: X- ray chest lateral view in constrictive pericarditis showing calcification around the cardiac silhouette (arrow)

Electrocardiogram will show atrial fibrillation in approximately one-third of cases. Low, QRS voltage, non-specific T-wave changes, and P mitrale are common. Chest X-ray usually shows normal or mildly enlarged cardiac silhouette. Pericardial calcification may be present, best seen in lateral view (Fig. 126.4). Echocardiographic findings of thickened pericardium, and abnormal Doppler flow patterns can point to the diagnosis of constriction. Computed tomography (CT) is a highly accurate method of evaluating pericardial thickness and therefore plays an essential role in the diagnosis and management of constrictive disease. Because of the close physiologic similarities of constrictive pericarditis and restrictive cardiomyopathy, increased pericardial thickness detected by CT scan is the most reliable means of distinguishing

between the two disorders, as normal pericardial thickness excludes most cases of constrictive pericarditis.

Treatment

Pericardiectomy is the definitive treatment for constrictive pericarditis. Surgery is not indicated in very early stages of constriction or in severe, advanced disease (functional class IV), when the risk of surgery is excessive. Medical therapy in constrictive pericarditis plays only a small role. In some patients, constrictive pericarditis resolves either spontaneously or in response to various combinations of nonsteroidal anti-inflammatory agents, antituberculous drugs, steroids, and antibiotics. Diuretics and, digoxin are useful in patients with atrial fibrillation who are not fit candidates for pericardiectomy.

127

Cor Pulmonale

C.G. Bahuleyan

Chapter Summary

- Acute Cor Pulmonale 873
- Chronic Cor Pulmonale 873
- Pathophysiology 873
- Clinical Features 874
- Treatment 875

GENERAL CONSIDERATIONS

Cor pulmonale is the enlargement of the right ventricle secondary to diseases of the lung parenchyma, pulmonary circulation, thoracic cage or the mechanics of ventilation. Right-sided heart dysfunction secondary to left-sided heart failure, valvular dysfunction, or congenital heart disease is excluded in the definition of cor pulmonale. Cor pulmonale may be acute or chronic.

Refer also to Section: 14 : Chapter: 140

ACUTE COR PULMONALE

Acute cor pulmonale is acute dilatation of the right ventricle, RV will be dilated and its muscular wall is

stretched thin. This most often is the result of massive pulmonary embolism and this leads to right sided heart failure or shock.

Chronic Cor Pulmonale

Chronic cor pulmonale is defined as the occurrence of hypertrophy and dilatation of the right ventricle resulting from pulmonary hypertension, which occurs as a consequence of disease of the pulmonary parenchyma and/ or the blood vessels between the origin of the pulmonary artery and the termination of the pulmonary veins. Normally, the lung is perfused by the pulmonary arteries at a low pressure (10-20 mm Hg), this circulation serving the function of gas exchange. The bronchial arteries arising from the aorta supply blood at systemic arterial pressure to the lung parenchyma and air passages. Normally these two systems do not communicate directly.

PATHOPHYSIOLOGY

The final common pathophysiologic event that causes chronic cor pulmonale is pulmonary arterial hypertension,

that is, chronically increased resistance to blood flow through the pulmonary circulation. The increase in pulmonary vascular resistance can be caused by various mechanisms. The main pathophysiologic processes that cause elevation of pulmonary vascular resistance are:

1. Persistent vasoconstriction – due to global constriction of resistance vessels in pulmonary circulation due to persistent hypoxia as in conditions like high altitude dwelling, hypoventilation syndromes and chest deformities.
2. Loss of cross-sectional area of the vascular bed, which occurs in emphysema, lung resection, chronic thromboembolic disease, fibrotic lung diseases and cystic fibrosis.
3. Obstruction of large pulmonary vessels as a result of extrinsic compression of pulmonary arteries or veins by lymph nodes or tumours, fibrosing mediastinitis and pulmonary veno-occlusive disease.
4. Chronically increased blood flow through the lungs as in left to right shunts result in pulmonary hypertension, reversal of shunt and Eisenmenger's syndrome.
5. Pulmonary vascular remodeling, which occurs in primary pulmonary hypertension and collagen vascular diseases.

See also chapters 137 and 140.

Pathology: As a result of factors which clinically elevate pulmonary arterial tension the right ventricle dilates and hypertrophies. At some stage, the myocardium is unable to function at the high-pressure load, dilates, and fails. Any sudden rise in pulmonary tension resulting from factors like hypoxia tip the patient into right ventricular failure.

Dysfunction of the left ventricle occurs in some patients with cor pulmonale, but the evidence available indicates that cor pulmonale per se does not cause disease of the left side of the heart. Most likely left ventricular dysfunction coexisting with cor pulmonale results from other causes, such as coronary ischemia or systemic hypertension.

Chronic hypoxia gives rise to secondary polycythemia and increase in the viscosity of the blood. This causes further increase in the RV afterload. Hypercapnea and the resulting acidemia can directly depress the myocardium and can contribute to cardiac failure.

Causes

1. *Diseases of the lung parenchyma:*
 - a. Chronic obstructive pulmonary diseases—emphysema, chronic bronchitis, bronchial asthma.
 - b. Restrictive lung diseases—diffuse interstitial fibrosis, pulmonary hemosiderosis, radiation fibrosis, scleroderma.
 - c. Pneumoconiosis.
 - d. Bronchiectasis and cystic disease of the lungs.

2. *Diseases of the chest wall which restrict proper ventilation:* For example kyphoscoliosis, myopathies, myasthenia gravis, and extreme obesity.
3. *Diseases affecting the pulmonary arteries or veins:* Primary pulmonary hypertension, pulmonary arteritis, veno-occlusive disease, schistosomiasis, recurrent thromboembolism, sickle cell anemia.
4. *Diseases which depress the respiratory center resulting in diminution of the respiratory drive.*
5. *Chronic mountain sickness.*

CLINICAL FEATURES

Clinical manifestations of cor pulmonale are often obscured by the signs and symptoms of underlying disease and therefore are closely related to the pulmonary disease or disorder. There is no suggestive symptom, that is specific for cor pulmonale. Episodes of leg edema, atypical chest pain, dyspnea on exertion, exercise-induced peripheral cyanosis, prior respiratory failure, and excessive daytime somnolence are all historical clues suggesting the presence of cor pulmonale. Cough and complaints of easy fatigability are common. Some patients with nocturnal hypoventilation and sleep apnea may present with personality changes, mild systemic hypertension, and headache. Shortness of breath is nearly a universal symptom in cor pulmonale. Abdominal pain may result from liver and bowel congestion if RVF is present.

The patients are often cyanosed and the extremities are warm due to vasodilatation. In overt RVF, cardiac enlargement, distended neck veins, hepatomegaly, and peripheral edema are present. The earliest signs are those associated with long standing pulmonary hypertension. The most sensitive sign for pulmonary hypertension is a loud pulmonary component (P_2) of S_2 , and right parasternal heave may be present. Pulmonary ejection click and right ventricular S_3 gallop may be heard. With very high pulmonary artery pressures (PAP), characteristic diastolic and systolic murmurs of pulmonary regurgitation and tricuspid regurgitation may develop.

Investigations: Hemoglobin may be considerably increased due to secondary polycythemia. X-ray chest may reveal the pulmonary abnormality. There may be right ventricular and PA enlargement. Right descending PA diameter greater than 16 mm suggests severe pulmonary hypertension. ECG diagnosis of RVH in cor pulmonale is usually difficult due to hyperinflated lungs. Atrial fibrillation and multifocal atrial tachycardia may be seen particularly in those with COPD. Features of RVH may be present and include right axis deviation, P pulmonale, and tall R waves in V_1 and deep S waves in lead V_6 . Echocardiography is often difficult because of the hyperinflated lungs is a poor conductor of ultrasound. Echocardiogram will show dilated and hypertrophied right ventricle and dilated right atrium. Pulmonary artery

Fig. 127.1: 2D Echocardiogram in cor pulmonale showing dilated right ventricle and right atrium
RV – right ventricle, RA – right atrium

pressure can be measured using echo – Doppler studies (Fig. 127.1). Investigations to assess ventilatory function, diffusing capacity of the alveoli and pulmonary vasculature are indicated to determine the nature and extent of pulmonary lesion. Blood gas analysis, arterial oxygen and carbon dioxide and estimation of pH and plasma bicarbonate serve to determine the severity of anoxia, hypercarbia and respiratory acidosis.

Course and prognosis: Prognosis depends more on control of the underlying lung disease than on control of pulmonary hypertension in most cases. The pink puffers tend to live longer than the blue bloaters. Once right heart failure develops, prognosis is poor. Patients with COPD requiring oxygen supplementation have 2-year survival of 50%, but some patients survive for 5 to 8 years.

TREATMENT

Treatment of the underlying lung disease is the focus of therapy and is the best way to reduce the pulmonary hypertension. If right heart failure has not appeared, a major goal is to prevent its onset by treatment of lung disease.

Measures to Reduce Pulmonary Hypertension

Relief of hypoxia is of prime importance in reducing pulmonary hypertension, both to prevent and to treat cor pulmonale. This may be done in two ways: (1) treatment of the underlying disease and (2) O₂ administration.

In COPD, alveolar ventilation may be improved by measures such as bronchodilators for bronchospasm,

antibiotics to prevent or treat acute exacerbations of bronchitis, bronchial toilet for removal of secretions, and avoidance of airway irritants such as tobacco smoke. Corticosteroids may be helpful in some patients with interstitial lung disease and in patients with a bronchospastic component of COPD. Measures should be instituted to treat the systemic disease in which obliterative vascular disease is associated or to prevent further pulmonary emboli if this is the problem.

Most patients with chronic cor pulmonale have a component of hypoxic pulmonary vasoconstriction, and all patients should be treated with oxygen in amounts adequate to restore arterial O₂ tension to greater than 60 mm Hg.

Pulmonary vasodilators like prostacyclins and nitric oxide are efficacious in some patients with primary pulmonary hypertension but are of unproven value in cor pulmonale from COPD. Epoprostanol (prostacyclin), given I V as continuous infusion in a dose of 2.4 ng/kg bw per minute, reduces pulmonary artery pressure. This may be tried in severe cases. Epoprostanol is available as Flolan, Glaxo welcome research, Triangle Park NC (USA).

Endothelin receptor antagonists e.g. Bosentan, has been approved for use in severe PAH, especially PPH, because of the role of endothelin in producing pulmonary vasoconstriction. It can produce hepatic dysfunction. It has to be used on a long-term to produce the benefit. It is costly and not freely available. Long-term anticoagulation with warfarin has been reported to prolong survival, since this may slow the downhill course of the disease. Calcium channel blockers, especially nifedipine in doses of 10 mg bd or tid have been reported to be beneficial. Cardiac failure is controlled by the use of diuretics, aminophylline and digoxin.

Treatment of Heart Failure

While treatment of the lung disease and relief of hypoxia are necessary to reduce cardiac work, general principles of management of heart failure apply. Beneficial effects of digitalis are not as obvious as in LVF, and arrhythmias caused by digitalis may occur at relatively low serum levels in patients with hypoxia and acidosis. Nevertheless, studies have shown that digitalis improves right ventricular function in cor pulmonale, and it is an appropriate drug for treatment of RVF when given with care and at controlled dosage levels. Diuretics are effective in the treatment of RVF, and indications for their use are the same as in other forms of heart disease.

When the hematocrit is above 55 to 60 percent, phlebotomy may reduce pulmonary artery pressure (PAP) and pulmonary vascular resistance (PVR) and possibly improve right ventricular function. Phlebotomy should be done cautiously in small volumes (200-300 mL).

Surgical Treatment

Pulmonary embolectomy is extremely efficacious for unresolved pulmonary emboli causing chronic thrombotic pulmonary hypertension. Single-lung, double-lung, and heart-lung transplantations are all used for salvage in the terminal phase of several diseases complicated by cor

pulmonale. The diseases most commonly treated by lung transplantation are primary pulmonary hypertension, emphysema, idiopathic pulmonary fibrosis, and cystic fibrosis. Volume-reduction surgery for selected patients with emphysema improves ventilatory function and gas exchange, and the long-term benefit of this approach is under study.

Diseases of the Aorta

C.G. Bahuleyan

Chapter Summary

- Takayasu's Arteritis 876
- Dissecting Aneurysm 877
- Aneurysms of the Aorta 879
- Cholesterol Crystal Embolism 880

Non-specific Aortoarteritis

13

An idiopathic inflammatory process involving the aorta and its major branches may occur as a primary abnormality as in Takayasu's arteritis or it may occur in association with conditions such as scleroderma, Hodgkin's disease or rheumatoid arthritis. It may produce stenosis of aorta and its major branches or dilatation of aortic root with aortic regurgitation or aneurysm of thoracic or abdominal aorta.

Takayasu's Arteritis

Syn: Pulseless disease, young female arteritis, or Harbitiz-Raedu syndrome

This condition is named after the Japanese ophthalmologist who first described changes in the central vessels of the retina in 1905. Women are affected 8 times more than men. More than half the patients are under 20 years of age. The disease is prevalent in India, Japan, south east Asia, south and east Africa, south America, and Mexico. Aorto-arteritis is the common form of large vessel

vasculitis seen in north Kerala. It is also a common cause of renovascular hypertension. Type III aorto arteritis was the most frequent form.

ref: Jacob BS and Krishnan R. abstract of IRACON 2002 JI. Ind Rhem. Asso. 10, suppl. Page 10.

Takayasu's disease is a chronic vasculitis mainly involving the aorta and its main branches such as the brachiocephalic, carotid, subclavian, vertebral and renal arteries as well as the coronary and pulmonary arteries. Chronic vasculitis involves the intima, media and adventitia. The etiology is not fully known. Symptoms are caused by stenotic lesions or thrombus formation. More acute progression leads to destruction of the media and consequent aneurysm formation and arterial rupture.

Pathology: The histological findings include panarteritis, fibrous scarring, intimal proliferation, thrombosis, and aneurysm resembling syphilitic aortitis, but there is no clinical or serologic evidence to suggest syphilitic etiology even remotely. Current thinking favours an autoimmune process to be operative.

In addition to the aorta, arteries of the neck, renal arteries and arteries of the lower limbs are also frequently affected. These may lead to strokes in the young, renal hypertension, limb ischemia and thromboembolic episodes. In India, renal artery involvement is one of the frequent causes of renal hypertension.

Clinical features: The early symptoms are non-specific. These include fever, myalgia, arthralgia and vague symptoms. The ESR and C-reactive protein levels are

raised in the early stages. Even at this stage MRI, CT, angiography or digital subtraction angiography may show lesions. Clinical presentation with arterial occlusion occurs later.

The presenting symptoms may be those associated with hypertension, viz. headache, giddiness, palpitation, congestive heart failure and pulmonary edema. Depending on the site of lesions, clinical manifestations may vary. When the arch and its vessels are involved, symptoms are due to ischemia to the brain and upper extremities. Pulse is absent in the upper limbs and there is hypertension in the lower extremities (reversed coarctation). Signs of aortic regurgitation may be present.

The middle aortic syndrome: This is the most prevalent type in India and is produced by involvement of the descending thoracic or abdominal aorta with or without stenosis of the renal arteries or left subclavian. This picture may mimic congenital coarctation but presence of abdominal, subclavian or carotid bruit, difference in blood pressure between the upper extremities, claudication in the lower limbs, and absence of collaterals around the scapula and rib notching suggest the diagnosis of aortoarteritis. Angina pectoris due to coronary arterial involvement, abdominal angina due to mesenteric involvement, and pulmonary artery involvement occur uncommonly. Early occurrence of unilateral cataract is more often seen in Indian patients.

Aortography is diagnostic. Hematological and serological investigations are not helpful in establishing the cause.

The clinical course is variable. In some the course is protracted, in the others it is self-limiting. Death is due to hypertensive complications or a cardiomyopathy-like picture.

Management: In established cases surgical treatment may have to be considered as a palliative measure, especially in localised lesions. Early institution of steroid therapy and low dose aspirin has been advocated. Immunosuppressant drugs are added on to the regimen in selected cases. The results are not uniformly predictable.

Dissecting Aneurysm of the Aorta

Definition: aortic dissection is a catastrophic illness characterized by dissection of blood between and along the laminar planes of the media, with formation of a blood filled channel within the aortic wall. This will lead to creation of a dissecting intramural hematoma. It will often rupture causing massive hemorrhage.

Causes

1. Hypertension: More than 90% of the patients suffer from chronic hypertension.

Fig. 128.1: Proposed mechanisms of initiation of dissection

2. Conditions that cause cystic medial necrosis, e.g. Marfan's syndrome, Ehlers-Danlos syndrome, pregnancy.
3. Other structural disorders of the aorta: coarctation of the aorta, aortic hypoplasia, aortic stenosis, bicuspid aortic valve, syphilitic aortitis, giant cell arteritis.
4. Trauma: Blunt trauma to the chest in automobile accidents, e.g. steering wheel injury, iatrogenic causes such as femoral artery cannulation. Men are affected twice as common as women.

Pathogenesis

Aortic dissection is believed to begin with the formation of a tear in the aortic intima that directly exposes an underlying diseased medial layer to the driving force of the intraluminal blood. This blood penetrates the diseased medial layer and cleaves the media longitudinally, there by dissecting the aortic wall (Fig. 128.1).

CLINICAL FEATURES

The symptoms start with sudden onset of severe pain in the chest, interscapular region, neck, mid-back, abdomen, sacral region, and lower limbs. The pain may be mistaken for myocardial infarction. Unlike the pain of acute myocardial infarction, the chest pain produced by aortic dissection is usually abrupt in onset, very severe from the start and unremitting. Rarely dissections involving ascending aorta will involve coronary artery ostium producing acute myocardial infarction. Several other manifestations may develop. These include syncope, blindness, dyspnea, nausea, vomiting, hematemesis, melena, oliguria, hematuria and paresis or paralysis of lower extremities.

Physical examination: The blood pressure may be elevated, or the patient may be in shock dissection flap can occlude the ostium of left subclavian artery and lead to absent pulse in left upper limb. Asymmetry of pulses and difference in blood pressure (anisophygmy) between two upper limbs helps to clinch the diagnosis. Aortic

Fig. 128.2: Classification of dissecting aneurysms

regurgitation may develop giving rise to the characteristic early diastolic murmur in the aortic area. The jugular vein may be engorged unilaterally. Other features include leftsided hemothorax, cardiac tamponade, silent abdomen due to paresis of intestines, presence of arterial bruits and variable neurological deficits.

Diagnosis: Aortic dissection should be suspected in all cases of intense chest pain associated with signs of shock, especially if the clinical features and ECG do not suggest myocardial infarction. X-ray chest may show widening of mediastinal shadow (Figs 128.3 and 128.4). Trans-esophageal echocardiography is helpful to make a bedside

diagnosis. Contrast enhanced CT gives excellent resolution to clearly delineate the dissection. Dissecting aneurysms have been classified in different ways (Fig. 128.2).

Course and prognosis: In extensive dissection, death occurs due to shock or rupture into the pericardium and pericardial tamponade.

Treatment: Supportive care includes careful monitoring of blood pressure, maintenance of fluid intake and output, and control of the blood pressure with a negative inotropic agent such as trimethaphan or a combination of sodium nitroprusside and propranolol. Drugs like hydralazine which increase the velocity of ventricular ejection, favour

13

Fig. 128.3: Chest X-ray of patient with dissection of the aorta (1) Original X-ray taken 2 years previously (2) Note the widening of the aortic knuckle—arrow

Note: T—true lumen F—false lumen I—flap of intima

progression of dissection and, therefore, these should be avoided. Once the medical condition is stabilized, surgery (resection and prosthetic reconstruction of the aorta) is undertaken, but mortality remains high. If medical treatment fails to arrest progression, emergency surgery may be required.

Dissection of the ascending aorta, irrespective of whether it originates there or extends from other sites is most likely to be fatal due to rupture into the pericardium. Such patients should be taken up for immediate surgery. When the dissection is confined to the descending aorta close monitoring and medical therapy are indicated.

Aneurysms of the Aorta

Definition: The term *aortic aneurysm* refers to a pathological dilatation of the aortic lumen involving one or several segments. One useful criterion defines aortic aneurysm as a permanent dilatation of the aorta having a diameter at least 1.5 times that of expected normal diameter of that given aortic segment. Morphology of an aortic aneurysm is typically either fusiform, which is more common or saccular.

Seventy-five percent of all aneurysms involve the abdominal aorta and the commonest site is below the renal arteries. The vast majority are caused by arteriosclerosis. In 60% of cases there is associated hypertension. Next in frequency to be affected is the descending thoracic aorta. The causes include arteriosclerosis, traumatic false aneurysms, tertiary syphilis and mycotic aneurysms. The most frequent cause of aneurysms of the ascending aorta is cystic medial necrosis secondary to Marfan's syndrome. Other causes, include Ehlers-Danlos syndrome, hypertension and aging. Syphilis used to be a frequent cause when this disease was more prevalent. Aneurysms of the aortic arch are the least frequent, and they are caused by arteriosclerosis or tertiary syphilis.

Fig. 128.5: CXR of a patient with aneurysm of ascending aorta. Note: bulge of the right cardiac border and widening of the upper part of the cardiac shadow (arrow)

Clinical features: Majority of aortic aneurysms, regardless of their location are asymptomatic. They are discovered accidentally when being evaluated for other diseases. When these aneurysms suddenly enlarge or rupture, they produce dramatic symptoms. Rapidly enlarging aneurysms produce severe pain depending on the location. On examination a pulsating mass is discovered. Thoracic aortic aneurysms produce pressure symptoms by impingement on other structures. It can produce compression of superior vena cava and produce SVC syndrome (non pulsatile engorgement of jugular veins with congestion), compression on recurrent laryngeal nerve can produce hoarseness of voice. Can cause traction on trachea and cause characteristic sign i.e. tracheal tug. Ruptured aneurysm should be suspected if the patient presents with severe pain followed by shock. Pulsating mass is no longer palpable. Rupture into esophagus will present as massive hematemesis, while rupture into pleural or peritoneal space would present as hemothorax or hemoperitoneum.

Investigations: CXR may show aneurysms and calcification along its margins (Fig. 128.5). Computerized tomography is the investigation of choice and it clearly delineates the extent, size and integrity of the aneurysm. Magnetic resonance angiography (MRA) is an alternative for the preoperative evaluation of aortic aneurysms. Aortography has several limitations and its use in the evaluation of aortic aneurysms have declined (Fig. 128.6).

Natural history: Rupture is the most frequent cause of death and occurs in 40-70%. Untreated, the 5-year survival rates for thoracic, thoraco-abdominal and abdominal aneurysms range from 13-39%. Aneurysms of the arch grow faster than those of the ascending and abdominal aorta. Aneurysms greater than 6 cm in diameter have faster growth rates and higher tendency to rupture. Coexistence of hypertension and cardiac ischemia worsen the prognosis.

Fig. 128.6: Aortogram of a patient with aneurysm of ascending aorta. Note: the increase in diameter of the ascending aorta beyond the valve (arrow)

Treatment: Treatment depends on the site involved, size of the aneurysm and the propensity for rupture. All thoracic aneurysms larger than 6 cm and those producing symptoms should be repaired with Dacron graft. If patient

has Marfan's syndrome, then aneurysm should be repaired if it is ≥ 5 cm. Abdominal aortic aneurysms should be repaired if it produces symptoms or ≥ 5.5 cm in size. Surgery for ruptured aneurysms carry a high mortality.

Cholesterol Crystal Embolism

This occurs when cholesterol crystals derived from atheromatous plaques existing in the major arteries embolise. The precipitating events are vascular surgery, angiography, angioplasty or institution of anticoagulant therapy. Typical features include ischemic damage to the kidneys or livedo reticularis especially in the legs, gangrene of toes in the presence of normal arterial pulsations of the feet, hypertension and splinter hemorrhages. Blood counts show eosinophilia. Renal failure occurs in 50% and intestinal bleeding in 10%.

Less common features include ischemic pancreatitis, cholecystitis and localised polypoid lesions in the colon. Reported mortality is 60-80%. Morbidity is considerable. Biopsy of skin lesions is diagnostic in cholesterol crystal embolism. Treatment consists of supportive measure, cessation of anticoagulant therapy and institution of corticosteroids in selected cases.

Cardiac Surgery

13

C.G. Bahuleyan

Chapter Summary

Congenital Heart Disease	881
Coronary Artery Surgery	881
Chronic Valvular Diseases	881
Cardiac Assist Devices	882
Cardiac Transplantation	882

At present cardiac surgery has reached a very high level of technical perfection. This has been made possible by advancements in anesthesia, maintenance of extracorporeal circulation by pumps and oxygenators, hypothermia,

methods to control cardiac arrhythmias, better methods of myocardial preservation, availability of newer prosthetic materials and progress in intensive postoperative care including circulatory assist devices.

Surgical treatment is available for the following conditions.

- Congenital heart diseases
- Acquired valvular diseases
- Ischemic heart disease
- Constrictive pericarditis
- Cardiac tumours
- Heart block and serious arrhythmias—pacemaker implantation.

- g. Correction of abnormal conducting tissues in the heart producing recurrent tachyarrhythmias e.g. WPW syndrome.
- h. Endomyocardial fibrosis
- i. Cardiac tamponade
- j. Cardiac aneurysms
- k. Cardiogenic shock not amenable to inotropic drugs—balloon counterpulsation, urgent revascularisation.
- l. Resistant and fatal cardiac failure — Transplantation.
- m. In addition, in several acute conditions such as rupture of valves or chordae, obstruction of aorta and pulmonary artery, traumatic lesions and infective endocarditis resistant to medical therapy, emergency surgical measures may be required.

Congenital Heart Disease

Most of the congenital heart diseases are amenable to surgical correction or palliation now, the present stress being on early detection and correction of congenital cardiac defects. Pediatric cardiac surgery, especially in infants and neonates has so progressed that defects like ventricular septal defects, Fallot's tetralogy, aortic stenosis, transposition of great arteries, tricuspid atresia and total anomalous pulmonary venous drainage are all operable in infancy or early childhood.

Life-saving palliative surgical procedures may be required in the neonates in the first few days of life in conditions which threaten life, e.g. transposition of great vessels, Hypoplastic left heart syndromes.

Definite corrective surgical treatment is undertaken at a later date. In many situations when functional two ventricular circulation can not be achieved, bypassing the right ventricle by anastomosing the vena cava to the pulmonary artery, i.e. total cavopulmonary connection (TCPC) is done. This achieves good functional capacity. Such circulation where in the right ventricular function is bypassed is called Fontan circulation.

Coronary Artery Surgery

The technique of coronary artery bypass using saphenous vein grafts was a epoch making discovery in the management of severe ischemic heart disease. At present coronary revascularization procedures include coronary angioplasty, and bypass surgery. In the surgical procedure, blood from the aorta is diverted through a conduit to the coronary artery distal to the occlusion. The common materials used are the saphenous vein, and the internal mammary artery. Synthetic prosthetic materials are also being tried upon. Revascularization procedures promptly relieve angina, reduce the extent of infarction and reinfarction, improve the quality of life and also prolong life compared to medical therapy in a selected subset. In good

centres, the intra and perioperative mortality is less than 3%.

Long-term results are good. Percutaneous angioplasty techniques are undergoing refinement and perfection. Except in a few situations, angioplasty is able to achieve effective revascularization. In complicated lesions, methods such as rotator atherectomy, laser atherectomy and stenting help to achieve success. The major disadvantage of angioplasty namely re-occlusion has been brought down to a great extent by the routine use of stents which help to retain the lumen patent for considerably longer periods. Use of newer antiplatelet drugs such as glycoprotein receptor antagonists have further reduced the occurrence of acute and delayed thrombotic occlusion of the stents. The newer interventions are highly successful but the escalation of cost is a deterrent. Irradiation of the coronary arteries after stenting, and impregnation of the stent with rapamycin or taxols help to reduce the incidence of re-occlusions.

At present the major surgical load in cardiovascular surgery is contributed by coronary revascularization procedures.

Surgery for Chronic Valvular Diseases

Hemodynamically significant valvular heart disease tends to progress with time in many cases and end up with cardiac failure if the valvular abnormality is not corrected. All the acquired and congenital valvular diseases are amenable to surgical correction. Stenotic lesions are corrected by valvotomy which can be done either by a closed or open heart procedure. Valve tissue which is not grossly damaged and which will lend itself to dilatation can be corrected by this method. Balloon valvotomy is a standard procedure for the management of pulmonary stenosis and mitral stenosis.

Valve replacement has to be undertaken for regurgitant lesions and when the valve tissue is grossly damaged. Prosthetic valves are in use for about forty years. The most commonly used valves are the Starr-Edward's ball in cage valve and Bjork-Shiley's tilting disc valve, though several others are also available. Tissue valves obtained from cadavers or from pig's aorta and valves made from tissues like dura mater, pericardium and fascia lata are also employed at times, depending on the individual circumstances. Each type of valve has its own advantages and problems. Main problems include thromboembolism, infective endocarditis, obstruction to the valve, valve degeneration and chronic hemolytic anemia. Patients with implanted valves have to take life-long anticoagulant therapy. This may pose an additional risk of bleeding in them. They all have to take prophylaxis against infective endocarditis.

From time-to-time there have been reports of failure of the different makes of valves. Indian made valves (Chitra valves) are available at lower costs than imported valves. The results are comparable to other valves, even though surgical experience is less, compared to the imported valves.

Reports of large series on valve surgery reveal that over 90% of them are well at five years and over 70% of them are well at ten years follow-up. Among those with implanted artificial valves 38% of deaths are valve problem related, 20% are due to other cardiac causes, which are not directly attributable to the valve. The remaining die of non-cardiac causes.

At present facilities for cardiac surgery are available in several centres in India. The bulk of the work is for the management of coronary artery disease, valvular heart disease and congenital heart disease.

Cardiac Assist Devices

Several attempts have been made from time-to-time to assist the failing ventricle to increase its output. From the early part of this decade, artificial hearts have been implanted into individuals suffering from irrecoverable congestive cardiac failure and the initial success in keeping such patients alive for weeks to months have encouraged the development of newer and newer devices.

Artificial hearts made of inert chemical substances are now available. Maximum clinical experience has been with Jarvik-7, developed by the cumulative efforts of William Kolft, Donald Olson and Robert Jarvik, and the surgical experience of William DeVries and his associates. This device has been used as a permanent cardiac replacement and life has been prolonged for twenty months or more, though complications are frequent. The main use of such artificial devices is to support a moribund patient with a definitely fatal cardiac failure till the time of cardiac transplantation.

Cardiac Transplantation

Cardiac transplantation has emerged as a definite therapeutic procedure with definite indications. At present several hundreds of cardiac transplantations are done in many centres in the world every year. The survival at the end of four years is above 75% in patients treated with the immunosuppressant drug cyclosporin A, tacrolimus, mycophenolate mofetil and others. Cardiac transplantation provides an advantage over implantation of an artificial heart in giving freedom from being tethered to an external support. In the United States alone there are more than sixty centres which undertake cardiac transplantation. Cardiac transplantation can be considered as a rational and socially acceptable therapy for a limited number of patients with irrecoverable cardiac failure under certain special conditions. The techniques of cardiac transplantation have improved progressively for the past twenty years. These advances include better definition of criteria for selection of patients, more effective immunosuppression, improved myocardial preservation and better surgical techniques. The introduction of cyclosporin A as an immunosuppressant has improved the 5-year survival of transplant recipients from 40% in 1984 to over 75% at present. Though a very effective immunosuppressant drug, cyclosporin A does produce grave complications. Newer immunosuppressants solve this problem partially. The excellent rehabilitation that follows heart transplantation returns over 80% of survivors to their previous occupations and earning capacity. The heavy cost (US \$ 70,000) is certainly a wise investment, if facilities permit. This technique is available in India in a few centres.

The first successful heart transplant was done at the All India Institute of Medical Sciences at New Delhi in September 1994. Since then more than 38 transplants have been done, 20 at AIIMS, 15 at Madras, 2 at Cochin and one at Bangalore.

Chapter Summary

Coronary Heart Disease 883

Hypertension 884

Cardiomyopathy 884

Many cardiovascular disorders like ischemic heart disease, hypertension, rheumatic heart disease, congenital heart disease and cardiomyopathy are preventable to a great extent by therapeutic intervention and alteration in the lifestyle. The management of these diseases once established is at best only partly successful and associated with high cost. Therefore, the science of preventive cardiology has grown remarkably in the recent past.

Coronary Heart Disease

There are two approaches of prevention (1) Primary, and (2) Secondary. Primary prevention includes modification of atherogenic risk factors prior to the development of clinical evidence of the disease. Secondary prevention includes methods adopted to prevent recurrences or delay progression of the disease in patients with clinically manifest coronary heart disease.

Primary prevention: Modifiable risk factors: *Plasma lipids:* The relation of plasma cholesterol to the development of atherosclerotic coronary heart disease and to coronary mortality is already established. Higher levels of plasma cholesterol cause higher risk. The relationship between dietary cholesterol and the plasma cholesterol is also well established; the higher the dietary cholesterol content, greater the serum level of cholesterol. Adjustment in the total calorie intake and reduction of saturated fat content in the diet can lower serum level of cholesterol and thereby arrest the progression and also lead to regression of coronary atherosclerosis. It has been found that specific lipid subfractions are involved in the pathogenesis and is considered targets of treatment. Low density lipoprotein (LDL) is the primary lipoprotein which is associated with atherogenesis. High density lipoprotein

(HDL) which scavenges the cholesterol to liver is considered 'good cholesterol'. Adult treatment panel III (ATP III) has recommended guidelines for evaluation and treatment of hypercholesterolemia.

Detailed recommendations are available for the various risk categories regarding ideal levels of total cholesterol, LDL cholesterol and HDL cholesterol. These may be referred to, for further details. In general, total cholesterol < 200 mg/dL, LDL cholesterol total < 100 and HDL cholesterol above 50-60 are desirable.

Regular physical exercise also helps to reduce total serum cholesterol triglycerides and other lipid fractions. Increased consumption of fish and fish oils which contain eicosapentaenoic acid and docosa-hexaenoic acid help to lower low density lipoproteins (LDL) and elevate high density lipoproteins (HDL), in the plasma, thus reducing the atherogenic risk further.

First step in the management of high lipid levels would be to initiate therapeutic life style changes (TLC).

This includes the following.

- A. **Dietary modification:** Saturated fat < 7% of the total calories, cholesterol < 200 mg/day, soluble fiber 10-25 g/day
- B. **Weight reduction** by 5-8% and
- C. **Increased physical activity** walking 3 km/in 35-40 minutes daily or at least 5 session a week.

In selected cases where the general measures do not achieve the full target levels, drug prophylaxis should be started. Drugs used for this purpose include the statins, bile acid sequestrants, nicotinic acid and fibric acids. Details are given in Section: 10 Chapter: 93. The metabolic syndrome is a constellation of risk factors, which in concert increase the risk for atherogenesis. For details refer to Section: 10 Chapter: 93.

Metabolic syndrome: Metabolic syndrome is a constellation of risk factors which in concert increase the risk for atherogenesis: For further details refer to Section: 10 Chapter: 93.

Cigarette smoking: Smoking increases the risk of coronary heart disease. Cessation of smoking brings down the

incidence of myocardial infarction as well as sudden death. After smoking is discontinued the coronary risk is decreased by about 50% within one year. The risk approaches that of non-smokers within 2-10 years. The cessation of smoking also increases the HDL:LDL ratio. (see Chapter 26).

Hypertension

Elevated systolic or diastolic blood pressure is an independent contributor to coronary risk, especially in people with hypercholesterolemia. It is advisable to control hypertension along with modification of other risk factors to minimize progression of coronary atherosclerosis.

Reduction in dietary intake of salt and foods containing high content of saturated fat instituted from childhood may be useful in preventing the onset of hypertension. This becomes more important especially in predisposed individuals with positive family history. There is evidence of a direct relation between serum lipids and blood pressure, independent of other variables such as age and body mass index. In some families hypertension may be present in several siblings, who also show elevation of low density lipoproteins (LDL) and triglycerides. Many trials have shown that reduction of cholesterol by diet and/or drugs lead to 25% reduction in the incidence of hypertension and reduction in nonfatal myocardial infarction in men. Regular exercise programmes, treatment of obesity and moderation of alcohol consumption, help to lower the blood pressure and reduce its ill effects. Yogic exercises, transcendental meditation and participation in leisure activities are also helpful.

Secondary prevention: These methods are undertaken in patients who have already developed clinical ischemic heart disease. Methods to salvage the myocardium include the use of drugs like anti-platelet drugs and beta blockers or interventional treatment like coronary angioplasty and coronary artery bypass surgery. Since the mortality and morbidity from acute myocardial infarction depends mainly on the quantum of myocardial damage, all the methods adopted to reduce the infarct size such as thrombolytic therapy, angioplasty, or myocardial revascularization surgery undertaken in the acute stage also can be included under secondary prevention.

Other recently identified atherosclerotic risk factors include the following: Management of these is given in the appropriate sections.

- High level of CRP
- Increase in lipoprotein LP(a)
- Alterations in tissue plasminogen activator and Plasminogen activator inhibitor levels
- Low density lipoprotein
- Increase in fibrinogen levels
- Other risk factor are also being detected.

Cardiomyopathy

The preventive aspect assumes an important role in hypertrophic cardiomyopathy which is transmitted as autosomal dominant. Genetic counselling may help to reduce the birth of affected children.

Deficiency of nutritional factors such as selenium and probably infection has been implicated in the etiology of endomyocardial fibrosis. Further studies are in progress.

General Considerations

INTRODUCTION

The main function of the respiratory organs is to provide a constant supply of oxygen to the tissues and to remove carbon dioxide from them through the lungs. Ultimately this gas exchange occurs between the alveolar air and mixed venous blood in the capillaries across the alveolocapillary membrane. The alveolocapillary membrane has a total area of 75 m² in an adult. Air is taken in through the air passages comprising the nose, pharynx, larynx, trachea, bronchi, and the bronchioles. The terminal portions of the air passages—the respiratory bronchioles and alveolar ducts—subserve the function of gas exchange. The part above the vocal cords is termed the upper respiratory tract and the parts below form the lower respiratory tract.

The trachea which is 11 cm long is kept permanently open by the presence of C-shaped cartilages on its wall. Several mucous glands present in the mucous membrane provide mucus which moistens the surface and facilitates ciliary action. The trachea divides into the right and left bronchi.

The bronchi are similar to the trachea in structure. The right main bronchus is 1-2.5 cm in length and it is in direct line with the trachea. This fact makes it more vulnerable for obstruction by foreign bodies entering through the trachea. The right main bronchus divides into branches which supply the right upper lobe, middle lobe, and lower lobe. The left main bronchus is longer (5 cm) and it forms an angle of 50°-100° with the right main bronchus. It divides into two branches which supply the upper and lower lobes. Further division of the lobar bronchi gives

rise to segmental bronchi which supply bronchopulmonary segments (Figs 131.1 and 131.2).

Bronchopulmonary segments: The bronchopulmonary segment is a wedge of lung tissue supplied by each bronchus along with the corresponding branches of the pulmonary artery and vein. The bronchopulmonary segments act as independent units and are separated by fibrous septa (Table 131.1).

Divisions of the bronchial tree: After 8-13 successive divisions the segmental bronchi break up into the smallest bronchi. They continue further as bronchioles. The bronchioles have no cartilage and mucous glands on their walls. The bronchioles divide further and the terminal

bronchioles are formed after the fourth division. The terminal bronchioles give rise to respiratory bronchioles. Alveoli begin to appear on the walls of the respiratory bronchioles. As the respiratory bronchioles divide further, the number of alveoli arising from them progressively increases. Normal adult lung contains about 300 million alveoli. Rapid division of the respiratory bronchioles results in enormous increase in surface area. The terminal portions of the respiratory bronchioles divide into alveolar ducts and sacs. Alveoli are 0.1-0.2 mm in diameter. Up to the respiratory bronchioles the airways only conduct

air passively, but beyond this they also take part in gaseous exchange. The part supplied by a single terminal bronchiole is called an “acinus”. An alveolar duct with its distal connections is called a “primary lobule”. A group of primary lobules separated by connective tissue septa form a “secondary lobule”.

Pores of Kohn and Canals of Lambert: Pores of Kohn are openings connecting alveoli, which allow communication between them and sometimes even between adjacent segments.

Canals of Lambert are short communications lined by epithelium which exist between distal bronchioles and some of the neighbouring alveoli. These take part in collateral ventilation between different regions of the lung. The lining of the trachea, bronchi, and bronchioles consists of ciliated columnar epithelium containing goblet cells. The respiratory bronchioles are lined by non-ciliated cuboidal epithelium. The lining epithelium of the alveoli is flattened and it comprises two types of cells—type I and type II pneumonocytes arranged on a basement membrane. Type I pneumonocytes are numerous and they cover most of the inner surface of the alveoli. Gas exchange occurs mainly across these cells. Type II pneumonocytes are smaller in number. They contain lamellated osmiophilic inclusion bodies which are thought to be of lysosomal nature. Surfactant is produced or stored in them.

Secretions of the airways and ciliary action: Mucus is secreted by the mucous glands and goblet cells. Mucous glands are seen all along from the trachea to the smallest bronchi. They are most numerous in the medium-sized bronchi and are absent from bronchioles. In the bronchioles there are only a few goblet cells. Vagus is secretomotor for the mucous glands. The goblet cells respond to direct irritation. The mucus contains acid and neutral polysaccharides mainly, and variable quantities of sodium, potassium, albumin, globulin, specific antibodies, lysozyme, and transferrin. In addition to its antibacterial action, the mucus provides a milieu for the cilia to function. Ciliary action helps to remove particulate matter. Each cell contains about 200 cilia, each being 6-7 μ long. By successive rhythmic movement, they produce a wave motion passing regularly from cell to cell. An optimum amount of mucus of the correct thickness (5 μ) and optimum viscosity is essential for proper ciliary function. Drying up of tracheal secretions, increase in thickness and viscosity of the mucus layer, inhalation of irritants, excessive intake of alcohol and drugs like cocaine impair ciliary function and predispose infection of the respiratory tract. Ciliary function is impaired in inherited disorders such as Kartagener's syndrome in which several other defects including loss of motility of the sperms are seen.

Surfactant: This is a substance produced by type II pneumonocytes from the 30th week of intrauterine life. It lines the alveoli. It contains an insoluble lipoprotein (dipalmitoyl lecithin) which forms a thin layer at the air-fluid interface and lowers surface tension. Pulmonary surfactant is a mixture of phospholipids and surfactant-specific proteins which reduce alveolar surface tension during respiration. Specific proteins (SP) A, B, C and D contribute to the biophysical properties of surfactant. SP-A, and SP-D also have antimicrobial properties. In infant respiratory distress syndrome surfactant is deficient from birth. In adult respiratory distress syndrome surfactant deficiency develops as an acquired defect caused by sepsis, pneumonia, traumatic damage and major surgery. Surfactant has beneficial therapeutic effects only if it contains the phospholipid as well as the specific proteins. Activated neutrophils clear the surfactant and lead to its dysfunction. Surfactant prevents the alveoli from collapsing by reducing surface tension within the alveoli. Absence of surfactant results in the collapse of small alveoli during expiration and hyperinflation of the larger alveoli during inspiration, in addition, increase in surface tension leads to transudation of fluid from capillaries into the alveoli. Absence of surfactant leads to the formation of hyaline membrane disease in the newborn. Impairment of pulmonary blood flow and prolonged administration of dry oxygen or air leads to reduction in surfactant.

Pleura: The lung is covered by visceral pleura on its surface and the thoracic cavity is lined by the parietal

pleura. The space between them contains 10-20 mL of serous fluid having a protein content of 1.77 g/dL. Pleural cavity is only a potential space. During inspiration the lung fills the pleural space. The pleural space is under negative pressure so that the lung is kept in apposition with the parietal pleura. At the end of a quiet expiration the pleural pressure is about -5 cm of water. The pressure inside the pleural cavity is not uniform throughout. The negative pressure is higher at the apices than at the bases. The pleural fluid is formed at the parietal pleura.

Pulmonary circulation: The main pulmonary artery divides into the right and the left pulmonary arteries which divide successively along with the bronchi. The proximal divisions of the artery contain muscular and prominent elastic coats but the branches corresponding to the bronchioles have more prominent muscular coats than elastic layers. The arterioles accompanying the terminal bronchioles and respiratory bronchioles are thin-walled and consist of an endothelial lining with elastic lamina, without the muscular layer. These end up as capillaries. The alveolar wall is supplied by a dense capillary network which provides a large perfusing area. The venous ends of the capillary bed join to form veins which traverse in the interlobar septa. They do not follow the bronchial tree. The veins end up finally as the four main pulmonary veins which drain into the left atrium.

Bronchial circulation: The bronchi and their branches derive their nutrition from the bronchial arteries which usually arise from the descending aorta, but they may arise from intercostal, subclavian or internal mammary arteries as well. The bronchial arteries and their branches supply only up to the level of the respiratory bronchioles. Beyond this the vascular supply is derived from the pulmonary vessels. Veins arising from the bronchial tree drain into the azygos veins, but some may also enter the pulmonary veins. Though the bronchial veins drain venous blood into the pulmonary vein, this is not significant in health. In conditions like bronchiectasis and lung abscess, these bronchial capillaries proliferate and larger volumes of venous blood may be added to pulmonary venous circulation.

Lymphatic drainage: The lungs and pleura are drained by three groups of lymphatics. These are: (1) Lymphatics arising from the visceral pleura and interlobular septa drain the peripheral portions of the lung. These lymphatics follow the pulmonary veins to the hilum. (2) Lymphatics draining the acini form the peribronchial lymphatics and pass to the hilum. (3) Anastomotic channels are formed between the two lymphatic systems. The lymphatics from the upper part of the left lung drain into the thoracic duct while those from the lower part of the left lung and the entire right lung drain into the right lymphatic duct.

Protective mechanisms of the airways: Apart from ciliary action, the cough, sneeze, and gag reflexes serve to protect the air passages.

1. **Cough reflex:** All irritating stimuli arising from the respiratory passages below the pharynx evoke cough. This reflex is triggered off by stimulation of the subepithelial receptors situated in the trachea and bronchi. Sequence of events during cough are: (1) Closure of the glottis, (2) muscular contraction to increase intrathoracic pressure, and (3) sudden release of air by opening of the glottis.
2. **Sneeze:** Irritant stimuli from the nose evoke sneeze. The mechanism is the same as for the cough reflex, but the air is expelled through the nose.
3. **The gag reflex:** This reflex prevents entry of materials into the trachea and this is associated with closure of the glottis.

Pulmonary Physiology

Gas exchange between the blood and the alveoli is brought about by different processes which include : (1) ventilation of the alveoli, (2) mixing of inspired air and alveolar air, and (3) diffusion of gases across the alveolar membrane. Under resting conditions, 5 litres of blood perfuse the pulmonary capillaries, and 6 litres of air enter and leave the lungs every minute. 250-300 mL of oxygen is taken by the pulmonary capillary blood to the tissues and 200-350 mL of carbon dioxide is released into the alveolar air. With exercise these go up considerably.

Control of Breathing

Nervous control of breathing: Respiration is controlled by the respiratory center situated in the medulla and pons. The respiratory center consists of inspiratory center, expiratory center and pneumotaxic center which control the rhythm, depth, and rate of respiration. Principal muscles of respiration are the diaphragm and intercostal muscles. When there is demand for increasing the ventilation or the effort for respiration is higher the accessory muscles of respiration come into play. These include the muscles attached to the thoracic inlet and the abdominal muscles.

Chemical control of breathing: Rise in carbon dioxide tension in the arterial blood is the strongest direct stimulus to the respiratory center to increase ventilation. Next in importance is hypoxia. Hypoxia stimulates the chemoreceptors of the carotid and aortic bodies attached to external carotid artery and ascending aorta respectively. A fall in pH stimulates breathing directly by its action on the respiratory center.

Types of Breathing

Cheyne-Stokes breathing: In this type of abnormal rhythm of respiration, there is increase in the rate and depth of respiration, which reach a maximum and then they come

down to reach a period of apnea. These cycles repeat. Cheyne-Stokes respiration is indicative of serious functional impairment of the respiratory centre. It is seen in cardiac failure, metabolic acidosis, increased intracranial tension, narcotic poisoning, and sometimes even during sleep (Fig. 131.3B).

Biot's breathing: This is a type of irregular breathing in which 3-4 respirations occur in clusters with apneic pauses. The respiration resembles sighs. This is commonly seen in meningitis and brain damage (Fig. 131.3C).

Kussmaul's breathing: In this type, the patient breathes with large tidal volume and so rapidly that there is virtually no pause between breaths. This is seen in all forms of metabolic acidosis, particularly diabetic ketoacidosis, renal failure and others (Fig. 131.3D).

Hyperventilation: The rate and depth of ventilation are increased. This occurs commonly in major pulmonary embolism, anxiety, neurocirculatory asthenia, meningitis, encephalitis, therapy with drugs like epinephrine, poisoning with salicylates or aspirin, hyperthyroidism, hypoxia, and acidosis. Hyperventilation results in excessive removal of CO₂ and consequent alkalosis. Kussmaul's respiration occurring in metabolic acidosis is a compensatory mechanism.

Causes of Alveolar Hypoventilation

1. **Obstruction to the airways**—both structural as in foreign body or secretion, and functional as in bronchospasm.
2. **Paralysis of respiratory muscles**—e.g., poliomyelitis, Guillain-Barré syndrome, or myasthenia gravis.
3. **Impairment of activity of respiratory centre**—e.g., narcotic poisoning, brainstem hemorrhage, coning of the brainstem.
4. **Alteration in the anatomy of the thoracic cage preventing effective ventilation** e.g., severe kyphoscoliosis, diaphragmatic paralysis, pectus excavatum, ankylosing spondylitis, flail chest injuries.
5. **Diseases which affect the lungs and pleura** e.g., pneumonias, atelectasis, pulmonary cysts, emphysema, acute pulmonary edema, malignant secondaries, pulmonary fibrosis, pleural effusion, pneumothorax.
6. **Conditions which interfere with movement of the thoracic cage and diaphragm** e.g., severe obesity, tense ascites.

Gas exchange in the alveoli: Air in the conducting airways is functionally inert and its volume is called the “*anatomical dead space*”. Functionally effective ventilation that the alveoli receive is called “*alveolar ventilation*”. When the alveoli are not perfused with blood, ventilation becomes ineffective. Ventilation occurring in alveoli which are not properly perfused with blood is called “*physiological dead*”

Figs 131.3A to D: (A) Normal respiration. Note the regular pattern—the tidal volume remains the same (B) Cheyne-Stokes respiration apnoeic spells interpose between episodes of waxing and waning respiratory movements (C) Biot's respiration. Apnoeic spells interpose between episodes of respiratory movements of similar amplitude (D) Kussmaul's respiration rapid and high volume respiratory movements occur continuously

space". In normal person, anatomical dead space is equal to physiological dead space. Dead space in typical adult male is equal to 150 mL.

Gas exchange in the alveoli is adversely affected by uneven ventilation, uneven perfusion or defective diffusion.

Ventilation perfusion abnormalities: Ventilation of unperfused alveoli leads to increase in dead space. Perfusion of unventilated alveoli results in the addition of unoxygenated blood to pulmonary venous blood. Taking effective minute ventilation to be 4 litres and pulmonary blood flow to be 5 litres, the normal ventilation perfusion ratio is 0.8.

Several conditions lead to imbalance in ventilation

1. **Normal variations:** The upper parts of the lungs receive less blood than the bases, the hydrostatic pressure of the blood being higher at the base. Though the perfusion is unequal in the different portions of the lung, ventilation is more or less uniform with only minor differences.
2. **Obstruction to pulmonary blood flow:** Pulmonary blood flow is obstructed in pulmonary embolism, vascular changes due to chronic inflammation, destructive lesions of the lung, pulmonary hypertension and vasoconstriction due to hypoxia. Since CO₂ is 20 times more easily diffusible than oxygen,

the ventilation perfusion imbalances lead to hypoxia from the beginning, only later hypercapnia develops.

Gas exchange by diffusion across the alveolar membrane: The alveolar membrane is 0.2 to 0.7 μ thick and it consists of a single layer of cells lining the alveoli, a thin basement membrane and the endothelial cells of the capillary. The alveolar capillaries contain mixed venous blood with high CO₂ and low O₂ tensions. Oxygen passes into the capillary and carbon dioxide passes into the alveoli within a few milliseconds. When the alveolar membrane is thickened, gas exchange is impaired. Diffusion of oxygen is affected early and, therefore, hypoxemia occurs first. Retention of CO₂ occurs only when the lesion is advanced. Several factors such as the structure of the alveolar membrane and ventilation perfusion abnormalities affect the diffusion capacity to a great extent. Hence, the term "transfer factor" is used instead of diffusion capacity.

BLOOD GASES

Both oxygen and carbon dioxide are carried by blood. Diffusion across the alveolar membrane depends upon the partial pressure of these gases on either side, and the diffusing capacity of these gases. Since carbon dioxide is much more readily diffusible than oxygen the level of CO₂ in blood closely follows the partial pressure of CO₂ in

alveolar air. The pattern of oxygen dissociation curve of hemoglobin is such that partial pressure of oxygen in arterial blood (PaO_2) does not fall significantly even when the partial pressure of oxygen in the alveoli falls from 100 mm Hg to 80 mm Hg. But when the alveolar PO_2 falls below 80 mm Hg arterial PO_2 falls steeply. The arterial PO_2 does not closely follow the alveolar PO_2 due to this phenomenon. Oxygen is carried by blood mainly in combination with hemoglobin (1.34 mL/g of Hb) and a small quantity as the dissolved form (0.003 mL/100 mL blood/mm Hg of oxygen tension). The oxygen content in blood can be expressed either as the percentage saturation (SaO_2) or the partial pressure (PaO_2). Arterial carbon dioxide level is expressed in terms of its partial pressure (PaCO_2). Alveolar gas concentrations are expressed in terms of their partial pressures.

Normal Blood Gas Values

Arterial oxygen saturation (SaO_2)	= 95-98%
Partial pressure of arterial oxygen (PaO_2)	= 80-100 mm Hg (11-14 kPa)
Partial pressure of arterial carbon dioxide (PaCO_2)	= 35-45 mm Hg (4.5-6 kPa)

Pulmonary mechanics – Work of breathing: The total work involved in moving the thoracic cage, expanding the lungs and moving the gases in and out is known as the work of breathing.

Pulmonary compliance: The elastic property of the lung is expressed in terms of pulmonary compliance. It is the distensibility of the lung per unit change in intrapleural pressure. Normal pulmonary compliance is about 0.2 litre per cm of water. In conditions like pulmonary fibrosis and pulmonary edema compliance is diminished. It is increased in emphysema.

Airway resistance: About 90% of resistance to flow of air is contributed by the larger air passages and 10% by the smaller airways. Airway resistance is expressed as cm H_2O /litre/second. Resistance to air flow offered by the air passages depends upon several factors like the caliber of the passage, driving pressure, rate of flow, type of flow (laminar or turbulent), density of the gas, and its viscosity. Airway resistance is calculated from values for atmospheric and alveolar pressures and the rate of air flow

Airway resistance =
$$\frac{\text{alveolar pressure} - \text{pressure at the airway opening}}{\text{rate of flow}}$$

In general, airway resistance is measured at a flow rate of 0.5 L/sec. In normals, during quiet breathing the airflow resistance varies between 1.5 to 3 cm water/L/sec. It reaches high values (above 10 cm of water/L/sec) in obstructive airway disease.

ASSESSMENT OF PULMONARY FUNCTION

Different aspects of respiratory function can be subjected to investigational study. These include:

- 1. Gas transport down the airways,
- 2. Gas mixing within alveoli,
- 3. Gas transfer across the alveolocapillary membrane, and
- 4. Lung perfusion.

1. Gas Transport Down the Airways

Entry of air down the airways and its return can be measured using static and dynamic spirometry. Body plethysmography is employed to measure lung compliance and airways resistance. Several parameters are used to determine the ventilatory capacity of the lung.

SPIROMETRY

Spirometry is a measure of air flow and lung volume during a forced expiratory maneuver from full inspiration. It is the simplest test of all respiratory functions. FEV_1 and VC which are the most important parameters to assess the ventilatory capacity, are estimated by spirometry (Fig. 131.4). Other clinical uses of spirometry include the following:

- Additional information to help to establish the *clinical diagnosis* in a patient
- Assess the *prognosis* in a patient
- Assess whether disease is present at an *early stage*, i.e. prior to overt clinical disease
- Assist in quantifying the *severity of airway disease*.
- Assess the *effect of therapy*
- Delineating *risk factors*, e.g. the odds of developing future respiratory disease, or operative risks
- Monitoring whether there is normal pattern of *lung growth or aging*.

Fig. 131.4: Static lung volumes. IRV, inspiratory reserve volume; VT, tidal volume; ERV, expiratory reserve volume; RV, residual volume; IRC, inspiratory reserve capacity; FRC, functional reserve capacity; VC vital capacity; RLC, total lung capacity

1. Lung Volumes

Tidal volume (TV) is the volume of gas inspired or expired during each respiratory cycle. Normally it is 0.5 litre in men and women.

Inspiratory reserve volume (IRV) is the maximal volume of gas that can be inspired from the end of tidal inspiration. Normal value is 2-3 L in men.

Expiratory reserve volume (ERV) is the maximal volume of gas that can be expired from the end of tidal expiration. Normal value is 1.3 litres in men.

Residual volume (RV) is the volume of gas still remaining in the lungs after maximal expiration. Normal value is 1.6 litres in men. In women the values are slightly lower.

2. Lung Capacities

Total lung capacity (TLC) is the volume of gas contained in the lung at the end of maximal inspiration. Normal value is 5.4 litres.

Vital capacity (VC) is the maximal volume of gas that can be expelled from the lung by forceful effort after maximal inspiration. In health, vital capacity is influenced by factors such as age, sex, position, body frame and state of physical conditioning. Average normal value is 3.8 litres in men.

Inspiratory capacity (IC) is the maximal volume of gas that can be inspired from the resting expiratory level. Normal value is 2.5 litres in men.

Functional residual capacity (FRC) is the volume of gas remaining in the lung at the end of tidal expiration. Normal value is 2.9 litres in men.

Forced expiratory volume in one second (FEV₁) [timed vital capacity]: The volume of air expelled in the first one second of a forcible expiration following a full inspiration is called forced expiratory volume in one second (FEV₁). Normally FEV₁ is above 75% of the total vital capacity, FEV₂ is above 85%, and FEV₃ is above 95%. Airways obstruction is indicated by FEV₁ below 70% of normal. Volume time curve is a very useful

spirogram (Fig. 131.5A). FEV₁ is the most useful and reproducible measurement. It is the volume of air expelled in the first second of forced expiration after a full inspiration. FEV₁ depends on the effort made by the patient, the elastic recoil of the lungs and the positive thoracic pressure applied around them by the expiratory muscles. In patients with obstructive airway disease successive FEV₁ measurements yield reproducible results. FEV₁ reflects severity of airway obstruction and correlates approximately with maximal exercise capacity (Fig. 131.6). Rate of decline is influenced by tobacco smoke.

Chronic Bronchitis emphysema syndrome which is mainly due to narrowing of the airways is diagnosed when: FEV₁ is < 80% of the predicted value and the FEV₁/FVC or FEV₁/ vital capacity is < 70%. Improvement or reversibility of airflow obstruction is defined as an improvement in FEV₁ by more than 15% and more than 0.3 litres after administration of the β -adrenergic agonist, salbutamol, 200 μ g by inhalation.

Bronchial challenge studies are very useful in demonstrating airway hyper-reactivity which is characteristic of asthma. Patients with asthma characteristically react to small doses of pharmacological bronchoconstrictors, exhibiting transient decreases in FEV₁ and increases in airway resistance. The most commonly reported measurements are the dose of methacholine or histamine needed to provoke a 20% reduction of FEV₁(PD₂₀). Healthy non-asthmatic subjects require doses that are, on an average, several orders of magnitude greater.

Note: (Fig. 131.5B) Volume time relationship in obstructive and restrictive lung disease. It shows the percentage of reduction the volume of air during the 1st second.

Forced expiratory time (FET) is the total time taken for completing a forced expiration. Normally it is 4-6 sec.

Peak expiratory flow rate (PEFR): PEFR is the maximum rate that can be sustained during the first 10 millsec. of a sudden forced expiration after a full inspiration. The PEFR depends upon the height and surface area of the individual. Nomograms are available for reference. It is

Figs 131.5A and B: Volume-time curves obtained during forced expiration
(A) Normal (B) Restrictive and obstructive lung diseases

Fig. 131.6: Annual decline in lung function. Note the relation between decline in FEV_1 in the normals (non-smokers) and smokers. Rate of decline in FEV_1 is many times higher in smokers. Note also the improvement in FEV_1 on stopping smoking

measured using Wright's peak flow meter. This is an easy and convenient method to assess airways obstruction. Other methods to assess PEFR employ the peak flow gauge and the De Bono Whistle. Distribution of inspired air in different parts of the lungs is studied by single breath oxygen test.

Maximal expiratory flow rate (MEFR): This is the flow rate at a specified portion of a forced expiration after a maximal inspiration, e.g. MEFR 300-1300 denotes flow rate for 1 litre of expired gas after the first 300 mL has been breathed out.

Maximal inspiratory flow rate (MIFR): This is the flow rate at a specified portion of a forced inspiration.

Maximal mid-expiratory flow rate (MMFR): This is the velocity of air expressed as litres per second during the middle third of the total expired volume. It is also denoted as forced expiratory flow (FEF 25-75%). In normals the values vary with age and height of the individuals. Average values lie between 1.5 and 5.5 litres/sec in men. Determination of MMFR helps to detect borderline cases of airway obstruction.

Maximal voluntary ventilation (MVV), or maximal breathing capacity is the total volume of air breathed by a subject using maximum effort over a period of 1 min.

Air velocity index (AVI): The ratio of the percentage of predicted MVV to the percentage of the predicted vital capacity is called air velocity index. The normal range is from 0.8 to 1.2.

Diffusing capacity: This is the volume of a gas transported across the alveolocapillary membrane in 1 min for one

unit of pressure gradient. It is expressed as mL/min/mm of Hg difference in partial pressure.

Closing capacity: During inspiration the air enters different portions of the lung in a definite order. The upper portions fill first and then the middle and lower parts in order. During expiration air escapes in the reverse order, the basal portions emptying first and the apical regions being the last. As a result, the smaller airways at the bases start to close even while air from apices is escaping. The volume of air contained in the lungs at the point where the airways first start to close is called closing capacity.

Closing volume (CV): The difference between the closing capacity and the residual volume is termed closing volume. This is often expressed as a percentage of the vital capacity. In normal subjects below 40 years it is less than 20%. The CV increases with age. In many cases increases in closing volume may be the only detectable abnormality in impending airway obstruction.

Entry of air down the airways and its return can be measured using static and dynamic spirometry. Body plethysmography is employed to measure lung compliance and airways resistance. FEV_1 and VC which are the most important parameters to assess the ventilatory capacity, are estimated by spirometry.

The modern equipment used for estimating the respiratory parameters such as vital capacity, PEFR, TLC, FEV and MEFR which represent different functional aspects of lung function are computerised and the results are given as graphs or loops (e.g. flow volume loop), which can be easily interpreted. In normal individuals the maximal expiratory flow rate decreases steadily throughout forced expiration. Reduction in maximal expiratory flow during the middle of forced expiration is caused by

small- airways disease and can be an early sign of small-airway disease. When tracheobronchial collapse occurs in emphysema or rare disorders of bronchial cartilage, flow rate decreases early in expiration. In obstruction of the airway outside the thorax, flow tends to be constant throughout the first part of expiration rather than decelerating.

Instantaneous flow values are easily read off from such graphs. These can distinguish between obstruction at different levels in the respiratory tree.

2. Gas Mixing within Alveoli

These measurements demand rapid analysis of expired air. The measurement of alveolar and arterial carbon dioxide tension is the method employed for this purpose.

3. Gas Transfer Across the Alveolocapillary Membrane

Estimation of transfer factor is conducted by using carbon monoxide which has a very high diffusing capacity.

4. Lung Perfusion

It is studied by isotopic methods.

Cardiopulmonary Exercise Test (CPET)

Cardiopulmonary exercise testing (CPET) involves the measurement of oxygen uptake (VO_2), carbon dioxide output (VCO_2), minute ventilation $\dot{V}$ or VE , and other variables in addition to the monitoring of 12-lead electrocardiogram (ECG), blood pressure, and pulse oximetry during a maximal symptom-limited exercise test. When appropriate, the measurement of the arterial blood gases provides important information about pulmonary gas exchange. During standard cardiac stress testing the focus is primarily on ECG and blood pressure measurements, whereas in CPET the focus is on gas exchanges. CPET helps to distinguish between pulmonary and cardiac lesions.

During CPET several ventilatory variables such as tidal volume, respiratory rate, ventilation in one minute, breath-to-breath variation in oxygen and carbon dioxide levels in expired air can all be estimated.

Oximeters which can be fitted to the finger tips can give values of arterial oxygen saturation fairly accurately.

SYMPTOMATOLOGY IN RESPIRATORY DISEASES

Cough with or without expectoration, chest pain, dyspnea and hemoptysis are the most frequent respiratory symptoms.

Cough with expectoration is a prominent symptom in inflammatory lesions such as bronchitis and pneumonia or in irritative and allergic lesions of the respiratory tract. Pharyngitis, laryngitis, tracheitis, and early stages of bronchitis give rise to cough without expectoration. In some infections like *Bordetella pertussis*, *Klebsiella* and some

viruses, paroxysms of cough are followed by a long inspiratory whoop caused by laryngeal spasm. Cough elicited by change of posture (postural cough) is characteristic of bronchiectasis, lung abscess, and bronchopleural fistula. “*Bovine cough*” or “*gander cough*” is the term used to denote cough devoid of its explosive (tussive) phase. This occurs in bilateral adductor paralysis of the vocal cords. In asthma cough and dyspnea tend to recur regularly at night. In left sided heart failure with pulmonary edema, cough occurs in the recumbent posture. Development of a sudden and uncontrollable paroxysm of cough in an otherwise healthy person should suggest the possibility of an aspirated foreign body. The change in character of the cough may be an early clue to the development of complications or superimposition of fresh pathology.

Otogenic cough: This is reflex cough elicited by stimulation of the external auditory meatus, part of which is supplied by the auricular branch of the vagus (Arnold’s nerve). In a rare case, impacted wax in the ear or a foreign body in the meatus may elicit reflex cough. Otoscopic examination may reveal the cause. Other reflex symptoms include vomiting and syncope.

Cough is generally a protective reflex designed to keep the airway patent and clear the exudates. Sometimes irritant cough becomes troublesome, interfering with sleep causing severe annoyance. Other untoward effects of cough include syncope (cough syncope), pneumothorax, mediastinal and surgical emphysema and rib fractures (*cough fracture*). In children paroxysmal cough may lead to subconjunctival hemorrhage.

Sputum: The material expectorated from the respiratory tract is called sputum. In healthy individuals the secretion of the respiratory passages is just adequate to provide a protective lining, and there is no expectoration. Expectoration in excess of 10-25 mL of sputum in 24 h should raise the possibility of disease. Copious amounts in excess of 300 mL are seen in bronchiectasis and lung abscess. Character of the sputum often suggests the underlying pathology. Sputum is serosanguinous in pulmonary edema, mucoid and sticky in asthma and chronic bronchitis, thick and purulent in bronchiectasis and lung abscess, creamy yellow in pulmonary tuberculosis, bloodstained in carcinoma, tuberculosis, bronchiectasis, mitral stenosis and pulmonary infarction, rusty in pneumonia and black in coal worker’s pneumoconiosis lung abscess or gangrene of the lung. Copious watery sputum occurs in alveolar cell carcinoma, this is known as bronchorrhea. Sputum is chocolate coloured in hepatopulmonary amebiasis.

Hemoptysis

Presence of blood in the sputum is termed “*hemoptysis*”. In true hemoptysis blood is derived from the airways or the lungs. The quantity of blood may be small as in mitral stenosis or massive as in cavitary pulmonary tuberculosis

or neoplasms. Sometimes blood is derived from the upper respiratory passages or mouth and this is termed “*spurious hemoptysis*.” Hemoptysis before middle age brings to mind tuberculosis, pneumonia, bronchiectasis and mitral stenosis. After 40 to 45 years of age, bronchogenic carcinoma and tuberculosis top the list. Hemoptysis is a manifestation of serious underlying disease warranting full investigation. Though rare, massive hemoptysis results in considerable loss of blood demanding emergency management. Non-respiratory causes of hemoptysis include pulmonary hypertension occurring in mitral stenosis, acute pulmonary edema, pulmonary infarction, trauma and hemorrhagic diseases. Rarely massive and fatal hemoptysis may develop when an aortic aneurysm erodes into the trachea or a bronchus. *Spurious hemoptysis* is commonly resorted to by hysterical individuals to attract medical attention.

Management of hemoptysis: The patient should be hospitalised as an emergency and a rapid clinical examination is done to determine the cause. It is important to avoid percussion, which may worsen the hemoptysis.

The patient is kept in bed rest and sedated with diazepam 10 mg administered intramuscularly. Respiratory depressants such as morphine should be avoided since they impair expectoration. Blood loss and its effects are assessed by monitoring the volume of blood expectorated and the pulse, respiration and blood pressure. If the blood loss exceeds 200-300 mL in 24 hours and it is persistent, blood transfusion is indicated.

In the majority of cases the underlying cause can be made out by clinical examination and chest radiography. Specific treatment is instituted early (e.g. antituberculosis drugs in tuberculosis, antibiotics in pneumonia and lung abscess) in conditions where such treatment is available. Majority of cases subside with rest, sedation, and blood transfusion. In conditions like pulmonary neoplasms, bleeding tends to persist. In such cases emergency bronchoscopy is done to locate the lesion and decide upon further management. If the site of bleeding is located, bronchial artery embolisation is a very effective method to arrest the bleeding promptly.

Digital clubbing (Syn: Hippocratic fingers): This is caused by increase in the volume of soft tissue in and around the distal phalanges of the fingers and toes, especially the nailbeds. This leads to increased curvature of the nails. Severity of clubbing varies and this has been graded for clinical purposes.

Grade 1: Fluctuation of the nail can be elicited on the nailbed.

Grade 2: The normal angle between the nail and nailbed is lost.

Grade 3: The terminal portion of the phalanx and nail appears as a drumstick or a parrot beak.

Grade 4: In addition to digital clubbing, other regions show pulmonary osteoarthropathy.

Being highly subjective, the value of grading is at best minimal in borderline cases. More than the severity of clubbing, the period taken to develop the clubbing may be more important. Occurrence of clubbing within weeks should suggest conditions like lung abscess, bronchogenic carcinoma and infective endocarditis. In these conditions the nails are painful.

Causes

- Respiratory diseases**—Suppurative lesions like bronchiectasis, lung abscess, empyema, and infected cysts; advanced tuberculosis with bronchiectatic changes, bronchogenic carcinoma, pneumoconiosis, fibrosing alveolitis, and pleural fibroma.
- Cardiovascular disorders**—Cyanotic congenital heart diseases and infective endocarditis.
- Alimentary disorders**—Malabsorption states, ulcerative colitis, cirrhosis of the liver, hepatomas and amebic liver abscess.
- Miscellaneous groups**—Clubbing may develop in thyrotoxicosis. At times it may occur non-pathologically in several members of a family (familial clubbing). Repeated trauma to the finger tips as occurring in carpenters and blacksmiths leads to occupational clubbing.

In pachydermoperiostosis which is a rare familial disorder, clubbing occurs in association with thickening of the ends of long bones and coarse thickening of the skin over several regions.

Dyspnea: Difficulty in breathing or shortness of breath associated with marked awareness of the effort of respiration is called dyspnea. The severity of dyspnea can be graded and this gives clue to the severity of the disease and its progression.

Medical Research Council Grading

Grade 1: Troubled by shortness of breath when hurrying on level ground or walking up a slight hill.

Grade 2: Short of breath when walking with people of own age or on level ground.

Grade 3: Has to stop for breath when walking at own pace on level ground.

In left-sided heart failure and in hypoventilatory states, the patient becomes more dyspneic in the recumbent posture and considerable relief is obtained by sitting-up. This is referred to as *orthopnea*. Attacks of severe breathlessness occurring during sleep at night may awaken the patient and assumption of the erect posture gives relief. This is termed *paroxysmal nocturnal dyspnea*. This is also characteristic of left-sided heart failure.

Respiratory disorders that lead to dyspnea may fall into different groups.

- Central causes for dyspnea affect the respiratory center, e.g. encephalitis or cerebrovascular accidents.

2. Significant airways obstruction is a common cause for dyspnea. Obstruction to the airway may be mechanical as due to a foreign body or functional as due to spasm. Larger airways may be obstructed by aspirated foreign bodies, diphtheritic membrane, tumors, blood or secretions. Obstruction to the larynx produces inspiratory stridor and indrawing of the chest wall. Dyspnea is felt both during inspiration and expiration. Obstruction to the smaller airways occurs in asthma, emphysema, chronic bronchitis, and extensive bronchiectasis. In these conditions the difficulty is felt more for expiration and the characteristic expiratory wheeze may be heard.
3. Disorders that impair the process of gas exchange, e.g. massive pulmonary collapse, pulmonary embolism, respiratory distress syndrome, fibrosing alveolitis, pulmonary fibrosis and extensive parenchymal diseases such as tuberculosis, cystic disease and malignancy.
4. Diseases that prevent expansion of the lung, e.g. pneumothorax, pleural effusion, kyphoscoliosis, injury to the chest wall, paralysis of respiratory muscles.
5. Dyspnea is commonly the first symptom when the inspired air does not supply adequate amounts of oxygen to the individual. This happens when the oxygen tension is low as in high altitudes or in gas poisoning.
6. Hysterical hyperventilation may present as dyspnea. In this, the subject voluntarily hyperventilates. Other traits of the hysterical personality may be evident. Excessive removal of carbon dioxide due to overventilation leads to respiratory alkalosis and tetany.
7. In diseases like pneumonia and pleurisy, painful restriction of respiratory movements leads to hypoventilation and dyspnea.

Cyanosis: Bluish discolouration of the skin and mucous membranes due to the presence of excess of reduced hemoglobin in peripheral blood is called cyanosis. In

extensive diseases of the lungs central cyanosis occurs due to defective oxygenation of arterial blood or the development of functional arteriovenous shunts. In chronic bronchitis and emphysema the main defects are those of ventilation and perfusion. In fibrosing alveolitis, the defect is mainly one of diffusion. Differentiation between respiratory and cardiac causes of cyanosis can be made on clinical grounds in many cases. In respiratory diseases inhalation of oxygen clears the cyanosis, whereas this is not so in cardiac lesions with right to left shunts.

PHYSICAL EXAMINATION

Examination of the respiratory system should be preceded by a careful general examination. Dyspnea, cyanosis, digital clubbing and cervical or axillary lymphadenopathy may suggest a primary respiratory disorder.

For purposes of physical examination, chest is divided into different areas with a view to enable anatomical localization of the lesion. The anterior part is divided into supraclavicular, infraclavicular, mammary and inframammary regions. The lateral aspect is divided into the axillary and infra-axillary regions and the back is divided into suprascapular, interscapular and infrascapular regions (Table 131.2).

Physical examination is carried out sequentially from inspection to palpation, percussion and auscultation. Measurement of the chest for its expansion is a simple and reliable clinical method for assessing the ventilatory capacity. Normal expansion in an adult ranges from 6-8 cm.

Percussion: The note raised by percussion and the vibration felt by the pleximeter finger give valuable clues to the state of the underlying lung and pleura. By percussion it is possible to assess the relative proportion of air, solid tissue or fluid underlying the area.

Special forms of percussion include “*tidal percussion*” and the “*elicitation of shifting dullness*”. The former is employed to distinguish dullness caused by the

TABLE 131.2

Shows the relationship of the clinical areas with the underlying lung

Anterior:	1. Supraclavicular region and infraclavicular region (from the clavicle down to the third rib) 2. Mammary region (from the third to the sixth rib) 3. Inframammary region (from the sixth rib to the costal margin)	Correspond to the apical and anterior segments of the upper lobe respectively Correspond to the anterior surface of the middle lobe on the right and the lingula on the left Parts of the middle lobe on the right and lingula on the left and parts of the lower lobe on both sides
Lateral:	1. Axilla (from the apex of the axilla down to the sixth rib) 2. Infra-axillary region (from the sixth rib to the costal margin)	Major part of the lateral aspect of the upper lobe and part of the lower lobe Lateral segments of the lower lobe
Posterior:	1. Suprascapular region (above the spine of the scapula) 2. Interscapular region (second to seventh dorsal spines) 3. Infrascapular region (below the seventh dorsal spine)	Part of the apical segment and contiguous posterior segments of the upper lobe Apical segment of lower lobe and contiguous posterior portion of the upper lobe Posterior basal segments of the lower lobes on both sides

TABLE 131.3

Clinical significance of alteration in percussion note

Normal lung	Resonant normally
Hollow viscus, pneumo- thorax	Tympanitic
Moderate pneumothorax, emphysema, bullae	Hyper-resonant
Consolidation collapse, fibrothorax	Impaired resonance to moderate dullness
Pleural effusion, empyema, thick fibrothorax	Stony dullness

upper border of the liver from that caused by pleural fluid or consolidation of the lower portion of the lungs. Shifting dullness occurs when there is fluid which is free to move with changing positions of the patient. This occurs in hydropneumothorax or in a large cavity containing fluid and air (Table 131.3).

Auscultatory findings: Breath sounds, vocal resonance and whispering pectoriloquy are elicited by auscultation. Breath sounds are produced by oscillation set-up in the larger air passages (trachea and larger bronchi) by turbulent flow of air. Over the larger air passages the character of breath sounds is bronchial. In the lower regions of the lungs, the parenchyma acts as a low pass filter which filters off the higher frequency components (200 Hz and above) and this changes the character of the breath sounds to vesicular. When this filtering effect is lost, the sounds are directly transmitted to the chest wall and the breath sounds become bronchial. This occurs in consolidation of the lungs. This is the acoustic basis of bronchophony and whispering pectoriloquy as well. Adventitious sounds heard during auscultation may be “wheezes” (previously called “rhonchi”) and “crackles” (used to be known as “crepitations”).

Breath sounds: Normal breath sounds are vesicular. This is characterized by the phase of inspiration, closely followed by a short expiratory phase (one-third of the inspiration) and the quality being rustling. In bronchial breathing the expiratory and inspiratory phases are equal with a pause in between and the quality is guttural or aspirate. Normally bronchial breathing is heard over the trachea, when auscultated over the front and back of the neck. Pathological associations of the bronchial breathing include pulmonary consolidation, collapse adjoining a patent bronchus or rarely other conditions. Based on the pitch, bronchial breathing has been described as “tubular” (high pitched), “cavernous” (low pitched) and “amphoric” (low pitched breath sounds with high pitched overtones). “Tubular breathing” is heard over pneumonic consolidation, “cavernous breathing” over communicating cavities and large air passages, and “amphoric breathing” over open pneumothorax and large communicating cavities. “Bronchophony” (increased vocal resonance) occurs over

areas of consolidation. “Whispering pectoriloquy” (whispered sounds being heard distinctly on auscultating the chest) can be elicited over areas of bronchial breathing. When only high frequency sounds of a spoken voice are transmitted to the chest wall, the vocal resonance attains a nasal quality and this is termed “aegophony”. This may be elicited above the level of a pleural effusion.

Adventitious sounds may be continuous or interrupted. “Continuous adventitious sounds” include: (1) “stridor” occurring in laryngeal and bronchial obstruction, and (2) “wheezes” arising from narrowed air passages. Wheezes are musical lung sounds. When heard by auscultation, they are termed rhonchi. Interrupted adventitious sounds include crackles (which may be fine, medium or coarse), and pleural rubs. Crackles (crepitations) are produced by explosive equilibration of gas pressure between boluses of air in the air passage and the sequential opening up of airways during respiratory cycles. Coarse crepitations may be due to the presence of exudate in the larger air passages and these disappear with coughing and expectoration.

Pleural friction rub: This is a leather-creaking sound heard superficially in pleural diseases. It may be heard both during inspiration and expiration at the same part of the respiratory cycle. It is not altered by coughing.

Pleuropericardial sounds: These are better heard when the breath is held in full inspiration, as rubbing sounds. They suggest the presence of pleurisy and pericarditis.

Crunching sounds: These are heard when auscultating over areas of surgical emphysema and sometimes over pericarditis.

Knocks: These are sharp adventitious sounds heard in pneumothorax caused by the movement of the collapsed lung over the mediastinum.

Investigations in Respiratory Diseases

General investigations of importance which point to disease of the respiratory organs include peripheral blood picture, total and differential leukocyte counts and determination of ESR. Lymphocytosis is suggestive of chronic inflammatory diseases like tuberculosis whereas neutrophil leukocytosis occurs in acute infections like pneumonia. Increase in eosinophils above 10% calls for estimation of the absolute eosinophil count. Mild and moderate increase in eosinophils is very common in Indian subjects. This is caused by factors such as helminthiasis and external allergens. In susceptible subjects even moderate eosinophilia may present with symptoms of respiratory allergy. Higher eosinophil counts are found in bronchial asthma, hydatid disease and pulmonary eosinophilia. Chronic hypoxemia results in the development of secondary polycythemia. Elevation of ESR is a non-specific indicator of inflammatory and neoplastic lesions in the lungs. ESR is not specific for diagnosis,

but in the follow-up of chronic diseases like tuberculosis, ESR is a helpful parameter.

1. Sputum Examination

- a. Sputum should be examined macroscopically, microscopically after proper staining, and bacteriologically. Total quantity of sputum in 24 h, colour, consistency and other characteristics like odour and presence of blood are of great value in diagnosis. Presence of fungi in mycotic infections, asbestos bodies in asbestosis and motile amebae in pulmonary amebiasis can be detected by direct microscopy of fresh sputum. *Gram's stain* and *Ziehl-Neelsen stain* are employed to identify the bacterial and mycobacterial pathogens in the smear. Malignant cells can be detected by cytological examination. Wet preparations stained with methylene blue may suggest the presence of malignant cells. Staining with Leishman's stain helps to identify leukocytes in sputum. Presence of numerous neutrophils suggests infective basis whereas predominance of eosinophils suggests allergic etiology. This distinction is very helpful in the management of asthma. *Papanicolaou staining* technique helps to identify the malignant cells further. Giemsa stain reveals *Pneumocystis carinii*.
- b. *Bacteriological tests*: Sputum culture is done to identify the organisms and their sensitivity to various antibiotics. Proper collection of the specimen is essential for getting reliable results. Sputum should be taken directly into sterile receptacles. Contamination by oropharyngeal organisms leads to fallacious results on culture. Uncontaminated specimens of sputum can be obtained by transtracheal aspiration. Bronchial washings collected through a bronchoscope or smears collected by a brush during bronchoscopy are ideal specimens for cytological and microbiological studies, wherever facilities are available.

line at the level of the lower margin of the anterior end of the second rib separates the upper from middle zone, and a horizontal line passing through the lower margin of the anterior end of the fourth rib separates the middle from the lower zone. Chest radiographs give evidence of morphological lesions. In many instances, radiological appearances help to infer the etiology as well.

Radiological Appearances Caused by Physical Abnormalities in the Lungs

Consolidation: Presence of homogenous opacities with well defined margins indicate pulmonary consolidation. Radiological consolidation is characterised by presence of air bronchogram that is seen thorough the consolidated lung. Since there is no change in the volume of the lung the trachea and mediastinum are not shifted.

Collapse: Pulmonary collapse throws a homogenous opacity with clearcut concave margins. The trachea, mediastinum, and interlobar fissure are shifted towards the area of collapse. The dome of the diaphragm on the affected side is elevated. The unaffected portions of the lung shows hypertranslucency due to compensatory emphysema.

Fibrosis: Presence of streaky linear or reticular shadows with shift of trachea and mediastinum to the same side and compensatory emphysema of the unaffected regions is suggestive of fibrosis.

Pleural effusion: Presence of small quantities of fluid (less than 300 mL) in the pleura causes only obliteration of the costophrenic angle. As the quantity of fluid increases, more extensive homogenous opacity appears with obliteration of the costophrenic and cardiophrenic angles. The upper margin tends to be concave with its higher level towards the axilla and the lower level towards the mediastinum. Midline structures are shifted to the opposite side.

Presence of fluid and air (*hydropneumothorax*) is diagnosed by the presence of a horizontal level of fluid below, with hypertranslucency (due to air) above. The lung markings are not visible since the lung is collapsed towards the hilum.

Pneumothorax: Presence of air in the pleural cavity leads to hyperlucency and absence of lung markings on the affected side. The margin of the collapsed lung is seen towards the hilum. The midline structures are pushed to the opposite side.

Cavities: Cavities are seen as areas of central translucency within areas of consolidation or fibrosis.

Morphology of the cavities vary with different lesions. Tuberculous cavities are thin-walled and empty. Thick-walled cavities containing fluid and air suggest the possibility of lung abscess or neoplasms.

2. Radiological Studies

Plain X-ray chest-posteroanterior (PA) view: Radiographs are taken in full inspiration with the film placed in front of the chest and the source of X-ray kept 1.5-2 m behind the patient. In addition to PA views, lateral views are also taken with the affected side close to the film to locate the bronchopulmonary segment which is the seat of disease. In normal skiagrams the lungs appear as translucent zones in which bronchovascular markings are clearly detectable and can be traced almost to the periphery.

The trachea, mediastinum, costophrenic, and cardiophrenic angles and the level of the diaphragm are taken as landmarks in the interpretation of chest skiagram. On either side the lung fields are compared zone by zone. For purposes of description the lung fields are divided into the upper, middle, and the lower zones. A horizontal

Opacities in the lung: Opacities may be single or multiple. Depending on their size and distribution, multiple opacities are grouped as *miliary mottling* (1-2 mm size), *nodularity* (1 cm or above) and *cannon balls*. Their size, density, distribution, and number give clues to their pathological nature. The lungs are hypertranslucent in emphysema and less translucent in conditions such as interstitial fibrosis or pulmonary edema.

Lesions in the apices of the lungs are brought out better by taking lordotic views or penetrated views. By this method, parts concealed behind ribs are visualized. The exact spatial location of any lesion can be obtained by taking the PA and lateral views. Oblique views may be required for further localization. Radiographs taken in the lateral decubitus are necessary to detect conditions such as intrapulmonary effusions. In cases where X-ray pictures are not conclusive, more informative procedures like high resolution computed tomography are done.

Fluoroscopy: This procedure helps in assessing the respiratory movements and the movements of mediastinal structures. Due to the risk of the radiation and want of accuracy in diagnosis this procedure is seldom used at present.

Contrast radiography: The technique of visualizing the bronchial tree using radio-opaque dyes is called *bronchography*. This is the only reliable method to assess the total extent and type of bronchiectasis.

Pulmonary angiography: It is performed to study the pattern and distribution of the pulmonary arteries and their branches. Arteriography is the method of choice to demonstrate pulmonary embolism and arteriovenous malformations.

Ultrasonography: has become an important investigational modality in respiratory diseases. Pulmonary parenchymal lesions, mediastinal lesions, pleural fluid, pleural lesions, cardiac and pericardial lesions and several others can be diagnosed confidently. Ultrasound directed biopsies and aspiration are also more effective than blind procedure.

Radioisotopic investigations: Isotopic techniques have made it possible to obtain visual images as well as precise quantitative information about the regional distribution of ventilation and perfusion. These methods are generally non-invasive. New machines incorporating computer facilities are available.

Perfusion imaging: This is employed to study the state of the pulmonary vasculature. The main clinical uses are in the investigation of pulmonary embolism, atresia or hypoplasia of pulmonary artery, presence of right-to-left intracardiac shunts and pulmonary venous hypertension.

Ventilation imaging: This can be made by using ¹³³Xenon.

Aerosol inhalation studies: Aerosolised radioactive particles can be administered for inhalation. Commonly ^{99m}technetium-labelled phytate, lactose, albumin or sulphur colloid are used. The radioactive particles are distributed in the lungs depending upon the patency of the air passages. The concentration or radioactivity is diminished in areas of poor ventilation. Another use of labelled aerosol particles is to study the efficiency of mucociliary function. When mucociliary function is impaired, the clearance of radioactivity from the lung is delayed.

Using perfusion and ventilation imaging studies, valuable information can be obtained. In pulmonary embolism ventilation is normal, but perfusion is diminished, whereas both ventilation and perfusion are diminished in parenchymal, pleural or obstructive airway disease.

Isotopic localization of pulmonary tumours: Isotopes such as ⁵²Gallium citrate and ⁵⁷Cobalt-labelled bleomycin which are concentrated by tumours are used to study neoplastic lesions.

Computed tomography: This is employed to detect abnormalities in the pleura, lungs, major blood vessels and mediastinal structures. CT scan distinguishes between cysts, tumours and vascular lesions. It is very helpful to diagnose bronchiectasis. It is a valuable adjunct when skiagrams are not conclusive. CT has become a regular investigation modality in respiratory medicine. High resolution CT (HRCT) is more useful to detect pulmonary infiltrative diseases and bronchiectasis early.

Magnetic resonance imaging (MRI): is also very helpful to bring out structural lesions of intrathoracic organs. The advantages over CT are its capacity to give pictures in the sagittal, coronal and transverse planes with higher resolution. Lesions occurring at the apices of the lungs and thoraco-abdominal junctions are picked up better by MRI. It can also distinguish between vascular and nonvascular structures at the hilum even without contrast.

Endoscopic studies: Several endoscopic procedures are available to study respiratory disorders. These include laryngoscopy, bronchoscopy, mediastinoscopy, and thoracoscopy. Laryngoscopy visualizes the upper respiratory tract up to the larynx and the trachea.

Bronchoscopy: Bronchoscopy is the endoscopic procedure used to visualise the trachea, bronchi and their branches, aspirate secretions for investigations, obtain biopsy material, and remove obstructions. Clinical indications for bronchoscopy include bronchial obstruction, pulmonary neoplasms, unresolved pneumonia, lung abscess and recurrent hemoptysis. Broncho-alveolar lavage can be done during bronchoscopy and the specimen can be examined further.

Availability of flexible fiberoptic bronchoscopes with facilities for aspiration and biopsy procedures has increased their importance in diagnosis and therapy in recent years. Flexible bronchoscopes can reach up to the second or third division of the bronchi whereas rigid bronchoscopes reach only up to the first division.

Video bronchoscope gives better clarity of the lesion. Advances in bronchoscopy include trans bronchial biopsy to grade peripheral lung cancers, application of trans bronchial stents to relieve obstruction and auto-fluorescence bronchoscopy for early detection of lung cancer. Newer instruments incorporating ultrasound and high magnification equipments give better diagnostic results.

Mediastinoscopes are used to inspect the superior mediastinum and perform biopsy procedures under direct vision.

Thoracoscopy is inspection of the thoracic contents with a thoracoscope after producing a partial pneumothorax. Video assisted thoracoscopy (VATS) is useful for conducting procedures like lung volume reduction surgery.

Investigations using aspirated material: In the diagnosis of pleural diseases, the examination of pleural fluid is most important. So also examination of bronchial aspirates and material from other sites gives valuable diagnostic clues. Macroscopic appearance, microscopy, cytology, microbiological studies, and biochemical investigations are helpful in diagnosis.

Biopsy Studies

Lymph node biopsy: Biopsy of the appropriate scalene lymph node or palpable axillary or cervical lymph nodes helps to diagnose granulomatous and neoplastic lesions.

Lung biopsy: Lung tissue can be obtained by percutaneous biopsy, bronchoscopically, or by open biopsy under vision. Percutaneous biopsy using a Vim-Silverman needle or a trephine is performed to diagnose diffuse lesions and peripherally situated localised lesions. When the lesions are small and not accessible superficially, thoracotomy and open biopsy are preferable.

Pleural biopsy: This is resorted to when pleural lesions have to be diagnosed. *Cope's needle* or *Abram's pleural biopsy punch* is used for obtaining material from the parietal pleura. *Vim-Silverman needle* or *Menghini's needle* can be used in the absence of the specialized needles. Aspiration and biopsy can be done as ultrasound or CT guided procedures for greater diagnostic yield.

Broncho-alveolar lavage: This procedure is adopted to obtain material from the terminal portions of the respiratory tree and alveoli. The specimen is subjected to microscopy and cytological examination. Organisms such as *Pneumocystis carinii*, *CMV*, *legionella*, *fungi* and *mycobacteria* can be identified in the washings. Broncho-alveolar lavage has been used therapeutically to remove occluding plugs in cystic fibrosis and severe asthma. In alveolar proteinosis lavage using heparin and acetyl cysteine helps to remove the proteinaceous material.

Respiratory Failure

14

C. Sudheendra Ghosh, Ronald Win B

Chapter Summary

General Considerations	900
Clinical Features	901
Management of Acute Respiratory Failure	902
Chronic Respiratory Failure	903
Acute Respiratory Distress Syndrome (ARDS)	903
Respiratory Distress Syndrome (RDS) of Newborn	904

General Considerations

The state in which the lungs cannot perform the function of gas exchange adequately during rest and exercise is called respiratory failure. In this condition the resting PaO_2 falls below 60 mm Hg (60 torr or 8 kPa) and/or the PaCO_2 rises above 49 mm Hg (49 torr or 7 kPa), when breathing room air at sea level. Lowered PaO_2 alone is not adequate to make the diagnosis of respiratory failure. In right to

TABLE 132.1

Causes of respiratory failure

1. <i>Interference with the mechanics of the chest wall</i>	Severe kyphoscoliosis, obesity, flail chest injury with multiple rib fractures, paralysis of the chest wall muscles and diaphragm, immobility of the chest wall as in progressive systemic sclerosis
2. <i>Pleural disorders</i>	Large collection of pleural fluid, tension pneumothorax, gross thickening of the pleura and others
3. <i>Diseases of the airways</i>	Severe asthma, advanced chronic bronchitis and emphysema, laryngeal edema, mechanical obstruction of air passages
4. <i>Pulmonary diseases</i>	Pulmonary interstitial fibrosis, neonatal and adult respiratory distress syndrome, allergic alveolitis, extensive malignancy, bilateral pneumonia
5. <i>Diseases of pulmonary vasculature</i>	Primary pulmonary hypertension, polyarteritis nodosa, repeated pulmonary embolism
6. <i>Metabolic</i>	Metabolic alkalosis
7. <i>Depression of the respiratory centre</i>	Injury to brainstem, raised intracranial tension and narcotic poisoning lead to central respiratory failure

left shunt lesions the PaO₂ may be lowered without respiratory failure. Causes of respiratory failure are many. Interference with any of the major processes-ventilation, perfusion or diffusion-may result in respiratory failure (Table 132.1).

The clinical picture depends on the speed of onset, cause and severity. Acute respiratory failure produces more dramatic symptoms whereas chronic respiratory failure may even remain asymptomatic. Respiratory failure may or may not be associated with dyspnea. Though in the early stages CO₂ retention causes dyspnea, with the passage of time the respiratory centre becomes adapted and unresponsive to elevated level of CO₂. At this stage the lowered PaO₂ (60 mm Hg or below) is the effective stimulus for respiration. There is no direct correlation between the blood gas levels and severity of dyspnea.

In the majority of cases the patient has a longstanding respiratory problem such as chronic obstructive airway disease and respiratory failure is precipitated by infection. The increased secretions and mucosal edema caused by infection aggravate the airway obstruction and this results in alveolar hypoventilation. As a result hypoxia and hypercapnia (rise in level of arterial carbon dioxide) develop. As the respiratory failure progresses the PaO₂ falls from 60 mm Hg (mild) to 20 mm Hg (severe).

Type I-respiratory failure: This type is characterized by lowered PaO₂ and normal or low PaCO₂. This is usually the result of conditions in which ventilation is normal, but there is defective diffusion or ventilation-perfusion imbalance. Conditions like pulmonary edema, respiratory distress syndrome, extrinsic allergic alveolitis and interstitial pulmonary fibrosis lead to type I respiratory failure.

Type II-respiratory failure: In this condition PaO₂ is reduced and PaCO₂ is elevated. Hypoxia is the more prominent feature. This results from conditions characterized by defective ventilation occurring along with ventilation-perfusion imbalance. Alveolar hypoventilation occurs in chronic bronchitis, emphysema, asthma and respiratory paralysis. Hypercapnia develops only when the FEV₁ goes down below 1.2 litres. With higher values of FEV₁, hypercapnia is rare. If the respiratory failure is of acute onset, retention of carbon dioxide leads to acidosis and fall of pH. If the respiratory failure becomes chronic, compensatory mechanisms come into play. Renal conservation of bicarbonate restores the pH to near-normal.

CLINICAL FEATURES

Respiratory failure may be acute or chronic. In the latter exacerbating factors lead to acute manifestations. The main biochemical factors are hypoxia and hypercapnia which in turn give rise to various other abnormalities in acid-base balance and electrolyte disturbances. The manifestations of hypoxia and hypercapnia vary from each other.

Manifestations of hypoxia: Hypoxia is more harmful to tissues than hypercapnia. Vital organs such as the brain, heart, liver and kidney, and the pulmonary vessels are adversely affected. Neurological symptoms include headache, irritability, insomnia, drowsiness, mental confusion, and coma. Objective evidence of cerebral dysfunction can be demonstrated by the electroencephalogram. If hypoxia is severe, fatty change, tissue necrosis, and focal hemorrhages develop in the myocardium. Cardiac arrhythmias are precipitated.

Constriction of pulmonary arteries leads to pulmonary hypertension and this may precipitate right sided heart failure. Liver cells become edematous and necrosed. In chronic hypoxia the liver shows fatty change and fibrosis. Severe hypoxia may give rise to renal tubular damage. Secondary polycythemia develops in chronic hypoxic states.

Manifestations of hypercapnia: In the initial stages hypercapnia stimulates the respiratory center and the resultant hyperventilation helps to lower the PaCO_2 to normal levels. In established hypercapnia the respiratory center becomes insensitive to raised PaCO_2 . In such cases the stimulus for the respiratory centre is hypoxia. In judicious administration of oxygen may abolish this hypoxic stimulus and this may give rise to further depression of respiration and carbon dioxide narcosis. Hypercapnia causes cerebral vasodilatation, headache, and rise in intracranial tension. As a result, papilledema may occur in severe cases. Peripheral vasodilatation develops and this gives rise to warm extremities, flushing, and rapid high volume pulse. When PaCO_2 levels exceed 50 mm Hg, drowsiness, confusion, muscle twitching, and flapping tremors develop. The deep tendon reflexes become sluggish. The patient lapses into coma when PaCO_2 rises above 80 mm Hg.

Management of Acute Respiratory Failure (ARF)

This should be managed as an emergency in an intensive respiratory care unit if facilities are available. Proper monitoring includes the record of heart rate, respiratory rate, blood pressure, temperature, serum electrolytes and blood gas levels. In addition to general supportive care, special attention should be paid to the airways and proper oxygenation.

Maintenance of the airway: Irrespective of the cause, in all cases of respiratory failure, the upper air passages should be fully inspected and foreign bodies and secretions should be removed. In the recumbent comatose patient, the chin should be pulled up to prevent the tongue from falling back and obstructing the pharynx. If the patient cannot expectorate freely, secretions should be aspirated. If the patient can cooperate, removal of secretions should be aided by postural coughing, gentle tapping on the chest, steam inhalation and administration of drugs like bromhexine hydrochloride. Bromhexine hydrochloride can be administered orally in a dose of 8 mg thrice daily. Mucolytic agents can be administered as aerosols, e.g., acetylcysteine. Adequate hydration is necessary, since it helps to loosen the secretions for easy expectoration. If bronchospasm is present, it can be relieved by drugs like salbutamol given 2-4 mg orally or

0.5 mg intramuscularly. Parenteral corticosteroids (betamethasone 4 mg) may have to be given if bronchospasm is not relieved by simple measures. Salbutamol and beclomethasone can also be given as metered aerosols. Tracheostomy may be required in some cases where the tidal volume is low.

Antibiotics: Since infection is a very common precipitating factor, antibiotic therapy is indicated. Preliminary assessment of the infecting agent can be made by Gram-staining and culture of the sputum and the suitable antibiotic can be started. In the acute case crystalline penicillin and in the chronic case a broad-spectrum antibiotic such as ampicillin or amoxicillin may be required. Antibiotic therapy may have to be reviewed when microbiological results are obtained.

Correction of hypoxia: This is the mainstay in the management of respiratory failure. Oxygen is administered with nasal catheter, or by more effective methods such as masks or tents. If given by nasal catheter, the rate is 2-3 litres per minute and the catheter tip should be located 15 cm from the nostril. The *venturi mask* which delivers oxygen at a preset low concentration is ideal if available. The concentration of oxygen can be adjusted at 24, 28 or 35% by giving oxygen at rates ranging from 4-8 litres/min. It is desirable to bring the PaO_2 level above 50 mm Hg and pH above 7.25. In chronic respiratory failure administration of oxygen should be closely supervised to avoid the development of carbon dioxide narcosis. Once the emergency has been tided over, the patient is weaned off from oxygen gradually.

Supportive measures: Administration of fluid and electrolytes, preferably with monitoring of central venous pressure (CVP) and maintenance of nutrition are important.

Assistance to ventilation: Mechanical assistance should be considered when the patient's own effort is inadequate to maintain oxygenation. If the PaO_2 remains below 60 mm of Hg and PaCO_2 remains above 55 mm Hg while receiving oxygen therapy, respiratory assistance is indicated.

The decision to assist ventilation should be individualised depending on several factors. Non invasive positive pressure ventilation (NIPPV) is delivery of mechanical ventilation to the lungs without an invasive (endotracheal) airway. This can be delivered with the use of either negative pressure ventilators or non-invasive positive pressure ventilators. Intubation is indicated when NIPPV has failed or contraindicated. Contraindications include inability to protect the airway, patient intolerance, and hemodynamic instability or cardiac arrest.

Different types of ventilators are available. Volume cycled ventilators are superior since these are more efficient and safe. If the patient's respiratory mechanism is active, it is desirable to assist it (assisted ventilation).

On the other hand, in patients in whom spontaneous respiration is abolished, controlled ventilation using a preset volume and rate is employed. Modern respirators are designed to assist respiration when the patient's own respiratory effort goes down and they are reciprocally inhibited when the patient's breathing recovers.

Positive end expiratory pressure (PEEP): One of the problems encountered in patients with respiratory failure maintained on assisted respiration is premature closure of the terminal airways during expiration, giving rise to air trapping. This is prevented by maintaining a positive end expiratory pressure. In addition, it helps to reopen bronchioles and alveoli which remain closed. The tidal respiration is improved. Positive end expiratory pressure also helps to reduce the functional intrapulmonary shunts, thereby increasing the PaO_2 . The disadvantage of PEEP is reduction in venous return to the heart due to increased intrathoracic pressure and consequent cardiac failure. Assistance to ventilation should be carried out by specially trained teams. As the patient improves, he is gradually weaned off the ventilator under supervision. Ventilatory support is a highly skilled job, which has to be undertaken by a team trained to establish the airway, activate the machines and monitor the progress of the patient clinically and from blood gases and acid-base values. In many centres this is done under the supervision of the anesthetist, intensivist and pulmonologist.

Extracorporeal membrane oxygenators are being employed in the management of severe hypoxemic respiratory failure when conventional methods fail. Solutions containing perfluorocarbon which dissolve oxygen and deliver it to tissues are also being introduced into the management of respiratory failure. As the patient improves, he is encouraged to undertake mild exercises. Respiratory exercises are advised to increase the tidal volume and help expectoration. He is also instructed on methods to avoid the precipitating factors. Incurable cases should be considered for lung transplantation which facility is still not available in India.

Chronic Respiratory Failure

Some patients with progressive respiratory disease eventually enter a state in which the arterial oxygen and carbon dioxide are persistently abnormal. Acute respiratory infection tips them into severe respiratory failure. In such cases prompt treatment of infections, bronchodilators and management of respiratory failure help to tide over the crisis. In irreversible chronic ventilatory failure, provision of continuous oxygen in the house is very beneficial in giving symptomatic relief. Lung transplantation is available in many countries, but not yet in India. This has to be considered when the chances of functional recovery sufficient to sustain life is improbable.

Acute Respiratory Distress Syndrome (ARDS)

(Syn. Shock lung, Wet lung)

The ARDS was first formally described by Ashbaugh and colleagues in 1967.

This is a syndrome characterised by a fairly acute onset of severe respiratory distress in adults who have normal pulmonary functions. Clinically it resembles respiratory distress syndrome of the newborn (RDS) but in the latter, changes in surfactant are the primary mechanisms for disease. This is not so in adults.

Diagnostic Criteria

1. Acute onset of respiratory failure
2. $\text{PaO}_2/\text{FIO}_2$: <300 mm Hg = acute lung injury (ALI),
3. $\text{PaO}_2/\text{FIO}_2$: <200 mm Hg = acute respiratory distress syndrome (ARDS)
4. Chest radiograph: Bilateral alveolar infiltrates consistent with pulmonary edema
5. Pulmonary capillary wedge pressure <18 mm Hg.

Etiology: Many factors contribute to the picture of ARDS. ARDS may follow several unrelated pathological conditions. These include prolonged shock, cardiopulmonary bypass surgery, severe infections like septicemia, viral, bacterial, fungal or pneumocystis pneumonia, inhalation of irritant fumes, drugs like nitrofurantoin, methadone and morphine, trauma to chest including major surgery, acute pancreatitis, fat embolism, massive blood transfusions, prolonged administration of oxygen in high concentrations, and immunological disorders like Goodpasture's syndrome.

Pathogenesis: The initiating factor is damage to the pulmonary capillaries leading to extravasation of fluid into the interstitium and alveoli. This results in ventilation-perfusion imbalance. Work required for respiration increases since the edematous lung is less compliant. Disseminated intravascular coagulation which may occur in shock favours the development of ARDS. Other pathogenetic mechanisms include microemboli produced from extracorporeal circulation, immune complexes and presence of excess of catecholamines. The lungs are airless, congested, hemorrhagic and edematous. In the acute phase interstitial and alveolar edema is present. Unlike as in left heart failure where pulmonary capillary pressure is high, it is normal in ARDS. Type I pneumocytes desquamate and are replaced by hyaline membrane. Type II, pneumocytes suffer damage resulting in the depletion of surfactant. This results in widespread microatelectasis. Vascular damage leads to interstitial edema. If the condition persists for more than ten days the epithelium undergoes cuboidal transformation and progressive interstitial fibrosis. This may be manifested functionally as alveolocapillary defects.

Fig. 132.1: X-ray chest shows bilateral alveolar infiltrate consistent with pulmonary oedema

Clinical features: ARDS sets in on a background of any of the various clinical conditions mentioned earlier. Early features include tachypnea and dyspnea. Auscultation may reveal diffuse wheezes and crackles. The arterial oxygen saturation falls progressively. Arterial CO_2 is maintained normal for considerable periods by hyperventilation. The chest X-ray shows progressive haziness of lung fields due to increasing quantity of fluid (Fig. 132.1). The fully established picture is one of severe respiratory failure which may be fatal. Prognosis depends upon the underlying condition and the stage at which respiratory support is given. The mortality used to be 50-60%, but with modern treatment it has come down. Those who recover do so without sequelae. Rarely emphysema may result.

Management: Prompt treatment of the predisposing factors like shock and infection may help to prevent the development of ARDS, and if already established, to prevent deterioration. The general management is the same as for respiratory failure. Fluid therapy should be carefully controlled as the lungs are already edematous. Administration of salt-free albumin along with frusemide has been beneficial. Institution of positive end expiratory pressure (PEEP) ventilation and more efficient cardiovascular support help to reduce mortality. PEEP serves to increase the lung volume, reduce intrapulmonary shunting and collapse of alveoli. Extracorporeal membrane oxygenation (ECMO) is life-saving in selected cases.

Inhalation of nitric oxide as a pulmonary vasodilator is under trial. Corticosteroids are indicated in cases where the primary disorder is immune-mediated.

Respiratory Distress Syndrome (RDS) of Newborn

This is a syndrome characterized by tachypnea, expiratory grunt and cyanosis caused by the lack of surfactant and often with a fatal outcome seen most frequently in premature babies below 38 weeks gestation. Fetal causes include neonatal asphyxia, acidosis and hypothermia. Antepartum hemorrhage, uncontrolled diabetic state in the mother, hypoxia, gross anemia and caesarean section done for fetal distress are the maternal causes associated with higher incidence of RDS.

Pathogenesis: The level of surfactant in the alveoli is reduced. This results in atelectasis of the alveoli. In addition to the reduction in surfactant, other abnormalities such as alterations in the pulmonary and systemic circulation, coagulopathy, fibrinolysis, interstitial edema, decreased plasma proteins and disordered pulmonary mechanics are important contributory factors leading to the final picture. The effort required to distend the alveoli during inspiration is greater. Reduction in compliance leads to rapid shallow breathing, inspiratory indrawing of intercostal spaces and cyanosis. Histopathologically there is extensive alveolar atelectasis, dilatation of alveolar ducts, interstitial edema and the presence of a hyaline membrane covering the respiratory bronchioles, alveolar ducts and alveoli. The hyaline membrane is formed by desquamated epithelial cell debris and fibrin.

Clinically the baby has tachypnea, grunting expirations, indrawing of the intercostal, subcostal and suprasternal spaces and cyanosis. Untreated, the mortality is very high. Children who survive RDS are predisposed to various chronic respiratory problems in later life.

Treatment: Neonatal intensive care units have reduced the mortality from RDS. The airway is maintained patent by careful suction of secretion and physiotherapy. Controlled administration of oxygen, positive end expiratory pressure respiration (PEEP), correction of acidosis and maintenance of normal body temperature (36.5°C skin temperature) are the important supportive measures. Antibiotics are indicated in the presence of infection. Corticosteroids have been employed, based on subjective observations.

Surfactant therapy: Instillation of surfactant directly into the airways helps to relieve the condition. EXOSURF NEONATAL (Burroughs Wellcome) is a protein free synthetic lung surfactant. The contents of a vial is reconstituted with 8 mL preservative-free sterile water. This solution contains 13.5 mg of dipalmitoyl phosphatidyl choline. Surfactant should be administered only in centres where facilities for assisted ventilation and

respiratory monitoring are available. The dose is 5 mL/kg body weight, repeated after 12 hours.

The baby is put on endotracheal ventilation and the surfactant solution is delivered into the infant's trachea through the sideport of the endotracheal tube, taking several minutes for the administration. The first dose should be administered as early as possible on diagnosing RDS.

Prenatal estimation of the lecithin: sphingomyelin ratio in amniotic fluid (obtained by amniocentesis) is useful to predict the chances of developing RDS. If L:S ratio is less than 1.5 the risk is high. If L:S ratio is over 2 the risk of RDS is minimal.

Administration of corticosteroids to mothers who go into premature labour helps to reduce the chances of RDS in the newborn.

Drug	Dose	Route	Frequency
Antihistamines			
Loratidine	5 mg	PO	Daily
Desloratidine	10 mg	PO	Daily
Cetirizine	10 mg	PO	Daily
Sodium cromoglycate	2% solution, metered dose	Nasal spray	4-6 hourly
Topical steroids			
Beclomethazone	2 doses of	Nasal spray	12 hourly
Budesonide	50 µg		
Mometazone			
<i>Prevention:</i> An attempt must be made to avoid known allergens or agents as far as possible.			

RHINITIS

Inflammation of the nasal mucosa is called rhinitis. The most frequent cause is allergy to inhaled substances such as pollen, dust, hair or animal dander. An immediate hypersensitivity reaction occurring on the nasal mucous membrane leads to sneezing, nasal obstruction, and watery nasal discharge. Ingested allergens may also lead to rhinitis. Rhinitis may be a predominant symptom in coryza and other respiratory viral infections. Edema of the mucosa occurring in rhinitis may lead to obstruction and infection of the paranasal sinuses.

Similar symptoms can be produced by physical irritants such as cold air, dry atmosphere or chemicals such

as strong perfumes. This condition is called ‘*vasomotor rhinitis*’.

Treatment: Allergic rhinitis responds to antihistamines, cromones and topical steroids. Vasoconstrictor nasal drops (xylometazoline 0.1%) may also be used. Continued use of nasal drops containing sodium cromoglycate may help to desensitize the nasal mucosa (Table 133.1).

EPISTAXIS

Epistaxis is bleeding from the nose. Usually bleeding occurs from the blood vessels over the anterior part of the nasal septum and anterior nares, areas easily examined

TABLE 133.2

Causes of epistaxis

Local causes:

Rhinitis, foreign bodies, sinusitis, carcinoma, trauma, rhinosporidiosis.

Systemic causes:

Infections: Influenza, typhoid, pertussis, malaria and rheumatic fever.

Other systemic diseases: Hypertension, hemorrhagic disorders and cirrhosis liver with hepatic failure.

by a nasal speculum. Epistaxis may result from local or systemic causes (Table 133.2).

Epistaxis is a frightening symptom. In majority of cases, it is self-limiting. *Treatment* consists of sedation, rest in bed and packing the nose with gauze soaked in adrenaline solution. Local vasoconstriction arrests the bleeding. If bleeding tends to be recurrent, the bleeding spot must be cauterized. In all cases of epistaxis, look for an underlying systemic disorder. Management of the systemic disorder is very important.

PHARYNGITIS

Pharyngitis is the most common cause of simple “sore throat”. In agranulocytosis and acute leukemia, necrotic ulceration of the tonsils and pharynx may be the presenting symptom. Excessive smoking, noxious fumes, corrosives and unaccustomed spicy foods are common irritants. Pharyngitis may also be caused by allergy to inhaled or ingested allergens (Table 133.3).

Clinical features: Pharyngitis gives rise to sore throat and dysphagia. The posterior and upper cervical lymph nodes may be enlarged and tender. Redness and edema over the

pharynx and adjoining areas may be seen. Pharyngitis may form part of the clinical picture of several systemic infections.

Treatment: Appropriate antimicrobial drugs are indicated in pharyngitis due to bacterial infections. Most cases respond to penicillin. Rest, steam inhalation, and analgesics give rapid symptomatic improvement. Throat lozenges containing menthol or eucalyptus oil give considerable relief to the pain and discomfort.

Acute Tonsillitis

Inflammation of the tonsils is more common during childhood. However, all age groups can be affected. *Hemolytic streptococcus-Lancefield group A* is the most common agent. Other pathogens causing pharyngitis may affect the tonsils as well. Tonsillitis is more common in poorer socioeconomic groups, where chances for cross infection are high.

Clinical features: Symptoms start with sore throat, pain over region of the tonsils, high fever, and dysphagia. Examination of the throat with a tongue depressor reveals enlarged, red tonsils covered with yellowish pus in the crypts on one or both sides. The exudate can be easily removed by a swab and the underlying mucosa does not bleed. Tonsillar and adjoining lymph nodes are moderately enlarged and tender. There is moderate neutrophilic leukocytosis.

Even if untreated, the acute symptoms and the tonsillar inflammation partially may subside in 7-10 days. In many patients, the streptococci persist within the crypts and give rise to recurrence of symptoms over several years. This is referred to as “chronic tonsillitis”.

TABLE 133.3

Common microbial causes of acute pharyngitis

TABLE 133.4

Complications of tonsillitis

1. Extension of infection due to contiguity: Pharyngitis, laryngitis, tracheobronchitis, pneumonia, sinusitis, eustachian catarrh and suppurative otitis media
2. Systemic spread of infection: Septicemia, pyemia
3. Local complications: Chronic tonsillitis, peritonsillar abscess
4. Immunological complications: Rheumatic fever and glomerulonephritis

Complications: Acute tonsillitis may lead to several complications (Table 133.4).

In India and other neighbouring countries, acute streptococcal tonsillitis is the most common cause of rheumatic fever.

Diagnosis: Acute tonsillitis is diagnosed from the characteristic appearance of the tonsils, acute febrile onset, and neutrophilic leukocytosis. Confirmation and isolation of the organism must be attempted by culture of the pus taken before antibiotic therapy.

Acute tonsillitis has to be differentiated from faucial diphtheria. In neutropenic states, necrotic ulceration of the throat may also develop.

Treatment: Aspirin relieves the pain and fever. Drug of choice is penicillin. Crystalline penicillin G sodium is given in a dose of 1.0 mega unit every 6 hours intravenously. Erythromycin, ampicillin or cotrimoxazole may be given in appropriate doses as alternate therapies. It is important to administer the full course of treatment and repeat bacteriological study at the end of the course to ensure that organisms are eradicated. Indications for tonsillectomy include recurrent exacerbations of tonsillitis (more than four times in one year), or where chronic tonsillitis is complicated by otitis media.

Sinusitis

Sinusitis is the acute or chronic inflammation of the paranasal sinuses. Maxillary sinusitis is the most common type of sinusitis. The ethmoid, frontal and sphenoid sinuses are affected less frequently.

Sinusitis is caused by a variety of bacteria such as streptococci, staphylococci, pneumococci *Haemophilus influenzae* and anaerobic bacteria. Viruses such as the influenza and the parainfluenza virus and less commonly fungi such as aspergillus also may produce sinusitis (Table 133.5).

Anatomical abnormalities interfering with the normal draining mechanisms predispose to infection. Often the disease starts as an acute respiratory infection. It may follow dental procedures or swimming in contaminated water.

Infection reaches the sinuses from the nose, mouth, tonsils, nasopharynx, and the upper canines or molars. The

TABLE 133.5

Causative organisms in acute maxillary sinusitis

Organism	Frequency (%)
<i>S. pneumoniae</i>	30

<i>S. pyogenes</i>	2
<i>B. catarrhalis</i>	2
Gram-negative bacteria	9

lining mucosa of the nose and sinuses is inflamed. Obstruction of the opening of the sinus leads to accumulation of secretion, which may get infected. Sinuses may become filled with pus.

Clinical Features: Malaise, fever, frontal headache, and nasal discharge are the presenting symptoms. In maxillary sinusitis, pain may be felt in the maxillary area of the face. Frontal sinusitis causes pain around the eyebrows. Ethmoid sinusitis causes pain behind the eyes and frontal headache. Sphenoid sinusitis causes pain in the occipital region. Tenderness may be elicited over the sinuses. Pus may be seen pouring from the opening of the affected sinus on speculum examination.

Chronic sinusitis leads to recurrent headache, which shows a diurnal periodicity. The headache starts in the morning and worsens by mid-day, and subsides by evening. Foul-smelling purulent nasal discharge may occur. Once established, the condition persists for months or even years. Table 133.6 gives the complications.

Diagnosis: History of chronic headache and the demonstration of purulent discharge from the nose coupled with tenderness over the sinuses should suggest the clinical diagnosis. Trans-illumination of the involved sinus produces a dark shadow while the normal one produces a light shadow. X-ray examination of the paranasal sinuses shows haziness or opacities in the region of the infected sinuses. CT scan may be required for

TABLE 133.6

Complications of sinusitis

1. Intracranial infection: Meningitis, thrombophlebitis of the intracranial veins, thrombosis of the cavernous sinus and sagittal sinus, extradural abscesses.
2. Infection of the eye socket: Orbital cellulitis
3. Infection of ethmoid sinus: Third nerve palsy
4. Frontal sinusitis: Osteomyelitis of the frontal bone and edema over the region (*Pott's puffy tumor*)
5. Respiratory tract: Aspiration of pus into the respiratory tract leading to recurrent bronchitis, aspiration pneumonia, bronchiectasis, and lung abscess.

confirmation. The discharge from the sinus on culture isolates the causative organism. Fungal scrapings and smears as well as fungal cultures are done if a fungal aetiology is suspected.

Treatment

Medical: Specific therapy is to administer antibiotics depending on bacteriological results. In the acute stage, one of the newer generation cephalosporins is effective. Decongestant nasal drops, nasal sprays and steam inhalations help to reduce nasal mucosal edema and thus favour drainage of pus. Aspirin gives symptomatic relief.

Surgical: In chronic sinusitis, if conservative measures fail to clear the infection, pus has to be removed by irrigation and drainage. Caldwell-Luc procedure for chronic maxillary sinusitis may be employed. Ethmoidectomy may be required for ethmoid sinusitis.

Acute Laryngitis

Inflammation of the larynx may result from bacterial or viral infection or inhalation of irritant gases. It often results as a complication of acute coryza. Unaccustomed overuse of the voice leads to edema of the vocal cords. Laryngitis is characterized by hoarseness or loss of voice and pain during attempted speech. Irritant nonproductive cough may be present. In children, acute laryngitis manifests as ‘croup’ secondary to partial obstruction of the small larynx.

Treatment consists of rest to the voice, steam inhalations, avoidance of smoking, and administration of analgesics (paracetamol 0.5g 6 hourly). In many cases the condition is self-limiting with rest and analgesics. Antibiotics are indicated only if bacterial infection is present. Rarely complications do occur, leading to chronic laryngitis, tracheitis, bronchitis or pneumonia.

Chronic Laryngitis

Chronic laryngitis is characterized by hoarseness of voice or aphonia in association with throat irritation and dry cough. This may result from repeated attacks of acute laryngitis, excessive use of voice, tobacco smoking or chronic sinusitis. Laryngoscopy is a must to exclude local tumours or vocal cord palsy. Treatment consists of absolute voice rest, abstinence from smoking and steam inhalations.

Laryngeal Paralysis

Paralysis of the vocal cords may be organic or functional. The abductors and the adductors are supplied by the recurrent laryngeal nerves, which are branches of the vagus nerves. In organic paralysis the abductors, the

tensors and the adductors are affected in the order of sequence. The completely paralysed vocal cord lies immobile midway between abduction and adduction (*cadaveric position*). Abductor paralysis is always organic in nature and it may be unilateral or bilateral. On the other hand pure adductor paralysis is always bilateral and it is functional in nature. This is frequently seen in hysteria.

Causes of organic laryngeal paralysis: Involvement of the left recurrent laryngeal nerve is common in mediastinal tumours, aortic aneurysm and enlargement of the left atrium occurring in mitral stenosis. One or other of the recurrent laryngeal nerves may be affected in the neck by enlargement of the cervical lymph nodes, goiter or other surgical causes.

Paralysis of the vagus may occur in infective polyneuritis, fractures of the base of the skull, space occupying lesions in the posterior fossa or diphtheria.

Vagal nuclei are affected in brainstem lesions. These include basilar artery insufficiency, bulbar poliomyelitis, motoneurone disease, syringobulbia and tumours.

Clinical features: Usual symptoms are hoarseness of voice, cough, dyspnea, and alteration in the quality of the cough. Organic paralysis is accompanied by cough, whereas hysterical paralysis is not. In bilateral abductor paralysis, the cough loses its explosive phase (*“Bovine cough”*). In unilateral vocal cord paralysis the hoarseness and loss of voice may disappear with time, since the opposite vocal cord crosses the midline and restores the vocal aperture. Laryngeal paralysis is confirmed by laryngoscopy.

Treatment: Treatment of the cause of the laryngeal paralysis must be instituted wherever possible. Otherwise management is symptomatic. Bilateral abductor paralysis results in obstruction of glottis and it is fatal if the airway is not established by tracheostomy or intubation. *Persons with laryngeal paralysis should avoid swimming and diving, since they cannot hold breath and, therefore, they run the risk of drowning.*

OBSTRUCTION TO THE RESPIRATORY TRACT

Acute Laryngeal Obstruction (Table 133.7)

Acute laryngeal obstruction may present as a life-threatening emergency.

Foreign bodies may get impacted in the larynx. This may include dentures or large chunks of meat. Obstruction by bolus of food is more common under alcohol intoxication. This is called *‘Café Coronary’*.

Clinical features: Stridor, aphonia, and dyspnea are the hallmarks of laryngeal obstruction. Acute obstruction in children leads to cyanosis and inspiratory in-drawing of the trachea. The movement of a foreign body within the

TABLE 133.7

Causes of laryngeal obstruction

1. Foreign body
2. Inflammatory or allergic edema (including angio-neurotic edema due to food, irritant fumes, corrosives or insect stings)
3. Acute laryngitis and epiglottitis (especially in infants)
4. Exudates
5. Laryngeal muscle spasm
6. Inhaled blood clot/vomit in the unconscious
7. Tumors: Chronic progressive obstruction – especially carcinoma
8. Bilateral vocal cord paralysis

larynx may be palpable during respiratory efforts. When obstruction due to large bolus of food occurs at the table, the victim becomes anxious, restless, and cyanosed. He tries to cry, but the voice is lost. If the obstruction is not relieved immediately, he falls unconscious and death may occur within minutes.

Diagnosis: Acute laryngeal obstruction should be suspected when an otherwise healthy individual suddenly becomes choked and cyanotic with loss of voice.

Management: First aid consists of the removal of the foreign body manually or with a pair of tongs. The impacted foreign body can be dislodged by a sudden forcible thud on the chest with the head lowered.

Heimlich maneuver: This effective method is to be learnt by all first aid teams. The patient is hugged from behind with the rescuer's hands crossing each other over the patient's epigastrium and the chest is compressed suddenly. This helps in dislodging the obstruction (Fig. 133.1).

If the above attempt fails, the airway should be made patent by tracheostomy or by inserting a few large-bore hypodermic needles into the trachea. The patient is transported to hospital for further management.

Management of chronic obstruction depends upon the cause.

Tracheal Obstruction

Total tracheal obstruction is rare but may be caused by a foreign body. More often it is partial and is caused by external pressure due to mediastinal masses, goiter, mediastinitis, mediastinal fibrosis or aortic arch aneurysm. New growths, especially adenomas or polyps arising from the wall cause intermittent obstruction.

Tracheal obstruction leads to stridor, viz. noisy breathing with a harsh crowing sound mainly during

Fig. 133.1: Heimlich maneuver. Application of sudden pressure over the abdomino-thoracic region may dislodge the laryngeal foreign body

inspiration, and dyspnea. In the case of pedunculated growths the obstruction may be postural. Tracheal obstruction has to be distinguished from asthma and other causes of dyspnea. *Treatment* is surgical, after confirmation by bronchoscopy.

Bronchial Obstruction

Bronchial obstruction can occur in the larger bronchi or in the bronchioles and may be acute or chronic. The clinical manifestations vary accordingly. Acute obstruction is mostly intraluminal. It may be caused by aspiration of vomitus, blood, pus, mucus plugs, foreign bodies, or edema and exudates from the inflamed bronchial wall itself. Chronic obstruction is due to extraneous pressure from glands or intraluminal adenoma or bronchogenic carcinoma. Bronchial obstruction leads to collapse of the lung with subsequent infection of the distal parenchyma, bronchiectasis and fibrosis.

Treatment: Put the patient with head low so as to drain any fluid that may be present. Gentle tapping on the chest helps drainage. Aspiration of the tracheobronchial tree is needed if secretions are copious.

Endoscopic examination with removal of the obstruction should be done without delay. Surgery may be required if the condition does not clear with endoscopic aspiration.

Pneumonias

C. Sudheendra Ghosh, Ronald Win B

Chapter Summary

- Staphylococcal Pneumonia 911
- Klebsiella Pneumonia 911
- Mycoplasma Pneumonia 912
- Aspiration Pneumonia 912
- Hypostatic Pneumonia 913
- Bronchopneumonia 913

Introduction

Pneumonia is the sixth leading cause of death in the world today. It is also the major cause of death from infectious diseases. The mortality resulting from severe pneumonia varies from 20-40%. Mortality is more common among the elderly, and patients with comorbidities like diabetes mellitus, chronic obstructive pulmonary diseases, congestive heart failure, coronary artery disease, interstitial lung disease and carcinoma. Depending on the severity of the disease, the average cost of treatment varies from small to very large amounts.

Refer also chapter 37. Pneumococcal infection

Definition

Inflammation of the lung is called pneumonia. Community Acquired Pneumonia (CAP) is defined as an infection that begins outside of the hospital or is diagnosed within 48 hours after admission to the hospital in a patient who has not resided in a long-term facility for 14 days or more before the onset of symptoms. Up to 20% of patients with CAP require hospitalisation (Figs 134.1 to 134.3).

Hospital Acquired Pneumonia (HAP) is defined as infection of lung parenchyma occurring more than 48 hours after admission to a hospital. When HAP occurs the subset of patients receiving mechanical ventilation it is termed **Ventilator-Associated Pneumonia (VAP)**. VAP usually occurs at 48 to 72 hours following intubation.

Health Care Facility Associated Pneumonia (HCAP) is defined as pneumonia following admission to an acute

Fig. 134.1: X-ray chest showing lobar pneumonia Note: the consolidation of the upper zone right lung uniform opacity with clearcut margins, midline structures not shifted

care hospital on two occasions during the previous 90 days or residence in a long-term care facility or recent intravenous antibiotic therapy.

HAP is a common nosocomial infection with a rate between 5 and 10 cases per 1000 hospital admissions. The incidence in patients who require mechanical ventilation is 6 to 20 times higher. HAP is the leading cause of death from hospital acquired infections.

Pneumonias may be caused by specific pathogens like *Pneumococcus* or *Klebsiella* or by mixed flora which reach the lungs due to aspiration of infected material from the upper respiratory passages, stomach or exterior. The latter group is called aspiration pneumonia (Table 134.1).

Till a decade ago invariably the organism causing pneumonia sporadically in the community used to be pneumococcus. There has been a change in the pattern of causative organisms more recently. Due to the increase in number of immunosuppressed individuals in the community and more opportunities for cross infection between hospitalized patients and their home contacts the organismal pattern has changed even for community acquired pneumonias.

Pneumococcal pneumonia is described in Chapter 37.		

predispose to staphylococcal pneumonia. This is a dreaded complication in children with cystic fibrosis and in patients receiving immunosuppressant therapy. The organisms reach the lung through the bloodstream (pyemia) or along the respiratory passages.

Clinical features: The onset is with mild symptoms, but soon the condition worsens to produce grave toxemia, purulent and blood stained sputum and cyanosis. The lesions are generally multiple, giving rise to thin walled abscesses. It may frequently spread to the pleura to produce empyema or pyopneumothorax. Signs of lobar consolidation may not be evident. Diagnosis should be suspected from the clinical setting and the presence of toxemia far out of proportion to the pulmonary signs. Gram staining of sputum and culture reveal the organisms. Mortality varies from 20-25%.

Treatment: At present most strains of hospital-acquired staphylococci produce penicillinase. Hence penicillinase-resistant drugs such as cephalothin, cloxacillin or vancomycin may be necessary.

- Cloxacillin0.25-0.5 g oral, intramuscular or intravenous 6 h
- Cephalothin2 g 6 h.
- Vancomycin0.5 g 6 h.
- or Nafcillin1-1.5 g 6 h
- Early diagnosis and prompt treatment ensures cure.

KLEBSIELLA PNEUMONIA
Syn: Friedlander's Pneumonia

This is a grave illness seen in patients above the age of 40 years. Debilitating diseases, alcoholism, and malnutrition predispose this condition. Common site of involvement is the posterior segment of the upper lobe. The right lung is involved more frequently. The condition sets in with sudden chills, rigors, fever, dyspnea and cough

Fig. 134.4: Klebsiella pneumonia X-ray chest showing lobar consolidation with abscess formation right and pneumonitis left. Note: the bulging fissure

with gelatinous thick sputum streaked with blood. The course may be subacute or fulminant and fatal. Abscess formation is a common complication (Fig. 134.4). Mortality is high, ranging around 30%.

Treatment: Once the condition is suspected urgent treatment with cephalexin 1 g 6 h I M should be started. Gentamicin in a dose of 5-8 mg/kg may be added as a second antibiotic. Treatment may have to be continued for 2 weeks or more to ensure cure.

MYCOPLASMA PNEUMONIA

Syn: Primary atypical pneumonia, Eaton-agent pneumonia, Cold-agglutinin-positive pneumonia. This is caused by *Mycoplasma pneumoniae* which is a bacterium devoid of cell wall. It spreads in closed communities and in families through the respiratory secretions. Clinically it may present as (1) tracheobronchitis, or (2) pneumonia (in 30%). The disease starts insidiously with lassitude, headache, myalgia, and chest pain. Expectoration is scanty. Hemoptysis may occur. Physical examination of the chest may reveal only minimal findings. The skiagram shows extensive lesions, not made out clinically. Over 50% of patients develop cold agglutinins in their serum in a dilution of 1:32 or more by the second week. These non-specific antibodies agglutinate human O group erythrocytes at 4°C. These antibodies may be present for long periods. Complement fixation tests help to demonstrate specific antibodies. Tetracycline and erythromycin are effective against this organism.

Haemophilus influenzae pneumonia occurs principally in patients with underlying chest diseases such as chronic bronchitis emphysema syndrome, bronchiectasis and others. The organisms show resistance to aminopenicillins. Combination with co-amoxyclav is effective. Pneumonitis is a part of the general picture of infections by chlamydia, rickettsiae, several viruses including AIDS and systemic fungal infections.

ASPIRATION PNEUMONIA (NONSPECIFIC PNEUMONIA)

Infective material may be aspirated into the trachea and bronchi.

Causes Predisposing to Aspiration

1. Conditions which suppress the cough reflex, e.g. coma, alcoholic intoxication, general anesthesia.
2. Spill over of pus or gastric contents into the respiratory tract, e.g. sinusitis, tonsillitis, achalasia cardia, pharyngeal paralysis, tracheo-oesophageal fistula.
3. Violent contraction of abdominal muscles forcing gastric contents into the respiratory tract, e.g. epilepsy, tetanus
4. Aspiration from outside, e.g. drowning

The microbial flora is mixed, depending on the source of infection. The pulmonary lesion may be a localized massive pneumonia or a bronchopneumonia.

Clinical features: Aspiration of large volumes presents as pulmonary collapse or as pneumonia. In the presence of any of the predisposing factors, aspiration pneumonia should be suspected. Right lower lobe is more often affected because of the disposition of its bronchus. The upper lobe is also not infrequently involved in alcoholics and comatose subjects. If the obstruction is not removed by coughing or by other means the consolidation tends to persist and proceed to lung abscess. So also, aspiration pneumonia tends to recur if the primary cause is not removed.

Treatment: The general principles of treatment of pneumonia are applicable. In addition, prompt attention should be given to clear the respiratory passages of obstructing material. This can be achieved by postural drainage, physiotherapy to the chest to encourage coughing, suction using a mechanical sucker, or by bronchoscopic aspiration.

General Guidelines to Start Initial Antibiotic Regimens

Empirical selection of antimicrobial agents for treating patients with community acquired pneumonia is recommended as follows:

Outpatients: Generally preferred antimicrobial drugs are (not in any particular order) doxycycline, macrolides, or fluoroquinolones.

Selection considerations: These agents have activity against the most likely pathogens in this setting, which include *Streptococcus pneumoniae*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*. Selection should be influenced by regional antibiotic susceptibility patterns for *S. pneumoniae* and the presence of other risk factors for drug-resistant *S. pneumoniae*. Penicillin-resistant pneumococci may be resistant to macrolides and/or doxycycline. For older patients or those with underlying disease, a fluoroquinolone may be a preferred choice; some authorities prefer to reserve fluoroquinolones for such patients.

For hospitalized patients, an extended spectrum cephalosporin combined with a macrolide or a β -lactam/ β -lactamase inhibitor combined with a macrolide or a fluoroquinolone (alone) are generally preferred.

For intensive care unit, an extended-spectrum cephalosporin or β -lactam/ β -lactamase inhibitor plus either fluoroquinolone or macrolide are generally preferred.

In patients with structural lung disease the preferred choice include: antipseudomonal agents (piperacillin, piperacillin-tazobactam, carbapenem, or cefepime) plus a fluoroquinolone (including high-dose ciprofloxacin). In patients, allergic to β -lactam, the preferred agents include fluoroquinolone or clindamycin. For suspected aspiration pneumonia, fluoroquinolone with clindamycin or metronidazole are the drugs of choices.

HYPOSTATIC PNEUMONIA

This is seen in elderly debilitated persons who are bed-ridden. It is a form of aspiration pneumonia. Inadequate cough reflex, excessive respiratory secretions and pulmonary congestion favour the development of hypostatic pneumonia. Microbial flora is derived from the upper respiratory secretions. The lesion is a bronchopneumonia. Hypostatic pneumonia acts as a preterminal event in many elderly debilitated individuals. Avoidance of prolonged recumbency, frequent change of posture (once in 2 h) in comatose and debilitated subjects and regular breathing exercises help to prevent this condition.

BRONCHOPNEUMONIA

Syn: *Acute lobular pneumonia, diffuse pneumonia*

Inflammation of the bronchial wall and the pulmonary parenchyma is the essential lesion in bronchopneumonia. This leads to patchy consolidation of the lung. The disease is more common during infancy and old age.

Fig. 134.5: Chest X-ray bronchopneumonia.
Note: Patchy opacities with indistinct margins

Causes: Bronchopneumonia may occur as a complication of several diseases such as whooping cough, measles and other viral infections in children. Chronic bronchitis, emphysema, and viral infections of the respiratory tract may be complicated by bronchopneumonia. Rarely bronchopneumonia may occur as the primary lesion.

Pathology: The common organisms are *staphylococci*, *streptococci*, *pneumococci*, and *H. influenzae*. Rarely *rickettsiae*, viruses and fungi may cause bronchopneumonia. The inflammatory lesions are widespread and patchy over both lungs, more in the lower lobes. The terminal bronchioles are affected initially and the alveoli are involved secondarily. There is collapse and consolidation in the affected lobule. Confluence of lesions may give rise to larger areas of consolidation. The exudate shows neutrophils and fibrin. Interstitial edema develops. There is compensatory emphysema around the collapsed alveoli.

Clinical features: The extent of pulmonary involvement and the virulence of the infective agent determine the clinical picture. Generally the onset is insidious. In the majority of cases bronchopneumonia follows the primary illness after a period of apparent improvement. The temperature goes up and tachypnea and cough may develop. The child may be cyanosed. Unlike as in lobar pneumonia, pleural involvement and herpes labialis are rare. Physical examination of the chest reveals widespread rales. Signs of extensive consolidation are rare. X-ray shows bilateral irregular and patchy shadows, more in the lower zones (Fig. 134.5).

Rarely bronchopneumonia may lead to bronchiectasis, pulmonary fibrosis, lung abscess or empyema. Mortality is higher in patients with chronic respiratory or cardiovascular disease.

Treatment: Prompt use of the appropriate antibiotic brings down the fever and helps in resolution of the lesions. In children suffering from measles and other viral infections, occurrence of bronchopneumonia should be anticipated

and early therapy started. In underdeveloped communities respiratory infections lead to severe setback in the growth and development of children and also predispose to prolonged morbidity and malnutrition.

Lung Abscess and
Pleuropulmonary Amebiasis

C. Sudheendra Ghosh, Dinesa Prabhu V.

Chapter Summary

Lung Abscess 914

Pleuropulmonary Amebiasis 916

Lung Abscess

Localized suppurative lesion in the lung is called lung abscess. Tuberculous and cystic cavities, though secondarily infected by pyogenic organisms, are not usually included under this term.

Causes

1. Aspiration pneumonia: Aspiration of gastric contents or materials from the upper respiratory tract occurs during coma, anesthesia or deep sleep.
2. Other types of pneumonias.
3. Systemic pyemia.
4. Secondary infection of pulmonary infarcts.
5. Necrosis and infection of bronchogenic carcinoma.
6. Spread of amebic liver abscess and primary pulmonary amebiasis.
7. Bronchial obstruction leads to abscess formation distally.

Impairment of cough due to painful conditions in the chest or during postoperative period and conditions which impair ciliary function (heavy smoking or bronchitis) predispose to abscess formation. Right lower lobe is a common site for aspiration and suppuration. In the supine comatose patient, the posterior segment of the right upper lobe and apical segment of the right lower lobe being the

most dependent parts suffer more frequently. Next in frequency are the corresponding segments on the left.

Factors Predisposing to Lung Abscess

1. Aspiration of material occurring in dental sepsis: depressed consciousness, alcoholic bouts, epilepsy, head injury, coma, disturbances of swallowing, oesophageal stricture, bulbar palsy, achalasia cardia, and pharyngeal pouch
2. Necrotizing pneumonias
3. Hematogenous spread
4. Pre-existing lung disease: bronchiectasis, cystic disease, bronchial obstruction
5. Immunodeficiency

Pathology: Suppuration and necrosis of lung tissue constitute the basic pathological process. The abscess is lined by granulation tissue which limits the spread of infection. Common organisms are those derived from the upper respiratory tract and mouth. These include *aerobic* and *anaerobic streptococci*, *staphylococci*, *pneumococci* and *spirochetes*. Less commonly *E. coli*, *clostridia* and *B. proteus* may be present. When the abscess ruptures into a bronchus, pus is expectorated. The cavity contains pus and air. The wall is thick and ragged compared to tuberculous cavity or cyst. Chronic abscesses may be multiloculated. When the contents are discharged, healing occurs by fibrosis.

Clinical features: Early symptoms are those of pneumonia with fever, cough, rigor, malaise and pleuritic chest pain. Initially cough may be unproductive. Hemoptysis is not uncommon. When the abscess ruptures into a bronchus the cough become postural. The sputum is large in volume

(300-500 mL/day), purulent, blood stained and foul smelling. Systemic symptoms depend on the virulence of the organisms and general condition of the patient. In a moderately severe case the patient is febrile, toxic, and dyspneic. Painful clubbing of the fingers and toes develops in a few weeks.

Physical examination may reveal the presence of consolidation due to the surrounding pneumonic process. Pleural rub may be heard. Once the abscess opens into a bronchus, the auscultatory signs of cavitation are found. The breath sounds are cavernous and coarse. Post-tussive crepitations are heard.

Laboratory Findings

Neutrophil leukocytosis is present in most cases. *Sputum*: Once the abscess starts discharging pus, the sputum is large in volume, purulent, foul-smelling and blood-stained. On allowing it to stand in a conical glass the sputum settles into the typical three layers (froth above, serous portion in the middle and thick nummular particles below). The organisms can be identified by Gram staining and culture.

X-ray chest reveals consolidation with clearance in its center. A partially drained abscess is seen as a cavity containing fluid and air. Both posteroanterior and lateral views are necessary to locate the abscess (Figs 135.1 to 135.3).

Diagnosis: Clinical diagnosis is made from the history, physical signs of consolidation and cavitation and the presence of copious amounts of purulent sputum. X-ray chest confirms the diagnosis in almost all cases. Location of the abscess can be made by taking the lateral view skiagram as well. Microbial flora can be determined by sputum examination and microbiological tests. In the vast

Fig. 135.1: Pyogenic abscess. X-ray chest lung abscess right upper zone: Note the abscess cavity containing air and fluid

Fig. 135.2: X-ray chest tuberculous abscess with secondary infection

Fig. 135.3: HRCT Pulmonary abscess left upper lobe: Note the abscess cavity with the area of consolidation around

majority of cases these are sufficient to institute treatment and follow-up the case to recovery.

Bronchoscopy is indicated if there is likelihood of bronchial obstruction and malignancy or doubt about the etiology. Bronchoscopy will help to remove obstruction, drain the pus, collect the secretions for microbiological studies and also for biopsy.

Further investigations such as CT scan or MRI will be required in a few cases which do not run true to type.

Complications

Pulmonary: (a) Severe hemoptysis; (b) extension to other parts of the lung and to the other side; (c) pleurisy, empyema, and pyopneumothorax; and (d) local fibrosis and bronchiectatic changes.

Extrapulmonary complications: Brain abscess may develop due to metastases of septic emboli from the lung

which reach the cerebral circulation through the vertebral system of the veins (Batson's system).

Other complications include pulmonary osteoarthritis, emaciation and cachexia due to loss of large amounts of proteins (in the form of purulent sputum) and infection. If left untreated, lung abscess proves fatal.

Differential diagnosis: Lung abscess has to be differentiated from bronchiectasis, bronchogenic carcinoma, pulmonary tuberculosis, fungal infection, pulmonary cysts, and secondary neoplasms. Bronchiectasis is more chronic and usually bilateral. A cavitating bronchogenic carcinoma may resemble an abscess clinically and radiologically. Carcinoma is more common in smokers. The sputum is seldom profuse or purulent. It is more often blood stained with necrotic tissue being expectorated at times. Presence of hilar lymphadenopathy is suggestive of carcinoma. In cavitary pulmonary tuberculosis the sputum is mucoid and often not foul-smelling. Digital clubbing is less common. Tuberculosis affects the upper lobes more often, whereas abscess usually occupies the lower lobes. X-ray reveals thin walled cavities, without free fluid level.

In endemic areas, lung abscesses should be investigated for fungal pathogens by sputum tests and immunological studies. Cystic disease of the lung is often bilateral and present from early life. Radiologically the cysts appear thin-walled. Rarely cysts may be solitary. Digital clubbing is less marked in cystic disease of the lung.

Treatment: Principles of therapy include antimicrobial drugs, drainage of the abscess cavity and surgery in intractable cases.

Antibiotics: A properly collected sputum uncontaminated by oropharyngeal microbes should be sent for culture and sensitivity studies and the antibacterial drugs should be given in appropriate dosage till radiological clearance is complete. In most of the cases recovery is full in 4-6 weeks. Anaerobic infection has to be treated with metronidazole 500 mg given intravenously every eight hours. Drainage of the abscess is achieved by postural drainage and gentle tapotement over the chest. Respiratory physiotherapy to stimulate cough and help expectoration is instituted early. If clearance of the abscess is unsatisfactory, bronchoscopic aspiration may help. With proper medical treatment majority get cure.

Surgery: It is indicated in circumstances such as failure of medical treatment, residual fibrosis with bronchiectatic changes, suspicion of bronchogenic carcinoma, severe hemoptysis and pleural suppuration. If a reasonable course of medical treatment fails to bring about recovery, surgical resection of the abscess should be considered without undue delay. Risks of surgery are greater if the general condition of the patient has deteriorated.

Prevention of lung abscess: Lung abscess is largely preventable disease by preventing aspiration pneumonia. Other measures include prompt removal of bronchial obstruction, complete treatment of pneumonia, and early diagnosis of pulmonary suppuration.

Pleuropulmonary Amebiasis

Involvement of pleura and the lung are common complications of amebic liver abscess. Though primary metastatic infection of the lung can occur rarely, in over 90% of cases the infection is transdiaphragmatic. Direct spread from liver through transdiaphragmatic lymphatics results in pleural and pulmonary amebiasis. The common lesions are mild pleurisy, pleural effusion, empyema, consolidation, abscess formation, bronchopleural fistula and rarely bronchobiliary fistula. The empyema shows a tendency for encystment.

Clinical features: Pleuropulmonary amebiasis is commonly seen in the age group of 20-40 years and is more common in men, especially alcoholics. The initial symptomatology is that of liver abscess with fever, chills and pain over the right hypochondrium. The liver is enlarged, acutely tender and there is intercostal tenderness. Bulging and edema of the chest wall are also occasionally seen. Pleural and pulmonary involvement are accompanied by pleuritic pain, dyspnea, chocolate coloured sputum and hemoptysis. When there is a bronchobiliary fistula, the sputum is bile stained. Examination of the chest reveals signs of pleural effusion or consolidation depending on the lesion.

Diagnosis: This diagnosis should be suspected in right lower lobe lesions and right sided pleural effusions. Liver enlargement is present in most cases. Trophozoites of *Entameba histolytica* can be demonstrated in 20% of cases in the sputum or pleural fluid. X-ray shows elevated right hemidiaphragm with pleural effusion or pulmonary consolidation or abscess formation. Ultrasound examination is most helpful to reveal the abscess in the liver and other lesions in the abdomen. CT scan will reveal the lesion accurately.

Treatment: Systemic therapy with metronidazole and chloroquine helps to localize the lesion and full resolution in mild or even moderate cases. Secondary infection is to be treated with appropriate antibiotics. Presence of secondary infection can be assumed by examination of the aspirated pus.

In a few cases medical treatment suffices to clear the lesions. In moderate and large collections of pus and in the presence of high fever and toxemia suggestive of secondary infection, pleural aspiration or aspiration of the liver abscess is indicated.

Treatment 920

Prevention of Recurrence 922

Acute Severe Asthma 923

Tropical Pulmonary Eosinophilia (TPE) 924

Bronchial Asthma

The term ‘asthma’ in Greek means ‘breathless’ or ‘breathe with open mouth.’

Asthma is a common chronic inflammatory condition of the airways whose mechanism is not completely understood yet. Epidemiological studies suggest that multiple genetic and environmental factors contribute to the causation of asthma, a clinical condition that is viewed as a cluster of related disorders. Genetic factors contribute to the variability with regard to age of onset, sensitivity of environmental causes and response to treatment. One study has identified a metalloprotein ADAM-33 that may have a role in inflammatory response to smooth muscle hypertrophy or hypersensitivity.

Airway inflammation is associated with airway hyper-responsiveness, airflow limitation, and respiratory symptoms. Airway inflammation leads to limitation of airflow by acute bronchoconstriction, edema of the airway wall, formation of mucus plugs, and airway remodelling.

Around 0.5-2% of the population suffers from asthma. The tracheobronchial tree reveals increased responsiveness to immunological and non-immunological factors. Several organic dusts, fumes, and chemicals precipitate immunological mechanisms. Non-immunological stimuli include thermal, chemical or psychological factors.

Bronchial asthma used to be classified into the *extrinsic (atopic)* and *intrinsic (cryptogenic)* types. In the former an external precipitating factor is identifiable, whereas in the latter, it is not. The antigens include ingested, inhaled or parenterally administered substances. The serum of such individuals may show elevated levels of specific antibodies belonging to the IgE and sometimes IgG classes. Persons developing extrinsic asthma have other atopic manifestations like eczema. The dermatological and respiratory manifestations show a see-saw relationship. In many cases family history of bronchial asthma may be present. Extrinsic asthma generally sets in by the age of 10-15 years. This type has a better prognosis from the point of response to therapy and mortality.

The age of onset for intrinsic asthma is after 30 years. Precipitating causes or raised antibody levels are not evident but these patients show a higher frequency of eosinophilia, aspirin sensitivity, and nasal polyposis.

Common stimuli which precipitate extrinsic asthma are inhaled allergens like house dust, pollens, fungi, animal hairs, insect scales and industrial fumes, and foods and drugs which are consumed in day-to-day life. Once sensitization occurs, these antigens release chemical mediators from the mast cells by interacting with the IgE molecules on their surface. Type I hypersensitivity reaction ensues. Asthma can also be caused by Type III (delayed) hypersensitivity mechanism mediated by IgG. In some individuals both Type I and Type III reactions occur, the former leading to an immediate asthmatic paroxysm and the latter leading to a delayed episode.

Exercise-induced asthma is a problem in children and young adults, in which bronchoconstriction is provoked by various forms of exercise such as running or climbing stairs, but others such as swimming may not do so. Provocation of bronchoconstriction by cold inspired air is a possibility in such cases. In many cases the attacks are brought on straight by the exercise, but in the others asthma sets in several hours after the exercise. The mechanism is a Type I hypersensitivity reaction. Short

acting β_2 -agonists are used to prevent exercise- induced asthma. Inhaled steroids are indicated and are useful. Systemic steroids are seldom necessary.

Respiratory infection and psychological stress play important roles in precipitating asthmatic paroxysms in both types. Both viral and bacterial infections may trigger off a paroxysm and the episodes tend to recur as long as the infections persist. In children, asthma may be the presenting symptom in primary tuberculosis. In adults, asthma may be aggravated by co-existent pulmonary tuberculosis. Cigarette-smoking and air pollution act as aggravating factors. The role of psychological stress is more in perpetuating the asthma than initiating the condition.

Many cases show familial predisposition. The atopic background may be inherited. Members of such families show asthma, eczema, hay fever and similar manifestations. The genetic locus for IgE, which is a mediator of Type I anaphylaxis is situated in the long arm of chromosome 11q. Obesity worsens asthma.

Extrinsic Allergic Alveolitis

This is a group of disorders caused by the inhalation of organic dusts. These organic substances induce a diffuse immune complex reaction in the walls of alveoli and bronchioles, leading to bronchioloalveolitis.

Clinically all these disorders cause dyspnea and systemic disturbances such as headache, muscle pain, fever and malaise within a few hours of exposure to the antigen (Table 136.1). Physical examination may reveal wheeze and end-inspiratory crepitations. X-ray of the chest may reveal diffuse small nodular shadows, predominantly involving the upper lobes (Fig. 136.1). High resolution CT thorax shows bilateral consolidation (Fig. 136.2). Pulmonary function studies show restrictive ventilatory defect with normal FEV₁/FVC ratio. Avoidance of the allergen causes relief of symptoms and recovery in the early stages, but in advanced cases the symptoms continue. Diffuse pulmonary interstitial fibrosis develops in those cases where exposure to the antigen

Fig. 136.1: X-ray chest: Extrinsic allergic alveolitis
Note: Bilateral diffuse opacities lower zones

Fig. 136.2: HRCT extrinsic allergic alveolitis. Note: The diffuse thickening of the interalveolar septa and honeycombing

continues. Further complications include pulmonary hypertension and cor pulmonale.

Treatment consists of avoidance of the allergen and bronchodilators. In acute cases oral prednisolone 40 mg per day is indicated for 3-4 weeks, along with oxygen supplementation for hypoxemic patients.

Apart from these well-defined conditions, several forms of extrinsic allergic alveolitis occur in different occupational groups e.g. coir workers, cashew workers, workers in godowns and others.

PATHOLOGY

Inflammation of the airways is brought on by several factors. Eosinophils, T-lymphocytes (CD4+), macrophages and mast cells infiltrate the bronchial wall. The epithelium is vacuolated and the ciliated cells desquamate. Several cellular factors play their roles in the inflammatory process. Neuropeptides such as bradykinins, substance P and neurotensin A lead to bronchoconstriction and excessive secretion of mucus.

TABLE 136.1

Some common types of bronchioloalveolitis

Condition	Source
Farmer's lung	Mouldy hay, straw, grain dust
Bagassosis	Sugarcane dust
Byssinosis	Cotton dust
Mushroom worker's lung	Mushroom compost
Malt-worker's lung	Mouldy barley, malt dust
Maple bark stripper's lung	Mouldy bark
Bird fanciers' lung	Bird's droppings
Cheese worker's lung	Mouldy cheese

Fig. 136.3: Pathological features of asthma

Mast cells initiate the response on exposure to allergens, excessive osmotic changes and variations in temperature. Macrophages produce cytokines, which are either bronchoconstrictor or bronchodilator. Presence of eosinophils in the inflammatory exudate is characteristic of asthma. Eosinophils are derived from bloodstream. Major basic proteins and cationic proteins of eosinophils lead to destruction of mucosal surface. T-lymphocytes, especially CD4⁺ produce cytokines IL-3, IL-4, IL-5 and GM-CSF which modify the inflammation. TNF which is an inflammatory cytokine is expressed in greater amounts by mast cells. The broncho-alveolar secretions contain higher levels of TNF. Possibly platelet derived humoral factors also modify the inflammation.

The main chemical transmitters, which alter the airways, are histamine, prostaglandin and leukotrienes. These lead to contraction of bronchial muscle, increase in vascular permeability and excessive secretion of abnormal mucus (Fig. 136.3).

Airway inflammation persists for several years. Its severity correlates with the severity of asthma. Hyper-responsiveness of the inflamed airways is aggravated by autonomic and neural mechanisms. **The final result is obstruction of the small and medium sized airways brought about by mucosal edema, tenacious mucus and bronchoconstriction.**

CLINICAL FEATURES

The attacks start with dyspnea (often at rest), expiratory wheeze, and cough. The onset is abrupt in most cases. These attacks may occur seasonally or during all times of the year (perennial asthma). The attacks may last for several hours if untreated. Severity of the paroxysm varies. In the moderately severe case the patient is orthopneic and cyanosed, and the accessory muscles of respiration are active. There may be ineffective cough with only very scanty and tenacious mucoid expectoration. The asthmatic paroxysm in many individuals is ushered in by a bout of coughing and sneezing on exposure to the allergen. The pulse is rapid. Blood pressure is normal or elevated. In

severe cases pulsus paradoxus may occur. Expansion of the chest is considerably diminished, often to less than 2 cm during the attack. The diagnostic feature of bronchial asthma is the presence of expiratory wheeze heard all over the chest.

Once asthma occurs, the tendency is for the condition to persist for varying periods, even life-long, with remissions and exacerbations. About 50-60% of patients get cure or very considerable relief by altering their lifestyle such as change of residence, change of jobs, exercise programs including yoga exercises, changes of diet and others. Appropriate medication may improve the quality of life in the vast majority. 20-30% of patients are not free from asthma. However, attacks can be suppressed considerably by drugs. About 10% have severe disability despite active treatment. Allergic bronchopulmonary aspergillosis (ABPA) may develop in some asthmatic individuals.

Laboratory findings: These are often non-specific and they help to identify the coexisting disease. Some cases show moderate eosinophilia (10-15%). Examination of feces may reveal helminths, which may also contribute to the allergic reaction and increase in eosinophils. Sputum may reveal numerous eosinophils, mucus plugs and Curschmann's spirals (casts of smaller airways). Purulent sputum is indicative of respiratory infection. Culture reveals the infecting organisms. A simple method to infer whether infective or allergic causes trigger off paroxysm is to examine a Leishman's stain preparation of the sputum smear. Predominance of neutrophils suggests an infective cause whereas predominance of eosinophils suggests allergic etiology.

Identification of the allergen: Several tests have been introduced to identify the precipitating allergen. Intradermal tests are performed using a battery of antigens prepared from the common allergens prevalent in the area. In many instances the causative agent can be detected by the positive skin tests. These tests are of help in long-term management after tiding over the paroxysm.

Respiratory function tests reveal marked airway obstruction, which is relieved by the administration of bronchodilators.

Skiagram taken during the acute attack may show hypertranslucency due to emphysema but there may be no abnormality in between the attacks. It should be remembered that the radiological appearances and clinical severity show wide disparity in bronchial asthma.

Diagnosis

Diagnosis of bronchial asthma is clinical. The history of sudden attack of paroxysmal dyspnea, cough, and the auscultatory hallmark of expiratory wheeze heard all over the chest are diagnostic. Long duration of complaints,

history of allergy, and positive family history are other helpful clinical points.

Objective assessment of the severity of airways obstruction and response to bronchodilator therapy can be made by use of **bedside peak flow meter**. Respiratory function tests reveal gross reduction in FEV_1 , FEV_1/FVC ratio and peak expiratory flow rate (PEFR) and increase in the time taken for forced expiration. It is important to assess the severity of airways obstruction.

Confirmation of the diagnosis of asthma is usually achieved by serial peak expiratory flow rate (PEFR) monitoring. PEFR in the majority of cases shows a diurnal variation of more than 15% and improvement with therapy.

When it is necessary to investigate for provocative factors bronchial challenge testing or bronchial provocation testing (BPT) may be desirable.

Clinical features which indicate severe ventilatory impairment are given in the box.

1. Inability to narrate history continuously or severe distress even on mild exertion,
2. Cyanosis, flapping tremors,
3. Mental confusion,
4. Respiratory rate above 25/minute,
5. Heart rate persistently above 110/minute.
6. Inspiratory fall in blood pressure exceeds 16 mm Hg,
7. PEFR less than 40% of predicted value, and
8. Feeble breath sounds.

Differential diagnosis: Bronchial asthma has to be differentiated from other causes of paroxysmal dyspnea. These include chronic bronchitis emphysema syndrome (CBES), acute left-sided heart failure, acute bronchitis, tropical pulmonary eosinophilia, metabolic acidosis, and tracheal obstruction by foreign bodies or tumours.

It is important to distinguish left-sided heart failure (cardiac asthma) from bronchial asthma. Left-sided heart failure complicates valvular heart disease, systemic hypertension or ischemic heart disease. It causes paroxysmal dyspnea in the first half of the night whereas bronchial asthma is more common in the early hours of the morning. In bronchial asthma there is generalized wheeze all over the chest, whereas in cardiac failure, basal crepitations are more prominent, though generalized bronchospasm may also be evident at times. In heart failure, gallop rhythm may be evident. Careful search for the underlying disease may reveal the etiology.

TREATMENT

Treatment may be described under three heads: (1) treatment of the acute attack; (2) treatment in between attacks; and (3) treatment of acute severe asthma. Goals of asthma treatment are given in the box.

1. Prevent death (acute exacerbations of asthma)
2. Achieve and maintain symptom relief
3. Restore lung function and prevent relapse
4. Reduce the side effects of treatment
5. Control cost of management
6. Avoid complications

TREATMENT OF THE ACUTE ATTACK

At present the drugs of choice employed to stop an acute **attack are beta 2-agonist drugs**. They act mainly on the bronchial muscle as relaxants without much effect on the cardiovascular system. These include salbutamol, terbutaline, salmeterol, bambuterol and others. These can be given orally, as inhalations (aerosol or powder) or parenterally. The oral dose is effective within 15-20 minutes and the action lasts for 4-6 hours. The oral dose is; salbutamol 2-4 mg, terbutaline 2-4 mg and bambuterol 10-20 mg. These drugs can be given as metered dose inhalers. The usual dose ranges from 25-200 µg. Salmeterol is given as inhaled dose of 25-50 µg. These drugs are also usual components of cough syrup. Since larger doses of drugs are required for oral use, adverse side effects such as palpitation and tremours may occur in about 50% of patients. Aerosols are available as canisters of metered dose inhalers (MDIs) containing 100-200 doses. Each dose delivers 50-100µg of drug per puff. Good co-ordination of inhalation and pressure-actuation of canister is necessary for proper drug delivery. These have to be used prophylactically and therapeutically at the slightest warning of an impending attack. The dose being small, adverse side effects are minimal. The effect is immediate to set in and it may last for 4-6 hours. To avoid the chance of inadequate inhalation using aerosol sprays, spacers are available. The metered dose can be sprayed into the spacer, from which the patient can inhale it comfortably. Dry powder inhaler devices are delivery systems which provide the dose in powder form (rotahalers, acuhalers turbohalers and diskhalers). Dry powder devices are easier to operate as no co-ordination is required. Irrespective of type of delivery system, the patient has to be instructed and demonstrated the proper method of usage of the device. In any case the drug has to reach the lower airways, in order to be optimally effective.

Nebulizers, which can be carried by the patient or operated in the emergency room, are available for administration of these drugs. These can deliver larger doses as required. The drug solution is nebulized by passing oxygen or air under pressure through it.

Parenteral preparations of beta-adrenergic agonists are helpful when the paroxysm is severe and immediate relief is required.

Short acting β_2 -agonists (called 'relief medications') have no significant effect on the inflammatory response. Over-dependence on these agents has been established as one of the causes for fatal or near-fatal asthma attacks.

TABLE 136.2

Comparative daily dosage of commonly used inhaled steroids (in µg)						
Drug	Low daily dose		Medium daily dose		High daily dose	
	Adult	Child	Adult	Child	Adult	Child
Beclomethazone	200-500	100-250	500-1000	250-500	>1000	>500
Budesonide	200-600	100-200	600-1000	200-600	>1000	>600
Fluticazone	100-250	100-200	250-500	200-400	>500	>400

Corticosteroids: Glucocorticosteroids are currently the most effective anti-inflammatory medications for the treatment of asthma. They effectively improve lung function, decrease airway hyper-responsiveness, reduce symptoms, reduce frequency and severity of exacerbations, and improve quality of life. Inhaled corticosteroids are the preferred treatment for patients with asthma of all levels of severity. Patients requiring short acting β_2 -agonists more than 2 to 3 times a day should be treated with inhaled steroids. It is recommended that a starting dose of 400 µg/day for adults and 200 µg/day for children be employed. The dose must be titrated to the lowest dose, which maintains effective control of asthma. Parenteral, oral or nebulized steroids may be used in acute severe asthma. Often steroids are life-saving.

Table 136.2 gives comparative dosage of commonly used inhaled steroids.

Ill-effects of inhaled corticosteroids include oropharyngeal candidiasis and dysphonia. Systemic side effects develop, though this is less common than with oral preparations. Cataract may develop in some.

Indications for Short-course Oral Corticosteroid Therapy

- 1. Symptoms and PEFr deteriorate day by day (All acute forms of asthma).
- 2. PEFr less than 60% of the patient’s best PEFr.
- 3. Insomnia due to asthma.
- 4. Morning wheeze persists up to mid-day or even beyond.
- 5. Other treatments fail.

Sympathomimetic drugs: Acute asthma readily responds to sympathomimetic drugs. The time-honored drug, **adrenaline, 0.5 to 1 ml of 1:1000 aqueous solution** given subcutaneously relieves bronchospasm and terminates the paroxysm in minutes. Adverse effects include rise in BP, tachycardia, palpitation and precipitation of angina, especially in the elderly. Hurst’s method of administration is to deliver adrenaline subcutaneously in a dose of 1 drop every minute till the bronchospasm is relieved. With the advent of safer drugs, the use of adrenaline has been reduced but still in some cases where other drugs fail, adrenaline may give immediate relief.

Ephedrine used to be given widely in doses of 25 mg/ daily oral. Due to its adverse side effects, this drug is not

commonly used at present even though several anti-asthmatic preparations containing ephedrine are still in vogue.

Sympathomimetic drugs should be used with caution in hypertensives and elderly subjects with coronary artery disease or urinary obstruction. Fatal arrhythmias may be precipitated by repeated doses of these drugs.

Methyl xanthines: The common preparations include theophylline and etophylline. They can be given orally or as IV injections, singly or in combination.

Dose IV-combination vials of etophylline 169.4 mg and theophylline 50.6 mg to be given as slow IV injections or as IV drip in glucose 2-3 times daily. Tablets containing etophylline 77 mg and theophylline 23 mg are available for oral use to be taken 3-4 times daily. Sustained release tablets containing etophylline 150 mg and theophylline 35 mg are available to be taken 2-3 times daily.

Their beneficial effects include bronchodilation, synergistic action on the movement of the diaphragm, stimulation of the respiratory center and mild diuresis. When combined with β_2 -agonists they act synergistically.

Sustained-release preparations are preferred for oral therapy. Long-term treatment with sustained-release theophylline is effective in controlling asthma symptoms and improving lung function. Sustained-release theophylline is useful in the control of nocturnal symptoms and as an additional bronchodilator in patients with severe asthma. Theophylline may be used in patients with milder disease and as an add-on therapy to low or high doses of inhaled corticosteroids where further asthma control is needed.

Some patients with severe asthma attacks may benefit from intravenous aminophylline. For those who were not previously on oral xanthines, 5 mg/kg body weight is administered over 20 minutes, followed by an infusion at the rate of 0.5 to 0.7 mg/kg/h. Higher incidence of side effects such as palpitation, vomiting and arrhythmias is met with in some cases receiving intravenous aminophylline. Sometimes sudden vasomotor collapse or allergic manifestations may develop.

Anticholinergic agents: Since vagal tone accounts for bronchial muscle tone, anticholinergic drugs have been found to be beneficial in asthma. Inhaled ipratropium bromide and oxitropium bromide are bronchodilators that block the effect of acetylcholine released from cholinergic

nerves in the airways. These agents produce bronchodilation by reducing intrinsic vagal cholinergic tone to the airways. They also block reflex bronchoconstriction caused by inhaled irritants. They have no effect on airway inflammation. They are less potent bronchodilators than inhaled β_2 -agonists. They have a slower onset of action (30 to 60 minutes to maximum effect), but the effect is more sustained in duration.

Ipratropium bromide has an additive effect when nebulized together with rapid-acting β_2 -agonists for exacerbations of asthma. Usual dose is 0.25 to 0.5 mg by nebulizer every 4-6 hours or 20-40 μ g from a metered dose inhaler. It is useful as an alternative bronchodilator for patients who experience adverse effects of tachycardia, arrhythmia, or tremors from rapid-acting β_2 -agonists. Inhalation of ipratropium or oxitropium may cause a dryness of the mouth and a bitter taste. Unlike atropine, they do not cause mucociliary dysfunction, bladder neck obstruction or rise in intraocular pressure. Tiotropium bromide which is similar to ipratropium is available as rotacaps for inhalation- The dose is 18 μ g/inhalation, to be given once daily.

Complications of asthma: Though mortality is low, severe asthma may result in respiratory failure and death even in the most unexpected situation. Other complications include frequent respiratory infections, pulmonary collapse due to obstruction by viscid secretions, pneumothorax, mediastinal emphysema and cough fractures (fractures of ribs due to violent coughing). Children with asthma may show retardation of growth, especially if treated with systemic corticosteroids on a long-term basis. Longstanding bronchial asthma, punctuated with frequent respiratory infections may lead on to emphysema and chronic cor pulmonale.

Prevention of Recurrence

It is important to avoid known allergens, which can be identified. In the case of some allergens like house dust and pollen, desensitization can be achieved by repeated challenges.

Inhaled corticosteroids 200-800 μ g per day has been recommended as the treatment of choice for regular preventive therapy of asthma.

Long-acting inhaled β_2 -agonists (LABA) include formoterol and salmeterol. Their duration of action lasts for 12 hours or more. They relax airway smooth muscle, enhance mucociliary clearance, decrease vascular permeability, and may modulate mediator release from mast cells and basophils. LABA are indicated when initial doses of inhaled corticosteroids fail to achieve control of asthma. LABA must be combined with inhaled corticosteroids to control airway inflammation. Addition of LABA to inhaled corticosteroids improves symptoms, decreases nocturnal asthma, improves lung function, decreases the use of rapid-acting inhaled β_2 -agonists and reduces the number of exacerbations.

Cromones are a group of nonsteroidal anti-inflammatory medications. Administered as an inhalation they prevent the IgE-mediated mediator release from the mast cells. Sodium cromoglycate or nedocromil sodium may be used as preventive therapy in mild persistent asthma. Administered prophylactically, these medications inhibit allergen-induced airflow limitation after exposure to exercise, cold dry air, and sulfur dioxide. Therapy has to be continued for 4-6 weeks to determine its efficacy in individual patient. Usual dose of sodium cromoglycate is 20 mg every 6 hours. This drug should not be used during an acute attack since it may cause aggravation of the symptoms.

Anti-IgE: Binding of specific allergens to receptor-bound IgE on mast cells and basophils signals these cells to release preformed mediators (e.g. histamine) and synthesize other proinflammatory molecules (e.g. leukotrienes, cytokines, and chemokines). Subcutaneously administered anti-IgE blocks such a pathway in patients with moderate to severe asthma with an allergic component. It allows for reduction of oral/inhaled corticosteroids, and improves asthma control. Anti-IgE appears to be safe as add-on therapy and may reduce features of airway inflammation. It is an expensive modality of treatment.

Leukotriene receptor antagonist (Montelukast) is indicated as add-on therapy in mild to moderate asthma, which is not adequately controlled with an inhaled corticosteroid and a short acting beta-2 stimulant used as required. It reduces the dose of inhaled steroids in moderate to severe asthma. It may also be used to prevent exercise or drug induced asthma (e.g. aspirin-sensitive asthma). It is less effective than long-acting inhaled β_2 -agonists as add on therapy. Montelukast is given in a dose of 10 mg at bed time daily. These receptor analogues block the effects of cysteinyl leukotriene.

Anti-allergic H_1 -antagonists have mast-cell stabilizing properties. **Ketotifen**, when given in a dose of 1 mg twice a day as oral tablets on a long-term basis it reduces asthmatic paroxysms due to its inhibitory effects on the allergic response. It also helps to reduce the severity of allergic diseases of the eyes, nose and lungs. Its effects are fully established only when the drug is given regularly for 2 months or more. Sedation and weight gain are the prominent side effects of ketotifen.

Systemic steroid-sparing therapies: Steroid-sparing therapies include immunomodulators and macrolides. Examples include troleandomycin, methotrexate, cyclosporin, and gold. Their potential steroid-sparing effect may not outweigh the risk of serious side effects. Intravenous immunoglobulin has been shown to have some steroid-sparing effect, but this treatment is very expensive and has a high frequency of adverse effects.

Respiratory and other systemic infections should receive prompt attention. The appropriate antibiotic should be selected, based on microbiological tests. Tranquilizers,

TABLE 136.3 Levels of severity of acute asthma exacerbations	
Brittle asthma	– Wide PEF variability despite intense therapy. Sudden severe attacks on a background of well controlled asthma
Moderate asthma exacerbation	– Increasing symptoms – PEF >50-75% of best predicted value – None of the features of acute severe asthma
Acute severe asthma	Any one of the following: – PEF 33-50% of best/predicted – Respiratory rate ≥ 25/min – Heart rate ≥ 110/min – Inability to complete sentences in one breath
Life-threatening asthma	Any of the following in a patient with acute severe asthma – PEF < 33% of best/predicted, PEF not recordable – SPO ₂ < 92% – Central cyanosis – PaO ₂ < 8 kPa (60 mm Hg), especially on oxygen – Pa CO ₂ Normal (4.6-6.0 kPa) – Low pH – Silent chest, bradycardia, feeble respiratory efforts, dysrrhythmia, hypotension, exhaustion, confusion and coma
Near fatal asthma	– Raised PaCO ₂ and / or requiring mechanical ventilation

psychotherapy or suggestion under hypnosis may be useful adjuncts in persons with prominent emotional overlay.

Yoga and controlled breathing exercises are of considerable benefit in allaying the paroxysms.

Levels of severity of acute asthma exacerbations: Based on the severity of symptoms and signs, the Global Initiative. Against Asthma (GINA) has classified acute asthma exacerbations into 5 levels of severity, as detailed in Table 136.3.

ACUTE SEVERE ASTHMA

Acute severe asthma is a life-threatening emergency that places the patient at risk of developing respiratory failure. Patients are severely dyspneic, cyanosed, and often moribund. At this stage many of them are unresponsive to the ordinary bronchodilators. Dehydration may be evident.

Any patient of asthma may develop acute severe asthma as a complication. It may be precipitated by infection, allergic factors or psychological stress. Even in mild cases such paroxysms may supervene without warning. The attacks usher in either as progressive worsening of an existing paroxysm or sudden onset of severe dyspnea and air-hunger in a mild or moderate asthmatic. The attack may be so severe that the patient may not even be able to cry for help. Unless emergency care is given many of such patients may die of respiratory failure (Table 136.4).

MANAGEMENT OF ACUTE SEVERE ASTHMA

This is a medical emergency. This condition is generally unresponsive to conventional drugs administered in the

TABLE 136.4 Common risk factors for acute severe asthma	
• Use of more than 2 canisters per month of inhaled short-acting β₂-agonist • Two or more hospitalizations for asthma in the previous year • Past history of sudden severe exacerbations • Prior admission for asthma to an ICU • Prior intubation and ventilation for asthma • Current use of/or recent withdrawal from systemic corticosteroids • Co-morbidity such as cardiovascular diseases or chronic obstructive pulmonary disease • Serious psychiatric disease or psychosocial problems	

usual manner. Clinical assessment of the severity can be made from the intensity of dyspnea, cyanosis and inability of the patient to speak uninterruptedly. Estimation of peak expiratory flow rate gives an objective assessment of the condition.

GENERAL MEASURES

These involve (1) putting the patient to bed rest propped up with a back-rest, and (2) starting an intravenous infusion of normal saline. This aids in the administration of drugs and fluid replacement is essential to correct dehydration.

Emergency management: Patients should be hospitalized and managed in acute care facility as an emergency.

1. **Start oxygen** inhalation at the maximum possible concentration.

2. **Give rapid acting β_2 -agonists** inhalation in high doses immediately. Salbutamol (5.0 mg) or levosalbutamol (2.5 mg) is given, preferably using an oxygen-driven nebuliser. This dose may be repeated thrice at 15-30 minutes intervals. Four to six puffs of a metered dose inhaler administered using a large-volume spacer can be equally effective. Next choice is to give ipratropium bromide given either as nebulisation (0.5 mg) or as aerosol in a dose of 20-40 μ g, repeated at 4-6 hourly intervals. If inhalational therapy is not reliable, give salbutamol 500 μ g intravenously. Intravenous salbutamol helps to build up the blood level rapidly. For children the IV dose is 15 μ g/kg body weight.
3. **Hydrocortisone 200 mg or any** equipotent analogue (betamethasone 8 mg, dexamethasone 8 mg or methyl prednisolone 80 mg) is given as an intravenous push. Nebulised budesonide 0.5 mg every 12 hours may be of help to many patients. Prednisolone 10-15 mg is started simultaneously and repeated 6 hourly. Continue prednisolone 40-50 mg daily for at least 5 days.
4. **Intravenous aminophylline drip** may be started for maintenance therapy, if the patient is not on theophylline drugs already.
5. **Intravenous magnesium sulphate** (1.2-2.0 g given as IV infusion over 20 minutes) is a safe and effective treatment for those patients without good initial response to treatment.
6. Routine prescription of antibiotics is not indicated for acute asthma.

Sudden death may occur any time within 3-5 days of the acute episode and, therefore, such patients should be under surveillance for this period.

Ventilatory Assistance

If the condition does not respond to treatment or the respiratory embarrassment is increasing, ventilation should be assisted. If the secretions are tenacious and difficult to be expectorated, throat suction or bronchoscopic aspiration and bronchoalveolar lavage may be required. The indications are summarized in the box.

1. Pulses paradoxus
2. Central cyanosis despite O_2 inhalation
3. Deterioration of arterial blood gases despite treatment
 - a. $PaO_2 < 60$ mm Hg (8 kPa) and falling
 - b. $PaCO_2 > 40$ mm Hg (6 kPa) and rising
 - c. pH of 7.3 and falling
4. Extreme physical exhaustion
5. Clouding of consciousness, confusion, drowsiness
6. Coma, and
7. Respiratory arrest

Points to remember

Bronchial asthma is a very common disease. It may be mistaken for cardiac failure, hysterical hyperventilation or metabolic acidosis. Correct diagnosis and institution of emergency management in acute severe asthma is absolutely essential to save life. The common mistake committed by patients and doctors is to overlook the seriousness and emergency that can be caused by acute severe asthma.

Tropical Pulmonary Eosinophilia (TPE)

Syn: Weingarten's syndrome, pulmonary eosinophilosis

This common disease of the tropics is an immune hyper-response to filarial infection. It is characterized by an absolute eosinophil count of $2000/mm^3$ or more in peripheral blood, pulmonary symptoms and radiological changes, fever, dyspnea, and loss of weight. The disease is prevalent in India, Sri Lanka, Malaysia, Pakistan, Bangladesh, and several other tropical countries.

Etiology: Current evidence suggests that eosinophilia is an allergic reaction to helminthic parasites, particularly filarial worms. It is considered to be an immunologically mediated response to lymphatic filariasis in India. The role of filarial worms in the causation of tropical eosinophilia is suggested by several epidemiological, histopathological, and serological studies (See also section 6 chapter 70).

A constant and characteristic feature of TPE is peripheral blood eosinophilia ($2,000-50,000$ cells/ mm^3) in the presence of circulating filarial antibodies. A rapid response to diethylcarbamazine or positive serology will be diagnostic. If TPE goes untreated, there may be progression to chronic pulmonary fibrosis.

Pathology: Microscopically the lesion consists of inflammatory cell infiltration of several tissues. Lymphocytes and histiocytes are the initial invaders, later to be replaced by eosinophils. Lung biopsy shows an eosinophilic bronchitis and bronchopneumonia, with multiple small granulomas and areas of necrosis. Foreign body giant cells form tubercle-like nodules, surrounded by mononuclear cells. The extent of lesion is related to the duration of the disorder. While intact microfilariae are not generally seen, there may be fragments in the granulomas. The histological changes are not pathognomonic for tropical eosinophilia, since similar lesions may result from allergy to several other allergens.

CLINICAL FEATURES

The onset is insidious and the patients may come for treatment with several months' history. Males are affected more than females. The severity of symptoms does not correlate with the eosinophil counts. Many patients with

high eosinophil counts may remain asymptomatic. In some cases the onset may be acute resembling influenza, bronchial asthma or gastrointestinal disturbances. Patients may present with severe breathlessness, and nocturnal paroxysmal cough, accompanied by little sputum production. There is often a low-grade fever with occasional hemoptysis. Extrapulmonary manifestations occur in about 15% of patients and include splenomegaly, hepatomegaly, and lymphadenopathy. Blood samples show eosinophilia. No microfilaria is seen in peripheral blood. High IgE levels, seropositivity to filarial antibody, and rapid clinical improvement with administration of diethylcarbamazine are the hall marks of TPE.

The chronic form may present with exertional dyspnea, vague ill-health or asthmatic symptoms. Auscultation over the chest may show rhonchi with crepitations. Some cases present with fever, loss of weight, generalized lymphadenopathy, splenomegaly, and bleeding tendencies. The absolute eosinophil count ranges from 2000-10,000/mm³. In some cases the total leukocyte count may go as high as 30-40,000/mm³ and the eosinophils may form 70-90% of the total. All of them are mature eosinophils. The bone marrow shows infiltration by eosinophils and their precursors. If TPE goes untreated, there may be progression to chronic pulmonary fibrosis. Vast majority of cases are self-limiting and symptoms subside.

Skiagram of the chest reveals diffuse fine mottling with nodules 2-3 mm in size bilaterally in about 50% of cases. Miliary nodules or non-segmental, patchy opacities may be seen. Rarely the radiological features may be unilateral.

Diagnosis: Tropical eosinophilia should be suspected in all cases of respiratory disorders presenting with asthmatic symptoms of short duration. An absolute eosinophil count above 2000/mm³ is essential for making the diagnosis. Many patients show impaired lung function with reduction of vital capacity, total lung function, and residual volume. Some show combination of restrictive and obstructive features.

Tropical eosinophilia has to be distinguished from other parasitic infections, which cause lower degrees of eosinophilia, Loeffler's syndrome, aspergillosis, allergic alveolitis, bronchial asthma, and pulmonary tuberculosis. In bronchial asthma too, the eosinophils may be increased but the counts seldom reach the levels seen in tropical eosinophilia. Helminthic infections also cause moderate eosinophilia. These may be associated with respiratory symptoms. In these cases, eosinophilia clears up with de-worming. Loeffler's syndrome is the allergic respiratory features occurring during larval migration.

The course of tropical eosinophilia is benign with remission and exacerbation extending over several months or years. Death is rare, though a few cases have been reported.

Treatment: Drug of choice is diethylcarbamazine in a dose of 4-12 mg/kg/day for 10-14 days. In most of the cases the eosinophil count and symptoms subside promptly. Side effects are mild. These include headache, joint pains, anorexia, nausea, and vomiting. In a few cases there may be slight aggravation of respiratory symptoms at the start of treatment. Such cases respond to bronchodilators or corticosteroids. Prolonged follow-up is necessary, since the condition is likely to recur. Relapses also respond promptly to diethylcarbamazine.

C. Sudheendra Ghosh, Dinesa Prabhu V.

Chapter Summary

Acute Bronchitis 925

Chronic Bronchitis 926

Bronchiectasis 930

Emphysema 932

Pulmonary Collapse 933

Acute Bronchitis

This is acute inflammation of the bronchi and its ramifications. This is characterized by cough, discomfort behind the sternum, scanty expectoration to start with, later developing productive cough. In healthy individuals,

the infective agents are viral to start with, later bacteriae such as pneumococcus or *H. influenzae* may complicate the picture. At this time the sputum becomes purulent. In patients with underlying disease such as chronic bronchitis and emphysema, and in heavy smokers bacterial superinfection is the rule. Physical examination of the chest reveals wheeze and at times scattered crepitations.

In otherwise healthy subjects the disease subsides in 1-2 weeks with simple therapy with analgesics, expectorants and simple antibiotics such as ampicillin or cotrimoxazole. In those with underlying parenchymal diseases the primary condition is exacerbated and recovery is much slower.

Chronic Bronchitis

Chronic bronchitis is defined as a disease characterized by hypersecretion of mucus sufficient to cause cough and sputum on most days for at least three months in a year for two or more consecutive years. This happens in the absence of any other specific respiratory or cardiovascular disease.

In the initial stages the inflammation of the bronchi is intermittent and recurrent, later it becomes established. The larger air passages are affected during the early part of the disease, later obstructive features set in when the smaller airways are also affected. Infection leads to periodic aggravation of the symptoms and the sputum, which is mucoid, becomes purulent during these episodes. As the airways obstruction progresses, emphysema sets in. These two processes become established in the majority of cases so that the condition is termed **chronic bronchitis emphysema syndrome (CBES)**. The disease is more common in damp, cold, and dusty regions. Atmospheric pollution is accompanied by a higher incidence of CBES.

Chronic Obstructive Pulmonary Disease (COPD) is a major cause of chronic morbidity and mortality throughout the world. The Global Initiative for Chronic Obstructive Lung Disease was created to increase awareness of COPD among health professionals, public health authorities, and the general public, and to improve prevention and management through a concerted worldwide effort. Chronic Obstructive Pulmonary Disease (COPD) is a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases.

The most important risk factor for COPD is cigarette smoking. Pipe, cigar and other types of tobacco smoking popular in many countries are also risk factors for COPD. Passive exposure to cigarette smoke also contributes to respiratory symptoms and COPD.

Other documented causes of COPD include occupational dusts and chemicals (vapours, irritants, and fumes) when the exposures are sufficiently intense or prolonged.

Indoor air pollution from biomass fuel used for cooking and heating in poorly ventilated dwellings. Outdoor air pollution, which adds to the lungs total burden of inhaled particles, although its specific role in causing COPD is not well understood.

Symptoms of COPD include:

Cough

Sputum production

Dyspnea on exertion

Episodes of acute worsening of these symptoms often occur. Chronic cough and sputum production often precede the development of airflow limitation by many years, although not all individuals with cough and sputum production go on to develop COPD.

Pathogenesis

Chronic obstructive pulmonary disease (COPD) is a descriptive term given to the syndrome seen mostly in the elderly, who have airflow obstruction, not completely relieved by therapy. At least three distinct pathological processes may occur concurrently or separately in different subjects lead to COPD.

These are:

1. Emphysema which is due to destruction of alveolar walls
2. Chronic bronchitis with hypersecretion of mucus, and
3. Asthma with airway remodeling.

COPD encompasses chronic obstructive bronchitis with obstruction of small airways and emphysema with enlargement of air spaces, destruction of lung parenchyma, loss of lung elasticity and closure of small airways.

The inflammatory process in COPD differs from that in asthma in several ways. The type of inflammatory cells, inflammatory mediators, final outcome and response to treatment are different. In COPD the inflammation affects the peripheral airways-the bronchioles. The cells are macrophages, CD₈ lymphocytes and neutrophils. The lung parenchyma is affected. Unlike as in asthma there is no preponderance of eosinophils.

Oxidative stress also plays a significant role in the pathogenesis. Even though the lungs bear the main brunt of the disease, systemic effects also occur. Muscle weakness and wasting may develop as part of the systemic disorder.

Pathology: The bronchial mucosa shows hypertrophy and increase of the mucous glands and goblet cells with consequent overproduction of viscid mucus. The distal airways show narrowing of lumen caused by increased height of the epithelium and increased thickness of the muscle and connective tissue. The mucosa becomes ulcerated and when the ulcers heal, fibrosis occurs resulting in distortion of the lumen with stenosis and dilatation.

Distortion of the airways leads to permanent obstruction. Secondary infection occurs in the later stages. The ciliary movement is further impaired by the abnormally viscid mucus. This aggravates infection and a vicious cycle is established.

Severe recurrent infections cause the development of microabscesses in the bronchial wall. These heal with fibrosis. Squamous metaplasia occurs. Distortion and obstruction of the bronchial lumen result in air trapping and emphysema of the alveoli, some show collapse and fibrosis. The main pathological process can be summarized as follows:

- 1. Inflammation of the bronchi with enlargement of mucous glands and smooth muscle hyperplasia, all leading to wall thickening
- 2. Acinar distension due to the destruction of lung parenchyma probably mediated by imbalance of protease-antiprotease (alpha-1 antitrypsin) enzymes causing loss of support of small airways
- 3. Fibrosis and narrowing of the airways leading to increase in airway resistance.

The capillary bed is distorted and truncated and this aggravates the progression of pulmonary arterial hypertension. The pulmonary arteries become distended and atheromatous. Pulmonary hypertension gives rise to right ventricular hypertrophy and dilatation. Chronic cor pulmonale supervenes as time passes.

CLINICAL FEATURES

The clinical picture is varied depending on the severity and duration. The most frequent early symptom is cough recurring year after year, especially so in winter months. Later the cough becomes constant. Expectoration is mucoid and the sputum is tenacious, especially on waking up in the morning. Main complaint is the feeling of tightness of the chest. Physical examination reveals mild wheeze which disappears as the patient clears the bronchi by expectoration. Variable degrees of bilateral rhonchi and coarse crepitations are heard as adventitious sounds. Initially acute infections give rise to fever and purulent sputum. As the infection becomes established, fever and other general symptoms come down. At this stage the quantity and character of the sputum are more reliable indicators of infection. The sputum becomes copious in amount when bronchiectatic changes develop.

With the development of emphysema the chest assumes the inspiratory position and the respiratory excursions are considerably diminished. At this stage dyspnea is far out of proportion to the physical findings in the chest.

Key Indicators for Considering the Diagnosis of COPD

Chronic cough: Present intermittently or every day. Often present throughout the day; seldom only nocturnal

Chronic sputum production: Any pattern of chronic sputum production may indicate COPD
Acute bronchitis: Repeated episodes
Dyspnea that is: Progressive (worsens over time)
Persistent (present every day)
Worse on exercise
Worse during respiratory infections
History of exposure to risk factors: Tobacco smoke (including popular local preparations)
Occupational dusts and chemicals and smoke from home cooking and heating fuel.

DIAGNOSIS

Chronic bronchitis should be diagnosed from the history of recurrent cough extending over several years, mucopurulent sputum and the physical findings of bronchial obstruction and emphysema. X-ray is normal in the early stages but the features of emphysema may be evident later. X-ray may be helpful in identifying precipitating conditions like pneumonia, pneumothorax during the time of an exacerbation. HRCT is useful in quantifying the severity of emphysematous changes and locating areas with bronchiectatic changes.

Lung function tests show reduction in vital capacity, increase in the closing volume and features of airway obstruction (Fig. 137.1). Based on the spirometry values severity of obstruction can be categorised as mild, moderate severe and very severe.

Differential diagnosis: Chronic bronchitis has to be distinguished from asthma. Differentiation is easy in the early stages but there is considerable overlap of symptoms and signs in the advanced stages, and, therefore, the clinical assessment is difficult.

Other conditions like pulmonary tuberculosis, bronchiectasis, heart failure and bronchogenic carcinoma, obliterative bronchiolitis, diffuse pan bronchiolitis have to be ruled out in atypical cases.

Course and prognosis: Established chronic bronchitis is incurable. Over several years the condition progresses to

Fig. 137.1: Example of spirometric tracings and calculation of FEV₁, FEV₁/FVC ratio in normal and COPD

produce complications and death. Each infective exacerbation leads to further deterioration in lung function and precipitates the development of respiratory failure and cor pulmonale. Exacerbation can occur as a result of bacterial infection of the lower respiratory passages, viral infections of the respiratory tract or due to non-infective causes such as environmental allergens and pollutants.

Complications: These include:

- 1. Frequent respiratory infections,
- 2. Respiratory failure, and
- 3. Right-sided heart failure (cor pulmonale).

MANAGEMENT

General measures: Most effective single step to prevent deterioration is to stop smoking. This single measure itself affords considerable relief of symptoms. Environmental allergens and pollutants must be avoided by the patient.

Other general measures include improvement in general health, regular exercise, deep-breathing exercises, adequate sleep, treatment of obesity, and eradication of foci of sepsis in the throat, nose and paranasal sinuses. If these measures are started during the early phase of the disease, further progression can be arrested.

Drugs: Apart from the general measures, no active treatment is indicated in the early stages.

Treatment

Treatment of infective episodes: A broad spectrum antibiotic should be employed for 7-10 days during an

infective episode. Tetracycline or ampicillin may be started initially. Depending on the microbiological tests, the antibiotic may have to be changed.

Bronchospasm has to be relieved by the use of bronchodilators such as aminophylline, salbutamol or any other β -agonist. Ipratropium bromide is an anticholinergic muscarine receptor blocker, which blocks vagal reflexes responsible for bronchoconstriction. It is indicated when bronchospasm is troublesome (see box).

Ipratropium bromide delivered by a metered dose inhaler in a dose of 40-80 μ g helps to relieve bronchospasm without appreciable side effects. In COPD response of the airways to ipratropium is excellent. Tiotropium is a newer analogue which is equally effective.

Inhibitors of inflammatory response: Since inflammation plays a major role in the pathogenesis of COPD newer pharmacological agents are under trial. These include mediator antagonists which are capable of counteracting the effects of leukotrienes, lipooxygenases, interleukin B, tumor necrosis factor and the like. Protease inhibitors which inhibit neutrophil elastases, cathepsin and anti-inflammatory agents such as phosphodiesterase inhibitors are all in the process of development.

Several newer drugs especially phosphodiesterase-4 inhibitors are under trial. Roflumilast is a drug of this class given in a dose of 250 or 500 mg orally daily for 24 weeks. Results are encouraging.

Use of N-acetyl cysteine or bromhexine hydrochloride 8 mg thrice daily orally helps to liquefy the sputum. Steam inhalations help to improve vital capacity, relieve

TABLE 137.1

Therapy at each stage of COPD					
Old	0: At Risk	I: Mild	II: Moderate		III: Severe
			IIA	IIB	
New	0: At Risk	I: Mild	II: Moderate	III: Severe	IV: Very Severe
Characteristics	• Chronic symptoms • Exposure to risk factors • Normal spirometry	• FEV₁/FVC <70% • FEV₁ $\geq$ 80% • With or without symptoms	• FEV₁/FVC <70% • 50% $\leq$ FEV₁ <80% • With or without symptoms	• FEV₁/FVC <70% • 30% $\leq$ FEV₁ <50% • With or without symptoms	• FEV₁/FVC <70% • FEV₁ < 30% or FEV₁ <50% predicted plus chronic respiratory failure
Avoidance of risk factor(s); influenza vaccination					
Add short-acting bronchodilator when needed					
Add regular treatment with one or more long-acting bronchodilator, Rehabilitation					
Add inhaled glucocorticosteroids if repeated exacerbations					
Add long-term oxygen if chronic respiratory failure. Consider surgical treatments					

Commonly Used Formulations of Bronchodilator Drugs				
Drug	Metered dose inhaler (µg)	Nebulizer (mg)	Oral (mg)	Duration of action (hrs)
β₂-agonists				
Fenoterol	100-200	0.5-2.0	-	4-6
Salbutamol (albuterol)	100-200	2.5-5.0	4	4-6
Terbutaline	250-500	5-10	5	4-6
Formoterol	12-24		-	12+
Salmeterol	50-100		-	12+
Anticholinergics				
Tiotropium	18			
Ipratropium bromide	40-80	0.25-0.5	-	6-8
Oxipropium bromide	200		-	7-9
Methylxanthines				
Aminophylline (SR)	-	-	225-450	Variable, up to 24
Theophylline (SR)	-	-	100-400	Variable, up to 24

emphysema and open up the airways by expectorating the sputum.

Nonpharmacological measures: Noninvasive positive pressure ventilation and oxygen therapy at home using a simple nasal mask which eliminates the need for endotracheal intubation is beneficial. Long-term oxygen therapy has shown improved survival with better quality of life.

Pulmonary rehabilitation: Structured programme of education and exercises is very effective. Blowing into an air pillow repeatedly for 10-15 times twice a day and bending over a pillow held firmly on to the abdomen, in order to push the diaphragm up during expiration are simple maneuvers which can be practised at home.

Management of chronic respiratory failure: When hypoxemia becomes severe, i.e. PaO₂ below 55 mm Hg or SaO₂ below 80% at rest, continuous oxygen inhalation may have to be instituted for at least 18 hours a day. Oxygen therapy helps to reduce pulmonary arterial tension and allay cor pulmonale. In intractable cases lung transplantation may have to be considered.

Lung volume reduction surgery (LVRS): This has been found to be useful in selected cases. The rationale for this technique is to reduce the volume of over inflated emphysematous lung by 20-30%, in order to improve the elastic recoil of the lungs, to improve the configuration of the diaphragm, chest wall mechanics and gas exchange.

Lung transplantation: This procedure is in vogue for more than a decade in advanced countries, it is still not available in India. Transplantation of a single lung or both heart and lungs as a whole is possible. Transplantation

should be considered if the recipient is below 55 years of age, and is free from underlying conditions such as advanced diabetes, malignancy, hepatic or renal failure and conditions which impair mechanics of the chest wall.

The donor should be ABO and HLA compatible with normal lungs, preferably between 12 and 50 years of age and with normal cardiopulmonary anatomy. Usually cadaver lungs are used for transplantation. Complications may occur as in the case of any other major organ transplantation.

Indications

- 1. Incurable respiratory failure—chronic or acute due to pulmonary causes
- 2. Irreversible structural and functional abnormalities in the lung such as fibrosis, extensive bronchiectasis, cystic disease, emphysema and others.

Appendix

Standard guidelines have been laid down by several National Societies for management of COPD. Tables 137.1 to 137.3 give the recommendations of the British Thoracic Society.

ACUTE EXACERBATIONS OF COPD

Tables 137.2 to 137.4.

Assessment of Bronchodilator Response

If there is an increase of at least 15% of the baseline FEV₁ or at least 200 mL it is considered beneficial (British Thoracic Society).

TABLE 137.2

Indications for hospital assessment or admission for acute exacerbation of COPD

- Marked increase in intensity of symptoms, such as sudden development of resting dyspnea.
- Severe background COPD.
- Onset of new physical signs (e.g. cyanosis, peripheral edema).
- Failure of exacerbation to respond to initial medical management.
- Significant co-morbidities.
- Newly occurring arrhythmias.
- Diagnostic uncertainty.
- Older age.
- Insufficient home support.

TABLE 137.3

Medical Research Council modified dyspnea scale for breathlessness during daily activities

Grade 0	No breathlessness.
Grade 1	Breathless with strenuous exercise.
Grade 2	Short of breath when hurrying on the level or walking up a slight hill.
Grade 3	Walks slower than people of the same age on the level or stops for breathe while walking at own pace on the level.
Grade 4	Stops for breath after walking about 100 yards.
Grade 5	Too breathless to leave the house or breathless when dressing or undressing.

TABLE 137.4

Hospital discharge criteria for patients with acute exacerbations of COPD

- Inhaled β_2 -agonist therapy is required no more frequently than every four hours.
- Patient, if previously ambulatory, is able to walk across the room.
- Patient is able to eat and sleep without frequent awakening by dyspnea.
- Patients have been clinically stable for 12-24 hrs.
- Arterial blood gases have been stable for 12-24 hrs.
- Patient (or home caregiver) fully understands correct use of medications
- Follow-up and home care arrangements have been complemented (e.g. visiting nurse, oxygen delivery and meal provisions).
- Patients, family and physician are confident patient can manage successfully.

Bronchiectasis

Permanent dilatation and distortion of the bronchi is called bronchiectasis.

Etiology and pathogenesis: Most of the cases of bronchiectasis result from acquired causes.

1. Obstruction to the bronchus due to any cause leads to distal collapse of the pulmonary segment. The pull on the bronchi by the collapsed alveoli leads to dilatation of the bronchi. In the initial stages this is reversible and the bronchi regain their normal size when the lung expands. If the obstruction persists, accumulation of mucus occurs distally, infection supervenes and the bronchial wall is destroyed permanently. This results in permanent dilatation. The infective organisms are streptococci, pneumococci, klebsiella, and anaerobes.
2. Bronchiectasis may follow several viral infections without passing through the obstructive phase.
3. Congenital defects in the bronchial wall lead to bronchiectasis. The classical example is *Kartagener's syndrome*, which is characterized by dextrocardia, situs inversus, sinusitis, and defects of ciliary function in the bronchi and non-motile sperms.
4. Middle lobe bronchiectasis is a sequel to pulmonary tuberculosis. This is caused by obstruction to the middle lobe bronchus by tuberculous glands. This is called "**middle lobe syndrome**" or "**Brock's syndrome**".

Pathophysiology

Bronchiectasis is primarily a disease of bronchi and bronchioles involving a vicious circle of transmural infection and inflammation with mediator release. Bronchial mucosa shows infiltration by neutrophils and T lymphocytes. The expectorated sputum has higher content of elastase and chemoatracants – interleukin – 8, TNF α , and prostanoids. The lesions may be localized or diffuse and generalized.

CLINICAL FEATURES

The clinical picture is very chronic, extending over several years. The common site of lesion is the left lower lobe. Though children may be affected, usually symptoms manifest in early adulthood or middle age. Males are affected more than females. Digital clubbing is a prominent sign, sometimes being associated with hypertrophic pulmonary osteoarthropathy.

Postural cough with the production of large quantities of purulent and foul smelling sputum is the presenting complaint in most cases. On standing the sputum settles into 3 layers as described under lung abscess. Hemoptysis may occur frequently. This may be mild or severe. Recurrent infections such as pneumonia may develop. Repeated affection of the same lobe or segment should suggest the possibility of underlying bronchiectasis.

Bronchiectasis sicca is the condition in which bronchiectasis presents with mild or severe hemoptysis without purulent sputum.

Physical examination may reveal impairment of the percussion note and diminution of respiratory sounds over

Fig. 137.2: Cystic bronchiectasis. Note: The cystic areas in both lower zones

the affected area. The diagnostic finding is the presence of coarse, persistent leathery rales.

Complications

At times bronchiectasis may present with one of its complications. These include massive hemoptysis, recurrent pneumonia, emphysema, septicemia, brain abscess, and cor pulmonale. Anemia develops in long-standing cases due to chronic sepsis and recurrent hemoptysis. In untreated cases secondary amyloidosis may develop.

Diagnosis: Bronchiectasis should be diagnosed by the long history, presence of clubbing, postural cough, coarse leathery rales over the affected part and reasonably normal general health. Once established, bronchiectasis is not curable by medical treatment.

Differential diagnosis: Bronchiectasis should be distinguished from chronic bronchitis and emphysema, lung abscess, tuberculosis, congenital cystic disease of the lung, pulmonary sequestration and malignancy.

Lung abscess generally develops acutely. The right lower lobe is affected more often and the signs are localised. Tuberculosis is more common in the upper lobes, and clubbing is not prominent in uncomplicated cases. Features like digital clubbing and copious sputum are seen in tuberculous bronchiectasis. Cystic disease is not uncommon. All age groups are affected. A long history of recurrent respiratory disease is present in the majority of cases. Clubbing is not prominent. The cysts may be localized or generalized. Clinical distinction from bronchiectasis is difficult. Presence of cysts in other organs like the kidneys, liver, etc. suggests the probability of congenital cystic disease of the lung. X-ray reveals the presence of soap bubble-like or ring shadows (Fig. 137.2).

Pulmonary sequestration is a developmental anomaly where a portion of the lung receives aberrant blood supply

Fig. 137.3: Pulmonary sequestration HRCT. Note: The vascular anomaly at the site of sequestration

usually from the abdominal aorta. Patient may present with recurrent hemoptysis and other features of bronchiectasis (Figs 137.3 and 137.4).

Diagnosis can be confirmed by bronchography which helps to determine the extent and type of bronchiectasis. The lesion may be sacular, fusiform or cylindrical. Plain X-ray of the chest is not a reliable investigation to assess the site and extent of bronchiectasis. High resolution computed tomography (HRCT) has become the investigation of choice to assess the lesions in bronchiectasis. Availability of HRCT has eliminated the need for bronchography.

Management: General measures include high protein diet, treatment of intercurrent infections, and removal of focal sepsis from the upper respiratory tract.

Principles of specific therapy include postural drainage, administration of antibiotics, respiratory exercises and in selected cases, surgical excision. Postural drainage helps to clear the bronchi and bring about relief. The patient should be instructed to practise postural drainage

Fig. 137.4: Pulmonary sequestration: Aortogram showing aberrant arterial supply from thoracic aorta

regularly. This gives relief of cough and also the foul smell. The fetid odor of the breath can be controlled by administering steam inhalations containing tincture benzoin co. or eucalyptus oil. The choice of antibiotic is determined by microbiological studies. Intermittent antibiotic therapy is required to clear infection and prevent exacerbation. The site of lesion may have to be excised if medical treatment fails.

Indications for Surgery

1. The disease is localized to one lung or one segment and is not amenable to medical therapy;
2. Socioeconomic factors such as noncompliance by the patient;
3. Uncontrollable hemoptysis in which the site of origin of blood may be detected by emergency bronchoscopy and surgical resection has to be planned;
4. To reduce the area of infection. Even in bilateral disease sometimes surgical resection may have to be done on the more affected side, with a view to reduce the surface area of infection; and
5. To remove an obstructive lesion which tends to perpetuate the condition e.g., bronchial growth or bronchostenosis.

Emphysema

Definition: Emphysema is defined as a pathological increase in the size of airspaces distal to the terminal bronchioles, with destruction of the alveolar walls. The term hyperinflation is used to denote non-pathological overdistension.

Etiology

Diseases of the airways: Chronic bronchitis, prolonged exposure to irritants and dusts (heavy cigarette smoking), and chronic partial bronchial obstruction.

Conditions associated with alpha-1 antitrypsin deficiency: Persons who have alpha-1 antitrypsin deficiency develop emphysema by the third or fourth decade of life.

Chronic bronchial asthma leads on to emphysema as a sequel. Persons who have to hold breath for prolonged periods for diving under water for collecting shells, clay and the like develop emphysema over a period of 15-20 years. *Bidi* or cigarette smoking and repeated respiratory infections accelerate the process.

Several pneumoconioses give rise to emphysema as part of the pathological process or as compensatory mechanism, e.g. coal worker's pneumoconiosis, silicosis.

Occupational causes: Several occupations which require forced expiratory effort as seen in furnace blowers, goldsmiths, and users of wind instruments predispose to the development of emphysema in susceptible subjects.

Exposure to cadmium leads to the development of emphysema and pulmonary fibrosis.

Pathology: The lungs are in the inflated position occupying the whole of the pleural cavity. Since the elastic tissue is damaged, the lungs lose their elasticity and they fail to collapse when the chest is opened during autopsy. The diaphragm is depressed and respiratory excursions are diminished. The alveoli are overdistended. The septa rupture and neighbouring alveoli coalesce to form air cysts. The pulmonary vascular bed is progressively diminished and pulmonary arterial hypertension results. Reduction of alveolar surface area leads to impairment of gas exchange. Right ventricular hypertrophy and cor pulmonale may develop. Emphysematous bullae may rupture to produce spontaneous pneumothorax.

CLINICAL FEATURES

The main symptom is exertional dyspnea. As the condition progresses, even ordinary activity like talking, eating or lying flat may cause dyspnea. The chest is distended in the position of full inspiration. Expansion is diminished and the accessory muscles of respiration are active. Expiration becomes an active process due to loss of elasticity of the lung. Infective episodes occur frequently.

Physical examination reveals barrel-shaped chest with diminished expansion, hyper-resonance on percussion, obliteration of cardiac and liver dullness and diminished breath sounds with prolonged expiration. Due to increased intrathoracic pressure especially during expiration, the neck veins become distended during expiration and collapse during inspiration. The apex beat is felt feebly because of interposition of the distended lung. Right ventricular hypertrophy produces a heaving impulse in the epigastrium and subxiphoid region. Left parasternal heave may not be evident on account of the inflated lung covering the heart (Fig. 137.5).

Special Forms of Emphysema

Compensatory emphysema: This is the condition in which the normal lung tissue undergoes hypertrophy to compensate for extensive damage to the other lung or other parts of the same lung. Being a compensatory phenomenon, this is asymptomatic. The respiratory excursion of the normal lung is increased in this case.

Atrophic emphysema: This condition is the result of senile atrophy of inter-alveolar septa. The total lung volume is not increased.

Bullous emphysema: In this condition air spaces exceeding 1 cm in diameter develop either congenitally or as a part of acquired generalized emphysema. With passage of time these bullae enlarge and become giant bullous emphysema. They may rupture to produce

Fig. 137.5: X-ray chest—Emphysema. Note: The inflated position of the rib cage, lower level of the diaphragm and hypertranslucent lung fields

Fig. 137.6: Multiple bullae-infected. Note: Large thin walled cystic spaces on the right and abscess containing air and fluid in the left lung

pneumothorax. At times the bullae may get infected to produce abscesses (Fig. 137.6).

Alpha-1 Antitrypsin Deficiency

Alpha-1 antitrypsin (AAT) is one among the serine protein inhibitors which occurs in the plasma. It is an inhibitor of neutrophil elastase. It has also got anti-inflammatory properties. AAT is a glycoprotein normally secreted by the liver and circulating in blood. It moves with the alpha-I band on serum protein electrophoresis. 90% of the trypsin-inhibitory activity of serum is attributable to AAT.

From the plasma, AAT diffuses into lung tissues, where it acts as an anti-elastase, the elastase being secreted

by neutrophils. Elastase is capable of destroying the connective tissue framework of alveolar walls. Excessive destruction of alveolar walls may lead to emphysema. Cigarette smoking which predisposes to accumulation of neutrophils in the lung aggravates the destructive process. Cigarette smoke also inhibits AAT directly. AAT deficiency may be congenital or acquired. The gene frequency of the defect occurs in 1 in 2000 to 1 in 5000 of the population. In the congenital form it is transmitted as an autosomal recessive. More than 75 alleles of AAT gene are known. In the inherited form the hepatic production of AAT is less than 15% of normal.

Patients with AAT deficiency develop panacinar emphysema by the third or fourth decade of life. The congenital form may also be associated with hepatitis and jaundice in the newborn and cirrhosis liver in adults. Such patients show accumulation of abnormal AAT in hepatocytes.

AAT deficiency can be treated by replacing AAT by IV infusion weekly or monthly to individuals whose serum AAT levels are below 1 mmol/L and who have abnormal lung functions. AAT for therapeutic purposes is obtained from pooled plasma. AAT can also be administered as an aerosol.

Pulmonary Collapse

When a portion of the lung becomes airless it is termed collapse or atelectasis. Collapse may be present from birth, when a portion of the lung fails to expand. Acquired collapse is more common and this is caused by absorption of air from a previously normal lung.

Causes

Obstruction to the air passages: The air passages may be obstructed by intraluminal or extraluminal causes.

1. Foreign bodies which may be inhaled accidentally or aspirated by comatose patient.
2. Tumours of the bronchus: Carcinoma, adenoma, bronchial stenosis.
3. Copious secretions and thick plugs of mucus.
4. Extrinsic pressure on the bronchus by lymph nodes, tumours, etc., e.g. middle lobe syndrome in pulmonary tuberculosis.
5. Pneumothorax and pleural effusion.

In bronchial obstruction the air already present in the alveoli is absorbed. The lobe or segment shrinks due to its inherent elastic recoil. Functional impairment depends upon the extent of lung tissue affected.

CLINICAL FEATURES

Symptoms depend upon the extent of collapse and its onset. Acute lesions are more symptomatic than chronic ones. Small areas of atelectasis may be asymptomatic. Massive collapse gives rise to dyspnea with or without

Fig. 137.7: X-ray chest. Pulmonary collapse. Note: 1. The uniform opacity with clearcut concave margins. 2. Shift of trachea to the affected side

cyanosis. The movement of the affected side is reduced and the chest is flattened. Trachea and cardiac apex are shifted to the same side. Percussion note over the affected

side is diminished. Breath sounds are absent or diminished. Adventitious sounds are usually absent.

Investigations

1. *Radiology:* Skiagrams show the collapsed portion as homogenous opacities with sharp concave borders. Both the posteroanterior and lateral views are required for proper localization (Fig. 137.7).
2. *Bronchoscopy:* It is necessary to visualize the affected bronchi.
3. *Bronchography:* It reveals the actual site and nature of the block.

Complications and sequelae: Pulmonary collapse leads on to infection, abscess formation, and fibrosis of the affected segment. Bronchiectasis may develop as a late sequel.

Management: Emergency measures include removal of the obstructive cause and physiotherapy to expand the lung. Antibiotic therapy should be started to prevent aspiration pneumonia. Pleural diseases must be treated promptly to prevent permanent damage to the lungs.

Prevention: Proper physiotherapy and measures to protect the respiratory tract from aspiration of gastric contents go a long way to prevent pulmonary collapse.

138

Occupational Lung Diseases
Syn: Pneumoconiosis

Chapter Summary

- General Considerations 934
- Silicosis 935
- Coal Worker's Pneumoconiosis 936
- Asbestosis 936
- Byssinosis 936

General Considerations

934 The term pneumoconiosis was coined by Zenker in 1866 to define a group of diseases caused by inhalation of dusts-

organic or inorganic. Inorganic dusts such as silica, asbestos or coal dust and organic dusts such as mouldy hay, cotton dust or sugarcane dust may lead on to pneumoconiosis. At present several occupations are known to be associated with this risk. More and more entities are likely to be recognized with the expansion of industry (Table 138.1).

Development of the pathological lesions depends upon several factors such as the nature of the substance inhaled, the concentration in the atmosphere, duration of exposure, particle size, and responsiveness of the individual. Particles below 10 µm in size reach the alveoli.

TABLE 138.1

Common causes of pneumoconiosis in India	
Condition	Industry
1. Silicosis	Mining, ceramics, potteries, foundries, metal grinding, stone crushing, agate grinding, slate pencil industry.
2. Coal workers' pneumoconiosis	Coal mining
3. Asbestosis	Asbestos cement, asbestos textile, asbestos mining and milling.
4. Byssinosis	Cotton textile industry

Alveolar macrophages carry them to the interstitial space where inflammatory reaction sets in. The process continues over the years and leads to gross functional and structural changes resulting in severe morbidity.

Lesions caused by inorganic dusts range from minimal inflammatory reaction around the dust particle to more marked changes like focal emphysema, interstitial fibrosis and calcification. Some dusts like asbestos are carcinogenic. In some disorders such as silicosis, the host's immune mechanism is altered making them more susceptible to develop tuberculosis.

Several organic dusts are widely distributed in the agricultural belts of India. They exert deleterious effects by local irritation, sensitization to the components of the dust or sensitization to fungal contaminants. They cause damage principally on the alveolar ducts to produce extrinsic allergic alveolitis.

The factors which lead to the final picture depend upon the substances inhaled. In general, they are:

1. Mechanical blockage,
2. Chemical irritation of the airways, chlorine and acid fumes,
3. Direct toxicity to the lung parenchyma, e.g. phosgene, methyl isocyanate,
4. Fibrosis, e.g. silica,
5. Sensitization, e.g. dander of animals, fungi, cotton dust,
6. Chronic granulomatous processes, e.g. beryllium toxicity
7. Predisposition to secondary infection, e.g. silicosis predisposes to tuberculosis, and
8. Neoplasia, e.g. asbestos.

Genetic factors modify the susceptibility to develop pneumoconiosis. On exposure, susceptible persons show early signs of ill-health, whereas the others are relatively immune. Other factors such as tobacco smoking, nutrition, and infections also may have roles in determining the final outcome in individual subjects. Industrial legislation requires adequate protective steps to be undertaken by establishments to safeguard against the development of pneumoconiosis amongst the workers.

SILICOSIS

Silicosis is the irreversible fibrosis of the lungs caused by inhalation of free silica dust (silicone dioxide). Over 3 million people working in various types of mines, ceramics, potteries, foundries, metal grinding, stone crushing, agate grinding, slate pencil industry, etc. are occupationally exposed to free silica dust and are at potential risk of developing silicosis. Silicosis may occur in combination with anthracosis. This is a major cause of permanent disability and mortality. In India it was first reported from Kolar gold mines, Karnataka in 1947.

The silica particles are ingested by the phagocytes, which accumulate and block the lymphatic channels. The lesions produced by silica dust are similar to those produced by coal dust, but the lesions are larger. In addition, silicosis also gives rise to pleural thickening and adhesions. Sometimes silicosis produces acute respiratory manifestations with dyspnea and impairment of gas exchange in the alveoli.

CLINICAL FEATURES

In the acute form the disease manifests with dyspnea, cyanosis and constitutional disturbances. In the chronic form the prominent manifestations are cough and hemoptysis. Physical signs may be those of bronchitis, emphysema, and pleural thickening. Silicosis predisposes to the development of tuberculosis and the two diseases may coexist (silicotuberculosis). The functional impairment is a combination of restrictive and obstructive features. Immunological abnormalities such as the presence of rheumatoid factor may develop in 50% of cases.

Radiology: Diffuse miliary or nodular lesions are found in simple silicosis. Chest radiograph may show snow-storm pattern. Development of progressive massive fibrosis leads to the presence of dense shadows in the upper zones and this is termed "complicated silicosis". Hilar lymph nodes may show peripheral calcification. Occasionally patients with silicosis develop scleroderma.

Fig. 138.1: X-ray chest—progressive massive fibrosis

COAL WORKER'S PNEUMOCONIOSIS

Syn: Anthracosis

Prolonged exposure to coal dust causes anthracosis among miners. These particles give a black colour to the lesions. Coal particles reaching the alveoli are ingested by the alveolar macrophages. The phagocytes are activated by the presence of substances like silica. Fibrosis develops at these regions. The affected lobules undergo centri-lobular emphysema. On prolonged exposure, progressive massive fibrosis (PMF) develops and this is the characteristic lesion in complicated pneumoconiosis. Radiologically the lesions of progressive massive fibrosis appear as sausage-shaped densities exceeding 1 cm in diameter, in the upper and mid zones of both lung fields (Fig. 138.1). Further complications such as chronic bronchitis, bronchiectasis, ischemic necrosis, thrombosis of pulmonary veins, pulmonary hypertension, cor pulmonale, or lymphatic obstruction may supervene.

Fig. 138.2: X-ray chest—Caplan's syndrome.
Note: The large nodular shadows

14

CLINICAL FEATURES

Gradual onset of dyspnea and cough with purulent expectoration mark the onset of the disease. Expectoration is more copious when bronchiectasis is also present. Dyspnea worsens when progressive massive fibrosis supervenes. Cavitation of these lesions gives rise to expectoration of huge amounts of black sputum. Large nodular lesions develop in the lungs in subjects with rheumatoid disease who develop pneumoconiosis. These lesions are 1-5 cm in diameter and detectable radiologically (Caplan's syndrome) (Fig. 138.2).

Asbestosis

Inhalation of asbestos dust leads to asbestosis. It is a complex silicate containing silicon, oxygen, hydrogen and

metals like calcium, magnesium, and iron. The raw material is obtained by mining. Different varieties of asbestos such as chrysotile, crocidolite, amosite and anthrophyllite are obtained from different regions.

Asbestos particles are needle-shaped and on account of this shape these preferentially settle in the lower lobes. They may reach the alveoli or may be arrested at the small air passages. They give rise to alveolar epithelial hyperplasia and interstitial fibrosis. Eventually fibrosis develops around the asbestos particles and this obliterates the alveoli. Fibrosis in asbestosis is due to mechanical irritation and it is peribronchial and diffuse in character.

Asbestos bodies are seen on histology of the lesions. These consist of asbestos fibers coated by proteinaceous material and ferritin granules derived from macrophages. Asbestos bodies may be demonstrable in the sputum. Mere presence of asbestos bodies in sputum is not sufficient to diagnose asbestosis. Asbestos fibers occur in two forms. The long thin fibers are called amphiboles (blue asbestos). The other one is the feathery form known as chrysotile or white asbestos. Both are carcinogenic, the former is more so. The pathogenesis of mesothelioma in the pleura involves four steps. These are (1) irritation of tissue (2) damage to mitotic spindle (3) generation of iron-related reactive oxygen molecules and damage to DNA and (4) phosphorylation of kinases. Pleural mesothelioma is an aggressive tumour of the serosal surface of the pleura. Widespread exposure to asbestos has increased the incidence of pleural and peritoneal mesotheliomas.

Asbestosis predisposes to bronchogenic carcinoma (especially in smokers) and mesothelioma of the pleura and peritoneum. It also predisposes to pulmonary tuberculosis. Malignancies of distant organs such as kidneys and breasts are more common in subjects with asbestosis.

Clinical features: The symptoms start with increasing dyspnea on exertion, cough, malaise, and weight loss. As the condition proceeds, cyanosis and digital clubbing supervene. The pulmonary functional defect is one of restrictive defect and impairment of diffusion. The clinical picture differs from case-to-case, depending on the extent of the lesion and presence of other coexistent conditions such as emphysema, bronchiectasis, tuberculosis, malignancy or pleural disease.

Radiologically, fine mottling and prominent streaky fibrosis are seen in the middle and lower zones. Pleural thickening, pleural effusion, and calcification may be evident in some cases.

Byssinosis

Pulmonary disease caused by exposure to cotton dust, flax or hemp is termed byssinosis. In the early stages the symptoms are tightness of the chest and wheeze usually felt by the patient when he resumes work after the weekly holiday. Later on cough and dyspnea become more prominent and persistent. Some subjects develop chronic obstructive airways disease. Persons employed in the carding section suffer more than those employed in other areas.

Cotton dust stimulates histamine release from mast cells in the lung. Pure cotton such as surgical cotton does not provoke the symptoms. The occurrence of dyspnea and cough at the beginning of the week and its subsidence during the working week is attributed to depletion of the mast cells of their histamine.

Radiological findings are non-specific. Treatment consists of withdrawal of susceptible persons from the environment and symptomatic measures.

Numerous other disorders have also been recognized as resulting from occupational exposure to different

TABLE 138.2	
Criteria for diagnosis of occupational lung disease	
1.	There should be an exposure to known, documented, hazardous agent
2.	The timing of exposure and onset of symptoms should be appropriate.
3.	The clinical syndrome should be consistent with the syndrome related to exposure.
4.	There should be no other more likely explanation for the signs and symptoms.

materials. It is beyond the scope of this text to describe all of them. Industrial medicine has assumed the importance of a sub-specialty, which includes occupational health hazards, trauma, exposure to toxins, effects of physical agents on health and legal problems arising out of these.

Management: Once established, pneumoconiosis is treated symptomatically since specific therapy is lacking.

Prevention: Workers who are employed in industry should be recruited only after proper pre-employment medical examination. Persons with family history of allergic respiratory disorders and those who have features of obstructive airway disease are more likely to develop permanent ill effects. Periodic examination of the workers to facilitate early detection and removal from the harmful environment is required by legislation. Industrial establishments where the risk of pneumoconiosis is present have to follow specifications intended to reduce the concentration of dust in the environment and also for giving protection to the workers. Many of the pneumoconiosis attributable to occupational exposure are eligible for compensation from the employers. Table 138.2 gives the general criteria for diagnosis.

139

Pulmonary Fibrosis

14

C. Sudheendra Ghosh, Dinesa Prabhu V.

Chapter Summary

- Replacement Fibrosis 938
- Interstitial Fibrosis 938

Definition: The term describes the abnormal formation of fibre like scar tissue in the lungs. There are over 140 known causes or associations with PF. The lung reacts to the insult by inflammation and subsequent fibrosis.

TABLE 139.1

Gives the causes of pulmonary fibrosis

Type of fibrosis	Causes
1. Replacement fibrosis	Pulmonary tuberculosis Bronchiectasis Lung abscess Pneumonias Fungal infections Pulmonary infarction Atelectasis Chronic pleural effusion Empyema Lipoid pneumonia Irradiation of lung
2. Focal fibrosis	Pneumoconiosis
3. Interstitial fibrosis	Fibrosing alveolitis Allergic alveolitis Connective tissue diseases 1. Progressive systemic sclerosis 2. Rheumatoid lung Asbestosis Sarcoidosis Radiation injury Pulmonary hemosiderosis Chronic pulmonary edema of long standing

Lung parenchyma has no power of regeneration. Hence destructive lesions lead on to fibrosis. Fibrosis of the lung parenchyma may take three forms—*replacement fibrosis*, *focal fibrosis*, and *interstitial fibrosis* (Table 139.1).

Replacement Fibrosis

In this form fibrous tissue is laid down over areas of lung destruction. The fibrosis is often localized and its extent depends on the extent of parenchymal destruction. The most common cause in India is pulmonary tuberculosis. The upper lobes are affected more frequently.

Clinical Features

The chest is asymmetrical with flattening of the affected side, drooping of the shoulder and diminution of movement. Trachea and mediastinal structures are pulled towards the same side, unless they were already fixed by pre-existing disease. The percussion note is diminished. Vocal fremitus and vocal resonance depend upon the severity of fibrosis. In extensive fibrosis they are reduced. If a major bronchus lies subjacent to the fibrotic area the vocal fremitus and resonance are increased and breath sounds become bronchial. In extensive fibrosis, especially fibrothorax, the breath sounds are considerably diminished.

Adventitious sounds may be heard and these are variable. Symptoms and hemodynamic disturbances depend upon the extent of pulmonary lesions and the cause.

Replacement fibrosis has to be distinguished from pulmonary collapse in which there may be ipsilateral shift of midline structures. Pulmonary collapse is usually of shorter duration and the underlying cause may be evident

Focal Fibrosis

This is seen in pneumoconiosis such as silicosis. The extent of fibrosis may vary from small nodular lesions to extensive areas (*progressive massive fibrosis*).

Interstitial Fibrosis

This is the end result of interstitial lung diseases. Interstitial fibrosis may result from allergic alveolitis, connective tissue disorders such as progressive systemic sclerosis and rheumatoid disease, cryptogenic fibrosing alveolitis, radiation injury to the lung, sarcoidosis, asbestosis, chronic pulmonary edema (occurring in mitral stenosis), and idiopathic pulmonary hemosiderosis.

Pulmonary fibrosis where the aetiology is unknown is termed as **Idiopathic Pulmonary Fibrosis (IPF)**. A common pathogenetic sequence occurs in most of the conditions leading to interstitial fibrosis, regardless of the etiology. The development of fibrosis follows injury to the alveolar walls that results from noxious agents which reach the alveolar walls either through vasculature or the airways. Studies show that the process begins with injury to alveolar wall and activation of coagulation cascade. Following injury, there is an influx of inflammatory and immunologically active cells which lead to alveolitis. The inflammatory cells and the mediators which are released produce oxidants resulting in continuous injury. This may induce connective tissue proliferation and remodeling in the lung by increase in the fibroblast. When alveolitis persists and progresses, this can result in partial or complete effacement of the alveolar capillary gas exchange apparatus. The resulting derangement of alveolar and interstitial architecture leads to functional and circulatory disturbances.

Clinical Features

The symptoms are those of ventilatory and diffusion defects, predominantly characterized by dyspnea, cyanosis, frequent respiratory infections, and chronic cor pulmonale. Physical examination may reveal gross clubbing, tachypnea, cyanosis, and diminished respiratory movements. Since these changes affect both lungs, there is no marked shift of midline structures. Breath sounds are diminished. Diffuse rales (crackles) which persist after coughing are characteristic. *The classical end inspiratory velcro crackles are present in IPF*. X-ray of the chest may show generalized loss of translucency and increased reticulation. Pulmonary function test will show restrictive pattern, usually decreased vital capacity. Earliest change

Fig. 139.1: HRCT of pulmonary interstitial fibrosis.
Note: The thickening of interalveolar septa

may be reduction in diffusion capacity. HRCT is very useful in assessing the nature of the lesion, extent of disease, and monitoring progress (Fig. 139.1). In advanced cases, traction bronchiectasis and subpleural honeycombing may be seen. Lung biopsy is useful for confirmation.

Cardiac findings include right ventricular enlargement and hypertrophy, and loud pulmonic second sound indicating pulmonary hypertension.

Course and prognosis: Replacement fibrosis does not usually progress further. The course of the disease and longevity depend on the extent of the lesion, occurrence of secondary infections and the development of cor pulmonale. In general, with reasonable care, localized fibrosis is compatible with prolonged survival. Diffuse interstitial fibrosis is progressive in most cases and life is considerably shortened. Death is due to respiratory failure or cardiac failure.

Management: General measures include the avoidance of smoking, treatment of intercurrent infections, reduction of weight and respiratory exercises. No definite treatment is available. Various drugs which block collagen synthesis and inhibitors of fibrogenic cytokines are under trial. Corticosteroids and immuno-suppressants are the main stay of treatment. But less than 20% of IPF patients respond to corticosteroids. High dose N-acetyl cysteine 600 mg tds orally added to the standard therapy – prednisolone and azathioprine preserves the vital capacity and improve the diffusion capacity. Long-term results are awaited. Fibrinolytic agents like pirfenidone are also being tried.

Cardiac complications are treated suitably. Lung transplantation is the only answer to those who do not respond to medical therapy.

Chapter Summary

Pulmonary Edema 939

Pulmonary Thromboembolism 940

Pulmonary Edema

ACUTE PULMONARY EDEMA

Acute pulmonary edema is a common medical emergency which can be brought about by diverse causes. There is accumulation of extravascular fluid within the lung. The mechanisms include rise in the pulmonary wedge pressure, changes in the dynamics of flow of fluids and

protein through the capillary walls and changes in the interstitium. Fluid may accumulate in the interstitium or in the alveoli.

Common Causes

1. Left-sided heart failure, e.g. acute myocardial infarction, hypertensive cardiac failure or mitral stenosis.
2. Aspiration of gastric contents (Mendelson's syndrome).
3. Neurogenic disorders such as subarachnoid hemorrhage, meningitis, encephalitis or brainstem injury with resultant depression of respiratory center

4. Fluid overload, e.g. overtransfusion of fluids, acute nephritic syndrome.
5. Drug hypersensitivity, e.g. hexamethonium, nitrofurantoin, busulphan.
6. Change in permeability of capillary wall, e.g. acute glomerulonephritis.
7. Narcotic poisoning with depression of respiratory center.
8. Irritant gases, e.g. phosgene, chlorine, acid fumes
9. Other forms of poisoning like paraquat, weedicides, organophosphorus.
10. Pulmonary embolism.
11. Uremia, aspiration of pleural effusion.

Rarer causes: Hanging, high altitude pulmonary edema, hypoproteinemia, disseminated intravascular coagulation, falciparum malaria, near-drowning, and pneumothorax.

Clinical features: Acute pulmonary edema ushers in with intense dyspnea, anxiety, and sweating. At its early phase the only obvious abnormality may be tachypnea. When fluid collects in the alveoli, the patient expectorates copious amounts of white or pink frothy sputum. Auscultation reveals widespread rales and occasional rhonchi. Initially the lower lobes are affected. Cyanosis may develop and it becomes deeper. Death occurs due to respiratory failure. Examination of the heart may reveal evidence of left-sided heart failure such as gallop rhythm or the presence of valvular lesions. See also chapter 116.

Management: Emergency management is indicated to save life. Cardiac causes have to be treated as for acute left-sided heart failure. The main steps in treatment include the administration of oxygen, frusemide, digitalis, aminophylline and vasodilator drugs. Physiological or open venesection may be required as an emergency rarely. The underlying cause should be attended to, after instituting the life-saving emergency measures. When pulmonary edema follows the inhalation of irritant fumes, massive doses of corticosteroids may be beneficial. In narcotic poisoning use of antidotes such as naloxone may help in bringing about dramatic improvement. Artificial ventilation is indicated in cases where respiratory failure develops. In addition, all the general principles of management of poisoning have to be adopted.

CHRONIC PULMONARY EDEMA

This occurs in chronic heart failure caused by mitral stenosis or left ventricular cardiomyopathy. The lungs are edematous, congested and brown on section (*brown induration*). Hemosiderosis may occur in long-standing cases. X-ray shows signs of chronic pulmonary venous congestion. Dilated interlobar septal lymphatics (Kerley's B lines) are seen. When pulmonary hemosiderosis develops, miliary shadows are seen in the radiograph. Treatment of cardiac failure clears the pulmonary edema as well in early cases.

Hypostatic congestion: This condition may develop in chronically bed-ridden patients due to diminished circulation, local anoxia, and infection. Hypostatic congestion can be prevented by early ambulation, respiratory physiotherapy, and adequate treatment of infection.

Pulmonary Thromboembolism

(See also Chapter 127)

Occlusion of the pulmonary artery or its branches by emboli constitutes pulmonary embolism. The emboli reaching the lungs usually originate from thrombosis of peripheral veins—particularly the calf vein and pelvic veins. It occurs in persons who are seriously ill due to other primary diseases. Pulmonary embolism may be acute and massive or recurrent and multiple.

Incidence: Acute pulmonary thromboembolism is detectable in 2-15% of all autopsy cases. The incidence reported from the West is very high (above 60%). Pulmonary embolism is more commonly associated with severe infection and dehydration. Probably there is a lower incidence of venous thrombosis and embolism in Asians and Africans compared to those in the West. It is possible that many cases are missed during life.

Conditions which predispose to pulmonary embolism:

1. Prolonged immobilization resulting from medical ailments and surgery or trauma, particularly involving the pelvis, abdomen and legs,
2. Diseases of veins of the lower extremities,
3. Congestive cardiac failure,
4. Pregnancy, contraceptive pills containing estrogens, and postpartum state,
5. Obesity,
6. Systemic malignancy, especially if widespread,
7. Hematological disorders such as polycythemia vera and chronic myeloid leukemia, and thrombophilic states
8. Miscellaneous conditions such as heat stroke, massive burns, and shock.

The widespread use of oral contraceptive pills has led to increase in the incidence of pulmonary thromboembolism in women, particularly in the age group 34-44 years. Women with previous episodes of thrombophlebitis or embolism are especially at risk. Pulmonary embolism tends to recur in survivors of the initial episode in up to 40%. Though the source of the embolus is not always evident, it is likely that in most of the cases veins of the legs and pelvis are the primary sources.

Clinical manifestations: The clinical features of pulmonary thromboembolism may be non-specific and vague in many cases. In some cases low grade fever may be caused by venous thrombosis. The intensity of

Fig. 140.1: X-ray chest: Pulmonary infarct. Note: The triangular opacity with the base towards the pleura

symptoms depends on the extent of pulmonary vascular obstruction and the development of pulmonary infarction.

Acute massive pulmonary embolism: This occurs as a grave medical emergency. In this condition more than 50% of the cross-sectional area of the pulmonary arterial tree is occluded. It manifests with sudden dyspnea, anginal pain, hemoptysis and circulatory collapse in a patient who is apparently well and progressing from other underlying disorders. The patient becomes cyanosed, convulsive and comatose. Cardiac auscultation reveals loud pulmonary second sound. Some cases present with signs of acute right ventricular failure with raised jugular venous pressure and hepatomegaly. If not relieved in time, a massive pulmonary embolus is rapidly fatal within minutes. Clinically acute massive pulmonary embolism may mimic acute myocardial infarction or dissecting aneurysm of the aorta. In acute myocardial infarction and dissecting aneurysm, hemoptysis is uncommon except when acute pulmonary edema develops. Electrocardiogram shows evidence of right ventricular strain and in a patient who had normal ECG, sudden development of right ventricular strain should raise the possibility of massive pulmonary embolism.

Examination of the lower limb may show edema or tenderness along the veins in some cases. *Homan's sign* may be elicitable in a few. In many, there may be no local signs to suggest venous thrombosis.

Submassive pulmonary embolism: This presents with the classic triad of symptoms consisting of cough, pleuritic pain, and hemoptysis. The patient may be dyspneic if the lesion is extensive. Physical examination reveals the presence of pleural rub and signs of consolidation. This classic clinical picture of pulmonary infarction usually

takes 3 to 5 days to develop. Infarction occurs only in 10-20% of cases. Fever may result from tissue necrosis and this may be mistaken for an infective episode. About 50% of those with infarction develop hemorrhagic pleural effusion.

Radiological features: The radiological features are not constant and they do not bear any direct correlation with the extent of arterial occlusion. Radiological abnormalities include elevation of the ipsilateral hemidiaphragm, pleural effusion, and linear opacities suggestive of atelectasis. 'Westermark' sign is the presence of diminution of vascular markings in a localised area which is seen in some cases. The main pulmonary artery may be distended. Pulmonary infarct produces a triangular opacity with the base of the triangle towards the pleura and its apex towards the hilum (Hampton's hump) (Fig. 140.1).

Symptoms and Signs of Pulmonary Embolism

Symptoms	Signs
Dyspnea	Tachycardia
Cough	Tachypnea
Substernal chest pain	Crackles
Sweating	Wheezes
Syncope	JVP elevated
Hemoptysis	Right ventricular gallop
Later pleuritic pain	Loud pulmonic second sound

Electrocardiogram: Classic ECG abnormalities develop only in a few cases. These include:

1. Prominent S-wave in leads I and II with the development of Q-wave and T-wave inversion in lead III;
2. T-wave inversion in V_1 - V_4 ;
3. Evidence of right bundle branch block in some cases;
4. Tall-peaked P-waves which reflect right atrial hypertrophy as a result of pulmonary hypertension; and
5. Arrhythmias such as tachycardias, ectopics and atrial fibrillation.

The acute electrocardiographic changes usually subside within a week.

Pulmonary angiography: This is the most specific method which unequivocally demonstrates pulmonary arterial obstruction. The common findings include abrupt "cut off" or amputation of lobar or segmental arteries and intraluminal filling defects.

Lung scan findings: Isotope lung scan is a useful investigation to demonstrate segmental perfusion defects (Fig. 140.2).

Course: The pulmonary vascular obstruction starts resolving within hours of its onset. Recovery depends upon several factors such as presence of collateral circulation, underlying pulmonary disease and the general

Fig. 140.2: Scintiscan pulmonary embolism. Note: The isotope does not reach the affected side (left side)

condition. About 25% of patients with mild embolism recover completely within two weeks.

MANAGEMENT

Emergency management: The patient is put to bed. Oxygen is administered and closed chest cardiac massage is started. An effective closed chest cardiac massage, in addition to restoring cardiac output, may help in fragmenting the thrombus and driving it into peripheral branches. If shock ensues, this should receive prompt attention. All cases should be assessed for thrombolytic therapy, early in the disease. In many cases this is a life-saving measures.

The patient should be transported rapidly to a centre where thrombolysis can be undertaken.

Thrombolytic therapy: This is employed to dissolve the clots already formed and recanalize occluded vessels. The most widely used enzymes are streptokinase, urokinase and tissue plasminogen activator (tPA). All are very effective in dissolving the clot. Streptokinase, is given in a dose of 1.2 mega units in 200 mL of dextrose in the first 1-2 h and then 100,000 units/hour for 24-48 h for maintenance. Urokinase is given IV in a dose of 4400 IU/kg over 10 minutes, followed by 4400 IU/kg hourly for 24 hours.

Recombinant human tissue type plasminogen activator (rtPA) acts locally at the site of clot formation with only less of generalized effect. 50 mg is given as IV bolus, repeated after 3 minutes, the total dose being 100 mg. The cost of 100 mg exceeds Rs.50,000. Once thrombolysis is achieved heparinization has to be continued. Thrombolytic agents can be given systemically IV or locally into the obstructed artery. Details of thrombolytic therapy are given in Chapter 124.

Anticoagulant therapy: Anticoagulant therapy is intended to prevent thrombosis and extension of the clot which is formed. It has no action on clot which has already been formed.

Heparin: Heparin is a very effective and widely used anticoagulant given parenterally. The usual dose is 10000-15000 units initially and maintenance dose is 5000 units/6 h. The drug is given intravenously or deep intramuscularly. The optimum effect is maintained by adjusting the dose by doing activated partial thromboplastin time (APTT) which is maintained at 1.5-2 times the normal control value. Low molecular weight heparin (LMWH) is effective, safer, and more frequently used at present despite its higher cost.

Oral anticoagulants: These are required as follow-up therapy in those who have peripheral venous thrombosis and those with conditions which predispose to thromboembolism. Warfarin or phenindione is given in appropriate doses to maintain the INR between 2.5 and 3 for periods varying from 6 months to several months.

Newer anticoagulant drugs: For acute anticoagulation several newer drugs have been introduced. These include fondaparinux which is a Factor X inhibitor. The direct thrombin inhibitors lepirudin, hirudin, and argatroban are currently available for use in heparin induced thrombocytopenia or thrombosis when heparin is contraindicated. Danaparoid is also available. Therapeutics of these anticoagulants is given in section 15 chapter 165.

Surgical therapy: Emergency removal of clots from the pulmonary artery is a heroic measure which is successful at times.

Surgical Prophylaxis

Since the veins of the pelvis and the lower limbs are the sources of pulmonary embolism, inferior venacaval ligation has been accepted as a procedure of choice to prevent recurrent pulmonary thromboembolism. Other elegant methods include the implantation of an umbrella device in the inferior vena cava which filters off emboli from travelling centripetally. Definite indication for surgical thrombectomy is recurrent thromboembolic pulmonary hypertension from an identified focus, especially when thrombolysis is contraindicated.

Prophylaxis: In all situations where confinement to bed is essential, regular physiotherapy to the lower limbs and breathing exercises help to prevent venous thrombosis. Heparin given in a dose of 5000 units subcutaneously 2 hours prior to surgery, and thereafter 5000 units 12 h until the patient is ambulant has been advocated in high risk patients. A combination of anticoagulant with compressive pneumatic stocking is found to yield better results.

Patients with single attack of venous thrombosis without any predisposing factor should receive anticoagulant therapy for 6 weeks, those with recurrence should receive medication for 12 months to indefinite periods.

Chronic Thromboembolic Pulmonary Hypertension

See also Chapter 127.
This is the result of multiple and recurrent microemboli obstructing the pulmonary vasculature. Patients who have thrombophilia and those with sources for recurrent emboli are possible candidates. The clinical picture may resemble that of primary pulmonary hypertension from which this condition has to be differentiated. The pulmonary artery pressures are elevated. Pulmonary angiography may help to delineate the vascular lesion in some cases, but not in the majority. Isotope scans and right heart catheterisation help to determine the extent and severity of the lesions. ECG helps to demonstrate the degree of enlargement and hypertrophy of the right sided cardiac chambers. Echocardiography can be used to estimate the pulmonary artery pressure and for serial follow-up.

Pulmonary Arterial Hypertension

It is a disease of the small pulmonary arteries that is characterized by vascular proliferation and remodeling. It leads to progressive rise in pulmonary vascular resistance and ultimately to right ventricular failure and death. It is of 2 types: primary and secondary. The pulmonary vascular bed is a high-flow, low pressure circuit that has the capacity to dilate and recruit unused vasculature in order to accomodate increase in blood flow. In pulmonary hypertension this capacity is lost resulting in elevation of pulmonary artery pressure at rest and further elevation during exercise. The pathological processes include proliferation of vascular smooth muscle cells and asymmetric neo-intimal hyperplasia in small pulmonary arteries and arterioles.

Causes

- 1. Increased pulmonary vascular resistance:

Obstructive	Hypoxic
Primary pulmonary hypertension	Chronic airway obstruction
Collagen vascular diseases	Restrictive lung diseases
Thromboembolism	High altitude
Tumour embolism	Chronic alveolar hypoventilation
Sickle cell disease	
Drug induced: fenfluramine, phenformin	

- 2. Increased pulmonary venous pressure
Mitral valve disease

- Left ventricular failure (LVF)
- Dilated cardiomyopathy
- Left atrial myxoma
- 3. Increased pulmonary blood flow:
 - Atrial septal defect (ASD)
 - Ventricular septal defect (VSD) and
 - Patent ductus arteriosus (PDA)

Primary Pulmonary Hypertension

This is a less common condition seen more frequently in women of child bearing age, and children. The etiology is not clear. Microembolisation of the pulmonary arterioles and capillary bed, and adverse reaction to drugs such as appetite suppressants, may very closely mimic primary pulmonary hypertension. The normal pulmonary artery pressure in health is 18-25 mm Hg/6-10 mm Hg. In pulmonary artery hypertension the mean pressure > is 30/20 mm Hg.

Pathological features include medial hypertrophy, fibrinoid necrosis and occlusion of the pulmonary arterial bed. This leads to rise in pulmonary artery pressure, right ventricular hypertrophy and cardiac failure.

Symptoms are vague until the lesion is advanced. Dyspnea of varying severity and signs of right heart failure develop. Anoxemia develops on exertion and this can be demonstrated by arterial oxygen studies.

Functional Classification of Pulmonary Hypertension

(Modified After the New York Heart Association Functional Classification According to the World Health Organization 1998)

- A. Class I—Patients with pulmonary hypertension but without resulting limitation of physical activity. Ordinary physical activity does not cause undue dyspnea or fatigue, chest pain or near syncope.
- B. Class II—Patients with pulmonary hypertension resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity causes undue dyspnea or fatigue, chest pain or near syncope.
- C. Class III—Patients with pulmonary hypertension resulting in pronounced limitation of physical activity. They are comfortable at rest. Less than ordinary activity causes undue dyspnea or fatigue, chest pain or near syncope.
- D. Class IV—Patients with pulmonary hypertension with inability to carry out any physical activity without symptoms. These patients manifest signs of right heart failure. Dyspnea and/or fatigue may even be present at rest. Discomfort is increased by any physical activity.

Fig. 140.3: Management of pulmonary arterial hypertension. CI—cardiac index; SvO₂, pulmonary arterial oxygen saturation; NYHA—New York Heart Association

A flow chart useful for institution of prostacyclin therapy is given above (Fig. 140.3):

Prognosis for recovery is poor. Majority die within 2-3 years of onset of symptoms. Symptomatic treatment includes the use of anticoagulants, vasodilators, nitrous oxide and calcium channel blockers such as nifedipine and diltiazem and oxygen therapy. When facilities permit, early lung transplantation may be of help.

Treatment

General measures including oxygen therapy.

Calcium Channel Blockers

Patients responding to first line vasodilators such as nitric oxide, prostacyclin or adenosine do respond to calcium channel blockers.

Prostacyclin: causes relaxation of vascular smooth muscles and inhibits growth of smooth muscle cells. It also inhibits platelet aggregation.

Side effects include: joint pain, headache, flushing, diarrhea. The drug is expensive.

Endothelin Receptor Antagonists

Bosentan: It is an orally active dual endothelin receptor blocker.

Dose: 62.5 mg BD for 1 month, then 125 mg BD thereafter.

Sildenafil: When given orally in doses of 25-50 mg orally repeatedly, it causes pulmonary vasodilatation. This drug is being used more frequently.

Neoplasms of the Lung

C. Sudheendra Ghosh, Ronald Win B

Chapter Summary

Benign Tumours 945

Bronchogenic Carcinoma 945

Pulmonary tumours may be benign or malignant, the latter may be primary or secondary. Malignant tumours far outnumber the benign ones.

Benign Tumours

The benign lesions include hamartoma, chondroma arising from the bronchi, bronchial adenoma, fibroma, neurofibroma, myxoma, and lipoma. Sclerosing angiomas, lymph cysts, histiocytomas, and endometriosis may be seen rarely. Hamartomas are tumours in which normal components of the lungs are combined in a disorganized manner.

BRONCHIAL ADENOMA

These constitute 1-6% of all pulmonary neoplasms. Females are affected more than males and the age group is lower than that of bronchogenic carcinoma. There is an association between bronchial adenomas and multiple endocrine neoplasia. Histologically, the tumours may be carcinoids, cylindromata, mucoepidermoid tumours or mixed tumours which resemble mixed parotid tumours.

Adenomas occur in the larger bronchi. They may be silent, or they produce symptoms such as cough, hemoptysis, bronchial obstruction and recurrent pneumonia. Hemoptysis may be massive and intractable.

The diagnosis should be suspected in any healthy young individual presenting with recurrent and massive hemoptysis and confirmed by bronchoscopy. Treatment is surgical excision.

Malignant Tumours of the Lung

Primary carcinomas are fairly common all over the world. The main types are, carcinoma of the bronchus and alveolar cell carcinoma (*bronchiolar carcinoma, pulmonary adenomatosis*).

The lungs are commonly the seat of secondary deposits from malignant tumours arising from many organs. Carcinomas of the breast, kidney, liver, gastrointestinal tract, testes, prostate, female genital tract and thyroid, and sarcomas from bone and soft tissues may all produce extensive metastases in the lungs.

Bronchogenic Carcinoma

This tumour originates from the basal cell layer of the bronchial wall. Bronchogenic carcinoma is the most common cause of cancer related mortality in the world.

Epidemiology: The disease is more common in the western world and the highest prevalence has been reported from Scotland. In India also the number of cases reported is steadily increasing and bronchogenic carcinoma accounts for 0.14-0.15% of all medical admissions in the major general hospitals. Incidence in males is 10-15 times more than that in females. The disease is most frequent in the fifth and sixth decades.

The role of external factors such as carcinogens derived from cigarette smoke, and from atmospheric pollution in the pathogenesis has been established by several epidemiological studies. In addition to cigarette smoke, exposure to several substances such as 3,4 benzpyrene from automobile smokes, asbestos, nickel chromate, arsenic, vinyl chloride, uranium and radioactive materials increase the risk of developing pulmonary cancer (Fig. 141.1). Among these the most widely investigated factor is cigarette smoking. **15% of male smokers develop lung cancer. Following cessation of smoking, risk of developing cancer decreases even by 10-20 years, the risk is still 2.5 times that of nonsmokers.**

Cigarettes and to a less extent bidis, considerably increase the risk of developing bronchogenic carcinoma, especially the squamous and small cell types. Adenocarcinoma and large cell carcinomas do not show this direct relationship. Smoking more than 20 cigarettes daily for 20 years or more, increases the risk of developing bronchogenic carcinoma 8-20 times above that of nonsmokers. Cigar and pipe-smoking is less harmful. Many substances present in tobacco, and the components

Fig. 141.1: Hypothesis for the development of different histological type of lung cancer from a single cell

of the paper have been found to increase the risk cumulatively. Both direct smoking and passive smoking, i.e. inhalation of smoke exhaled by others in a closed environment, are found to be harmful.

Histological classification: Histologically the tumours are classified into small cell type—otherwise known as oat cell carcinoma, and non-small type which includes squamous cell carcinoma, adenocarcinoma and large cell carcinoma. Oat cell carcinomas are invariably disseminated at the time of presentation. In contrast, large cell carcinomas which are detected early may be localised and hence amenable to surgical resection. One variety of adenocarcinoma is bronchiolo-alveolar cell carcinoma. In some tumours both epidermoid and adenocarcinomatous patterns are seen. Around 50% of tumours are situated centrally proximal to a segmental bronchus, and the rest are peripheral. Site of predilection is the right upper lobe. In some cases adenocarcinoma may supervene on areas of infarction or scars of tuberculosis. Lung tumours have been staged, taking into account the size, location, local effects, local lymphadenopathy and distant metastases.

Squamous cell or epidermoid carcinoma arises from the central bronchi in over 80% of cases. Among superior sulcus tumours it forms 30% or more. These tumours undergo cavitation readily. Metastasis occurs later in the disease.

Small cell carcinoma (SCLC) also known as oat-cell carcinoma is made up of cells containing large nuclei in relation to their cytoplasm. These are also seen more centrally in the lungs. Compared to squamous cell carcinoma the evolution of the disease is more rapid and metastasis occurs earlier.

Adenocarcinomas are more commonly associated with previous scars in the lungs. They form acinar and glandular patterns. They are situated more peripherally. Metastasis occurs early. Bronchioloalveolar carcinoma is a variant of adenocarcinoma, forming about 5% of the total primary malignant tumours. It may arise from the mucin-secreting bronchial epithelial cell, nonciliated secretory bronchiolar cells or type 2 alveolar epithelial cells. It is more common in women. Local spread throughout the airspaces occurs early. In many cases the origin may be multicentric.

Large cell carcinoma These consist of anaplastic large cells without squamous or glandular differentiation. They also occur more peripherally. Local spread and metastasis occurs early. These tumours tend to cavitate. Though distinct histological patterns can be identified in most cases, some may show overlap in cell types e.g. adeno-squamous carcinoma.

Several cytogenetic abnormalities are being elucidated. Oncogenes play a role in malignant transformation. Several tumours produce autocrine secretions which enable them to proliferate autonomously.

CLINICAL FEATURES

In many cases a long latent period may elapse before the tumour produces symptoms. Sometimes the radiological abnormality may be the finding that draws attention. In some cases metastases are the first to produce symptoms.

World Health Organisation (WHO) classification of malignant tumours of the lungs

Type	Frequency
Squamous cell (epidermoid)	30%
Small cell carcinoma	20
Adenocarcinoma	25
Large cell carcinoma (anaplastic)	10-15
Adenosquamous carcinoma	
Carcinoid tumour	
Bronchial gland tumours	
Others	

The incidence of squamous cell carcinoma is coming down and that of adenocarcinoma is going up.

Over 90% of the total number is constituted by squamous cell carcinoma, adenocarcinoma, small cell carcinoma and anaplastic large cell type. Histological diagnosis is important since the different types have different biological behaviour.

Clinical features may be described as (1) intrathoracic manifestations, (2) symptoms due to metastases, and (3) paraneoplastic syndromes. General symptomatology includes non-specific manifestations such as tiredness, anorexia, weight loss, clubbing of fingers and toes, fever, and pulmonary osteoarthropathy.

Pulmonary manifestations: Cough due to irritation of the bronchus may be troublesome, interfering with sleep. In the chronic smoker this is likely to be mistaken for cough due to excessive smoking. Hemoptysis occurs in many cases. Bleeding may be from the tumour or from other pulmonary complications. The tumour may block the bronchus and lead to obstructive symptoms like unilateral or localized wheezing, atelectasis, recurrent pneumonia or lung abscess. Further complications like pleurisy or empyema may be evident. At times the obstruction to the bronchus becomes valvular and the affected segment undergoes localised emphysema.

In some cases, a peripheral tumour undergoes central liquefaction and abscess formation.

Tumours of the apical region of the lung may invade the pleura, the brachial plexus and the cervical sympathetic chain. In most cases the tumour is a squamous cell carcinoma and this is called '*Pancoast's tumour*' or **superior sulcus tumour**. Involvement of the brachial plexus leads to intense neuralgic pain along the arm. Paralysis of the sympathetic chain gives rise to ipsilateral Horner's syndrome.

Pancoast's syndrome is a constellation of characteristic symptoms and signs that include pain over the shoulder and arm along the distribution of the C₈, T₁ and T₂ nerve roots, *Horner's syndrome*, weakness and atrophy of muscles of the hand, most commonly caused by extension of an apical lung tumour at the thoracic inlet.

Malignant pleural effusion may develop due to spread to the pleura. At times, the tumour may grow along the pleural surface resulting in pleural thickening. The hilar lymph nodes are enlarged. Mediastinal glands may be affected and enlargement of these structures gives rise to mediastinal syndrome. Compression of the phrenic nerve gives rise to diaphragmatic paralysis. Malignant pericardial effusion may develop. Direct spread to the ribs may lead to their destruction.

PHYSICAL EXAMINATION

Physical examination of the chest may reveal signs of consolidation, cavitation, atelectasis, or pleural effusion. Enlargement of pretracheal and scalene lymph nodes and recent onset of finger clubbing should suggest the possibility of malignancy.

Extrathoracic manifestations: Widespread secondaries may occur in the liver, bone, adrenal glands, brain, kidney, spleen, peritoneum, skin, and other organs. Manifestations caused by metastases may be the presenting features in many. For example, late onset seizures or a pathological

fracture may be the first evidence of a bronchogenic neoplasm.

Non metastatic metabolic or neuromuscular manifestation of lung cancer is known as paraneoplastic manifestation.

DIAGNOSIS

Bronchogenic carcinoma should be considered in the diagnosis of all respiratory disorders. Malignancy can mimic virtually all common pulmonary diseases such as tuberculosis, pneumonia, lung abscess, atelectasis, localized emphysema and pleural effusion.

The term *lymphangitis carcinomatosa* is given to the condition where the cancer has spread extensively through the lymphatics into the adjacent part of the lung giving rise to a picture of pneumonia or bronchopneumonia. X-ray shows characteristic streaky shadowing possibly representing the lymphatic spread.

When a solitary pulmonary nodule ('coin' shadow) is detected and diagnosis is not evident, the patient should be followed up to see the progress of the lesion. In general, malignant lesions have a doubling time of 20 to 400 days. More rapid growth is suggestive of inflammatory lesions. Calcification is in favour of non-malignant lesions.

INVESTIGATIONS

Radiological findings: Radiological findings may be varied. The presence of a circular or irregular shadow in an asymptomatic patient may be the only finding. The classic circular shadow is called "*coin*" lesion. In more advanced cases the lesion may be more extensive. Hilar glands are enlarged. The growth may undergo central cavitation and the resulting abscess shows thick and ragged walls. The presence of hilar adenopathy should suggest the malignant nature of the lesion. Presence of diaphragmatic paralysis along with a hilar mass should strongly suggest the possibility of bronchogenic carcinoma. Other features like collapse, consolidation, localized emphysema, and pleural and pericardial effusion may also be present (Figs 141.2 to 141.8).

Golden 'S' sign This is a radiological sign seen in central bronchogenic carcinoma obstructing the upper lobe bronchus. This produces collapse. The margin of the collapse segment produces the inward curve of 'S' and the mass will produce the outward curve of the 'S' in the lower part. Radiologically this is characteristic of upper lobe carcinoma (Fig. 141.6).

CT scans and MRI give good delineation of the tumour and its extensions in the thoracic cavity and thoracic cage. PET scans improve the rate of detection of local and distant metastases, especially in patients with non-small cell lung cancer. Positron emission tomography scan using 18F fluorodeoxy glucose, a new investigative modality to detect mediastinal and distant metastases in non-small cell lung cancer is superior to CT scan.

Fig. 141.6: Golden 'S' sign

Other diagnostic procedures include bronchoscopy, needle biopsy of peripherally placed tumours, biopsy of palpable lymph nodes in the neck and axilla and **scalene fat pad biopsy**. The right scalene node should be biopsied in cases of lesions of the right lung and the left lower lobe. The left scalene node should be biopsied for left upper lobe neoplasms. Mediastinoscopy and biopsy of nodes is a more rewarding procedure. Fluorescent bronchoscopy is a specialized form of bronchoscopy in which the malignant tissue emits fluorescence. This enables more easy detection of the lesions and helps to make more accurate biopsy.

Modern ultrathin fiberoptic bronchoscopes which can reach beyond the eighth generation bronchi are available. These help to diagnose peripheral lesions. When the nature of the lesion cannot be confirmed by the common investigation PET scan allows precise diagnosis and risk stratification. Measurement of tumour markers will also helps in the diagnosis of carcinoma lung.

Special Tests to Stage the Diseases

1. Staging-Correct staging of patients with lung cancer is crucial in determining the proper therapeutic approach. One of the most important parts of staging is a thorough

Sputum examination: Hemoptysis is present in many cases and the sputum is typically described as “currant jelly”. Malignant cells may be detected in the sputum by examining a wet preparation with methylene blue staining and this can be confirmed by *Papanicolaou’s method*.

Fig. 141.7: X-ray chest—carcinoma lung. Note: The mass with hazy margins extending outwards from the right border of the mediastinum

Fig. 141.8: Pancoast's tumour. Note: The rounded opacity in the right upper region—arrowhead

history and physical examination. All patients need serum electrolyte estimation, liver function tests [including alkaline phosphatase and lactate dehydrogenase (LDH)], and chest X-ray. Elevated alkaline phosphatase suggests bone metastases. In the past, patients routinely had head CTs and radionuclide bone scans as part of the diagnostic workup, but large studies have shown that these tests should be ordered only if the patient's signs and symptoms indicate their necessity. For example, CNS symptoms or an abnormal neurological examination necessitate a brain CT with contrast.

NSCLC and SCLC are staged differently. Due to the high incidence of micrometastases early in the disease state, SCLC is divided into two stages: limited disease (25-30%), in which the tumor is limited to ipsilateral hemithorax (including contralateral mediastinal nodes), and extensive disease (70-75%), in which the tumor extends beyond the hemithorax (including pleural effusions). SCLC is treated with chemotherapy and radiation therapy. NSCLC is staged using the TNM staging system (T is tumor size, N is nodal involvement, and M is presence or absence of metastases).

TNM Descriptors and Staging for Lung Cancer

TNM Descriptors

T (primary tumor)

- T₀ No evidence of primary tumor
- T_x Tumor proven by presence of malignant cells in bronchopulmonary secretions
- T_{is} carcinoma *in situ*
- T₁ Tumor <3 cm (not in mainstem bronchus)
- T₂ Tumor >3 cm or present in mainstem bronchus but not within 2 cm of carina, invasion of visceral pleura, associated atelectasis or pneumonitis extending to hilar region.

- T₃ Tumour of any size that invades the chest wall, diaphragm, mediastinal pleura and parietal pericardium; tumor <2 cm from carina, associated atelectasis or pneumonitis of entire lung.
- T₄ Tumor of any size with invasion of mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or carina; malignant pleural or pericardial effusion; satellite tumor nodules in the same lobe.

N (nodal Status)

- N₀ no nodal involvement
- N₁ metastases to ipsilateral peribronchial or ipsilateral hilar region (including direct extension)
- N₂ metastases to ipsilateral mediastinal and/or sub carinal lymph nodes
- N₃ metastases to supraclavicular or contralateral mediastinal, hilar, or scalene nodes

M (distant metastases)

- M₀ no distant metastasis
- M₁ distant metastasis

Staging of Bronchogenic Carcinoma

Stage	TNM Descriptor
Occult carcinoma	Tx N ₀ M ₀
0	Tis (carcinoma <i>in situ</i>)
IA	T ₁ N ₀ M ₀
IB	T ₂ N ₀ M ₀
IIA	T ₁ N ₁ M ₀
IIB	T ₂ N ₁ M ₀ or T ₁ N ₂ M ₀
IIIA	T ₁ N ₁ M ₀ or T ₁₋₃ N ₂ M ₀ (N ₂ disease)
IIIB	AnyT ₃ N ₃ M ₀ or T ₄ , any N ₀
IV	Any T, anyN, M ₁

PROGNOSIS

Since most of the cases are diagnosed late in the disease, overall prognosis in bronchogenic carcinoma is poor. Asymptomatic subjects detected by investigations have the best prognosis. Next in line are subjects with symptoms referable to the primary tumour with duration of less than six months. Metastases in CNS and liver confer a poor outcome. Small cell carcinomas have a poor prognosis since metastases develop early. In the majority of patients only palliative therapy is possible. Five-year survival figures for squamous cell carcinoma vary from 40-50% for stage 1 to less than 10% for stages III and above.

TREATMENT

Management depends on the stage of the tumour on diagnosis, histological type, and presence of complications. Treatment may consist of surgery, irradiation, and chemotherapy.

Surgery: When the primary is small and is detected before clinical manifestations develop and there are no metastases, surgical treatment is ideal. Contraindications for surgery include infiltration of the trachea, carina, superior vena cava, recurrent laryngeal nerve paralysis and pleural effusion. Involvement of the mediastinal nodes precludes the chance of resection in non-small carcinoma. Staging of the tumour by the presence of mediastinal lymph node involvement is absolutely essential for deciding on surgery. Stage I with N_0 (i.e.) no lymph node involvement and stage II with N_1 (i.e.) only ipsilateral mediastinal or bronchopulmonary node is present, are amenable to surgical resection which is the treatment of first choice. Surgical results are less satisfactory in those cases which have developed symptoms, and those with small cell carcinoma.

Radiotherapy: Radical radiotherapy is preferred in selected cases. In practice, in the majority of cases radiotherapy is given as a palliative measure in inoperable cases with local spread or distant metastases. Several recent advances in radiotherapy techniques such as split dose radiotherapy, use of radiosensitizers, and the availability of radiation equipment like linear accelerator, betatron, neutron beams and meson beams have made radiotherapy more effective with less of hazard. In some centers radiotherapy is also used prophylactically to the brain to prevent the development of metastases.

Chemotherapy: It is indicated in 90% of patients with bronchogenic carcinoma. The choice of drugs is based on the tumour histology, facilities for supportive therapy, and tolerance by the patient. Chemotherapy may be used as the sole modality of treatment in advanced cases or as an adjuvant to surgery and radiotherapy. Commonly used chemotherapeutic agents are methotrexate, cyclophosphamide, vincristine, CCNU, adriamycin, etoposide and cisplatin. Small cell cancer responds well whereas the others do not.

Other modalities of treatment are laser therapy which is employed in order to reduce the tumour mass and relieve obstructive symptoms. Incurable cases should receive terminal care which includes the provision of comfort, analgesics to relieve pain, management of symptoms, maintenance of nutrition, treatment of infection and proper attention by friends and family members. Preoperative radiotherapy followed by in en-bloc surgical resection is the most common treatment used for Pancoast's tumour.

SMALL CELL LUNG CANCER (SCLC)

It forms 20% of all primary lung cancers. It is associated with smoking. It is characterized by very rapid local and metastatic spread.

Paraneoplastic syndromes are more common with this subtype. Possibly SCLC is a tumour of neuroendocrine cells.

Mechanism of paraneoplastic syndromes:

1. Inappropriate secretion of hormones or other peptides such as growth factors, cytokines and prostaglandins by the tumour.
2. Immunological cross-reaction of antitumour antibodies with normal tissues.

In SCLC the genes encoding these hormones and humoral agents are not mutated, but they are deregulated, so that secretion goes on without feedback inhibition. Moreover, biologically inactive forms of hormones may result from aberrant processing of the RNA peptide.

Hormonal abnormalities: Syndrome of inappropriate antidiuretic hormone (SIADH) occurs in 10% cases.

Peptide Hormones Produced by SCLC

Atrial natriuretic peptide, corticotrophin, beta endorphin, beta human chorionic gonadotrophin, calcitonin, granulocyte colony stimulating factor, erythropoietin, gastrin releasing peptide, glucagon, growth hormone, interleukin-10, melanocyte stimulating hormone, neurone specific enolase, neurophysin, neurotensin, parathyroid hormone, physalemin, somatostatin, vasoactive intestinal peptide, vasopressin and others.

Immunologically Mediated Paraneoplastic Neurological Syndromes

These result from the cross-reaction of anti-tumour antibodies with antigens present in neural tissue, neuromuscular junction or muscle e.g., Lambert-Eaton myasthenic syndrome occurs in 6% of SCLC cases, and Myasthenia gravis may also occur rarely.

Myasthenia results from autoantibody mediated functional blockade of the calcium channels involved in the release of acetylcholine at nerve terminals. Polymyositis/dermatomyositis.

Peripheral Nervous System

1. Autonomic neuropathy
2. Intestinal pseudo-obstruction

Sensorimotor Peripheral Neuropathy

1. Subacute motor neuropathy
2. Subacute sensory neuropathy

Central Nervous System

Angioendotheliosis, dementia, encephalomyelitis—(brainstem encephalitis, limbic encephalitis), myoclonus-opsoclonus, optic neuritis, cancer-associated retinopathy, subacute cerebellar degeneration, subacute necrotizing myelopathy.

Cachexia

The most common paraneoplastic phenomenon is cachexia which is a complex metabolic syndrome probably resulting from a host response to tumour.

TREATMENT OF SCLC

Chemotherapy is the first line of treatment. The common regimens are:

- A – Adriamycin (doxorubicin),.
 - C – Cyclophosphamide,
 - E – Etoposide
- and A – Adriamycin

C – Cyclophosphamide

V – Vincristine

70-90% get effective symptom relief. SCLC is highly radiosensitive but relapse occurs frequently and rapidly. Combination of chemotherapy and radiotherapy is more useful. SCLC is common to produce brain metastasis and, therefore, PCI (prophylactic cranial irradiation) may help to prevent intracranial metastases. Still life is not prolonged since metastases at other sites prove fatal. At the time of diagnoses, brain metastases are seen in 10%, liver metastases in 25% and bone metastases in 20%.

Two year survival rate is about 30% in the cases with limited spread whereas it is below 10% in more advanced cases. *SCLC- the median survival without treatment is 6 to 8 weeks for limited disease*

At presentation less than 30% have limited disease.

Prophylaxis: Bronchogenic carcinoma is at least partially preventable by avoidance of smoking. The risk of cancer comes down quantitatively with the reduction in the number of cigarettes smoked and in those who give up smoking completely the increased risk of cancer comes down after a period of a few years.

Occupational exposure to asbestos, environmental pollutants and radioactive materials should be reduced to the minimum and persons engaged in these industries should receive protection.

142

Pulmonary Cysts

C. Sudheendra Ghosh

14

Chapter Summary

Congenital Cysts 951

Acquired Cysts 952

Cysts of the lung may be congenital or acquired.

Congenital Cysts

These cysts are of three varieties:

1. *bronchogenic*—these may be solitary or multiple;

2. *alveolar cell types*—these also may be solitary or multiple; and

3. *mixed types* having elements of both bronchogenic and alveolar cysts.

These vary in size and may be unilateral or bilateral. They may be located anywhere in the lung. They are filled with fluid at birth, but air enters the cavity later when bronchial communications develop. The cysts may be thick-or thin-walled.

Cystic disease of the lung: This may occur in association with fibrocystic disease of the pancreas. This is common in western countries, but is rare in India.

Acquired Cysts

These may present as bullous emphysema, subpleural cysts or parasitic cysts, which include hydatid disease and paragonimiasis.

Clinical features: The severity of symptoms is determined by the extent, size, time of diagnosis, and presence of complications. When the lung parenchyma is grossly reduced, respiratory embarrassment and respiratory failure may develop. Superadded infection is common and this is characterized by fever, cough, purulent sputum, and even hemoptysis. Though pulmonary osteoarthropathy may occur, it is a late feature. This is in contrast to bronchiectasis, in which clubbing is an early feature. Potential complications are infection, hemoptysis, pneumothorax, fibrosis, and cor pulmonale.

Diagnosis: Cystic disease has to be suspected when a child presents with recurrent respiratory infections. Presence of other congenital abnormalities should strengthen this suspicion. X-ray shows thin-walled cysts, which may be single or multiple. HRCT is very useful in locating the lesion and confirming the diagnosis. Tuberculosis, bronchiectasis, and lung abscess have to be differentiated.

In congenital cystic lung bronchography delineates the lesions. In the case of single non-communicating cysts the dye does not enter the cavity.

Treatment: A large single cyst producing respiratory embarrassment from infancy has to be excised. Video assisted thoracoscopy is used at present for the surgical excision of cysts. When the cysts are too numerous, surgery is contraindicated. Medical management is on the same lines as for bronchiectasis.

143

Pulmonary Involvement in Systemic Diseases

C. Sudheendra Ghosh, Dinesa Prabhu V.

Chapter Summary

Collagen Diseases 952

Ankylosing Spondylitis 953

Sarcoidosis 953

Wegener's Granulomatosis 954

Goodpasture's Syndrome 954

Collagen Diseases

Systemic lupus erythematosus, dermatomyositis, progressive systemic sclerosis, rheumatoid arthritis, polyarteritis nodosa and Sjögren's syndrome involve the lung in varying degrees. Of these rheumatoid arthritis is most common.

Rheumatoid arthritis: Pleurisy, nodular intrapulmonary lesions, diffuse interstitial fibrosis, rheumatoid pneumoconiosis (Caplan's syndrome) and pulmonary hypertension are the common manifestations. Diagnosis depends on the total clinical picture and laboratory tests.

Systemic lupus erythematosus: Pleurisy with or without effusion which may be unilateral or bilateral, lupus pneumonia, diffuse interstitial fibrosis, and pulmonary hypertension are the usual manifestations. Diagnosis is based on other clinical features and demonstration of anti-nuclear antibodies.

Polyarteritis nodosa: In this there is a necrotizing vasculitis affecting the systemic arteries. In addition it may affect the pulmonary arteries as well, producing pulmonary hypertension. This condition has to be distinguished from Goodpasture's syndrome. X-ray shows patchy infiltrates or nodular type of lesions and pleural effusions. Steroids are the mainstay in the management.

Progressive systemic sclerosis: Pulmonary fibrosis starts in the lower lobes and is seen as a honeycomb pattern of the lungs in the skiagram. Spontaneous pneumothorax is a common complication. Alveolar cell carcinoma may develop in some.

Dermatomyositis: Lung involvement is rare. The early lesions are in the form of a lymphocytic interstitial

pneumonia of the lower lobes which gradually leads on to interstitial fibrosis.

Sjögren’s syndrome: Pulmonary lesions are in the nature of lymphocytic interstitial pneumonia leading on to interstitial fibrosis. Secondary bacterial pneumonias and later bronchiectasis occur. Infections are more common due to drying up of the secretions.

Ankylosing Spondylitis

Here the upper lobes are involved. The initial lesion is consolidation which progresses to cavitation and fibrosis. The lesions are considered to be part of the disease process itself.

Sarcoidosis

This is a granulomatous disease of unknown etiology which may involve several organ system in the body. Though common in western countries, this disease is less commonly seen in India. Several reports of this disease have appeared from all parts of India.

Sarcoidosis is characterized by several immunological abnormalities. These include relative deficiency of cell mediated immunity along with an enhanced B lymphocyte mediated humoral immune response. Several MHC alleles confer susceptibility to sarcoidosis, e.g. DR 11, 12, 14, 15, 17. Some alleles are protective, e.g. DR1, DR4 and DQ. Histologically the lesions of sarcoid show granuloma formation with large closely packed epithelioid cells and a few multinucleated giant cells. Some of these giant cells show cytoplasmic inclusion bodies. Hypercalcemia caused by increased intestinal absorption of calcium is a common finding. Sarcoidosis affects several organs and therefore the presentation is protean (Table 143.1). The commonest presentation of the disease is as bilateral hilar lymphadenopathy with associated fever and erythema nodosum (Figs 143.1 and 143.2).

Course and prognosis: This disease follows a chronic recurrent course extending over several years. A few may recover completely. The pulmonary lesions may progress to fibrosis, emphysema and cor pulmonale. Prognosis is best in those who present with hilar adenopathy, without pulmonary parenchymal involvement.

Diagnosis: Sarcoidosis should be considered in the differential diagnosis, of other pulmonary lesions, hilar lymphadenopathy, erythema nodosum and other systemic illnesses presenting with hypergammaglobulinemia or hypercalcemia. Skiagram of the chest reveals hilar adenopathy and the pulmonary lesions (Fig. 143.1). Tuberculin test is usually negative or only weakly positive (anergy). The gamma globulins are considerably elevated. Hypercalcemia occurs in 20% of cases. The *Kveim-Siltzback test* is an intradermal test using the material

Fig. 143.1: X-ray chest sacoidosis.
Note: Bilateral hilaradenopathy with miliary lesions

TABLE 143.1	
Sarcoidosis—clinical manifestations	
General symptoms	Fever, lymphadenopathy, uveoparotid fever (a picture resembling atypical mumps) hypercalcemia, renal calculi.
Respiratory system	Hilar lymphadenopathy, diffuse pulmonary lesions which may be miliary, nodular or linear infiltrations, cavitation, confluent lesions, diffuse fibrosis, nasal granuloma, laryngeal plaques.
Eyes	Anterior and posterior uveitis, non-specific and phlyctenular conjunctivitis, glaucoma, enlarged lachrymal glands, Sjögren's syndrome.
Nervous system	Peripheral neuropathy, meningitis, cranial nerve palsies, intracranial space occupying lesions, transverse myelitis.
Endocrine	Diabetes insipidus-due to lesion in the posterior pituitary
Bones and joints	Polyarthralgia, cysts seen especially in terminal phalanges, and subcutaneous tissue swellings.
Abdomen	Hepatosplenomegaly
Skin	Erythema nodosum, lupus pernio (violaceous lesions at the tip of the nose), plaques, papules, nodules and scars
Cardiovascular	Myocarditis, congestive heart failure, conduction disorders, cor pulmonale.

obtained from sarcoid lesions and this is positive in over 80% of cases. This test is seldom done now due to the risk of transmission. Sarcoidosis should be differentiated from tuberculosis, lymphoma, metastatic malignancy and berylliosis. Distinction from tuberculosis can be quite difficult in some cases. Histologically presence of caseation in biopsy specimen is very suggestive of

Fig. 143.2: HRCT sarcoidosis. Note: Hilar lymph nodes

tuberculosis. In sarcoidosis caseation is absent. Serum angiotensin converting enzyme (ACE) is elevated in sarcoidosis. Similar elevation may occur in other diseases as well, so that this is not a specific diagnostic test. Gallium⁶⁷ scan reveals increased uptake in sarcoid granulomas occurring in the hilar lymph nodes and parenchymal tissues. Gallium⁶⁷ scan when considered along with raised serum levels of ACE gives a high degree of diagnostic specificity. Examination of material obtained by bronchoalveolar lavage is of value in the diagnosis of pulmonary sarcoidosis. In active lesions the proportion of lymphocytes is high. This also is not a specific test. Fiberoptic bronchoscopy with transbronchial biopsy is the confirmatory test to prove pulmonary sarcoidosis.

TREATMENT

Corticosteroids are indicated in life-threatening situations arising out of vital organ involvement. The other indications for steroids include lesions of the eyes, nervous system, cardiovascular system and hypercalcemia. Prednisolone has to be started in a dose of 20-60 mg/day initially and tapered off as the condition improves. Maintenance dose has to be given for 3-6 months. Other drugs which are also beneficial include chloroquine, hydroxychloroquine, methotrexate, azathioprine, cyclophosphamide and TNF α receptors blockers such as pentoxifylline, thalidomide and the monoclonal antibody infliximab.

Wegener's Granulomatosis

Friedrich Wegener a German Physician described the condition in 1939. This is characterized by necrotizing vasculitis and granulomatous inflammation affecting mainly the upper and lower respiratory tract and the kidneys. The exact etiology is unknown but the lesions are due to a hypersensitivity reaction. Both granuloma and necrotizing vasculitis should be evident for making the histological diagnosis. Most commonly lesions are seen in the paranasal sinuses, lungs, skin and kidneys. Indian

experience is that 82-100% get upper respiratory passage lesions, 40-50% get pulmonary lesions and 65-70% get renal lesions.

Clinical features: It may manifest at any age, the mean age of onset is 40 years and males are more affected. Initial symptoms are headache, sinusitis, rhinorrhea and vague general ill-health. Cough and hemoptysis may occur. Pulmonary manifestations are pneumonitis, hemoptysis, pleurisy, pneumothorax or cavitation. Acute glomerulonephritis syndrome may occur. Renal biopsy shows focal glomerulonephritis, rapidly progressive glomerulonephritis, or necrotizing and proliferative lesions.

The eyes are involved, leading to iritis, scleritis and conjunctivitis. Intraorbital granulomas may occur. Cardiac lesions include coronary arteritis and pericarditis. Mononeuritis multiplex or cranial nerve palsies may be seen. Skin shows purpura, vesicles and necrotic ulceration.

The ESR is raised. Leucocytosis and thrombocytosis are seen in many cases. The condition has to be distinguished from systemic lupus erythematosus, polyarteritis nodosa, Goodpasture's syndrome, and midline granuloma. Circulating anti-neutrophil cytoplasmic antibodies are demonstrable in patients having pulmonary and renal lesions. Measurement of cANCA (anti-neutrophil cytoplasmic antibodies with cytoplasmic staining) has good specificity for the diagnosis of Wegener's granulomatosis from other forms of vasculitis such as microscopic polyangiitis and Churg Strauss' syndrome. Confirmation of diagnosis is by biopsy of the lung lesion or lesions elsewhere. Untreated, the mortality is 82% at the end of one year.

Treatment: Corticosteroids and immunosuppressant drugs like cyclophosphamide and azathioprine are effective. 50% get full remission, 30% get partial remission and 10-20% may die of the disease. Therapy with cotrimoxazole (160 mg trimethoprim and 800 mg of sulphamethoxazole) b.d for 24 months has been found useful to reduce the frequency of relapses.

Pulmonary Involvement in Goodpasture's Syndrome

(Syn: Lung purpura, Idiopathic pulmonary hemosiderosis)

This is a rare disease characterized by hemorrhage into the alveoli leading to hemoptysis and in some cases associated with proliferative glomerulonephritis. The pulmonary lesion shows degeneration, excessive shedding, and hyperplasia of the alveolar epithelium and cytoplasmic vesiculation. Antibodies to basement membrane antigens are often demonstrable and there is cross reactivity with glomerular and alveolar capillary basement membrane. The disease starts in childhood

below the age of 7 years. If it starts above the age of 15, renal lesions are also found. There is recurrent hemoptysis of varying severity with hemosiderin-laden macrophages in the sputum. Iron deficiency anemia occurs due to blood loss. Occasionally enlargement of liver, spleen and lymph nodes and clubbing of fingers occur. After recurrent episodes extending over several years, radiological lesions develop in the form of micronodular shadows. There is no fibrosis. The course is variable. In a third, death occurs

within three years and in another third the disease becomes inactive. Renal lesion is progressive and death occurs due to renal failure (see Section 16, Chapter 170).

Treatment is with moderate to high doses of corticosteroids. Oral iron should be given to correct the anemia.

Pulmonary involvement in mucoviscidosis (see section 9 chapter 89).

144

Diseases of Pleura

C. Sudheendra Ghosh, Dinesa Prabhu V.

Chapter Summary

Pleurisy	955
Pleural Effusion	956
Tuberculous Pleural Effusion	958
Empyema	958
Tumours of the Pleura	959
Pneumothorax	959
Hydropneumothorax	960

Both visceral and parietal pleura have a single layer of mesothelial cells. Mesothelial cells contain abundant microvilli that are present diffusely over the entire pleural surfaces. They are 0.1 μm in diameter and about 1.5 μm length. They produce collagen, elastin, fibronectin and laminin. The visceral pleura can be considered to consist of three layers. The endopleura, which is the continuous mesothelial layer; then the external elastic lamina; and the third layer the vascular layer consisting of connective tissue containing lymphatics and blood vessels. This lies over the internal elastic lamina. In health the surfaces of the pleural cavity are coated with a thin layer of pleural fluid that allows frictionless apposition of visceral and parietal pleura during each respiratory cycle. Pleural fluid is formed as ultrafiltrate of plasma just enough to wet the pleural surfaces. The rate of production of pleural fluid is 0.01 ml/kg/hr and it maintains a balance between

production by the systemic vessels of the parietal pleura and removal by the parietal pleural lymphatics. Pleural fluid does not enter the visceral pleural lymphatics. The pressures vary during the entire respiratory cycle from $-5 \text{ cm H}_2\text{O}$ at mid chest at full expiration to $-30 \text{ cm H}_2\text{O}$ at mid chest at full inspiration.

Pleurisy

Inflammation of the pleura is called pleurisy. In dry pleurisy, the pleural surfaces are inflamed without fluid in between them. In many cases pleurisy is associated with effusion. Both dry pleurisy and pleural effusion may develop at different stages of the same disease process.

Dry or fibrinous pleurisy: In this condition the lesion in the underlying lung spreads to the pleura. Trauma to the chest may also lead to pleurisy. The suggestive symptom is the catching pain felt acutely over the affected area by inspiratory movements brought about by deep breathing, coughing or sneezing.

Etiology of Pleurisy

1. Pulmonary tuberculosis,
2. Pneumonia, lung abscess, bronchiectasis,
3. Bronchogenic carcinoma with secondaries,
4. Pulmonary infarction,
5. Connective tissue disorders such as systemic lupus erythematosus, polyarteritis nodosa, and rheumatoid disease,

6. Rheumatic fever,
7. Viral infections, especially Coxsackie (Bornholm's disease),
8. Hepatopulmonary amebiasis,
9. Uremia,
10. Pleural malignancy-mesothelioma,
11. Secondaries from other malignancies,
12. Lymphomas,
13. Lymphatic obstruction, especially filariasis,
14. Trauma to chest wall,
15. Complication of surgery in the abdomen or thorax, and
16. Pleural effusion in association with tense ascites.
17. Pancreatitis.

PLEURAL EFFUSION

In this condition fluid accumulates between the two layers of the pleura. Normally pleural cavity contains only a small amount of fluid. Movements of the lung favour the movement of the fluid in and out of the pleural space.

Normal composition of pleural fluid

Volume:	0.1 to 0.2 ml/kg
Cells per cmm:	1000 to 5000
%Mesothelial cells	3-70
%Monocytes:	30-70
%Lymphocytes:	2-30
%Granulocytes:	10
Protein:	1-2 gm%
%Albumin:	50-70
LDH:	<50% of plasma LDH
pH:	7.6

In most of the disease states, absorption of the fluid is reduced. The fluid may be contained in the general pleural space or it may be loculated in the interlobar fissure, intrapulmonary space or may remain adjacent to the mediastinum. The fluid progressively compresses the adjacent lung which undergoes collapse.

CLINICAL FEATURES

The development of symptoms depends upon the speed of accumulation of fluid and its quantity. Common symptoms include dyspnea, pleuritic pain, or symptoms of the underlying disorder. High fever may occur in acute pyogenic infections. Tuberculosis may be associated with low grade fever.

Physical examination: Physical examination reveals diminution of movement on the affected side and the presence of pleural friction rub on auscultation. Pleural rub has a superficial grating quality. The rub is heard better by gentle pressure of the chest piece of the stethoscope on the chest wall. Unlike rales it is not altered by coughing. With the development of pleural effusion, the rub may disappear in many cases. Pleural rub has to be distinguished from crepitations and sounds arising from movements of the chest wall. Other painful conditions like

pneumonia, myocardial infarction, and herpes zoster have to be differentiated from pleurisy.

Pleural fluid is clinically detectable only when it is about 500 mL in volume but radiologically it may be detected even when the volume is 300 mL. A fully developed moderate or massive effusion reveals fullness of the intercostal spaces and restriction of respiratory movements on the same side. Midline structures are shifted to the opposite side. Percussion elicits stony dullness with the highest level in the axilla and lower levels in front and back (*S-shaped curve of Ellis*). This is the most constant physical sign. The Traube's space which is the area overlying the gas bubble of the stomach, is obliterated in left-sided effusions. Breath sounds, vocal fremitus and vocal resonance are diminished or absent. Aegophony may be present above the level of effusion. At times bronchial breathing may be heard over a pleural effusion.

Complications: These include: (1) Respiratory embarrassment, (2) massive bilateral effusions which may be fatal due to respiratory failure, (3) secondary infection of the pleural fluid which converts it into empyema, (4) organization of fibrin from the fluid on the surface of the collapsed lung (*cortication*) that (*prevents re-expansion*), and (5) fibrosis of the pleura and obliteration of the pleural space (*fibrothorax*) which develop as a sequel to long standing pleural effusions.

Characteristics of Uncomplicated and Complicated effusion		
	Uncomplicated	Complicated
Appearance	Clear fluid	Cloudy/turbid
pH	>7.30	7.1 – 7.29
Glucose mmol/L	>2.2	<2.2
LDH IU/L	<1000	≥1000
Organism	–ve	–ve/+ve

Radiographic appearances: If the fluid volume is small only the costophrenic angles are obliterated. As the fluid accumulates further, it throws a triangular lateral opacity obscuring the hemidiaphragm. Large pleural effusions shift the midline structures to the opposite side (Fig. 144.1). An interlobar effusion in the oblique fissure produces an elongated cigar-shaped shadow seen well in the lateral view. Fluid in the horizontal fissure throws a rounded shadow seen in the PA view. The term “*vanishing pulmonary tumour*” has been used for interlobar effusions since they clear up with treatment.

Character of the fluid may be transudate or exudate. The light criteria help to identify exudates.

Light criteria
• Pl. fluid/Serum protein ratio >0.5
• Pl. fluid LDH >200U/Lit
• Pl. fluid/Serum LDH >0.6

Fig. 144.1: X-ray pleural effusion-right side Note: The homogenous opacity on the right hemithorax with highest level in the axilla. Costophrenic and cardiophrenic angles are obliterated

Types of Pleural Effusion – Transudate and Exudate	
Cause of Transudate Pleural Effusion	Cause of Exudate Pleural Effusion
LVF	Tuberculosis
Cirrhosis	Parapneumonic
Nephrotic syndrome	Malignancy (primary and metastatic)
Hypoalbuminemia	Collagen vascular diseases
Hypothyroidism	RHD disease, SLE, Churg-Strauss syndrome
Pulmonary embolism	Post-myocardial infarction syndrome
Meig's syndrome	Pulmonary infarction
Peritoneal dialysis	Pancreatitis
	Pseudopancreatic cyst
	Esophageal rupture
	Drugs
	Chylothorax, Pseudochylothorax

Tuberculous effusion is straw-coloured. The fluid is hemorrhagic in malignancy and infarction and it is chylous (milky) in lymphatic obstruction due to filariasis and lymphomas. Collection of purulent fluid in the pleura is called *empyema*.

Microscopy: In acute bacterial infections, neutrophils predominate, while lymphocytes predominate in tuberculosis. Eosinophils may predominate in dyscollagenoses and pulmonary infarction.

Examination of a wet preparation stained by methylene blue reveals malignant cells in over 90% of cases of malignant effusions. Identification of the nature

of the malignant cells is done by *Papanicolaou's technique*. The nature of chylous fluid is confirmed by demonstrating the presence of fat. Elevated amylase levels are suggestive of acute pancreatitis (500 units/mL or higher). Levels of LDH are raised in exudates. Gram-staining, Ziehl-Neelsen staining, and culture help to identify the causative microbes. When the diagnosis is not arrived at by these investigations, pleural biopsy may be attempted. Biopsy is done with a *Cope's needle* or *Abrams' needle*. Though a positive biopsy is diagnostic, a negative biopsy does not exclude pleural malignancy.

MANAGEMENT

Pleural effusion may rarely present as an emergency with respiratory embarrassment. In such cases emergency measures are required to give relief especially if the effusion is massive or bilateral.

Emergency aspiration: Aspiration is done to get a specimen of fluid for diagnostic tests and to relieve distress.

The fluid is aspirated by thoracentesis done in the eighth or ninth intercostal space in the posterior axillary line after anesthetizing the part. Sufficient fluid is removed to relieve the distress. Whenever pleural fluid is aspirated, it is also subjected to diagnostic investigations.

Elective aspiration: Medical therapy is instituted depending on clinical features and pleural fluid analysis. It is ideal to aspirate the fluid after instituting specific drug therapy for 3-4 days.

Indications for aspiration: (1) to make the diagnosis, (2) to relieve distress, and (3) to remove the exudate so as to hasten full recovery of the pleura and avoid complications. It is generally advisable to restrict the volume of fluid removed at one sitting to 1 litre or less in order to avoid pulmonary edema. Aspiration has to be repeated at times. Two or three aspirations will be adequate in most of the cases of tuberculous effusion. In malignant pleural effusion and pulmonary infarction the pleural fluid tends to reaccumulate even after repeated aspirations. Sometimes aspiration of the pleural cavity may give rise to complications. These include pleural shock, anaphylactic shock due to anesthetic, bleeding into the pleural cavity, pulmonary edema, infection, and accidental introduction of air into the pleura.

Pleural shock: The patient develops vasomotor collapse on puncturing the pleura. Inadequate local anesthesia may be a predisposing factor. Urgent resuscitatory measures include the injection of adrenaline, parenteral steroids, and intravenous fluids. Pleural shock may be fatal, if not recognized in time.

Bleeding into the pleural cavity is from vessels on the pleural surface. Bleeding should be suspected when the

aspirated fluid becomes progressively blood-stained. In severe cases hypovolemic shock may ensue. When bleeding is evident, it is advisable to stop the procedure.

Entry of air inadvertently during aspiration converts a simple pleural effusion into hydropneumothorax. Rarely subcutaneous emphysema or air embolism may develop.

Pulmonary edema occurs in some cases of chronic effusion when the lung expands on removal of the fluid. Slow aspiration and limiting the volume of fluid aspirated at one sitting to 1 litre helps to reduce these complications. Onset of pulmonary edema is heralded by troublesome cough with frothy expectoration. Auscultation reveals the presence of rales. Onset of pulmonary edema is an indication for stopping aspiration.

Pleural effusion which is a part of generalised edema, clears up when the underlying condition is treated. Unless there is respiratory embarrassment, thoracentesis is required only for diagnostic purposes.

Tuberculous Pleural Effusion

Tuberculosis is perhaps the most common cause of pleurisy occurring in young adults in India. The pleura may be directly involved by the tuberculous process. In most cases it spreads from an underlying pulmonary focus and the effusion is almost always on the side of the pulmonary lesion. Sometimes a caseous subpleural focus may rupture into the pleural cavity or the pleura may be the seat of miliary lesions. In the majority of cases the classic adolescent pleural effusion is a postprimary tuberculous phenomenon though rarely it may occur in primary tuberculosis. The effusion may develop rapidly or insidiously. Strongly positive tuberculin test favours tuberculous etiology. The fluid is an exudate. The cells are mainly lymphocytes. Tubercle bacilli are difficult to demonstrate in serous effusion by conventional methods. Culture and animal inoculation may be positive. In tuberculous empyema the organisms are more easily demonstrable. Needle biopsy is helpful, but this is not required in the ordinary case.

Management: Standard antituberculosis treatment is started. Pleural aspiration is done electively. Repeated aspiration may be required to make the pleural cavity dry. Respiratory physiotherapy is essential to restore function promptly.

Empyema

Collection of pus in the pleural cavity is called empyema. Pus may be free in the pleural space or loculated.

Pathogenesis: Empyema may result from the extension of infection from the underlying lung, or it may complicate chest injuries, thoracentesis, or generalized pyemia.

Pneumonia, lung abscess, bronchiectasis, tuberculous cavities, hepatopulmonary amebiasis, bronchogenic carcinoma, osteomyelitis of the ribs, fungal infections and actinomycosis are all common causes. Thoracic and upper abdominal surgery may lead to empyema (Fig. 144.3). Common bacterial flora includes *Streptococcus*, *Staphylococcus*, *Pneumococcus*, *Pseudomonas*, *Klebsiella*, *H. influenzae*, anaerobes, *M. tuberculosis*, and Actinomycetes.

CLINICAL FEATURES

All ages may be affected, but children suffer more. Onset is marked by high fever, pleuritic or dull chest pain and dry cough. Physical signs of pleural effusion may be evident. Unlike as in simple pleural effusion the chest wall becomes edematous. Digital clubbing is common. Sometimes the empyema communicates with the bronchus (**bronchopleural fistula**). In this case postural cough is a troublesome symptom and the findings are those of pyopneumothorax. The pus may work its way outside and point on the chest wall. This is called **empyema necessitans**. Left-sided empyema may pulsate due to transmitted pulsation from the heart—'**pulsating empyema**'.

Radiologically the findings closely resemble those of pleural effusion (Fig. 144.1). Demonstration of pus in the pleural cavity by aspiration confirms the diagnosis. The causative organism can be identified by examination of the pus.

Clinically a large lung abscess may resemble an empyema or encysted pyopneumothorax and these two conditions have to be differentiated. Fever, toxemia and digital clubbing occur in both. Shift of the mediastinum to the opposite side and stony dullness on percussion are in favour of empyema. Special radiological techniques may be necessary to differentiate them. In a loculated pyopneumothorax the airfluid interphase may transgress anatomical boundaries of lobes, whereas a lung abscess is limited by the interlobar fissures (Fig. 144.2).

Fig. 144.3: Common causes of empyema

Complications of empyema include severe toxemia, cachexia, anemia, pulmonary fibrosis, pleural fibrosis, metastatic brain abscesses and in longstanding cases, secondary amyloidosis. The overall mortality is 10-11%.
